The responses to pre-TCR signaling include changes in expression of other cell-surface receptors that can themselves affect TCR signaling (Figure 12.5). An important one is CD5, which is induced in direct proportion to TCR signal strength, but which also acts as an inhibitor of subsequent TCR signal transduction (150,151). The stable conversion of developing thymocytes from CD5-low to CD5-intermediate during β selection should make signaling a little more difficult for the resulting DP cells. Most provocatively, it should make future signaling weaker, in direct proportion to the strength of the signal by which the cells were selected. CD5 is even more strongly up-regulated during $\gamma\delta$ selection, as already noted, in agreement with the model that TCR$\gamma\delta$ complexes signal more strongly than pre-TCR. It is also interesting that the transcription factor Ikaros, which plays a checkpoint-enforcement function in β selection, appears to act as a brake on spontaneous TCR triggering in later development (152). Signaling thresholds can thus be determined and fixed for individual cells through the balance of regulators that triggered their β selection.

The threshold-setting functions mobilized in β selection may turn out to be an important immunological legacy of the process. Conceivably, the levels of threshold-setting functions such as CD5, Csk, and Ikaros could be maintained from β selection through proliferation and into the DP population. If so, then the later positive/negative selection thresholds for individual DP cells could depend on the strength of the pre-TCR signals that triggered their β selection initially.

Uniqueness of DP Thymocytes

The CD4$^+$CD8$^+$DP thymocytes produced through β selection are physiologically specialized for undergoing selection on the basis of TCR recognition (Figure 12.5). These cells are a paradoxical combination of extreme sensitivity to TCR ligands and, by some criteria, extreme functional paralysis. Unable to turn on any of the functional response genes of mature T cells in response to stimulation, they nevertheless do recognize TCR ligands with ultrasensitive dose–response relationships. Antigenic peptides presented on conventional antigen-presenting cells can trigger apoptosis of DP thymocytes with median effective dose values that are substantially lower ($\sim$10-fold) than those needed to trigger responses of mature T cells with the same TCR (109–111). This is especially surprising because the cell-surface density of TCR on DP thymocytes, even after productive TCRα rearrangement, is about 10-fold lower than on SP thymocytes. Operationally, this means that DP thymocytes can make responses to peptide/MHC complexes that are low-affinity ligands for their TCR, too low to be stimulatory for mature cells with the same TCR.

One important mechanism contributing to this ultrasensitivity is the distinctive glycosylation state of many DP thymocyte surface molecules. These are strikingly deficient in terminal sialylation in comparison with surface glycoproteins of mature T cells and immature DN cells alike, reducing the electrostatic repulsion between DP thymocytes and other cells with a more typically strong negative surface charge. This reduced repulsion apparently lowers the affinity threshold for TCR signaling (153). Another feature enhancing the sensitivity of DP cells is the fact that they still express a relatively low level of CD5, the negative regulator of TCR signaling (150,151), as compared to mature cells. For these or additional reasons, immunological synapses formed by DP thymocytes with thymic epithelial cells are distinct in organization from those that mature T cells form with professional antigen-presenting cells (154,155).

DP thymocytes have other features that bear on their eventual fates. Because of the regulatory changes that generate them during β selection, these cells are extremely sensitive to death induced by glucocorticoids, and, even without perturbation, they die quickly outside of the thymic microenvironment. These properties are especially pronounced in the mouse; human and rat DP thymocytes are somewhat more robust. Thymocyte glucocorticoid sensitivity exactly coincides with the cell-surface carbohydrate changes (peanut agglutinin–binding phenotype) and the lack of class I MHC and is tightly developmentally regulated; it can be used as an efficient method to deplete DP cells specifically. Even mildly elevated physiological levels of glucocorticoids *in vivo* shrink the thymus dramatically through loss of DP cells. It is widely assumed that normal circulating levels of glucocorticoids play a major role in setting the three- or four-day deadline for DP thymocyte selection or death. However, DP cells are not just death-row inmates awaiting a reprieve. Throughout their few days of passage, they maintain their own antiapoptotic functions by expressing Bcl-xL and Bcl2A1 (109,111). Further, the regulatory molecule that turns on these DP-specific antiapoptotic molecules is the orphan nuclear receptor RORγt, and this is the same regulatory molecule that appears to shut off the ability of DP cells to make conventional effector responses (111,112,156). Thus, in the DP stage, developing thymocytes exchange one kind of response program for another (Figure 12.5).

DP Thymocyte Impact on the Thymic Microenvironment

Most interestingly, recent work has shown that part of this DP cell program is to take an active role in shaping the thymic environment. There is a long history of evidence for cross-talk between DP cells and the thymic stroma, which affects the state of the epithelium, its ability to maintain thymocyte viability through β selection, and indirectly the

carrying capacity of the thymus (77,157,158). The presence of DP cells causes a polarization of the cortical structure, with IL-7 production compartmentalized in the inner regions close to the cortical-medullary junction (13). DP cells also act to control the programming of new waves of precursors through a more direct route. As they emerge from β selection, DP cells turn on lymphotoxin-β, a tumor necrosis factor (TNF)–family secreted molecule that is used by embryonic lymphoid tissue-inducing cells to initiate lymph node development. RORγt is also important for making this possible (159). The cells that receive the lymphotoxin-β signal are not just other DP cells or thymic epithelial cells, but also the immature DN cells migrating past them in the bidirectional traffic of the cortex. DP-derived lymphotoxin-β has a remarkable effect on the gene expression patterns in these immature precursors and even on the maturation of TCR$\gamma\delta$ cells from those precursors (159). Thus, the presence of normally developed DP cells may be important even for the maturation of cells that took an alternative pathway.

There are two other features of DP cells that are increasingly seen to be important for thymic function. One is that as they take up most of the cellular volume of the thymic cortex, DP cells may buffer outwardly migrating DN cells against the effects of competition for Notch ligands. This is possible because DN but not DP cells express high levels of Lunatic Fringe, a modifying enzyme that greatly enhances the efficiency with which a cell can engage with Delta-family Notch ligands. It is now clear that the amount of Delta presented by thymic stroma is limited, and T cell development can be deranged or blocked when there is excessive competition (160–162). By their "self-denying" down-regulation of Lunatic Fringe, the DP cells provide a neutral neighborhood for DN cells. In this role, DP cells could be analogous to the control rods in a nuclear reactor. At the same time, it is possible to imagine such a mechanism helping to regulate the carrying capacity of the thymus.

A last important feature of the DP cells is that they may themselves be the antigen-presenting cells for certain kinds of positive selection. The DP cells themselves express neither classical class I nor class II MHC: The lack of class II is normal for murine T cells, and the shutoff of conventional class I MHC expression is another unique feature of the DP state (Figure 12.5). However, DP cells in several mammalian species express nonclassical class I MHC antigens, such as TL or CD1, which are the restricting elements for antigen recognition by specific subsets of $\alpha\beta$-T cells such as NKT cells with an invariant TCRα (iNKT) and epithelial-associated T cells using CD8$\alpha\alpha$ homodimers. The importance of these minority T cell lineages is suddenly becoming appreciated, as these cells have some characteristics of innate immune cells and play a role in the regulation of peripheral immune responses. Both cell types undergo thymic development, pass through a DP stage, and appear to be positively

selected on high-affinity agonists presented in the context of the nonconventional MHC molecules (163–165). Thus, DP cells may themselves take the place of thymic epithelium for selection of cells that will mature in these particular lineages.

POSITIVE SELECTION AND CHOICE OF CD4 OR CD8 CELL FATE

Positive selection is the canonical example demonstrating that quantitative differences in TCR signaling can elicit wholly different developmental outcomes. Transgenes encoding pre-rearranged TCRα and TCRβ genes impose a predictable recognition specificity on developing T cells, blocking most endogenous TCR gene rearrangement and diversity by allelic exclusion. From the earliest such experiments, it has been evident that the recognition specificity also imposes a predictable developmental fate. Transgenes encoding a receptor that recognizes some foreign peptide antigen in the context of the same MHC allelic forms expressed in the thymus give thymocytes a greatly increased chance of survival (positive selection). Transgenes encoding a receptor that recognizes both self-MHC and a self-peptide expressed in the thymus generally cause the transgenic TCR$^+$ cells to be eliminated (negative selection). Further, the nature of the ligand recognized controls the developmental programming of two major effector classes of T cells. Transgenes encoding a receptor for peptide complexes with class II MHC direct the cells to mature into CD4 SP cells, whereas transgenes encoding a receptor for peptide complexes with class I MHC direct development to a CD8 SP lineage. Although details of the expression of TCR transgenes *in vivo* are not normal (they are expressed at an earlier stage, typically, than normal TCR that depend on TCRα rearrangement), they have revealed the overwhelming importance of details of TCR signaling for thymocyte fate determination. Clever experimental strategies have now made it possible to tease out how the cells distinguish between interactions with different ligands and how they translate these features of a transient interaction into an irreversible choice of developmental program.

Positive Selection and the TCR Recognition Repertoire

Positive selection ensures that only thymocytes expressing a useful TCR can survive the DP stage and mature beyond it. *Useful* here means capable of mediating interactions with either class I or class II MHC, but not with such high affinity as to cause autoreactivity. In practice, this usually involves a weak interaction with MHC complexes that include thymic self-peptide, as some other "foreign" antigenic peptide in the same MHC is likely to exist that has much stronger interaction with such a receptor in the

periphery. Positive selection and its importance for repertoire selection are discussed in detail in many reviews (166–169). It is important to note that positive selection does not need to be precise in terms of antigen specificity. After all, the thymus only expresses self-antigens. Therefore, it cannot positively select for a particular foreign antigenic peptide specificity, but only for the competence to contribute to a useful TCR repertoire. The process can also afford to be permissive, because any positively selected cells that turn out to have too high an affinity for self-antigen will still have time to be negatively selected or diverted to a T_{reg} fate in the thymic medulla (170). It is the superimposition of the positive selection window and the more stringent negative selection window that selects the useful, self-tolerant T cell repertoire.

The TCR-ligand interactions that trigger positive selection appear to be low affinity and fairly promiscuous. As a result, a single peptide/MHC complex can positively select DP cells with any of numerous different TCR specificities, as long as they cross-react weakly with that complex (171). The heightened sensitivity of DP cells to certain weak TCR interactions means that the peptide/MHC complex that actually triggers positive selection may bind with an affinity that becomes undetectable, or detectable only as competitive antagonism, once the cell has matured into a peripheral T cell. However, mature T cells continue to recognize other peptides in association with the same class I or class II MHC molecule that mediated their positive selection.

Triggering of Positive Selection

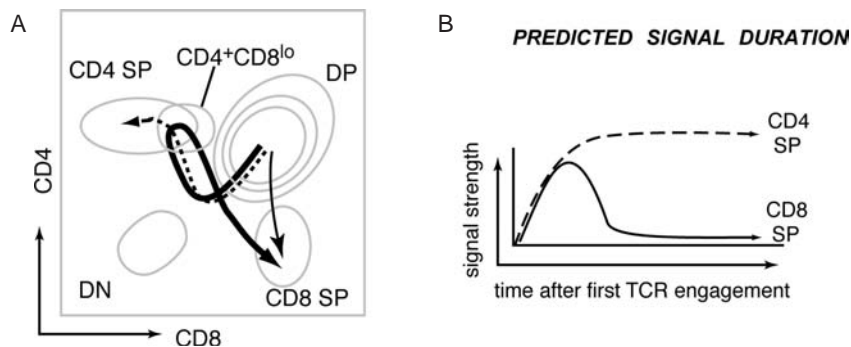
The receptors that are important for positive selection include not only the newly expressed TCR$\alpha\beta$ complexes, but also the CD4 and CD8 coreceptors (especially in the form of CD8$\alpha\beta$ heterodimers), which interact with Lck through their cytoplasmic tails. CD4 co-engages class II MHC, and CD8 co-engages class I MHC. Because the DP cells express both CD4 and CD8, one or the other coreceptor can be engaged to bring Lck to the vicinity of the engaged TCR, whether the MHC that is being recognized is class II or class I. In either case, this triggers a TCR signaling cascade including activation of Lck, ZAP70, Ras, Vav, Itk, calcineurin, and protein kinase C. These events have been extensively studied and validated by knock-out mutations in various signaling components (reviewed in refs. 127,166,167,172–174). Structural features of the TCR$\alpha\beta$ complex, as opposed to the pre-TCR, may cause positive selection signaling to differ qualitatively from β selection signaling: There are hints that a particular subdomain of TCRα and the presence of CD3δ in the TCR$\alpha\beta$ complexes may be crucial for activating the MAP kinases ERK1, 2 (175,176). Distinctively, positive selection elicits sustained ERK activation, which depends on calcineurin B (177) and activates a cascade of SAP-1 (Elk4), Egr1, and Id3 (178;179). CD8$\alpha\beta$ coreceptor complexes bring less Lck

to the immunological synapse than CD4 coreceptor complexes, but both trigger seemingly similar response pathways.

Time Window for Positive Selection

Positive selection occurs in the cortex. DP thymocytes in the cortex have only a three-day lifespan on average before they die "by neglect," and throughout this time they actively carry on V-J rearrangement of the TCRα locus. This starts as soon as RAG expression resumes after β selection and sometimes even before the cells finish proliferating (see Figure 12.2). There is no allelic exclusion of TCRα gene rearrangement; the process is terminated either by positive selection, which finally shuts off RAG expression, or by cell death. Individual cells can rearrange the α-chain genes on both chromosomes, not only once but many times, because the locus offers more than 50 possible Jα segments as well as Vα segments in a permissive topology (180). Expression of an in-frame TCRα chain replaces pTα in complexes with TCRβ, enabling the cells to be auditioned for positive selection immediately based on the interaction with ligands on the cortical epithelial cells. The cortical epithelium provides a rich source of MHC class I and class II surface complexes with a notable lack of costimulatory molecules for T cells. This is important because at the DP stage, costimulation causes not activation but negative selection (reviewed in ref. 166; see next section). Thus, the cortical epithelial microenvironment provides a uniquely forgiving testing ground for newly generated TCR recognition specificities.

The sequence of events triggered by positive selection includes little if any proliferation, in contrast to β selection. CD69 is up-regulated, RAG genes are turned off permanently, CD5 levels increase, and TCR/CD3 complexes are stabilized so that their surface expression increases in parallel. Concomitantly, expression of the chemokine receptor CCR7 is turned on. This enables the cells to migrate from the cortex to the medulla, starting another multiple-day maturation process (181). Glycoprotein processing is altered back to a more "normal" pattern, so that new glycoproteins are once again fully sialylated. The cells regain the Bcl-2 and class I MHC expression that they had lost at β selection, and they begin to recover the functional responsiveness that had disappeared at that time (Figure 12.5). As this proceeds, the cells eventually become resistant to negative selection, and they down-regulate CD24 (HSA) as TCR/CD3 levels rise even higher and CD69 expression finally subsides. Eventually, the cells are enabled to leave the medulla and migrate out to the periphery through a process dependent on a G protein–coupled receptor for the glycolipid sphingosine 1-phosphate (182). The TCR up-regulation, rescue from death by neglect, release to the medulla, and functional maturation events appear to be common to all positively selected thymocytes.

FIGURE 12.6 CD4/CD8 developmental regulation and signal kinetics in positive selection. **A:** Observed paths of phenotypic change through which DP thymocytes differentiate into CD4 SP (broken arrow) or CD8 SP (solid arrows) cells. Some CD8 SP cells can develop by immediate loss of CD4 (thin arrow), but the majority transiently lose CD8 expression and go through a CD4$^+$ CD8^{low} intermediate (thick arrow). **B:** Implications of the initial CD8 loss for the duration of Lck signaling during positive selection of CD4 SP (broken line) and CD8 SP cells (solid line). See text for details.


The process of positive selection is more than the initial contact with MHC ligand, therefore, and the interesting fact is that TCR signaling must continue for several days for the process to be completed (183,184). This has been shown elegantly *in vivo* by genetically engineering mice so that the expression of the crucial TCR signaling mediator, ZAP70, is tightly limited to the DP stage and turned off by the first flashes of positive selection signaling (185). In these mice, positive selection can begin, and a first wave of phenotypic changes is seen, but the cells cannot complete the process. This requirement for ongoing or repeated TCR signaling after the first responses to positive selection signals now appears to be a crucial element of the mechanism that determines the CD4/CD8 lineage choice.

Duration and Strength of Signal Control CD4/CD8 Lineage Choice

The problem of what determines whether $\alpha\beta$ T cell lineage cells will differentiate into CD4$^+$ helper T cells or CD8$^+$ cytotoxic T cells was passionately debated for years (127,186–190), though a consensus is now emerging. The basic questions were whether the signals through the TCR and CD4 versus CD8 coreceptors alone could provide a sufficiently informative difference to instruct the choice between divergent differentiation programs for CD4 helper cells and CD8 killer cells, and whether any other signaling pathway played a major role. Candidates for other pathways were widely discussed. In fact, a skewing of CD4/CD8 differentiation was one of the first aspects of thymocyte development observed to be affected by Notch signaling (191). This was historically critical in bringing Notch to the attention of the T cell development field, although the mechanism of this Notch effect is now thought to be indirect (192).

There are two differences between the positive selection signals experienced by cells selected on class II MHC and those experienced by cells selected on class I MHC. The first difference is quantitative: TCR/class I MHC/CD8 complexes, on average, induce less Lck activation than TCR/class II MHC/CD4 complexes, because Lck is bound less efficiently to CD8 cytoplasmic tails than to CD4. The second difference is kinetic: The time course of Lck signaling in the case of class I recognition is more interrupted, while Lck signaling induced by class II recognition is sustained. This is because the initial response to positive selection includes asymmetrical changes in the surface expression of the two coreceptors, even before any sign that the cell can distinguish a class I ligand from a class II ligand. Figure 12.6A shows the pathways the cells take from DP to CD4 SP or CD8 SP. There is a relatively straight path from DP to CD4 SP by CD8 down-regulation and silencing. In contrast, the major pathway to the CD8 fate is a sinuous loop as the cells initially down-regulate CD8—the wrong coreceptor—so that they are first intermixed with the cells undergoing CD4 selection, and only afterward do they reverse phenotype by reexpressing CD8 and silencing CD4 ("coreceptor reversal"). Reexpression of CD8 then makes use of different cis-regulatory elements and different transcription factors than prior expression of CD8 in the DP stage (193). This makes a qualitative difference because the cell is not finished being selected when it first downregulates CD8 (186). Cells that used CD4/TCR coengagement to bring Lck to the immunological synapse at the start of positive selection still have plenty of CD4 to provide an equally strong signal the next time its TCR engages. Cells that used CD8/TCR coengagement for a signal of equal initial strength, however, have far less CD8 available to mobilize Lck the second time, and they experience a sharp time-dependent falloff in Lck signal intensity (Figure 12.6B).

Signal intensity in the aggregate can have a powerful effect on the lineage choice. Lck especially has been implicated by transgenic manipulations that modestly increase or reduce Lck activity levels in developing thymocytes. Although the effect is not visible in a normal thymocyte population with diverse receptors, there is a dramatic effect on thymocytes with a fixed TCR specificity (194). Cells expressing a class II–restricted TCR transgene can be switched from CD4, helper-lineage positive selection to CD8, cytotoxic-lineage positive selection, through low-level expression of a dominant negative form of Lck. Cells expressing a class I-restricted transgene, conversely, can be switched from CD8 to CD4 lineage by low-level expression of activated Lck. It is interesting to note that an important design feature in this experimental system was the

expression of the modified Lck transgenes from a promoter that is expressed mostly *after* positive selection begins— that is, affecting the duration of the Lck signal as well as the initial amplitude. Downstream of Lck, ERK activity levels have also been shown to affect CD4/CD8 lineage choice in a similar way (168,173,188,195,196).

The importance of signal duration has emerged from increasing evidence that differences in initial signaling intensity are not required for the CD4/CD8 choice. Strikingly, the same signal through the same TCR can result in posi-

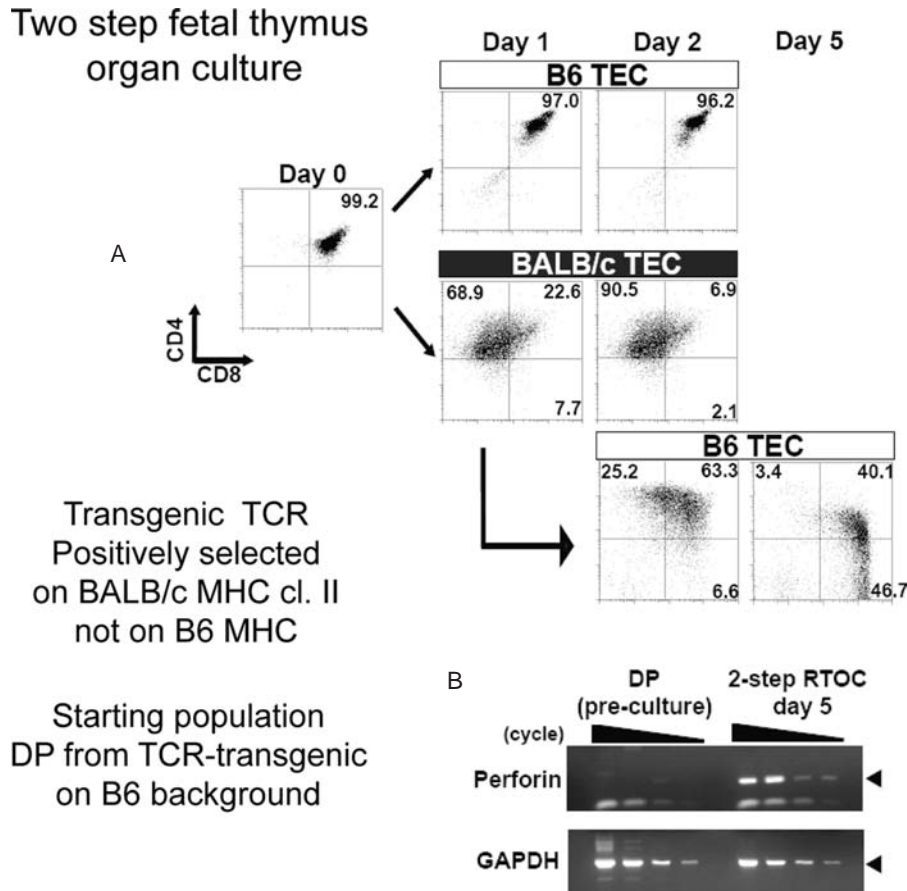
tive selection of CD4 cells, if sustained, while it results in positive selection of CD8 cells, if interrupted (197–199). To control the timing of the signal in these experiments, both elegant transgenic designs and extremely high-resolution fetal thymic organ culture approaches have been used, and these give dramatic and concordant results *in vivo* and *in vitro*. An example in a two-stage fetal thymus organ culture system is illustrated in Figure 12.7 (199). To rule out any remaining question about special signaling capabilities of the CD4/TCR/MHC class II complex as opposed


FIGURE 12.7 Signaling through TCR-class II MHC interaction can drive either CD4 or CD8 SP development depending on duration of signal. The figure shows a two-step fetal thymic organ culture system in which cells can be exposed to the same positively selecting ligands for longer or shorter periods. **A:** Fetal thymocytes with an MHC class II–restricted TCR transgene would normally develop into CD4 SP cells if exposed to the correct MHC haplotype. However, in the B6 genetic background, the right MHC class II product is not expressed. Therefore, in the thymus of a TCR transgenic on the B6 background, the thymocytes cannot progress beyond the DP stage in spite of their expression of a good TCR (left panel). These DP cells can be rescued into differentiation toward CD4 SP within 1–2 days if they are transferred to a reaggregate fetal thymic organ culture (RTOC) with TECs from a BALB/c mouse (middle panels), but they remain arrested at DP in RTOC with TEC from a B6 mouse (upper panels). However, if they are aggregated with the BALB/c TEC for just one day, and then are reisolated and reassociated with B6 TEC, they turn on CD8 again and begin differentiating into CD8 SP cells instead (lower panels). Note that transient exposure to selecting signals, followed by return to nonselecting conditions, has distinct effects from a continuous exposure to either nonselecting or selecting conditions. **B:** RT-PCR analysis of gene expression in cells derived from two-step RTOC, showing that the cells not only differentiate toward the CD8 SP phenotype but also turn on expression of the CD8-lineage associated gene, perforin. From ref. (199), with permission.

to CD8/TCR/MHC class I, targeted mutation experiments have now been done to place CD4 itself under the control of regulatory elements in the CD8 locus, so that CD4 is expressed with a transient down-regulation during positive selection like CD8 instead of its normal stable expression (200). In these mice, class II MHC interaction with TCR and CD4 now selects CD8 cells instead of CD4 cells. Thus, the different kinetic profiles of signaling via TCR-CD4 interaction and via TCR-CD8 interaction in DP thymocytes turn out to be fully sufficient to determine the paths the cells will take.

Molecular Regulators that Control CD4/CD8 Lineage Divergence

That a sustained signal and a discontinuous signal might activate different downstream regulatory cascades is not biologically novel. The general phenomenon of receptor desensitization, for example, or habituation, is based on the need to discriminate between these two kinds of stimuli. However, kinetic discrimination of this kind usually involves not just a pathway, but a control network—for example, by use of a signal-activated feedback inhibitor with a short half-life. The challenge in CD4/CD8 discrimination has been to identify the members of the regulatory network that are responsible for converting a difference in transient activation experiences into the execution of two divergent developmental programs. Since 2002, a small group of transcription factors have emerged as major players in these programs. Their identification is a huge stride toward defining the actual mechanisms that operate during the lineage choice itself (199,201–204).

The regulatory gene with the most remarkable effects on CD4/CD8 lineage choice is a zinc finger, BTB/POZ[1] domain transcription factor called variously Th-POK, cKrox, Zfp-67, or Zbtb7b. This gene was discovered by two completely independent kinds of approach that converged on the same target. It was identified by the Kappes group (201) as the site of a spontaneous point mutation that caused a dramatic "helper-independent" phenotype: In spite of normal TCR interaction with MHC class II, mice with this mutation could not make helper T cells but generated CD8 cells instead (205) (Figure 12.8A). The same gene was also discovered in the Bosselut group as one of the top few genes that were most differentially expressed between developing CD4 SP cells and CD8 SP cells (202). The Zbtb7b gene is normally turned on only in the later half of CD4 cell positive selection, not as an initial response to TCR signaling. Complete loss of its expression, like the point mutation, completely blocks CD4 cell development, while forced ex-

pression of this gene in thymocytes diverts class I MHC–restricted cells completely to the CD4 cell lineage. This is illustrated in Figure 12.8. The converted cells have not just changed expression of surface CD4 and CD8 molecules, but have adopted the whole gene expression program that goes with the new phenotype (201) (Figure 12.8C). This transcription factor thus can duplicate the effect of sustained TCR-CD4-Lck signaling in positive selection, imposing the CD4 helper fate in a dominant way, and it is likely that the sustained signal is required especially to induce this factor's expression (206).

CD4 cell development also depends on GATA-3, the same factor that is essential for early T cell development, as shown by experiments where it is deleted or down-regulated in DP thymocytes (204,207). Surprisingly, GATA-3 is normally down-regulated at the DP stage and virtually shut off in CD8 SP cells, but it can reactivated by strong TCR signals consistent with CD4 positive selection. Forced expression of GATA-3 blocks CD8 cell selection, but it does not have the power on its own to cause redirection of CD8 cells to a CD4 fate (204). This suggests that GATA-3 is not sufficient to activate Zbtb7b expression in the absence of sustained TCR signaling, in contrast with Zbtb7b, which may help to activate or sustain GATA-3 expression.

The drivers of CD8 cell development most prominently include the transcription factor Runx3, with assistance from Ikaros and an HMG-box transcription factor named TOX (199,208,209). Runx3 in particular is probably a general driver of the CD8 cell fate. It is seen to cause the repression of CD4 (210), as well as participating with Ikaros in CD8 upregulation, and it must be activated as CD8 cells finally make the "coreceptor reversal" turn and become $CD4^- CD8^+$. In the two-step culture system shown in Figure 12.7, CD8 cell development cannot occur when Runx3 is antagonized (199). There has been some controversy about whether forced expression of Runx3 can actually impose the CD8 fate on cells with a class II MHC–specific receptor (211,212); it is possible that this depends on the level at which Runx3 is expressed. Similarly, the roles of Ikaros and TOX in positive selection seem to be more complex than the simple fate-determining activity seen with Zbtb7b. The reported activities of these factors have to be considered in light of the evidence that CD8 cell fate is likely to be a default fate, one that can be overridden by sustained TCR/Lck signaling, as discussed earlier. If the CD4/CD8 lineage choice is inherently asymmetrical like this, then a true CD8-promoting factor need not work as dominantly as Zbtb7b. CD8 cell programming could even begin in the majority of positively selected cells regardless of selecting ligand, only to be repressed by Zbtb7b in cases where Lck signaling is sustained (206).

The positive selection process thus provides a developmental cascade in which evolving transcription factor expression states are confronted repeatedly with TCR and Lck signals over a period of days. Many if not all of the

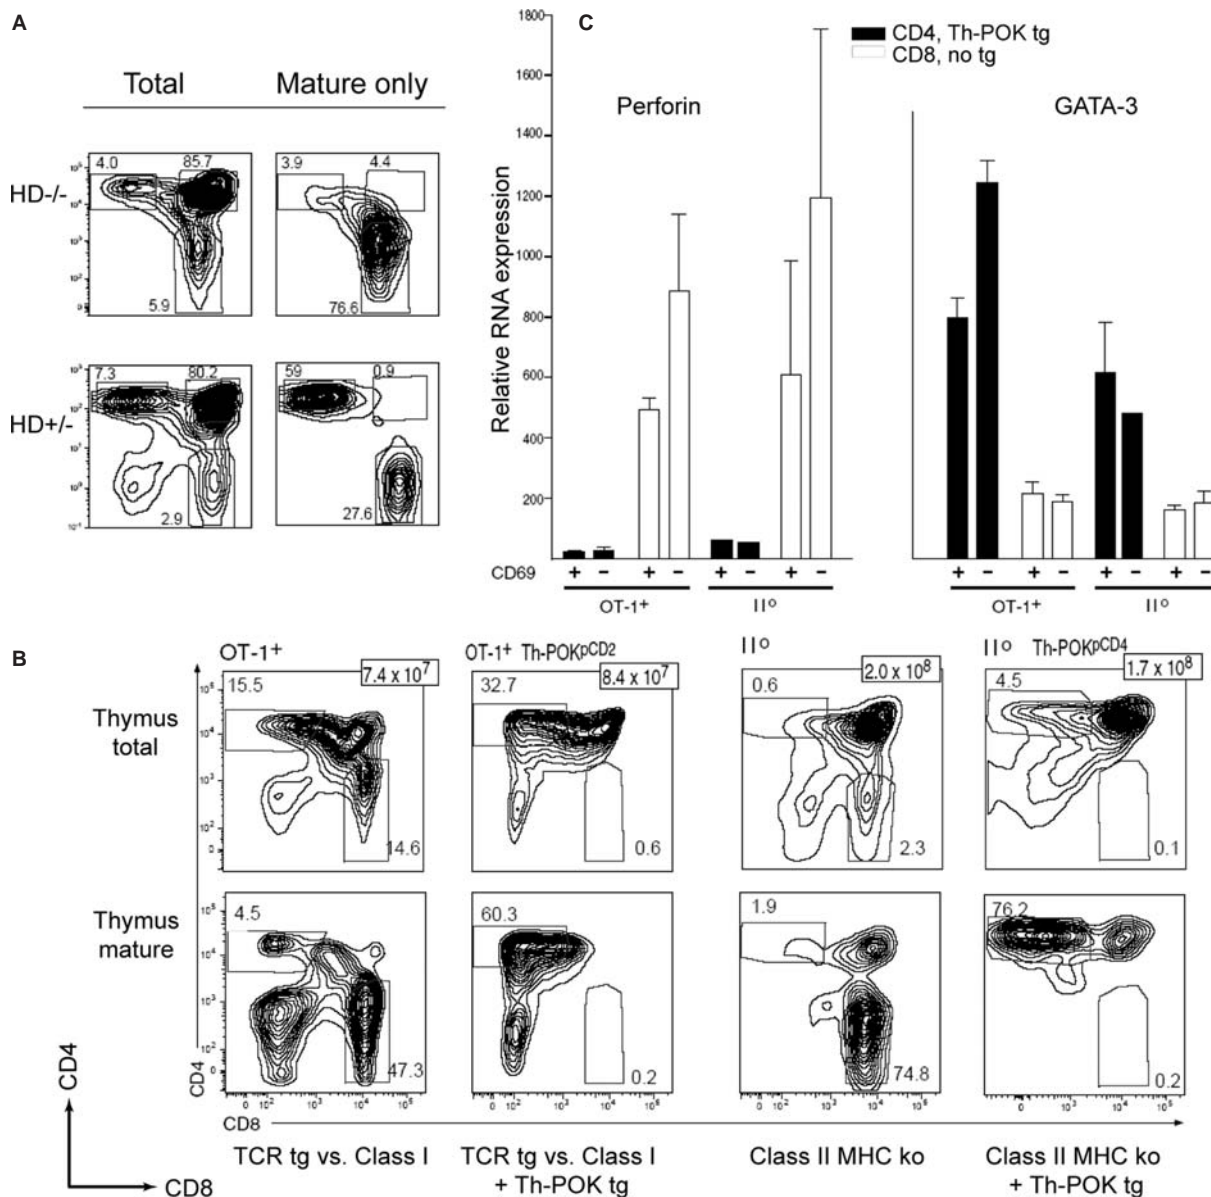

FIGURE 12.8 Zbtb7b (Th-POK) is necessary for CD4 SP maturation and can override TCR–MHC interactions that normally promote CD8 development to direct thymocytes into CD4 SP maturation instead. From ref. (201), with permission. **A:** Lack of normal Zbtb7b (Th-POK) function in HD$^{-/-}$ mice causes a specific absence of mature CD4 SP cells in the thymus. Mutant phenotype: top panels. Wild-type phenotype: lower panels. Mature thymocytes here are the subset defined by low expression of CD24 (HSA) and high expression of the marker CD62L. Note that there are some CD4$^+$ CD8^{low} cells in the mutant (left upper panel), but these are transitional cells that are not fully mature (right upper panel). **B:** Forced expression of Zbtb7b (Th-POK) from either of two T cell–specific transgenes (Th-POK^{pCD2}, Th-POK^{pCD4} = Th-POK tg) can force cells that would otherwise develop into CD8 SP cells to become CD4 SP cells instead. Normally only CD8 SP cells mature in mice with a class I MHC-restricted TCR transgene (OT-I), or with a genetic deficiency of class II MHC expression (II°) (lower panels, "TCR tg vs. Class I," "Class II MHC ko"). Combining these mutations with Th-POK transgenes overrides CD8 cell programming to drive maturation to the CD4 SP fate instead (lower panels). Numbers in boxes in upper panels show total thymocyte cellularity in each transgenic. These results imply that the Th-POK transgenes cause redirection of cells without gross changes in survival. **C:** Cells converted to CD4 phenotype by Th-POK transgenes up-regulate the CD4-associated transcription factor GATA-3 and downregulate the CD8-associated effector gene perforin, even if they were positively selected by a class I-restricted TCR transgene (OT-I) or in the absence of class II MHC (II°). RNA expression levels are shown for the CD8 SP cells that would normally be selected in each of these conditions (open bars), compared with those for the CD4 SP cells that are selected instead when a Th-POK transgene is present (black bars). The figure confirms that the change occurs during positive selection itself, as similar effects are seen in subsets of each population that are enriched for cells just undergoing selection (CD69$^+$) and subsets that are fully mature (CD69$^-$).

critical regulators of the lineage choice are now in hand, and good preliminary guesses can be made about the ways through which they regulate each other to guide the cells to two distinct developmental fates. These linkages can be directly tested, and then the way positive selection guides the choice between helper and killer fates will be truly understood.

CENTRAL TOLERANCE

An inevitable outcome of the random generation of TCR diversity and the relatively promiscuous positive selection process is the survival of cells that can be highly reactive to both foreign and self-peptides bound by self-MHC. TCR-positive cells go through an additional checkpoint in the thymus, which shapes the final TCR repertoire by pruning out or altering self-reactive cells. Positively selected cells continue to mature for several additional days in the thymic medulla during which time they not only acquire effector function but also undergo "central tolerance" mechanisms. In the process, they repetitively test their TCRs for self-reactivity through interactions with medullary epithelial cells (mTECs) and dendritic cells (DCs) expressing a huge range of self-peptide–MHC complexes (Figure 12.9). The outcome of these selective processes is a final TCR repertoire that is self-tolerant. The first of these mechanisms, negative selection or clonal deletion, results in the apoptotic death of cells with high affinity TCRs for at least one of the self-antigen–MHC complexes. Another thymic selection mechanism has been elucidated only in recent years with the discovery of regulatory T cells (T_{reg}) that are potent dominant suppressors of autoimmune T cells, which also arise in the thymus. These T cells, whose TCRs also recognize high-affinity self-antigen–MHC, are not induced to undergo apoptosis, but instead survive in an altered state from conventional positively selected CD4 and CD8 SP cells. Failure of either of these central tolerance mechanisms can result in systemic autoimmune disease in humans and mice. What intrinsic and extrinsic factors, in addition to TCR specificity and affinity, determine these very different alternative fate choices made by developing $\alpha\beta$-T cells, are areas of very active research.

Negative Selection

The phenomenon of negative selection of self-reactive T cells in the thymus was first demonstrated in response to endogenous superantigens and self-MHC (213), and studies using transgenic TCRs over the past two decades have shown that T cells with high-affinity TCRs to self-antigen–MHC complexes are induced to undergo apoptotic death (reviewed by 214,215). Using these transgenic model systems, deletion was found to occur at a range of stages

from the DN or DP stage of T cell development in the thymic cortex to the SP stage in the medulla. The exact stage of T cell development and thymic location in which negative selection normally occurs is controversial because of the early timing and high level of transgenic TCR expression relative to normal T cells (215,216). However, several lines of evidence suggest that under normal conditions, negative selection may be predominantly separated from positive selection, both developmentally and spatially, as shown in Figure 12.9. In a transgenic TCR model system where the TCR was expressed with normal timing, deletion was found to predominantly occur in SP cells in the medulla (217). In addition, the medulla is the specific site of two kinds of antigen-presenting cells, which are potent inducers of negative selection: mTECs and dendritic cells (DCs). These cells express high levels of MHC and costimulatory molecules, both of which greatly facilitate negative selection and are highly specialized for the presentation of a large array of peripheral self-antigens acquired by several unique mechanisms. Finally, the critical importance of the thymic medulla to central tolerance, but not SP cell maturation, was demonstrated in experiments showing that when T cells are prevented from migrating from the cortex to the medulla by the lack of the chemokine receptor CCR7 or its ligand, cells undergo normal maturation and export from the thymus, but the animals develop autoimmunity (218). The autoimmune phenotype resembles a failure of negative selection, although faulty regulatory T cell development (see later discussion) has not been ruled out. This shows that central tolerance is, at least in part, dependent upon T cell passage through the medulla and interactions with medullary cells.

Long after negative selection was discovered, it was unknown whether the thymus could express and present the vast array of protein peptides found throughout the body for negative selection at a sufficient level to maintain self-tolerance and to avoid autoimmunity, and if so what mechanism could allow for such expression. In the absence of such a mechanism, and with evidence that self-reactive T cells can be found in the circulation of even normal healthy animals, it was debated whether negative selection was necessary or sufficient to prevent autoimmune disease. The discovery of the transcription factor gene, *Aire,* which causes a rare autoimmune disease, APECED (autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy) syndrome, when mutated in humans and mice, has now confirmed the critical importance of negative selection in the maintenance of self-tolerance and has contributed greatly to our understanding of this process (219–223). Central to this mechanism are the mTECs. *Aire* plays a unique, though as yet poorly understood, role in inducing the expression in mTECs of clusters of genes that are normally highly restricted in their tissue specificity or timing of expression. Genes from tissues throughout the body are expressed in the mTECs, and each mTEC expresses
FIGURE 12.9 Progressive narrowing of the $\alpha\beta$-TCR repertoire during development based upon affinity to self-peptide–MHC complexes, leading to MHC restriction and self-tolerance. **A:** TCR^{lo} CD4$^+$CD8$^+$ DP cells in the thymic cortex test their newly generated TCRs against self-peptide–MHC complexes presented by cortical cells with three major outcomes: those unable to bind self-MHC die by "neglect," those binding self-peptide–MHC with high affinity die by negative selection, and those with weak affinities to self-peptide–MHC are positively selected to undergo differentiation to CD4 or CD8 lineages. The TCRs of these positively selected cells are restricted to self-MHC and migrate to the medulla for further selection and maturation. TCR^{hi} CD4 or CD8 SP cells in the thymic medulla pass through a new network of different antigen-presenting cells expressing a larger subset of peptide antigens plus costimulatory molecules. Self-reactive T cells, those with high-affinity interactions with self-peptide–MHC, are either induced to die by negative selection (arrow) or are positively selected into the T$_{reg}$ lineage, upregulating Foxp3 and CD25. The cells with highest affinity interactions in the cortex are not necessarily those with the highest affinity for antigens expressed in the medulla due to the changes in cell properties and antigen presentation. Note that the affinity range for T$_{reg}$ selection overlaps with the affinity range for negative selection. These selective mechanisms establish the level of T cell central tolerance in the individual. T cells with TCRs of weak affinity to the constellation of presented self-peptides undergo maturation, downregulation of CD69 and CD24 (HSA), and they eventually emigrate into the periphery as naïve CD4$^+$ or CD8$^+$ T cells. Hatched lines indicate compartment boundaries. Gradient shading indicates the range of TCR affinities, on surviving cells, for ligands within the relevant compartment. **B:** The relative numbers of $\alpha\beta$-T cells decline precipitously during development from the DP to mature SP stages due to neglect and negative selection in the thymus.

and presents peptides from a subset of these genes to T cells in the medulla. Although *Aire* is responsible for this promiscuous expression of peripheral antigens in mTECs, not all tissue-specific genes are dependent upon *Aire* for expression in mTECs. However, even in cases where antigens are expressed in mTECs in the absence of *Aire,* negative selection of specific T cells is still impaired even though levels of MHC and costimulatory molecules are not different (224,225). Thus, in addition to its novel transactivating activity, *Aire* clearly plays an additional critical role in mediating negative selection by mTECs.

DCs are more abundant in the thymic medulla than in the cortex and are very potent mediators of negative selection, even more so than mTECs. They do not express *Aire* and and so do not express the huge range of tissue-specific genes that mTECs do. However, DCs have the capability to cross-present antigens obtained from various other cells. It has been demonstrated that that medullary DCs can cross-present antigens expressed by mTECS, possibly acquiring these antigens from the short-lived mTECs as they die (226). In addition, DCs have been shown to be capable of acquiring antigens from the periphery, migrating to the thymic medulla for antigen presentation to developing T cells, and inducing apoptosis in antigen-specific T cells (227). Thus, DCs in the medulla have access to antigens obtained in the periphery and indirectly from promiscuous gene expression by mTECs, as well as those they express themselves, for presentation to T cells.

In addition to their extraordinary capacity for acquiring and presenting self-antigens, mTECS and DCs also express costimulatory molecules such as B7 and CD40. CD28/B7 or possibly CD40/40L interactions appear to play an important role in negative selection, although neither is absolutely required for deletion (228) (reviewed in 166). It is possible that in the absence of these molecules very strong TCR signals or other costimulatory molecules may be able to provide the additional signal.

Negative selection triggers apoptosis that appears to be mediated by up-regulation or phosphorylation of a pro-apoptotic Bcl-2 family member, Bim (229), in collaboration with Bax and Bak (230). Up-regulation of the orphan steroid receptor, Nur77, also plays a role in this apoptosis (231). Distinctive signaling pathways from TCR and costimulatory molecules that may activate these mediators are under intense investigation. In knockdown experiments using small interfering (si)-RNA, the serine-threonine kinase MINK has recently been reported to be involved in negative selection specifically, potentially linking TCR signals with JNK and p38, as well as Bim, activation (232).

Negative vs. Positive Selection

What are the molecular mechanisms that developing T cells use to distinguish between positive and negative selection signals from the TCR? Once again, TCR signal strength helps to determine the outcome of TCR engagement by antigen-MHC complexes: Weaker signals result in survival and differentiation, while stronger signals trigger cell death. How these signals give such different outcomes is still not well understood, and conflicting results have been obtained using different models of selection (reviewed in 214,215). Both modes of selection use the Lck proximal signaling pathway, but signals transduced during positive selection appears to be particularly dependent upon calcineurin and ERK, while negative selection depends upon JNK and p38 activation, although ERK also appears to be activated. One model for how T cells distinguish between weak and strong TCR signals predicts that positive selection results from low, sustained ERK activation, while negative selection results from a transient burst of ERK activation and JNK and p38 activation. A recent study showed that differences in the subcellular compartmentalization of Ras/MAPK signaling intermediates, in response to variants of agonist peptides giving differing TCR signal strengths, may determine the thresholds for positive versus negative selection (233).

The difference may not simply be based on signal strength. The physiological context changes between positive selection, occurring in the more immature DP cells in the thymic cortex, and negative selection, occurring typically, but not exclusively, in more mature positively selected SP T cells in the thymic medulla (Figure 12.9). Not only do the SP T cells pass through a network of mTECs and DCs expressing an expanded array of self-peptides and MHC complexes as well as costimulatory molecules, but also, as a result of positive selection, these SP T cells have undergone major changes in differentiation programming as CD4 or CD8 cells (Figure 12.5). The higher levels of surface TCR and other changes as a result of positive selection, such as up-regulation of CD5 and restored sialylation of surface glycoproteins, are likely to change sensitivity of SP cells to high-affinity TCR signals. Thus, the different developmental states (DP versus SP), levels of surface TCR and other signaling components, gene expression programs, and microenvironment of the T cells, as well as the differing arrays of presented antigens in the cortex versus medulla, are all factors that likely to contribute to the different outcomes of high- versus low-affinity TCR-peptide–MHC interactions leading to negative versus positive selection.

Development of Regulatory T Cells

Negative selection of autoimmune cells was originally thought to be the major mechanism of tolerance in the thymus. However, recently, a very potent and critically important T cell population which mediates active suppression of immunity, including autoimmunity, was found to develop in the thymus. They are known as regulatory T cells or T_{reg} cells (see Chapter 30). This specialized lineage of highly immune suppressive

T cells was first characterized by surface expression of CD4 and CD25, having a dependence upon exogenously supplied IL-2, and uniquely expressing the transcription factor *Foxp3* (*Scurfin*) (234,235). *Foxp3* is a lineage-determining factor for T_{reg} cells and retroviral transduction of this gene into peripheral *Foxp3*$^-$ T cells can induce them to adopt a regulatory T cell phenotype and function. This factor is absolutely required for the development of T_{reg} cells as shown in mixed bone marrow chimera experiments (236). *Foxp3*, a forkhead winged-helix transcription factor family member, was initially identified as the mutated gene causing a severe autoimmune disease in humans, immuno-dysregulation, polyendocrinopathy and enteropathy, X-linked (IPEX) syndrome, and a similar disease in *scurfy* mice (reviewed by 234,237). These mutations, along with *Foxp3*-gene knockouts, result in complete loss of T_{reg} cells, demonstrating their vital importance in the maintenance of self-tolerance.

The first evidence that a population of suppressive T cells might arise as a separate lineage from the thymus came from experiments in which neonatal mice thymectomized 2–3 days after birth were not only lymphopenic as expected, but also surprisingly developed autoimmune disease (238). The missing population was eventually identified and characterized as CD4$^+$CD25$^+$T cells which first appear in the thymus around 2–3 days after birth (239). These thymic T cells were found to be capable of dominantly suppressing the activation and proliferation of antigen-activated T cells similarly to the peripheral CD4$^+$CD25$^+$ regulatory T (T_{reg}) cells. Using mice with the marker green fluorescent protein (GFP), knocked into the *Foxp3* locus to study the development of T_{reg} cells, it was confirmed that *Foxp3* expression can begin in the thymus. The majority of the GFP$^+$ cells in the thymus are CD4 SP cells in the medulla, although some DP cells are also positive, and there is evidence that they develop within the thymus (240). In fact, regulatory T cells make up approximately 5% of thymic CD4$^+$ cells and the TCRs expressed by T_{reg} cells have a comparable range of diversity to conventional T cells (241). Mice with various rearranged transgenic TCRs also contain CD4$^+$CD25$^+$ regulatory T cells, in a process that requires the presence of the cognate antigen for their development (242,243).

Overall it appears that commitment to the T_{reg} lineage and negative selection occur in the same developmental stages and thymic regions, and are dependent on similar or at least overlapping sets of TCR-ligand affinities (Figure 12.9). Several lines of evidence suggest that selection for T_{reg} cells, like negative selection, can be a response to high-affinity TCR-peptide-MHC interactions (235,244). Using a model system with influenza virus hemagglutinin (HA) expressed as a neo–self-antigen and transgenic TCRs with varying affinities to HA, the proportion of regulatory T cells that was generated declined with decreased TCR affinity (245). Indeed, the affinity range permissive for T_{reg} development overlaps considerably with the range

promoting negative selection. When *Foxp3* is mutated so that T_{reg} cannot develop, the same TCR as used by suppressive T_{reg} cells can be used by pathogenic autoimmune cells instead, demonstrating that there is overlap in these two self-reactive TCR repertoires (246). In double transgenic systems, regulatory T cell development is accompanied by deletion of T cells sharing the same rearranged TCR genes. However, the relative proportions of cells undergoing these two modes of central tolerance change with alterations in amount or mode of antigen expression. Careful analysis of transgenic TCR with graded doses of agonist peptide/MHC resulted in dramatic changes in the numbers of cells undergoing negative selection, while the numbers of T_{reg} cells changed only modestly (247). Taken together, these results show that, above a certain minimum TCR-ligand affinity, the choice between apoptosis due to negative selection and differentiation and survival as a regulatory T cell may be due to differences in the intrinsic state of the T cell, conferred by earlier developmental events, or due to extrinsic factors rather than the precise affinity of the TCR.

Although it is currently unknown what intrinsic and extrinsic factors distinguish these two central tolerance mechanisms, recent studies are just beginning to provide insights (reviewed in ref. 247a). One possibility is that *Foxp3* induction depends on a special kind of stimulatory experience. CD28 constimulatory molecules appear to be necessary for T_{reg} development and can play a role in the upregulation of *Foxp3* in T cells (248,249), although CD28 may also be important in negative selection, suggesting that the cell response to CD28 or additional signals distinguish these fates. It also appears that earlier developmental events may in fact determine a subpopulation of cells that is more likely to respond to high-affinity TCR engagement in the thymus with survival rather than death. Two recent studies have shown that pT$\alpha^{-/-}$ mice, which generate few DP and mature T cells due to an incomplete block at β selection, have a relative enrichment of T_{reg} cells in the thymus and periphery (250,251). This effect may be due to the atypical β selection experience these cells undergo, or due to the reduced exposure of their DN precursors to an intercellular mediator produced by DP cells (159). If confirmed, these findings suggest that immature thymocytes undergoing selective events are intrinsically diverse in their ability to respond to TCR ligation and costimulation due to as yet uncharacterized variations in their developmental history.

Autoimmunity as a Result of Failures of Central Tolerance

Overall, positive and negative selection processes in the thymus act to narrow the TCR repertoire of an individual to be responsive to self-MHC molecules but not responsive to high-affinity self-peptides when presented by self-MHC, in principle allowing survival of only TCRs that can respond to non–self-peptides presented by self-MHC (Figure 12.9). Not all T cells with high affinity to

self-peptide–MHC are deleted, but this "exception proves the rule": Many are diverted to the T_{reg} lineage, which in the periphery can dominantly suppress any surviving autoreactive T cells that avoided negative selection. This process of selection and passage through TCR-mediated events during T cell development results in major changes in overall repertoire sensitivity to self-antigens. Autoimmunity may result from several failures of central tolerance: (1) a failure to present specific self-antigens in the thymus, (2) the failure of clonal deletion of conventional T cells with TCRs of high self-reactivity due to intrinsic or extrinsic factors, or (3) a failure of T_{reg} cell generation due to intrinsic or extrinsic factors. The human diseases APECED syndrome and IPEX, and their mouse counterparts with mutations in *Aire* and *Foxp3*, emphasize the critical importance of negative selection and generation of T_{reg} cells respectively in preventing autoimmune reactions. Understanding the different means by which central tolerance is achieved, and determining what mechanisms can lead to its failure and autoimmunity, is a major challenge in the study of T cell development and lineage choices.

CONCLUSION

We have focused in depth on several aspects of intrathymic T cell development that are particularly significant in terms of developmental mechanisms or immunological impact. These are areas in which work since 2000 has offered new glimpses of understanding how a momentous developmental choice or transition will be made. But it is worth returning to the larger picture of T cell development sketched in Figures 12.2 and 12.9. In overview, it is striking how much functional diversity and lineage choice remain with cells after they have undergone T lineage commitment. The cells take advantage of the intricate architecture of the thymus to migrate from one domain to another, using a core group of signaling molecules, carefully modulated interactions with environmental ligands, and a few newly induced transcription factors that interact with another, more persistent set of transcription factors, to refine progressively what kind of T cell their initial T lineage commitment will produce. T cell development begins in the thymus as we have seen, but the ultimate working-out of a T cell's destiny extends through many rounds of differentiative response to TCR-mediated signals, not only in the thymic medulla but also long after they have left the thymus, in the periphery.

Peripheral T Lymphocyte Responses and Function

Steven L. Reiner

INTRODUCTION

After a thymus-derived T lymphocyte enters the peripheral circulation, it constantly, albeit indirectly, samples the body for evidence of its cognate foreign antigen via encounters with dendritic cells (DCs) in secondary lymphoid organs. Once activated in secondary lymphoid organs, a naïve T cell undergoes a regulated process of division and differentiation, leading to alterations in gene expression of its migrating progeny, allowing them to mediate the functional properties associated with T cell–dependent immunity at sites of infection and inflammation. After an immune response has ended, a system for preserving the T cell with useful antigen specificity is hard-wired into the differentiation process, leaving behind a remnant of memory T cells. This chapter will provide an overview of the milestones in the lives of T cells as they function in anticipation of, during, and after an immune response.

THE FUNCTIONAL IMPLICATIONS OF T CELL DEVELOPMENT

Prior to their entry into the thymus, progenitors of the T cell lineage develop in the bone marrow. T cells are born in the thymus, which together with the bone marrow, are

considered the primary lymphoid organs. After expression of α-β T cell antigen receptors and coexpression of CD4 and CD8, so-called *double positive thymocytes* undergo a matchmaking process to determine their suitability for specific functions in the periphery. Among the first major criteria being assessed is whether the T cell receptor is of too high an affinity for self-peptide/major histocompatibility complex (MHC). Such cells should undergo negative selection through trigger of T cell receptor (TCR) signaling–dependent apoptosis. To ensure that self-peptides are adequately foreshadowed in the restricted confines of the thymus, the putative transcription factor *Aire* mediates expression of numerous nonthymic genes in thymic medullary epithelial cells (1). Thymocytes that sample their way through hematopoietic-derived DCs and this "self-shadow" on epithelial cells are thereby screened for virtual whole-body reactivity (2). Mutation of *Aire* results in the autoimmune polyendocrinopathy candidiasis ectodermal dystrophy (APECED) syndrome (1,3).

Cells that seem to fall just short of the critical threshold for negative selection but are in some ways still self-reactive undergo an unusual differentiation process to become natural regulatory T (Treg) cells (4). This likely occurs in the thymic medulla when DCs receive a signal from epithelial cells expressing thymic stromal lymphopoietin (5). The differentiation of Treg cells involves induction of the forkhead transcription factor, FoxP3, which specifically marks and specifies the major attributes of the Treg lineage (6–9). Natural Treg cells do not undergo typical antigen-induced proliferation and effector differentiation; their behavior, instead, is likened to an anergic state (10). These cells are far from functionless, however, as they mediate critical inhibitory activity of other autoreactive T cells and, potentially, of T cells engaged in immune responses against pathogens. Their mode of suppression or inhibition is not fully understood but may involve actions directly on T cells or indirectly through antigen-presenting cells. Mutation of FoxP3 results in immune dysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX) syndrome (11).

Double-positive thymocytes with a TCR of too weak an affinity to have signaling engaged by self-peptide–MHC will subsequently die from this neglect. In contrast, thymocytes with a TCR of a suitably weak affinity to have some (but not too much) signaling elicited by self-peptide–MHC undergo positive selection, their licensure for eventual export to the peripheral lymphoid system. In general, thymocytes with TCRs recognizing self-peptide–MHC class I become CD8$^+$ (CD4$^-$) single positive thymocytes and then naïve CD8$^+$ (or cytotoxic) T cells when they exit the thymus and populate the periphery. Thymocytes with TCRs recognizing self-peptide–MHC class II become CD4$^+$ (CD8$^-$) single positive thymocytes and then naïve CD4$^+$ (or helper) T cells when they exit the thymus and populate the periphery.

Expressing CD4 versus CD8 has significant functional bearing on helper and cytotoxic T cell function, respec-

tively. Nonetheless, these coreceptors are not sufficient to specify all of the attributes specific to helper or cytotoxic T cells. How coreceptor (CD4 versus CD8) and lineage (helper versus cytotoxic) choices could be coupled has been a central enigma of T lymphocyte development and function (12,13). Recently, there has been increasing evidence that a key transcriptional regulator can coordinately activate and silence one coreceptor versus the other while also imparting essential differences on the helper versus cytotoxic potential of the single positive thymocyte (14,15). In developing CD4$^+$ thymocytes, ThPOK is necessary for *Cd4* gene expression, induction of several molecules that are helper T cell–specific, including Gata3, a transcriptional activator implicated in CD4$^+$ T cell positive selection and function. In addition, ThPOK can repress *Cd8* gene expression and inhibit other essential aspects of the cytotoxic lineage. More information about this can be found in the chapter Development of T Cells.

The discovery that a single factor can coerce developing thymocytes to adopt the helper fate and abandon the cytotoxic fate provides a satisfying mechanism for coupling coreceptor and lineage choice. It also raises some new questions about the evolution of effector diversity in adaptive immunity. Whether this means that the cytotoxic T cell lineage is a more ancestral lineage or more of the default pathway of thymic development than the helper T cell lineage is uncertain. In terms of peripheral functions, however, a CD8$^+$ T cell bears closer resemblance to a natural killer (NK) cell than does a CD4$^+$ T cell (16).

NAÏVE T CELLS

Transitioning to the Periphery: New Place, New Name

After positive selection, mature single positive thymocytes are licensed to leave the thymus and dwell in secondary lymphoid tissues. An essential signaling pathway for thymic exit, or egress, to the periphery involves sphingosine 1-phosphate receptor-1 (S1P1), which will also turn out to be dually critical for the ability of peripheral T cells to leave lymph nodes (17). The transcriptional regulator KLF2 is likely to be an essential activator of this receptor (18). The secondary (or peripheral) lymphoid tissues include the spleen, lymph nodes, and mucosal-associated lymphoid tissues (gut and bronchial, among the best studied). Gut-associated lymphoid tissues include Peyer's patches and other organs such as tonsils and adenoids. Their detailed anatomy is covered in the chapter on lymphoid tissues and organs.

After its birth and export from the thymus, what was once the most mature of thymocytes from the perspective of the primary lymphoid organs (a single positive CD4$^+$ or CD8$^+$ cell) is now considered to be the most immature lineage from the perspective of the secondary lymphoid organs and T cell functioning. The nomenclature for the

continued T cell development that occurs during peripheral function is, however, slightly different than the terminology of thymopoiesis. Instead of calling a nascent peripheral T cell immature, it is referred to as a naïve CD4$^+$ or CD8$^+$ T cell, the operative term designating that the T cell has yet to encounter antigenic foreign peptide/MHC ligands. After being engaged by antigenic foreign peptide–MHC ligands, naïve T cells are then considered to be antigen-experienced. Antigen experience, however, represents a considerable variety of maturational states and fates including, but not limited to, acutely activated but not fully differentiated, abortively differentiated (or anergic) and fully differentiated effector and memory cells. The distinctions between these conditions will be discussed later in this chapter.

How Naïve T Cells Live

Naïve T cells have often been described as "resting," owing to the fact that they are not actively dividing. A naïve T cell that has not yet been activated by antigen is, however, far from physically inactive (Figure 13.1). Instead, naïve T cells undergo a relentless process of migration through blood, entry into lymph node, extensive sampling of self-peptide/MHC, exit through lymph, return to blood, and re-entry into another lymph node that repeats incessantly for many months—this is the lifespan of naïve cells (19–21). Among the concerns in life of a bona fide naïve T cell that is suited to undergo an immune response are survival, migration, and surveillance. These essential processes are geographically united by secondary lymphoid

FIGURE 13.1 T cells during homeostasis and immunity. **A:** A naïve T cell circulating through the blood enters a secondary lymphoid tissue and quickly arrives at the T cell–rich zone. It undergoes random migration through the T cell zone for many hours. After exiting the lymph node, it reenters the circulation briefly before arriving at another lymph node and repeating the process. The lengthy stopovers in secondary lymphoid tissue provide survival signals for the long-lived, nondividing cell. **B:** Upon encounter with foreign pathogen-associated antigen, random motion changes to purposeful but brief contacts with DCs during the first several hours, followed by sustained contact lasting for hours, followed by the first cell division and resumption of brief encounters. During the second stage, sustained contact is augmented by several factors, including inflammatory signaling received by the DC and, for CD8$^+$ T cells, the presence of CD4$^+$ T cells. The presence of Treg cells, conversely, limits the degree of sustained contact for newly activated CD4$^+$ T cells. Correlates to immunity emerging from these variations suggest that the sustained contact is a key checkpoint in the activation process. **C:** After the first division, still in the secondary lymphoid tissue, further division coincides with acquisition of new effector (or memory) potency and migratory instructions, for relocating to other zones in the lymph node or non-lymphoid tissue.

organs, which contain attractants to lure T cell entry, survival signals to license their nourishment, and the relevant display of peptide/MHC complexes that would reflect the likelihood (or not) that foreign invaders are violating innate defense mechanisms (22,23).

Naïve T cells arrive at each surveillance stopover in a secondary lymphoid organ via the bloodstream (22). In the case of lymph nodes and Peyer's patches, the high endothelial venules (HEVs), which are specialized blood vessels, serve as the nidus of attraction for the T cell to enter the tissue. HEVs express a unique set of ligands that interact with the receptors characteristic of naïve T cells. Among the most critical attractant molecules on HEVs are the chemokine CCL21 that engages CCR7 and vascular addressins that engage CD62L, or L selectin. From a functional perspective, the expression of high levels of CCR7 and CD62L are important T cell markers used to identify populations such as naïve cells, newly activated cells that have not yet been licensed for tissue migration, and a subset of memory cells with migration patterns similar to naïve cells, with preference for secondary lymphoid organs. Extravasation of the naïve lymphocyte through HEVs relies on intercellular adhesion molecules (ICAMs) that engage the integrin LFA-1. Entry into the spleen differs from entry into lymph node and mucosal lymphoid tissue. Naïve T cells enter the spleen through terminal arterioles, not HEVs, and this does not require CD62L. Subsequent migration to the white pulp, however, does require integrins and chemokine receptor signaling.

Secondary lymphoid organs are composed of distinct zones enriched with T or B lymphocytes (22). In the lymph node, the paracortical T cell zone contains T cells and the critical supplier of peptide/MHC complexes, DCs. By virtue of their location, migration, and function, DCs are assumed to be a specialized cell that exists to supply the demands of T cells and ensure that they remain quiescent during homeostasis or alert and educate T cells during an attack. In the spleen, T cells and DCs primarily reside in the periarteriolar lymphoid sheath (PALS) within the white pulp. Once inside the secondary lymphoid organs, naïve T cells are lured and retained in the T cell–rich zones by CCL21 and CCL19 produced by stromal cells, which signal to CCR7 on naïve T cells. DCs also express CCR7, thereby insuring colocalization of T cells and DCs in these tissues. Naïve T cells dwell in the T cell–rich zones for several hours before exiting the secondary lymphoid organs (Figure 13.1).

Coupling Survival and Surveillance

Within the T cell–rich zones of secondary lymphoid organs, naïve T cells gain access to the ligands of their antigen receptor, peptide/MHC complexes, presented primarily on the surface of resident or newly arrived DCs. For a naïve T cell that does not encounter antigenic foreign peptide/MHC complexes, it receives critical survival signals from self-peptide/MHC complexes (24–27). In addition to a survival signal, this periodic engagement of the TCR may offer refinement or validation of the suitability of the TCR for eventual antigenic peptide/MHC engagement. It is thought that naïve $CD8^+$ T cells may show greater dependence than naïve $CD4^+$ T cells for continual low-level, or "tonic," signaling through the TCR. Nonetheless, the long life span of nondividing naïve T cells of both subsets is dependent on receipt of the peptide/MHC signal.

The other major survival signal for both subsets of naïve T cells is IL-7 (28–33). Although it has not been well visualized, it is presumed that IL-7 will also be accessed in the secondary lymphoid organs, probably expressed by stromal cells, analogous to its provision in the primary lymphoid organs. Loss of IL-7 signaling results in fairly rapid disappearance of naïve T cells. Although deprivation of cytokine and TCR signals impairs survival of naïve T cells, it is probably not the only reason these signals are embedded in the T cell zones. Without them, T cells also undergo atrophy, decreased metabolic activity, and become sluggish in response to proliferative signals (28,29). Secondary lymphoid tissues, thus, seem to provide the necessary cues to elicit T cell entry, survival, and health while focusing the attention of T cells in the event of an invading pathogen.

Because T cells and secondary lymphoid tissue evolved for host defense, their major function could be thought of as surveillance and reaction against pathogens. This is accomplished by continuous scanning of the peptide/MHC complexes on DCs and the intrinsic capacity to rapidly mobilize growth and proliferation when antigenic foreign peptide/MHC is encountered (34). It can thus be imagined that T cells, as they are tending to their most primitive need of finding trophic signals to license their metabolism and survival, have their functioning thrust upon them. This conveniently occurs by virtue of the fact that secondary lymphoid tissues not only provide survival signals but also antigenic foreign peptides/MHC complexes.

When Not Encountering Pathogen

Our understanding of the time spent in the T cell zone of secondary lymphoid tissues is getting progressively more detailed, in large part owing to technical advances in fluorescence microscopic imaging of *in vivo* or *ex vivo* tissues (19,35–43). Naïve T cells move rapidly (12 micrometers/minute) through the T cell zone in a pattern termed *random walk*. It is estimated that hundreds ($CD8^+$) to thousands ($CD4^+$) of naïve T cells can interact with a single DC in an hour (Figure 13.1). After thoroughly sampling DCs for several hours without encountering antigen, naïve T cells exit the lymph node through the efferent lymphatic vessels and then return to the bloodstream via the thoracic duct. Exit from the spleen probably occurs through migration from white pulp to red pulp and entry into venous

sinuses then bloodstream. Naïve T cells will only spend short intervals in the blood before rapidly finding a new secondary lymphoid organ to enter, repeating the cycle of migration and surveillance, then exiting.

Exit from the secondary lymphoid tissues, like exit from the thymus, is dependent on signaling through the S1P1 on T cells (22,44). The ligand, sphingosine 1-phosphate, is found in high concentrations in plasma and lymph. A working model for egress from secondary lymphoid tissue, therefore, entails that an S1P gradient at exit vessels of the secondary lymphoid tissues counterbalances the chemokine gradients that retain naïve T cells as they move through the T cell zones. In the event that the T cell does encounter foreign antigen, as will be discussed later, the egress process must be temporarily dampened in favor of prolonged retention in secondary lymphoid tissues (45).

T CELLS IN THE IMMUNE RESPONSE

When Encountering Pathogen

Secondary lymphoid tissues are the focal point of an adaptive immune response because they unite anticipatory naïve lymphocytes with the arrival of foreign antigens (46). At least two routes exist to bring antigen to secondary lymphoid organs (47). Free antigen can travel by blood to the spleen, or by lymph via the afferent lymphatic vessels to lymph nodes. Productive foreign peptide/MHC complexes on resident DCs can form in the lymph node by this soluble route of antigen delivery within a few hours of antigen injection into tissue and quickly result in the initial T cell activation to jumpstart an immune response.

More slowly, from several hours to a few days, antigen-bearing, CCR7-expressing DCs will migrate from infected tissues through the lymphatic vessels in a CCL21-dependent process (47). This wave of antigen presentation may be important for sustaining responses, because CD4$^+$ T cells may need extended antigen presentation for effective expansion and differentiation (48,49). Generally, DCs resident in nonlymphoid tissue will undergo maturation and migrate to lymph nodes because of pathogen-associated inflammatory signals (22,47,50). In addition to influx of antigen-bearing DCs from tissues, resident DCs and macrophages can also rearrange locations within secondary lymphoid tissues in response to inflammation (22). The ontogeny, activation, maturation, migration, and functioning of myeloid, lymphoid, plasmacytoid, and follicular DCs can be found in earlier chapters. This chapter will, instead, focus on the immune response from the perspective of the T cell as it encounters a mature DC in the lymph node.

If a pathogen breaches the innate defense mechanisms, this will result in inflammatory signaling to DCs in the form of a combinatorial variety of pathogen- and host-associated ligands. Pathogen-associated ligands interact with intracellular and extracellular Toll-like receptors and other classes of intracellular (NOD) and extracellular (C-type lectin) pattern recognition receptors on DCs that will be discussed in detail in the chapter covering innate immunity. Together pathogen-associated signals refine the gene expression pattern of the activated DCs. Depending on the type of pathogen that is encountered, the DC provides quantitatively and qualitatively distinct soluble and membrane-bound signals to the newly activated T cell (34,51–54). The specific ligands that are made by DCs to inform T cells of each class of pathogens are not yet fully understood, but are an area of active investigation.

Host cells, especially innate immune cells such as macrophages or the initially activated T cells themselves, will provide other critical signals for DCs that contribute to the ability to successfully trigger a T cell–mediated immune response. TNF-α and IL-1 made by a neighboring parasitized macrophage or IFN-γ and CD40L expressed by a recently activated T cell will contribute to the ability of a mature DC to support productive clonal expansion and differentiation of the antigen-specific T cells. Pathogen and host-associated signaling to the DC contribute to its stabilized expression of foreign peptide/MHC complexes and induction of CD80, CD86 (the ligands for CD28), and other so-called *costimulatory* molecules (34).

The net effect of infection is to load the DC with novel peptide/MHC complexes, which by virtue of being foreign, should be bound by one of the many anticipatory TCRs with high affinity (54). Inflammation from infection allows DCs to simultaneously deliver abundant ligation of CD28, which together with sufficient foreign peptide/MHC initiates mitogenic signaling in the naïve T cell, triggering a clonal burst of division. Mature DCs must, therefore, provide sufficient amount of proliferative information (through peptide/MHC and costimulatory ligands) to kick-start the division of naïve T cells. But mature DCs must also convey, through a set of specific signals that may involve a combinatorial code (costimulatory receptors, cytokines, Notch ligands), information about the class of invading pathogen to the newly activated T cell (53). During an immune challenge, DCs alert T cells about the presence of infection and the type of pathogen. The latter information is especially useful to helper T cells that have several fates they can adopt during immune response differentiation, each of them well-suited to orchestrate elimination of different classes of pathogens (Figure 13.2).

Dynamic T Cell–DC Interactions During Immune Response

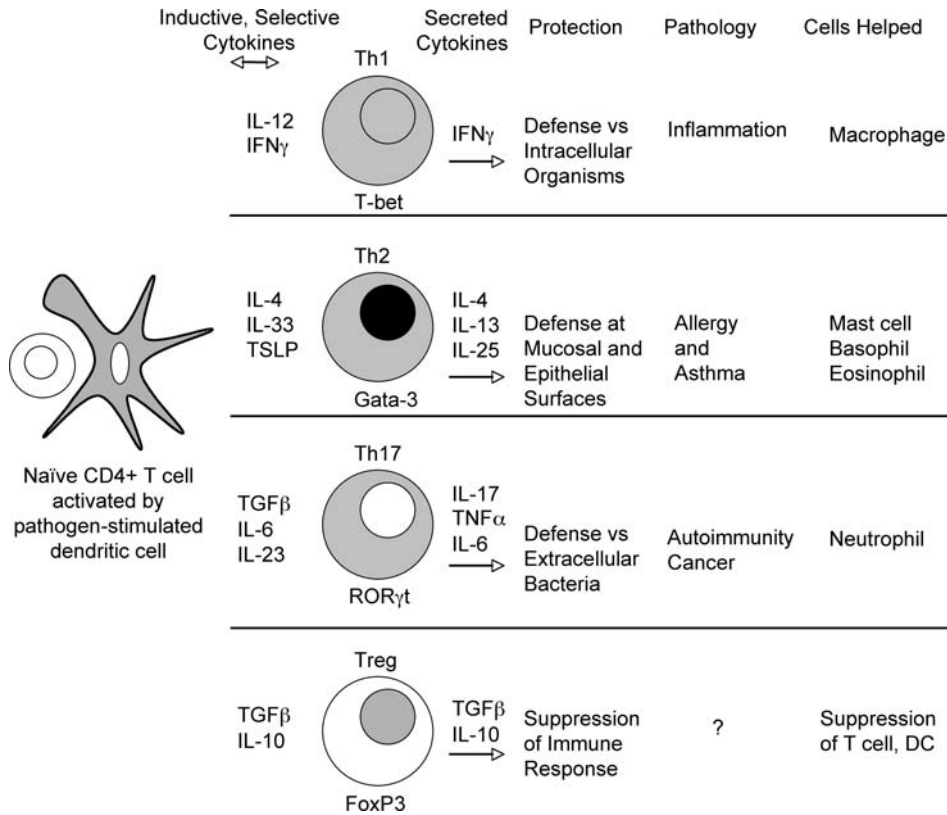
Activation of a naïve T cell during the immune response involves physical contact between the T cell and a mature DC presenting specific foreign peptide/MHC complex. When T cells are activated *in vitro* they undergo a


FIGURE 13.2 Lineage choices of effector CD4+ T cells. The progeny of antigen experienced CD4+ T cells exposed to specific pathogen-associated signals, especially cytokines (listed), can develop into Th1, Th2, and Th17 effector cells that can migrate to tissue. Hypothetically, some may become adaptive Treg cells and exert intraclonal control over the magnitude of the response. Some effector cells will develop into follicle-homing helpers of B cells ThF cells, probable variants of Th1, Th2, or Th17 (not shown). The critical transcription factor directing lineage commitment of each subset is listed below the cell. Roles in host defense, pathological processes, and mobilization of other cell types are listed.

signature reorganization during this attachment, which has been called the *immunological synapse* (55). The immunological synapse will be discussed in greater detail in the chapter on T cell signal transduction. The stereotyped features of the immunologic synapse are a cluster of T cell signaling molecules (including TCR, CD28) encircled by adhesion molecules (LFA-1) at the site of contact with an antigen-bearing cell. In addition, chemokine and cytokine receptors have also been shown to colocalize at the immunological synapse (56,57). Other molecules move to the distal pole of the T cell, away from the contact. Another characteristic of the immunological synapse is that the organizing center of microtubules, called the *centrosome* or *MTOC,* is pointing toward the site of contact at or near the cortex beneath the immunological synapse. Located between the MTOC and the nucleus, the Golgi apparatus is also polarized toward the site of contact. It is believed that this latter feature facilitates the directional or polarized secretion of IL-2 and IFN-γ into the contact zone between T cell and DC (58,59). Although this has not all been documented to occur with precise subcellular resolution *in vivo,* there is reason to postulate that such reorganization occurs during an immune response when newly activated T cells are engaged by mature DCs. T cell–DC conjugates have been observed *in vivo* within the first 18 hours of the immune response, and they appear to exhibit characteristic accumulation of TCR and IL-2 at the side of DC contact,

with exclusion of distal markers from the site of contact (37,59).

In contrast to the random walk of naïve T cells exposed to immature DCs that are presenting self-peptide/MHC, movement of the T cell changes to purposeful but brief (less than 10 minutes in duration) serial encounters with those DCs that specifically display foreign peptide/MHC complexes (19,37–39,41,60). Even if the DC is inflamed and presenting antigen, the interactions are primarily brief but specific serial contacts in the initial 8 to 10 hours of the immune response *in vivo* (Figure 13.1). This phase of T cell activation *in vivo* is followed by a period of approximately 15 to 20 hours in which the T cell has prolonged interactions (up to several hours or more) with the antigen-presenting DCs (Figure 13.1). In this phase, T cells exhibit characteristic markers of activation and are starting to secrete early response cytokines such as IL-2 in a polarized manner and TNFα in a nonpolarized fashion (58,59). At approximately 25 to 30 hours after initial antigen presentation, the quality of the interactions again changes to rapid motion with brief interactions (39). Importantly, the onset of this stage is coincident with the first T cell division of the immune response (Figure 13.1).

The foregoing behavior, as chronicled by time-lapsed fluorescence imaging within intact and explanted lymph nodes, was largely similar in the hands of several investigators. Nonetheless some differences emerged that could

either be due to intrinsic differences in CD4$^+$ versus CD8$^+$ T cells, or experimental nuances such as the immunization or adoptive T cell transfer system employed. In this vein, it is important to note that many experimental approaches upon which the field relies may inevitably have confounding features.

One potential pitfall of a modeled antigen-specific response *in vivo* relates to the fundamental nature of how adaptive immunity protects the host. According to the clonal selection theory of lymphocyte biology, an adaptive immune response might be initiated by the response of very few, or perhaps one, cell(s). In essence, immunologists seek to determine the cellular and subcellular composition of a clonal burst that emanated from a single cell under the circumstance where only a single cell is responding (Figure 13.1). The only experimentally tractable approaches to model this behavior, however, are often reliant on observations made when tens of thousands of cells respond in unison. Although all of the T cells in an experiment may have the identical antigen receptor, there is increasing evidence to postulate that they may behave differently as group than they might as individuals because of their competition for rare ligands (61–65). The very similarity that makes it useful to employ transgenic T cells carrying a fixed TCR may also make them behave in a way that might not occur if only a small few were able to respond.

When Encountering Self-antigen

How does the initial encounter of naïve T cell with antigenic peptide/MHC appear if the antigen is not a derivative of foreign life, but rather a component of self? In this situation, vigorous clonal expansion and effector differentiation on the part of a T cell would not be desirable. Instead, there seem to be peripheral mechanisms to deal with highly self-reactive cells that escaped the screening of negative selection in the thymus (10). Their net effect is to abort the incipient program of clonal expansion and effector differentiation on the part of the self-reactive T cell. Some of these mechanisms involve cell intrinsic negative regulators of T cell activation, so-called mediators of "recessive tolerance." Emerging as an essential and increasingly well-characterized mechanism is the counter-regulation in *trans* by natural Treg cells, so-called mediators of "dominant tolerance." These principles will be discussed in greater detail in the chapters on tolerance and suppression.

The aforementioned scenario describing rapid motion/brief contact, then sustained contact, followed by rapid motion and cell division is primarily the behavior associated with productive immune responses when antigenic peptide/MHC is presented in an inflammatory context. In parallel with the realization that there is stereotyped sustained contact between the newly activated T cell and antigen-presenting DCs prior to the first division of the immune response, another set of findings, discussed later in this chapter, pointed to an important function of this newly appreciated phase of initial T cell activation. The phase of sustained contact is, thus, emerging as a key checkpoint in the ability of the T cell undergoing mitogenic signaling to proceed through successful versus abortive activation (Figure 13.1).

Several lines of evidence support the functional importance of the signaling that might occur during the sustained, premitotic interaction that occurs *in vivo*. There is a positive relationship between productive immunity, DC inflammation, and the duration of contact in that phase of T cell activation occurring prior to the first division (41,60). CTLA4, an intrinsic negative regulator of T cell activation, negatively influences the sustained contact phase (66). Consistent with these findings, there is an inverse relationship between the presence of natural Treg cells and the duration of the sustained contacts between self-antigen–specific T cell and DCs (35,36). Finally, the activation of Toll-like receptors on DCs can disarm the suppressive effect of Treg cells to promote successful immune activation (67). In this manner, integrity of the sustained contact appears to have an essential role in arming the nascent progeny of the T cell for further division, appropriate effector differentiation and function (Figure 13.1). By contrast, disruption of the sustained contact is associated with unproductive immunity, or tolerance. An emerging subtext of these and other new findings that will be discussed later in this chapter is that the dynamics of intercellular communication will be a critical component in illuminating the inside of the "black-box" of initial T cell activation and differentiation *in vivo*. In addition to preventing newly activated cells from becoming armed, Treg cells may also act at later stages of the immune response to disarm effector cells (68). This will be discussed in greater detail in the following sections and in the chapters on tolerance and suppression.

Before and After the First T Cell Division

The first day of the immune response looks largely similar for a pathogen-specific CD8$^+$ and CD4$^+$ T cell in terms of the general dynamics of initial T cell interaction with and activation by DCs as outlined earlier. Although each subset is activated by a different class of MHC molecule presenting foreign peptide, the initial activation of the two cell types can be physically united by a cross-presenting DC (69). This mode of presentation of exogenous antigens to CD8$^+$ T cells will be discussed in the chapter on antigen presentation and the section on immunity to infectious agents. *In vivo* imaging studies suggest that the initial interaction between CD8$^+$ T cell and DC is promoted by a CD4$^+$ T cell interacting with the same DC (42,43). This may play a role in both effector (43) and memory (42) differentiation of CD8$^+$ T cells. Of note, this enhanced

response by CD8$^+$ T cells is accompanied by more sustained contact between T cell and DC (Figure 13.1). The ability of CD4$^+$ T cells to enhance contact appears to involve secretion of the chemokines CCL3 and CCL4 (42) and ligation of CD40 on the DC, but without necessarily imposing greater maturation on the DC (43). Thus, the phase of sustained contact prior to the first division is emerging as an important quality-control checkpoint for CD8$^+$ T cell–mediated immunity (Figure 13.1).

There are, however, some differences between the CD4$^+$ and CD8$^+$ T cell responses to antigen. The degree of clonal expansion is one well-characterized difference. As mentioned earlier, it is generally assumed that the response to infection will involve very few initially responding cells. For instance, it is estimated that there are 2 million different antigen-specific clones in the spleen, with approximately10 duplicate cells of each specificity (70). A naïve mouse has five cells specific for the Db/gp33 epitope of lymphocytic choriomeningitis virus (LCMV) per million CD8$^+$ T cells, or about 100 cells per mouse. These cells can expand 100,000-fold, suggesting that 15 or more rounds of division can occur (71). For CD4$^+$ T cells, clonal expansion has been estimated to be a few to several orders of magnitude lower than for virus-specific CD8$^+$ T cells, depending on the class of pathogen (72,73). Likewise, there are some CD8$^+$ T cell responses with lesser expansion than seen following LCMV infection.

After the first day of the immune response, a newly activated T cell begins to divide, and its resulting progeny begin to acquire the properties of more mature effector cells. CD8$^+$ T cells seem capable of undergoing substantial division and differentiation without the daughter cells needing to reconnect with antigen-bearing cells, although such experiments do not rule out important potential contributions from such interactions (74,75). In contrast, CD4$^+$ T cells seem to be dependent on more persistent antigen presentation for full expansion and differentiation, and renewed contact between daughter cells and antigen-bearing DCs has been documented (48,49). It is not yet known, however, after which daughter generation antigen may no longer be required. The possibility for continued education of the T cell's progeny on antigen-loaded cells is afforded when the S1P1 on activated T cells becomes temporarily repressed, in part due to inflammatory cytokines that act via induction of CD69 (45). Thus, the initial clonal burst of T cell progeny in response to a pathogen is sequestered temporarily in the lymph node, perhaps to ensure appropriate exposure to differentiation signals (Figure 13.1).

Division and Beyond: Instructions and Directions

A response of 10 or so naïve T cells by itself would be unlikely to muster the "fire power" necessary to eradicate a typical infection, even if those cells could differentiate into fully armed effector cells. Clonal expansion thereby serves at least one purpose of providing a sufficiently large armamentarium for host defense (Figure 13.1). With the advent of dyes that allow analysis of cell division, it has become increasingly appreciated that the newly activated antigen-specific cell (the "parent," if you will) does not itself undergo effector/memory differentiation. Instead, it is its daughter cells or, more accurately, even later cell generations that are the real participants in clearance of the pathogen (48,76). Examination of the timing or division number required to achieve effector cytokine expression, induction of homing molecules that permit access to infected tissue, loss of lymph node homing/retention molecules, and reacquisition of exit receptors all point to a concerted division-dependent mechanism that licenses the later cell generation progeny to mature and migrate for immune reactions at the site of infection (45,48,76–78).

In the first few days after activation, T cells have transiently down-regulated the egress molecule, S1P1 (45). After re-expression of the receptor and recovering their ability to exit the secondary lymphoid organs, the newly minted mature effector T cells must additionally migrate to the appropriately inflamed or infected tissue to exert their function (79,80). This is partly promoted by the loss of homing receptors for the secondary lymphoid organs, such as CD62L and CCR7. In addition, a new set of homing molecules is acquired, such as PSGL-1, CD44, CCR5, and CXCR3, which bind ligands in inflamed tissue. Much in the same manner that the character of their effector differentiation choice is instructed by their environment to be matched with the type of pathogen encountered, so too are their directions and "ZIP codes" for migration to specific tissues imprinted from the history of their antigen-presenting cell's experiences (79). DCs that arose in the gut induce intestinal homing receptors, while DCs from cutaneous sites induce skin-homing receptors on effector T cells (81,82). Some antigen-experienced CD4$^+$ T cells, called *follicular helper T cells* (ThF), however, are fated to stay in the lymph nodes and migrate to B cell follicles to perform their helper functions (83,84).

Like entry of a naïve T cell into secondary lymphoid organs, the entry of an effector T cell into inflamed or uninflamed nonlymphoid tissues proceeds through characteristic multistep adhesion cascades of tethering, rolling, integrin activation, and firm adhesion (80). This involves specific patterns of expression of ligands for selectins, chemokine receptors, and integrins on the T cell. Skin-homing effector T cells or regulators of atopic skin inflammation would express cutaneous leukocyte antigen (or other ligands for P- and E-selectin), CCR4 (receptor for CCL17), or CCR10 (receptor for CCL27). Small bowel-homing effector T cells or mediators of Crohn's disease would express PSGL-1 (ligand for P-selectin), $\alpha 4\beta 7$ integrin (receptor for MAdCAM), and chemokine receptors CCR9 (receptor for CCL25) and CXCR3 (receptor for

CXCL9). More details can be found in other chapters of this book. Although some differences in tissue homing receptors between mature effector CD4$^+$ and CD8$^+$ T cells are evident, the overall strategy for both activated subsets is similar: to coordinate the acquisition of specific nonlymphoid tissue migratory information with the acquisition of specific effector function (Figure 13.1). The DC and the rest of the cellular/soluble milieu of the secondary lymphoid organ are responsible for this coordinated imprinting process, although the specific signals are not fully understood (85,86).

EFFECTOR T CELLS

Differences Between Effector CD4$^+$ and CD8$^+$ T Cells

Armed effector CD4$^+$ T cells must move to sites of infection or inflammation to perform their function, which is primarily orchestration of other immune cells and nonimmune cells to eradicate a pathogen (Figure 13.2). In addition, a subset of CD4$^+$ effector T cells will remain in the lymph node to provide help for B cells (83,84). The most influential function of effector CD4$^+$ T cells is not the direct elimination of pathogen but instead the mobilization and activation of other cells. An effector CD4$^+$ T cell is truly a helper cell more than it is an effector cell. The term *effector* is used here (and elsewhere) primarily to imply that the cell is competent to immediately express maximal levels of its signature gene products, usually cytokines. In this regard, effector CD4$^+$ T cells differ greatly from effector CD8$^+$ effect T cells, which by themselves are the mediators of pathogen clearance. Thus, as used in this chapter, the term *effector CD4$^+$ T cell* implies full functional maturation following antigen experience for helper T cells, while effector CD8$^+$ T cell implies full functional maturation following antigen experience for cytotoxic T cells. As will be discussed later, CD4$^+$ and CD8$^+$ T cells differ greatly in the spectrum of effector fates they can adopt.

Effector Choice for CD4$^+$ T Cells

After naïve helper T cells become activated and begin to divide and differentiate, they adopt different patterns of gene expression or fates that correspond to a division of labor designed for the eradication of pathogens with diverse life cycles and evasion strategies (Figure 13.2). One of the most remarkable aspects of the differentiation process of helper T cells is how environmentally sensitive is the selection of lineage choices (87–89). The newly activated T cell and its daughters or granddaughters integrate signals from DCs, which already reflect an imprint of the type of pathogen that was encountered by the combinatorial ligation of pattern recognition receptors (34). The DCs take their impression of the class of pathogen and transmit this information to the T cell by the elaboration of distinct cytokines or costimulatory molecules and Notch ligands. In addition, other innate and noninnate cells that bear a reflection of the type of pathogen contribute other cytokines or membrane-bound ligands that will influence the differentiation decisions of the maturing helper T cell progeny.

The combinatorial signaling that the newly activated T cell receives is somehow processed to create a dominant subset for many immune responses (53). In some immune responses, however, there is more of a mixed-lineage differentiation pattern of the maturing helper T cells. The degree of polarization or heterogeneity may vary according to the chronicity of the infection and the complexity of the pathogen's life cycle. Chronic infestations with intestinal worms are often characterized by polarized Th2 responses (90–93), yet IL-4-producing cells are also evident early in the Th1 response against *Leishmania* (73). Organisms that have intracellular and extracellular stages might be capable of evoking a mixed response of helper T cell subsets so that diverse effector mechanisms can be mobilized. Several important themes have emerged concerning effector CD4$^+$ T cell lineage choice during the immune responses. Many of these principles are specific to CD4$^+$ T cells, but others apply broadly to CD8$^+$ T cells and atypical T cell subsets.

Division of Labor

At least three subsets of effector CD4$^+$ T cells are now recognized (Figure 13.2), Th1, Th2, and Th17 (87,94,95). Th1 cells are characterized by the secretion of IFN-g and are important activators of macrophages, NK cells, and CD8$^+$ T cells (96). Th1 cells are thought to be involved in systemic immunity, in particular the defense against intracellular pathogens. Th2 cells secrete IL-4, IL-13, and IL-25 and are important for barrier defense at mucosal and epithelial surfaces. Th2 cells mobilize and activate eosinophils, basophils, mast cells, and alternatively activated macrophages (97). Th17 cells produce IL-17A, IL-17F, IL-6, and TNFα and are responsible for regulating acute inflammation (98). Th17 cells act in concert with neutrophils and are important for defense against extracellular bacteria (99,100).

Antibody responses are quite likely to be mediated by subsets of effector CD4$^+$ T cells with specialized homing properties and function. Follicular helper T cells, or ThF cells, are antigen-experienced CD4$^+$ T cells found in the lymph node and are identified as being PSGL-1$-$ and CXCR5$^+$ (83,84,101). ThF cells are found at the periphery of B cell follicles and appear to mediate naïve B cell activation and germinal center formation, probably through the expression of ligand for CD40 and the secretion of Th1- and Th2-like cytokines. It is possible that ThF cells might arise

as branches in the Th1 and Th2 differentiation pathways, veritable ThF1 or ThF2 cells, but their precise lineage relationship to the other effector CD4$^+$ T cell subsets is still uncertain.

Good Can Be Bad: Division of Damage

Effector CD4$^+$ T cell subsets, thus, provide a division of labor in mobilizing the immune armamentarium to combat the diversity in the microbial world. An additional theme relating to the diverse but unique protective role played by each subset is that each subset contributes to pathological conditions mediated by T cells (Figure 13.2). Th1 cells cause tissue damage in response to inflammation and infection and may mediate some forms of autoimmunity (102,103). Th2 cells mediate allergic disease and asthma (104). Th17 cells are responsible for some forms of organ-specific autoimmunity, notably experimental arthritis and multiple sclerosis, and may contribute to cancerous states (98,105–107). Finally, dysregulated ThF cells can cause systemic autoimmunity and auto-antibody production or contribute to T cell–mediated organ-specific autoimmunity (108). One of the costs associated with adaptive host defense is the extra burden of inflammatory and autoimmune diseases for the species. An emerging theme in immune response regulation is that collateral damage mediated by cytokines is often limited by other cytokines. IL-27, TGF-β, and IL-10 have been particularly implicated to varying degrees as signals that dampen Th1-, Th2-, and Th17-associated inflammation (99,102,109–115).

Inductive and Selective Signals

The critical signaling pathways for eliciting distinct helper T cell subsets are still not completely resolved. Several potent positive and negative regulators, however, have been defined. Curiously, among the most prominent positive regulators of subset induction are the products of that subset itself. IFN-γ promotes Th1 induction, IL-4 promotes Th2 induction, and IL-6 (together with TGFβ) promotes Th17 induction (87,89,95,96,112,113,116). This chameleon-like property of the helper T cell lineages may contribute to fortification of a particular subset if progeny are dividing in spatially restricted niches. For example, complex instructions received by the newly activated helper T cell from a DC could be relayed from daughter to granddaughter in a simpler form via the paracrine actions of these cytokines, especially if the clonal burst is expanding away from the original DC.

Other cytokines are also critical during and after lineage commitment (Figure 13.2). IL-12 acts selectively to promote the survival, proliferation, and enhanced gene expression of Th1 cells. Combinatorial TLR signaling to DCs can synergistically induce IL-12 and a Th1-associated Notch ligand pattern (53). Thymic stromal lymphopoietin (TSLP) can seemingly act on DCs to cause them to induce Th2 responses (117–120). A signature set of pathogen-associated receptors for helminths has not yet been found on DCs, raising the possibility that Th2 skewing results from the absence of Th1-associated ligands plus receipt of the TSLP signal. IL-4, IL-25, and IL-33 may augment the survival, proliferation, and action of Th2-committed cells and counter the development of Th1 cells (92,93,121,122). IL-23 is a critical signal for Th17 cells, but primarily for maintenance and not induction (99,112,113,123). Other inductive signals that have recently emerged are Notch signaling pathways and costimulatory ligands (124–127). For ThF cells, ICOS has proven to be a particularly critical signal, although it is not clear if that role is in induction or progressive maturation (101,108).

Key Transcriptional Regulators

For each of the well-characterized helper T cell lineages, there is a key transcription factor that is essential for their lineage commitment (Figure 13.2). T-bet is a critical regulator of Th1 cells (96,128,129). It acts to promote the IL-12 responsiveness of activated cells by enhancing expression of IL-12Rβ2, and it directly promotes IFN-γ expression (130–133). Gata-3 is the central transcription factor for lineage commitment of Th2 cells, although it also plays some essential roles in various stages of thymopoiesis (134–136). Gata-3 functions directly to activate the Th2 cytokine cluster, containing IL-4, IL-13, and IL-5, and it may promote the selective growth of Th2 cells in response to IL-4 signaling (137–139). T-bet and Gata-3 gene expression is induced by TCR signaling, specific cytokine signals, specific Notch ligand signaling, and by their own gene products (124,125,127,130,132,133,140–142). T-bet and Gata-3 are negatively regulated by cytokines from opposing subsets and TGFβ. T-bet is able to physically interact with Gata-3, which may contribute to the counter-dominance observed between Th1 and Th2 subsets (143–145). Factors that may provide additional transcriptional control of Th1 and Th2 cells during their maintenance phase include c-maf and Hlx, respectively (133,146).

RORγt has been identified as a critical lineage commitment factor for the Th17 cells (123). IL-6 and TGFβ seem to synergistically induce RORγt. Both IL-6 and TGFβ contribute to the induction of IL-23 receptor expression, which would allow IL-23 to promote maintenance of Th17 cells, although it is not known if IL-23R expression is dependent on RORγt (99,123). Bcl-6 is factor identified in ThF cells, but it may have roles that extend beyond this subset, because it has been implicated in memory CD8$^+$ T cell development (147,148). Blimp-1, an important factor for plasma cell differentiation, is an emerging intrinsic regulator of T cell function, because its loss leads to severe dysregulation of effector and memory T cell subsets (149,150). Yet to be determined is whether Bcl-6 and

Blimp-1 will act in a counter-regulatory loop against one another in peripheral T cell differentiation, as they have been proposed to function during memory B cell homeostasis versus plasma cell differentiation.

Slow to Learn but Quick to Remember

In the differentiation of effector CD4[+] T cell subsets, several peculiar demands are placed on the signaling and transcriptional networks needed to achieve the end results of mature Th1, Th2, Th17, and ThF cells. Although the naïve (parent) T cell is the cell that first receives a critical set of instructions from the DC, within one day the parent cell does not formally exist, having become two daughters. After the first division, subsequent divisions proceed even faster, perhaps occurring every 6 hours, such that daughters and granddaughters may not be present shortly. In addition, it is evident that parents, daughters, and granddaughters do not typically exhibit effector maturity—that is, being fully armed to secrete maximal amounts of their signature cytokine. There must, therefore, be a mechanism for progressive learning and imprinting of the type of effector function being taught in the draining lymph node so that it can eventually reach maximal productivity and be remembered by the ensuing progeny as they migrate to follicle or tissue, temporally and spatially removed from the inductive signal (Figure 13.1).

It is thought that one of the ways in which the signaling events are amplified and remembered by the progeny of the T cell as they divide and move to tissue is the result of so-called epigenetic effects (87–89,151,152). The term *epigenetic* has at least two connotations: (1) the mediators of this effect are not alterations in primary nucleotide sequence (genetic material), but instead covalent modifications of histones and CpG dinucleotides, and (2) the consequence of a signaling pathway (genetic circuit) is still manifest after the initiating signal has disappeared, either on account of cell division, migration, or temporal decay. The epigenetic aspect of effector CD4[+] T cell differentiation involves a progressive dismantling of condensed chromatin structure at the signature cytokine loci expressed by effector CD4[+] T cells. Chromatin remodeling involves feed-forward cascades of cytokine signals and transcription factors that, by building in concerted potency, eventually unfurl the repressed structure of the gene so that it is readily activated (within minutes) by general and lineage-specific factors. This progressive de-repression is occurring in tandem with cell divisions, making it a matter of cellular inheritance (76). Once fully unfurled, the remodeled state is capable of being locked in, in such a way that the cytokine signals and transcription factors used to create the remodeled active state are not always required to maintain its activity in a mature cell or one of its subsequent daughter cells (153). For example, the Th2 cytokine cluster containing IL-4, IL-5, and IL-13 cannot be activated and remodeled during Th2 differentiation without signaling through the IL-4 receptor or the transcription factor Gata-3. Yet both are dispensable to maintain the ability of mature Th2 cell or their subsequent daughters to rapidly secrete copious amounts of IL-4 upon reencountering antigen (134,136).

Epigenetic repression of the cytokine genes in CD4[+] T cells seems to play an additional role in the proper functioning of an immune response. The appropriate repression of the forbidden cytokines within a maturing lineage is enforced by gene silencing mechanisms that operate to further dampen the multipotential state of gene activity that is necessary for the naïve T cell to be able to make multiple choices, but deleterious for mature Th1 or Th2 cells with restricted functional repertoires (137,154–158). The epigenetic effects that operate during effector CD4[+] T cell differentiation, therefore, help to pace the progress of effector maturation, restrict the potential options of the progenitor as discrete subsets emerge, and help the signaling pathways that are ignited in the parent cell move through division, space, and time, so that a distant progeny knows exactly what to secrete upon arrival at the site of infection.

Other Subsets

In an idealized immune response, the critical players are the naïve T cell, the DC, and other cells that have encountered pathogen. It is likely that some regional immune responses may have more complex interactions. The intestines, for example, exhibit an active interplay between pro- and antiinflammatory regulators. Within various intestinal tissues, there are previously activated, constitutively cytokine-expressing (IL-10, TGF-β, IL-17, IL-25) T cell subsets (92,123). In a site with constitutive inflammatory mediators and counter-reactive suppressive factors, the shaping of Th1, Th2, Th17, and regulatory responses might be expected to follow distinct rules.

CD4[+] T cell subsets with atypical differentiation patterns have also been induced *in vitro* and *in vivo,* such as IL-10-producing regulatory T cells that do not express FoxP3, and so-called *adaptive Treg cells* that are the progeny of conventional naïve T cells activated by antigen plus TGFβ or low doses of antigen and that express FoxP3 like their thymically derived cousins (114,115). It is yet unknown whether these cells have physiological roles in the response to self- or foreign antigens and, if so, under what circumstances. It is tempting to speculate that an adaptive Treg cell could regulate the magnitude and degree inflammation of its kindred (sharing the same TCR) effector CD4[+] T cells in the response to foreign antigen. This has not yet been visualized, however, in the responses to pathogens that have thus far been interrogated (9). As mentioned earlier, there remain many uncertainties about whether suppressive action of thymically derived Treg cells during an immune response is likely to be at the

site of induction (secondary lymphoid tissue) or infection (peripheral tissue), or both. Indeed whether control of immune response against pathogens is primarily the responsibility of another T cell (dominant mechanism) or owing to cell-intrinsic negative regulators within the effector cell itself (recessive mechanism) is not fully resolved (35,36,66,68,159).

Effector CD8[+] T Cells

During the immune response to viruses and some intracellular microbes, naïve CD8[+] T cells are activated to undergo a program of massive clonal expansion, with acquisition of new effector functions in the resulting progeny (16). The primary effector products of CD8[+] T cells are IFN-γ and the contents of cytotoxic granules, notably perforin and granzymes. Unlike effector CD4[+] (helper) T cells, effector CD8[+] (cytotoxic) T cells make limited choices in their repertoire of effector genes. Primarily type 1 or Tc1 effector cells predominate *in vivo*. Also contrasting with effector CD4[+] T cells, which migrate to infected sites to orchestrate the actions of other cells, effector CD8[+] T cells are the direct executioners of pathogen-infected cells. The pro-inflammatory and toxic products of effector CD8[+] T cells are themselves regulators of the magnitude of expansion and contraction of the T cell response, and loss of certain effector proteins alters the dynamics of effector and memory cell generation (160).

The induction of effector CD8[+] T cells is dependent on many of the same classes of signals as for effector CD4[+] T cells, antigenic peptide/MHC, pathogen-related inflammatory signals including costimulators, and cytokine signals. CD4[+] T cell help has become recognized as an important component of the activation of antigen-specific CD8[+] T cells. Although CD4[+] T cell help may be imparted early in the response and influence effector function (43), its effects may be more manifest in memory CD8[+] T cells (42,161–165). T-bet, the transcription factor responsible for Th1 lineage commitment, is expressed in CD8[+] T cells and may play a similar role inducing effector gene expression in both cell types (166,167). Another transcription factor that is highly homologous to T-bet, called Eomesodermin (Eomes), is also expressed in antigen-specific CD8[+] T cells. It is thought that T-bet and Eomes may play some redundant and nonredundant roles in the spectrum of cytotoxic effector and memory cell programming (166–169).

MEMORY T CELLS

After migration to inflamed tissues, T cells mediate their function by the secretion of cytokines or cytotoxic granules. Following successful clearance of a pathogen, there is a phase of massive cell death, which results in elimination of most effector T cells (Figure 13.3). The basis for the demise is not completely understood but may in-

volve some combination of cytokine withdrawal, receptor-mediated death signaling, or toxicity from effector products. After the elimination of approximately 90 percent of effector cells, a group of memory T cells persist, often for the life of the host (Figure 13.3). For example, if one naïve T cell expands 10,000-fold in response to a pathogen, and 90 percent of effectors are eliminated after the resolution, then the original clone has seeded 1,000 memory cells to deal with subsequent reinfections. Thus, the remnant population of memory T cells is typically orders of magnitude higher in frequency than the pre-immune state. Some general features of memory cells will be discussed later, but more information can be found in the chapter on T cell memory.

Virtually Indestructible but Not Always Faster and Better

After an acute infection, it is highly unusual for the host to be left without a remnant of antigen-experienced memory T cells (Figure 13.3). If the naïve T cell pool that is specific for a pathogen is small in number, and all such cells are recruited into the effector response, there would seem to be a hard-wired mechanism associated with T cell activation that ensures the generation of an indestructible subpopulation. From an evolutionary perspective, this would likely be advantageous, so that a host retains an armamentarium against a pathogen that has now been validated as an actual, rather than simply a potential, threat. In fact, without robust insurance that all clonal bursts leave some memory cells behind, there would routinely be a selective T cell immunodeficiency (temporary or permanent) for the pathogen subsequent to the resolution of infection. In dealing with pathogens requiring cellular defense, where antibodies may serve no benefit, a temporary hole in the T cell repertoire might be an unacceptable state for the host. Despite the near-invariant appearance of antigen-experienced, or memory, T cells following resolution of infection, however, the host is not always left with heightened state of resistance to reinfection, as one might expect from a successful vaccination. This has raised some fundamental issues about the nature of memory T cells, including their purpose and their lineage relationship to naïve and effector T cells (170,171).

Two Models for Memory Formation

One way to think about memory cells is that they are simply effector cells that escaped clonal deletion and have entered a resting, rather than activated, state (Figure 13.3). This sort of model for memory T cell formation is considered a linear or progressive form of differentiation, because it implies that memory cells are derived from effector cells (170,171). An alternative theory suggests that, at some point after initial activation, a subset of antigen-specific
FIGURE 13.3 Models for memory T cell formation. Pathogen-derived antigen exposure causes clonal expansion and effector differentiation. Clearance of pathogen results in cell death of the majority of effector cells (clonal contraction). Clonal elimination is typically incomplete, leaving a remnant of memory cells. Scenario A places memory T cells as posteffector cells that underwent progressive development. Scenario B places memory T cells as being committed to the lineage without becoming an effector cell. The pathway of memory cells arising in scenario B and their subsequent ability to have self-renewing and terminally differentiated progeny has been likened to the behavior of stem cells.

progeny split off before the effector pathway of differentiation and instead become memory cells. This type of model is considered a branching or divergent form of differentiation because two clonally related T cells adopt different cell fates. The relative contribution of each of these models of memory T cell formation during various immune responses has not yet been resolved (46,64,172–174).

Two Memory Habitats

Analysis of memory T cells has demonstrated that antigen-experienced T cell populations can exhibit two distinct patterns of migration after infection and during homeostasis, those that migrate through lymphoid tissues and those that migrate through nonlymphoid and inflamed tissue. Memory cells that express the lymph node homing molecules CCR7 and CD62L are termed *central memory cells,* because of their access to primary and secondary lymphoid tissue, including the bone marrow (46,64,173–176). In contrast, memory cells with loss of CCR7 and CD62L expression but displaying inflammation-associated chemokine receptors are called *effector memory T cells* because of their immediate expression of effector genes upon reactivation and their

ability to access nonlymphoid tissue. Thus, central memory cells can continually be sampling secondary lymphoid tissue alongside the parade of naïve cells, while effector memory cells may be patrolling peripheral tissues for a heightened level of security.

A Stem Cell Model

The original concept of central memory cells represented one of the first concrete challenges to the linear paradigm of memory differentiation that had considered memory cells as effector cells that had transitioned to a resting, long-lived state (173). Instead, these central memory cells seemed to be the early byproduct of antigen experience, representing a cell that dropped out of the normal path of effector-bound cells that progressively divide and differentiate. As progeny of the newly activated T cell, the less terminally differentiated central memory daughter is, in a sense, a closer approximation of its naïve parent cell than its siblings that go on to be full-fledged, terminally differentiated effector cells (Figure 13.3). This way of looking at the clonal burst is reminiscent of the paradigm of a stem cell, which is capable of dividing and giving rise to

a self-renewing daughter and a terminally differentiated, nonrenewing daughter (177). Although yet in its formative stages, the stem cell model of immunological memory may be applicable to both T and B lymphocytes (178). A corollary to the stem cell model is that the memory cell is capable of continuing to produce asymmetric progeny, those that are more effector-like and those that are more self-renewing to varying degrees, depending on the demands of rechallenge and homeostasis (Figure 13.3).

Lineage Relationships Not Fully Resolved

Whether memory cells represent the precursor or the product of effector cells, there must be a mechanism for self-renewal to maintain a steady number during homeostasis that will offset the attrition owing to a finite life span. Central memory CD8$^+$ T cells undergo slow cytokine-dependent, peptide/MHC-independent proliferation in response to basal IL-7 and IL-15 signaling (32,179–181). Slow proliferation has also been suggested to occur in central memory CD4$^+$ T cells, although it is not clear which signals are necessary to achieve this (182). For both CD4$^+$ and CD8$^+$ T cells, then, central memory T cells may carry the burden of durability in the absence of antigen, the defining property of a memory cell. Nonetheless, there has not been direct quantitative comparison of the proliferative capacity and turnover of CD4+ versus CD8$^+$ central memory T cells. It, thus, remains possible that memory CD8$^+$ T cells are more stable than memory CD4$^+$ T cells in the absence of antigen (72).

The precise role of the effector memory cell and from whence it arises is not yet resolved. Effector memory T cells might be the byproduct of central memory T cells. This could be akin to another type of stem cell behavior, such that during homeostasis a central memory cell could periodically give rise to central memory daughters with potential to renew, and effector memory daughters that are not self-renewing but are continually generated for heightened security to explore even more peripherally than secondary lymphoid tissue (Figure 13.3). On the other hand, effector memory cells might simply be a direct descendant of a recently generated effector cell, which escaped clonal deletion.

Even for central memory T cells, lineage relationships have not been resolved. For CD4$^+$ T cells, there are well-characterized instances where the central memory T cell appears to have bifurcated or diverged prior to effector maturation (171,173,183). Central memory CD8$^+$ T cells have been alternatively suggested to arise sequentially from effector/effector memory T cells or as a branch distinct from the effector pathway (64,172,174). It remains possible that more than one pathway may lead to each lineage in physiological circumstances. Indeed, many uncertainties about memory cell programming remain. The discovery of several critical transcription factors, includ-ing T-bet, Eomes, Bcl-6, Bcl-6b, and Blimp-1 as regulators of memory T cell homeostasis may open avenues for more sophisticated fate mapping studies that could refine the lineage relationships of effector and memory subsets (148–150,166–168,184).

Differences Between CD4$^+$ and CD8$^+$ Central Memory T Cells

Long-lived, central memory CD4$^+$ and CD8$^+$ T cell subsets may not be equivalent in their ability to protect the host. In a prototypical cytotoxic response (against LCMV), central memory CD8$^+$ T cells function as highly effective, long-lived memory cells, capable of mediating vaccine-like protection upon reinfection, and in a manner superior to effector-like memory cells (174). In the CD4$^+$ Th1 response against *Leishmania*, complete elimination of parasite (which is not the norm) leaves the host with a residual, long-lived central memory CD4$^+$ T population. Such cells, however, function according to their original conception, as a reservoir of not-yet-effector cells, some of which will achieve effector status in the event of reinfection (183). By themselves, the central memory CD4$^+$ T cells afford protection to their host, but not at the level of immunity achieved when effector-like cells are present. In essence, central memory cells seem to share the property of durability in the absence of antigen across both the CD4$^+$ and CD8$^+$ lineages, perhaps with some quantitative differences (72). In regard to mediating highly effective heightened immunity, there may be greater disparity between the two central memory lineages. Determining whether this is strictly a CD4$^+$ versus CD8$^+$ difference will, however, require interrogation of a great variety of immune responses.

If Pathogen Is Not Eliminated

Previously activated T cells that exist in a host with chronic infection or nonsterile immunity have been difficult to categorize. If infection, and hence antigen, is not cleared, then remnant T cells are not necessarily memory cells, possibly being overly activated or recently generated effector cells. In LCMV infection, inability to eliminate virus completely results in a persistent population of CD8$^+$ T cells that fails to acquire the characteristics of highly effective central memory cells (185). These cells do not seem to behave like freshly minted effector cells and instead have been considered "exhausted" by overexposure to antigen. Their suboptimal functional properties can be partially reversed by blocking the negatively acting costimulatory family receptor, PD-1 (186,187).

Persistent infection has also been associated with enhanced protection by T cells. The phenomenon in which the nonsterile state is essential for heightened protection is called concomitant immunity. In such a situation, a host

that harbors continual low-level infections is more protected than a host that has eliminated the pathogen. In *Leishmania* infection, for example, incomplete clearance of parasite is an essential requirement for optimal immunity to secondary challenge (159,183). In this case, central memory CD4$^+$ T cells that persist after pathogen eradication are long-lived in the absence of antigen but afford less protection from rechallenge than the continual stream of short-lived effector cells being generated by exposure to persisting parasite antigen. Optimal, or vaccine-like, protection afforded by nonsterile immunity is, therefore, not mediated solely by bona fide antigen-independent central memory CD4$^+$ T cells, but instead requires their continual conversion to effector cells owing to persistence of the parasite.

THE FUTURE

The past decade has seen tremendous advances in developing *in vivo* techniques that allow for a better understanding of the actual sequence of events that occur when a naïve T cell is born, undergoes migration, becomes activated, and gives birth to differentiating progeny. These *in vivo* techniques are on the verge of achieving subcellular resolution. Models of activation and differentiation during the immune response often regard the newly activated T cell as adopting a new fate and having similarly fated progeny. If differentiation decisions are delayed until at least the first cell division or two, the formal possibility remains that one newly activated T cell can have progeny with diverse fates. It is still uncertain if, for example, effector cells arise from the first antigen-specific naïve cell to arrive on the scene, while central memory cells are derived from a second naïve cell that arrived later. It might be the case, instead, that central memory CD4$^+$ T cells represent a minority subset of progeny within the clonal burst of a single naïve cell, in which the majority of the progeny were destined to be effector cells. If true intraclonal heterogeneity were possible, that is one single cell having daughters with different fates, it is unclear whether the mechanism for such a diversification event would be a stochastic or instructed process. Recent evidence suggests daughtee T cell diversity could be achieved in a non-random fashion through a mechanism known as asymmetric cell division (188). One of the main challenges facing the field of peripheral T cell differentiation in the coming years will be to visualize some of these fundamental uncertainties about the initial stages of peripheral T cell maturation during the immune response.

The Intersection of Innate and Adaptive Immunity

The Innate Immune System

Ruslan Medzhitov

INTRODUCTION

Host defense against microbial infection is mediated by a variety of mechanisms that fall into two categories: innate and adaptive (or acquired). The adaptive immune system is found only in jawed vertebrates and apparently developed as a result of the acquisition of the recombinase activating gene (RAG) by common ancestors of the vertebrate lineage (1). Accordingly, the adaptive immune system exists only in the context of vertebrate physiology and relies on the function of the RAG genes for somatic recombination of gene segments that encode antigen receptors. Clonal distribution and selection of antigen receptors from a randomly generated and highly diverse repertoire of specificities are the two unifying principles of the adaptive immune system. Innate immunity, however, is an evolutionarily ancient and universal form of host defense found in all multicellular organisms studied.

The vast majority of metazoan species (>98%) rely exclusively on the innate immune system for their defense against microbial infections. The main distinction between innate and adaptive immune systems is in their mechanisms and targets of recognition. The adaptive immune system can recognize an almost unlimited universe of antigens using a somatically generated repertoire of antigen receptors. The innate immune system, however, relies on germline-encoded receptors to detect a limited set of microbial structures that are uniquely associated with microbial infection. Another important distinction is that innate immunity is not a function of a single defined physiologic system; rather, it is a product of multiple and diverse defense mechanisms as discussed in more detail next.

MODULES OF THE INNATE IMMUNE SYSTEM

The innate immune system consists of multiple distinct subsystems, or modules, that perform different functions in host defense. The following is a list of some of the major modules and the immune functions associated with them:

Surface epithelium is an ancient and universal module of innate immunity found in all metazoans. The surface epithelium generally represents the main site of interaction with the microbial world, both pathogenic and commensal, and plays many important functions in protecting the host from pathogen entry as well as in establishing a mutualistic coexistence with commensal microbiota. Accordingly, some types of surface epithelia, notably mucosal epithelium, evolved with specialized functions essential for antimicrobial defense, including the production of mucins that help prevent the attachment and entry of pathogens, and the production of antimicrobial peptides and other microbicidal products that limit the viability and multiplication of pathogens.

The *phagocyte system* is an essential component of innate immunity, particularly in complex metazoans where specialized (or professional) phagocytes (macrophages and neutrophils) perform various host defense functions that rely on phagocytic uptake of pathogens. Phagocytes are equipped with multiple antimicrobial mechanisms that become activated upon the initial contact with pathogens. The phagocyte system is critical for the defense against both intracellular and extracellular bacteria as well as fungal pathogens. The functions of phagocytes are greatly aided by opsonins—secreted proteins that bind to microbial cell walls and facilitate phagocytosis through cell surface receptors specific for them. Opsonins are products of the acute phase response and complement systems.

The *acute phase response and complement* are part of a module consisting of a variety of secreted proteins that function in the circulation and in tissue fluids. These proteins are secreted by hepatocytes in response to the inflammatory cytokines IL-1 and IL-6, and their concentration rises dramatically soon after infection. Acute phase proteins and complement products opsonize pathogens for phagocytic uptake, recruit phagocytes to the site of infection, and have direct antimicrobial activities.

Natural killer (NK) cells are specialized in the elimination of infected host cells and in aiding defense against viral and other intracellular infections through production of cytokines, particularly IFN-γ. The activity of NK cells is regulated by type I interferons (IFN-α/β) either directly or through the induction of IL-15.

Type I IFNs and IFN-induced proteins play a critical role in defense against viral infections. Type I interferons are produced in response to viral infections and trigger the expression of more than a hundred so-called IFN-induced genes, many of which are either known or presumed to have antiviral functions. There are two major modes of IFN-α/β production and action: First, virtually any virally infected cell can produce IFNs-α/β, which act in an autocrine or paracrine fashion to induce an antiviral state in the local site of infection. Second, IFN-α/β can be produced by specialized IFN-producing cells known as *plasmacytoid dendritic cells* (pDC). pDCs produce large amounts of IFN-α/β that can act systemically, and this production does not necessarily require that the pDCs are virally infected themselves. In addition to inducing the antiviral state, IFN-α/β has many other functions in host defense, including the control of NK cell functions.

Mast cells, eosinophils, and basophils are specialized in defense against multicellular parasites, such as helminthes. Although mast cells reside in mucosal and connective tissues, eosinophils and basophils are recruited to the sites of infection from the circulation. These cells play multiple important functions in host defense against parasites through their effects on vasculature and mucosal epithelium to limit parasite spread and to facilitate their excretion from the host organism. They also produce

proteins that are toxic to parasites. The function of this module is regulated by several cytokines, including IL-4, IL-5, IL-9, and IL-13.

Importantly, some of the modules of the innate immune system evolved independently from each other and appeared at different stages of phylogeny. For example, surface epithelium and antimicrobial peptides are evolutionarily ancient modules that exist in all metazoans, whereas NK cells and type I interferons are only found in higher vertebrates. NK-mediated killing of virally infected cells is presumably a viable host defense mechanism in complex metazoans with renewable tissues, but not in most invertebrates that are made up of postmitotic cells that do not self-renew. Similarly, mast cells, eosinophils, and basophils and the host defense functions associated with them exist only in vertebrates.

Another important aspect of the modular organization of innate immunity is that some modules are functionally linked with each other, while others are not. The phagocyte system and the acute phase proteins are functionally linked through the inflammatory cytokines (IL-1 and IL-6) produced by phagocytes that stimulate the acute phase response. In turn, many acute phase proteins function as opsonins that facilitate phagocytosis by macrophages and neutrophils.

Another example of functionally coupled modules are NK cells and type I interferons, which cooperate in host defense against viral infections. However, type I interferons and eosinophils/basophils are not functionally linked, presumably because they never become coinduced by the same infection.

Finally, different modules are activated by different sets of receptors of the innate immune system. In fact, different strategies of innate immune recognition have evolved to activate different modules of the innate immune system with their distinct mechanisms of defense from infection.

INNATE IMMUNE RECOGNITION

Strategies of Innate Immune Recognition: Microbial Nonself and Missing Self

The innate immune system uses at least two distinct strategies of immune recognition: recognition of *microbial nonself* and recognition of *missing self*. The first strategy, often referred to as *pattern recognition,* is based on the recognition of molecular structures that are unique to microorganisms and that are not produced by the host (2,3). Recognition of these microbial products directly leads to the activation of immune responses. The second strategy is based on the recognition of molecules expressed only on normal, uninfected cells of the host (4). These molecules function as molecular "flags" of normal (i.e., healthy) self

because they are not produced by micro-organisms, and their expression is lost on infected cells. These flags are recognized by inhibitory receptors (e.g., on NK cells), or by proteins that inhibit activation of innate immune effector mechanisms (e.g., factor H of complement). Recognition of missing self plays an important role in the function of NK cells and complement and is discussed in the context of NK and complement biology in Chapters 16 and 34, respectively.

Targets of Innate Immune Recognition

The pattern recognition strategy is based on the detection of conserved molecular structures produced by microbial pathogens, but not by the host organism (3). There are multiple differences between the metabolic pathways of prokaryotic and eukaryotic cells, as well as of protozoan pathogens and multicellular hosts. Some of the pathways that are unique to microbial metabolism have essential physiologic functions and are, therefore, found in all micro-organisms of a given class. The products of these metabolic pathways, as well as some individual gene products, are referred to as *pathogen-associated molecular patterns* (PAMPs) and represent targets of innate immune recognition. The receptors of the innate immune system that evolved to recognize PAMPs are called *pattern-recognition receptors* (PRRs) (2,5). The best-known examples of PAMPs include lipopolysaccharide (LPS) of gram-negative bacteria; lipoteichoic acids (LTA) of gram-positive bacteria; peptidoglycan; lipoproteins generated by palmitylation of the N-terminal cysteines of many bacterial cell wall proteins; lipoarabinomannan of mycobacteria; double-stranded RNA (dsRNA), which is produced by most viruses during the infection cycle; and β-glucans and mannans found in fungal cell walls. All these structures are produced by different classes of microbial pathogens, but importantly, not by the host organisms. Therefore, they function as "molecular signatures" of microbial metabolism, and their recognition by the innate immune system signals the presence of infection. PAMPs derived from different species of pathogens may differ from one another in the details of their chemical structure, but they always share a common molecular pattern. For example, the lipid A region of LPS is highly conserved across a wide range of gram-negative bacteria and is responsible for the pro-inflammatory activity of LPS, whereas the core region and the O side chain can be variable even among closely related strains and are not recognized by the innate immune system. Although different PAMPs are not structurally related to each other, they all share several features that reflect the evolutionary strategy of innate immune recognition (2,5). First, all PAMPs are produced by microbes, but not by the host organism. This is the basis of self/nonself discrimination, a key aspect of innate immune recognition that enables innate and adaptive

immune responses to be mounted only against microbial cells and antigens. Second, PAMPs are invariant among pathogens of a given class. This allows a limited number of germline-encoded PRRs to detect any microbial infection. For example, recognition of the conserved lipid-A portion of LPS allows a single PRR to detect the presence of almost any gram-negative bacterial infection. Third, PAMPs often perform physiologic functions that are essential for microbial survival, which means that loss or mutational change of PAMPs would be lethal or at least highly disadvantageous for the micro-organism. Therefore, microbial pathogens are limited in their ability to either mutate or lose expression of PAMPs in order to avoid recognition by the innate immune system. It is important to note that while PAMPs are unique to micro-organisms, they are not unique to pathogens. Indeed, all the known PAMPs are produced by both pathogenic and nonpathogenic (e.g., commensal) micro-organisms. For example, LPS derived from commensal gram-negative bacteria is as potent in inducing host macrophages as LPS derived from pathogenic species of bacteria. This means that the receptors of the innate immune system cannot distinguish between pathogens and nonpathogenic microbes. This distinction, however, clearly has to be made by the innate immune system, because all multicellular organisms live in close and continuous contact with commensal microflora. Failure to tolerate or ignore PAMPs derived from commensal microbes would have disastrous consequences to the host. The mechanisms that allow the innate immune system to distinguish between pathogens and commensals are not well understood. However, anti-inflammatory cytokines (such as IL-10 and TGF-β) and compartmentalization (confinement of the commensals to the apical side of the surface epithelia) play an important role in preventing the inappropriate triggering of innate immune responses.

THE RECEPTORS OF THE INNATE IMMUNE SYSTEM

The innate immune system detects infection using a variety of PRRs that recognize PAMPs and trigger various effector responses (6). Several classes of PRRs that evolved to perform these functions differ in expression profile, localization (cell surface, cytosolic, secreted into serum and tissue fluids), and function. All PRRs can be broadly categorized into three functional classes (Figure 14.1):

1. PRRs that signal the presence of infection. These can be expressed on the cell surface or intracellularly. In either case, recognition of PAMPs by these receptors leads to the activation of "pro-inflammatory" signaling pathways, typically NFκB, interferon regulatory factors (IRFs), Jun N-terminal kinase (JNK), and p38 MAP

kinase. Activation of these evolutionarily conserved signaling pathways by PRRs leads to the induction of numerous genes. There are three categories of gene products induced by PRRs: (a) proteins and peptides that have direct antimicrobial effector functions (e.g., antimicrobial peptides and lysozyme); (b) inflammatory cytokines and chemokines (e.g., TNF, IL-1, IL-8) that induce multiple physiologic reactions aimed at optimizing conditions to combat the infection); and (c) gene products that control activation of the adaptive immune response (e.g., MHC, CD80/CD86, IL-12). The best-known receptors of this class are the family of Toll-like receptors (TLRs), Dectin-1, NOD proteins, and RIG-I and MDA-5 proteins.

2. Phagocytic (or endocytic) PRRs. These receptors are expressed on the surface of macrophages, neutrophils, and dendritic cells (DCs). As the name implies, these PRRs recognize PAMPs on pathogen surfaces and mediate their uptake into the phagocytes. Phagocytosed micro-organisms are delivered into lysosomal compartments where they are killed by several effector mechanisms available in phagocytes. In DCs and macrophages, phagocytosis is followed by processing of pathogen-derived proteins and their presentation by MHC molecules for recognition by T cells. PRRs of this class include the macrophage mannose receptor (MR) and MARCO (macrophage receptor with collagenous structure).

3. Secreted PRRs. PRRs of this class perform three types of functions: They activate complement, opsonize microbial cells to facilitate their phagocytosis, and, in the case of some PRRs, function as accessory proteins for PAMP recognition by transmembrane receptors, such as TLRs. Some PRRs are secreted by macrophages and epithelial cells into tissue fluids. Most, however, are secreted into the serum by the liver; many of these are acute phase proteins, as their production is increased dramatically during the acute phase response. Examples of secreted PRRs are the mannan-binding lectin (MBL) and peptidoglycan-recognition proteins (PGRPs).

Toll-like Receptors

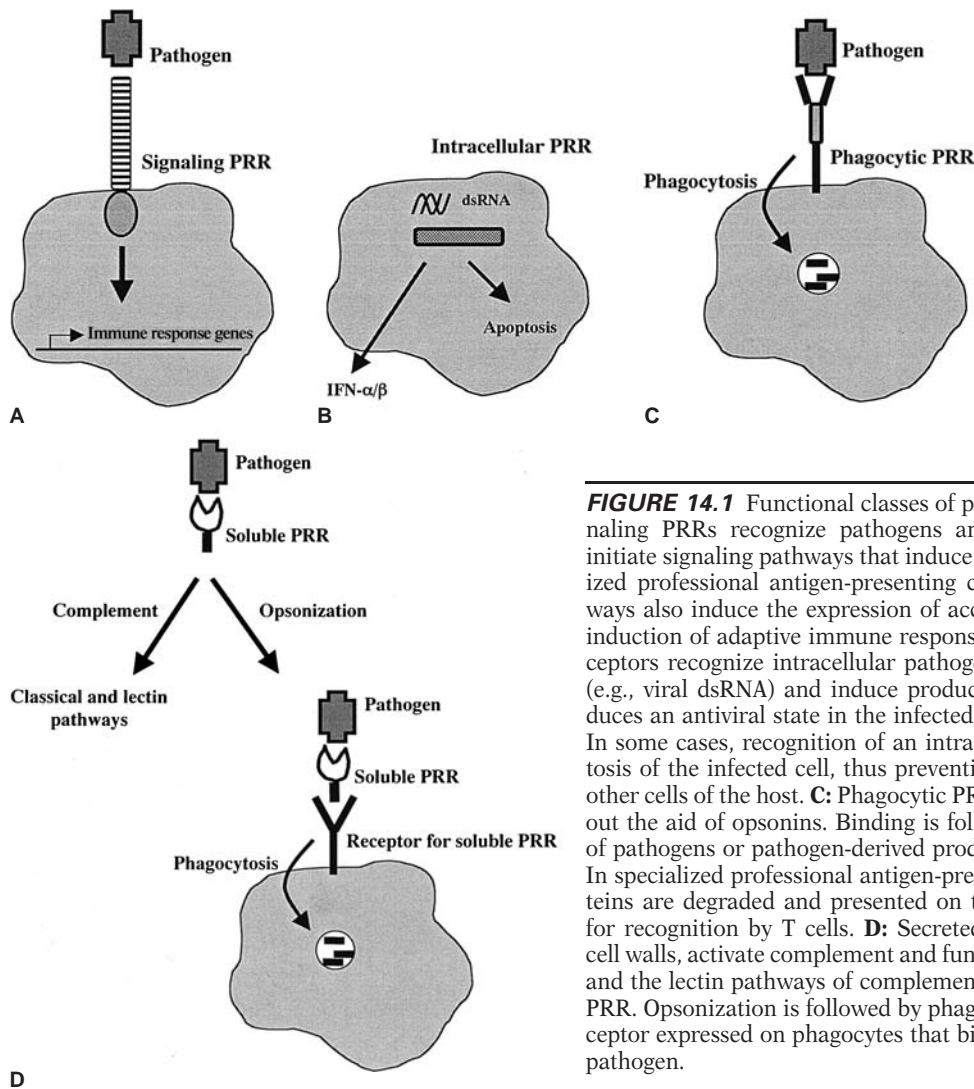
The Toll-like receptors play a unique and essential role in innate immune recognition. TLRs comprise a family of type I transmembrane receptors that are characterized by leucine rich repeats (LRRs) in the extracellular portion and an intracellular TIR (Toll/IL-1 receptor) domain, which is homologous to the intracellular domain of IL-1 receptor family members (7,8). LRRs are found in many functionally distinct proteins where they appear to be involved in protein interactions and ligand recognition (9). The TIR domain is a conserved signaling module found in a number of cytoplasmic proteins


FIGURE 14.1 Functional classes of pattern recognition receptors. **A:** Signaling PRRs recognize pathogens and pathogen-derived products and initiate signaling pathways that induce inflammatory responses. In specialized professional antigen-presenting cells, PRR-triggered signaling pathways also induce the expression of accessory molecules necessary for the induction of adaptive immune responses. **B:** Intracellular PRRs. These receptors recognize intracellular pathogens and pathogen-derived products (e.g., viral dsRNA) and induce production of IFN-α/β, which in turn induces an antiviral state in the infected cell as well as in neighboring cells. In some cases, recognition of an intracellular pathogen can induce apoptosis of the infected cell, thus preventing the pathogen from spreading to other cells of the host. **C:** Phagocytic PRRs bind to pathogens directly, without the aid of opsonins. Binding is followed by phagocytosis and delivery of pathogens or pathogen-derived products into lysosomal compartments. In specialized professional antigen-presenting cells, pathogen-derived proteins are degraded and presented on the cell surface on MHC molecules for recognition by T cells. **D:** Secreted PRRs, upon binding to pathogen cell walls, activate complement and function as opsonins. Both the classical and the lectin pathways of complement can be induced, depending on the PRR. Opsonization is followed by phagocytosis, which is mediated by a receptor expressed on phagocytes that binds to the PRR complexed with the pathogen.

in animals and plants in addition to Tolls and IL-1 receptors. Interestingly, most, if not all, TIR domain–containing proteins in animals and plants are involved in host defense pathways. The number of functional TLRs in mammalian species varies, because of species-specific gene loss. Thus, TLR10 is a pseudogene in mice, but appears to be intact in humans. TLRs 11, 12, and 13, however, are pseudogenes in humans but are intact in mice (10). The reasons for this lineage-specific gene loss are currently unknown. Unlike Drosophila Tolls, all mammalian TLRs function as receptors of the innate immune system. TLRs differ from one another in their expression pattern, their ligand specificities, the signaling pathways they utilize, and the cellular responses they induce. Most TLRs have at least one known ligand (the exceptions are human TLR10 and mouse TLRs 12 and 13). All well-defined TLR ligands are conserved microbial products (PAMPs) derived from all the major classes of pathogens—bacterial, viral, fungal, and protozoan. It is not yet known if any of the TLRs can

recognize molecular products associated with multicellular parasites. The PAMPs that are known to signal through TLRs are structurally quite diverse and, importantly, lack any common chemical features. The exact mechanism of PAMP recognition by TLRs is not yet known, but the available information suggests that TLRs either directly recognize their ligands, or at least contribute to direct recognition and, therefore, may function as *bona fide* PRRs (11–13). It is interesting in this regard that at least some of the TLRs can recognize more than one ligand, and again, these ligands can be structurally unrelated to each other (10). Another important feature of TLR-mediated recognition and function is that at least some TLRs use accessory proteins for ligand recognition.

TLRs can be grouped into two classes based on their subcellular localization, signaling mechanisms, and the nature of the ligands they recognize: TLRs 1, 2, 4, 5, and 6 are expressed on the plasma membrane and detect bacterial and fungal cell wall components. TLRs 3, 7, and 9

are expressed in endosomal compartments and recognize viral nucleic acids.

TLR4

TLR4 is expressed on many cell types in humans and mice, most predominantly in the cells of the immune system, including macrophages, DCs, neutrophils, mast cells, and B cells (14). TLR4 is also expressed on various nonhematopoetic cell types, including endothelial cells, fibroblasts, surface epithelial cells, and muscle cells. TLR4 is the signal transducing receptor for LPS. This was discovered by positional cloning of the *Lps* gene in the LPS-unresponsive C3H/HeJ mouse strain (15,16) and by a targeted deletion of the *Tlr4* gene in mice (17). In C3H/HeJ mice, TLR4 fails to signal in response to LPS due to a point mutation in the TIR domain that results in the substitution of proline for histidine at position 712 (15–17). Analysis of C3H/HeJ mice and TLR4 knockout mice demonstrated that TLR4 is absolutely crucial for LPS recognition and responsiveness by macrophages, DCs cells, and B cells. *In vivo* responses to LPS (e.g., endotoxic shock) are also completely abrogated in TLR4-deficient mice (17). The mechanism of LPS recognition by TLR4 is quite complex and requires several accessory proteins. LPS first binds to LBP (LPS-binding protein), a serum protein that binds LPS monomers and transfers them to CD14 (18). CD14 is a GPI-linked protein expressed on the surface of macrophages and some subsets of DCs. CD14 also exists as a soluble protein in the serum. Both forms of CD14 bind LPS with high affinity (18). The mechanism of CD14 function is unknown but appears to be important for LPS recognition, as demonstrated by the profound defect in LPS responsiveness in CD14-deficient mice (19). The ectodomain of TLR4 is associated with another accessory protein called MD-2. MD-2 is a small protein that lacks a transmembrane domain but is expressed on the cell surface in a complex with TLR4 (20). The function of MD-2 is not known except that it is required for LPS recognition by TLR4 (21). Several experimental approaches have indicated that TLR4 and MD-2 make a direct contact with LPS (11–13), although much remains to be learned about the composition of the TLR4 complex and the mechanism of LPS recognition. The issue of LPS recognition is complicated even further by the discovery of another cell-surface receptor that appears to cooperate with TLR4 in LPS recognition in B cells. This protein, called RP105 (22), is expressed on B cells and some subsets of DCs and has an ectodomain closely related to that of TLR4. Similar to TLR4, RP105 is associated through its ectodomain with an accessory protein called MD-1, which is a homolog of MD-2 (23,24). Unlike TLR4, RP105 lacks a TIR domain, and instead has a short cytoplasmic tail that contains the tyrosine phosphorylation motif, YXXI (22). Cross-linking of RP105 leads to B cell proliferation and upregulation of CD80/CD86 costimulatory molecules, similar to the effect of LPS stimulation (23). RP105 is also

known to induce activation of Src-family tyrosine kinases, including Lyn (25). Deletion of the RP105 gene results in reduced responsiveness of B cells to LPS stimulation, although the defect is not as complete as the defect seen in TLR4-deficient B cells (26). In addition, RP105 is involved in B cell responsiveness to at least some TLR2 ligands, including bacterial lipoproteins (27). Thus, RP105 appears to cooperate with TLR2 and TLR4 in lipoprotein and LPS recognition by B cells, but the molecular mechanism of this cooperation in recognition and signaling remains unknown.

In addition to LPS, TLR4 is involved in recognition of several other ligands. A heat-sensitive factor associated with the cell walls of *Mycobacterium tuberculosis* was shown to signal through TLR4, but the chemical nature of the ligand is not yet known (28). TLR4 along with CD14 was also shown to mediate responsiveness to the fusion (F) protein of respiratory syncytial virus (RSV) (29). However, it is not clear yet whether TLR4 recognizes some feature of the F protein that is shared with other viral fusion proteins. In other words, it is not clear whether TLR4 evolved to recognize the F protein, or if the F protein evolved to bind to TLR4 and trigger its activation because it provides some unknown benefit to RSV.

TLR2, TLR1, and TLR6

TLR2 is involved in recognition of a surprisingly broad range of microbial products. These include lipoteichoic acids (LTA) and peptidoglycan from gram-positive bacteria (30,31), bacterial lipoproteins (32–34), mycoplasma lipoprotein (34,35), mycobacterial lipoarabinomannan (28,36), a phenol-soluble modulin from *Staphylococcus epidermidis* (37), zymosan of yeast cell walls (38), and glycosylphosphotidylinositol from *Trypanosoma cruzi* (39). TLR2 was also shown to mediate recognition of two kinds of atypical LPS, one derived from *Leptospira interrogans* (40) and the other from *Porphyromonas gingivitis* (41). In terms of their structure, most of these ligands are completely distinct from each other. It is puzzling, then, how all these different microbial products can signal through the same receptor. Although the answer to this question is unknown at the moment, there are at least two factors that can help explain the broad range of ligands recognized by TLR2. One is the use of accessory proteins. Indeed, recognition of some TLR2 ligands (e.g., peptidoglycan) requires CD14 (18), and recognition of lipoproteins requires CD36 (42). As mentioned earlier, RP105 is also involved in recognition of some TLR2 ligands. It is quite possible that recognition of other TLR2 ligands may be assisted by additional accessory proteins. Different accessory proteins could conceivably recognize structurally distinct PAMPs and then bind to and trigger TLR2. The second factor that contributes to the diversity of TLR2 ligands is the cooperation of TLR2 with two other TLRs, TLR1 and TLR6, such that the TLR2/TLR1 heterodimer recognizes one set of

ligands, whereas the TLR2/TLR6 heterodimer recognizes a different set of ligands (35,43). These observations were made using mice with targeted deletions in either the TLR2 or TLR6 genes: While both triacylated (tripalmitylated) bacterial lipopeptides and MALP-2 (mycoplasmal macrophage-activating lipopeptide 2kD) failed to signal in TLR2 knockout cells, only MALP-2 (but not tripalmitylated bacterial lipopeptides) required TLR6 for cellular responsiveness (35). Recognition of tripalmitylated lipopeptides, however, requires the TLR2 and TLR1 heterodimer (10). *In vitro* studies, which showed that TLR2 can heterodimerize and signal cooperatively with TLR1 and TLR6 (43), are also consistent with these observations. Interestingly, the only relevant difference between the two ligands is that bacterial lipopeptides have a third palmityl chain attached to the amino group of their N-terminal cysteine, while MALP-2 does not. It is not yet known if any of the other TLRs can heterodimerize for ligand recognition and signaling, but *in vitro* studies suggest that at least TLR4 and TLR5 may function as homodimers (43). TLR2 is expressed constitutively on macrophages, DCs, and B cells and can be induced in some other cell types, including epithelial cells. TLR1 and TLR6, however, are expressed almost ubiquitously (44). In human DCs, expression of TLR2 and TLR4 is restricted to monocyte-derived DCs. Accordingly, this subtype of DCs, but not plasmocytoid DCs, respond to TLR2 and TLR4 ligands (LPS and peptidoglycan, respectively) by producing IL-12 and other inflammatory cytokines (45–47).

TLR3

TLR3 functions as a receptor for dsRNA (48). dsRNA is a molecular pattern associated with viral infections, as most viruses produce dsRNA at some point of their infection cycle. dsRNA and its synthetic analog, poly(IC), have long been known to activate inflammatory responses. As discussed in the next sections, dsRNA is also recognized by the intracellular recognition systems that mediate antiviral responses in infected cells. TLR3 can mediate responses to poly(IC), and TLR3 knockout mice and cells are deficient in their responsiveness to poly(IC) and viral dsRNA (48). TLR3 is expressed on DCs, macrophages, and surface epithelial cells, including intestinal epithelium. In the mouse, TLR3 is expressed in CD8$^+$ DCs, which are known to be particularly efficient in cross-presentation of antigens by MHC class I molecules. CD8$^+$ DCs have also been demonstrated to present antigens derived from virally infected apoptotic cells. Interestingly, viral dsRNA present in apoptotic cells is recognized by TLR3 expressed by CD8$^+$ DCs, and this recognition is important for cross-presentation of viral antigens to CD8 T cells (49). These findings strongly suggest that TLR3 is involved in viral recognition, although the contribution of TLR3 to antiviral immunity remains to be demonstrated.

TLR5

TLR5 is the receptor for flagellin, the protein that polymerizes to form bacterial flagella (50). An interesting aspect of this TLR ligand is that, unlike most other PAMPs, flagellin does not undergo any posttranslational modifications that would distinguish it from cellular proteins. However, flagellin is extremely conserved at its amino- and carboxyltermini, which presumably explains why it can be a target for innate immune recognition. TLR5 is expressed on epithelial cells as well as on macrophages and DCs, particularly the DCs present in the lamina propria (51). Interestingly, expression of TLR5 on intestinal epithelium is polarized such that TLR5 is expressed only on the basolateral side of the cell (52). Since pathogenic but not commensal microbes cross the epithelial barrier, confining TLRs to the basolateral side may help the host to distinguish between pathogenic and commensal microbes, although this notion has not yet been experimentally proven.

TLR7

TLR7 shares many functional properties with TLR9. Both receptors are involved in viral recognition and both detect nucleic acids. TLR7 recognizes viral ssRNA (derived from RNA viruses), whereas TLR9 recognizes unmethylated DNA derived from DNA viruses (discussed later) (10). Consistent with their function in viral recognition, both receptors are expressed primarily by plasmacytoid dendritic cells (pDC) and utilize similar signal transduction pathways for the induction of type-I interferons. TLR7 was first shown to be activated by small antiviral compounds, such as imiquimod (10). Subsequent studies have shown that TLR7 is responsible for recognition of ssRNA from a variety of RNA viruses, including Sendai virus and influenza virus (53–55). Endocytosis of viruses by pDCs leads to uncoating of viral RNA genomes, which are recognized by TLR7 in the acidic environment of late endoseomes and lysosomes. This recognition generally does not require viral infection and replication in pDC. Interestingly, however, in the case of some viruses, including vesicular stomatitis virus (VSV), TLR7-mediated recognition of viral RNA and IFN-α production were found to require viral infection and replication in pDC. Viral replication and production of viral RNA occurs in the cytosol whereas TLR7-mediated recognition takes place inside the late lysosomes; therefore, the viral RNA somehow has to gain access to lysosomes. It was found that the delivery of viral RNA to lysosomes occurs via autophagy—a process whereby cellular constituents, including organelles and portions of cytosol, become engulfed by internal membranes into specialized vesicles (autophagosomes) that fuse with and deliver their content to the lysosomes (56).

Interestingly, TLR7 appears to be able to recognize ssRNA regardless of its origin (cellular or viral). Normally only viral RNA is efficiently delivered to lyosomes through endocytosis of virions or autophagy of viral RNA. Whether

and how the autophagic process can discriminate between viral and cellular RNAs is unclear. Self-RNA, usually in the form of RNA-protein complexes, can be released into the extracellular space from dying cells. However, the concentration of self-RNA in extracellular fluids is normally very low due to efficient removal of apoptotic cells by macrophages and due to activity of RNAses that degrade extracellular RNA. However, when removal of apoptotic cells is compromised (e.g., due to genetic defects in phagocytic pathways), the amount of self-RNA can rise to the levels sufficient to activate TLR7 in pDC and B cells. This can result in activation of autoreactive B cell responses directed at self-RNA–protein complexes and can lead to the development of systemic autoimmune diseases such as lupus (57).

TLR9

DNA that contains unmethylated CpG dinucleotides has long been known for its immunostimulatory properties (58,59). Oligonucleotides that contain unmethylated CpG motifs strongly induce B cell proliferation and cytokine production by dendritic cells and murine macrophages (58,59). Permutation of a single nucleotide or methylation of the CpG motif results in a complete loss of activity (58,59). The stimulatory property of CpG DNA is due to its ability to trigger TLR9 (60). TLR9 knockout mice are completely unresponsive to CpG DNA, demonstrating that all the known effects of CpG DNA are mediated by this TLR (60). Signaling by CpG DNA requires its internalization into late endosomal/lysosomal compartments (59,61). Optimal responsiveness to CpG DNA by mouse versus human cells requires a slightly different sequence motif flanking the CpG dinucleotide (58). Interestingly, the CpG motifs that preferentially stimulate mouse cells also induce a much stronger activation of transfected mouse TLR9, and correspondingly, the CpG motif that elicits optimal responsiveness in human cells preferentially activates transfected human TLR9. This observation suggests that TLR9 itself can distinguish between the two CpG motifs and, therefore, that it presumably recognizes CpG DNA directly (62). Similar to TLR7, expression of TLR9 in humans is restricted to B cells and plasmocytoid dendritic cells, whereas in the mouse, TLR9 is also expressed in macrophages and conventional DCs. Expression of TLR9 in type I INF–producing plasmacytoid DCs (45–47) suggested that TLR9 may be involved in antiviral host defense. Indeed, it was demonstrated that TLR9 is involved in recognition of DNA viruses, such as herpes simplex virus (HSV). Viral genomic DNA becomes accessible to TLR9 in acidified lysosomes following endocytosis and uncoating of virions (63).

While more prevalent in bacterial and viral genomes, unmethylated CpG DNA is present in the mammalian genomes and can trigger TLR9 activation under certain conditions. Similar to the situation with TLR7 and self-RNA–protein complexes, chromatin complexes containing immunostimulatory CpG DNA can be found in the extracellular environment when the removal of apoptotic cells (the major source of self-nucleic acids) is compromised in some way. Indeed, it has been shown that chromatin fragments derived from apoptotic cells can efficiently stimulate B cell activation via TLR9, provided that B cell receptors can recognize and internalize these complexes, whether directly or through recognition of immune complexes containing chromatin fragments (64). The requirement for B cell receptor involvement is presumably due to its ability to deliver CpG DNA to TLR9 in lysosomal compartment. Other receptors capable of delivering chromatin complexes to lysosomes (e.g., Fc receptors) can also promote TLR9 activation in DCs.

Activation of TLR9 by chromatin complexes was initially thought to contribute to the development of pathogenic autoantibodies and the development of lupus. Interestingly, however, TLR9-induced antibodies, particularly of IgM class, can actually contribute to protection from lupus, because these antibodies help to clear chromatin complexes from the circulation. Why this is not the case for TLR7 and its ligands is not yet clear. Currently available evidence in the mouse model indicates that TLR7 and TLR9 play distinct (and perhaps even opposite) roles in promoting or protecting from lupus development, respectively (57).

TLR11

TLRs 11, 12, and 13 are found in mice but not in humans. Mouse TLR11 was found to play a role in defense against uropathogenic infections (65). In addition, TLR11 was found to play a critical role in immunity against a parasitic protozoan *Toxoplasma Gondii* (66). *T. gondii* infection results in the induction of a robust Th1 immune response in mice, which is required for protection from infection. The major immunostimulatory activity was found to be present in the soluble antigen extract of *T. gondii* tachyzoites (STAg). The active component of STAg was found to be profilin—a cytoskeletal protein. Profilin, in turn, was shown to be a potent activator of TLR11. Activation of TLR11 by profilin leads to the production of IL-12 and other cytokines by CD8α DCs, which results in the induction of protective Th1 immune responses. Profilin is also a major immunodominant antigen of recognition of *T. gondii*, and this property was shown to be due to its ability to stimulate TLR11.

TLR Signaling Pathways

Activation of TLRs by microbial products leads to the induction of numerous genes that function in inflammatory and immune responses. These include cytokines, (e.g., TNF, IL-1, IL-6, and IL-12), inflammatory chemokines

(e.g., the neutrophil chemoattractant IL-8), antimicrobial effector molecules (e.g., inducible nitric oxide synthase and antimicrobial peptides), and MHC and costimulatory molecules (7,8,14). Stimulation of TLRs activates several signaling pathways, including the NF-κB pathway, as well as three MAP kinase signaling pathways, JNK, p38, and ERK (7,8,14). In addition, TLRs induce the activation of several members of the IRF family of transcription factors.

Specificity of signaling pathways activated by TLRs is controlled by four receptor-proximal adaptor proteins: MyD88, TIRAP, TRAM, and TRIF. All four adaptors contain TIR domains that are involved in homophilic TIR–TIR interactions with each other and with TIR domains of TLRs. MyD88 controls a canonical TLR signaling pathway and is utilized by all TLRs with the exception of TLR3, as well as by the members of the IL-1 receptor family. In addition to the TIR domain, MyD88 contains a death domain, which is also involved in homophilic interactions. In response to receptor activation, MyD88 is recruited to the receptor complex and initiates the downstream signaling cascade. The components of the MyD88 signaling pathway include serine/threonine protein kinases of the IRAK family (IRAK1 and IRAK4), the ubiquitin ligase TRAF6 (TNF receptor–associated factor 6), and several members of the MAP3K family, including TAK1, ASK1, and MEKKs, which are responsible for activation of NF-κB and three MAP kinase cascades: JNK, p38, and ERK (10).

In addition to IRAKs 1 and 4, two closely related kinases, IRAK2 and IRAKM, have also been identified and have been reported to function in the TLR and IL-1R signaling pathways (67,68). While function of IRAK2 is currently unknown, IRAKM is a negative regulator of MyD88-dependent signaling. Recruitment of IRAKs 1 and 4 to the receptors results in IRAK4 activation and phosphorylation of IRAK1, followed by their dissociation from the receptor complex. Once IRAK1 is phosphorylated, it interacts with and activates TRAF6 (69,70). TRAF6 is a member of the TRAF family of RING-finger E3 ubiquitin ligases (71). Other members of the TRAF family mediate signal transduction by receptors of the TNF receptor superfamily (72). Activation of TRAF6 is thought to be triggered by oligomerization induced by interaction with phosphorylated IRAK. Once activated, TRAF6 functions in concert with the noncanonical E2 ubiquitin–conjugating enzymes, Ubc13 and Uev1A, to conjugate polyubiquitin chains onto itself (and perhaps other as yet unidentified targets) (71). Unlike the polyubiquitin chains that target substrates for degradation by the 26S proteasome, which are linked through K48 of ubiquitin, TRAF6 catalyzes conjugation of noncanonical K63-linked polyubiquitin chains (71). In *in vitro* reconstitution systems, this ubiquitination event is necessary and sufficient for subsequent activation of the IκB kinase (IKK) complex by the kinase TAK1 (73). As TAK1 does not seem to be a target of ubiquitination, how autoubiquitina-

tion of TRAF6 activates TAK1 is not yet clear. Nevertheless, TRAF6-activated TAK1 phosphorylates IKK-β, which leads to activation of the NF-κB pathway (see later discussion) (73). In addition, TRAF6-activated TAK1 also phosphorylates the MAP kinase MKK6, which in turn phosphorylates the MAPK JNK. Therefore, activation of TAK1 by a TRAF6-catalyzed ubiquitination reaction leads to activation of both the NF-κB and AP-1 pathways (73). The NF-κB family of transcription factors plays a crucial role in innate immunity. In flies as well as mammals, most inducible host defense genes are critically regulated, at least in part, by the NF-κB pathway (74,75). NF-κB is usually composed of a heterodimer of two Rel/NF-κB family transactivators (most commonly p50 and p65) bound to an inhibitory subunit called IκB (inhibitor of κB). In unstimulated cells, IκB masks the nuclear localization signal on NF-κB and thus blocks its nuclear translocation. Upon stimulation by TLR ligands and IL-1 (as well as other signals), IκB is rapidly phosphorylated and degraded by the 26S proteasome. Freed of its cytosolic inhibitor, NFκB can then translocate to the nucleus, where it turns on expression of target genes (74,75). Phosphorylation-dependent degradation of IκB, a pivotal checkpoint in activating NFκB, is controlled by the IKK complex (76). The IKK complex consists of two kinases, IKK-α and IKK-β, and a third noncatalytic subunit, IKK-γ. Mutagenesis studies have established serines 32 and 36 of IκB as the targets of IKK-β phosphorylation (76). Phosphorylation at these sites enables recognition of IκB by the F-box/WD protein, β-TrCP, the receptor subunit of a multisubunit SCF ubiquitin ligase complex that subsequently ubiquitinates IκB, thereby targeting IκB for degradation (74,75).

While all TLRs (except TLR3) and IL-1R family members use the MyD88 dependent signaling pathways described earlier, in the case of some TLRs, MyD88 engages additional components for signal transduction. Thus, activation of MyD88 signaling downstream of TLR2 and TLR4 requires an additional adaptor called TIRAP. In addition to a TIR domain, TIRAP contains a phosphoinositide (2,5) biphosphate (PIP2) binding domain. TIRAP associates with the plasma membrane through its PIP2 binding region and recruits MyD88 to TLR2 and TLR4 receptor complexes.

In addition to the recruitment and activation of IRAKs, MyD88 associates with and activates several members of the IRF family. Specifically, MyD88 recruits IRF1 and IRF5. These IRFs in turn play a critical role in transcription of target genes, including inflammatory cytokines and chemokines. IRF1 is an IFN-γ–inducible gene and induction of IRF1 by IFN-γ provides an important mechanism of synergy between IFN-γ and TLR ligands in the induction of multiple genes in macrophages. IRF4 can also associate with MyD88 but plays an inhibitory role by competing with IRF1 and IRF5 for MyD88 binding. Finally, TLR7 and TLR9, but not other TLRs, can induce activation of IRF7

in a MyD88-dependent fashion. Downstream of these receptors, MyD88 associates with and activates IRF7, which plays a critical role in induction of IFN-α genes by these TLRs in pDCs. Activation of IRF7 depends on ubiquitination by TRAF6, as well as on phosphorylation. Three kinases, IRAK1, IRAK4, and IKK-α, have been demonstrated to be responsible for IRF7 phosphorylation (77). The mechanism responsible for TLR-specific activation of IRF7 is currently unknown.

In addition to the MyD88-dependent signaling pathway described earlier, TLR4 and TLR3 signal through a distinct signaling pathway via the adaptor called *TRIF*. TRIF can directly bind to TLR3 and indirectly to TLR4 via another adaptor called *TRAM*. Activation of TRIF leads to the induction of the IKK-related kinases TBK-1 and IKK-ε. TBK-1 in particular plays a critical role in phosphorylation and activation of IRF3, a transcription factor involved in the induction of type I IFNs in most cell types. In addition to IRF3 activation, TRIF induces NF-κB and MAP kinases via TRAF6 and RIP1. These pathways synergize with IRF3 in the induction of IFN-β and other target genes (77).

The diversity of signaling pathways activated by TLRs presumably reflects their differential role in defense against different classes of pathogens. With the exception of TLRs 3, 7, and 9, which are all involved in viral recognition and induction of type I IFNs, it is not yet clear why some of the other differences in signaling pathways exist. For example, it is not yet obvious why TLR4, but not TLR2, can activate the IRF3 signaling pathway. These questions will likely be answered by the future analyses of TLR signaling and function in host defense.

Phagocytic Receptors

Scavenger Receptors

Scavenger receptors (SRs) are cell-surface glycoproteins that are defined by their ability to bind to modified low-density lipoprotein (LDL) (78). There are six classes of structurally unrelated SRs (79). The class A SRs include the macrophage SR (SR-A), the founding member of the SR family, and MARCO (macrophage receptor with collagenous structure). Both SR-A and MARCO are type II transmembrane glycoproteins that contain a collagenous region and a so-called scavenger receptor cysteine-rich (SRCR) domain. The SR-A isoforms generated by alternative splicing are referred to as SR-AI and SR-AII. SR-AII is the shorter isoform that lacks the C-terminal SRCR domain. Both SR-A and MARCO are homotrimeric proteins. SR-A also contains an α-helical–coiled coil region that is absent in MARCO. SR-A is expressed in most macrophage subtypes, as well as in endothelial cells. This receptor has an unusually broad ligand specificity and has been reported to bind, in addition to oxidized and acetylated LDL, a variety of microbial ligands, including gram-negative and gram-positive bacteria, LPS, LTA, and poly(IC) (78). Inter-

estingly, SR-AI and SR-AII have almost identical ligand-binding specificities, suggesting that the SRCR domain is not required for ligand binding. Indeed, binding of the polyanionic ligands has been shown to be mediated by the collagenous domain (78). The role of SR-A in host defense is demonstrated by the increased susceptibility of SR-A–deficient mice to *Listeria monocytogenes*, HSV, and malaria infection (80). SR-A–deficient mice are also more susceptible to endotoxic shock than wild-type mice, suggesting that SR-A may be involved in the clearance of LPS from the circulation (81). MARCO is expressed predominantly in the macrophages of the marginal zone of the spleen, but its expression can be induced in other macrophage subsets by LPS and inflammatory cytokines (82,83). MARCO binds gram-positive and gram-negative bacteria but not yeast zymosan (82,83) and mediates phagocytosis of bound bacteria (82,84). Unlike SR-A, MARCO binds its ligands through the SRCR domain (85). A definitive demonstration of the role of MARCO in host defense will have to await the generation of MARCO-deficient mice.

Macrophage Mannose Receptor

The MR is a 175-kD type I transmembrane protein expressed primarily in macrophages (86). The MR contains cysteine-rich and fibronectin type 2 domains at the N-terminus followed by eight carbohydrate recognition domains (CRD) of the C-type lectin family (86,87). Individual CRDs of the MR appear to have different carbohydrate specificities, with CRD4 being primarily responsible for mannose specificity (88). Although the MR has been implicated in the recognition of microbial carbohydrates, it can also recognize oligo-mannoses found in host-derived, high-mannose asparagine-linked carbohydrates. Indeed, in addition to microbial ligands, the MR has been shown to endocytose several host-derived, high-mannose glycoproteins (89). Although the MR appears to be a multiligand receptor and may have several physiologic roles, the main function of MR is thought to be in phagocytosis of microorganisms (86,89). Indeed, the MR has been implicated in the phagocytosis of a variety of pathogens. Many of these studies are based on the inhibition of MR-mediated phagocytosis by soluble carbohydrate ligands, such as mannan. As micro-organisms contain multiple carbohydrate ligands that presumably engage several receptors on the host cell, some of these analyses are inconclusive and will need to be confirmed using MR-deficient macrophages. A combination of inhibition and transfection studies demonstrated that MR is involved in phagocytosis of bacterial (*M. tuberculosis, Pseudomonas aeruginosa, Klebsiella pneumoniae*), fungal (*Saccharomyces cerevisiae, Candida albicans*), and protozoan pathogens (*Pneumocystis carinii*) (86,89). Upon recognition of microbial ligands, the MR presumably delivers them to the late endosome/lysosome. Thus, the MR was shown to deliver mycobacterial

lipoglycan lipoarabinomannan (LAM) into the late endo-somal compartment where LAM binds to CD1b for subsequent presentation to T cells (90). While the MR clearly can mediate phagocytosis of micro-organisms, the outcome of MR-mediated phagocytosis is not well defined and appears to depend on several factors, including the activation and differentiation status of the macrophage. At least some carbohydrate structures recognized by the MR on micro-organisms (e.g., α-linked branched oligo-mannoses) are similar to mammalian high-mannose oligosaccharides. However, these structures may be present as particulate ligands (in the context of a microbial cell), or as soluble ligands (in host glycoproteins). As the mechanism of uptake differs for particulate and soluble ligands, the effect of MR ligation may be distinct depending on the origin of the carbohydrate that is bound. The most important factor influencing the outcome of MR ligation by microbial versus host-derived ligand, however, is the co-ligation of the microbial cell by other cell-surface receptors, in particular the TLRs. Some of the results implicating the MR in inducing cytokine production may be due to the co-engagement of TLRs by complex microbial structures, such as yeast cell walls. The MR is structurally related to DEC205, a member of the C-type lectin family expressed preferentially on dendritic cells (91). Although the binding of DEC205 to microbial cell walls has not yet been demonstrated, this protein is very likely to function as a PRR, given the high degree of similarity between the CRD domain structures of the MR and DEC205. Moreover, DEC205 has been shown to direct bound material into antigen-processing compartments in DCs (91), supporting the notion that it may function as a phagocytic PRR.

Dectin-1

Dectin-1 is a type II transmembrane receptor that contains one CRD at the C-terminal portion of the protein and an atypical ITAM motif in the N-terminal, cytoplasmic region (92). The CRD of dectin-1 belongs to the C-type lectinlike subfamily of the CTL domain. Unlike the classical CTL domain, the C-type lectinlike domain lacks amino acid residues required for calcium binding and, therefore, binds its ligands in a calcium-independent manner. Dectin-1 was first identified as a DC-specific lectin, but was later found to be expressed on macrophages as well (93). An expression-cloning approach led to the identification of dectin-1 as a β-glucan receptor (93). Dectin-1 is specific for β-1,3–linked and β-1,6–linked glucans, which are PAMPs found in fungal and other microbial cell walls. Dectin-1 binds and phagocytoses β-glucan–rich zymosan and functions as a phagocytic PRR on macrophages and DCs (93).

Zymosan recognition is mediated by both TLR2 and Dectin-1, and analysis of macrophage responses to zymosan revealed that the two receptors cooperate to induce unique TLR2 and Dectin-1–dependent responses. Im-portantly, the ITAM motif of Dectin-1 was found to be tyrosine phosphorylated upon receptor ligation. This phosphorylation results in the recruitment of Syk-27 tyrosine kinase, which initiates downstream signal transduction (94,95). The Dectin-specific signaling pathway was dissected using the β-glucan, curdlan, which activates Dectin but not TLR2. Interestingly, the Dectin-induced signaling pathway is remarkably similar to the antigen receptor–induced signaling pathway. Indeed, in addition to Syk-72 kinase, both antigen receptors and Dectin-1 utilize CARD-coiled-coil adaptor proteins to link to the Bcl10-Malt1 complex and activate NF-κB and MAP kinases (96,97). Antigen receptors employ the adaptor Carma1, whereas Dectin-1 uses CARD9. In addition, activation of Syk-72 leads to Ca^{+2} mobilization and activation of the transcription factor NFAT. The target genes induced by Dectin-1 include IL-2 and IL-10, as well as inflammatory cytokines. Importantly, Dectin-1 induces expression of IL-23, but not IL-12 through the selective induction of the p19 and p40 subunits of IL-23, and the lack of induction of the p35 subunit of IL-12. Analysis of Dectin-1–deficient mice demonstrated that Dectin plays a critical role in antifungal defense. Specifically, Dectin-1 was found to be required for host defense against *Candida albicans* (94,95).

Secreted Pattern-recognition Molecules

Secreted pattern-recognition receptors (or pattern-recognition molecules, PRMs), similar to PRRs expressed on the cell surface, are specific to microbial PAMPs, but their physiologic roles in host defense are different. The two main functions of secreted PRMs are activation of complement and opsonization of microbial cells for phagocytosis. In addition, some secreted PRMs have direct bactericidal effects on bound bacteria. Soluble PRMs are produced and secreted into the circulation mainly by the liver (primarily by hepatocytes), and to a lesser degree by several other cell types, including phagocytes. The serum concentration of these PRMs increases dramatically during the acute-phase response, a systemic inflammatory response induced by inflammatory cytokines such as IL-6, IL-1, and TNF-α. Secreted PRMs, therefore, are sometimes referred to as *acute-phase proteins*. Depending on their domain composition, secreted PRMs fall into four major structural classes: collectins, pentraxins, lipid transferases, and PGRPs. The function of each of these classes will be discussed next.

Collectins

Collectins comprise a group of structurally related PRMs characterized by the presence of a carbohydrate recognition domain of the C-type lectin family at the C-terminus, and a collagenous domain at the N-terminus (98). The CRD domains of the collectins are engaged in ligand recognition, whereas the collagenous portions are responsible

for the effector functions, such as activation of the complement cascade. All collectins form multimers in solution, which permits higher avidity interactions with their cognate ligands (99). Multimerization is also responsible for orienting the CRD domains such that they match the spatial arrangement of their carbohydrate ligands on the microbial surface, thereby allowing the collectins to distinguish microbial carbohydrates from mannose residues on self-glycoproteins (100). MBL is the best-characterized member of the collectin family. MBL binds to terminal mannose and fucose residues in a calcium-dependent manner and has been reported to recognize a broad range of pathogens, including gram-positive (*Staphylococcus aureus, Streptococcus pneumonia*) and gram-negative (*P. aeruginosa, K. pneumonia, Escherichia coli, Salmonella enteritidus*) bacteria; mycobacteria (*M. tuberculosis*); yeast (*Cryptococcus neoformans, C. albicans, S. cerevisiae*); viruses (influenza A, HSV, HIV); and protozoan pathogens (*T. cruzi, P. carinii*) (101). The main function of MBL is to activate the lectin pathway of complement. MBL is associated with two serine proteases, MASP-1 and MASP-2 (MBL-associated serine proteases). Upon binding to microbial cells, MBL induces a conformational change in the associated MASPs that leads to MASP activation, similar to the activation of C1r and C1s by antibody-bound C1q. Activated MASPs then cleave C2 and C4 complement components, thus initiating the complement cascade. In addition to the triggering of the lectin pathway of complement, MBL can function as an opsonin. MBL bound to pathogen cell walls promotes phagocytosis by interacting with C1qRp, a receptor for C1q and MBL expressed on phagocytes (101). Surfactant proteins A and D (SP-A and SP-D) are collectins expressed in the lung and secreted by airway epithelial cells into the alveolar fluid. Both SP-A and SP-D interact with a variety of pathogens, including gram-positive and gram-negative bacteria, fungi, and several viruses (102). Similar to MBL, SP-A and SP-D recognize terminal mannose, fucose, and N-acetyl glucosamine residues expressed on microbial surfaces. SP-A and SP-D proteins function as opsonins and bind to several macrophage receptors that mediate the phagocytosis of the bound micro-organism (99). SP-A, similar to MBL and C1q, binds C1qRp expressed on macrophages. SP-D binds to Gp340 (also known as hensin), a receptor expressed in macrophages and epithelial cells (102). It is not yet clear if Gp340 plays any role in phagocytosis (102). SP-A–deficient mice show increased susceptibility to infection with a number of bacterial, fungal, and viral pathogens—for example, *Group B streptococci, S. aureus, P. aeruginosa, K. pneumoniae, P. carinii,* and respiratory syncytial virus (RSV) (102). SP-D–deficient mice are also compromised in their resistance to several pathogens; however, this defect is difficult to interpret because deletion of SP-D leads to abnormalities of alveolar macrophages and surfactant homeostasis (102).

Pentraxins

C-reactive protein (CRP) and serum amyloid P (SAP) are two structurally related proteins that belong to the pentraxin family (103). Both CRP and SAP are acute-phase proteins in humans and mice, respectively. They are produced primarily by hepatocytes in response to inflammatory cytokines, particularly IL-6. CRP and SAP bind to bacterial surfaces, in part through recognition of phosphorylcholine (104). These PRRs function as opsonins and can activate the classical pathway of complement by binding to and activating C1q (103,105). All pentraxins form multimeric (usually pentameric) structures. CRP and SAP are referred to as short pentraxins, as opposed to long pentraxins that, in addition to the conserved pentraxin domain, have an additional long N-terminal sequence. PTX3 is a prototypical long pentraxin that plays an important role in antibacterial and antifungal defense (106). PTX3 is expressed by a variety of cell types, most notably by DCs, macrophages, and neutrophils. PTX3 can be induced directly by TLR engagement on these cells, or indirectly, through inflammatory cytokines. Like CRP and SAP, PTX3 binds directly to microbial cell walls, activates complement, and facilitates phagocytosis (106).

LBP and BPI

LBP and bactericidal permeability-increasing protein (BPI) are members of a lipid transferase family that also includes cholesteryl ester transfer protein (CETP) and phospholipid transfer protein (PLTP). All four proteins are related to each other in primary structure, which suggests a common origin; however, unlike LBP and BPI, CETP and PLTP do not play any role in host defense, but rather function as lipid carriers in the serum. Both LBP and BPI are components of the acute-phase response, although BPI can also be produced by activated phagocytes. Given that BPI functions as a bactericidal protein, it will be discussed later, along with other effector mechanisms of innate immunity. LBP functions as a transfer protein for LPS and various host-derived lipids. In this sense, LBP is not a true pattern recognition receptor. However, LBP does play a role in LPS recognition by monomerizing LPS from aggregates or micelles and transferring it onto CD14, the high-affinity LPS receptor (18,107). LBP can also function as an opsonin—LBP bound to LPS or gram-negative bacteria was shown to bind to CD14 expressed on the macrophage plasma membrane (107). This binding can subsequently lead to endocytosis of the bound bacteria or LPS. The physiologic significance and mechanism of LBP-mediated phagocytosis are currently unknown. The function of LBP in LPS recognition may be redundant as LBP-deficient mice exhibit normal responsiveness to LPS injection *in vivo* (18).

PGRPs

PGRPs comprise a family of recently discovered PRRs that function as receptors for peptidoglycan in evolutionarily distant organisms, including insects and mammals (108–110). All PGRPs contain a highly conserved peptidoglycan binding domain. Some PGRPs have putative transmembrane regions and presumably function as cell surface receptors, whereas other PGRPs are secreted proteins (109,110). There are four known PGRPs in humans, but more are likely to exist. Human PGRPs are differentially expressed, with one gene predominantly expressed in the liver, one in neutrophils, and one in the esophagus (109). The function of mammalian PGRPs is unknown, but one mammalian PGRP was shown to inhibit bacterial growth, suggesting that at least some PGRPs may function as bactericidal effector molecules (111). Surprisingly, one PGRP that has been analyzed so far inhibited phagocytosis of gram-positive bacteria by macrophages (111). This PGRP also blocked peptidoglycan-induced cytokine production and oxidative burst in macrophages. These effects were presumably due to competition for peptidoglycan binding between PGRP and PGN-binding cell-surface receptors such as TLR2. Since PGRPs were shown to trigger a serine protease cascade in insects in response to bacterial infection, it is likely that at least some mammalian PGRPs may have a similar role—for example, in inducing the complement cascade—to the way in which the lectin pathway is activated by MBL upon microbial recognition (18,107).

Intracellular Recognition Systems

Although most of the initial recognition of microbial infection occurs outside the host cell, many pathogens, and in particular, viruses, gain access to intracellular compartments such as the cytosol. Several intracellular recognition systems have evolved to detect pathogens in the cytosol of infected cells. In addition to the typical outcomes of innate immune recognition—induction of microbicidal effector mechanisms and production of cytokines that activate effector cells— intracellular immune recognition often leads to apoptosis of the infected cell. This is true for both innate and adaptive immune systems (compare NK and CD8 T cell functions). Apoptosis of the infected cell can be cell autonomous or can be triggered by specialized effectors.

Several receptor families are involved in the intracellular recognition of viral and bacterial pathogens. Some are involved in the initial detection of intracellular infections, and others play a role in effector responses. These pathways and their role in innate host defense are described next.

RIG-I/MDA-5

Intracellular recognition of viral dsRNA has long been known to result in a potent induction of IFN-β in infected cells. The identity of the receptors responsible for the initial detection of viral RNA has recently been discovered. Two proteins, called RIG-I and MDA-5, are responsible for detection of two forms of viral RNAs—ssRNA containing 5′ triphosphate and dsRNA, respectively. Most cellular RNAs either contain short hairpin structures with a limited stretch of dsRNA (e.g., tRNAs and rRNAs), or in the case of mRNA, a 5′ cap structure. In contrast, viral RNAs have extended double-stranded structures recognized by MDA-5, or they have 5′ triphosphate ss RNAs, which are detected by RIG-I (113). Thus, structural differences allow for self-/nonself discrimination by these intracellular sensors of viral RNA.

RIG-I and MDA-5 have similar structures, with two N-terminal CARD domains followed by a DEAD family helicase domain. The helicase domain is responsible for RNA recognition, while CARD domains activate downstream signaling pathways leading to IFN production Recent studies have demonstrated that the CARD domain of RIG-I, but not MDA-5, is K63 ubiquitinated by a RING finger E3 ligase, TRIM25. Further, TRIM25 was found to be essential for virus-induced, RIG-I–mediated IFN production (112). Both RIG-I and MDA-5 signal through a downstream adaptor, MAVS (also known as IPS-1, CARDIF and VISA). MAVS is associated with the mitochondrial membrane through a C-terminal hydrophobic region. This mitochondrial attachment is essential for MAVS signaling. Interestingly, hepatitis C virus–encoded protein NS3/4A is a protease that specifically cleaves MAVS off the mitochondrial membrane and thus effectively shuts off RIG-I–mediated induction of the antiviral response. Downstream of MAVS is the serine/threonine kinase TBK-1, which is the kinase responsible for IRF3 phosphorylation and activation. TBK-1 also induces NF-κB and AP1 activation resulting in activation of the IFN-β gene (113).

The role of RIG-I and MDA-5 in antiviral defense has been established using mice deficient in these receptors. Interestingly, RIG-I was found to be essential for the recognition of paramyxoviruses, including influenza virus and Japanese encephalitis virus. MDA5, on the other hand is critical for the detection of picornaviruses, including encephalomyocarditis virus. Accordingly RIG-I$^{-/-}$ and MDA5$^{-/-}$ mice are highly susceptible to infection with these respective RNA viruses compared to control mice (114). MAVS/IPS-1–deficient mice, as expected, are highly susceptible to infection with both classes of RNA viruses, consistent with its role as a critical mediator of RIG-I and MDA-5 signaling (114).

PKR

PKR is a serine/threonine protein kinase that contains three double-stranded RNA (dsRNA) binding domains at the N-terminal part of the protein and a C-terminal kinase domain. PKR can be activated by dsRNA and thus may function as an intracellular sensor of viral infection, as

dsRNA of the length that is sufficient to activate PKR is produced by many viruses, but not by host cells. PKR is expressed ubiquitously, and its expression can be further induced by interferons. Activated PKR phosphorylates the translation initiation factor eIF-2α on Ser 51, which results in a block of cellular and viral protein synthesis (115). PKR can also induce apoptosis in infected cells, thus preventing the further spread of the virus.

2′-5′-Oligoadenylate Synthase and RNaseL. 2′-5′-Oligoadenylate synthases (OAS) are a family of IFN-inducible enzymes that synthesize an unusual polymer—2′-5′-oligoadenylate (116,117). Activation of OAS requires dsRNA and, therefore, is triggered by viral infection. 2′-5′-Oligoadenylate produced by activated OAS then induces dimerization and activation of a dormant endonuclease, RNaseL. Once activated, RNaseL degrades viral and cellular RNA, including ribosomal RNA, which leads to a block of mRNA translation and to apoptosis (116,117) (Figure 14.2). There are at least three genes encoding OAS proteins, and one of them can induce apoptosis through an additional pathway—by binding the anti-apoptotic proteins Bcl2 and BclXL via the C-terminal BH3 domain of the OAS. Sequestration of Bcl2 and BclXL then results in apoptosis of virally infected cells. Interestingly, the dsRNA-binding specificity of OAS evolved independently of that of PKR, as the dsRNA-binding domains in OAS and
FIGURE 14.2 Recognition of viral infection by oligoadenylate synthase (OAS). OAS is activated by viral dsRNA and generates 2′, 5′-oligoadenylate, which functions as a second messenger to activate a dormant ribonuclease, RNaseL. Once activated by 2′5′-oligoadenylate, RNaseL degrades cellular and viral RNA, which results in an inhibition of viral replication. Activated RNase L can also trigger pathways that lead to apoptosis of the infected cell. Some OAS proteins can induce apoptosis more directly by additional pathways that involve the sequestration of the anti-apoptotic members of the Bcl2 family.

PKR are not related to each other. The importance of the OAS/RNaseL system in antiviral defense is demonstrated by the increased susceptibility of RNaseL-deficient mice to ECMV infection (117).

NOD-like Receptors

The NOD-like receptor (NLR) family of proteins is a large group of intracellular proteins named after the prototypical family members NOD1 and NOD2. There are approximately 20 different NLRs in humans and mice with a characteristic arrangement of a C-terminal LRR and a central nucleotide binding and oligomerization domain. Three NLR subfamilies can be defined by the identity of the N-terminal protein–protein interaction domain. Thus, the NOD subfamily contains a CARD domain, the NALPs contain a pyrin domain, and the NAIPs contain a Bir domain (118). In all cases studied, the N-terminal domain is responsible for interaction with adaptor proteins or kinases, whereas the LRR region is presumably responsible for ligand recognition (although direct ligand recognition has not yet been demonstrated for any of the NLRs).

Although a number of NLRs have yet to be functionally characterized, available information indicates that NLRs have diverse functions in the immune system. Some NOD proteins, including NOD1, NOD2, and NOD10—all of which contain CARD domains—activate NFκB and MAP-kinase signaling pathways (119–122). The N-terminal CARD domains of these NODs interact with and activate the serine/threonine protein kinase RIP2, which in turn induces the NFκB and MAP-kinase signaling pathways (119–121).

Nod1 and Nod2 are involved in intracellular bacterial recognition. Both proteins detect different structures derived from bacterial peptidoglycan. Specifically, Nod2 detects muramyl dipeptide, the conserved molecular structure common to gram-negative and gram-positive bacteria. In contrast, Nod1 is involved in the recognition of peptidoglycan fragments containing *meso*-diaminopimelic acid (*meso*-DAP), which is more characteristic of gram-negative bacterial peptidoglycan (118). It is not yet known whether NOD proteins recognize peptidoglycan directly, or via some accessory protein. Regardless of the mechanism, detection of peptidoglycan by NOD1 and NOD2 leads to induction of inflammatory cytokines and chemokines and the recruitment of neutrophils to the site of infection (118). In addition, NOD proteins contribute to the initiation of the adaptive immune responses. Importantly, mutations in NOD2 proteins have been implicated in the pathogenesis of Crohn's disease (123,124).

The NALP subfamily of NLRs includes 14 members, and at least some of them play an important role in the regulation of inflammatory responses mediated by the IL-1 family of cytokines (125–127). The IL-1 family members,

IL-1β, IL-18, and IL-33 are produced as inactive precursors that have to be processed in the cytosol by the inflammatory caspases, caspase-1 and caspase-5/caspase-11. Recent studies have demonstrated that activation of caspases occurs in a mutisubunit complex named the *inflammasome* (125–127). There are several different types of inflammasomes, depending on their composition and the involvement of a particular NALP protein. The two best characterized are the NALP3 inflammasome and the IPAF inflammasome. Both of these contain a critical adaptor protein known as *ASC* that couples the pyrin domain of NALP3 or IPAF to the CARD domain of caspases (125–127). There are several pathways of inflammasome activation triggered by bacterial or endogenous stimuli. The NALP3 inflammasome can be activated by TLR ligands together with ATP. ATP induces K$^+$ efflux through the P2X7 receptor. Bacterial pore-forming toxins, such as nigericine and maitotoxin, can also induce K$^+$ efflux and thus bypass the requirement for ATP and P2X7. The NALP1 inflammasome can be activated by the anthrax lethal toxin, while Salmonella virulence factor SipB activates the IPAF inflammasome. In addition, *Legionella pneumophila* infection induces caspase-1 activation via NAIP5, which presumably forms yet another type of inflammasome. Both *Legionella* and *Salmonella* can induce IPAF-dependent caspase-1 activation (125–127).

Interestingly, several endogenous products have been shown to activate the inflammasome. Crystals of monosodium urate (MSU) and calcium pyrophosphate dihydrate (CPPD), the causative agents of gout and pseudogout, respectively, induce the NALP3 inflammasome and consequently IL-1 production. Because MSU, CPPD, and extracellular ATP can all be produced by stressed or damaged cells, it is possible that the NALP3 inflammasome induces inflammatory responses to tissue damage.

Importantly, several gain-of-function mutations associated with inflammatory diseases have been identified in NALP3, also known as *cryopyrin*. These occur in Muckle-Wells syndrome, familial cold autoinflammatory syndrome, and neonatal onset multisystem inflammatory disease. In addition, similar mutations in NALP1 (also known as *pyrin*) are responsible for the Mediterranean fever syndrome. Characterization of the pathways of inflammasome activation has revealed the molecular basis for these inflammatory diseases and suggested novel forms of therapy, including the blockade of IL-1 by IL-1 receptor antagonist (128).

THE CELLS OF THE INNATE IMMUNE SYSTEM

Unlike antigen receptors of the adaptive immune system, which are expressed exclusively on lymphocytes, the receptors of the innate immune system are expressed on many cell types. In fact, some of these receptors, most notably the intracellular receptors involved in the detection of viral infections, are expressed in almost every cell type. In this sense, innate host defense is not a function of a few specialized cell types. However, several cell types do have specialized functions related to innate immunity, although some of these cell types have other functions unrelated to immunity as well. Among these cells are macrophages, neutrophils, NK cells, mast cells, basophils, eosinophils, and surface epithelial cells. These cells are specialized to function at different stages of infection and to deal with different types of pathogens.

Macrophages

Macrophages have the most central and essential functions in the innate immune system, and have multiple roles in host defense. Mature, resident macrophages differentiate from circulating monocytes and occupy peripheral tissues and organs where they are most likely to encounter pathogens during the early stages of infection. Upon encounter with infectious agents, macrophages can employ a broad array of antimicrobial effector mechanisms, including phagocytosis of the pathogen and the induction of microbicidal effector systems, such as reactive oxygen and nitrogen intermediates and antimicrobial proteins and peptides. In addition, interaction of macrophages with pathogens leads to the induction of a plethora of inflammatory mediators, such as TNF-α, IL-1, and IL-6, and chemokines, such as KC-1 (and IL-8 in humans). TNF-α and IL-1 induce a local inflammatory response, and at higher concentrations, these cytokines (along with IL-6) induce the acute-phase response by triggering the expression of acute-phase genes in the liver. IL-8, a neutrophil chemoattractant produced by resident macrophages, recruits neutrophils to the site of infection. Production of antimicrobial effector genes, cytokines, and chemokines is mediated primarily by TLRs, whereas phagocytosis is mediated by multiple phagocytic PRRs. Many of the effector functions of macrophages are strongly augmented by IFN-γ, which comes from either NK cells or Th1 T cells. IFN-γ also induces the antigen-presenting functions of macrophages by turning on the expression of a battery of genes involved in antigen processing and presentation.

In addition to their roles in host defense, macrophages have multiple "housekeeping functions," the most appreciated of which is their function as the body's scavengers. Macrophages phagocytose apoptotic cells, cell debris, oxidized lipoproteins, and other byproducts of the normal physiology of multicellular organisms. Kuppfer cells (liver macrophages) remove from circulation senescent cells and desialated glycoproteins through phagocytosis mediated by asialoglycoprotein receptors (100). Similarly, macrophages located in the red pulp of the spleen phagocytose and remove from circulation senescent

erythrocytes. Thus, in addition to the recognition of microbial nonself by PRRs, macrophages are equipped with a separate set of receptors for the recognition of "altered self" (desialated self-glycoproteins and phosphotidylserine exposed on apoptotic cells) and missing self (e.g., the lack of expression of CD47 on senescent erythrocytes) (129–131). It is important to note that, unlike the phagocytosis of pathogens, which is mediated by PRRs and is followed by the induction of inflammatory mediators, phagocytosis of apoptotic and senescent cells is immunologically "silent" in that it does not lead to the induction of inflammatory responses. In fact, recognition and phagocytosis of apoptotic cells result in the production of the antiinflammatory cytokine TGF-β (132). This phagocytosis pathway is mediated by the recently characterized macrophage receptor specific for phosphatidylserine (133). Thus, functionally distinct receptors expressed on macrophages determine the functional outcome of phagocytosis mediated by these versatile cells.

Neutrophils

Neutrophils are short-lived cells (average life span is about 24 to 48 hours) equipped with numerous antimicrobial effector mechanisms. Unlike resident macrophages, mast cells, and immature dendritic cells, neutrophils do not reside in peripheral tissues prior to infection. Rather, neutrophils are recruited from the circulation to the site of infection by cytokines and chemokines produced by resident macrophages and mast cells that have encountered pathogens. Recruited neutrophils accumulate at the site of infection and phagocytose and kill pathogens using several microbicidal mechanisms. In addition to reactive oxygen and nitrogen intermediates, neutrophils employ a number of antimicrobial proteins and peptides that are stored in neutrophil granules. Neutrophils contain several types of granules, including primary (or azurophil) granules, and secondary (or specific) granules that are specialized for the storage and secretion of antimicrobial products. Neutrophils are capable of both extracellular and intracellular killing of micro-organisms, depending on the type of granules used. The content of primary granules is predominantly secreted into the extracellular space, whereas antimicrobial peptides of the secondary granules are predominantly released into the phagolysosome for the intracellular killing of pathogens.

Mast Cells

Although mast cells are best known as effectors of allergic responses, they are also an important component of innate immunity. Mature mast cells reside in connective and mucosal tissues, where they encounter and phagocytose infecting micro-organisms and produce inflammatory mediators that play an important role in leukocyte recruitment (134–136) The role of mast cells in innate host de-

fense has been addressed using Kit^w/Kit^{w-v} mice, which carry an inactivating mutation in the c-kit gene and are essentially mast cell-deficient. Experiments carried out in these mice demonstrated that mast cells play an essential role in antibacterial defense in a model of acute septic peritonitis (137,138). Moreover, the protective role of mast cells is mediated mainly by the rapid production of TNF-α and leukotriene B4, which in turn are responsible for neutrophil recruitment to the site of infection (135,137,138). The dramatic effect of mast cell deficiency revealed in the acute septic peritonitis experiments performed on Kit^w/Kit^{w-v} mice reflects the unique ability of mast cells to store preformed TNF-α that can be quickly secreted upon interaction with pathogens (139). Mast cells also produce lipid mediators of inflammation and a vast array of cytokines, including the "type II cytokines" IL-4, IL-5, and IL-13 (134,135).

Eosinophils

Mature eosinophils are found mainly in tissues, primarily in the respiratory, intestinal, and genitourinary tracts. Eosinophils, similar to mast cells, are rich in granules and produce a variety of cytokines and lipid mediators. In addition, eosinophil granules contain several cationic effector proteins that have potent toxic effects against parasitic worms (140). Unlike neutrophils and macrophages, eosinophils are poor phagocytes and consequently release the content of their granules into the extracellular space. The production of various cationic antiparasitic proteins (which include major basic protein, eosinophil cationic protein, and eosinophil-derived neurotoxic protein), as well as the fact that eosinophilia is induced in several model parasitic infections, implicate this cell type as an effector involved in host defense against parasite infections.

Dendritic Cells

Immature DCs reside in peripheral tissues and are highly active in macropinocytosis and receptor-mediated endocytosis (141). DCs express a number of PRRs, including phagocytic receptors and TLRs. DCs are best known for their role in the initiation of adaptive immune responses, but these cells can also contribute to direct antimicrobial responses (141). Thus, stimulation of DCs with microbial products leads to the induction of several antimicrobial effector responses, such as nitric oxide production. The role of DCs in the initiation of the adaptive immune responses is discussed later in this chapter. The biology of DCs is described in more detail in Chapter 15.

Surface Epithelium

The epithelial cells that line the mucosal surfaces of the intestinal, respiratory, and genitourinary tracts provide an important physical barrier that separates the host from the

environment. Mucins, which are highly glycosylated glycoproteins expressed on the surface of these cells, help to prevent pathogen attachment and invasion. In addition to providing physical separation of the host from the microbial environment, surface epithelial cells produce antimicrobial effectors, such as β-defensins and lysozyme, and secrete a number of cytokines and chemokines that contribute to the local inflammatory response and to the recruitment of leukocytes to the site of pathogen entry (142).

THE EFFECTOR MECHANISMS OF THE INNATE IMMUNE SYSTEM

The innate immune system possesses a wide variety of antimicrobial effector mechanisms that differ in inducibility, site of expression, mechanism of action, and activity against different pathogen classes. The major categories of antimicrobial effectors are as follows:

1. Enzymes that hydrolyze components of microbial cell walls (lysozyme, chitinases, phospholipase A2)
2. Antimicrobial proteins and peptides that disrupt the integrity of microbial cell walls (BPI, defensins, cathelicidins, complement, eosinophil cationic protein)
3. Microbicidal serine proteases (serprocidins)
4. Proteins that sequester iron and zinc (lactoferrin, NRAMP, calprotectin)
5. Enzymes that generate toxic oxygen and nitrogen derivatives (phagocyte oxidase, nitric oxide synthase, myeloperoxidase)

The major sites of expression of antimicrobial effectors are granulocytes (especially neutrophils), macrophages, and surface epithelium. It is worth pointing out that the antimicrobial activities of most of these effectors were demonstrated *in vitro*; physiologic roles in *in vivo* host defense have only been demonstrated for a few of these gene products.

Lysozyme

Lysozyme (also known as *muramidase*) and its antimicrobial properties were first described by Alexander Fleming in 1921. Lysozyme is a 14-kD enzyme that degrades the peptidoglycan of some gram-positive bacteria by cleaving the β-1,4-glycosidic linkage between N-acetylmuramic acid and N-acetylglucosamine. Disruption of the peptidoglycan layer leads to the osmotic lysis of the bacteria. Some gram-positive pathogens with highly cross-linked peptidoglycans are resistant to the action of lysozyme, and gram-negative bacteria are also generally protected from lysozyme by their outer membrane. Lysozyme is highly concentrated in secretions such as tears and saliva. In humans, there is a single lysozyme gene that is expressed in neutrophils and macrophages. In the mouse

there are two lysozymes: lysozyme M, which is expressed in macrophages, and lysozyme P, which is expressed by Paneth cells of the small intestine.

Chitinases

Chitinases comprise a family of enzymes that degrade chitin, a structural polysaccharide that forms the cell wall of fungi and the exoskeleton of insects. Chitinases are secreted by activated macrophages and presumably play a role in antifungal defense, although direct evidence for this function is lacking (143). Several members of the chitinase family are enzymatically inactive due to amino acid substitutions in their catalytic sites. Some of them are expressed in human neutrophils, but their physiologic role is not known.

Phospholipase A2

Phospholipase A2 (PLA2) belongs to a family of disulfide rich enzymes that share similar structures and catalytic mechanisms, but differ in substrate preferences and disulfide arrangements. Group II PLA2 is a 14-kD enzyme that hydrolyses the ester bonds at the 2-acyl position in the phospholipids of bacterial membranes. PLA2 is found in primary granules of neutrophils (and, therefore, is secreted upon degranulation), Paneth cells, and epithelial secretions (e.g., in tear fluid) and is produced by the liver as an acute-phase protein. The bactericidal activity of PLA2 is strongly potentiated by other antimicrobial products of neutrophils and by complement (144). PLA2 is particularly efficient against gram-positive bacteria (145). Killing of gram-negative bacteria is potentiated by antimicrobial effectors that disrupt the outer membrane, such as BPI. The important role of PLA2 in innate host defense is demonstrated by the finding that PLA2-deficient mice are more susceptible to infection with *S. aureus* than their wild-type controls (145–147).

BPI

BPI is a cationic 55-kD protein that has several effector activities against gram-negative bacteria but is inactive against gram-positive bacteria (148). BPI is structurally related to the acute-phase reactant LBP and, similar to LBP, binds to the conserved lipid-A portion of LPS. BPI exerts its bactericidal activity by disrupting the integrity of the outer and inner membranes of gram-negative bacteria, thereby increasing their permeability and susceptibility to the action of other antimicrobial proteins, such as PLA2. BPI can also function as an opsonin by binding to gram-negative bacteria and facilitating their uptake by neutrophils. Unlike LBP, which functions by potentiating LPS recognition by CD14/TLR4, BPI neutralizes free LPS and inhibits LPS signaling (148). BPI is expressed

predominantly in neutrophils, where it is found in large quantities in the primary granules and is secreted into inflammatory fluids upon neutrophil activation (148).

Defensins

Defensins are small (3 kD to 4 kD) cationic peptides with a broad spectrum of antimicrobial activities. Defensins are active against gram-positive and gram-negative bacteria, fungi, parasites, and some enveloped viruses (140,149). Defensins kill micro-organisms by forming multimeric voltage–dependent pores in their membranes. The selective toxicity of defensins toward microbial cells can be explained in part by the differences in phospholipid composition between microbial and mammalian cell membranes and by the presence of cholesterol in mammalian but not in bacterial membranes (150). Defensins are characterized by a common structural feature—a hydrophobic β sheet stabilized by three disulfide bonds. Depending on the pattern of disulfide bond formation between the six conserved cysteines, vertebrate defensins fall into two classes—α-defensins and β-defensins (140,149,150). The α-defensins are generally presynthesized and stored in granules of neutrophils (in humans but not in mice) and Paneth cells of the small intestine. The β-defensins, in contrast, are produced by epithelial cells and in most cases are not stored in cytoplasmic granules (140,149,150). The secretion of β-defensins is controlled primarily at the level of gene transcription and is inducible by microbial products (through TLRs) and by inflammatory cytokines (140,149,150). Like all known antimicrobial peptides, defensins are synthesized as inactive precursors that contain a prodomain (which includes a leader sequence) and an acidic region that neutralizes and inactivates the cationic mature peptide. Processing of defensins results in the generation of active peptides. In neutrophils, active (processed) defensins are stored in the granules, whereas the epithelial defensins are secreted as propeptides and are processed in the lumen of the crypt (140,149,150). For mouse α-defensins, the lumenal processing enzyme has been shown to be the matrix metalloprotease matrilysin (151). Matrilysin-deficient mice do not contain active α-defensins in their intestinal crypts and consequently are susceptible to intestinal infection (151).

Cathelicidins

Cathelicidins comprise a family of antimicrobial peptides that contain a conserved N-terminal prodomain called *cathelin* and a C-terminal peptide that becomes active after cleavage from the cathelin domain. The C-terminal peptide is highly divergent between different cathelicidins within and between mammalian species (152,153). In the single human member of the cathelicidin family, the C-terminal peptide is 37 amino acids long and lacks cys-

teines but can form an amphipathic α helix that allows it to interact with microbial membranes. Cathelicidins are active against gram-positive and gram-negative bacteria and fungi and can act synergistically with other antimicrobial proteins (152,153). Cathelicidins are produced in neutrophils and stored as inactive proproteins in the secondary granules. Activation of cathelicidins occurs when the neutrophil protease elastase cleaves off the cathelin domain. Interestingly, elastase is stored in the primary granules of neutrophils and gains access to cathelicidin precursors only when the primary and secondary granules fuse with the phagosomes of activated neutrophils (140,152).

Serprocedins

Serprocedins comprise a family of 25- to 35-kD cationic serine proteases with antimicrobial activity and include neutrophil elastase, proteinase 3, cathepsin G, and azurocidin/CAP37 (140,154). Unlike other members of the family, azurocidin/CAP37 is catalytically inactive. Serprocedins are localized in the primary granules of neutrophils and are structurally related to the granzymes of NK cells and CD8 T cells. Serprocedins exert their antimicrobial activity either by direct perturbation of microbial membranes, or by proteolysis (140,154). Neutrophil elastase, as discussed earlier, converts cathelicidin precursors into active bactericidal peptides. Mice deficient for neutrophil elastase are more susceptible to gram-negative and fungal infections (155).

Lactoferrin, NRAMP, and Calprotectin

The antimicrobial activities of lactoferrin, NRAMP, and calprotectin are due to their ability to sequester iron and zinc, which are essential for microbial metabolism and replication. Lactoferrin is an 80-kD iron-chelating protein of the transferrin family that contains two iron-binding sites. Lactoferrin is found in the secondary granules of neutrophils, in epithelial secretions such as breast milk, in the intestinal epithelium of infants, and in airway fluids. Lactoferrin has two mechanisms of antimicrobial activity: bacteriostatic and microbicidal. The bacteriostatic effect is due to iron sequestration (156). Pathogens depend on iron provided by the host, and iron deprivation is an efficient strategy to block microbial metabolism, as iron is critically required for both oxidative and anaerobic pathways of ATP generation. In addition, lactoferrin can be processed by limited proteolysis to yield a cationic microbicidal peptide called *lactoferricin* (157). The bactericidal effect of lactoferricin is not dependent on iron sequestration and is thought to be due to a perturbation of microbial membranes (157). NRAMP (natural resistance–associated macrophage protein) is a 65-kD integral membrane protein that functions as an ion pump in the phagocytic

vacuoles of macrophages and neutrophils (158). NRAMP is thought to function by pumping out iron from phagocytic vacuoles that harbor mycobacteria and other such bacteria that can persist in these vacuoles. Indeed, the gene encoding NRAMP is mutated in mouse strains that are highly susceptible to mycobacterial infections (155). NRAMP is inducible by IFN-γ. Calprotectin, a member of the S-100 family of calciumbinding proteins, is composed of 8- and 14-kD subunits and is found in large amounts in the cytoplasm of neutrophils. The antimicrobial activity of this protein resides in its histidine-rich regions, which chelate and sequester zinc ions (159).

Phagocyte Oxidase, Myeloperoxidase, and Nitric Oxide Synthase

Phagocytes (granulocytes and macrophages) are equipped with an enzymatic machinery that generates highly toxic reactive oxygen and nitrogen intermediates that have potent antimicrobial activities (160). The induction of these antimicrobial effector responses is tightly regulated and is triggered upon interaction of phagocytes with pathogens (160,161). Phagocyte oxidase (also known as NADPH oxidase) is responsible for the mitochondria-independent respiratory burst induced in phagocytes during the phagocytosis of micro-organisms. NADPH oxidase is a multicomponent enzymatic complex that consists of three cytosolic subunits (p40phox, p47phox, and p67phox) and a membrane-associated flavocytochrome complex (p22phox and p91phox). Assembly of the subunits into a functional NADPH complex is induced by phagocyte activation through a Rac GTPase–dependent pathway. Once the complex is assembled, it produces superoxide anions (a primary product) and hydrogen peroxide (a secondary product), which are released into phagocytic vacuoles or outside the cell where they exert their direct and potent microbicidal effect. Mice deficient for various components of the NADPH complex are susceptible to multiple microbial infections (160,161). Superoxide and hydrogen peroxide, in addition to their own antimicrobial activity, can also be used as substrates for another neutrophil enzyme called *myeloperoxidase* (160,161). Myeloperoxidase is stored in the primary granules of neutrophils and is also expressed in monocytes. Using the products of the NADPH oxidase as substrates, myeloperoxidase generates hypochlorous acid and chloramines as well as other reactive oxygen intermediates, all of which have potent microbicidal activities. Myeloperoxidase-deficient mice are highly susceptible to infection with *Candida albicans* (160,161). Inducible nitric oxide synthase (iNOS) is expressed in neutrophils and macrophages and generates large amounts of nitric oxide (NO). NO is toxic to bacteria, although the exact mechanism(s) of its toxicity is not yet known (162). iNOS is inducible by IFN-γ and TLR ligands such as LPS (in mouse but not in human macrophages) (162). The role of iNOS

and NO in the innate immune resistance to infection has been demonstrated in mice deficient for this enzyme. INOS knockout mice are more susceptible than their wild-type counterparts to infection with multiple bacterial, viral, and protozoan pathogens (161,162). Interestingly, mice deficient for both NADPH oxidase and iNOS are severely immunocompromised and are highly susceptible not only to infection with pathogens, but also to commensal microorganisms (163).

The Antiviral Effector Mechanisms of the Innate Immune System

NK cells, which play a major role in the innate antiviral host defense, are discussed in depth in Chapter 16. Therefore, the discussion here is focused on cell-autonomous effector mechanisms that appear to be unique to antiviral defense. These mechanisms include the induction of apoptosis in virally infected cells and the inhibition of the viral life cycle by IFN-α/β–inducible gene products. Apoptosis of infected cells is an efficient way to prevent viral spread and can be induced either by cell-autonomous mechanisms (e.g., through PKR and OAS pathways, as discussed earlier in this chapter), or with the help of NK or CD8 T cells. The best-characterized IFN-inducible gene products with intrinsic antiviral activity are members of the Mx protein family (164). The Mx protein and the closely related GBP (guanylate-binding protein) are members of the dynamin family of GTPases. The antiviral function of Mx proteins was discovered by the demonstration that the mouse Mx-1 gene confers resistance to influenza virus infection in A2G mice, whereas most other mouse strains carry a defective allele of Mx-1 and consequently are highly susceptible to influenza infection (164). Mx-1 appears to block transcription of the viral genome by inhibiting the influenza-virus polymerase complex (164–167). The second mouse Mx protein, Mx-2, is also mutated in most inbred strains of mice, except in the feral mouse strains NJL and SPR. In these mice, IFN-inducible Mx-2 protein confers resistance to VSV infection. Unlike the Mx-1 protein, which functions in the nucleus, the Mx-2 protein is cytoplasmic (168). In human cells, there are two IFN-inducible Mx proteins, Mx-A and Mx-B. Mx-A is a cytoplasmic protein that inhibits replication of several viruses, including influenza, measles virus, and VSV. Transgenic expression of the Mx-A protein in mice deficient for the IFN-α receptor protects these mice from lethal viral infections and demonstrates that Mx-A has intrinsic antiviral activity independently of other IFN-inducible genes (165,169). GBP proteins are structurally related to Mx proteins and likewise are inducible by IFN-α/β and confer resistance to some viral infections (170). Not all the mechanisms of the antiviral function of Mx and GBP are known. Cytoplasmic Mx and GBP proteins may interfere with viral infection by blocking viral assembly, as suggested by the

similarity of these proteins to other members of the dynamin family that play a role in vesicular trafficking and fusion.

CONTROL OF ADAPTIVE IMMUNITY BY THE INNATE IMMUNE SYSTEM

In addition to directly activating antimicrobial effector responses, innate immune recognition plays a critical role in controlling the activation of adaptive immunity. Many aspects of innate control of adaptive immunity are covered in detail elsewhere in this book. Discussion here will be limited to an overview of some general concepts.

As noted earlier, there are several classes of PRRs in the mammalian innate immune system. PRRs that signal the presence of infection (e.g., TLRs, Dectins, RIG-I/MDA-5, NODs, etc.) not only induce the inflammatory and antimicrobial responses, but also activate the adaptive immune system. Innate immune recognition is required for the activation of adaptive immune responses in part because the innate immune system can determine the origin of the antigen (2,3,5). Adaptive immune recognition relies on two types of antigen receptors—the T cell receptor and the B cell receptor. The specificities of these receptors are generated by random processes such as gene rearrangement and, therefore, are not predetermined to recognize pathogen-derived antigens. Receptors of the innate immune system, on the other hand, are specific for microbial structures and thus their activation can signal the origin of the associated antigens. The translation of the innate, nonclonal recognition into signals that activate adaptive immune responses is mediated in part by antigen presenting cells, particularly DCs (171).

Immature DCs are located in peripheral tissues where they are likely to encounter invading pathogens (141). Interaction of DCs with pathogens leads to the activation of signaling PRRs, such as TLRs or Dectins, and the phagocytosis of pathogens by phagocytic PRRs, such as DEC205 and the mannose receptor. Once activated through PRRs, DCs begin to express high levels of MHC class II and costimulatory molecules and migrate to the T cell zone in the draining lymph nodes where they present pathogen derived antigens to T lymphocytes (7,8,141). In addition, PRRs induce expression by DCs of cytokines that control T cell differentiation into different effector lineages. Thus, TLRs induce production of IL-12 and IL-23 in response to intracellular and extracellular pathogens favoring Th1 and Th17 differentiation, respectively. Dectin-1 selectively induces expression of IL-23 and thus enhances Th17 differentiation in response to extracellular fungal pathogens. RIG-I/MDA-5 induces high levels of IFN-α/β, which are important for CD8 T cell activation and differentiation. Helminths induce production of IL-4 and TSLP in an unknown cell type through an unknown mechanism, and these cytokines lead in turn to Th2 differentiation and IgE production. Thus, different classes of PRRs detect different types of infection and induce the appropriate effector response of the adaptive immune system.

It should be noted that although the basic principles of innate immune recognition and induction of adaptive immunity, as originally proposed by Janeway, have now been confirmed, little is known about the mechanisms of adaptive immune activation. The key signals that are induced by PRRs and required for induction of adaptive immune responses are arguably unknown. The molecular mechanisms that couple innate immune sensing with activation of T cells and their differentiation into the appropriate effector type are also unknown. Although cytokines that play an essential role in inducing T helper cell differentiation have been characterized, it is not yet clear what are the relevant features of the pathogens that are detected by the PRRs and translated into the appropriate set of effector cytokines. Likewise, it is not clear why self-/nonself discrimination by the innate immune system is not sufficient to ensure peripheral tolerance, as evidenced by the severe autoimmune phenotype of mice and humans deficient in regulatory T cells.

These and many other exciting questions await elucidation in the near future.

CONCLUSION

Innate immunity is an evolutionarily ancient and universal system of host defense. Innate immunity is a function of multiple cell types, receptors, signaling systems, and effector mechanisms. Innate immune recognition is directed at conserved molecular patterns unique to micro-organisms, which allows the innate immune system to distinguish self from microbial nonself. Recognition of infectious microorganisms by the innate immune system leads to the induction of antimicrobial effector mechanisms and thus provides the first line of host defense. In addition, the innate immune system plays an essential role in the initiation of adaptive immune responses and in the control of the effector responses of the adaptive immune system.

Dendritic Cells

Muriel Moser

DISCOVERY AND DEFINITION

In the 1960s, several research groups demonstrated that a population of adherent cells was required for the induction of B and T cell responses *in vitro* and *in vivo*. Most immunologists believed at that time that macrophages were the critical "accessory" cells, on the basis of their adherent properties *(1)*.

In 1973, during the course of observations of murine splenic cells that adhere to glass and plastic surfaces, Stein-

man and Cohn (2) noticed large stellate cells whose cytoplasm was arranged in pseudopods of varying length and form. These authors reported that these cells, named *dendritic cells (DCs)* because of their branchlike projections (from δενδρεον, tree), undergo characteristic movements, do not exhibit the endocytic capacities of macrophages, and adhere to glass. The function of DCs was elucidated 5 years later when it was reported that these cells were the most potent stimulators of the primary mixed leukocyte reaction in mice, which led to the suggestion that DCs

instead of macrophages could be the accessory cells required in the generation of many immune responses (3). This hypothesis was amply demonstrated in the years that followed.

The dendritic family includes many members located throughout the body that share phenotypic and functional properties:

- Dendritic morphology (at least at some stage) and low buoyant density
- Elevated expression of major histocompatibility complex (MHC) molecules (class I and class II) and intermediate to high expression of costimulatory molecules
- Motility
- Specialization of function over time—that is, a shift from an antigen-capturing mode to a T cell sensitizing mode

The hallmark of the DC family is the conversion of these cells from immature sentinels to mature immunostimulatory cells, a phenomenon called *maturation*.

Figure 15.1 illustrates the development of DCs *in vivo* at the precursor, immature, and mature stages. The right column corresponds to the induction of DC maturation by a "danger signal" (pathogen invasion), and their subsequent migration to lymphoid organs. The left column describes the movement of (presumably immature) DCs at the steady state. These pathways are described in the following chapters.

ORIGIN AND DISTRIBUTION OF DENDRITIC CELLS *IN VIVO:* A MULTIMEMBER FAMILY

Interstitial Dendritic Cells

DCs are found as immature cells in virtually all organs (except the brain) within the interstitial spaces that are drained by afferent lymphatic vessels. DCs have been isolated from the heart, kidney, dermis, liver, and other organs.

DCs are found in mucosal surfaces, such as those of the lung and intestine. In the lung, the network of airway DCs is particularly well developed to capture inhaled antigens *(4)*. Its location above the basement membrane of the airway epithelium ensures accessibility to inhaled antigens. There is some evidence that these DCs are maintained in an immature state by an inhibitory mechanism that may involve macrophages *(5,6)*. In the intestine, DCs from Peyer's patches have been characterized and are known to contain three populations that differ by their phenotype and function *(7,8)*.

In the mouse, all splenic DCs express similar amounts of CD11c, class II MHC, and costimulatory molecules CD80, CD86, and CD40. Two major subtypes can be found: The first is positive for the CD8α marker and the C-type lectin
FIGURE 15.1 Developmental stages of DCs *in vivo*. The generation of DC precursors in the bone marrow, the recruitment of immature DCs in peripheral tissues, and the migration of DCs into the lymphoid organs are illustrated. The maturation of DCs into potent APCs in case of infection or inflammation and their migration have been amply documented (right), but there is also evidence that in the "steady state"—that is, in the absence of a "danger signal"—these immature DCs may migrate into the lymphoid organs while remaining at the immature stage (left). The phenotype of the DC migrating in baseline conditions is still unclear. The movement of maturing DCs and the "constitutive" migration of immature DCs have been shown to depend on chemokine gradients.

CD205 (CD8α^+ DEC205$^+$), and the second lacks CD8α and expresses the antigen recongnized by the 33D1 monoclonal antibody CD8$^-$ 33D1$^+$ (9). The subsets also differ by their localization: The majority of DCs in the marginal zone are CD8α^-, whereas most DCs in the T cell areas express the

CD8α homodimer (ref. [9], and our own observations). The DC populations in lymph nodes appear to be even more complex. In addition to the populations present in the spleen, two DC subtypes that likely correspond to dermal- and epidermal-derived DCs *(10)* have been described. The mouse thymus *(11)* has been shown to contain two DC types that differ at the level of CD8α expression.

Precursors of DC Populations

Geissmann et al. have recently identified a clonogenic bone marrow progenitor specific for macrophages and DCs (12). A mouse bone marrow population that expresses CD117 (c-kit, the receptor for stem cell factor) and the chemokine receptor CX3CR1 but not markers of lineage-committed precursors (Lin-) gives rise to monocytes, several subsets of macrophages, and steady state CD11c$^+$ CD8α^+ and CD11c$^+$ CD8α^- DCs *in vivo*. In contrast, this progenitor is devoid of lymphoid, erythroid and megakaryocytic potential. No plasmacytoid DC was detected in the progeny of this bone marrow progenitor, suggesting that this DC subset may originate from a distinct lineage.

Several reports have suggested that monocytes are capable of generating DCs in mice. Randolph et al. *(13)* investigated the differentiation and trafficking *in vivo* of inflammatory monocytes that phagocytosed subcutaneously injected fluorescent microspheres. They found that most of the monocytes became macrophages in the subcutaneous tissue, but that 25% of latex$^+$ cells migrated to the T cell area of draining lymph nodes several days later, where they expressed DC-restricted markers and high levels of costimulatory molecules. In another report, some monocytes transferred into animals with experimentally induced peritonitis were shown to infiltrate the peritoneal cavity and acquire CD11c and MHCII expression, suggestive of differentiation into DC *(14)*. A third study demonstrates *(15)* that monocytes can generate DCs on extravasation from the bloodstream during homing to the spleen when adoptively transferred in irradiated recipients.

Whether monocytes can differentiate into DC in noninflammatory conditions is less clear. A recent study (16) suggests that monocytes from spleen, blood, or bone marrow generate few if any conventional DCs. However, when systemic inflammation was induced, transferred monocytes in the spleen upregulated both CD11c and MHC II and could be classed as DCs, They express intermediate levels of CD11c and high levels of CD11b, a phenotype distinct from the resident steady state DCs (CD11c^{hi}CD11b^{int}). Of note, monocytes remained as monocytes in the blood, bone marrow, and peritoneum in the same inflammatory conditions (16). Varol et al. *(17)* similarly concluded from their adoptive transfer experiments in WT and mononuclear phagocyte-depleted recipient mice that monocytes appear to be dedicated to DC replenishment of nonlymphoid organs, such as the intestinal lamina propria, whereas splenic DCs seem to arise from local precursors without a monocytic intermediate. Collectively, these data suggest that monocytes give rise to inflammatory DCs but not to classical steady-state subset resident in lymphoid organs (Figure 15.2).

Another form of inflammatory DCs, which produces TNFα and iNOS, was identified in spleens of *Listeria monocytogenes*–infected mice *(18)*. It is interesting that this subset is not essential for T cell priming but, as the major producer of TNF and iNOS during the first 48 hours of bacterial infection, mediates the innate defense and is critical to clear the infection. The TNF/iNOS-producing DCs are not present in an uninfected spleen but are recruited following systemic infection through a mechanism dependent on CCR2 (a chemokine receptor known to target monocytes to sites of inflammation) signaling. Similar cells have recently been found to be the dominant DC and the dominant source of TNFα in the human skin disease psoriasis *(19)*, which is treated by blockade of TNFα.

A splenic precursor population was identified [16] that produces all splenic CD8$^+$ and CD8$^-$ conventional DCs (but not plasmacytoid DCs or other lineages), suggesting that the spleen contains a substantial reservoir of immediate DC precursors. They comprise 0.05% of splenocytes and expressed a CD11c^{int}CD45RA^{lo}CD43^{int}SIRP-a^{int}CD4$^-$CD8$^-$MHC$^-$ phenotype. This population accounts for most of the total conventional DC precursor activity. There is evidence that precommitment to the separate CD8$^+$ versus CD8$^-$ DC subtypes can be found in the splenic precursor population (differing by CD24 expression), suggesting that these subsets are separate sublineages.

The origin of plasmacytoid DCs is less clear. Based on the observation that FLT3 ligand is a growth factor for hemopoietic progenitors and can promote the expansion of both conventional and plasmacytoid DCs, D'Amico and Wu *(20)* examined the expression of Flt3 on the surface of bone marrow cells. They found that the majority of Flt3$^+$ cells were within the Lin- c-kit fraction of bone marrow that contains the common lymphoid precursor (CLP) and the common myeloid precursor (CMP). Of note, the DC precursor activity for both conventional and plasmacytoid DCs was strongly enriched in the CMP and CLP Flt3$^+$ fractions. These observations suggest that early precursors for all DC subtypes are within the bone marrow Flt3$^+$ precursor population. The separation of the pathways leading to conventional or plasmacytoid-restricted DC precursors at some point downstream the bone marrow Flt3$^+$ precursor is yet to be defined.

Langerhans Cells

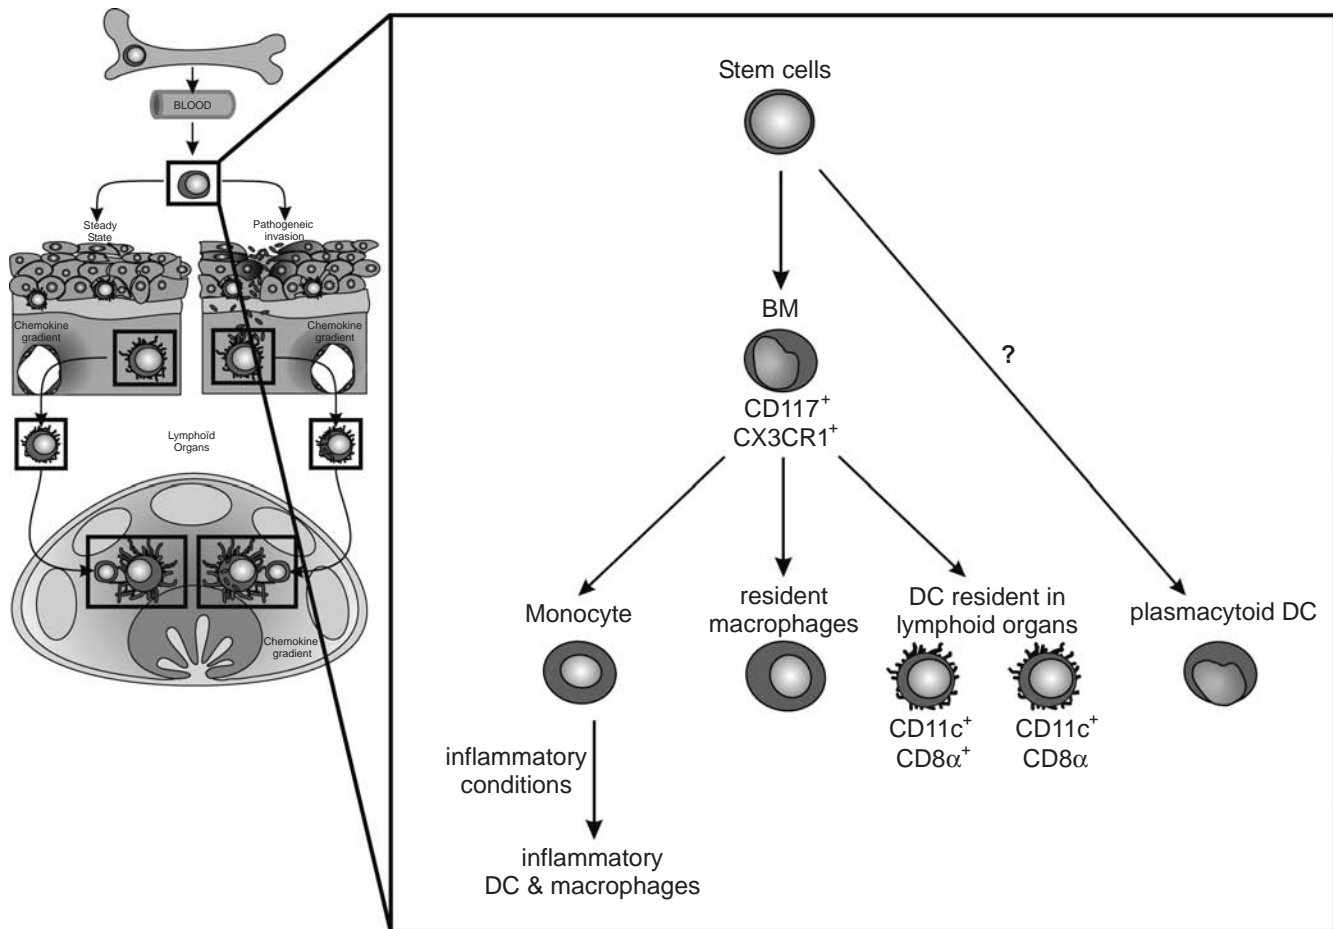
Cells with a dendritic structure were visualized in the skin by Paul Langerhans in 1868. They were described as cells displaying long processes and were considered to belong to


FIGURE 15.2 DC development. A clonogenic bone marrow progenitor specific for macrophages and DCs was recently identified (12). Cells expressing CD117 (c-kit, the receptor for stem cell factor) and the chemokine receptor CX3CR1 give rise to monocytes, some macrophages, and CD11c$^+$ CD8α^+ and CD11c$^+$ CD8α^- DCs in lymphoid organs. No plasmacytoid DC was detected in the progeny of this progenitor. Recent data suggest that monocytes give rise to inflammatory DCs but not to classical subsets resident in lymphoid organs.

the nervous system. The nature of these so-called Langerhans cells remained obscure until they were shown to be derived from bone marrow and to express class II MHC and were identified as the active cells in epidermis for presenting antigen to T cells (*21–22*,23) The relationship of these epidermal Langerhans cells to DCs was established by the observations that murine epidermal Langerhans cells mature into potent immunostimulatory DCs *in vitro* (24).

Ultrastructurally, Langerhans cells are characterized by a unique pentalamellar cytoplasmic organelle: the Birbeck granule. Valladeau et al. (25) identified a type II Ca^{2+}–dependent lectin displaying mannose-binding specificity, exclusively expressed by Langerhans cells. This lectin was called *langerin* (now CD207) and is constitutively associated with Birbeck granules. Although the role of Birbeck granules remains enigmatic, they are attractive candidate

receptors for nonconventional antigen routing in Langerhans cells.

Distinctly present in the epidermis, but also found in other stratified squamous epithelia in the pharynx, upper esophagus, vagina, and external cervis, LCs are distributed in a network fashion (although cell–cell contacts have yet to be described) that covers the entire body surface, constituting the first immunological barrier against the external environment. LC migrate to draining lymph nodes at a low rate in the steady state and at an accelerated rate in the context of inflammation. Whether migrating LCs simply carry the antigen (26) to DC resident in the lymph node or whether they directly prime or tolerize antigen-specific T cells is still under investigation.

Merad et al. (27) recently identified the immediate circulating LC precursor that repopulates LC *in vivo*. They exposed skin to ultraviolet irradiation, leading to strong

decrease in Langerhans cell numbers, and monitored the repopulation of Langerhans cells in skin with ultraviolet irradiation injury. They used chimeric mice (i.e, lethally irradiated recipient mice) reconstituted 3 weeks earlier with mixed hematopoietic precursors expressing or not expressing the CSF-1 receptor (*Csf1r*$^{-/-}$ and *Cfs1*r$^{+/+}$). Analysis of chimeric mice 3 weeks after ultraviolet irradiation showed that *Csf1r*$^{-/-}$ Langerhans cells were absent, showing that *Csf1r*$^{-/-}$ hemopoietic cells are unable to differentiate into Langerhans cells in inflamed skin. Of note, the requirement for CSF-1R appears restricted to LCs as mutant and wild-type splenic DCs were similarly reconstituted. The authors further confirmed that the GR-1^{hi} monocytes were the direct circulating Langerhans cells precursors using monocyte tagging *in vivo* with fluorescent latex beads and adoptive transfer.

Veiled Cells

Typical DCs are found in afferent lymphatic vessels and are called *veiled cells* because of their sheetlike cell processes, or lamellipodia. Early studies underscored the crucial role of the afferent lymphatics during cell-mediated immunity: Priming to skin transplants was shown to be blocked by lymphatic ablation *(28)*. In contrast, efferent lymphatic vessels seem to lack DCs, which suggests that they do not leave the lymph nodes. Indeed, there is evidence that mature DCs undergo apoptosis in the lymphoid organ *(29)* and can be widely processed by other DCs in the node to form peptide MHC complexes *(30)*.

Plasmacytoid-derived Dendritic Cells

CD4$^+$CD11c$^-$ DC precursors with the appearance of plasma cells have been identified in human blood and are identical to natural interferon (IFN) α/β–producing cells, which secrete high amounts of IFN-α/β in response to viruses. These plasmacytoid cells can give rise to DCs *in vitro* in the presence of IL-3 or during viral infection. IFN-α/β and TNFα produced by virus-activated plasmacytoid cells act as an autocrine survival factor and a DC differentiation factor, respectively (31). These cells appear, therefore, to play a role in innate immune responses as IFN-α producers and in adaptive immune responses as antigen-presenting cells (APCs).

The equivalent murine type of type I IFN-producing cells (mIPCs), described in 2001, consists of a population of immature DCs Ly6C/Gr-1$^+$, B220$^+$, CD11c^{lo}, and CD4$^+$ *(32,33)*, showing a homogeneous plasmacytoid structure—that is, a round shape, a smooth surface, and an eccentric nucleus. Upon activation, these cells display a more irregular shape, up-regulate their immunostimulatory properties, and produce IFN-α, IL-12, or both, depending on the stimulus.

HALLMARKS OF CELLS FROM THE DENDRITIC FAMILY

Among the populations of APCs, which include DCs, B lymphocytes, and macrophages, DCs display some unique properties aimed at sensitizing T lymphocytes specific for dangerous antigens encountered earlier in periphery. Indeed, pathogens often invade peripheral tissues, whereas the immune response is initiated in lymphoid structures in which T and B lymphocytes reside *(34)*. DCs appear to form a physical link between the periphery and the secondary lymphoid organs: They act as sentinels for "dangerous" antigens in the peripheral tissues and then migrate to the areas where T cells are located to transmit information about the nature of the pathogen and the infected tissues. To efficiently perform these different tasks, most DCs have a specialization of function over time and location, with a possible exception for plasmacytoid DCs.

During the process of maturation, often associated with their migration from the periphery to the lymphoid organs, DCs shift from an antigen-capturing mode to a T cell–sensitizing mode. The maturation process is induced by microbial products and inflammatory chemokines, thereby favoring the sensitization of T lymphocytes specific for non–self-infectious antigens (Figure 15.3). The following sections review the properties of DCs that confer on them the capability to focus the adaptive immune response on pathogens, avoiding autoimmunity.

The Process of Maturation

The relationship of Langerhans cells to DCs isolated from lymphoid organs was provided in 1985 by Schuler and Steinman (24). The authors showed that fresh Langerhans cells are weak stimulators of T cell proliferation but undergo a progressive increase in stimulatory capacity *in vitro*. The development of enhanced stimulatory activity during culture was called *maturation* (Figure 15.3) and could not be ascribed only to an increase in the level of class II MHC molecules. The authors suggested that functioning DCs, present in lymphoid organs, may be derived from less mature precursors located in nonlymphoid tissues. By comparing the efficacy of fresh and cultured DCs to present a protein to T cell clones, Romani et al. (35) showed that the capacity of DC populations to present proteins varies inversely with stimulating activity in the mixed leukocyte reaction (MLR). Freshly isolated Langerhans cells are very active in presenting proteins, whereas cultured spleen DCs and epidermal Langerhans cells present native protein weakly. These observations suggested that DCs in nonlymphoid tissues such as skin act as sentinels for presenting antigens *in situ*, whereas DCs in lymphoid organs have the capacity to sensitize naïve T cells. This hypothesis was further confirmed, although many DCs in spleen can be found at the immature state (36,37).
FIGURE 15.3 The phenomenon of maturation. In the presence of inflammatory cytokines, microbial products or antigen-activated T lymphocytes, DCs undergo a phenomenon of maturation—that is, they shift from an antigen-capturing mode to a T cell–sensitizing mode. The phenotypic and functional changes are associated with their migration into the T cell area of lymphoid organs.

Therefore, cells of the dendritic family have a specialization of function over time, as they shift from an antigen-capturing mode to a T cell–sensitizing mode during a process called *maturation* (Figure 15.3). DC maturation induces multiple alterations in the function and intracellular transport of class II MHC molecules, leading to the redistribution of class II MHC from intracellular compartments to the plasma membrane (see later discussion). Importantly, the type of maturation stimulus determines the type of DC differentiation pathway and then the type of T cell response (e.g, exposure of human blood DCs to thymic stromal lymphopoietin yields a mature DC that induces an inflammatory type of Th2 cell, while exposure to CD40L yields a mature DC that induces a Th1 type response *[38]*). To recognize antigen, T cells need to establish contact with APCs. The two cell types form an immunological synapse, in which T cell receptors (TCRs) and costimulatory molecules are congregated in a central area surrounded by a ring of adhesion molecules (see later discussion). In particular, the B7 family has been shown to contain six members, which positively or negatively regu-

late the expansion or function of T cells, or both (for review, see Coyle and Gutierrez-Ramos *[39]*). The CD80 and CD86 molecules, the first CD28 ligands to be described, have been shown to promote clonal expansion of resting T cells through CD28 and inhibit T cell expansion through interactions with CTLA-4. Expression of ligands for the CTLA-4/CD28 molecules was shown to be up-regulated on epidermal Langerhans cells *(40)* and splenic DCs *(41,42)* during their functional maturation *in vitro*. The process of maturation also occurs *in vivo:* Systemic administration of endotoxin (lipopolysaccharide [LPS]) induces the migration of most splenic DCs from the marginal zone between the red and white pulp to the T cell area in the white pulp (43,44). This movement parallels a maturation process, as assessed by down-regulation of processing capacity and up-regulation of immunostimulatory properties (43).

Maturation can be mediated by inflammatory cytokines (TNF-α, IL-1), T cells (through CD40/CD40L interaction), microbial constituents (LPS, CpG oligonucleotides), and stress (necrosis, transplantation). DC maturation has been shown to involve signaling cascades initiated by the

Toll/interleukin-1 receptor homology domains of Toll-like receptor (TLR) family that can lead to activation of nuclear factor κB (NF-κB) and mitogen-activated protein kinase (MAPK). TLR4 is the mammalian homolog of *Drosophila* Toll, which is involved in dorsoventral patterning and in host defense against fungal infection. To date, more than 10 members have been reported to belong to the TLR family in mammals and seem involved in recognizing pathogen-associated molecular patterns (for review, see Kaisho and Akira *[45]*). Other pathways that induce powerful stimulatory DCs involve interaction with innate natural killer (NK) *(46)* and NKT lymphocytes *(36,47)* and selective triggering through activating Fcγ receptors *(48,49)*.

Antigen Uptake

At the immature stage, DCs exhibit some endocytic activity. To sample their environment in peripheral tissues, they can take up extracellular fluid and concentrate the macrosolutes in the endocytic compartment. The fluid volume taken up per hour by a single cultured monocyte derived DC has been estimated to be 1,000 to 1,500 μm^3, a volume that is close to that of the cell itself, but similar levels of uptake have yet to be documented *in vivo (50)*.

In addition, DCs express various receptors mediating endocytosis and phagocytosis of antigens, pathogens, and dying cells: crystallized fragment (Fc) receptors for IgE and IgG, which internalize immune complexes receptors for heat shock proteins; receptors, such as CD36 and $\alpha v \beta 5$, which bind and phagocytose apoptotic bodies; and C-type lectins, such as macrophage mannose receptor and DEC-205 *(51)*, which contain 8 and 10 contiguous C-type lectin domains, respectively *(52)*. Whereas most receptors, including the macrophage mannose receptor, internalize and recycle through early endosomes, the DEC-205 cytosolic domain mediates a unique recycling pathway through late endosomes or lysosomes, rich in antigen-presenting class II MHC products, and greatly enhances antigen presentation relative to the mannose receptor tail *(53)*.

Antigen uptake is down-modulated during the process of maturation *(50)*. Most receptors are expressed at lower levels on mature DCs, except DEC-205 in the mouse, which is expressed at higher levels. In addition, endocytosis and macropinocytosis are down-regulated. Garrett et al. *(54)* found that endocytic down-regulation reflects a decrease in endocytic activity controlled by Rho family guanosine triphosphatase Cdc42. Blocking Cdc42 function in immature DCs abrogates endocytosis, whereas injection of active Cdc42 in mature DCs reactivates endocytosis *(54)*, which suggests that the regulation of endocytosis during maturation is at least partly controlled by the levels of active Cdc42. Another report, however, demonstrates that the Rho family guanosine triphosphatases Cdc42 and Rac are required for constitutive macropinocytosis by DCs but do not control its regulation *(55)*.

The differential expression of innate receptors that sense microbial products on the human and mouse DC subsets could form the basis of a selective response to different pathogens. TLRs are highly conserved from *Drosophila* to humans and recognize molecular patterns specific to microbial pathogens. Different TLRs are triggered by a distinct set of microbial compounds (e.g, TLR4 is triggered by lipopolysaccharide, TLR9 by unmethylated oligonucleotide, TLR3 by double-stranded RNA), are coupled to distinct signal transduction pathway (all TLRs except TLR3 are coupled to the MyD88 adaptor, and TLR3 and TLR4 couple to the adaptor TRIF), are localized in different compartments (most TLRs are present on the cell surface, TLRs 7, 8, and 9 are in the endosomal compartement, and TLR3 is intracellular) and are expressed in a constitutive or induced way in different cell types. DCs express the broadest repertoire of TLRs: Freshly isolated human plasmacytoid DCs express TLR7 and TLR9, whereas CD11c$^+$ human myeloid cells express TLR1, TLR2, TLR3, TLR5, TLR6, and TLR8. In mice, all splenic subsets express TLRs 1, 2, 4, 6, 8, and 9. TLR3 is expressed on CD8$^+$ and CD4$^-$CD8$^-$ DCs, TLR5 and TLR7 are expressed on all subsets except CD8$^+$(for review see *[56]*). Similarly, C-type lectins appear differentially expressed on DCs, depending on the subset, activation state, and tissue localization *(52)*.

Recent reports have identified the pathways involved in the recognition of various pathogens. Plasmacytoid DCs have been shown to produce high levels of IFN-α in response to the influenza virus, and this requires endosomal recognition of influenza genomic RNA and signaling by means of TLR7 *(57)*. Murine CD8α^+ DCs, which are the principal cross-presenting APCs *in vivo*, are activated by double-stranded RNA present in virally infected cells. DC activation requires phagocytosis of infected material, followed by signaling through the double-stranded RNA receptor TLR-3 *(58)*. Thus, TLR-3 is crucial for cross-priming of CTL against viruses that do not directly infect DCs. Another important class of receptors is the C-type lectin receptor family, which is involved in the recognition and uptake of glycan structures. The β-glucan receptor Dectin-1 is a yeast binding C-type lectin, which has been shown to synergize with TLR-2 to induce TNF-α and IL-12. A second pathway involving Syk has been identified that induces IL-2 and IL-10 and seems to take place in DCs, but not in macrophages. DEC-205 is a DC-specific lectin receptor in mice and humans but its natural ligands have yet to be characterized. Studies using anti-DEC-205 antibodies have demonstrated its efficacy to mediate adsorptive uptake and presentation by DCs *in vivo (59)*. This was determined by selective *in vivo* targeting of antigens to DEC-205 using the corresponding monoclonal antibody. The SIGN (specific ICAM-3-grabbing nonintegrin) family consists of three members (DC-SIGN, L-SIGN, LSECtin) in human and five homologues (mDC-SIGN and mSIGNR1-to-4) in mice. DC-SIGN is specifically expressed by DCs.

Notably, DC-SIGN recognizes and internalizes a number of viruses (e.g, HIV-1, Dengue virus, HCMV, Ebola), bacteria, and protozoa. Pathogen interactions with DC-SIGN result in infection of DCs in the case of Dengue virus *(60)* and transmission—in the absence of infection from DCs—to permissive cells in the case of HIV (61). It is thought that, after capture of HIV-1 by DC-SIGN or other receptors, DCs migrate to lymphoid organs and present HIV-1 (which survives in the nonlysosomal compartment) to T cells leading to transinfection. The mannose receptor binds a range of bacteria, yeasts and viruses through interactions between a mannose-type carbohydrate recognition domain and pathogen-associated high mannose structures. The significance of the mannose receptor contribution in microbial uptake *in vivo* is still unclear. Lee et al. *(62)* used mannose receptor–deficient mice to examine the role of this receptor in immune response during disseminated candidiasis and found that mannose receptor was not required for host defense or for the phagocytosis of Candida albicans.

Interestingly, Yarovinsky et al. (63) have recently shown that TLR recognition may affect the antigen presentation *in vivo* and regulate immunodominance in an antimicrobial CD4[+] T cell response. They showed that the immunogenicity of profilin, a TLR11 ligand present in the parasite, was entirely dependent on both TLR11 recognition and signaling through the adaptor MyD88 at the level of the DC.

Antigen Processing

Class II MHC–restricted Presentation

Stimulation of naïve T and B lymphocytes is likely to occur in primary lymphoid organs, which are organized to favor cellular interactions. Because DCs are posted as sentinels in peripheral organs, an initial step of the immune response most probably requires the migration of DCs to the zone where lymphocytes reside. Of importance is that DCs have the unique capability to present antigens encountered earlier in periphery after they have migrated to lymphoid organs (Figure 15.4). This property, a form of "antigenic memory," results from (a) a shift in class II MHC half-life in mature versus immature DCs, (b) the sequestration of class II MHC/peptide combinations intracellularly in immature DCs, and (c) a blockade of the peptide-loading step in immature DCs. A discussion of each follows.

A Shift in Class II Half-life in Mature versus Immature Dendritic Cells

Class II MHC molecules of immature DCs are expressed at low levels at the plasma membrane but are abundant in endocytic compartments. In contrast, mature DCs express high levels of class II MHC loaded with peptides at the surface. The mechanism that controls class II MHC expression in DCs has remained elusive until recently. Two models

were proposed that involved the modulation of cathepsin S activity or the rate of endocytosis. According to the first model, cathepsin S activity is inhibited by the presence of protease inhibitor cystatin C in the class II MHC compartments of immature DCs, thereby preventing the full degradation of the invariant chain. The complexes formed by the class II MHC and partly degraded invariant chain would be transported to lysosomes and degraded. In mature DCs, cystatin C would be down-regulated, thereby enabling cathepsin S to fully degrade the invariant chain and class II MHC to bind antigenic peptides and shuttle to the cell surface *(64)*. However, the similar regulation of class II MHC expression for cathepsin S–independent class II MHC allotypes and in cathepsin S–deficient mice *(65)* argues against this hypothesis. The second model suggests that class II MHC expression is regulated in murine *(65)* and human *(66)* DCs by controlling the rate of endocytosis and subsequent degradation of peptide-loaded class II MHCs. In immature DCs, class II MHC molecules are rapidly internalized and recycled, turning over with a half-life of about 10 hours, whereas in mature DCs, there is a rapid and transient boost of class II MHC synthesis, and the half-life of class II MHC molecules increases over 100 hours. Indeed, in immature DCs, biotinylated Fab fragments of an anti-DR antibody bound to surface class II molecules are rapidly internalized and recycled back to the cell surface, whereas the pool of recycling class II molecules progressively disappears after maturation *(66)*. Thus, delivery of class II MHC/peptide combinations to the cell surface would proceed similarly in immature and mature DCs, but immature DCs would reendocytose and degrade the complexes much faster than the mature DCs. A recent report by Mellman et al. strongly supports the second model (67). They show that MHC II β-chain cytoplasmic tail is ubiquitinated in mouse immature DCs. The ubiquitination has an important role in endocytosis and enhances the rate of MHC II degradation in lysosomes, thus decreasing its accumulation at equilibrium. Notably, ubiquitination of MHC II ceases upon maturation, resulting in the accumulation of MHC II at the cell surface.

The Sequestration of Class II/Peptide Combinations Intracellularly in Immature Dendritic Cells

There is evidence that immature DCs exhibit a phenotype in which most class II MHC molecules are intracellular and localized to lysosomes. Upon maturation, these cells progressively differentiate into cells in which intracellular class II MHC molecules are found in peripheral nonlysosomal vesicles and then into mature DCs that express almost all of their class II MHC molecules on the plasma membrane *(68,69)*. Of note, although early DCs do not present antigen immediately after uptake, they efficiently present previously internalized antigen after maturation. By delaying antigen presentation, DCs retain the memory of antigens encountered in the periphery.
FIGURE 15.4 Antigen handling and class II MHC expression in immature and mature DCs. The maturation of DCs is associated with a redistribution of class II MHC molecules from intracellular compartments to the plasma membrane. In immature DCs (left), class II MHC molecules are associated mainly with invariant chain and are sequestered intracellularly in lysosomes. Indeed, the activity of cathepsin S (which has a major role in the cleavage of the class II MHC–associated invariant chain) remains low, thereby slowing the processing of the invariant chain, which contains a lysosomal targeting signal in its cytoplasmic domain. Although the majority of new class II MHC molecules are targeted directly to endosomes and lysosomes upon exit from the trans-Golgi network, some class II MHC molecules also seem to reach lysosomes after endocytosis from the plasma membrane. Maturation (right) has been shown to enhance the peptide loading of class II MHC molecules that have accumulated in lysosomes before maturation. The peptide/MHC combinations are then transported to the class II MHC vesicles and reach the cell surface as small clusters, partly associated with CD86 (not shown). In addition, the activity of cathepsin S is enhanced, allowing a greater fraction of new class II MHC molecules to avoid lysosomes and reach the cell surface after antigen loading in endosomes. Redrawn from Mellman and Steinman *(319)*, with permission.

Blockade of the Peptide-loading Step in Immature Dendritic Cells

There is evidence that DCs also regulate the intracellular formation of immunogenic class II MCH/peptide combinations. Indeed, although a protein antigen has been shown to colocalize with class II MHC products in late endosomes and lysosomes, class II MHCs do not form unless the DCs are exposed to maturation agents. These observations suggest an arrest to antigen presentation at the peptide-loading step at the immature stage *(70,71)*.

Of importance is that the down-regulation of antigen processing may help avoid induction of autoimmune reactions. Indeed, by turning off endocytosis, a mature DC arriving in the lymph node with pathogenic peptides would be unable to pick up self-antigens and would present only epitopes generated at sites of infection. Of note, adjacent DCs in the T cell area in the steady state may present self-antigens and contribute to peripheral tolerance (see later discussion).

Dudziak et al. recently reported (9) that DC subsets differentially processed antigen *in vivo*. To examine antigen processing and presentation, they specifically targeted antigens to the CD8α^+DEC205$^+$ or to the CD8α^-33D1$^+$ subset using chimeric monoclonal antibodies. They found that CD8α^+DEC205$^+$ were biased for MHC I presentation, whereas CD8α^-33D1$^+$ were biased for MHC II

presentation, and that these subsets were enriched in components of the MHC I and MHC II processing pathways, respectively.

Class I Major Histocompatibility Complex–restricted Presentation

In most cells, class I MHC molecules associate exclusively with peptides derived from endogenous cytosolic proteins, such as virus-encoded proteins or tumor antigens. In contrast, peptides derived from internalized exogenous antigens associate not with class I MHC molecules but, instead, with class II MHC molecules. The class I MHC–restricted presentation of endogenous but not exogenous antigens should prevent cytotoxic T cell (CTL) lysis of noninfected neighboring cells that have phagocytosed infected cells.

The class I MHC–restricted presentation of antigens in DCs is similar to that seen in other cells, except for three features:

1. There is a marked increase in class I MHC synthesis during maturation, and half-life is increased *(72)*.
2. Several proteasome subunits characteristic of the immunoproteasome are induced during maturation (73).
3. DCs appear very efficient in presenting exogenous cell–associated antigens in the context of class I MHC molecules, a processed referred to as *cross-presentation*. Albert et al. (74) demonstrated that human DCs have the capability to efficiently present antigens derived from apoptotic, influenza-infected cells and to stimulate class I MHC–restricted CD8[+] cytotoxic T lymphocytes. Regnault et al. *(75)* showed that Fcγ receptors induce the maturation of DCs and mediate efficient internalization of immune complexes. This process requires proteasomal degradation and is dependent on functional peptide transporters associated with antigen processing (TAP) 1 and 2. Glycoprotein 96–associated antigens can be cross-presented on class I MHC by DCs *(76)* as well as foreign proteins expressed by bacteria *(72)*. There is evidence that internalized antigens may access the cytosol for processing by the proteasome and loading in the endoplasmic reticulum (ER).

Crosspresentation requires antigen transit through endosomes or phagosomes and eventually partial proteolysis. The antigen is then transported to the cytosol, degraded by the proteosome, and the resulting peptides translocated into ER or ER-phagosome compartments and loaded on MHC class I molecules. Three unique features have been described: (1) DCs have developed a unique membrane transport pathway for the export of exogenous antigens from endocytic compartments to the cytosol. Endosome-to-cytosol transport is restricted to DCs and allows internalized antigens to gain access to the cytosolic antigen-processing machinery and to the conventional class I MHC antigen-presentation pathway (77). (2) A mix ER-phagosome compartment brings together all the MHC class I processing and loading machinery as well as exogenous antigens in a single subcellular organelle. Of note, this unique phagosome/ER compartment may limit the competition with endogenous antigens. (3) Amigorena et al. have recently described a specialization of the phagocytic pathway of DCs that ensures a fine control of antigen processing. They have shown that the phagosomes of DCs maintain a neutral, even slightly alkaline, pH in contrast to macrophage phagosomes, which become acidified rapidly (78). The alkalinization of the phagosomal lumen is maintained by the recruitment of the NADPH oxidase NOX2, which mediates the sustained production of low levels of reactive oxygen species. DCs lacking NOX2 show impaired cross-presentation, revealing that NOX2 is involved in the control of adaptive immunity in addition to its role in microbe killing in innate immune responses.

Of importance is that the cross-presentation can lead to the generation of cytotoxic responses to viruses that do not infect DCs themselves. This pathway may also account for the *in vivo* phenomenon of cross-priming, whereby antigens derived from tumor cells or transplants are presented by host APCs. Cross-priming of antigen via DCs would allow nonreplicating vaccines to prime for CD8[+] T cell immunity. It has been shown that DCs are able to cross-present HIV gag proteins across a spectrum of MHC haplotypes *(79)*.

A potentially critical role of cross-presentation could be to allow DCs in the steady state to present self-antigens on class I MHC and thereby to induce tolerance (see later discussion). This process would be essential to prevent the induction of autoimmunity when DCs capture dying infected cells *(80)*.

Migratory Properties

The trafficking events that bring together T cells, B lymphocytes, and DCs involve chemokines, which are small basic proteins that engage seven transmembrane receptors on responsive cells and promote chemotaxis *(81)*.

Chemokines and their receptors regulate the movement and interaction of APCs such as DCs and T cells. CC chemokine receptor (CCR) 2 has been shown to be required for Langerhans cell migration to the lymph nodes and is also an important determinant of splenic DC migration, especially in the localization of CD8α^+ cells (see later discussion) *(82)*. Two other chemokines have been suggested to serve a homing function in the T cell compartment: the secondary lymphoid tissue chemokine (SLC)/6Ckine and the Epstein-Barr virus–induced molecule 1 ligand chemokine (ELC)/macrophage inflammatory protein (MIP)-3β. SLC and ELC are structurally related chemokines, and both bind the receptor CCR7. Immature DCs express CCR6 and respond to MIP-3α, whereas maturing DCs down-regulate expression of

CCR6, up-regulate expression of CCR7, and chemotactically respond to ELC/MIP-3β (83). SLC appears to be needed for efficient passage of DCs from lymphatic vessels into the T cell zone of lymph nodes *(84)*. Interaction of CXCR4 on DCs with stromal cell factor might also contribute to the localization of DCs into the T cell area.

The tight regulation of chemokine receptors allows DCs to be recruited to inflammatory sites and to leave these sites after antigen capture to reach secondary lymphoid organs. Mature DCs have been shown to produce ELC/MIP-3β, an observation that correlates with their unique capacity to organize the structure of T cell areas within the lymph nodes by attracting antigen-carrying DCs as well as naïve T cells *(85)*.

The DC migration to the draining lymph node has a strong impact on T cell priming. Indeed, Martin-Fontecha et al. (86) have reported that the magnitude and quality of CD4$^+$ T cell response was proportional to the number of antigen-carrying DCs that reach the lymph nodes. Lack of CCR7 prevented the migration of DCs, whereas preinjection of inflammatory cytokines, which increased the expression of the CCR7 ligand CCL21 in lymphatic endothelial cells, strongly increased DC migration. These results delineate an additional level at which inflammation acts to increase T cell responses: Inflammatory stimuli promote recruitment of immature DCs into tissues, initiate the DC maturation process, and boost recruitment of mature DCs into lymphatics.

Migration In Situ

The capability of DCs to transport antigen has been illustrated in several models *in situ.* Larsen et al. (87) showed that, when mouse skin is transplanted, the DCs enlarge, express higher levels of class II MHC, and begin to migrate. Xia et al. *(88)* showed that primary sensitization of naïve T cells after an airway challenge occurs predominantly within local lymph nodes and not in the lung- or bronchial-associated lymphoid tissues and that antigen presentation by DCs shifts from lung to lymph node during the response to inhaled antigen. Antigen transport from the airway mucosa to the thoracic lymph nodes was studied by intratracheal instillation of fluorescein isothiocyanate (FITC)–conjugated macromolecules (ovalbumin). After instillation, FITC$^+$ cells with stellate structure were found in the T cell area of thoracic lymph nodes. The FITC signal was detected only in migratory airway-derived lymph node DCs, which display a mature phenotype and present ovalbumin to TCR transgenic T cells specific for an ovalbumin peptide (89). In the intestine, Huang et al. (90) identified a DC subset that constitutively endocytoses and transports apoptotic epithelial cells to T cell areas of mesenteric lymph nodes *in vivo.*

The importance of DC recruitment in the induction or maintenance of immune responses has been recently demonstrated: Lauterbach et al. *(91)* have reported that adoptive immunotherapy of exogenously derived pathogen-specific memory T cells to mice burdened with a persistent lymphocytic choriomeningitis virus (LCMV) infection resulted in eradication of the pathogen from all tissues, including the central nervous system. As a consequence of immunotherapy, a substantial number of DCs were recruited in the brain parenchyma and were required for TNF-α production and successful viral clearance. These results underline the dependence of memory T cells on DCs and the importance of DC migration for successful immunotherapeutic clearance.

Whether plasmacytoid DCs, like classical DCs, migrate from peripheral mucosal tissues via afferent lymph is still unclear. To determine whether plasmacytoid DCs migrate in lymph, Yrlid et al. removed intestine- or liver-draining lymph nodes and collected thoracic leukocytes in rats *(92)*. They found that intestinal and hepatic lymph were devoid of plasmacytoid DCs under both steady-state conditions and after TLR7/8 stimulation. These observations suggest that the antigen-presenting capacity of plasmacytoid DCs may not result from peripheral antigen capture followed by migration to the lymph nodes. How these cells in lymph nodes do acquire peripheral antigens remains an open question. Another report suggests, however, that plasmacytoid DCs migrate from the lung to the draining lymph nodes under steady-state conditions, as inhaled antigens were found to be associated with this subset in the lungs and the draining lymph nodes *(93)*.

Cytokine Release

Interleukin-12

In 1995, Macatonia et al. (94) demonstrated that murine splenic DCs produce IL-12 and direct the development of Th1 cells *in vitro.* Similar observations were reported by Koch et al. *(95)*, who further showed that ligation of either CD40 or class II MHC molecules independently triggered IL-12 production in splenic DCs and that IL-12 production was down-regulated by IL-4 and IL-10. Biedermann et al. *(96)* found, however, that IL-4, when present during the initial activation of bone marrow–derived DCs, could instruct these cells to produce bioactive IL-12.

Although previous *in vitro* studies had suggested that the macrophage was a major source of the IL-12 produced on microbial stimulation, DCs but not macrophages were shown to be the initial cells to synthesize IL-12 in the spleens of mice exposed *in vivo* to an extract of *Toxoplasma gondii* or to LPS (44). The major producers of IL-12 are CD8α^+ DCs in response to bacterial or intracellular parasite infection (44,97), whereas plasmacytoid DCs can produce IL-12 in response to various viruses, to CpG oligodeoxynucleotides, and *in vivo* to mouse cytomegalovirus (MCMV) *(32)*. Iwasaki and Kelsall *(7,8)*

demonstrated that CD11b⁻CD8α⁺ Peyer's patch DCs but not CD11b⁺CD8α⁻ or double-negative subset produce IL-12 p70 on stimulation *in vitro*.

Although the CD8α⁺ DC subset seems to have the greatest capacity for IL-12 production, different stimuli can change the balance. *Escherichia coli* LPS induces IL-12 p70 in the CD8α⁺ DC subset, presumably through TLR4, whereas *Porphyromonas gingivalis* LPS does not. Both LPSs activate the two DC subsets to up-regulate costimulatory molecules and produce IL-6 and TNF-α *(98)*. Of note, all splenic populations respond with increased IL-12 p70 production *in vitro* when IL-4 is present during stimulation, whereas only CD8α⁺ DCs produce IL-12 in the absence of IL-4 *(99)* (for review, see Maldonado-López and Moser *[100]*). Both subsets have the capacity to produce IL-12 after *in vivo* priming with *Toxoplasma* extracts *(97)*. CD8α⁻ DCs from IL-10–deficient animals have an increased capacity to produce IL-12, in comparison with DCs from wild-type animals, which suggests that IL-12 release is tightly controlled in this subset *(101)*.

In humans, Langerhans cells, particularly after maturation, have been shown to release functional IL-12 heterodimer *in vitro (102)*. Rissoan et al. (103) reported that CD40L activation up-regulates the expression of mRNA for IL-12 p40 in human monocyte–derived but not plasmacytoid-derived DCs *in vitro*.

IL-12 exerts a powerful positive regulatory influence on the development of Th1 helper T cell immune responses and is a potent inducer of IFN-γ production and cytotoxic differentiation and function, which suggests that DCs could dictate the class selection of the subsequent adaptive response (see later discussion).

The release of heterodimeric IL-12 p70, which is potentially harmful, appears tightly regulated *in vivo*. The production of IL-12 has been shown to depend on two signals: initial APC activation by a microbial stimulus and an amplifying signal through DC–T interaction *(104)*. Numerous negative regulatory mechanisms have been described *(105)*: IL-10 has been shown to down-regulate the production of IL-12 by murine splenic DCs *(101)*; IL-12 production by DCs is rapid and intense but relatively short-lived *(97,106)*. This paralysis of DC IL-12 production is likely to prevent infection-induced immunopathology *(97)*. In addition, IL-12 inhibition can be achieved by the engagement of G-protein–coupled receptors, by a mechanism mediated by activation of the phosphatidylinositol 3-kinase-protein 3 kinase B/Akt pathway and JNK *(105,107)*.

IL-12 is a disulfide-like 70-kD heterodimer composed of 35-kD (p35) and 40-kD (p40) subunits, each of which is encoded by a distinct gene. Although the regulation of IL-12 expression may be largely focused on p40 in other cell types, one report demonstrated that the regulation of IL-12 p70 expression at the transcriptional level by Rel/NFκB is controlled through both the p35 and p40 genes in CD8α⁺ DCs *(108)*.

IL-23

In 2000, it was discovered that p40 can also dimerize with p19 to form IL-23. Like IL-12, IL-23 is primarily secreted by activated DCs, monocytes and macrophages, and transgenic mice constitutively overexpressing IL-23p19 develop fatal multiorgan inflammation *(109)*.

IL-23 was first thought to activate adaptive Th17 cells only. However, Kullberg et al. provided evidence that IL-23 induce both Th1 and Th17 cells (110). Using two models of Helicobacter hepaticus-triggered T cell–dependent colitis, they showed that IL-23, and not IL-12, was essential for the development of maximal intestinal disease. Their results support a model in which both Th1 and Th17 may be overactivated by IL-23 and synergize to trigger severe intestinal inflammation. Another study showed that depletion of IL-23 was associated with decreased proinflammatory responses in the intestine but had little impact on systemic T cell inflammatory responses (111). In a CD40-induced colitis, a strong increase in IL-12 and mainly IL-23 expression was found in both DCs and monocytes/macrophages, with the highest amount of IL-23 p19 found among colonic DCs *(112)*.

Interferon-α

In the mouse, a population of plasmacytoid cells has been shown to produce IFN-α when cultured with inactivated influenza virus. These cells were detected in low numbers in the spleen, bone marrow, thymus, lymph nodes, blood, lungs, and liver. *In vivo* activated CD8α⁺Ly6G/C⁺CD11b⁻ DCs appear to be the major producers of IFN-α/β during MCMV but not LCMV infection, and they probably derive from plasmacytoid CD11c⁺CD8α⁻Ly6G/C⁺CD11b⁻ immature APCs *(32,113)*. Interestingly, IFN-α/β appear to regulate DC cytokine production by enhancing their own expression while inhibiting IL-12 synthesis during MCMV infection *(113)*. Another report demonstrates that among the splenic DCs, only the CD4⁻CD8⁺ DCs produced IFN-α in culture when stimulated by a combination of CpG and polyinosine:polycytidylic acid poly(I:C) *(99)*. The relationship between both IFN-α–producing populations requires further study, especially because a proportion of plasmacytoid APCs has been shown to express CD8α *(32)*. In humans, plasmacytoid-derived DCs release IFN-α during viral infection or inflammation *(31,114)*.

Interleukin-2

The analysis of genes that are differentially expressed upon maturation induced by exposure to gram-negative bacteria revealed that IL-2 mRNA was transiently up-regulated at early time points (4 to 6 hours) after bacterial encounter (115). The same authors showed that DC-derived IL-2 mediates T cell activation, inasmuch as the ability of IL-2⁻/⁻

DCs to induce proliferation of allogeneic CD4$^+$ and CD8$^+$ T cells was severely impaired. Of note, DC-derived IL-2 and type I interferons have been shown to promote the IFN-γ production and cytotoxic function of NK cells *(116)*.

In addition, DCs have been shown to produce IL-6 *(117)*, IL-10, and IFN-γ *(118,119)*. Mature DCs, predominantly of CD8α phenotype, appear to constitutively produce small amounts of IL-12, which induces the secretion of IFN-γ, leading to up-regulation of IL-12 production. Liver-derived DC progenitors *(120)* and freshly isolated Peyer's patch DCs *(7)* have the capacity to produce IL-10.

EXPRESSION AND FUNCTION OF ACCESSORY MOLECULES

There are many molecules that are constitutively or potentially expressed in almost all T cells and whose deficiencies or expression anomalies affect the balance between effector and regulatory function. The critical positive costimulatory molecules are the immunoglobulin (Ig) superfamily molecules CD28 and ICOS (inducible costimulator), which bind the B7 family ligands B7-1/B7-2 and B7h, respectively. The negative costimulatory receptors include cytotoxic T lymphocyte antigen (CTLA)-4, which also binds to B7-1 and B7-2; programmed death (PD)-1, which binds PD-1 ligand (PD-L1 or B7-H1) and PD-L2 (also known as B7-DC); and B and T lymphocyte attenuator, which binds herpes virus entry mediator. Other B7 family ligands have been identified (B7-H3 and B7-H4), but their receptors on T cells are not yet known. More recently, members of the

TNF-R family have been shown to display costimulatory fucntion.

The B7:CD28 Superfamily

The expression of B7-1 (CD80) and B7-2 (CD86) is restricted to professional APCs, suggesting that these molecules are mainly involved in initial priming in lymph nodes. By contrast, other B7 family members are widely expressed in many different tissues by both hematopoietic and nonhematopoietic cells. For example, PD-L1 is expressed in the placenta during gestation and is involved in fetomaternal tolerance.

The members of the CD28 family (including ICOS, CTLA-4, BTLA, PD-1) have a single extracellular Ig variablelike domain followed by a short cytoplasmic tail (Figure 15.5). The cytoplasmic domains of CD28, ICOS, and CTLA-4 have a common Tyr-Xaa-Met motif that binds to the SH2 domain of the p85 subunit of phosphatidylinositol 3-kinase.

Common to all three coreceptors is the recruitment of PI3K and the downstream regulation of proteins with pleckstrin-homology domains, such as PDK1 and PKB, that leads to the regulation of events as diverse as cytokine production, cell death and cellular metabolism (for review, see [121]).

CD28

CD28 is a type I transmembrane glycoprotein expressed constitutively on all murine T cells, all human CD4 T cells, and 50% of CD8 T cells. Ligation of CD3 and CD28
FIGURE 15.5 Molecules involved in the T cell/DC synapse. The interaction between DCs and T lymphocytes involves several ligand/receptor pairs that include MHC, adhesion, and costimulatory molecules.

promotes increases in glucose metabolism, high levels of cytokine/chemokine expression, resistance to apoptosis, and long-term expansion of T cells.

Upon interaction with its ligand, CD28 becomes phosphorylated on tyrosines. One tyrosine (Y170 in mouse CD28, Y173 in human CD28) permits CD28 to recruit SH2-containing signaling molecules, including phosphoinositide 3 kinase, Grb2, and Gads. Okkenhaug et al. (122) built a CD28 mutant that uncouples these SH2-mediated interactions from CD28. This mutant was unable to upregulate expression of the prosurvival protein Bcl-xL, but still promoted T cell proliferation, IL-2 secretion, and prevented the induction of anergy. Another report confirms that the ability of CD28 to regulate proliferation and induction of Bcl-X(L) maps to distinct motifs: Indeed, mutation of C-terminal proline residues abrogated the proliferative and cytokine regulatory features of CD28 costimulation, while preserving Bcl-X(L) induction. Conversely, mutation of residues important in phosphatidylinositol 3-kinase activation partially inhibited proliferation but prevented induction of Bcl-X(L) *(123)*.

The signals generated from CD28 ligation seem to modify the gene regulation induced by TCR stimulation rather than turning on the expression of a separate subset of genes. Indeed, Diehn et al. *(124)* have shown that the principal effect of simultaneous engagement of CD28 was to increase the amplitude of the CD3 transcriptional response. They showed that CD28 signaling promotes phosphorylation, and thus inactivation, of the NFAT nuclear export kinase glycogen synthase kinase-3 (GSK3), leading to decreased nuclear export of NFAT. This decreased nuclear export and the increased nuclear import induced by increased calcium flux *(125)* lead to increased NFAT activation and transcription of genes such as IL-2. These observations suggest a critical role of NFAT in the integration of the TCR and CD28 signals. In addition, CD28 has been shown to favor accumulation and activation of signaling components, and amplify PLCγ1 activation and Ca^{2+} responses *(125)*.

Finally, CD28 costimulation enhances the downregulation of transcripts of suppressor genes, such as genes coding for factors whose role is to keep T cells in G$_0$. A strong support for a quantitative view of costimulatory signaling comes from microarray analysis showing that TCR-induced expression of several thousands of genes in primary T cells is amplified or suppressed, but that no new gene is induced by CD28 coligation (126).

It is interesting to note that an antigen-loaded APC may present low numbers of potential TCR ligands (a few hundred?) and much higher density of ligands with which CD28 interacts, suggesting that CD28 may also stabilize APC/T cell contact and favor TCR/MHC peptide engagement. Of note, the CD86 costimulatory molecule is not only abundant on DCs but also associates with antigen-presenting MHC products in stable patches on the DC surface. The polyvalent configuration may facilitate the activation of quiescent T cells *(69)*.

Further, Viola et al. (127) proposed that CD28 may induce a reorganization of the signaling machinery. They stimulated human resting T cells with surrogate APCs, consisting of beads coated with antibody to CD3 in the presence or absence of CD28. They tested whether CD28 engagement affected the distribution of rafts, which concentrate various molecules involved in signal transduction such as Lck, LAT, Ras. Using a fluorescent marker that binds the GM1 glycosphingolipids, they showed that rafts segregated in the zone of contact only when CD3 and CD28 were simultaneously engaged. In unstimulated T lymphocytes, the surface distribution of GM1 was homogeneous, and this pattern did not change when the cells were stimulated with anti-CD3–coated beads.

CTLA-4

CTLA-4 (CD152) was discovered by screening for genes differentially expressed in cytotoxic T lymphocytes. CTLA-4 expression is merely detectable on resting T cells and undergoes complex intracellular trafficking mediated by its binding to the clathrin-adaptor molecules AP-1 and AP-2. Upon T cell activation, CTLA-4 traffics to the sites of TCR engagement *(128)* and is rapidly upregulated on CD4$^+$ and CD8$^+$ T cells.

A crucial Met-Tyr-Pro-Pro-Pro-Tyr loop in the CD28 and CTLA-4 Ig-like domain provides a structural specificity for the interaction with CD80 and CD86, but the increased strength of this binding by CTLA4 is mediated by nonconserved residues in the CDR1- and CDR3-analogous regions *(129)*. CD28 has been shown to interact with a single binding domain, whereas each CTLA-4 dimer binds two independent bivalent B7 molecules in the formation of a zipperlike matrix *(130)*. This observation suggests that B7-1 interactions with CTLA-4 may be markedly favored over interactions with CD28.

While there is a general agreement that CTLA-4 is a potent inhibitor of T cell activation, the mechanism by which this inhibition is achieved remains unclear. CTLA-4 may out-compete with CD28 for their shared ligands, inhibit proximal signal transduction by interacting directly with TCR complex proteins, or transduce a negative signal to T cells. CTLA-4 has been shown to inhibit signal transduction by recruiting the tyrosine phosphatase SHP-2 to the TCR, resulting in dephosphorylation of the ζ chain of the complex and components of the RAS signaling pathway *(131)*. There is evidence *(126)* that CTLA-4 engagement selectively blocks augmentation of gene regulations by CD28-mediated costimulation and does not ablate gene regulation induced by TCR triggering alone.

Chikuma et al. have shown that, after T cell activation, CTLA-4 is induced and translocates from the intracellular vesicles to the immunological synapse where it associates with TCR ζ in the lipid rafts attenuating T cell signaling

(132). Two phosphatases, SHP-1 and SHP-2, have been suggested to mediate CTLA-4-mediated inhibition either directly by dephosphorylating TCRζ or indirectly through dephosphorylation of the regulatory tyrosine of ZAP-70. A recent study has shown that CTLA-4 signaling may also inhibit Akt directly by activation of the type II serine/threonine phosphatase (PP2A) (133).

CTLA-4 not only regulates TCR and CD28 signals in T cells but also delivers signals via B7 into APC. Grohmann et al. have shown that B7 can transmit suppressive signals into DCs, following engagement of CTLA-4: engagement of B7-1/B7-2 on murine DCs by CTLA-4Ig activates a signaling pathway that stimulates DCs to produce IFN-γ, which in turn induces indoleamine 2, 3-dioxygenase (IDO). CTLA-4 on mouse CD4$^+$CD25$^+$ Treg can mediate the same IDO-inducing effect *in vitro* (*134–136*,137) in DCs by interacting with their CD80/CD86.

Although most of the evidence establishes that CTLA-4 is a key negative regulator of T cell responses, it may also act as a positive regulator of T cell activation. Linsley et al. (*138*) have shown that CTLA-4 and CD28 could act synergistically to enhance T cell proliferation. Ligation of CTLA-4 with mutant B7-1 that had lost its ability to bind CD28 also resulted in T cell clonal expansion.

CD4$^+$CD25$^+$ natural Tregs in the thymus and the periphery constitutively express CTLA-4 (*139,140*). There is evidence that CTLA-4 may actively contribute to Treg suppression, although the presence of functional Tregs in CTLA-4–deficient mice suggest that CTLA-4 may be dispensable in some conditions.

PD-1

PD-1 (CD279) was isolated as a gene upregulated in a T cell hybridoma undergoing apoptotic cell death and was thus named *programmed death 1*. PD-1 has an extracellular domain with a single Ig domain and a cytoplasmic domain with two tyrosines, one that constitutes an immunoreceptor tyrosine-based inhibitory motif. The broad expression of PD-1 contrasts with the T cell–restricted expression of CD28 and CTLA-4. Indeed, PD-1 is inducibly expressed on CD4 and CD8 T cells, NKT cells, B cells, and monocytes upon activation. PD-1 transduces a signal only when engaged in combination with TCR ligation.

PD-L1 expression can be induced by IFN-γ (its promoter region contains several IFN-γ–responsive elements) in several tissues including tumor cells where it can facilitate tumor evasion (*141*). Keir et al. have recently reported a greater increase in IL-2 and IFN-γ production in doubly deficient mice (lacking PD-L1 and PD-L2), suggesting that PD-L1 and L2 synergistically inhibit T cell activation. Double-deficient NOD mice develop early and fulgurant diabetes, with 100% penetrance in males and females (142). Of note, PD-L1 is the main factor preventing autoimmune attack at the islet level, and PD-L1 expressed by parenchyma cells seems to play a more important role in preventing diabetes than PD-L1 expressed by APCs. B7-H4 is expressed in multiple nonlymploid tissues and in human breast and ovarian cancers. Krycez et al. report (*143*) the intracellular expression of B7-H4 in ovarian tumor cells and the cell surface expression on macrophages isolated from the tumor. B7-H4 is the critical immunosuppressive molecule expressed by macrophages as blocking B7-H4, but not arginase-inducible nitric oxide synthase, or B7-H1 restored the T cell stimulatory capacity of the macrophages and contributed to tumor regression *in vivo*. This finding adds a new level of regulation of tumor-specific immunity by macrophages that have been shown to promote angiogenesis and secrete matrix metalloproteinases and epidermal growth factor that promote the escape of the tumor cells. Iwai et al. showed that liver nonparenchymal cells and Kuppfer cells constitutively expressed PD-L1 and that the blockade of the PD-1 pathway could augment antiviral immunity (*144*). Recent studies have shown that PD-1 is highly expressed by CD8 T cells during chronic LCMV infection and that *in vivo* PD-1-PD-L blockade may reverse CD8 exhaustion and reduce tumor load (*145*). Three recent studies show that PD-1 expression is elevated on HIV-specific CD8 T cells and that blocking this pathway leads to increased T cell proliferation and effector functions, including cytokine production and cytolysis (*146–148*).

Parry et al. (133) have shown that PD-1 and CTLA-4 blocked CD3/CD28–mediated up-regulation of glucose metabolism and Akt activity, using distinct mechanisms. PD-1 signaling inhibits Akt phosphorylation by preventing CD28-mediated activation of phosphatidylinositol 3-kinase (PI3K), whereas CTLA-4 preserves the activity of PI3K. These observations suggest that CTLA-4 and PD-1 may control T cell activation through additive or synergistic mechanisms.

ICOS

The CD28 homolog ICOS is upregulated on T cells after activation. Like CD28 and CTLA-4, ICOS is a glycosylated disulfide-linked homodimer. The ICOS cytoplasmic tail contains a YMFM motif that binds to the p85 subunit of PI3K, similar to the YMNM motif of CD28. Riley et al. (126) compared gene expression triggered by CD28 and ICOS costimulation. They showed that gene regulations induced by ICOS and CD28 costimulation were very similar, although a few genes (IL-2, ICOS, IL-9, . . .) were more regulated by CD28 than ICOS stimulation.

While CD28 costimulation is crucial for priming the immune response, ICOS seems more important for maintaining a T cell response and for the effector function. ICOS does not stimulate T cell expansion. The level of expression of ICOS has been shown to correlate with the type of cytokines produced, with ICOS^{high} T cells linked to IL-10 production, ICOS^{medium} T cells with IL-4, IL-5 and IL-13 (320) secretion, and ICOS^{low} with IL-2, IL-6, IFN-γ production. Studies in ICOS$^{-/-}$ and ICOSL$^{-/-}$ mice have revealed a

critical role for ICOS in T cell–dependent B cell responses: Mice lacking ICOS exhibit reduced germinal centers in response to primary immunization and defects in IgG class switching *(321)*.

ICOS has been shown to be involved in the suppressive function of regulatory T cells *in vivo*. Herman et al. have reported (149) that Tregs and T effector cells coexist within the pancreatic lesion before type 1 diabetes onset. These CD4$^+$CD25$^+$ Tregs express higher levels of IL-10 and ICOS than their lymph node counterparts. Of note, blockade of ICOS rapidly converts early insulitis into diabetes.

ICOS and ICOS-L appear to be a monogamous pair, as mice deficient for ICOS or ICOS-L display similar phenotypes. ICOS-L has been detected on the surface of B cells, macrophages, DCs, and other nonlymphoid cell types, including endothelial cells and epithelial cells.

BTLA

B and T lymphocyte attenuator (BTLA), the most recently recognized member of the CD28 family, is expressed in activated B and T cells. BTLA is preferentially expressed on CD4 Th1 cells *(150)*, while ICOS may more dedicated for Th2 and Treg cells.

BTLA contains a single IgV domain and two intracellular immunoreceptor tyrosine-based inhibitory motifs that are phosphorylated after BTLA coligation to antigen receptors, resulting in recruitment of protein tyrosine phosphatases SHP-1 and SHP-2 and inhibition of T cell activation.

BTLA, as the other CD28-like proteins, does not interact with members of the B7 family but instead interacts with the TNFR family member HVEM (herpes virus entry mediator). The interaction between BTLA and HVEM is the only receptor-ligand interaction that directly bridges the two families of receptors. There is evidence that engagement of HVEM with its endogenous ligand (LIGHT) from the TNF family induces a powerful immune response, whereas HVEM interactions with BTLA negatively regulate T cell responses *(151)*.

Tumor Necrosis Factor Receptor Superfamily

Several members of the TNF receptor family, including CD27 and its close relatives 4-1BB (CD137) and OX40 (CD134) have been shown to display the function of costimulatory receptors.

CD27

The TNF-receptor family member, CD27, acts as a costimulatory molecule to elicit T and B cell responses. Its activity is governed by the transient availability of its TNF-like ligand CD70 on lymphocytes and DCs. CD27 is found on a large proportion of NK cells and on most CD4$^+$ and CD8$^+$ T cells and is induced on B cells upon priming. CD27

determines the magnitude of primary and memory T cell responses to influenza virus. Hendriks et al. *(152)* have examined the relative contributions of CD27 and CD28 to generation of the virus-specific effector T cell pool and its establishment at the site of infection (the lung). They reported that, in contrast to CD28, CD27 does not affect cell cycle entry but rescues activated T cells from death from the onset of TCR/CD3 stimulation, throughout successive divisions. Although the antigen-specific CD8$^+$ T cell response to intranasal influenza virus is reduced in CD28$^{-/-}$ mice, significant accumulation of virus-specific CD8$^+$ T cells in the lung still occurred, which was dependent on CD27.

Of note, persistent delivery of costimulatory signals via CD27-CD70 interactions, as may occur during chronic active viral infections, has been shown to exhaust the T cell pool, leading to lethal immunodeficiency *(153)*. In particular, Matter et al. have analyzed the role of CD27 signaling in the virus control after infection with LCMV. They recently showed that, during LCMV infection, CD27 signaling on CD4$^+$ T cells enhances the secretion of interferon-γ and TNF-α. These inflammatory cytokines lead to the destruction of splenic architecture and immunodeficiency with reduced and delayed virus-specific neutralizing antibody responses. Blocking the CD27-CD70 interaction reduced immunopathology, improved antibody responses, and prevented chronic infection (154). Interestingly, CD70 is overexpressed on B cells and T cells in active HIV infection, suggesting a possible role for this costimulatory pathway in the induction of suppression.

OX40

OX40 is expressed very transiently on T cells. OX40$^{-/-}$CD8 cells become activated and expand relatively normally, but fail to sustain their numbers over time. OX40 signaling has been shown to selectively promote TNF secretion in CD4 and CD8 T cells and cytotoxicity in CD8 T cells. Recent data using human DCs activated by thymic stromal lymphopoietin (TSLP) have demonstrated a critical role of OX40/OX40L interaction in driving Th2 cell responses but only in the absence of IL-12. By contrast, OX40L has the ability to promote IL-12–mediated Th1 autoimmunity by enhancing TNF-α and IFN-γ production while inhibiting IL-10 production. These observations suggest that the development of a Th2 cell response depends on a Th2 cell-polarizing signal OX40L, as well as a default mechanim of no IL-12. Of note, only TSLP seem to stimulate DCs to provide both (155,156).

4-1BB

4-1BB is expressed on activated CD4$^+$ and CD8$^+$ T cells, activated NK cells, and DCs. Its ligand 4-1BBL is expressed on resting B cells and can be regulated on activated APCs. Agonist anti-4-1BB can lead to opposite effects: Anti-4-1BB can augment CTL generation and improve immunity

against tumors and viruses, but it can also inhibit immune responses in autoimmune models. Treatment with an agonistic monoclonal antibody to 4-1BB blocks lymphadenopathy and spontaneous autoimmune diseases in Fas-deficient mice and prolongs their survival. This treatment rapidly augments IFN-γ production and induces the depletion of autoreactive B cells and abnormal double-negative T cells, probably by increasing their apoptosis *(157)*. Similarly, lupus-prone NZB × NZW F1 mice given three injections of anti-4-1BB mAb can reverse acute disease and block chronic disease. The suppression of IgG autoantibody production may be attributed to the suppression of B cell maturation in germinal centers due to the lack of CD4+ T cell help. The authors hypothesize that the antibody acts at the T cell–DC interface during antigen priming, at a time when DC, but not yet T cells, express 4-1BB.

4-1BB and OX40 appear to be closely related in terms of their inducible expression patterns and their apparent signaling capacity (e.g, they recruit TNFR-associated factors [TRAF] and activate Pi3K-Akt-NF-kB pathways). Lee et al. compared the role of OX40 and 4-1BB in generating effector CD8 T cells to Ag delivered by adenovirus. They demonstrated that OX40 and 4-1BB physiologically operate in an opposing manner during initial priming of CD8 effector cells: OX40-deficient CD8 T cells had multiple defects in expression of effector cell surface markers, the synthesis of cytokines and in cytotoxic activity, whereas 4-1BB–deficient CD8 T cells displayed hyper-responsiveness, expanding more than wild-type cells. These results suggest that OX40 can positively regulate effector function and survival, whereas 4-1BB can initially operate in a negative manner to limit primary CD8 responses.

Collectively, these observations suggest that several TNFR family molecules, originally thought to play overlapping and potentially redundant roles, might function as a positive manner (OX40, CD27), whereas others might function positively and negatively (4-1BB, HVEM) depending on either the stage of the T cell response or the availability of multiple opposing ligands.

CD40-L (CD154)

The CD40-CD154 pathway is required for effective T and B cell responses. Activated CD4+ T cells express CD154 and bind to APCs expressing CD40. Engagement of CD40 provides critical signals for B cell expansion, Ig production, and isotype class switching. There is evidence that CD154 binding on APCs enhances B7-1 and B7-2 and the secretion of cytokines, suggesting that CD154 indirectly promotes T cell differentiation. CD40 (a 40-45 kD type I membrane protein) is expressed on B cells, activated macrophages, DCs, thymic epithelium, and endothelial cells, whereas CD154 (a 39 kD type II intramembrane protein) is expressed on activated CD4+ T cells, some CD8+ cells, eosinophils, basophils, and NK cells. CD40/CD154 interactions are critical for the development of a protective immune response against an intracellular parasite, bacterial, and viral infections. Conversely, blocking this interaction has been shown to prevent autoimmune disease and transplant rejection. A model of NKT cell–mediated DC maturation *in vivo,* using α-galactoceramide as activator, demonstrated that antigenic and costimulatory signals do not induce immunity and that a distinct CD40/CD40L signal is required to generate CD4+ T helper cells and CD8+ cytolytic T lymphocytes (36).

Adhesion Molecules

In addition to costimulatory moleules, adhesion molecules seems to play a major role in strengthening the early interaction between DC and T lymphocytes. Early studies indicated that DC and T cells tend to form clusters in an antigen-dependent manner *(2)*. Exploiting a flow cytometric adhesion assay, Figdor et al. tested the capacity of DC and monocytes to bind to fluorescent beads coated with ICAM-3-Fc. ICAM-3 was studied because of its extremely high expression on resting T cells. Whereas ICAM-3 binding by monocytes was found essentially LFA-1 mediated, binding of ICAM-3 by DC was completely LFA-1 independent. The authors found that a novel ICAM-3 binding C-type lectin, exclusively expressed by DC, mediated strong adhesion between DC to ICAM-3 on resting T cells and was essential for DC-induced T cell proliferation (61). DC-SIGN not only functions as a cell-adhesion receptor that regulates DC migration (through its interaction with ICAM-2 *[158]*) and DC–T cell interaction (via ICAM-3 binding), but is implicated in the recognition of multiple pathogens. DC-SIGN recognizes the viral envelope glycoproteins that contain a large number of N-linked carbohydrates, such as HIV-1, Ebola, Dengue, cytomegalovirus, hepatitis C, etc. In addition, nonviral pathogens interact with DC-SIGN, and in particular Mycobacterium tuberculosis, and parasites such as Leishmania amastigotes and Schistosoma mansoni.

DENDRITIC CELLS AND T CELL–MEDIATED IMMUNITY

Immunostimulatory Properties *In Vitro*

The first evidence that DCs have a potent capacity to activate T cells was provided in 1978 by Steinman and Witmer (3), who showed that these cells are at least 100 times more effective as MLR stimulators than are other splenic cells. Selective removal of DCs dramatically reduced stimulation of the primary MLR, whereas populations enriched in DCs were potent stimulators *(159)*. DCs have been shown to activate both CD4+ and CD8+ T lymphocytes in various models *(160–162)*. Although DCs have the capacity to directly sensitize CD8+ T cells, differentiation of CD8+ T cells into killer cells requires help from CD4+ T lymphocytes.

The classical model suggests that T helper and T killer cells recognize their specific antigens simultaneously on the same APC and that cytokines (e.g., IL-2) produced by the activated T helper cells facilitate the differentiation of the killer cell. The three-cell interaction seems unlikely, inasmuch as all cell types are rare and migratory. According to an alternative theory, proposed by P. Matzinger and demonstrated by three independent groups (*163*,164,*165*), the interaction could occur in two steps: The helper cell can first engage and condition the APC and in particular the DC (164), which then becomes empowered to stimulate a killer cell.

Immunostimulatory Properties *In Vivo*

DCs were further shown to be powerful stimulators of immune responses *in vivo* after adoptive transfer. Injection of epidermal Langerhans cells *(166)* or splenic DCs *(166)*, coupled to trinitrophenyl, was shown to activate effector T cells in mice, in contradiction with other coupled cells. In a model of rat kidney allograft, Lechler and Batchelor *(167)* found that injection of small numbers of donor strain DCs triggers an acute rejection response, which suggests that intrarenal DCs provide the major stimulus of a kidney allograft. The *in vivo* priming capacity of DCs has been documented in several CD4$^+$ *(117,168)* and CD8$^+$ T cell responses in rodents and in humans (see later section on tumor immunity). In addition, adoptive transfer of syngeneic DCs, pulsed extracorporeally with an antigen, induces a primary humoral response characterized by the secretion of IgG1 and IgG2a antibodies (169).

Whether the very same DCs that have captured antigen migrate to the T cell areas in lymphoid organs and directly sensitize T lymphocytes is still a matter of speculation. Direct priming by injected antigen-pulsed DCs has been suggested by studies showing that, in F1 recipient mice, parental DCs prime only T cells restricted to the MHC of the injected DCs *(168,170)*. In addition, migratory DCs (which may be apoptotic) can be processed, distributing their peptides widely and efficiently to other DCs to form MHC/peptide combinations *(30)*. Surprisingly, a protein from phagocytosed cells can be presented 1,000 to 10,000 times better than preprocessed peptide. DCs that have captured the antigen may also transfer their antigen through the release of antigen-bearing vesicles (exosomes) (171).

In favor of an indirect priming, Knight et al. *(172)* have provided evidence for a transfer of antigen between DCs in the stimulation of primary T cell proliferation. *In vivo* studies by Inaba et al. *(30)* demonstrated that short-lived migrating DCs could be processed by most of the recipient DCs in the lymph node. More recently, Allan et al. (26) have shown that after skin infection with HSV, CTL activation required CD8$^+$ DCs rather than skin-derived DCs. Their observations suggest that initial transport of antigen by migrating DCs is followed by its spreading over a wider DC pool, thereby increasing priming efficiency. Whether this inter-DC antigen transfer is a general phenomenon or is restricted to skin infection with HSV will require further investigation.

Dendritic Cells as Physiological Adjuvant

Several observations suggest that DCs play a major role in the initiation of immune responses in physiological situations *in situ*. DCs are the major cell type transporting the antigen in an immunogenic form for T cells. Rat intestinal DCs have been shown to acquire antigen administered orally, can stimulate sensitized T cells *in vitro,* and can prime popliteal lymph node CD4$^+$ T cells *in vivo* after footpad injection *(170)*. DCs but not B cells present antigenic complexes to class II MHC–restricted T cells after administration of protein in adjuvants *(173)*. Pulmonary DCs are able to present a soluble antigen shortly after it is introduced into the airways *(88)*. In spleens of mice injected with protein antigens, DCs are the main cell type that carry the protein in a form that is immunogenic for T cells *(174)*. DCs have been shown to migrate rapidly out of mouse cardiac allografts into recipients' spleen, where they home to the peripheral white pulp and associate predominantly with CD4$^+$ T lymphocytes. This movement probably represents the initiation of the graft rejection (175). The essential role of DCs in the activation of T cells *in vivo* has been demonstrated in a model of asthma. Lambrecht et al. (176) used conditional depletion of airway DCs by treatment of thymidine kinase–transgenic mice with the antiviral drug ganciclovir to deplete DCs during the second exposure to ovalbumin. The depletion of DCs before challenge with inhaled antigen results in a decrease in the number of bronchoalveolar CD4 and CD8 T lymphocytes and B lymphocytes and prevents the Th2 cytokine–associated eosinophilic airway inflammation (176).

DCs are presented as nature's adjuvant as they function to initiate immune responses *in vivo*. In line with this hypothesis, DCs are activated by endogenous signals received from cells that are stressed, virally infected, or killed necrotically *(177)*.

T Cell/Dendritic Cell Synapses

The concept of synapse proposes a central contact zone between APCs and T cells and is characterized by the large-scale segregation of cell surface molecules into concentric zones. Synapse formation has been shown to follow and depend on T cell antigen receptor signaling and may fulfill several roles: It participates in sustained TCR signaling, facilitates costimulation, polarizes the T cell secretory apparatus toward the APC, and may play a role in the late signaling. The zone contains multiple copies of molecular couples: the TCR and peptide/MHC molecules and the adhesion and costimulatory molecules (Figure 15.5).

Observations made *in vitro* have suggested that a large number of productive interactions (5,000 to 20,000) are needed for T cell activation. According to the serial triggering model, proposed by Valitutti et al. (178), the threshold could be reached by serial engagement of a limited number of MHC molecules loaded by the cognate peptide on each APC. The immunological contact appears dynamic, as, when offered another APC displaying ligands in greater quantities, T cells that have been activated by encounter with a first APC can form a new synapse within minutes *(179)*. The time of commitment of naïve CD4$^+$ cells varies from 6 hours (high antigen and costimulatory APCs) to more than 30 hours (low antigen or absence of costimulation). In contrast, primed CD4$^+$ cells respond rapidly, within 0.5 hours to 2 hours *(180)*. Some results suggest that CD8$^+$ T cells might achieve commitment more rapidly than CD4$^+$ T cells *(181)*. Indeed, naïve CTLs become committed after as little as 2 hours of exposure to APCs, and their subsequent division and differentiation can occur without the need for further antigenic stimulation, whether priming is *in vitro* or *in vivo*.

An elegant study explored the *in vivo* significance of the number of molecules engaged and the duration of engagement in transgenic mice expressing TCRs in a quantitatively and temporally controlled manner *(182)*. Very few surface TCR molecules were found to be needed for T cells to respond to immunization *in vivo* (100 or less). These results would be compatible with models in which TCR:MHC/peptide combinations form on a one-to-one basis and persist for a long time, rather than forming serial engagements. Whether *in vivo* T cell differentiation requires stimulation by a single DC or by continuously recruited DCs is still a matter of speculation.

Zell et al. *(183)* analyzed signaling events in individual CD4 T cells after antigen recognition *in vivo*. Phosphorylation of c-jun and p38 MAPK was detected within minutes in virtually all antigen-specific CD4 T cells in secondary lymphoid organs after injection of peptide antigen into the bloodstream. The rapidity of signaling correlates with the finding that about 60% to 70% of the naïve DO11.10 T cells are constantly interacting with class II$^+$ MHC CD11c$^+$ (presumably DCs) in the T cell zones of lymphoid organs. Contrary to predictions from *in vitro* experiments, the rate and magnitude of c-jun phosphorylation appears independent of CD28 signals. Collectively, these observations highlight the efficiency of T cell sensitization under physiological conditions *in vivo,* in comparison with *in vitro* models.

Dynamics of Dendritic Cell–T Cell Interaction *In Vivo*

A few reports have examined the dynamics of the contact between antigen-bearing DC and antigen-specific T. In intact explanted lymph nodes, Stoll et al. (184) have reported cell–cell contact and prolonged interactions between DC

and T cells, followed by the activation, dissociation and rapid migration of T cells away from the antigenic stimulus. A similar sequence of events was observed *in vivo* in lymph nodes where antigen-specific stable DC–T cell interactions were observed during the induction of priming of CD4$^+$ *(185,*186) and CD8$^+$ *(187–189)* T cells. Whether the duration of interaction is associated with commitment to immunity or tolerance is still unclear. Hugues et al. (190) have shown that, in tolerogenic conditions, naïve CD8 T cells remained motile and established serial brief contacts with multiple DCs, whereas Shakhar et al. have reported that tolerance and immunity were similarly characterized by an early arrest and stable CD4 T cell–DC interaction followed by restoration of mobility (186).

Adjuvants

The induction of immune response *in vivo* is typically performed with antigens administered in external adjuvants. The presence of adjuvants has been shown to increase the level of antibodies and the duration of the immune response, to modify the Th1/Th2 balance, and to induce an anamnestic response. The mechanism by which adjuvants coinitiate an immune response is still poorly understood. Their role could be to provide a signal of "danger" that is necessary to turn on the immune system and could be detected by DCs *(177)*. In favor of this hypothesis, it was shown that the adjuvant monophosphoryl lipid A provokes the migration and maturation of DCs *in vivo (191)*. LeBon et al. *(192)* demonstrated that type I interferons, the major ones of which are IFN-α and IFN-β, potently enhance humoral immunity and can promote isotype switching by stimulating DCs *in vivo*. Adjuvants such as poly(I:C) or complete Freund's adjuvant (containing heat-killed mycobacteria) may act through the induction of endogenous type I IFN production and the subsequent stimulation of DCs by type I IFN *(192)*. Although TLR were considered as key contributors of enhancing effects of vaccine adjuvants, Gavin et al. recently reported that mice deficient in the critical signaling components for TLR mounted robust antibody responses to T cell–dependent antigen given in classical adjuvants (193). These observations suggest that TLR signaling does not account for the action of alum, Freund's complete and incomplete adjuvants.

Immune Escape

Viruses and parasites have developed various means to evade the immune response. MCMV infects and productively replicates in DCs and strongly impairs their endocytic and stimulatory capacities *(194)*. Of note, infected DCs appear incapable of transducing the "danger" signals required to induce antiviral immune responses. DCs appear to be the major target of measles virus proteins, which is related to the profound defect in lymphocyte priming.

The capacity of DCs to stimulate T cells was shown to be impaired after measles virus infection *in vitro,* and their production of IL-12 was down-regulated *in vitro* and *in vivo (195).* Schistosomes have been shown to inhibit Langerhans cell migration *in vivo,* probably through the production of prostaglandin D2 *(196).*

DENDRITIC CELLS AND THE POLARIZATION OF THE IMMUNE RESPONSE

There is evidence that the onset of an immune response may not be sufficient to eliminate all pathogens but that the character of the response (the Th1/Th2/Th17 balance) determines its efficiency. Of importance is that an inadequate immune response may even be deleterious and result in tissue damage, allergic reactions, or disease exacerbation. Th1 cells, by their production of IFN-γ and lymphotoxin, are responsible for the eradication of intracellular pathogens, but they may also cause organ-specific autoimmune diseases if dysregulated. Th2 cells, by their production of IL-4 and IL-5, can activate mast cells and eosinophils and induce humoral immune responses, but they can also provoke atopy and allergic inflammation. The recently described Th17 subset exhibits proinflammatory cytokines such as IL-1β and TNF-α and mediates protective cellular immunity against bacterial infection, but in addition appears to be responsible for tissue inflammation in various autoimmune disorders. The identification of the factors that affect T helper subset development is therefore a prerequisite for the development of effective vaccination strategies.

Role of Antigen-presenting Cells

Several observations suggest that APCs may govern the development of T helper cell populations:

1. The development of Th1 versus Th2 cells seems to be determined early on, at the stage of antigen presentation. Indeed, T cell proliferation and up-regulation of mRNA for interferon-γ in response to Swiss-type murine mammary tumor virus and IL-4 in response to haptenated protein has been shown to start on the third day after immunization *(197).*
2. APCs release cytokines (IL-12, IL-23, IFN-γ, IL-10), which play a central role in Th1/Th2/Th17 differentiation.
3. The strength of interaction mediated through the TCR and MHC/peptide combination or the dose of antigen appears to affect lineage commitment (198). The number of TCR molecules engaged has also been correlated with the outcome (for review, see Lanzavecchia et al. [199]).
4. Membrane-bound costimulators, as CD80 or CD86, may influence Th development *in vitro* and *in vivo.*

In favor of this notion, it was shown that the nature of the cell presenting the antigen *in vitro* and *in vivo (117)* strongly influences the development of Th1 versus Th2 cells.

Polarizing Dendritic Cell–derived Cytokines

IL-12 plays a major role in immunity to intracellular pathogens by governing the development of IFN-γ–dependent host resistance (for review, see O'Garra *[200]*). IL-12 receptor–deficient patients display severe mycobacterial and *Salmonella* infections, which indicates an essential role of IL-12 and type 1 cytokine pathway in resistance to infections by intracellular bacteria *(201).*

DCs appear to be the initial cells to synthesize IL-12 in the spleens of mice exposed to microbial stimulants. The production of IL-12 in mice exposed to an extract of *T. gondii* or to LPS occurs very rapidly, is independent of signals from T-lymphocytes, and is associated with DC redistribution to the T cell areas, which suggests that DCs function simultaneously as APCs and as initiators of the Th1 response (44). It was subsequently shown that CD40 ligation induces a significant increase in IL-12 p35 and IL-12 p70 heterodimer production *(104).* Thus, production of high levels of bioactive IL-12 appears to be dependent on two signals: a microbial priming signal and a T cell–derived signal.

There is strong evidence that the Th1-prone capacity of murine DCs is dependent on its IL-12 production, although the role of IL-23 (a combination of p19 and the p40 subunit of IL-12 *[202]*) and IL-18 *(203)* has not been clearly assessed *in vivo.* The role of IL-12 in Th1 priming by DCs has been demonstrated by the correlation between IL-12 production and Th1-prone capacity (204). In parallel with the loss of IL-12 production, human DCs appear to switch from a Th1- to a Th2-inducing mode *(106).* An important determinant of Th1 development in CD4$^+$ T cells is STAT4 activation by IL-12 *(205),* although a STAT4-independent pathway has been reported. Among the transcription factors selectively expressed in Th1 cells, T-bet seems to play a crucial role, and its overexpression by retroviruses in T cells increases the frequency with which Th1 and Th2 cells that produce IFN-γ develop *(206).*

There is no evidence so far that indicates that DCs produce a Th2-prone cytokine. In contrast to IL-12, IL-4 has been shown to skew the development of naïve T cells toward an IL-4–producing Th2 phenotype *(207).* Activated CD4$^+$ T cells themselves may provide the IL-4 required for Th2 differentiation. Other sources of IL-4 or IL-13 include mast cells and basophils (for rev see [208]). The contribution of DCs to Th2 development does not appear to require APC-derived IL-4, inasmuch as injection of DCs from wild-type or IL-4–deficient mice induces similar Th2-type responses in wild-type recipients *(101).* Also, in humans, activated plasmacytoid-derived DCs do not seem to produce

detectable amounts of IL-4, and blocking IL-4 at the beginning of culture does not prevent generation of IL-4–producing cells *(103)*. This view is, however, still controversial *(209,210)*. The costimulatory molecule CD86 has been shown to be required for Th2 development *in vitro* and *in vivo (117,211)*, whereas CD80 is a more neutral costimulatory molecule. Of note, CD28 signaling alone appears to induce the pro-Th2 transcription factor GATA-3 and the presence of IL-12 has been shown to repress Th2 development *in vivo*. Indeed, CD8α^+ DCs from IL-12p40–deficient mice prime for Th2, whereas the same subset from wild-type animals primes for Th1 (204). It is, therefore, conceivable that Th2 is a default pathway—that is, that type II T cells would develop spontaneously in the absence of IL-12. The hypothesis that Th2 is a default pathway suggests that IL-12 has a greater opportunity to drive naïve T cells to polarize to Th1 than Th2-prone stimuli such as IL-4. In favor of this notion, TCR ligation has been shown to transiently desensitize IL-4R by inhibiting STAT6 phosphorylation *(212)*. The mechanism by which IL-12 would prevent Th2 priming is still unclear, but it involves inhibition of GATA-3 expression by IL-12 signaling through STAT4, indirect inhibition through IFN-γ production, or both. The requirements for Th2 induction may, therefore, be less stringent and may require only priming and relief from Th1 induction.

Neutralization of IL-4 has been shown to prevent the differentiation of Th2 responses, and IL-4 acts as antagonist of Th1-induced inflammatory responses. However, it has been clearly demonstrated that, paradoxically, IL-4 may promote Th1 development and induce IL-12 production by DCs. These contradictory observations were resolved by a report showing that IL-4 has opposite effects on DC development versus T cell differentiation. When present during the initial activation of DCs by infectious agents, IL-4 instructs DCs to produce IL-12 *(213–215)* and favor Th1 development, but when present later, during the period of T cell priming, IL-4 includes Th2 differentiation. These opposing effects correlate with resistance/sensitivity to *Leishmania major in vivo (96)*.

Unlike murine T cells, human T cells respond to type I interferons by inducing Th1 development. The basis of selective Th1 induction by IFN-α in human T cells appears to be a difference in IFN-α signaling between the mice and humans *(216)*. In particular, IFN-α has been shown to activate STAT4 in human but not mouse T cells. Of note, it has been reported that the COOH-terminal region of human and murine STAT2, which acts as an adapter for STAT4, are widely divergent, because of the insertion of a minisatellite region in mouse exon 23 (which encodes this region).

It has recently been recognized that in many of the mouse autoimmune disease models that have been attributed to Th1 cells, disease severity was in fact increased in the absence of these cells. The characterization of a third subset of T helper cells that secrete IL-17 and expand in response to IL-23 has helped to resolve the paradox. Within tissues, Th17 effector cells stimulate production of a variety of inflammatory chemokines, cytokines, metallopreoteases, and other proinflammatory mediators and promote recruitment of granulocytes. Although IL-23 has a clear role in Th17-mediated inflammation *in vivo*, recent studies have demonstrated that *in vitro* polarization of naïve CD4$^+$ T cells to the Th17 lineage requires a combination of TCR stimulation and the cytokines TGF-β and IL-6, but seems independent of IL-23 *(217,218)*. Instead, IL-23 may be required for promoting survival or maintaining the Th17 phenotype. Therefore, TGF-β at the steady state will induce regulatory T cells, whereas, on infection or inflammation, IL-6 produced by the activated immune system (and in particular by DCs) will suppress the generation of TGF-β–induced regulatory T cells and induce a proinflammatory response of Th17-type (217).

Ivanov et al. recently showed that the nuclear receptor RORγt directs the differentiation program of Th17$^+$ T helper cells. RORγt induces transcription of genes encoding IL-17 in naïve CD4$^+$ T cells and is required for their expression in response to IL-6 and TGF-β, the cytokines known to induce IL-17 (219).

Mechanisms of Dendritic Cell Polarization

Kalinski et al. *(220)* suggested that migrating DCs not only provide an antigen-specific signal 1 and a costimulatory signal 2, but also carry an additional signal 3, contributing to the initial commitment of naïve T helper cells into Th1 or Th2 subsets. This would allow the efficient induction of T helper cells with adequate cytokine profiles during early infections without requirement for a direct contact between antigen-specific T cells and the pathogens *(220)*.

Reports in the literature are consistent with three models through which DCs may control T cell polarization: (a) subclasses of DCs, (b) the nature of the stimuli that activate DCs, and (c) the kinetics of DC activation.

Dendritic Cell Subclasses

In the mouse, three *in vivo* studies have demonstrated that DC subsets differed in the cytokine profiles that they induce in T cells. In one study (221), TCR transgenic T cells from DO11.10/SCID mice were adoptively transferred into Balb/c recipients. CD11c$^+$CD11b$^{dull/-}$ (mainly CD8α^+) or CD11c$^+$CD11b^{bright}CD8α^- cells were loaded with ovalbumin peptide *in vitro* and injected into the footpads of transferred animals. Both DC subpopulations induced antigen-specific proliferation *in vivo* and *in vitro* upon restimulation with the antigen. Assessment of cytokine production revealed that both subsets induced IFN-γ and IL-2 production but that the CD11c$^+$CD11b^{bright}CD8α^- subset induced much greater levels of IL-10 and IL-4 production. The differences in the cytokine profiles of T cells

correlated with class-specific differences in the antibody profiles. In the second study (204), antigen-pulsed CD8α^+ and CD8α^- DCs were injected into the footpads of syngeneic recipients. Administration of CD8α^- DCs induced a Th2-type response, whereas injection of CD8α^+ DCs led to Th1 differentiation. In a third study, CD11b$^+$CD8α^- DCs from murine Peyer's patch have been shown to prime naïve T cells to secrete high levels of IL-4 and IL-10 *in vitro,* whereas the CD11b$^-$CD8α^+ and double-negative subsets from the same tissue primed for IFN-γ production *(8)*. The role of murine DC subsets in the regulation of Th1/Th2 balance *in vivo* has been more directly assessed by the targeting of antigens to receptors that are DC subset-restricted. Steinman et al. have shown that injection of 33D1 mAb-coupled to an antigen targeted CD8α^- DCs and induced the development of T cells producing IL-4 and little IFN-γ, whereas the same antigen coupled to anti-DEC-205 mAb was presented by CD8α^+ DCs and led to the secretion of higher levels of IFN-γ and no IL-4 *(322)*.

In humans, monocyte-derived DCs were found to induce Th1 differentiation, whereas DCs derived from plasmacytoid cells favor Th2 development of allogeneic T cells (23). Subsequent work has demonstrated, however, that the T cell stimulatory function of plasmacytoid-derived DCs was regulated by the environment: Virus-induced plasmacytoid DCs stimulate naïve T cells to produce IFN-γ and IL-10, whereas IL-3 induced plasmacytoid DCs stimulate naïve T cells to produce Th2-type cytokines (IL-4, IL-5, and IL-10) *(31)*. Cella et al. *(114)* reported that blood plasmacytoid DCs represent the principal source of type I interferon during inflammation and participate in antiviral Th1-type responses.

There is evidence that DC subsets express distinct pattern-recognition and presentation receptors that differentially regulate the production of cytokines known to direct the T helper cell differntation (see previous discussion, antigen uptake).

Little is known on the nature of the DCs which produce IL-12 versus IL-23. Like IL-12, IL-23 is expressed predominantly by activated DCs and phagocytic cells, and both cytokines may induce IFN-γ by T cells. The discovery that IL-23, but not IL-12, is essential in some models of chronic inflammation led to a model in which IL-12 is required to induce IFN-γ–producing Th1 cells, whereas IL-23 mediates Th1 effector functions. In favor of this notion: (1) IL-23 has been shown to be the effector cytokine in two models of intestinal inflammation (110,111) and in an experimental model of autoimmune encephalitis. (2) Vaknin-Dembinsky et al. have quantified the expression of IL-23 in monocyte-derived DCs in multiple sclerosis patients and found that DCs from these patients secrete elevated amounts of IL-23 (222). They reported increased IL-17 production by CD4$^+$ T cells, but no differences in IFN-γ secretion. (3) IL-23 appears as an essential promoter of end-stage collagen-induced arthritis in mice, whereas IL-12 paradoxically mediates protection from autoimmune inflammation *(223)*.

Other reports, however, suggest that the IL-23/IL-17 axis may display suppressive functions. Mice deficient for IL-23 appear highly susceptible for the development of experimental T cell–mediated TNBS colitis (224). The authors reported an over-expression of IL-12 by DCs from lamina propria in the absence of IL-23, suggesting that IL-23 inhibits IL-12 secretion. Similarly, IL-17 has a dual role: It is essential during antigen sensitization to establish allergic asthma and attenuates the allergic response in sensitized mice by inhibiting DCs and chemokine synthesis *(225)*.

Morelli et al. *(226)* have analyzed the APC function of different subsets of human DCs that migrate spontaneously from human skin explants. Langerhans cells and dermal DCs induced Th1 memory cells, and this function depended on their ability to produce IL-23.

Nature of the Stimuli

Vieira et al. *(227)* showed that the Th1- and Th2-inducing function of human monocyte-derived DCs is not an intrinsic attribute but depends on environmental instruction. DCs that matured in the presence of IFN-γ induce Th1 responses, whereas DCs that matured in the presence of prostaglandin E$_2$ induce Th2 responses. Similarly, the presence of IL-10 during maturation has been shown to lead to the development of DCs with Th2-driving function, whereas incubation of DC subsets with IFN-γ favors the priming of Th1 cells to the detriment of Th2 cell development *(101,220,228)*. This provides evidence for the adaptation of DC function to the conditions that they encounter in the pathogen-invaded tissue.

The antigen itself has been shown to regulate DC function. DCs have the capacity to discriminate between yeasts and hyphae of the fungus *Candida albicans* and release distinct cytokines *(209)*. Using oligonucleotides microarrays, Huang et al. (229) measured gene expression profiles of DCs in response to *E. coli, C. albicans,* and influenza virus. The data show that a common set of 166 genes, as well as particular subsets of genes, is regulated by each pathogen, which demonstrates that DCs discriminate between diverse pathogens and elicit tailored pathogen-specific immune responses.

TLRs have been shown to translate the information regarding the nature of the pathogens into differences in the cytokines and the chemokines produced by DCs: Re et al. have reported that activation of DCs by microbial agonists of TLR2 and TLR4 led to comparable activation of NF-kB and MAPK family members but that only the TLR4 agonist promoted the production of IL-12 p70 and the chemokine IP-10, which is associated with Th1 responses (230) (see also earlier discussion, antigen uptake).

It is interesting that synergic TLR stimulation appears to increase the production of IL-12 and IL-23 as well as the Delta-4/Jagged-1 ratio, leading to DCs with enhanced Th1-polarizing capacity (231).

Sporri and Reis e Sousa have tested whether inflammatory mediators produced in physiological amounts *in vivo* can substitute for direct PAMP recognition in DC activation and T cell priming (230). Interestingly, they have shown that indirectly activated DCs upregulate MHC molecules and costimulation and drive T cell proliferation, but not their differentiation in cytokine-producing T helper cells. They conclude that direct PAMP recognition is required for T helper–polarizing signals (of Th1- or Th2-types).

Kinetics of Dendritic Cell Activation

In addition to the nature of the maturation stimulus, the kinetics of activation may influence the capacity of DCs to induce different types of T cell responses. Recent *in vitro* observations suggest that, indeed, DCs produce IL-12 during a narrow time window and afterward become refractory to further stimulation. The exhaustion of cytokine production has been shown to affect the T cell polarizing process: DCs taken at early times after induction of maturation (active DCs) prime strong Th1 responses, whereas the same cells taken at later times ("exhausted" DCs) preferentially prime Th2 and nonpolarized cells *(106)*. These observations, although made *in vitro,* suggest a dynamic regulation of the generation of effector and memory cells during the immune response.

Two subsets of memory T lymphocytes with distinct homing potentials and effector functions have been described *(232)*. Expression of CCR7, a chemokine receptor that controls homing to secondary lymphoid organs, divides memory T cells into CCR7$^-$ effector memory cells, which migrate to inflamed tissues and display immediate effector function, and CCR7$^+$ central memory cells, which home in the lymph nodes and lack immediate effector function. Both subsets may persist for years, and the central memory cells give rise to effector memory upon secondary stimulation.

It has been proposed that the nature of DCs bearing antigen and costimulatory molecules, as well as the amount and duration of TCR triggering, determines whether effector memory or central memory cells are generated. A short TCR stimulation may expand nonpolarized T cells that home to lymph nodes and respond promptly to antigenic stimulation. In contrast, a prolonged stimulation in the presence of polarizing cytokines may drive differentiation of Th1 or Th2 effector cells that home to inflamed peripheral tissues.

DENDRITIC CELLS AND T CELL TOLERANCE

Central Tolerance

The normal development of T cells in the thymus requires both positive and negative selection. During positive selection, thymocytes mature only if their TCRs react with

some specificity to host MHC and host peptides. Laufer et al. *(233)* used the keratin promoter to reexpress a class II MHC antigen in class II–negative mice and showed that autoimmunity develops in transgenic mice in which class II MHC products are expressed only by epithelial cells and not by bone marrow–derived APCs. Autoreactive cells that constitute up to 5% of the peripheral CD4 T cells were generated.

During negative selection, developing T cells reacting strongly to self-peptide/self-MHC combinations are eliminated. Brocker et al. (234) demonstrated that thymic DCs are sufficient to mediate negative selection *in vivo*. Using a CD11c promoter, they targeted the expression of an MHC class II I-E transgene to DCs and showed that tolerance to I-E was induced. These observations demonstrate that thymocyte development is a sequential process: Positive selection occurs on thymic cortical epithelium independently of negative selection, which is mediated by thymic DCs.

Of note, a report demonstrates that the level of class I MHC protein is 10-fold higher on thymic DCs than on thymic epithelial cells and that an increase in the level of a particular cognate peptide/MHC ligand may be sufficient to result in negative rather than positive selection. This finding suggests a role for the quantitative differences in the level of MHC expression in thymic selection *(235)*.

Mathis et al. have emphasized the crucial role of the transcription factor AIRE (autoimmune regulator gene) in the "central" tolerance. They showed that AIRE regulates autoimmunity by promoting the ectopic expression of peripheral tissue-restricted antigens in thymic medullary epithelial cells (apparently not in DCs) (236). They recently reported that AIRE exerts its tolerance-promoting function not by positive selection of regulatory T cells, but rather by negative selection of T effector cells. It is interesting that, in addition, AIRE appears to enhance the antigen-presentation capability of medullary epithelial cells by a mechanism still unknown. Very recent data have confirmed the link between aire-driven regulation of tissue specific expression in the thymus and the development of a spontaneous autoimmune disease in mice. It was shown that autoimmune eye disease in aire-deficient mice develops as a result of loss of thymic expression of a single eye antigen, interphotoreceptor retinoid-binding protein (IRBP). In addition, lack of IRBP expression solely in the thymus, even in the presence of aire expression, is sufficient to trigger spontaneous eye-specific autoimmunity *(237)*.

Peripheral Tolerance

Many proteins, however, may not have access to the thymus during development, and a significant proportion of self-reactive T cells has been shown to escape negative selection, which suggests that a mechanism must be able to silence autoreactive T cells in the periphery. Bouneaud et al. *(238)* studied a peptide-specific T cell repertoire in the

presence and absence of the deleting ligand. The authors used mice transgenic for the TCR-β chain of an anti-HY T cell clone and compared the preimmune repertoire reactive to the male-specific peptide in male and female animals. Interestingly, their results showed that a large proportion of CD8$^+$ T cells specific for the male-specific peptide persist in male animals, as detected by MHC/peptide tetramer staining and functional assays. Of note, male T cells (specific to the male peptide) that escape clonal deletion do not react with the endogenous male peptide, as predicted by the observation that the threshold of antigenic stimulation is lower for negative selection that for activation of mature cells, but those cells are still capable of functional reactivity with self-peptides when facing high doses of antigen.

There is evidence that, besides their immunostimulatory functions, DCs may also maintain and regulate T cell tolerance in the periphery. This control function may be exerted by certain maturation stages, specialized subsets, or cells influenced by immunomodulatory agents such as IL-10.

Immature Dendritic Cells

In the periphery, immature DCs are specialized for antigen capture but display weak stimulatory properties for naïve CD4$^+$ and CD8$^+$ T cells. Several observations *(65,66)* show that immature DCs express MHC/peptide combinations, albeit at low levels. On the basis of *in vitro* studies showing that TCR engagement in the absence of costimulation may lead to anergy of T cell clones *(239)*, it was postulated that immature DCs may induce a state of unresponsiveness in antigen-specific T lymphocytes. This hypothesis would be in agreement with several observations: (a) Both immature and mature DCs are constantly acquiring peptide cargo, although immature DCs clearly display lower levels of antigen/MHC combinations; (b) immature DCs are in close contact with T lymphocytes in lymphoid organs; and (c) immature DCs present self-antigens *(240)*.

Consistent with tolerogenic properties of DCs, several reports suggest a major flux of tissue antigens via DCs migrating to the lymph nodes. Huang et al. (90) have identified in rat a DC subset (OX41$^-$) that constitutively transports apoptotic bodies derived from the intestinal epithelium to T cell areas of mesenteric lymph nodes *in vivo*. OX41$^-$ DCs are weak APCs despite expressing high levels of B7 molecules and may play a role in inducing and maintaining self-tolerance. In addition, rat intestinal lymph contains another subset of OX41$^+$ DCs that are strong APCs but may not reach the T cell area in the absence of inflammation. Specific migratory DCs rapidly transport antigen from the airways to the thoracic lymph nodes in baseline conditions (89). These observations suggest that DC internalize potential self-antigens from tissues and from noninfectious environmental proteins. It is important to note that exposure of DCs to primary tissue cells or apoptotic cells do not induce their maturation *(241)*. These observations led to the hypothesis *(242)* that immature DCs phagocytose tissue cells undergoing normal cell turnover by apoptosis, leading to unresponsiveness of self-reactive T cells in the draining lymph node.

Hawiger et al. (243) examined the function of murine DCs in the steady state, using as antigen delivery system a monoclonal antibody to a DC-restricted endocytic receptor DEC-205. Targeting the antigen on DCs resulted in transient antigen-specific T cell activation, followed by T cell deletion and unresponsiveness. T cells initially activated by DCs in these conditions could not be reactivated when the mice were challenged with the same antigen in complete Freund's adjuvant. In contrast, coinjection of the DC-targeted antigen and anti-CD40 agonistic antibody resulted in prolonged T cell activation and immunity. These observations suggest that, in the steady state, the primary function of DCs may be to maintain peripheral tolerance. Consistently, an initial burst of CD8$^+$ T cell proliferation followed by deletion was observed when antigen was expressed as transgene in pancreatic β cells, in kidney proximal tubular cells, and in the testes of male mice. The antigen was shown to be presented not by pancreatic β cells, but by bone marrow–derived APCs in the draining lymph nodes (244). Similar results were obtained by Morgan et al. *(245)*, who further demonstrated a direct correlation between the amounts of antigen expressed in the periphery and the rate of tolerance of specific CD8$^+$ T cells. Another study showed that administration of immature DCs may prolong cardiac allograft survival in nonimmunosuppressed recipients *(246)*. Probst et al. used an elegant system to demonstrate that resting DCs induced peripheral CD8$^+$ T cell tolerance (247). Injection of double-transgenic DIETER (DC-specific inducible expression of T cell epitopes by recombination) mice with tamoxifen induced the presentation of three transgenic CTL epitopes by 5% of all DCs. Of note, this presentation resulted in peripheral tolerance if the DCs are resting and in protective immunity if DCs are activated *in vivo* by coinjection of agonistic CD40 antibodies. The authors further reported that CD8$^+$ T cell tolerance depended on signaling via the costimulatory molecule PD-1 (248). Collectively, these observations support the hypothesis that activation of T cells in a noninflammatory environment, presumably by immature DCs, could be part of a normal mechanism of peripheral tolerance.

In humans, Dhodapkar et al. *(249)* analyzed the immune response induced after injection of immature DCs pulsed with influenza matrix peptide and keyhole limpet hemocyanin (KLH) in two healthy subjects. A decline in matrix peptide–specific IFN-γ–producing T cells was observed, whereas such cells were detected in both subjects before immunization as expected, because most adults

have been exposed to the influenza virus. Of note, the decline in IFN-γ production was associated with the appearance of IL-10–producing cells specific for the same antigen. KLH priming was much greater when mature DCs were used and KLH-specific, IFN-γ–secreting cells were detected. *In vitro* studies *(250)* have shown that repetitive stimulation with immature human DCs induced nonproliferating, IL-10–producing CD4$^+$ T cells. These T cells, in co-culture experiments, have been shown to inhibit the antigen-driven proliferation of Th1 cells in a contact- and dose-dependent but antigen-nonspecific manner.

The Existence of Specialized Subsets of Dendritic Cells

The existence of these cells, which would display tolerogenic properties, is still a matter of speculation. Initial *in vitro* studies by Suss and Shortman *(251)* demonstrated that splenic CD8α^- DCs induced a vigorous proliferative response in CD4$^+$ T cells, whereas CD8α^+ DCs induced a lesser response that was associated with T cell apoptosis. The tolerogenic capacity of CD8α^+ DCs was demonstrated *in vivo* in one report, but the negative regulatory effect appears restricted to tumor/self-peptide P815AB and was not observed with other antigens *(252)*. The potential role of CD8α^+ DCs in peripheral tolerance was challenged by numerous reports showing that these DCs are the major producers of IL-12 and induce the development of IFN-γ–producing T cells *in vivo* (see earlier discussion).

There is evidence that DC subsets may display tolerogenic functions. De Heer et al. have shown that lung plasmacytoid DCs had an essential role in preventing asthmatic reactions in mice (253). Depletion of pDCs during inhalation of normally inert antigens led to cardinal features of asthma, whereas adoptive transfer of plasmacytoid DCs before sensitization prevented disease. Recently, plasmacytoid DCs were identified as phagocytic APCs essential for tolerance to vascularized cardiac allografts in mice (254). These cells acquire and process MHC class II–derived donor allopeptide in allografts, migrate to peripheral lymph nodes across high endothelial venules, and induce the peripheral development of CD4$^+$CD25$^+$FoxP3$^+$ Treg. Depletion of plasmacytoid DCs or prevention of their lymph node homing inhibited peripheral regulatory T cell development. In humans, herpes virus–stimulated plasmacytoid DCs have been shown to induce allogeneic naïve CD4$^+$ T cells to differentiate into cytotoxic regulatory T cells that inhibit proliferation of coexisting naïve CD4$^+$ T cells *(255)*. Similarly, human CD40$^-$activated plasmacytoid DCs induce the differentiation of CD8 T cells into IL-10–producing anergic CD8 T cells that suppress the allospecific proliferation of naïve CD8 T cells.

A recent report by Kaplan et al. (256) examined the functional requirement of LCs in skin immunity and generated mice with a constitutive and durable absence of epidermal Langerhans cells. Unexpectedly, they found that Langerhans cells were dispensable for contact hypersensitivity but regulated the response.

Powrie et al. (257) have identified a subpopulation of DC at mucosal sites that expresses CD103 (the α_E integrin) and is crucial to allow CD4$^+$ CD25$^+$ Treg cells to dominate and suppress the colitogenic effector cell response. They showed that CD103$^+$DCs, but not their CD103$^-$ counterparts, promoted expression of the gut-homing receptor CCR9 on T cells. Although the mechanism by which CD103 regulates the balance of effector and regulatory responses in the intestine is still unknown, it may involve TGF-β, which has been shown to induce CD103 on T cells *(258)*. A minor population of murine splenic CD19$^+$ DCs (distinct from plasmacytoid DCs) appears to acquire potent IDO-dependent T cell suppressive functions following CpG oligonucleotide treatment *(259)*.

A population of CD11c^{low}CD45RB^{high} DCs has been described in the spleen and lymph node of normal mice, which displays plasmacytoid morphology, secretes high levels of IL-10 after activation, and induces tolerance through the differentiation of Tr1 cells (260). Finally, Svensson et al. (261) reported that spleen-derived stromal cells promote the development of CD11c^{lo}CD45RB$^+$ IL-10–producing regulatory DC from lineage-negative c-kit$^+$ progenitor cells. These DCs have the capacity to suppress T cell responses and induce IL-10–producing Treg. Stromal cells from Leishmania donovani–infected mice are more efficient in supporting their development, suggesting that regulatory DCs may have an impact on the outcome of parasitic disease.

Interleukin-10

IL-10 has been shown to suppress multiple activities of the immune response. The immunosuppressive properties of IL-10 on DCs are caused by a reduction in the upregulation of expression of class II MHC, costimulatory, and adhesion molecules, as well as an inhibition of the production of inflammatory cytokines (IL-1, IL-6, TNF-α, and IL-12). Of note, IL-10 modulates the function of immature DCs but has little effect on mature DCs (for review, see Jonuleit et al. *[262]*). Human DCs generated from peripheral progenitors and exposed to IL-10 for the last 2 days of culture were shown to induce a state of antigen-specific anergy in T cells *(263)*. The tolerogenic properties of these IL-10–treated DCs correlate with a reduced expression of class II MHC molecules, CD58 and CD86 costimulatory molecules, and the DC-specific antigen CD83. The role of IL-10–producing DCs has been illustrated in the lung (264). Pulmonary DCs from mice exposed to respiratory antigen transiently produce IL-10 and induce antigen unresponsiveness in recipient mice. Although they are phenotypically mature, these DCs stimulate the development

of CD4+ T regulatory cells that also produce high amounts of IL-10. Upon transfer, these pulmonary DCs induce antigen unresponsiveness in recipient mice.

DENDRITIC CELLS AND REGULATORY T CELLS

The mechanims responsible for peripheral T cell tolerance can be divided into those acting directly on the responding T cells, such as inactivation or deletion of specific T cells (T cell intrinsic), and those that act through additional cells or factors, such as regulatory T cells or suppressive cytokines (T cell extrinsic).

Interest in Treg cells has exploded since the discovery by Sakaguchi et al. of a minor population of CD4+ CD25+ T cells that plays a central role in the prevention of autoimmune reactions *in vivo* (for review see *[265]*). "Natural Treg" develop in the thymus, are present in naïve animals, and their depletion causes the development of a spectrum of autoimmune diseases.

By contrast, "adaptive or induced" Treg develop in peripheral lymphoid tissues under partcular conditions of antigen stimulation. In particular, TGF-β seems to be involved in the conversion of CD4+ CD25− T cells into CD4+ CD25+ FoxP3+ (317). Another factor is the mode of antigen presentation: Regulatory T cell populations can be induced in subimmunogenic conditions and expanded by delivery of antigen in immunogenic conditions (266), suggesting that a limited antigen dose and the delivery of antigen to unactivated DC may be a strategy to develop adaptive Treg.

The role of CD8+ T cells as Treg cells is still poorly documented. Of note, a few reports *(267,268)* have shown that plasmacytoid DC could induce antigen-specific CD8+ IL-10–producing cells.

The respective role of thymic-derived versus peripherally generated FoxP3+ Treg still needs to be established. The molecular mechanism(s) underlying their suppressive activity is (are) still elusive and may involve cell-contact pathway, suppressor cytokines, or killing. A recent report (269) suggests that mast cells are critical in Treg-dependent allograft tolerance and would be recruited and activated through IL-9, which is produced by all categories of Treg cells, Therefore, Treg through the production of IL-9, IL-10, and TGF-β may interact with cells of the innate system (mast cells, macrophages, and DCs) leading to inhibition of the immune responses.

Bidirectional Dendritic Cell-T Signaling: Role of CD28 and CTLA-4

It is interesting that tolerogenic DCs not only display antigens in a way that makes T cells tolerate that antigen, but that the Treg cells can modulate DC function, so that they are no longer able to alert the adaptive cells to danger. Grohmann et al. have identified a reverse signaling through B7 molecules in tolerogenic DCs, which leads to cytokine-dependent tryptophan catabolism. Thus, exposure of DCs to CTLA-4-Ig *in vitro* and *in vivo* induces IDO protein expression and promotes a tolerant state and long-term allograft survival (137). Of note, Munn et al. have identified the GCN2 kinase as a downstream mediator for the immunoregulatory action of IDO in T cells *(270)*. GCN2 is a stress-response kinase that can be activated by elevations in uncharged tRNA. In addition, *in vivo* studies have demonstrated that regulatory T cells can modify DCs to down-regulate expression of costimulatory molecules *(271,272)*. In particular, CD4+ CD25+ FoxP3+ T cells appear in the airway mucosa and regional lymph nodes within 24 hours of initiation of aerosol exposure and inhibit subsequent T helper–mediated up-regulation of resident airway mucosal DC functions *(272)*.

DENDRITIC CELLS AND B CELL ACTIVATION

Several observations have underscored the role of DCs in the induction of humoral responses. Inaba et al. (273,274) demonstrated that DCs were required for the development of T cell–dependent antibody responses by murine and human lymphocytes *in vitro*. Injection of syngeneic DCs, which have been pulsed *in vitro* with soluble protein antigen, induced a strong antibody response in mice that were boosted with soluble antigen (169). Antigen-specific antibodies of isotypes similar to the Ig classes produced after immunization with the same antigen in complete Freund's adjuvant were detected in treated animals. In particular, IgG1 and IgG2a antibodies were produced, which suggests that Th1 and Th2 cells are activated and a memory response was induced.

The classical view of DC function in antibody formation was that these cells activate CD4+ T helper cells, which in turn interact directly with B cells to provide help. However, more recent findings have suggested a role for direct DC–B cell interaction. CD40-activated DCs have been shown to enhance both the proliferation and IgM secretion of CD40-activated B lymphocytes *(275)* and to switch naïve IgD+ cells to become IgA secretors in the presence of IL-10 *(276)*.

Further, Grouard et al. (277) identified a population of DCs capable of stimulating T cells in the germinal center. This population of germinal center DCs is distinct from the follicular DCs, which retain immune complexes and promote the activation and selection of high-affinity B cells. Germinal center DCs express CD11c and CD4 and represent 0.5% to 1% of all germinal center cells in human tonsils, spleen, and lymph nodes. Germinal center DCs display much stronger T cell stimulatory function than do germinal center B cells and were found in close association with memory T cells *in situ,* which suggests that they may maintain the germinal center reaction by sustaining the activation state of germinal center memory T cells.

DENDRITIC CELLS AND CELLS OF THE INNATE SYSTEM

In addition to their major role in the induction or adaptive immune responses, DCs appear to activate the innate arm of antitumor immunity; that is, NK and NKT effector cells.

NK cells participate in the innate response against transformed cells *in vivo (278)*. Murine DCs have been shown to enhance proliferation, cytotoxicity properties, and IFN-γ production by NK cells *in vitro (279)*. Moreover, in mice with class I MHC–negative tumors, DCs promote NK-dependent antitumor effects *in vivo*. The activation depends on direct DC–NK cell contact and on secreted factors that include IL-12, IL-18, and possibly IL-15. In addition, IL-2 released by DCs *(115)* could play a role in the activation of NK functions by DCs.

Gerosa et al. *(46)* analyzed the interaction between human peripheral blood NK cells and monocyte-derived DCs. Fresh NK cells were activated, and their cytolytic activity was strongly augmented by contact with mature DCs. Reciprocally, fresh NK cells cultured with immature DCs strongly enhance DC maturation and IL-12 production. A recent study shows, however, that immature NK cells may suppress DC functions during the development of leukemia in a mouse model *(280)*.

NKT cells are TCRα/β^+ CD4$^+$ or CD4$^-$CD8$^-$ T cells that display distinctive phenotypic and functional properties *(281–283)*. They can be distinguished from conventional T cells by their expression of the NK cell locus–encoded C-type lectin molecule NK1.1. Another hallmark of murine NKT cells is their restricted TCR repertoire: The great majority express an invariant TCR-α chain structure. NKT cells are relevant in innate antitumor immunosurveillance. Both mouse and human NKT cells rapidly secrete cytokines associated with both Th1 (IFN-γ) and Th2 (IL-4) responses upon TCR engagement or stimulation with the synthetic CD1d ligand, the α-galactosylceramide. This ligand induces IL-12 production by DCs and IL-12 receptor expression on NKT cells, thereby activating NKT cells for production of IFN-γ (284). Injection of the α-galactosylceramide has been shown to stimulate the full maturation of DCs *in situ*, by a mechanism dependent on NKT cells, and to induce T helper CD4$^+$ and CD8$^+$ T cell immunity to a coadministered protein *(285)*.

Neutrophils are also able to communicate with DCs. Neutrophils not only instantly kill pathogens when they invade tissues, but they can also travel from the site of infection to the nearest lymph node to directly or indirectly present antigen. Neutrophils can induce DCs to mature and to produce IL-12, thereby favoring a Th1-type response. Of note, DCs and neutrophils are found in close proximity in the mucosa of patients with Crohn's disease (a Th1-type inflammation) (286).

DENDRITIC CELL–BASED IMMUNOTHERAPY FOR CANCER

The first experimental evidence that lack of immunogenicity could be caused by the tumor's inability to activate the immune system rather than the absence of tumor antigens was provided by Boon and Kellerman in 1977 (287). This observation was confirmed in various tumor models and paved the way for a vaccination therapy of cancer.

As a complement to other less specific therapies, the immunotherapy may be highly beneficial to tumor patients because it would ideally induce an antigen-specific, widespread, long-term protection. DCs are currently under active clinical investigation, mostly for their immunostimulatory properties in cancer.

A large body of literature involves animal models showing that DCs loaded with tumor-associated antigens are able to induce a protective immune response, even to established tumors. In mice, successful protection against a B cell lymphoma was achieved by immunization with idiotype-pulsed splenic DCs *(288)*. Naïve mice injected with bone marrow–derived DCs pulsed with tumor-associated, class I–restricted peptides were protected against a subsequent lethal tumor challenge and against preestablished C3 sarcoma cells or 3LL lung carcinoma cells *(289)*.

In addition, immunity has been induced against unidentified antigens by injecting DCs pulsed with tumor cell membranes, RNA from tumors, peptides eluted from class I MHC molecules, or DC/tumor cell hybrids. The fusion of DCs with tumor cells has been shown to generate hybrid cells that display the functional properties of DCs and present one or more tumor antigens. Administration of hybrid cells prevents the growth of preimplanted tumor cells in various models, induces long-lasting tumor resistance *in vivo (290–292)*, and can reverse unresponsiveness to a tumor-associated antigen *(293)*. Another strategy is to expand DCs *in vivo* through administration of Fms-like tyrosine kinase 3 (FLT-3) ligand, which results in mobilization of DC precursors from the bone marrow and induction of antitumor immunity. FLT-3 ligand and CD40L synergize in the generation of immune response against two poorly immunogenic tumors, leading to complete rejection in a high proportion of mice and long-lasting protection *(294)*.

Although animal studies provided the proof of principle for antigen-pulsed DC vaccination against cancer, this approach is still in an early stage in humans, due to numerous variables to be tested that are pertinent to DC function and induction of innate and adaptive immune responses against cancer.

The use of DCs as adjuvants for immunotherapy of cancer has been possible because of the discovery that DCs might be generated from peripheral monocytes or CD34 bone marrow precursors, in the presence of certain cytokines such as GM-CSF, IL-4, and TNF-α (295).

DCs loaded with tumor antigens have been used in a number of trials in humans (for review, see Fong and Engelman *[296]* and Gunzer and Grabbe *[297]*). It was initially demonstrated that DCs can be used to vaccinate B cell lymphoma patients with the induction of antigen-specific T cells, and clinical responses were achieved in two of four patients *(298)*. DCs were further used to treat melanoma, prostate cancer, and bladder cancer (for review, see Nestle *[299]*). Nestle et al. *(300)* injected the DC preparation directly under ultrasound control in a normal inguinal lymph node. KLH was added as a CD4 helper antigen and immunological tracer molecule. DC vaccination induced delayed-type hypersensitivity reactivity toward KLH in all 16 patients and toward peptide-pulsed DCs in 11 patients. Objective clinical responses were obtained in five patients. In another trial *(301)*, injection of mature monocyte-derived DCs, pulsed with a MAGE-3 peptide and a recall antigen, was shown to enhance circulating MAGE-3–specific cytotoxic effectors in patients with melanoma and lead to regression of individual metastases in 6 of 11 patients. Antigen-specific immune response was induced after intradermal injection but decreased after intravenous injection *(301)*. In another study, Banchereau et al. *(302)* used DCs derived from CD34$^+$ cells that consist of two phenotypically and functionally distinct populations: Langerhans cells and the interstitial/dermal DCs (similar to those derived from blood monocytes). Patients with metastatic melanoma received subcutaneous injections of CD34 progenitor–derived autologous DCs, pulsed with peptides derived from four melanoma antigens, as well as control antigens (influenza matrix peptide and KLH). The long-term outcomes in vaccinated patients showed that patients who have survived longer are those in whom vaccination with CD34-DCs elicited T cell immunity to at least two melanoma peptides *(303)*.

It is still unclear whether the rates of tumor regression are clearly different in the trials involving DCs from those observed with other vaccine modalities. Of note, the analysis of the clonal diversity of CTL responses in patients vaccinated with DCs pulsed with the HLA-A1–restricted MAGE-3 peptide showed that several CTL clones were amplified *(304)*. This polyclonality contrasts with the monoclonality of the CTL responses observed in patients vaccinated with MAGE-3.A1 peptide or with ALVAC recombinant virus coding for this antigenic peptide.

A critical aspect of immunotherapy is the identification of immunologic markers that will permit prediction of clinical efficacy. The analysis of immune responses in melanoma patients vaccinated with antigens encoded by MAGE genes revealed a possible involvement of T cells directed against tumor antigens other than the vaccine antigen (305,306). T. Boon, P. Coulie, et al. found a low frequency of antivaccine T cells and a high frequency of antitumor CTLs with high enrichment in regressing metastases, suggesting that the antivaccine CTLs are not the effectors that kill the tumor cells, but that their interaction with the tumor induces activation of competent tumor-specific CTL.

Although promising, DC vaccination is in an early stage, and several parameters that may be critical for the immunological and clinical outcome need to be defined: the DC type, antigen loading, site of injection, DC dosage, and frequency of injections. Labeling studies with radioactive tracers have demonstrated significant differences in the distribution of DCs administered by different routes, although only a minor fraction of the injected DCs can be recovered in the draining lymph nodes in mouse and human experiments *(307,308)*. A more direct and less laborious strategy would be to target antigens *in vivo* via specific surface receptors. DEC-205 and DC-SIGN (DC-specific intercellular adhesion molecule 3-grabbing nonintegrin) were identified as target molecules. Steinman, Nussenzweig, et al. found that proteins delivered to DCs by antibodies to DEC-205 receptor in combination with a maturation stimulus were higly effective in inducing cellular *(59)* and humoral *(309)* immune responses. Figdor et al. developed a humanized antibody directed against the C-type lectin DC-SIGN, which was crosslinked to an antigen. They demonstrated delivery of antigen to DCs via DC-SIGN, resulting in naïve as well as recall responses by T cells *(309)*. Steinman et al. introduced the HIV p24 gag protein into a mAb that targets DEC-205 and assessed the processing of noreplicating internalized antigens onto MHC class I (cross-presentation) for recognition by CD8$^+$ T cells *(79)*. They found that αDEC205-gag stimulated proliferation and IFN-γ production by CD8$^+$ T cells isolated from blood of HIV-infected donors. αDEC205 was found more effective than αDEC209/DC-SIGN.

There is clear evidence that, although immunity can be induced in cancer patients, mechanisms may exist that impair effective tumor rejection. Suppressive cell populations have been described and include myeloid suppressor cells, natural or induced regulatory T cells, NKT cells, etc. Therefore, novel therapeutic approaches are envisaged that combine vaccination and treatment(s) to overcome tolerance.

"Killer" Dendritic Cells

Two recent reports have identified a novel subset of cells coexpressing DC and NK cell markers, which kills tumor cells through a predominantly TRAIL-dependent pathway (310). The infiltration of activated NK/DCs into the tumor mass was induced by a combination of IL-2 and Gleevec (imatinib mesylate), and the NK/DCs recognize and kill tumor cells *in vitro* and *in vivo*. These cells produce substantial amounts of IFN-γ and were termed interferon-producing killer DCs (IKDC). There is evidence that their cytolytic capacity is inversely regulated with their antigen-presenting activity (311), suggesting that these cells provide a link between innate and adaptive immunity. It is still unclear whether a human equivalent exists and whether immunosurveillance is a normal function of IKDC (i.e, in

mice not treated with Gleevec and IL-2). Further studies are needed to determine whether the IKDC are indeed a form of antigen-presenting DC or a form of NK cell.

DENDRITIC CELLS AND THE DEVELOPMENT AUTOIMMUNITY

An interesting question is whether cells of the dendritic family are implicated in the onset and the pathogenesis of autoimmune diseases. Indeed, these cells produce inflammatory cytokines, play a key role in immunity and peripheral tolerance, and express TLRS, which appear to have an important role in triggering disease onset in experimental models of arthritis, multiple sclerosis, and diabetes (for review see *[312]*).

Nonobese Diabetic Mouse Model

Studies of autoimmune diabetes are facilitated by mouse models such as nonobese diabetic (NOD) mice, which develop diabetes spontaneously. This disease is biphasic: in the first stage, named *insulitis,* the islets are invaded by DCs, macrophages, and B and T cells, but this is followed by a benign interlude. Progression to diabetes occurs only at a second stage, when the islet infiltrate converts to a destructive process, resulting in destruction of β cells, and eventually loss of insulin and glucose homeostasis. There is evidence that CD4$^+$ or CD8$^+$ T cells, specific for β cell epitopes in the context of self-MHC, are first sensitized in pancreatic lymph nodes at 15 days of age. Turley et al. have tested whether changes in APCs may underlie the initiation of antigen exposure. Interestingly, they found that the stimulus initiating insulitis was a ripple of β cell death that occurs physiologically and that the APC that ferries β cell debris from the pancreas to the draining lymph nodes is a DC of CD11b$^+$CD8α^- phenotype (313).

The reason why this sequence of events leads to immunity and not tolerance (as apoptotic cells are considered as tolerogenic) is still unknown, but could involve the loss of the balance between effector and regulatory T cells. Of note, a recent report (314) visualized islet-specific regulatory T cells and helper T cells *in vivo* in the lymph nodes of NOD mice. It was found that regulatory T cells can dampen the stability of T helper–DC interactions, possibly preventing T helper cells from receiving optimal activation signals from DCs.

Recent studies have shown that DCs are active APCs for expanding natural Treg, as well as differentiating or inducing Treg from Foxp3 and CD25 negative, CD4$^+$ precursors. These treg exhibit efficacy in treating recent onset diabetes in NOD mice *(315)*.

Human Diseases

There is some evidence that DCs may also play a role in the induction of autoimmune diseases in humans. Jego et al. (316) underscored the role of two DC subsets in patients suffering from systemic lupus erythematosus. They found that the sustained overproduction of IFN-α produced by plasmacytoid DCs, contributes to peripheral tolerance breakdown through the activation of immature conventional DCs, leading to expansion of autoreactive B cells and sensitization of cytotoxic CD8$^+$ T cells. Plasmacytoid DCs were also found to massively infiltrate the skin of psoriatic patients and become activated to produce IFN-I during disease formation. Howard et al. have shown that two retinal antigens, S-antigen and interphotoreceptor retinoid-binding protein, which are associated with uveitis, can attract immature DCs and lymphocytes, suggesting that DCs may be involved in the early steps of autoimmune uveitis *(317)*. Similarly, the autoantigen PR3, which is involved in the pathogenesis of autoimmune-mediated vasculitis in Wegener granulomatosis, is increased in the extracellular space and induces phenotypic and functional maturation of a fraction of blood monocyte–derived iDCs, leading to increased expression of interferon-γ (IFN-γ), which favors the development of a granulomatous inflammation. Of note, PR3-matured DCs derived from WG patients induce a higher IFN-γ response of PR3-specific CD4$^+$ T cells compared with healthy controls *(318)*.

CONCLUSION

DCs perform several tasks with high efficiency. They present the antigenic sample at the time of danger through evolutionary conserved pattern-recognition systems and sensitize lymphocytes specific for these dangerous antigens. They also seem to play an active role in central and peripheral tolerance by silencing autoreactive T cells generated by the stochastic recombination of the T cell variable pattern-recognition receptors. There is indeed evidence that DCs constitutively present self-antigens and that tolerogenic DCs that directly or indirectly prevent the activation of T cells specific to self may exist. Regulatory DCs may also control and dampen immune responses to foreign antigens to avoid excessive inflammatory responses that are deleterious to the organism. This dual role—ensuring tissue integrity through activation of adaptive reactions and maintenance of privileged microenvironment—seems to be a general feature of innate cells, as illustrated for mast cells (269), and macrophages.

The immune system is confronted with the difficult task of combining the detection of potential pathogens in the periphery with the ability of adequately instructing cells of the adaptative immune system often located in lymphoid organs distant from the infection site. In general, when distant cells of a multicellular organism must communicate with one another, they secrete chemicals (hormones) that travel in the bloodstream to reach their target cells (endocrine communication). The immune system has

developed a unique form of cell–cell communication, implying the migration of DCs carrying the biological information gathered at the site of infection (signals 1, 2, and 3) to the lymphoid organ, where they establish immunological synapses with lymphoid cells, exchanging information through locally secreted (paracrine communication) or membrane-bound molecules. This unique form of cell communication (which may be referred to as *motocrine communication*), combines long-distance communication between the periphery and the lymphoid organs, with the confidentiality and specificity of a short-range synapse.

Natural Killer Cells

Wayne M. Yokoyama

GENERAL DESCRIPTION

Natural killer (NK) cells were initially described as such because they spontaneously kill certain tumor targets (1,2,3,4). Morphologically, NK cells are typically large lymphocytes containing azurophilic granules (5). However, the large granular lymphocyte (LGL) morphology is not invariably associated with NK cells because small, agranular lymphocytes may display natural killing (6) and activated cytotoxic T lymphocytes (CTLs) can display this morphology *(7)*. Indeed, human LGL leukemias are now recognized to contain NK and T cell variants (8).

Recent studies have provided strong evidence that NK cells belong to the lymphocyte lineage (discussed in detail later). Although NK cells express B220 (CD45R) that is often used as a B cell–specific marker indicating that CD19 rather than B220 is more reliable to distinguish B cells from NK cells *(9)*, NK cells more closely resemble T cells than B cells. Indeed, before the molecular description of the T cell receptor/CD3 (TCR/CD3) complex, NK cells were frequently confused with T cells. Thus, it is useful to compare and contrast these two lymphocyte populations as well as consider another enigmatic cell termed "lymphokine activated killer" (LAK) cell.

NK Cells versus T Cells

NK cells are most often confused with T cells because they may have similar morphologies, express several cell surface molecules in common *(10,11)*, and share functional

capabilities, including responses to target cells, such as cytotoxicity and cytokine production (described in greater detail later). However, mature NK cells are clearly not T cells by several criteria (12). NK cells do not require a thymus for development and are normal in athymic nude mice. NK cells do not express the TCR on the cell surface, do not produce mature transcripts for TCR chains, and do not rearrange TCR genes (13,*14*). Mice with the *scid* mutation or deficiencies in *Rag1* or *Rag2* lack TCR gene rearrangements and mature T cells but possess NK cells with apparently normal function (15,16,*17,18*). Several CD3 components may be found in the cytoplasm of NK cells, particularly immature NK cells, but they are not displayed on the cell surface *(19)*, with the exception of CD3ζ. But CD3ζ is expressed in association with FcγRIII (CD16) and other NK cell activation receptors instead of the TCR/CD3 complex (20,*21*). Whereas mice lacking CD3ζ lack most T cells, NK cell number and function are minimally affected *(22)*. However, NK cells are completely absent in mice with only partial defects in T cell subsets, such as in mice lacking components of the IL-15R (discussed later). Finally, in an important functional distinction from CD8$^+$ major histocompatibility complex (MHC) I–restricted T cells, NK cells do not require the presence of MHC class I molecules on their targets for lysis. Instead, NK cells kill more efficiently when their targets lack MHC-I expression. Thus, NK cells can be clearly distinguished from T cells.

NK Cells and LAK Cells

Another area of overlap between NK and T cells concerns responses to high concentrations of IL-2 (800 U/mL to 1,000 U/mL) that induce robust lymphocyte proliferation *in vitro* (i.e., generation of LAK cells) (23–25,*26*). Although most are CD3$^-$ NK cells, TCR/CD3$^+$ T cells are also found. To distinguish NK cells within this population, they are sometimes called "CD3$^-$ LAK" cells or "IL-2-activated NK cells." In a related phenomenon, NK cells are activated when mice are injected with polyinosinic-polycytidylic acid (poly I:C) or other agents that trigger through Toll-like receptors (TLRs), often on plasmacytoid dendritic cells (pDCs) *(27)*. NK cells can also be activated *in vitro* with IFNα/β, IFNγ or low concentrations of IL-2 that are insufficient to induce proliferation *(3,4,28)*. NK cells activated in these various ways display enhanced killing of typical NK-sensitive targets.

Activated NK cells also kill a broader panel of targets, including those that are generally resistant to freshly isolated NK cells, such as the murine P815 mastocytoma cells, and freshly explanted tumors. Many agents that enhance killing by NK cells may also activate T cells, such that even T cell clones may display promiscuous killing of targets that is no longer MHC-restricted (29). This phenomenon

was a source of confusion between NK cells and T cells during the initial characterization of both cell types.

Why IL-2-activated NK or T cells display enhanced killing is not completely understood. Cytokines enhance expression of perforin and granzymes that presumably contribute to more lytic capacity *(30)*. The activated cells express additional receptors that may deliver stimulatory signals (31,*32*), but their contribution to the LAK phenomenon is as yet unclear. Recent studies implicate a receptor termed *NKG2D* (discussed later), although how much this applies to conventional NK cells is not understood (33). Enhanced killing may also be due to adhesion molecules on targets and their appropriate counter-receptors on the effector cells *(34,35)*.

It seems unlikely that high concentrations of IL-2 can be achieved, even locally, to stimulate NK cells *in vivo*. Further, NK cells tend to be early responders in immune responses, whereas the prime reservoir of IL-2 is the activated T cell that produces it somewhat later. Although recent studies suggest that dendritic cells (DCs) can produce IL-2 to enhance NK lytic activity *(36)*, whether such IL-2 concentrations is sufficient to generate LAK cells is unclear. Interestingly, NK cells are apparently normal in mice with a targeted mutation in the IL-2 gene or the IL-2Rα chain *(37,38)*, indicating that IL-2 itself is not required for normal NK cell development.

Paradoxically, NK cells are deficient in mice with a mutation in either IL-2Rβ or IL-2Rγ (39,40,*41*). In brief, the high-affinity IL-2 receptor (IL-2R) is a heterotrimeric receptor complex comprised of α (p55), β (p75), and γ (p64) chains *(42)*. Although individual components may bind IL-2 with low affinity, only the intermediate-affinity $\beta\gamma$ receptor (K_d ~1nM) and the high-affinity $\alpha\beta\gamma$ receptor (K_d ~10 pM) are capable of signaling. Resting NK cells constitutively express IL-2R$\beta\gamma$ *(42,43)* and, upon activation, may induce α and further up-regulate γ chain expression *(42)*. In contrast, resting T cells generally do not express any functional IL-2 receptors, and most naïve T cells do not respond to high concentrations of IL-2 *(44)*.

The discrepancy in NK cell dependence on IL-2 versus IL-2R may be best understood when considering that the IL-2Rγ chain is also termed the *common γ subunit* (γc) because it is a required component of the multimeric receptor complexes for other cytokines, including IL-4, IL-7, IL-9, IL-15, and IL-21 *(45)*, with IL-15 having special relevance to NK cells. IL-15 does not bind to IL-2Rα but instead utilizes a unique IL-15Rα chain to form a high-affinity complex with IL-2R$\beta\gamma$ *(46,47)*. The IL-15Rα chain does not directly signal. Its distribution is widespread on numerous cell and tissue lineages, including NK cells. IL-15 is required for NK cell development and also has anti-apoptotic effects on NK cells (48–50). Interestingly, IL-15 is expressed at very low levels and is difficult to detect *in vivo (51)*. The IL-15Rα chain can present IL-15 in *trans*

to NK cells that can respond through IL-2/15R$\beta\gamma$ *(52)*. For example, IL-15Rα–deficient NK cells develop in bone marrow (BM) chimeric mice in which IL-15Rα–deficient BM was used to reconstitute IL-15Rα–sufficient animals *(53)*. It remains to be established whether *trans* presentation of IL-15 is physiologically important to NK cell function. When NK cells are transferred to NK cell–deficient mice, there is "homeostatic" proliferation *(54,55)*, akin to T cell homeostatic proliferation *(56)*. Like memory CD8$^+$ T cell homeostasis, NK cell homeostasis is IL-15-dependent *(54,55)*, to a more or less degree *(57)*, consistent with the role of IL-15 as a proliferative and anti-apoptotic factor (50). Finally, LAK cells can be generated with IL-15 (58). These studies strongly suggest that LAK cells are generated because high-dose IL-2 acts through the IL-2R$\beta\gamma$ that is expressed with IL-15Rα as components of the constitutively expressed IL-15 receptor complex on resting NK cells. Thus, the LAK cell phenomenon has helped illustrate the importance of IL-15 and its receptor in NK cell biology.

SELECTIVE NK CELL SURFACE MARKERS

The constitutive expression on NK cells of IL-15R complex with IL-2Rβ has practical usefulness because anti–IL-2Rβ (CD122) is sometimes used to identify naïve CD3$^-$ NK cells or deplete them in mice *(59)*. (Anti–IL-15Rα antibodies are not widely available at this time.) Other markers have also proven to be useful for analysis of NK cells.

The NK1.1 molecule is especially important as a marker on mouse NK cells in C57BL strains (12). NK1.1 is encoded by *Nkrp1c* (60), a member of the *Nkrp1* gene family (discussed later). In FACS sorting experiments, the NK1.1$^+$ fraction contained all of the natural killing activity in the spleen (61). *In vivo* administration of the anti–NK1.1 mAb PK136 *(62)* abrogated natural killing but did not affect adaptive immune responses (63). (mAb PK136 is available from the American Type Culture Collection [ATCC], Manassas, VA [HB-191] and is an IgG2a isotype [ATCC, and data not shown], not IgG2b as originally described *[62]*.) Unfortunately, mAb PK136 recognizes an epitope on NK1.1 that is confined to C57BL/6, C57BL/10, and a few other strains *(62)*. Moreover, in Swiss.NIH and SJL/J mice, mAb PK136 recognizes another NKRP1 family member, NKRP1B *(64,65)*. However there are now available NK1.1$^+$ congenic strains, such as BALB.B6-*Cmv1^r* (catalogued as C.B6-*Klra8^{Cmv1-r}*/UwaJ, stock number 002936 at The Jackson Laboratory, Bar Harbor, ME) in which the C57BL/6 allele of NK1.1 has been genetically bred onto the BALB/c background which otherwise lacks the NK1.1 epitope.

A subpopulation of T cells expresses NK1.1 *(66)*. These so-called *NKT cells* express the TCR/CD3 complex and typically are restricted by the nonclassical MHC-I molecule, CD1, which presents glycolipid antigens to NKT cells. NKT cells respond early during the course of an immune response and may potently activate conventional NK cells (67). NKT cells are described in detail in Chapter 17; they can be distinguished from conventional NK cells by expression of TCR/CD3 complex (i.e., conventional NK cells are NK1.1$^+$ CD3$^-$).

The mAb DX5 recognizes a molecule that is coexpressed on most NK1.1$^+$ CD3$^-$ cells and on small populations of splenocytes in NK1.1$^-$ strains, consistent with identification of NK cells in all strains. However, mAb DX5 recognizes the α2 integrin that is widely expressed on other leukocytes, not just NK cells (68,69), and its expression is regulated (70). Nevertheless, the DX5 mAb is helpful in identifying NK cells, especially in mouse strains that do not express the NK1.1 epitope, especially when coupled with other nonpolymorphic markers, such as NKG2D or CD122.

The glycolipid determinant asialo-GM$_1$ is expressed by most if not all murine NK cells and a subpopulation of T cells *(71–73)*. Although the functional significance of this molecule is unknown, polyclonal rabbit anti–asialo-GM$_1$ (Wako Chemicals USA, Richmond, VA) has been used to effectively deplete NK cells. In more recent studies, the anti–NK1.1 mAb PK136 has become the reagent of choice for NK cell depletion because of an available defined mAb and its more restricted reactivity with NK cells (12,61,*62*,63). However, anti–asialo-GM$_1$ remains useful when mAb PK136 cannot be used due to absence of the NK1.1 allele *(62)*.

Human NK cells selectively express CD56. Although it is also found on neural tissues and some tumors, CD56 is generally not expressed by other hematopoietic cells or lymphocytes *(74,75,76)*. This 140 kDa molecule is derived from alternative splicing of the gene encoding neural cell adhesion molecule (NCAM) involved in nervous system development and cell–cell interactions *(77,78)*. CD56 may be involved in adhesion between NK cells and their targets *(79)*, but this function is controversial. Curiously, mouse CD56 is not expressed on hematopoietic cells *(80)*, suggesting that its functional role on NK cells is not conserved. Nevertheless, CD56 is particularly useful as a pan-NK cell marker in humans.

Recent data suggest that human NK cells can be functionally divided according to the level of CD56 expressed (75,*81*). Most human peripheral blood NK cells are CD56^{dim}, a phenotype associated with more cytotoxicity and less cytokine production than a smaller subset of NK cells that express CD56 at higher levels (CD56^{bright}). These cells also tend to differentially express receptors involved in target recognition as well as CD16. The CD56^{bright} cells may undergo a different maturation process than the CD56^{dim} subpopulation (82).

Additional specific markers on NK cells are more thoroughly discussed later under the general topic of NK cell

receptors because they are molecularly defined and their ligands are known.

A MOLECULAR DEFINITION OF NK CELLS?

A precise molecular definition of NK cells has been elusive. There are no known molecules that are exclusively expressed on NK cells and are responsible for critical functions only displayed by NK cells. The NK cell is therefore still defined by function to the exclusion of other cells, a concept first articulated 20 years ago (12).

The defining functional feature of NK cells remains their intrinsic ability to perform natural killing—that is, they spontaneously lyse certain tumor cells in a perforin-dependent manner. Unlike other lymphocytes, NK cells do not express surface immunoglobulin (Ig) or the TCR/CD3 complex and generally do not require MHC-I expression on targets for lysis. Therefore, a current working definition is that an NK cell is a sIg$^-$, TCR/CD3$^-$ lymphocyte that can mediate perforin-dependent natural killing against targets that may lack MHC-I expression.

It is noteworthy that T cells were historically defined by an awkward functional definition (thymus-derived, sIg$^-$ lymphocytes responsible for cell mediated immunity) (83). With the molecular definition of the TCR and coexpressed CD3 molecules, immunologists can now define a T cell as a cell expressing the TCR/CD3 complex (84). The availability of molecular probes and mAbs directed against this complex provides precise definition even in pathologic tissue sections, without the need for functional analysis (cell mediated immunity, thymus dependence). Similarly, a molecular definition should permit unequivocal identification of NK cells to define their role in normal immune responses and pathologic settings.

Presumably such a definition will require further knowledge of the molecular basis for NK cell function, such as the receptors involved in natural killing. On the other hand, one difficulty is that the function that is most attributed to NK cells, natural killing, can be displayed by other cells, such as cytokine-treated T cells. Moreover, NK cells can utilize more than one receptor for target recognition, and individual NK cells can simultaneously express several of these receptors. Thus, there is, as yet, no consensus on the elusive "NK cell receptor" analogous to the TCR.

Meanwhile, most investigators consider the following phenotypes to be surrogate markers of bona fide NK cells. Mouse NK cells are typically NK1.1$^+$ (in appropriate strains), FcγRIII$^+$ (CD16), CD122$^+$, and CD3$^-$. Human NK cells are generally CD56$^+$ and CD3$^-$. Note that these markers are generally correlated with cells having natural killing capacity, but the markers themselves are not required for target recognition. Nevertheless, these markers have helped shape our current concepts of NK cell biology and elaborate their effector functions.

EFFECTOR FUNCTIONS OF NK CELLS

Cytotoxicity

"Natural killing" does not require prior host exposure to the target cells and is mediated by granule exocytosis. Like CTLs, NK cells possess preformed cytoplasmic granules that resemble secretory lysosomes with properties of both secretory granules and lysosomes (85). Granule formation is affected by Lyst, the molecule defective in beige (bg) mice and humans with Chediak-Higashi syndrome (86,87). The granules contain perforin and granzymes (granule enzymes). Perforin, a pore-forming protein, is rendered inactive by association with calreticulin and serglycin, and is activated by a cysteine protease (reviewed in [88]). Granzymes are first produced as inactive proenzymes that are activated by N-terminal cleavage by dipeptidyl peptidase I (DPPI), also known as cathepsin C. However, granzymes are rendered inactive by the acidic pH of the granules. Upon activation by a sensitive target, NK and T cells are triggered to polarize the granules and reposition the microtubule organizing center (MTOC) and Golgi apparatus toward the target (89,90). By a process requiring Rab27a, a GTPase in the Ras superfamily, the granule membrane ultimately fuses with the plasma membrane and externalizes, releasing granule contents. Ca^{++}-dependent polymerization of perforin results in "perforation" of the target cell plasma membrane, leading to apoptosis. This exocytic process can be initiated by specific activation receptors for target cell ligands and is blocked by inhibitory receptors (described in more detail later).

Human T and NK cells also express another pore-forming molecule, granulysin, that is related to a family of saposin-like proteins that includes NK-lysin, found in porcine T and NK cells (91). Based on crystallographic studies, these molecules appear to be active against bacteria, fungi, and tumor cells by charge association with target membranes and subsequent disruption, leading to target cell lysis (92). Granulysin, however, is not expressed in mouse cytotoxic lymphocytes.

Natural killing was first assessed with a simple in vitro assay for target membrane integrity that is still used today, the standard ^{51}Cr-release assay (93). The prototypical NK-sensitive tumor target for mouse NK cells is YAC-1 (TIB-160 from ATCC), a thymoma derived from Moloney virus–infected A strain mice, whereas the standard human target is K-562 (CCL-243 from ATCC), an erythroleukemic cell line derived from a human patient with chronic myelogenous leukemia in blast crisis (94). Although a small amount of label is released spontaneously, much larger amounts are released into the supernatant when membrane integrity is disrupted during the killing process. In most experiments, the data are represented according to a standard formula that takes into account spontaneous

and maximal release of ^{51}Cr from labeled targets. Varying numbers of effector cells are often used as indicated by effector-to-target (E:T) ratios. Maximal killing by enriched, activated NK cells usually occurs with E:T ratios of <10:1, whereas unfractionated, freshly isolated peripheral blood or splenocyte preparations usually require E:T ratios of >100:1. Even at high E:T ratios, not all targets are killed, with % specific cytotoxicity typically ranging from ~10% with fresh NK cells to ~80% with activated NK cells. Note that perforin-dependent leakage of ^{51}Cr is mostly complete at about one hour; 4-hour assays are standard. Longer periods may assess other apoptotic processes, such as Fas-induced apoptosis.

While ^{51}Cr-release is still the standard assay, there are also numerous nonradioactive tests for perforin-dependent killing, including release of intracellular enzymes or use of fluorochromes for target labeling *(95–97)*. The release of granule components, including granzymes, into the supernatant can be determined by conversion of an appropriate substrate, such as granzyme A–mediated cleavage of alpha-N-benzyloxy-carbonyl-L-lysinethiobenzyl ester (BLT) (also known as *BLT-esterase activity*) *(98)*. New assays have been developed that exploit the association of cytotoxic granules with lysosomal-associated membrane protein-1 (LAMP-1, CD107a) on the luminal side. During granule exocytosis, the granule fuses with the plasma membrane, resulting in externalization of the granule membrane and exposing CD107a on the surface as an indicator of NK cell activation (99,*100,101*). By contrast to other assays, the CD107a assay provides the opportunity for measuring individual NK cell responses, isolating triggered NK cells *(102)*, and possibly simultaneously assessing other NK cell functions.

Activated NK cells and CTLs also induce perforin-independent target cell killing by expressing Fas ligand (TNF superfamily 6, TNFSF6) that binds Fas (TNF receptor SF 6, TNFRSF6) on the target, triggering apoptosis *(103–108)*. Similarly, other tumor necrosis factor (TNF) superfamily members, such as TNF-related apoptosis-inducing ligand (TRAIL, TNFSF10), can be involved in related processes *(109)*. However, mice deficient in TNF family members or their receptors may manifest significant alterations in lymphoid organogenesis and splenic architecture, and NK cell number and function *(110–112)*, such that the relative contributions of these pathways to NK cell function are incompletely understood. On the other hand, NK cells from mice deficient in perforin, granzymes, or molecules involved in granule formation or exocytosis (Lyst, Rab27a) demonstrate profound defects in natural killing *in vitro* (113,*114*,115). Similar defects have been found with NK cells derived from patients lacking these components *(116)*. Thus, the available data strongly suggest that granule exocytosis is the predominant mechanism for natural killing.

Cytokine Production

When exposed to NK-sensitive targets or cross-linking of receptors, NK cells also produce cytokines, including interferon-γ (IFNγ), TNF-α, and granulocyte-macrophage colony stimulating factor (GM-CSF) (*117*,118,119). They can also be similarly triggered to produce chemokines, such as RANTES, lymphotactin, MIP-1α and MIP-1β (120). NK cells also produce a similar repertoire of cytokines in response to other cytokines. For example, in response to IL-12, NK cells produce IFNγ (121). Similarly, NK cells respond to type I IFNs (IFN$\alpha\beta$), which are generated by *in vivo* administration of poly-I:C and other TLR ligands. Cytokine-stimulated responses tend to be independent of expression of target recognition receptors such that they may obscure detection of specific activation *in vivo* (120).

In immune responses, NK cell production of cytokines should occur relatively early and may thereby influence the subsequent adaptive immune response. Moreover, their responses to cytokines are regulated by complex interacting pathways *(122)*. A more in-depth description of NK cell cytokine responses and production is discussed in the upcoming sections on NK cell responses during infections and interactions with DCs.

NK CELL RECOGNITION OF TARGETS

Intense interest in the past two decades devoted to delineation of the receptors responsible for target recognition and activation yielded several surprises. In contrast to CTL recognition: 1) The NK cell receptors are germline-encoded, and the receptors are not strictly "clonotypic" as defined in terms of clonotypic TCRs (unique receptor only expressed by the rare effector clone and its progeny.) 2) Individual NK cells express both inhibitory and activation receptors for target recognition and often simultaneously express several different receptors of each type. 3) The receptors are often promiscuous and frequently have overlapping specificities. 4) NK cell receptors specifically bind MHC-I molecules, but they are functionally and structurally distinct from other receptors that bind MHC-I (i.e., TCR and CD8). In the following sections, we will discuss NK cell receptors involved in target recognition by first considering the relationship between target susceptibility to natural killing and expression of MHC-I.

Target Cell MHC-I and NK Cells: The "Missing-Self" Hypothesis

Whereas initial studies suggested that natural killing was "MHC-unrestricted" (12), substantial progress in understanding NK cell recognition began with ascertaining the role of MHC-I molecules in natural killing (Figure 16.1).
FIGURE 16.1 MHC-I expression on targets is inversely related to natural killing. Targets expressing MHC-I are more resistant to lysis by NK cells than targets lacking MHC-I expression, such as following viral infection. This is the exact opposite of the requirements for MHC-I–restricted CTLs that recognize foreign peptides presented by MHC-I. As depicted, viruses may evade T cells by down-regulating MHC-I, but infected cells should then become more susceptible to NK cells.

Kärre and colleagues discovered that MHC-I–deficient tumors remained susceptible to *in vivo* rejection, apparently by NK cells (123). Conversely, target cell expression of MHC-I molecules appeared to have a protective effect against NK cell–mediated lysis *in vitro*. A number of methods, such as IFNγ treatment, to upregulate MHC-I correlated with target protection, but other effects could not be excluded *(124)*. There was significant variability in capacity of specific MHC-I molecules to protect targets (125,126), *in vitro* culture conditions could influence NK cell specificities (127), and the specificities of individual human NK cell clones were not easily assignable to specific MHC-I alleles (128). Thus, the MHC-I effect on natural killing was controversial for some time.

Several groups, however, observed that MHC-I–expressing parental targets were resistant to natural killing, whereas mutants selected for absence of MHC-I expression became susceptible (Figure 16.1). The parental (resistant) phenotype could be restored by reconstitution of MHC-I expression by transfected expression of molecules to correct the defect, such as β_2-microglobulin (β2m) (129) or transporter associated with processing (TAP) *(130,131)*. Studies utilizing mice with a targeted mutation in the β2m gene added substantial support to the MHC-I protective effect, because normal expression of MHC-I heavy chains requires β2m (132,*133*). β2m-deficient lymphoblasts were susceptible to lysis by normal NK cells. Moreover, β2m$^{-/-}$ BM transplanted into otherwise syngeneic normal hosts was rejected by recipient NK cells (*133*,134). These results resembled hybrid resistance, whereby NK cells in irradiated F_1 hybrid mice reject parental BM transplants (135). Hybrid resistance is regulated by parental determinants that are genetically linked to the MHC-I region, H-2D *(136)*. Thus, in several distinct NK cell recognition systems, the target cell expression

of certain MHC-I molecules correlated with resistance to natural killing, whereas absence of MHC-I was associated with susceptibility to NK cells.

NK cells, therefore, have a different relationship to target cell MHC-I molecules than MHC-I–restricted CTLs (Figure 16.1). Strictly speaking, NK cell lysis is "MHC-unrestricted" (12), at least as far as MHC restriction is precisely defined for T cells having a requirement for specific self-MHC molecules presenting a given peptide antigen *(137)*. However, the term *MHC-unrestricted* (and its synonyms) is now somewhat outdated because it implies, when defined in a broader sense, that MHC plays no role in NK cell cytotoxicity. Avoidance of these terms will minimize confusion concerning the relationship of target cell MHC-I molecules with NK cell specificity.

As initially observed and discussed by Kärre in the "missing-self" hypothesis, the relationship between target expression of MHC-I and resistance to natural killing highlights a fundamental distinction between NK and T cells (138) (Figure 16.1). Whereas T cells are triggered by detection of "foreign" epitopes, Kärre proposed that NK cells are equipped to detect the absence of "self" epitopes. The "missing self" hypothesis suggests that NK cells survey tissues for expression of MHC-I molecules that are normally ubiquitously expressed and that chronically prevent NK cell activity. If MHC-I molecules are down-regulated or mutated, NK cells are released to lyse the target. The generally opposite requirements of NK and T cells for target cell MHC-I expression may be physiologically important. Several pathogens, including herpes viruses, possess mechanisms that prevent the normal expression of MHC-I molecules on infected cells, providing means to avoid MHC-I-restricted T cells *(139)*. Moreover, tumorigenesis is frequently associated with alterations in MHC molecules, either mutation in structural genes or decreased expression, again leading to escape from T cell surveillance *(140–142)*. In either case, however, the MHC-I–deficient cells should become more susceptible to natural killing. The host therefore is endowed with two components (T and NK cells) with opposing requirements for self–MHC-I expression. This fail-safe system should eliminate pathologic processes that might otherwise evade immune responses by any alteration of MHC-I expression (either increased to avoid NK cells or decreased to avoid T cells). The missing-self hypothesis thus provided a teleological explanation for MHC-I–associated resistance, creating a framework for initial attempts to define NK cell recognition of their targets.

Current Principles of Target Recognition by NK Cells

The MHC-I–associated resistance to natural killing inspired a panoply of models and their variants to explain not only resistance but also natural killing (125). The *target*

interference or *masking* model predicted that a single NK cell receptor activates natural killing when it engages its putative target cell ligand (138). MHC-I molecules mask the putative target cell ligand and block its recognition by the NK cell receptor. This hypothesis was initially favored because it was the simplest *(143)*. Moreover, it made the most sense if one considered that NK cells should have only one defined receptor analogous to the TCR. The *effector inhibition* or *inhibitory receptor* model suggested that NK cells are inhibited from natural killing by an NK cell receptor that binds MHC-I on the target and delivers negative signals overriding a default pathway of activation (138).

Although the target interference model has not been refuted, it is now known that NK cells express inhibitory receptors specific for MHC-I (144) (Figure 16.2). All known inhibitory receptors contain cytoplasmic immunoreceptor tyrosine-based inhibitory motifs (ITIMs) consisting of V/I/L/SxYxxL/V (single amino acid code where x is any amino acid) *(145)*. Ligand engagement leads to phosphorylation of the ITIM, presumably by a Src family tyrosine kinase. Two phosphorylated ITIMs are generally required for recruitment of the intracellular tyrosine phosphatase, SHP (SH2-containing protein tyrosine phosphatase)-1 (also known as SHP; hematopoietic cell phosphatase, HCP; protein tyrosine phosphatase 1C, PTP1C; and protein-tyrosine phosphatase, nonreceptor-type, 6, PTPN6). Other phosphatases, such as SHP-2, and SHIP (SH2-containing inositol polyphosphate 5-phosphatase) can also be recruited to phosphorylated ITIMs, depending on the receptor and cell, but the predominant phosphatase recruited by the NK cell inhibitory receptors appears to be SHP-1, which is activated by ITIM recruitment, leading to inhibition of NK cell activation.

MHC-I inhibitory receptors on NK cells have either of two general structures *(146)*: (a) C-type lectinlike receptors that are disulfide-linked dimers with type II transmembrane topology (extracellular carboxyl termini); these receptors are encoded in the NK gene complex (NKC) and were first described in mice. (b) Ig-superfamily receptors that have type I transmembrane orientation. These molecules are encoded in a different genetic region, termed the *leukocyte receptor complex* (LRC), and were first described in humans. Although ongoing studies indicate that both structural types of receptors are expressed on mouse and human NK cells, the lectinlike receptors (Ly49 receptors) are the major MHC-specific inhibitory receptors in mouse, whereas the Ig-like receptors (killer Ig-like receptors, KIRs) predominate in human.

The absence of MHC-I does not always result in killing, indicating that release from inhibition does not result in activation by default (Figure 16.2B). Instead, it was suggested that NK cells express two functionally different receptors for target cell ligands *(147,148)*. In this *two receptor model*, one receptor would be capable of interacting with a target cell ligand for activation (Figure 16.2C) whereas
FIGURE 16.2 Current principles of target recognition by NK cells. Pictured are several scenarios of interactions between ligands on targets (top row) and receptors on NK cells (bottom row). Successful activation of NK cells is shown by the dashed upward line. **A:** Targets expressing MHC-I are resistant to lysis by NK cells because of MHC-I–specific inhibitory receptors. **B:** The absence of MHC-I (or lack of receptors specific for target MHC-I, not depicted) does not automatically result in target killing. **C:** Activation receptor engagement is required to trigger target killing. **D:** In the situation where both inhibitory and activation receptors are engaged, the inhibitory receptor effect often dominates and no killing occurs. **E:** In the induced-self model, induced expression of NKG2D ligands can overcome the inhibitory influence of MHC-I, resulting in NK cell activation. **F:** Normal epithelium masks ligands for NK cell activation receptors at the tight junctions. **G:** Under pathologic situations, the epithelial architecture may be disrupted, leading to ligand exposure. (Not depicted are inhibitory ligands at the epithelial tight junctions, which may inhibit NK cells when they transmigrate through epithelial barriers.) NK cells can also recognize pathogen encoded ligands on infected cells (not shown but similar to C or E).

MHC-I–specific receptor inhibits activation by negative signaling. In many circumstances, the inhibitory receptor effect dominates over the activation receptor (Figure 16.2D), but the outcome is likely to reflect the integration of signals from both types of receptors that can be affected by ligand expression or affinities (not shown).

Many NK cell activation receptors are encoded in the NKC and LRC, having similar structural properties as their inhibitory receptor counterparts except for absence of cytoplasmic ITIMs. The activation receptors typically do not have signaling motifs in their cytoplasmic domains but contain charged transmembrane residues that facilitate association with reciprocally charged residues in the transmembrane domains of signaling chains having immunoreceptor tyrosine-based activation motifs (ITAMs) analogous to ITAMs in TCR and BCR complexes (D/ExxYxxL/Ix_{6-8}YxxL/I). NK cells express three ITAM-containing signaling chains: CD3ζ, FcεRIγ, and DAP12 (DNAX associated protein of 12 kDa, also known as killer activating receptor associated protein, KARAP; Ly83; tyrosine kinase binding protein, Tyrobp). NK cells also express DAP10 (hematopoietic cell signal transducer, Hcst) that lacks ITAMs and instead contains a motif for recruitment of phosphatidylinositol 3-kinase (PI3K). The signaling chains typically endow the activation receptors with two major functions, capacity for cell surface expression, and signal transduction.

To date, the ligands for activation receptors fall into several major groups. One group is encoded by the host and expressed normally. Presumably, NK cell attack against cells expressing these ligands is limited by inhibitory receptors (Figure 16.2D). Another group of ligands is characterized by their relatively low expression on normal tissues and is induced expression under "stress" conditions (Figure 16.2E). Other ligands become exposed when tissue architecture is altered (Figure 16.2F,G). Because the ligands are encoded in the normal host genome, they would be recognized by the NK cell as indicators of pathologic conditions, either as "induced-self" or "exposed-self," respectively. Another group of ligands is found on infected cells and is encoded by the pathogen (not shown but similar to Figure 16.2C or E).

Finally, many other NK cell receptors have been discovered that do not fall neatly into the categories described here. Some appear to have similar inhibitory function as the MHC-specific inhibitory receptors but bind non-MHC ligands, strongly suggesting MHC-independent self-recognition. The function of these and other receptors remain under intense investigation.

In the following sections, we will describe the major receptors on NK cells in detail by first discussing the MHC-specific inhibitory receptors, which helped elucidate NK recognition paradigms, before delving into MHC-independent inhibitory receptors, activation receptors, and other receptors found on NK cells.

NK CELL RECEPTORS

Inhibitory NK Cell Receptors Specific for MHC-I Molecules

Mouse Ly49

The Ly49A receptor was the first inhibitory MHC-I–specific receptor to be described in molecular terms (144,*149*). Ly49A was originally identified as a molecule of unknown function on a T cell tumor *(150,151)*. It is a disulfide-linked homodimer (44 kDa subunits), with type II membrane orientation, and has C-type lectin superfamily homology (152,153). Previously termed *Ly49*, it is now appreciated that Ly49A (Klra1) belongs to a family of highly related molecules (*148,154,155*,156). Indeed, genetic analysis revealed that the genes for Ly49A and NK1.1 are linked in the NKC (Figure 16.3), leading to studies indicating that Ly49A is constitutively expressed on a distinct subpopulation (20%) of NK cells in C57BL/6 mice (156).

Multiple lines of evidence indicate that Ly49A is an inhibitory receptor specific for MHC-I, particularly H2D^d: 1) Functional analysis: The Ly49A$^+$ NK cell subset could not lyse a large panel of targets that were lysed by Ly49A$^-$ NK cells; this phenotype was related to MHC-I expression of certain H2 haplotypes (144,*157,158*). Transfected expression of H-2D^d selectively rendered a susceptible target resistant to natural killing by Ly49A$^+$ NK cells. Moreover, killing through disparate stimuli by Ly49A$^+$ NK cells was also inhibited. 2) Cell binding: Ly49A$^+$ tumor cells bound specifically to immobilized MHC-I molecules *(159)* and to H-2D^d-transfectants *(160)*. 3) Antibody blocking: F(ab')$_2$ fragments of mAb directed against either Ly49A or the α1/α2 (but not the α3 domain) of H-2D^d reversed resistance in killing experiments (permitted lysis) and blocked the cell binding assay (144,*157,159,160*). 4) *In vivo* expression: The apparent level of Ly49A expressed per NK cell was down-regulated in MHC congenic and transgenic (Tg) mice expressing H-2D^d (161,*162,163*). This was not due to negative selection because the percentage of Ly49A$^+$ NK cells was unchanged. 5) Gene transfer: Primary NK cells and T cells expressing a Ly49A transgene and a Ly49A-transfected NK cell line were specifically inhibited by H-2D^d (164,165). 6) Inhibition by Ly49A is ITIM-dependent, based on gene transfer of mutant Ly49A molecules (165). 7) H2D^d tetramers bind Ly49A transfectants (166). 8) Ly49A tetramers bind H2D^d on transfected cells (167,*168*). 9) Biophysical studies: Recombinant Ly49A binds recombinant H2D^d in surface plasmon resonance (SPR) studies with $K_D = \sim 2.0$ μM *(169)*. 10) Crystallography: The structure of Ly49A complexed with H2D^d was determined (170). 11) Less extensive studies also indicate that Ly49A recognizes H-2D^k and H2D^p (144,161,166,*171*). Therefore, Ly49A is an MHC-I–specific receptor for H-2D^d, H-2D^k and H2D^p.

NK Gene Complex (NKC)

Leukocyte Receptor Complex (LRC)

FIGURE 16.3 The genomic organization of the NKC and LRC in humans and mice. The figures are not drawn to scale, but the organization is accurate. The grey shading is coordinated to represent related genes. Question marks indicate genes whose precise location is not known. An "X" indicates genes not homologous to other aligned genes. Double slashes represent large genomic distances. Note that most but not all genes are expressed on NK cells. Many remain orphan genes because the functions of their gene products have not been determined. Modified from (246).

The nature of the Ly49A interaction with MHC-I, however, is fundamentally different from TCR/MHC-I interactions because the former appears to be independent of the specific peptide bound by H2D^d (172,*173*). However, bound peptides are required for appropriately folded MHC-I molecules that can be recognized. Despite its structural homology to C-type lectins that are carbohydrate-binding proteins *(174,175)*, Ly49A does not have the residues for coordinate binding to Ca^{++} that is required for lectin binding. Notwithstanding initial studies to the contrary *(176–178)*, Ly49A binding to its MHC ligands is not carbohydrate-dependent because Ly49A functionally interacts with H2D^d molecules with mutations in all of its Asn-linked residues *(179)*. Further, SPR reveals binding between bacterially produced H2D^d (lacking carbohydrates) and Ly49A *(169)*. Although carbohydrates could still affect receptor-ligand interactions, such as their affinities or kinetic parameters, this has not been studied in depth.

The x-ray crystallographic structure of lectinlike domain of Ly49A complexed to H2D^d was solved to 2.3Å resolution (170) (Figure 16.4). Two interaction sites were seen: site 1 involving the "left" side of the peptide-binding cleft of H2D^d and a wedgelike site 2 involving the undersurface of the peptide-binding cleft. The residues in Ly49A involved in binding either ligand site are overlapping. Mutational analysis revealed that Ly49A binds site 2, where it contacts α1, α2, and α3 of H2D^d and β2m (167,*169,180*). This site is near Asn80, an Asn-linked glycosylation site conserved in all MHC-I molecules, leaving open the issue of whether carbohydrates could affect the interaction. These studies also provide a structural explanation for species-specific β2m requirements *(181)* as revealed by functional studies. Thus, Ly49A recognizes site 2 in the MHC molecule in

terms of *trans* recognition between the NK cell receptor and target cell MHC-I molecule.

Recent studies strongly suggest that Ly49 molecules also bind MHC in a *cis* interaction between receptor and ligand on the NK cell itself (182,183). For example, an MHC ligand for Ly49A or Ly49C on the same cell prevents binding of MHC tetramer (182,183). If the cells are briefly exposed to mild acidic conditions, MHC-I expression is lost (due to disruption of the noncovalently linked MHC-I heterotrimer), and Ly49A binding to cognate MHC-tetramers is restored. This *cis* interaction is dependent on site 2 residues in the MHC molecule. These findings may help explain the observation that the presence of self-MHC ligands leads to "down-regulation" of Ly49 expression, as previously noted on primary NK cells in MHC congenic mice (161,*162,163*). *Cis* interactions may also explain functional differences in NK cells that do or do not express MHC ligands in Tg mice that are mosaic for MHC expression (184,*185*). At the moment, however, the physiologic importance of *cis* interactions is incompletely understood but may be relevant because NK cells do express MHC-I molecules (as well as MHC-specific receptors).

Other Ly49 receptors are also MHC-I-specific inhibitory receptors, although they have been less well studied than Ly49A. First noted by Southern blot analysis and cDNA cloning, genome sequence analysis now reveals 16 complete Ly49 genes in C57BL/6 mice (152,153,*154,155,186*). Notably, Ly49C has broad specificity for H2 alleles as revealed by tetramer staining and is the only known receptor specific for an H2^b haplotype allele (H2K^b) in C57BL/6 mice (166,183,*187*). It is recognized by two mAbs, 5E6 which also binds Ly49I and 4LO3311 which has exquisite specificity for Ly49C *(188–190)*. Ly49G2 (also known as

FIGURE 16.4 Crystal structures of NK cell receptors in complex with their ligands. **A:** Mouse Ly49A bound to H2D^d at site 1 (PDB ID = 1QO3) (170). Site 2 interaction is not shown. **B:** Mouse Ly49C bound to H2K^b at site 2 (PDB ID = 1P1Z) (193). Ly49A interaction with site 1 of H2D^d is very similar (170). **C:** Human LILRB1 (LIR1, ILT2) bound to HLA-A2 (PDB ID = 1P7Q) (266). Figures were produced using the UCSF Chimera package from the Resource for Biocomputing, Visualization, and Informatics at the University of California, San Francisco (www.cgl.ucsf.edu/chimera) *(776)*. The structures are viewed from the side with the NK cell positioned at the top of the figure and the target cell surface at the bottom. The MHC molecules are oriented similarly. (See color insert.)

LGL-1, recognized by mAb 4D11) binds H2D^d in tetramer binding experiments, and conversely, H2D^d binds several different Ly49 receptors, indicating the overlapping and promiscuous specificities (166,*191*). Finally, there is evidence for alternative splicing of the Ly49 genes *(155,192)*, though their importance has not been elucidated.

X-ray crystallographic studies have indicated that Ly49C binds H2K^b in a manner similar to Ly49A interaction with H2D^d (193) (Figure 16.4). Only a site 2 interaction was seen with the contact residues showing a similar but distinct topology to the Ly49A-H2D^d interaction. Interestingly, however, peptides bound to H2K^b clearly affect functional interactions with Ly49C (194) and affinities as measured by SPR (193). However, Ly49C does not directly engage the peptide, indicating long-range effects. Thus, Ly49 receptors bind their MHC ligands in a structurally related manner.

Individual NK cells may express multiple Ly49 receptors simultaneously *(163,190,195)*, often (but not always) two or more Ly49s, suggesting that individual NK cells may be inhibited by more than one MHC-I molecule. Detailed ontogenetic studies demonstrate that the total repertoire of Ly49 expression does not reach adult levels until sometime after 3 weeks of age, concomitant with attainment of full NK cell cytolytic activity (196). Thereafter the expression of Ly49 receptors is generally thought to be fixed and stable on an individual NK cell.

The expression of Ly49 receptors appears to occur in a stochastic manner. There is evidence for monoallelic expression of Ly49 receptors (expression from one chromosome), initially described as *allelic exclusion,* a term that has fallen out of favor because it has a specific meaning

and mechanism for TCRs and B cell receptors *(197)*. Recent studies indicate that Ly49 genes possess bidirectional, overlapping promoters, directed in opposite orientations (198). Factors driving transcription in one direction prevent binding of other factors driving transcription in the opposite direction. Directionality and monoallelic expression may also be controlled by DNA methylation *(199)*. A "probabilistic" model has been proposed to explain these findings, and it may also explain the stochastic expression of Ly49 genes and their stable expression.

The description of the Ly49 receptors thus far is based on analysis of the C57BL/6 alleles, but the Ly49 receptors display extensive polymorphism. The Ly49 family is encoded in the NKC located on mouse chromosome 6 with the syntenic human region being chromosome 12p13.2 (*148*,156,200,*201*) (Figure 16.3). Although the NKC also contains genes for other lectinlike receptors, the Ly49 genes are clustered with the exception of *Ly49b*. Corresponding to restriction fragment length polymorphic (RFLP) variants originally detected with the Ly49A cDNA (156), there is significant allelic polymorphism of the Ly49 cluster between inbred mouse strains with differences in gene number as well as alleles for the *Ly49* genes *(186,202–205)*. Genomic sequence analysis shows 8 putative *Ly49* genes in BALB/c mice, and 19 potential *Ly49* genes in 129S6 mice (of which at least 9 appear to be pseudogenes), in contrast to C57BL/6 mice. There are also multiple alleles for individual *Ly49* family members *(186,197,204–206)*. Thus, there is significant polymorphism of the *Ly49* molecules.

The polymorphisms raise practical issues when studying NK cells. mAbs specific for one Ly49 allele may bind

another molecule with a different function or specificity in another mouse strain *(207,208,209)*. Perhaps the profound allelic differences are to be expected because the Ly49 molecules bind highly polymorphic MHC molecules.

Human Killer Immunoglobulinlike Receptors (KIRs)

In contrast to mouse NK cells, human NK cells can be cloned by limiting dilution in the presence of irradiated feeder cells, phytohemagglutinin, and IL-2, leading to establishment of short-term NK cell clones that have differences in target killing and surface molecules. mAbs were isolated that reacted specifically with these clones; reactivity correlated with the capacity of the clones to kill certain tumors, and the mAbs affected cytotoxicity. This general approach led to the identification of the human NK cell receptors.

A series of studies, for example (210,211,*212*), showed that the mAbs GL183 and EB6 identify serologically distinct 55 kDa or 58 kDa molecules, initially termed *p*58. These molecules had several features: 1) Selective expression on overlapping NK cell subsets. 2) Expression on NK cell clones correlated with expression of certain HLA class I alleles on resistant targets. 3) A target susceptible to a given NK cell clone bearing p58 molecules reactive with either mAb was made resistant by transfection of cDNAs encoding certain HLA-C molecules. 4) The otherwise resistant HLA-C-transfected targets could be lysed in the presence of the appropriate anti-p58 mAbs. The mAb effect occurred with $F(ab')_2$ fragments, suggesting that the interaction between p58 and an HLA class I molecule on the target cell inhibits the NK cell. Thus, the p58 molecules displayed features consistent with a role as inhibitory human NK cell receptors specific for MHC-I, analogous to the mouse Ly49A receptor that was being studied in parallel as described earlier.

Other studies noted that NK cell specificity was skewed when the NK cells were grown in the presence of cells bearing allo-MHC determinants (213,*214*). This specificity correlated with reactivities that mapped to paired residues at position 77 and 80 in the α1 domain of HLA-C. All known HLA-C molecules could be divided into two groups, one with Asn77-Lys80 (HLA-Cw2, Cw4, -Cw5, -Cw6) and the other with Ser77-Asn80 (HLA-Cw1, -Cw3, -Cw7, -Cw8). Indeed, transfection analysis showed that p58 specificity for HLA-C molecules was related to expression of the EB6 epitope for the former (specificity 1), whereas the latter was related to the GL183 epitope (specificity 2) on the NK cell clones (213,*215,216*). Thus, human NK cell receptors showed promiscuous specificity that was dependent on residues 77 and 80 in HLA-C.

The NKB1 (p70) molecule was serologically similar to p58 molecules with regard to subset expression and correlation of expression on NK cell clones to specificity for HLA class I (217,*218*). In contrast to p58 molecules, however, NKB1 had a distinct M_r (70 kDa) and specificity for HLA-B. The NKB1$^+$ clones were specifically inhibited by targets expressing transfected HLA-Bw4 molecules, and the anti-NKB1 mAb reversed the inhibition. Analysis of informative HLA-B alleles showed that this specificity was conferred by a region in the α1 domain overlapping the area on HLA-C recognized by p58 molecules *(219)*. Finally, HLA-A3, -A11-specific receptors have similar properties to p58 and NKB1 except that they appear to be disulfide-linked dimers termed p140 *(220)*, whereas others have found that a monomeric HLA-A3–specific receptor resembles NKB1 *(221)*. Thus, representative alleles of all classical HLA class I loci are capable of inhibiting NK cells through p58/NKB1/p140 receptors, although HLA-B and -C alleles dominate human NK cell specificities, and it is not yet known whether there are receptors reactive with *each* HLA allele.

When the cDNAs for the p58 and NKB1 molecules were cloned, they were surprisingly found to encode type I integral membrane proteins with Ig-like domains (222,223,*224*) rather than features similar to the lectinlike Ly49 family of type II receptors. Subsequently, multiple cDNAs were identified *(212,214,218,225–229)*.

The Ig-like receptors are now collectively known as killer Ig-like receptors (KIRs) or CD158 *(230)*. The KIR nomenclature is based on whether the receptor has two or three Ig-like external domains (KIR2D or KIR3D, respectively), and possession of a long (L) or short (S) cytoplasmic domain. In general, the L forms are inhibitory because they contain ITIMs, whereas the S forms appear to be activation receptors (discussed later). Each distinct receptor is also designated by a number. The KIR2DL1 (CD158a, p58.1) molecule thus bears the original EB6 epitope and is specific for HLA-C (Asn77-Lys80), whereas KIR2DL2 (CD158b, p58.2) has the GL183 epitope and is specific for HLA-C (Ser77-Asn80). KIR3DL1, originally named NKB1, is specific for HLA-Bw4. KIR3DL2 was originally named p140 and has HLA-A specificity.

There is unequivocal evidence that the KIR2DL and KIR3DL molecules are inhibitory HLA class I–specific receptors. In addition to the data with NK cell clones and mAbs mentioned earlier, the following have been described: 1) KIR bind directly to HLA class I: Soluble KIR2DL-Fc fusion proteins bind cells expressing the appropriate transfected HLA class I alleles (231,*232*). In addition, a soluble KIR2DL molecule containing only the extracellular domain bind specifically to its HLA-C ligand in solution *(233)*. 2) Gene transfer of KIR: KIR2DL specificity and inhibitory function were transferred when KIR2DL cDNAs were transiently expressed with vaccinia constructs in human NK cell clones (231). Similarly, Tg expression of KIR2DL2 conferred inhibition of rejection of BM expressing Tg HLA-Cw3 *(234)*. 3) SPR measurements indicate that the KIRs bind their HLA ligands with $K_d = \sim 10$ μM *(235,236,237)*. Binding is affected by peptide bound by HLA molecule (*237*). Through histidine-rich

domains, the KIRs bind Zn^{++}, which affects KIR multimerization and binding kinetics to HLA ligands (*238,239*). 4) Crystallographic studies demonstrate KIR2DL1 (2.8 Å resolution) and KIR2DL2 (3.0 Å resolution) interactions with their cognate HLA ligands (236,240). Thus, KIR molecules are clearly MHC-I–specific inhibitory receptors on NK cells.

Interestingly, the KIR molecules bind HLA class I molecules in a manner analogous to recognition of MHC by TCRs (Figure 16.5). In particular, both KIR2DL1 and KIR2DL2 use surface loops near their interdomain hinge regions to bind their cognate HLA-C ligands (Cw4 and Cw3, respectively) with a footprint overlying the "right" side of the peptide-binding cleft (when viewed from the "top" in standard depictions of MHC-I molecules) (236,240). The receptors bind both α1 and α2 helices with interactions between KIR2DL1 and Lys80 of HLA-Cw4 and between KIR2DL2 and Asn80 of HLA-Cw3. These interactions with residue 80 of the HLA-C molecules would be lost if the reciprocal residues were swapped, accounting for the previously described HLA-C groupings and KIR specificities in functional studies (213,*214*) and mutational analysis indicating that residue 80 is more significant for KIR interaction than residue 77 *(241–244)*. Although neither KIR2DL molecule has extensive contacts with peptides bound to HLA-C, KIR2DL interactions with HLA-C imposes physical constraints on the p8 position of the peptide, accounting for observed peptide preferences in functional studies *(245)*. Thus, KIRs and Ly49s bind their MHC ligands in markedly different ways, despite their analogous functions as MHC-specific inhibitory receptors.

Also unlike the Ly49s, the KIRs are encoded in the leukocyte receptor complex (LRC) on human chromosome 19q13.4 that encodes many other Ig-like receptors (Figure 16.3); the KIR genes are clustered toward the telomeric end of the LRC (246). Interestingly, the mouse LRC on chromosome 7qA1 does not include genes for KIR-like molecules that instead are encoded on the X chromosome *(247,248)*. However, like the Ly49s, the KIRs display remarkable polymorphism (249,250). (See http://www.ebi.ac.uk/ipd/kir/index.html for updated database.) The human KIR complex demonstrates considerable haplotype diversity (249,250). Two major types of haplotypes have been described. Haplotype A contains nine genes that appear to be fixed but may display extensive allelic polymorphism. Haplotype B shows more widespread variation in gene content, with more than 20 different haplotypes described. Regardless, the *3DL3*, *3DP1*, *2DL4*, and *3DL2* genes (P designates pseudogene) and possibly *2DL2* (or *2DL3*) and *3DL1* (or *3DS1*) have been termed *framework loci* because they appear to be present in all haplotypes described thus far. With such extensive polymorphism, a large number of different KIR genotypes have already been described, and they are distributed differently in the various ethnic populations. Studies of these genetic variants have not only provided clues to new receptors and ligand specificities, but also valuable links to the role of NK cells and their
FIGURE 16.5 Additional structures of NK cell receptors in complex with their ligands. **A:** Human KIR2DL2 with HLA-Cw3 (PDB ID = 1EFX) (236). Two KIR molecules are apparent in the crystal structure with only one molecule (KIR A) contacting the HLA molecule. In this view, the D2 domain of the KIR A obscures the D1 domain behind it. **B:** Human NKG2D with MICA (PDB ID = 1HYR) (412). The figures were produced and oriented as described in Figure 16.4. (See color insert.)

receptors in disease pathogenesis and, more broadly, human evolution.

Recent studies also suggest that understanding of KIR specificities may be clinically useful. For example, in BM transplantation for leukemia, donor NK cells may help provide an anti-leukemia effect against residual malignant cells in the recipient if there is a mismatch between the donor and recipient HLA alleles (251). However, this observation has not been uniformly observed in other transplant centers (252,253,254). It is possible that differences in transplantation protocols may influence this effect or that there are additional parameters affecting NK cell tolerance (255).

Combinations of KIR and HLA genotypes may affect clinical outcomes (250,256,257,258,259). For example, hepatitis C virus (HCV) can cause a chronic, persistent infection in some patients, whereas other patients resolve the infection. Interestingly, patients who are homozygous for a KIR gene (KIR2DL3) are more likely to clear HCV if they are also homozygous for the HLA-C alleles recognized by KIR2DL3 (257). In papillomavirus infections that can go on to produce cervical carcinomas, resistance to developing neoplasia is similarly associated with genotypes encoding certain KIR-HLA receptor-ligand pairs *(258)*. While the means by which certain KIR-HLA combinations lead to protection is a topic under current investigation, the emerging data nonetheless demonstrate the importance of NK cells and KIR specificities in human disorders and treatments.

Other Human Ig-like Receptors Specific for MHC

The human LILR (leukocyte Ig-like receptor) family is encoded in the LRC (Figure 16.3), just centromeric to the KIR genes. In contrast to the highly polymorphic KIR genes, the LILR genes appear to be much more stable *(260)*. There are two general forms of these receptors: subfamily A, which appear to be activation receptors, and subfamily B, which have the ITIMs characteristic of inhibitory receptors. At least two members, LILRB1 (also known as CD85, Ig-like transcript 2 [ILT2] or leukocyte Ig-like receptor 1 [LIR1]) and LILRB2 (ILT4 or LIR2), recognize HLA class I molecules (261,262,263). LILRB1 is broadly expressed, whereas LILRB2 is not expressed on NK cells but is expressed by myelomonocytic cells, including DCs and monocytes, and can bind HLA-G tetramers *(264)*. Interestingly, a human cytomegalovirus (CMV) protein, UL18, binds LILRB1 with 1,000-fold higher affinity than HLA molecules, implicating a role for LILRB1 in host defense *(265)*.

LILRB1 has four Ig-like domains and binds a conserved region in the $\alpha3$ domain of most, if not all, classical and nonclassical HLA class I molecules (HLA-A, -B, -C, -E, -F, and -G) *(265)*. Interestingly, the crystal structure of LILRB1 bound to HLA-A2 (3.4 Å resolution) reveals that it binds MHC molecule under the peptide-binding domain where it contacts $\alpha3$ and $\beta2$m, more akin to Ly49 engagement of MHC than KIR (266) (Figures 16.4, 16.5).

Human and Mouse CD94/NKG2

The analysis of CD94 (Klrd1) and NKG2 (Klrc, excluding NKG2D [Klrk1]) family of molecules was especially challenging and required insightful investigations. Identified by subtractive hybridization, the human NKG2 molecules are type II integral membrane proteins with external C-type lectin domains (267) encoded in the NKC *(268)* (Figure 16.3). Initial attempts to express NKG2 molecules on the cell surface were thwarted. Meanwhile, mAb reactivity suggested that CD94 was variably expressed on human NK cells as a disulfide-linked dimer (70 kDa NR, 43 kDa R) (269), and both activation and inhibition functions for CD94 were described *(270–273)*. Surprisingly, cDNA cloning revealed that CD94 has a short 7 amino acid cytoplasmic domain, suggesting that it cannot signal on its own *(272)*. Further, anti-CD94 immunoprecipitates were not detectable from radiolabeled CD94 transfectants, despite easily detectable expression on FACS analysis with the same mAbs (274,275). These apparent discrepancies were resolved when it became clear that CD94 heterodimerizes with NKG2 molecules (274); NKG2A is the 43 kDa molecule previously identified as Kp43 with anti-CD94 mAbs (276,277). (NKG2B is an alternatively spliced form of NKG2A. The rest of the NKG2 family is discussed later.) Although CD94 may be expressed as a homodimer, the NKG2 partner provides the signaling motif, whether activation (discussed later) or inhibition (276,278).

The ligand specificity for NKG2/CD94 receptors was also initially thought to be promiscuous as interactions with many classical (class Ia) and nonclassical (class Ib) HLA molecules had been described (271,274,276, 279–282). However, human CD94/NKG2 receptors directly recognize HLA-E, a MHC-Ib molecule homologous to mouse Qa-1 (283,284,285). HLA-E (and Qa-1) is widely expressed with limited polymorphism (286–288). While HLA-E heavy chain is expressed with $\beta2$m and a peptide occupying its peptide-binding cleft, its peptide repertoire is largely derived from the leader sequences of MHC-Ia molecules, as previously noted for mouse Qa-1 (289,290). HLA-E (or Qa-1) expression thus requires normal production of HLA-E (or Qa-1) and synthesis of certain MHC-Ia molecules. Mouse CD94/NKG2 recognizes Qa-1 that shares many features with HLA-E (291,292). These findings need to be considered in the context of the prevailing view at the time that mouse and human NK cells use structurally different receptors to recognize MHC-I molecules *(293)*. Clearly, the studies on CD94/NKG2 receptors and their ligands in humans and mice indicate the conservation of this receptor-ligand pair.

Despite its conservation, the role of CD94/NKG2 receptors in NK cell function is still incompletely understood.

For example, viruses encode peptides that bind and enhance expression of HLA-E, providing a CD94/NKG2A-dependent mechanism to avoid NK cell attack (294,295). However, human NK cells expressing CD94/NKG2C (an activation receptor) expand in response to CMV-infected targets (296). When a large number of human NK cell clones were obtained from two normal individuals, CD94/NKG2 seemed to account for the majority of self-MHC–specific receptors on clones from one individual, whereas KIRs dominated the self-specific receptors on clones from the other individual, suggesting that some individuals may depend on CD94/NKG2 for self-tolerance (297). Qa-1 and HLA-E can present peptides derived from other molecules, including the signal sequence of heat shock protein 60 (Hsp60) that is induced by a number of stimuli (298,299), a multidrug resistance transporter (300), or blastocyst MHC expressed in embryonic tissues (301). This may result in loss or gain of recognition by the inhibitory CD94/NKG2A receptor, suggesting intrinsic mechanisms to perturb inhibition by CD94/NKG2A in certain circumstances. Yet CD94 appears to be dispensable in certain strains of mice, such as DBA/2J, that do not appear to have any untoward NK cell phenotype (302).

CD94/NKG2 molecules may be important in T cell function. CD94/NKG2A is rapidly induced on antigen-specific CD8+ T cells during polyoma virus and other infections (303,304,305), and CD8+ T cells expressing CD94/NKG2A preferentially proliferate during persistent infection, suggesting that CD94/NKG2 receptors may play a role in memory T cell responses (306) and that TCR specificity is correlated with CD94/NKG2A expression by human CTL (307). Indeed, CD94/NKG2A inhibits antigen-specific cytotoxicity in polyoma virus responses although this effect is pathogen-dependent. Thus, CD94/NKG2 receptors may regulate T cell responses.

Convergent Evolution of MHC-Specific Receptors

More than a decade has passed since the mouse Ly49s and human KIRs and LILRs were first cloned and identified. Detailed genome sequence information is available on the NKC and LRC in mice and humans and other species. In the mouse, MHC-specific NK cell receptors with Ig-like domains have not yet been described, although there is conservation of several genes in the broader LRC on mouse chromosome 7 (246) (Figure 16.3). Activated mouse NK cells do express gp49b (Lilrb4), an Ig-like inhibitory receptor also expressed on other leukocytes, including mast cells (308–311). However, it is not expressed by resting NK cells and is not specific for MHC. Instead it binds the integrin $\alpha v\beta 3$ and appears more important in terms of neutrophil and inflammatory responses (312,313,314). A mouse molecule is closely related to human KIR3DL1 (247,248). It is encoded on the X chromosome (Figure 16.3) and expressed in NK and T cells, but its function and ligand are not known. The Ly49 locus in humans consists

only of LY49L (KLRA1), which is a pseudogene because of a point mutation that gives rise to a splicing abnormality (315). Perhaps further investigation may reveal additional human or mouse NK cell receptors for MHC-I ligands that are orthologues to Ly49 or KIR, respectively, because genomic sequencing has revealed a multitude of candidate orphan receptors in the LRC and NKC that have yet to be studied.

The alternative view is that mice and humans independently evolved analogous receptors to serve the same function. While both human and mouse NK cells express a conserved lectinlike receptor, CD94/NKG2, it does not possess many of the features that are shared by mouse Ly49 and human KIRs: 1) Both are constitutively and selectively expressed on naïve, unstimulated NK cells (with exceptions for rare populations of T cells). 2) Both bind MHC-I molecules with intermediate affinity ($K_D = {\sim}2$ to $10\ \mu M$). 3) Binding to MHC is promiscuous. 4) MHC-bound peptides have only a modest effect, if at all, on recognition. 5) Both use ITIMs to inhibit NK cell activation. 6) They are expressed in a stochastic fashion on overlapping subsets of NK cells. 7) A single NK cell simultaneously expresses one or more of either type of inhibitory receptor; each may be functional. 8) Once they are expressed, their expression appears to be stable. 9) Both are germline encoded by small families of genes that are clustered in the genome. 10) Both display impressive polymorphism, in terms of gene number and alleles for each gene. 11) Both are related to molecules that lack ITIMs and instead are activation receptors. Thus, the mouse Ly49 receptors and human KIRs are analogous receptors in a striking example of convergent evolution (316).

In other species, Ly49 and KIR genes have been analyzed primarily with respect to sequence and gene number. For example, the LY49L gene in baboons appears to be functional, but the putative polypeptide lacks an ITIM (317). In rats, the Ly49 cluster appears to have markedly expanded with at least 25 genes (318,319), demonstrating one of the most rapid rates of gene expansion (320). Dog, cat, and pig appear to have only one Ly49, whereas the horse represents the only known nonrodent mammal with several Ly49 genes (321). However, multiple KIR genes have been described in primates and cattle (322–325). In rat, a KIR-like sequence has been reported (248). Studies on the expression and functions of these putative receptors should be forthcoming.

Additional studies of the Ly49- and KIR-like molecules and their specificities will be of interest to evolutionary biologists, especially when considered in the context of MHC genes that are co-evolving (326) and the possibility that these molecules may have evolved other functions. In a somewhat broader context, the NKC, not just Ly49, has been described in other species and a number of genes are conserved, suggesting that the NKC is conserved in all placental species (327). Evolutionary

consideration of the NKC also demonstrates complexity and heterogeneity at several levels. More distantly, the chicken genome has several lectinlike receptor genes, and at least some are genetically linked to the MHC (327,*328,329*). In teleost fish, a large number of novel immune-type receptors (NITRs) with Ig-like domains have been described with sequence homology to mammalian LRC-encoded receptors *(330)*. Interestingly, genes for these molecules are clustered with genes for putative lectinlike receptors *(331)*.

MHC-independent NK Cell Inhibitory Receptors

As already mentioned, NK cells also express inhibitory receptors for non-MHC ligands, such as mouse gp49b, which binds the $\alpha v \beta 3$ integrin (312), and there is a growing list of other molecules (332). Some of these receptors (2B4, Nkrp1, Klrg1, and CEACAM1) will be discussed in a more appropriate context in the following sections. Most of these receptors contain cytoplasmic ITIMs, so their inhibitory function can be predicted even if not directly tested, though some caution is required because the motifs may be involved in other signaling processes.

Human and mice NK cells express the ITIM-bearing LAIR-1 (leukocyte associated Ig-like receptor 1), which is an Ig-like molecule broadly expressed by most leukocytes *(333,334)*. Initial reports indicating that LAIR-1 binds epithelial cellular adhesion molecule (Ep-CAM) were proven to be irreproducible (335,*336*). A recent report suggests that LAIR-1 binds multiple forms of collagen *(337)*. Although the *in vivo* context for functional interaction awaits further characterization, it is reminiscent of the broader reactivity of the Siglecs.

The Siglecs (sialic acid binding Ig-like lectins) are CD33-related type I receptors with varying numbers of Ig-like domains expressed on a broad array of cells and encoded in the "extended" LRC (246,*338*) (Figure 16.3). Despite having sialic acid recognition in common, the Siglecs appear to show differences in carbohydrate recognition, depending on the specific glycan context *(338)*. Human NK cells express Siglec-7 (p75, adhesion inhibitory receptor 1, or AIRM1)(339), Siglec-9, and Siglec-11, whereas mouse NK cells express a related Siglec-E *(338,340,341)*. Siglec-7 has been most extensively studied. As expected, its cytoplasmic ITIM can recruit SHP-1 and inhibit NK cell functions (339,*342*). Moreover, expression of its ligand on targets inhibits NK cells in a Siglec-dependent manner *(343)*. However, the effects appear to be modulated by *cis* interactions between the Siglec receptor and its carbohydrate ligands on the NK cell itself *(338,343,344)*.

Thus, NK cells (and other leukocytes) express multiple inhibitory receptors that are capable of MHC-independent recognition. How they participate in NK cell responses is beginning to be elucidated, and some appear to play a specific role in the context of activation receptors, as discussed later.

NK Cell Activation Receptors

Despite evidence for MHC-independent inhibitory receptors, NK cells clearly kill MHC-I-deficient targets more efficiently than MHC-I-sufficient targets. However, this enhanced killing does not occur simply because a nonspecific default pathway is released when MHC-I is absent. Instead, evidence indicates that susceptible targets express ligands for NK cell activation receptors. These receptors and their ligands have been under intense investigation during the past few years.

Approaches to Identification of Activation Receptors

Initial progress in elucidating NK cell activation receptors was difficult. The approaches that yielded the molecular definition of the TCR, such as subtractive hybridization, mutagenesis of T cell tumors, and anticlonotypic mAbs *(345–347)*, were of limited success *(348,349)*. Indeed, there was incomplete understanding of what principle governed NK cell activation by targets, unlike the working paradigm of MHC-restriction that guided the molecular identification of the TCR. Breakthroughs in identifying NK cell activation receptors thus required other approaches.

Some receptors were recognized because they were first identified on other cells, such as FcγRIII. Other activation receptors were identified by genetic means, such as cDNA clones for molecules resembling the inhibitory receptors but lacking cytoplasmic ITIMs. Others were identified by a genetic positional cloning approach. The ability to induce specific stimulation of NK cells through mAbs proved to be extremely useful for the initial identification of candidate activation receptors and for validating the activation function of receptors identified by other means.

NK cells can be stimulated to mediate antibody-dependent cellular cytotoxicity (ADCC) through the FcγRIII (CD16) receptor which binds the Fc portion of IgG coating a target. In a related way, anti-FcγRIII can also trigger through CD16 in a process termed *redirected lysis* or *reverse ADCC,* because the antibody binds in the opposite orientation to ADCC. Several mAbs can activate NK cells in the redirected lysis assay, highlighting a relatively unique functional property of the recognized molecules, since activation does not occur when most NK cell surface molecules are cross-linked. First popularized for analysis of anti-TCR antibodies *(350)*, redirected lysis occurs when IgG reacts specifically with the NK cell receptor and its Fc portion binds a target cell Fc receptor (FcγR) that apparently provides bridging and cross-linking effects *(350)*. Target lysis does not occur if FcγR binding on the target is prevented with FcγR-deficient targets, F(ab′)$_2$ fragments of the anti-NK cell receptor antibody, or anti-target cell FcγR Ab blockade. In the latter case, Fc regions must be

removed to prevent inadvertent triggering of conventional ADCC via CD16 on the NK cell. Thus, the redirected lysis assay is a very helpful experimental tool.

Gene transfer studies have been helpful adjuncts to study NK cell receptors. NK cells are difficult to transfect, and there are few useful tumors with the notable exception of RNK-16, a rat NK tumor line *(351)*. Viral vectors, such as vaccinia virus, have been useful for gene transfer with the caveat that functional experiments have to be performed within a small time frame *(352)*.

Recent studies have exploited reporter cell assay systems similar to those used to identify TCR ligands *(353)*. ITAM-mediated signaling leads to inducible, NFAT (nuclear factor of activated T cells)–dependent expression of a reporter molecule, such as β-galactosidase or green fluorescent protein (GFP). Even an inhibitory receptor can be used to activate the reporter cell by fusion of its extracellular domain to a suitable transmembrane and cytoplasmic domain containing ITAMs. Such reporter cells can then be used to detect ligands on other cells (354–356).

In the following sections, we will describe NK cell activation receptors with an emphasis on those with known ligands.

Activation Receptors Related to MHC-specific Inhibitory Receptors

Despite initial characterization as inhibitory receptors for MHC-I, other members of the Ly49 family—that is, Ly49D and Ly49H in C57BL/6 mice—do not contain cytoplasmic ITIMs. Instead, they are activation receptors associated with DAP12 *(357–360)*. Although Ly49H will be considered later in the context of viral infection, Ly49D has no known role in viral defense. A positional cloning approach indicated that Ly49D is the product of the *Chok* locus, which controls NK cell specificity for killing of a xenogeneic target, Chinese hamster ovary (CHO) cells *(361,362)*, due to recognition of a Chinese hamster MHC-I molecule *(363)*. Interestingly, when Ly49D was transfected into RNK-16 cells, Ly49D can recognize H2D^d *(351)*, but H2D^d tetramers do not bind Ly49D for unclear reasons (166,207). Several other Ly49 receptors have been identified in other mouse strains that have properties of activation receptors (charged transmembrane residues, no ITIMs), but they have been less well characterized *(204,205)*. Finally, the available anti-Ly49 mAbs show cross-reactivity with inhibitory and activation receptors, depending on the allele and mouse strain *(207,364)*. Thus, some members of the Ly49 family are activation receptors involved in recognition of MHC-I molecules on targets.

Molecular cloning of the KIR family also led to the identification of two domain receptors (also known as p50) or three domain Ig-like receptors with short cytoplasmic domains lacking the ITIM (365,*366*). These molecules are now known as the KIR2DS or KIR3DS, respectively, and

can be recognized by anti-p58 mAbs for the KIR2DL inhibitory receptors, making it sometimes difficult to distinguish activating from inhibitory receptors by mAb reactivity alone. KIR2DS2 and KIR2DS4 can associate with DAP12 and can activate NK cells in the redirected lysis assay. Also, T cell clones constitutively express p50 that are costimulatory with concomitant activation through the TCR/CD3 complex *(367)*. For example, KIR2DS4-Ig binds HLA-Cw4–expressing cells and not HLA-Cw6–expressing cells, and it binds less well than KIR2DL1-Ig proteins *(368)*. KIR2DS1 binds HLA-Cw7, but much weaker than KIR2DL1 *(369)*, and KIR2DS2 did not bind any HLA allele tested *(370)*. Thus, the activating forms of KIRs apparently bind HLA alleles less well than the inhibitory receptors, perhaps providing an explanation for the dominance of inhibition over activation (Figure 16.2D), although ligand information for the activating KIRs is limited.

Alternatively, the activating forms of the Ly49s and KIRs have other ligands, and perhaps their MHC specificities are misleading or cross-reactive. Indeed, this has been demonstrated for Ly49H that recognizes a virus-encoded ligand with a putative MHC-I-like fold (354,356). Moreover, KIR2DS4 may recognize a non-MHC ligand *(371)*. However, rat Ly49 activation receptors can recognize MHC allodeterminants *(372,373)*, providing an explanation for genetic analysis showing that MHC-linked allorecognition is stimulatory for NK cells *(374)*. Thus, further analysis is required for understanding the role of Ly49 and KIR activation receptors in MHC recognition, particularly with respect to their inhibitory counterparts.

In addition to NKG2A, the NKG2 family also contains NKG2C, NKG2E, and NKG2F, which are products of different genes (267,375). (NKG2H is an alternatively spliced isoform of NKG2E). NKG2C and NKG2E lack cytoplasmic ITIMs and contain charged transmembrane residues for association with DAP12 (376). Although the role of NKG2F is unknown because it lacks an external domain and remains inside the cell, associated with DAP12 but not with CD94 *(377)*, NKG2C and NKG2E form functional heterodimers with CD94 (276). Like NKG2A/CD94 receptors, these heterodimers recognize HLA-E or Qa-1, but unlike NKG2A/CD94 receptors, they activate NK cells (*378,379*). Interestingly, the inhibitory form appears to bind with higher affinity to HLA-E than the activating form *(380)*. There also appears to be some peptide preference between the different functional forms *(381)* that may be relevant in certain stress situations. Thus, perhaps unlike the activating and inhibitory forms of the Ly49s and KIRs, the CD94/NKG2 receptors may discriminate between subtle differences in their MHC-Ib ligands.

FcγRIII (CD16)

Frequently overlooked but perhaps the first molecularly defined activation receptor on NK cells is FcγRIII (CD16), through which NK cells mediate ADCC against

IgG-coated targets *(382,383)*. Unlike other Fcγ receptor-bearing effector cells, NK cells are generally thought to express only one of the known Fcγ receptors that binds IgG with low affinity *(384)*, although others suggest that human NK cells may express FcγRII isoforms *(385)*. There are two human FcγRIII isoforms with identical extracellular domains *(384)*. Human NK cells express only FcγRIIIA, which is a transmembrane molecule, whereas FcγRIIIB has a glycosylphosphatidyl-inositol (GPI) linkage and is expressed by neutrophils. In mice, only the transmembrane isoform (FcγRIII) is present *(386)* and displays 95% sequence conservation with muFcγRII. There are species differences in CD16 binding to mouse IgG isotypes; mouse IgG3 mAbs bind human CD16 the most efficiently (3>2a>2b>>1), while they bind mouse CD16 with the lowest affinity (2b>2a>1>>3) *(384)*. In the laboratory, a rabbit anti-mouse Ig polyclonal Ab, which binds strongly to both human and mouse CD16, could be added to facilitate Fc receptor binding.

The transmembrane FcγRIII molecules are physically associated with FcεRIγ and less commonly with CD3ζ *(387)*. FcγRIII can also associate with γ–ζ heterodimers. The associated chains are required for optimal cell surface expression of FcγRIII and for signal transduction. After cross-linking, FcγRIII activates biochemical events that are reminiscent of T cell activation, leading to granule exocytosis and cytokine production (118,388,*389–391*). *In vivo*, ADCC may be useful in host defense against pathogens or infected cells if Abs are bound to their surface, triggering not only killing but also cytokine production and other NK cell responses. Although NK cells are generally thought to participate early in a primary immune response (discussed later), the delay required for isotype switching to IgG production suggests that CD16 cross-linking on NK cells plays a role in secondary immune responses *in vivo*.

Regardless, ADCC is remarkably similar to natural killing and was important for the initial establishment of the concept of NK cell activation receptors (118). Yet CD16 is not required for NK cell target recognition because human CD16⁻CD3⁻ lymphocytes can still mediate natural killing *(392)*. Moreover, CD3ζ is phosphorylated upon CD16 ligation, but not when NK cells are exposed to NK-sensitive targets. Deficiency of γ chain abrogated ADCC but not natural killing *(382)*. Thus, CD16 is not involved in natural killing.

CD16-related artifacts must be considered when studying NK cells. Flow cytometry experiments may be flawed if CD16 binding is not taken into account. To eliminate this possibility, F(ab')₂ fragments should be used. Alternatively, blockade of FcγRIII binding may be sufficient with protein A or G (that bind Fc region on Ig) or anti-FcγRIII mAbs, such as unlabeled mAb 2.4G2 (ATCC HB 197) that reacts with both mouse FcγRII and FcγRIII *(386)*. Similarly, as discussed earlier, antibody blockade experiments should be done with caution if the antibody specifically reacts with the target because ADCC may be stimulated.

NKG2D

NKG2D (KLRK1) was first cloned from human NK cells as a cDNA related to NKG2A and C (267). However, NKG2D is distinct from other NKG2 molecules for several reasons. There is only limited sequence homology between NKG2D and other NKG2 molecules (28% amino acid identity for the lectinlike domain), whereas other NKG2 molecules are closely related to each other (70% identity). Rather than heterodimerizing with CD94, NKG2D is expressed as a disulfide-linked homodimer on all NK cells in humans and mice. In humans, NKG2D is also expressed on all γδTCR⁺ and CD8⁺ T cells, whereas in mice, NKG2D is expressed on most NKT and γδTCR⁺ T cells, but not on resting CD8⁺ T cells (393–395). However, essentially all activated mouse CD8⁺ T cells express NKG2D. In both humans and mice, CD4⁺ T cells do not normally express NKG2D, but it is found on a subset CD4⁺CD28⁻ T cells in rheumatoid arthritis patients (396). Finally, NKG2D has functional properties and ligand specificities that distinguish it from the other NKG2 molecules, indicating that NKG2D should not be considered as a member of the NKG2 family.

NKG2D does not have any known cytoplasmic motif and was first shown in humans to preferentially associate with a signaling chain termed *DAP10*, encoded by a gene localized 130 bp away from the gene for DAP12 (397). DAP10 does not have any ITAMs; instead it contains a YxxM motif for recruitment of PI3K (397) (similar to CD28), and initial functional studies suggested that NKG2D acts as a costimulatory molecule on human T cells (398).

Other studies have suggested that NKG2D functions as a primary activation (triggers alone) rather than costimulatory receptor (does not stimulate unless it synergizes with another receptor) on NK cells *(399,400)*. Such studies will need to be reconsidered now that several factors that have come to light: 1) Many studies of NKG2D function use targets that are poorly killed by NK cells. When transfected with NKG2D ligands, killing is enhanced in an NKG2D-dependent manner. However, such studies do not distinguish whether NKG2D functions as a primary activation receptor or as a costimulatory receptor (analogous to CD28 requirement for full activation of T cells) because the same experimental outcome is anticipated in either case. When cross-linking is done with immobilized mAbs alone, NKG2D functions as a costimulatory receptor on mouse IL-2-activated NK cells *(400)*. 2) In mice but not humans, there are two alternatively spliced isoforms of NKG2D (401,*402*). A long form (NKG2D-L) contains a 13 amino acid extension at the amino terminus (cytoplasmic domain) as compared to the short form (NKG2D-S). Resting NK cells predominantly express NKG2D-L that preferentially associates with DAP10. However, activation

of NK cells with cytokines causes a transient increase in NKG2D-S that associates with DAP12 as well as DAP10. These latter two points, however, appear to be unresolved, as others have found that NKG2D-L can associate with DAP12, albeit to a lesser degree, and that both isoforms are present in resting NK cells (403). Regardless, in the absence of DAP10, mouse NKG2D can associate with DAP12 (404), allowing it to signal akin to a primary activation receptor. Thus, mouse NKG2D is an unusual example of a receptor with the same extracellular domain (and presumably ligand specificity) but with potentially different functional outcomes (primary activation versus co-stimulation), depending on its associated partner chain (DAP12 versus DAP10, respectively).

Human NKG2D ligands are MICA and MICB (MHC-I chain-related) encoded on chromosome 6p21.3), and the ULBP (UL16 binding protein) family encoded on chromosome 6q24.2-q25.3 (393,405). The ULBPs are also known as being encoded by genes in the 10 member *RAET1* gene family (official HUGO nomenclature) discovered by genomic mining. ULBP1 (RAET1I), ULBP2 (RAET1H), ULBP3 (RAET1N), ULBP4 (RAET1E), and RAET1G have been most extensively studied as ligands for NKG2D (405,*406,407*), whereas *RAET1F, RAET1J, RAET1K*, and *RAET1M* are pseudogenes *(408)*. Mouse NKG2D interacts with H-60, the retinoic acid early inducible gene-1 (RAE-1) family, consisting of RAE-1α, β, γ, δ, and ε, and murine ULBP-like transcript (MULT1) (394,395,409,*410*). There are reciprocal strain-specific differences in ligand expression—BALB/c mice express H60, RAE-1α, β, and γ, whereas C57BL/6 mice do not express these molecules and express RAE-1δ and ε *(411)*. Finally, there is remarkable plasticity for NKG2D in that it can bind many apparently disparate ligands that are only superficially related to each other by sequence alignment (only ~20% to 25% amino acid identity in pairwise comparison), and mouse NKG2D can bind human ligands and vice-versa.

Where studied, all NKG2D ligands have structural relatedness to MHC-I, although they do not associate with β2m or bind peptides (412,413,*414,415*). Many contain only the α1/α2 platforms and many are GPI-linked to the plasma membrane. The ligands display binding to NKG2D in two ways based on affinity (410,412,*416*,417). RAE1α, β, γ, and δ demonstrate a low-affinity interaction with mouse NKG2D, similar to MICA to human NKG2D ($K_D = $ ~300 to 1,000 nM). In contrast, RAE1ε, H60, and MULT1 show a much higher-affinity interaction ($K_D = $ 6 to 30 nM). Thus, closely related molecules may display wide disparity in affinities, whereas distantly related molecules can show high affinity with NKG2D.

Structural studies indicate that NKG2D binds its ligands more analogous to TCR docking on MHC (Figure 16.5) and unlike Ly49 recognition (Figure 16.4), despite the relationship of NKG2D and Ly49 receptors as NKC-encoded, lectinlike homodimers that bind MHC-related molecules (412,*418,419*). Moreover, NKG2D uses largely nonoverlapping patches to engage a similar orthogonal footprint on its disparate ligands. Two mechanisms have been proposed to account for this binding, induced fit where NKG2D has conformational flexibility (413) and rigid adaptation in which NKG2D has a rigid binding site *(419)*, an important issue in the context of multispecific immune receptors *(420)*. Thermodynamic studies support the rigid adaptation mechanism to explain how one receptor can bind disparate ligands *(421,422)*. However, structures of NKG2D complexed with other ligands may yield other information.

NKG2D function has been described in the "induced-self" model (Figure 16.2E) because the expression of many of its ligands appears to be inducible and can override inhibitory influences of MHC-I *(423,424,425)*. Human MICA and MICB expression is markedly enhanced on epithelial tissues in inflammatory bowel disease (426). In mice, RAE-1 transcripts are induced by retinoic acid treatment or by phorbol ester stimulation (409). Moreover, TLR signaling and ionizing irradiation and other DNA-damaging agents can induce NKG2D ligand expression (*427*,428). Recent studies also indicate that NKG2D ligand expression can be regulated by the transcription factor JunB *(429)*. Thus, while transcripts for the ULBP and MULT1 molecules are readily detectable in normal tissues (405,*410*), the function of NKG2D is generally thought to trigger immune cells in the context of inflammatory reactions which lead to stress-induced expression of self-molecules *(430)*.

Chronic exposure to NKG2D ligands results in down-regulation of NKG2D expression and lower functional responsiveness *(431–433)*. Soluble forms of NKG2D ligands can also mediate these effects. Patients with tumors expressing MIC frequently contain soluble MIC in their peripheral blood, presumably as a result of proteolytic cleavage of membrane-expressed ligands *(431)*. Localized ligand expression can also result in impotent NKG2D responses in mice *(434)*. These findings may explain why tumors frequently express NKG2D ligands which otherwise would enhance their susceptibility to NK cell attack, supporting a role for NKG2D in tumor surveillance.

Additional studies support a role for NKG2D in tumor surveillance. For example, mice are more sensitive to developing methylcholanthrene-induced fibrosacromas when NKG2D is neutralized *(435)*. Moreover, mice lacking $\gamma\delta$T cells are more susceptible to carcinogenesis apparently due to an NKG2D-dependent effect (409). IFNγ is a known host mediator that shapes the tumor phenotypes in a broader process known as "immunoediting" *(436,437)*, and IFNγ also mediates down-regulation of H60 expression on tumors *(438)*. Thus, NKG2D and its ligands are important in the host response (or lack thereof) to tumors.

A role for NKG2D in antiviral responses is indicated by studies indicating that viruses encode molecules that interfere with ligand recognition by NKG2D. This was first noted when the human CMV protein UL16 was found to

bind ULBPs (405). In infected cells, UL16 retains some (MICB, ULBP1, and ULBP2) but not all NKG2D ligands in the endoplasmic reticulum and cis-Golgi, preventing their expression on the cell surface and protecting from NK cell lysis (*439,440*,441). In mice, murine CMV (MCMV) encodes gp40 from the *m152* open reading frame (ORF) that down-regulates all five RAE-1 ligands but has no effect on H60 or MULT1 (*411*,442). However, H60 is down-regulated by the product of the *m155* ORF at a post-Golgi level, perhaps by targeting H60 for proteasomal degradation *(443,444)* and MULT1 expression is affected by *m145 (445)*. Recent studies also indicate that H60 and MULT1 are down-regulated by the herpesvirus Fc receptor (fcr-1), the product of the *m138* ORF *(446)*. Thus, the multitude of CMV proteins that affect NKG2D ligands strongly suggest that NKG2D plays an important role in the host response to CMV infections.

Finally, emerging data suggest that NKG2D may play a role in autoimmune disorders. There is an unusual population of $CD4^+$ $CD28^-$ T cells that is expanded in human patients with inflammatory syndromes, such as rheumatoid arthritis (RA), Wegener's granulomatosis, and unstable angina *(447–449)*. NKG2D may provide a missing costimulatory signal, at least in RA (396). NKG2D expression is upregulated by $TNF\alpha$ and IL-15 and RA synovium expresses NKG2D ligands. IL-15 also induces NKG2D expression on intestinal epithelial T lymphocytes, which then display a LAK cell-like promiscuous killing capacity against enterocytes, which upregulate NKG2D ligands from gliadin exposure, suggesting that NKG2D may play a pathogenic role in celiac sprue (33,*450,451*). Finally, NKG2D ligands are expressed in the prediabetic NOD mouse pancreas, and anti-NKG2D blockade prevents autoimmune diabetes mellitus *(452)*. Thus, NKG2D may play a pathogenic role in several autoimmune disorders in humans and mouse models.

Nkrp1 and Clr (LLT1)

First identified in redirected lysis assays with mAb 3.2.3, rat Nkrp1 is expressed as a disulfide-linked homodimer with 30 kDa subunits *(453)*. Expression is relatively selective for NK cells, although in rats and mice, Nkrp1 molecules are also expressed by NKT cells *(454,455)* (see Chapter 17). Nkrp1 (Klrb1) is now known to belong to a family of lectinlike molecules with type II orientation encoded in the mouse and rat NKC (60,200,*456–458*) (Figure 16.3). However, there is only a single gene (*NKRP1A*) in humans that is expressed on a subpopulation of NK cells *(459)*. The continuing allure of the Nkrp1 family stems from observations that NK1.1 (the best serologic marker of NK cells) is encoded by *Nkpr1c* (*Klrb1c*) in C57BL/6 mice (60), Nkrp1 receptors are conserved, and they have interesting genetics with respect to their ligands.

Initial functional studies indicated that rodent Nkrp1 molecules can activate NK cells through redirected lysis (31,*453,460–462*), which can be prevented by inhibitory Ly49 receptor engagement *(98)*. Mouse Nkrp1c (NK1.1)

is functionally associated with $Fc\varepsilon RI\gamma$, although its deficiency does not affect NK1.1 expression (463). An Nkrp1a loss mutant of rat RNK-16 cells failed to kill certain targets; transfection restored killing capacity, suggesting that rat Nkrp1a is an activation receptor specific for target determinants *(464)*. Thus, Nkrp1 molecules were among the first described NK cell-specific activation receptors.

Inasmuch as Nkrp1 molecules are homologous to C-type lectins, the ligands for Nkrp1 molecules were presumed to be carbohydrates, but Nkpr1 molecules lack residues for coordinate binding of Ca^{++} that is required for authentic C-type lectin recognition of carbohydrates *(174)*. While the ligands for Nkrp1c have not yet been identified, Nkrp1f recognizes C-type lectin-related g (Clrg, also known as Clec2i, Dcl1) (355,*465,466*). Nkrp1f is presumed to be an activation receptor, because it has a charged transmembrane residue and no cytoplasmic signaling motifs. The inhibitory receptor, Nkrp1d, is expressed on all NK cells in C57BL/6 mice and is specific for Clrb (Clec2d; osteoclast inhibitory lectin, Ocil). Thus, the Nkrp1 family is an MHC-independent system that is presumably involved in self-tolerance and is the first example of a lectinlike receptor recognizing a lectinlike ligand unlike MHC-like ligands for other NKC-encoded receptors.

Recent genome sequence analysis suggests that *Nkrp1d* in other mouse strains is represented by *Nkrp1b*, an inhibitory receptor (*64,65,457,467*). The Nkrp1b molecule from SJL and SW mice was discovered to be reactive with the anti-NK1.1 mAb, highlighting the close similarities of these molecules and serologic cross-reactivity. Whereas the older literature suggested that there are also strain differences in transcript expression with markedly lower expression in BALB/c NK cells *(468)*, more recent data demonstrate abundant expression of Nkrp1 transcripts *(467)*. Moreover, the BALB/c allele of Nkpr1b also reacts with Clrb, indicating conserved specificity and function.

The Clr molecules belong to a small NKC-encoded family with type II orientation and C-type lectin homology *(469)*. They are most closely related to the CD69 molecule encoded by an adjacent gene. In C57BL/6 mice, seven Clr genes have been identified at the genomic level. RT-PCR analysis indicates that *Clrb* is broadly expressed, whereas *Clrg* and *Clrf* genes are present in restricted and nonoverlapping tissues, including NK cells, and *Clra* and *Clrc* transcripts have not yet been identified. *Clre*, a probable pseudogene, demonstrates numerous stop codons in its expected open reading frame. Genomic analysis indicates the existence of a rat *Clr* family *(458)*, whereas in humans, three genes, *LLT1 (470)*, *AICL (471)*, and *DCAL-1 (472)* are localized next to CD69 and are related to the Clr family of genes. Indeed, human NKRP1A binds LLT1, indicating that at least human LLT1 is a functional homologue of mouse Clr *(473,474)*. Thus, the Clr family consists of conserved molecules that are ligands for Nkrp1 receptors.

The genetics of the *Nkrp1* and *Clr* loci is especially interesting from several viewpoints. 1) These loci are comingled in the NKC, from rodents to humans (355,*458,467,473–475*) (Figure 16.3). 2) There is limited allelic polymorphism, with conservation of gene order and content, despite genetic proximity to the highly polymorphic *Ly49* cluster (355,*467*). 3) The *Nkpr1* alleles appear to be much less divergent than the corresponding *Ly49* alleles in the same inbred mouse strains (*204,355,467*). 4) The *Nkpr1-Clr* interval of the NKC appears to be genetically protected with suppression of recombination *(476,477)*. Genetic linkage of Nkrp1 and its ligands thus resembles the tight genetic linkage of receptor and ligand genes and recombinational suppression of the self-incompatibility (SI) loci in plants to prevent self-fertilization and related mating loci in other species *(478,479)*. Further, the coevolution of such linked genes for receptors and ligands also represents an interesting issue in evolutionary biology because reciprocal mutations in both receptor and ligand genes are simultaneously needed to generate new specificities *(478)*. Nevertheless, the genetic pressure to conserve the *Nkrp1-Clr* gene order and coding sequences may therefore reflect a critical role for Nkrp1 and Clr molecules in innate immune cell interactions and functions.

2B4, CD2, and Related Receptors

The 2B4 (CD244) molecule was originally identified on mouse NK cells with a mAb that perturbed mouse NK cell function (480). 2B4 is a type I integral membrane protein that belongs to the family of Ig-like molecules homologous to CD2, including CD48, CD58, signaling lymphocytic activation molecule (SLAM) (CD150), CD84, NTBA (NK, T, and B cell antigen; also known as SLAMF6, or Ly108), CD229 (Ly9), CD319 (CRACC, CD2-like receptor activating cytotoxic cells), and B lymphocyte activator macrophage expressed (BLAME) *(481,482,*483).

Although these receptors may be broadly expressed, 2B4, CD2, NTBA, and CRACC are expressed on NK cells. Whereas NTBA and CRACC are involved in homophilic interactions, 2B4 recognizes CD48, a GPI-linked molecule expressed on hematopoietic cells (483,*484*). CD48 itself is also recognized by CD2, albeit at a 9-fold lower affinity than by 2B4 ($K_d = \sim 16\,\mu M$). Anti-CD2 mAbs can stimulate NK cells in the redirected lysis assay *(485)* and granule exocytosis *(486)*, but CD2$^-$ NK cells can still mediate natural killing (10). The cytoplasmic domains of 2B4, NTBA, and CRACC as well as SLAM, CD84, and CD229 contain a motif with sequence similarity to the ITIM, termed the *immunoreceptor tyrosine-based switch motif* (ITSM) consisting of TxYxxV/I consensus sequence *(487)*. The ITSMs allow interactions with a signaling adapter, SLAM-associated protein (SAP, also known as SH2D1A). The importance of SAP and its associated receptors is highlighted by the X-linked lymphoproliferative syndrome (XLP, also known as Duncan's disease), a human immu-

nodeficiency involving abnormal proliferation of T and B cells during Epstein-Barr virus infections due to mutations in SAP *(488)*.

SAP is related to Ewing's sarcoma–associated transcript (EAT2, also known as SH2D1B) and EAT2-related transducer (ERT, also known as SH2D1C) in rodents (483). SAP and the SAP-related molecules contain a single Src homology 2 (SH2) domain for interaction with the ITSM. 2B4 and NTBA can recruit SAP, whereas CRACC does not *(489,490)*. Instead, CRACC recruits EAT2, which functionally substitutes for SAP *(482)*. Subsequently, the SAP-related proteins appear to recruit a Src-family tyrosine kinase for downstream activation events.

The complexities of this receptor-ligand signaling pathway are still being unraveled. 2B4 can apparently inhibit as well as activate mouse NK cells (480). These outcomes may depend on spatial distribution, 2B4 isoforms, or differential recruitment of SAP or its related molecules (483). However, a 2B4-deficient mouse primarily displays effects consistent with 2B4 being primarily an inhibitory receptor *(491)*, although the inhibitory effect of 2B4 is more apparent in mice than humans (483). CRACC recruitment of EAT2 can promote signaling *(482)*, whereas in other studies recruitment leads to inhibition *(492)*. These differences may be species specific due to presence of Tyr residues in mouse but not human EAT2 that are required for inhibition *(482)*. Analysis of these discrepancies should enlighten NK cell function and signaling because 2B4 and related receptors demonstrate MHC-independent regulation of NK cells, mediate inhibition in a functionally distinct manner from the MHC-specific inhibitory receptors, and can activate NK cells.

Natural Cytotoxicity Receptors (NCRs)

A series of mAbs that redirected lysis of human NK cell clones lacking KIRs led to the identification of the "natural cytotoxicity receptors" (NCRs), NKp46 (NCR1, CD335), NKp44 (NCR2, CD336), and NKp30 (NCR3, CD337) (493,*494–497*). These molecules are selectively expressed on NK cells, although NKp44 is expressed only upon activation. Whereas NKp46 is encoded in the LRC (Figure 16.3), NKp44 and NKp30 are encoded in the class III region of the MHC on human chromosome 6 *(498,499)*. cDNA cloning revealed that they are type I integral proteins with one (NKp30, NKp44) or two (NKp46) Ig-like extracellular domains. They contain charged transmembrane residues for association with ITAM-signaling chains—that is, ζ–γ heterodimers (NKp46, NKp30) or DAP12 (NKp44). They appear to play a role in cytotoxicity against tumors of varying origins because anti-NCR antibodies block target killing *(500)*. However, NKp46 fusion proteins do not bind well to targets that appear to be recognized by NCRs (501), and a ligand for NKp44 appears to be up-regulated on CD4$^+$ T cells during HIV infection *(502)*, implying complex interactions that require further investigation.

In the mouse, only the gene for NKp46 is present in the syntenic region of chromosome 7, with the genes for other NCRs being absent (NKp44) or a pseudogene (NKp30) *(503)*. A mouse NKp46-Ig fusion protein binds RMA-S targets, and deficiency of NKp46 leads to impaired *in vivo* clearance of RMA-S cells *(504)*. Interestingly, human NCRs apparently recognize mouse tumors and vice versa, suggesting conservation of these receptor-ligand pairs across species but their tumor target ligands have remained elusive *(500)*.

Human NKp46 appears to recognize influenza hemagglutinin on infected cells (501). The interaction is dependent on sialic acid residues on oligosaccharides on NKp46 itself, but this specificity is difficult to explain due to the ubiquitous expression of sialylated saccharides. Conversely, NKp30 and NKp46 may recognize heparan sulfate proteoglycans on their cellular targets, although this is also controversial *(505,506)*. Nevertheless, a NKp46-deficient mouse is susceptible to influenza, consistent with a role for NKp46 in defense against influenza *(504)*, albeit possibly in an indirect manner *(507)*. These studies may provide important clues to understanding of a conserved receptor (NKp46) and other NCRs.

Other Activation Receptors

Several other NK cell-expressed molecules can activate cytolysis. For example, mAbs against mouse CD69 and Ly-6 and rat gp42 can trigger killing (31,*32*). CD69 is encoded in the NKC and is structurally related to other NKC-encoded receptors. Interestingly, CD69 expression is up-regulated upon stimulation *(311)*, and its expression is not confined to NK cells *(508)*. CD69 is functionally active on a large variety of hematopoietic cells when cross-linked by anti-CD69 mAbs. Ly-6 belongs to a large family of small (15 to 18 kDa) GPI-anchored molecules that can activate lymphocytes when cross-linked *(509,510)*. Rat gp42 is a GPI-anchored protein with two Ig-like domains that was originally identified on IL-2-activated NK cells and the rat RNK-16 NK cell line *(32)*. Anti-gp42 can activate RNK-16 but not IL-2–activated NK cells. However, CD69, Ly-6 and gp42 are not expressed on freshly isolated NK cells and are expressed only after activation through other pathways, and are therefore not involved in triggering natural killing by freshly isolated NK cells. Although their physiological role is unknown, their activation potential and enhanced killing by IL-2–activated NK cells suggest that these molecules may contribute to this phenotype.

Receptors Involved in Recognition of Epithelial Tissues

Recent studies indicate that NK cells possess receptors that are specific for ligands expressed at cell–cell junctions in epithelial tissues. Interestingly, ligands, such as cadherins, carcinoembryonic antigen (CEA)–related adhesion molecules (CEACAMs), nectins, and nectinlike proteins (necls), are involved in forming adherens junctions and are engaged in homotypic or heterotypic interactions, and thus, are not normally exposed *(511)*. KLRG1 (also known as mast cell–associated function antigen, MAFA) is a lectinlike receptor with cytoplasmic ITIMs *(512–514)*. Unlike human *KLRG1*, mouse *Klrg1* resides relatively distant and centromeric from the rest of the NKC, consistent with gene duplication and chromosomal inversion events. First discovered on rat mast cells, it has a broader distribution in human and mouse, including NK and T cells, but not mast cells. Expression of KLRG1 on NK cells is down-regulated in MHC-I-deficient mice, unlike the Ly49s, which are upregulated, but no MHC binding has been observed for KLRG1 *(515)*. Recently, mouse KLRG1 was found to bind the "classical" cadherins, E-, N-, and R-cadherin (516,517). E-cadherin recognition by KLRG1 led to inhibition of NK lysis. Similarly, the human CEA-CAMs appear to be involved in MHC-independent inhibition of NK cell activity. In particular, CEACAM1 contains a cytoplasmic ITIM and can directly bind CEA, thereby potentially regulating NK cell activities in human MHC-I-deficient patients and during pregnancy (518,*519,520*). Thus, NK cells express inhibitory receptors for ligands normally expressed at adherens junctions.

NK cells also express activation receptors for molecules at the adherens junction—that is, nectins and necls. Specifically, they express CD226 (DNAM-1, DNAX accessory molecule-1), an LFA-1–associated receptor that recognizes necl-5 (CD155, poliovirus receptor, PVR) and nectin-2 (CD112) *(521)*. NK cells also express CD96 (tactile) that binds necl-5, and CRTAM (class I–restricted T cell–associated molecule), a receptor that recognizes necl-2 (522,*523,524*).

These studies suggest that these receptors may affect different NK cell functions as related to epithelial tissues (*511*,516). For example, the inhibitory receptors may regulate NK cell transmigration across an epithelial barrier or prevent NK cell attack against normal tissues (516,*525*). While the activation receptors could also affect NK cell transmigration (516,*525,526*), the activation receptors could be poised to attack cells that have disordered cell–cell junctions, such as tumors, which typically lose cadherin expression and expose nectins and necls, potentially making them more susceptible to NK attack, consistent with an "exposed-self" model for NK cell activation (Figure 16.2F, G). However, tumors may be become resistant to NK cells by altering expression of these molecules. Current evidence provides some support to these complex scenarios that will require further investigation *(511)*.

Accessory Molecules

The role of accessory molecules in NK cell activation has been difficult to address without knowledge of the "NK cell (activation) receptor." Nevertheless, NK cell function

is critically dependent on classical accessory and adhesion molecules, such as LFA-1 *(527,528)*. Insect cells expressing ICAM-1, a ligand for LFA-1, can be killed by human NK cells through an LFA-1–dependent process, suggesting that LFA-1 alone is sufficient to trigger killing *(529)*. However, the insect cell targets could express ligands for unknown NK cell receptors. Recent studies also indicate that LFA-1 cross-linking does not lead to granule polarization, suggesting that it may be insufficient for triggering the killing process by itself *(101)*. How LFA-1 or other "accessory" molecules contribute to each activation receptor on NK cells remains to be systematically determined.

SIGNAL TRANSDUCTION IN NK CELLS

In general, the signal transduction pathways stimulated by NK cell activation receptors coupled to ITAM-containing signaling chains resemble those of TCR and B cell receptor (BCR) signaling (530). Activation receptor cross-linking leads to ITAM phosphorylation by Src family tyrosine kinases, recruitment and activation of Syk family tyrosine kinases, and subsequent downstream activation events. Inasmuch as TCR and BCR signaling is covered in detail in other chapters, we will highlight here some notable differences with TCR and BCR signaling.

In addition to difficulties in dissecting NK cell activation because of differences due to species (mouse, human), and cell origin (freshly isolated, activated, NK cell clones), there are additional complexities. 1) Like CTLs, NK cells form discrete protein clusters at the site of contact with their targets, termed the *immunological synapse* (*531*,532), although obviously the TCR is not involved. The NK immunological synapse (NKIS) is formed in discrete stages whereby CD2, f-actin, LFA-1, and Mac-1 accumulate in the peripheral supramolecular activation complex (pSMAC) whereas granules (perforin) accumulate centrally (cSMAC) (533). Inhibitory receptor engagement results in early KIR and SHP-1 recruitment to areas surrounded by LFA-1 *(534)*. Other pSMAC and cSMAC patterns are found depending on whether or not the contacts lead to cytolysis (532,535). Also, there is emerging data on the contribution of NKG2D/DAP10 and Vav1 to the NKIS *(536)*. 2) Individual NK cells may simultaneously express multiple activation receptors, each of which may associate with different ITAM-signaling chains that could be phosphorylated by different Src family tyrosine kinases. 3) NK cells express multiple Src kinases, including Lck, Fyn, Src, Yes, Lyn, and Fgr *(537)*, with redundancies in their contributions to ITAM phosphorylation. For example, Fyn is activated following Ly49D (DAP12) cross-linking, but NK cells deficient in Fyn, Lck, or both still kill in a Ly49D-dependent manner (538). 4) NK cells express both Syk family tyrosine kinases, ZAP-70 and Syk itself, whereas T and B cells express either, respectively, but not both. Further, deficiency of either ZAP-70, Syk, or both has only minimal effects on NK cell killing *(539)*, suggesting other pathways for transmitting NK activation signals. 5) NK cells express many adapter molecules found in T and B cells, but their contributions to NK signal transduction is less well defined. For example, SLP-76 is dispensable for NK cell signaling, although it is required for T cell signaling *(540)*. 6) Different isoforms of signal transduction molecules are responsible for NK cell activation. For example, mouse NK cells utilize phospholipase C-γ2 (PLCγ2) as a critical signaling mediator *(541)*, more like B cells than T cells *(542)*. 7) Finally, most studies have been performed on bulk populations of NK cells or NK cell clones, which may not be representative of pathways triggered in individual NK cells that may express only some but not all signaling molecules detected in the entire NK cell population. Taken together, these data strongly suggest multiple pathways for signal transduction in NK cells that may be dependent on which activation receptor (and associated signaling chain) is triggered *(543)*.

Reinforcing this concept are recent studies on the Vav family of guanine nucleotide exchange factors, Vav1, Vav2, and Vav3, which are all expressed in NK cells (544). Vav2 and Vav3 are required for FcRγ and DAP12 signaling, whereas Vav1 is required for DAP10 signal transduction. Additionally, NK cell number and differentiation are not apparently affected by Vav deficiencies even when they are required for NK cell activation. In contrast, deficiencies in Vav family members leads to T and B cell development defects *(545)*. Similarly, NK cells are not deficient in number or maturation state in PLCγ2-deficient mice, unlike B cells, which require PLCγ2 for development *(541,542)*. These observations suggest that signal transduction through NK cell activation receptors is generally not required for NK cell development, unlike T and B cells, or that there is redundancy in the pathways that contribute to NK cell development.

Recruitment and activation of PI3K appears to be critical to NK cell activation for target killing (546). How PI3K is activated depends on proximal signal transduction events. In the case of NKG2D, the YxxM motif in DAP10 is phosphorylated and recruits PI3K directly (547) that appears to be sufficient to activate NK cell killing in the absence of DAP12 or Syk family tyrosine kinases *(548)*. The pathway may be more complex in human NK cells, where recent evidence suggests that DAP10 also recruits a Grb2-Vav1 intermediate for activation *(549)*. For other activation receptors, Syk activation is upstream of PI3K *(550)* and may directly recruit PI3K *(551)*. PI3K in turn activates a mitogen-activated protein kinase (MEK) for stimulation of extracellular signal-regulated kinase (ERK) (546). Ultimately, actin polymerization occurs, and a large

molecular weight complex is formed containing actin binding proteins *(552)*. Granules become polarized toward the target and exocytosis occurs, resulting in target apoptosis. Thus, the complexities of NK cell activation remain under investigation.

Biochemical Mechanism of Inhibition by NK Cell Receptors

A typical human KIR molecule has two ITIMs separated by ∼24 residues. In contrast, Ly49A has only one ITIM per chain, but Ly49 molecules are normally expressed as homodimers. Each ITIM can be phosphorylated upon receptor cross-linking (difficult to visualize) or tyrosine phosphatase inhibition (165,553,*554–556*), presumably by a Src family tyrosine kinase as in B cells *(557)*, although redundant expression and function have precluded identification of a single kinase required for ITIM phosphorylation in NK cells. In studies of KIR transfectants of human Jurkat T cells, the KIR ITIM is phosphorylated by Lck *(558)*, but it is not known if this tyrosine kinase is responsible for phosphorylation of all inhibitory receptors in primary NK cells, especially because NK cells express multiple Src family tyrosine kinases. ITIM phosphorylation results in SHP-1 recruitment and activation (165,553,*554,555,559*). Two ITIMs are required for sequential binding of the two Src homology-2 (SH2) domains in SHP-1 *(560)*. The NK cell inhibitory receptors preferentially recruit SHP-1 rather than SHIP, although they may occasionally bind SHP-2 (553,*561,562*). However, a SHIP-deficient mouse demonstrates abnormalities in NK cell function and receptor expression (563). Nevertheless, available data strongly support an inhibitory mechanism consisting of receptor cross-linking followed by ITIM phosphorylation and recruitment of SHP-1, and that this mechanism operates with both structural types of inhibitory receptors.

The downstream target of the ITIM-recruited tyrosine phosphatase appears to be Vav1 in human NK cells (564). However, in view of the differential role of Vav2 and Vav3 but not Vav1 in murine NK cell activation by ITAM-signaling chains (544), this observation will need further evaluation. Moreover, other studies suggest earlier events in NK cell activation are blocked by inhibitory receptors, such as formation of the NKIS *(534,565,566)*. However, KIR phosphorylation occurs within clusters at the NKIS, which may serve to focus inhibition on downstream targets (567), such as Vav1, which is recruited into the mature synapse during NKG2D/DAP10 signaling *(536)*. Future studies should clarify these relationships.

Finally, investigators have observed that Ly49 receptors on NK cells can acquire their cognate MHC-I ligands from surrounding cells, resulting in display of both molecules on the NK cells *(568,569)*. Whether this contributes to *cis* effects on inhibitory receptor function or is physiologically important requires further evaluation.

NK CELL DEVELOPMENT

Early evidence indicated that the complete phenotypic and functional maturation of NK cells occurs in the BM and requires an intact microenvironment because BM ablation or congenital BM defects lead to abnormal NK cells *(570–574)*. Indeed, certain aspects of NK cell development are regulated by direct interactions between developing NK cells and stromal elements, such as interactions between membrane lymphotoxin-α (LTα)–expressing NK cell precursors and LTα-responsive stromal cells that are necessary for normal development *(112,575)*. *In vitro*, NK cells can be generated from early hematopoietic cells *(576–580)* in a cytokine cocktail consisting of stem cell factor (c-kit ligand), IL-7, flt-3 ligand (FL), and IL-15 (*581*,582). However, direct contact with stromal cells is required for acquisition of Ly49 receptors by developing NK cells. Recent evidence implicates the Tyro3 family of receptors (Tyro3, Mer, Axl) on NK cells and their ligands (Gas6, protein S) on stromal cells as being critical for expression of NK cell receptors and functional differentiation *in vitro* and *in vivo* (583). Thus, NK cell development requires certain cytokines and direct stromal cell contact.

A model has been proposed for the developmental process of mouse NK cells in the BM that is divided into several major steps (reviewed) in *[584,585]*. The earliest step involves the commitment of hematopoietic stem cells (HSC) in the BM to the common lymphoid progenitor (CLP) that can give rise to NK, T, and B cells, but not to myeloid cell lineages *(586,587)*. Mice deficient in various transcription factors, including Ikaros and PU.1, display severe defects in the development of all lymphoid cells, including NK cells, while myeloid and erythroid lineages are less affected (588,*589–592*). Thus, the earliest step of NK cell development appears to share a common pathway with other lymphocytes, providing evidence that NK cells belong to the lymphocyte lineage.

The CLP differentiates to a bipotential T/NK progenitor (T/NKP), reflecting the close resemblance of T and NK cell effector functions. T/NKP can give rise to T and NK cells, but not to other lineages, depending on culture conditions (593,*594–597*). Consistent with this bipotentiality, CD3ε and FcεRIγ Tg mice exhibit selective defects in both NK and T cell development *(598,599)*. More recently, in *in vitro* studies using BM stromal cell monolayers, T or NK cells can be generated from precursor populations, including undifferentiated thymocytes, depending on whether Notch signaling occurs (*594,600*,601).

MARKERS	I	II	III	IV	V

CD43		Lo	Lo	Lo	Hi
Cytotoxicity/IFN-γ				Lo	Hi
FIGURE 16.6 Developmental stages of committed mouse NK cells. During development in BM, informative surface markers characterize distinct stages from the NK cell progenitor to mature NK cells. After acquisition of NK cell receptors (NKG2 and Ly49), significant proliferation occurs while the cells are still immature. The licensing process may affect the proliferation phase (183). Modified from *(584)*.

The acquisition of IL-2/15Rβ subunit (CD122) marks the transition from T/NKP to a committed NKP *(596,602)* (Figure 16.6). In Ets1- or Id2-deficient mice, NK cell development appears to be blocked here because NK cells fail to develop while T and B cells develop normally (603,604). The committed NKP appears to become responsive to IL-15 at this stage because IL-15 or IL-15Rα–targeted mutations produce a relatively selective NK cell deficiency with effects only on relatively rare T cell subsets, such as NKT cells (48,49). Not surprisingly, mice deficient in other components of the IL-15R complex and its signaling pathway (IL-2Rβ, Jak3 and STAT5α/β) exhibit similar defects in NK cell development (39,605–607). IRF-1 (interferon regulatory factor 1)–deficient mice lack NK cells, and this defect can be overcome by the addition of IL-15, suggesting that stromal cells produce IL-15 in an IRF-1-dependent manner (608). Deficiency in T-bet, a T-box transcription factor involved in T helper development, also results in a defect in NK and NKT cell maturation *(609)*, further supporting a close developmental relationship between NK and NKT cells.

NKPs next differentiate into mature NK cells in a series of putative developmental intermediate stages that occur in the BM (70,602). The CD122$^+$ NK1.1$^-$ NKP has been denoted as intermediate Stage I (Figure 16.6) (70) and has also been isolated from fetal thymus (579,596). Thereafter, NK1.1 (Nkrp1c) is expressed (Stages II to V), comparable to studies of *in vitro* differentiation of human NK cells where NKR-P1A molecule is one of the earliest markers expressed *(610)*. Among the mouse CD3$^-$ CD122$^+$ NK1.1$^+$ population, there is an integrin αv$^+$ c-kit$^-$ population (Stage II) that can express CD94/NKG2 and NKG2D but not Ly49 (70). Subsequently, Ly49s are expressed along with both αv and c-kit (Stage III). The acquisition of CD94/NKG2 and Ly49 receptor expression on immature adult BM NK cells recapitulates their expression on fetal and neonatal NK cells in which CD94/NKG2 receptors are first expressed, then the cells acquire Ly49 expression in an ordered manner (196,611,*612*).

At Stage IV, integrin α2 (DX5) expression is increased and developing NK cells undergo vigorous proliferation (70) (Figure 16.6). Thereafter, as NK cells acquire high-level expression of Mac-1 (αMβ1) and CD43 (Stage V), proliferation markedly decreases unless challenged by pathogens such as viruses that can stimulate mature NK cell proliferation (70,613). NK cells at Stage V become fully capable of functional activities associated with mature peripheral NK cells. A selective NK cell deficiency in a Tg is manifested by a failure to generate mature, functional Mac-1^{high} cells *(614,615)*, consistent with this terminal differentiation step.

The aforementioned models suggest that developing murine NK cells expand at a phenotypically distinct stage and that NK cell development is characterized by a dynamic process involving changes in surface receptors for cytokines, extracellular matrix, and self- and target-recognition. Whether expression of these receptors represent functionally important, rate-limiting steps needs to be determined. Nevertheless, current models provide guidance for future investigation.

Like developing mouse NK cells, human NK cells display regulated *in vitro* development *(610,616–618)*, but there are some differences with mouse NK cell development. For example, IL-12 is important in human NK cell development *in vitro* (619), whereas mouse NK cells do not require IL-12 *(620–622)*. Human NK cell development also appears to be dependent on IFN-γ or IL-18, but there is no NK cell defect with deficiencies of IFN-γ or IL-18 *(623)*. Therefore, there may be *in vitro* versus *in vivo*

or species effects to explain these differences in NK cell development.

ACQUISITION OF NK CELL TOLERANCE

Influence of Host MHC-I Environment

Although the MHC-specific inhibitory receptors explain the influence of MHC expression on NK cell effector functions against target cells, how these receptors are related to self-tolerance *in vivo* has been a challenging issue. Several hypotheses have been considered. An individual NK cell can simultaneously express multiple inhibitory receptors, but some may not recognize self-MHC. The "at least one receptor model" suggests tolerance is achieved as long as each NK cell expresses at least one receptor with self-MHC-specificity (297,624). There are changes in the repertoire of MHC-I-specific inhibitory receptors, depending on the MHC haplotype, but these differences are modest, regardless of whether the receptor is self-specific (297,624,625,626). As determined by antibody reactivity, the expression level of an NK receptor on an individual NK cell decreases when the host expresses the MHC ligand for that receptor (161,162,627). Functional analyses of NK cells with "down-regulated" receptor expression suggest that such NK cells are more sensitive to small changes in MHC ligand expression on the target, as explained by the "receptor calibration" model (625,628). However, these studies involved *in vitro* conditions that could alter their intrinsic functional capacities. Thus, several hypotheses based on the MHC-specific inhibitory receptors were proposed to account for NK cell self-tolerance.

There are several observations that need explanation when considering the role played by MHC-specific inhibitory receptors in NK cell self-tolerance. The "missing self" hypothesis implies that there should be overt NK cell autoreactivity in MHC-I–deficient hosts, but this was not observed in humans or mice (132,*133,1*34, 629,*630–632*). Instead, NK cells from MHC-I–deficient mice demonstrate poor killing of MHC-I-deficient targets or rejection of MHC-I–deficient BM, even though they appear normal in number, tissue distribution, and expression of activation receptors. Another very difficult issue is related to hybrid resistance whereby host NK cells in an F_1 hybrid animal can reject BM grafts from either inbred parent *(633,634)*. It was difficult to understand how NK cells discriminate between cells expressing the full complement of self-MHC alleles versus those otherwise normal cells expressing only some self-MHC molecules. NK cell–mediated rejection of MHC-I–sufficient BM grafts also depends on which host MHC-I allele is present (635,*636*). Thus, NK cells are regulated by host MHC environment, not just by the target cell in effector responses.

Also unexplained was the pairing of polymorphic inhibitory receptors with their highly polymorphic cognate MHC ligands (*202*,249). The genes for the receptors and their ligands are located on different chromosomes (i.e., the receptor and ligand genes segregate independently). Thus, there must be mechanisms to provide NK cells with the appropriate inhibitory receptors with specificity for self-MHC because the appropriate pairs are not inherited together, unlike the closely linked *Nkpr1-Clr* gene pairs (355).

The Licensing Hypothesis

Recent studies with target cell-free stimulation and single cell assays of NK cell responsiveness have been revealing (183,637). Freshly explanted, resting murine NK cells from MHC-I-deficient mice were functionally defective in triggering by immobilized antiactivation receptor antibodies (183). Conversely, in wild-type mice, functional competence correlated with expression of a Ly49 inhibitory receptor for self-MHC-I (183). Moreover, NK cells without expression of known self-receptors were hyporesponsive (637). Particularly informative were studies with a single chain trimer (SCT) MHC-I molecule, consisting of antigenic peptide-linker-β2m-linker-H2K^b as a single polypeptide that binds only Ly49C (183). In Tg mice expressing only this MHC-I molecule, only Ly49C$^+$ NK cells were functionally competent. Thus, NK cells normally acquire the competence to be triggered through their activation receptors by their MHC-specific receptors interacting with host MHC-I (Figure 16.7), a process termed *licensing*.

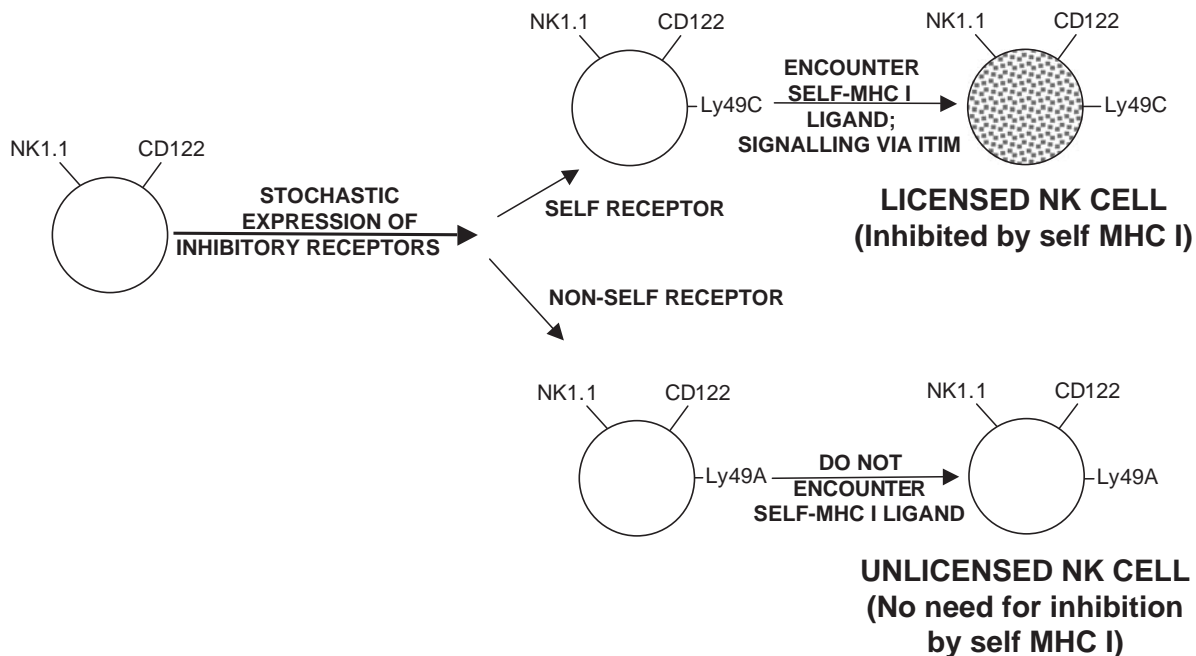
Licensing thus leads to appropriate pairing of inhibitory receptors with self-MHC and strongly suggests that there are two types of self-tolerant NK cells (Figure 16.7). Regardless of the MHC-I environment, licensed NK cells are tolerant because they have inhibitory receptors for self-MHC, the same receptors involved in licensing. Unlicensed NK cells are also tolerant because they are not functionally competent and have no need for inhibition by self-MHC under steady-state conditions. In hosts heterozygous for MHC alleles, each MHC allele could potentially license different NK cell populations. This aspect of licensing is relevant to hybrid resistance because an $(A \times B)F_1$ hybrid animal should have NK cells that are separately licensed on different MHC alleles. F_1 hybrid NK cells that were licensed by MHC alleles from parent A should be inhibited by A alleles but not B alleles and thus reject BM from parent B. The converse should also be true. In the F_1 animal itself, NK cells are licensed by either parental allele, so all NK cells should be inhibited by normal tissues that codominantly express both MHC alleles. Licensing potentially explains how NK cells distinguish cells expressing the full complement of MHC-I from those expressing only some alleles.


FIGURE 16.7 Licensing of NK cells by host MHC-I. Depicted is the situation in a mouse expressing only H2K^b that is a ligand for Ly49C but not Ly49A. Cells expressing Ly49C therefore have a self-specific receptor whereas those expressing Ly49A do not. Ly49C engagement by self-MHC-I results in a licensed NK cell that has functional competence to be triggered through its activation receptors. These cells can be inhibited by self-MHC through the same receptor that conferred licensing. Ly49A$^+$ NK cells remain self-tolerant because they are unlicensed. For clarity, only one MHC allele and cells expressing one Ly49 receptor are shown. Normally, the host has multiple MHC alleles, each of which could license different NK cells, and individual NK cells express multiple Ly49s simultaneously. Each NK cell is likely to be licensed separately, potentially by different MHC alleles, and through different Ly49s. Taken from (183).

Although licensing is a positive outcome (i.e., the acquisition of functional competence), it requires the ITIM of the self-specific Ly49 receptor to deliver signals that ultimately result in a licensed NK cell (183) (Figure 16.7). Although this appears to occur in the BM, the nature of such signals is not yet known. At least two qualitatively different models are being considered. The MHC-specific receptor could confer licensing in a positive way (stimulatory model) by delivery of signals that directly induce a differentiation process and license NK cells. In the inhibitory model, the MHC-specific receptors may act to decrease the effect of a putative, as yet uncharacterized, self-specific activation receptor. When unimpeded by self-MHC-I, NK cells may become hyporesponsive due to overstimulation through the activation receptor. This model is somewhat akin to T cell anergy. Both models are similar to those previously proposed *(638)*, but engagement of the MHC-specific receptor with self-MHC is now known to be a required key step (183) and is common to both models. Also, the models are not mutually exclusive and either could be affected by co-receptors or adhesion molecules. Thus, studies of these tolerance mechanisms should be forthcoming.

Recent studies suggest that human NK cells are also subjected to a similar process involving KIR and self-HLA ligands (639). These effects may be relevant to the increasing awareness that the outcome of human disorders is associated with certain combinations of KIR and HLA genotypes (250). Such KIR-HLA relationships frequently involve pairs with high affinities and resolution of chronic infections (257) and are difficult to explain when only considering effector inhibitory function of the KIRs. Thus, licensing may be clinically relevant.

ROLE OF NK CELLS IN IMMUNE RESPONSES

Mature NK cells in the periphery are involved in rapid innate defense. However, they constitute only a small population of cells (about 2.5% of splenic leukocytes in C57BL/6 mice). How can this small population quickly respond with enough of a critical mass to effect significant innate defense? One mechanism involves the expression of multiple activation receptors by individual NK cells *(359)*. In contrast to clonally distributed TCRs endowing the individual

T cell with the ability to respond only to one antigen, an individual NK cell appears capable of responding to multiple activation receptor ligands. Further, the naïve T cell population contains only rare cells with a TCR for the relevant antigen, whereas large percentages of the NK cell population express any given activation receptor in an overlapping fashion. This multiple activation receptor expression on sizeable subpopulations would allow a substantial number of NK cells to quickly respond to a given specific insult. Another mechanism is related to their constitutive expression of cytokine receptors that permit many NK cells to be stimulated by pro-inflammatory cytokines produced early in the course of an immune response. Thus, large numbers of NK cells can rapidly respond to a particular stimulus through their activation or cytokine receptors.

Another issue in NK cell immune responses concerns their tissue location. Mature peripheral NK cells are found primarily in the blood, spleen, and liver. The homing of NK cells to these locations is not well characterized, but NK cells appear to have developmentally regulated expression of a number of integrins that may play a role in their localization as well as effector functions (70,*640*). In addition, several chemokines, including CXCL12 and MIP1α, have been implicated in NK cell localization to other tissues during immune responses (*641,*642–*646*).

Interestingly, immunohistochemical *in situ* staining has shown that NK cells are localized to the red pulp of the spleen (*647,648*). In the liver, they are in the sinusoidal regions rather than the parenchyma, and few NK cells are present in other solid organs. Surprisingly, there are relatively few NK cells in naïve lymph nodes (*647,649*). Injection of tumor targets leads to NK cell accumulation if the targets are sensitive to natural killing *in vitro* (*650*). In viral infections, NK cells infiltrate the liver parenchyma in the vicinity of infected foci (*644,647*). Although NK cells may be less effective in killing when they migrate into parenchymal tissues (*651*), others have not recapitulated tissue-specific differences in NK effector function (*652*). Thus, NK cells seem best suited for surveying the blood for transformed or infected cells and pathogens though interactions with DCs support additional roles (discussed later).

NK Cells and Tumor Surveillance

Abundant literature supports a role for NK cells in resisting tumor growth and metastasis (*3*). In addition, LAK cells have been infused into patients with cancers refractory to conventional therapy (*653*). Several cases of complete remission were reported, but the treatment required intravenous administration of high doses of IL-2 that has significant toxicity.

Most prior work on NK cells and anti-tumor effects utilized experimental protocols involving adoptive transfer of tumor cells into mice where NK cells can eliminate >90% of tumor cells within the first 24 hours (*654*). Several long term assays of *in vivo* tumor clearance are available, such as survival or lesion size. However, T cell immune responses need to be excluded even in syngeneic hosts due to the possibility of tumor-specific peptides. Clearance of intravenous-administered radiolabeled tumor cells can be measured with radioactivity of the lung as an index of tumor burden. Because this lung clearance assay can be performed as early as 4 hours after tumor inoculation, it is relatively confined to innate NK cell responses in the unimmunized host (16,*614*). With these assays, perforin-deficient mice are unable to clear tumors (*655*), and augmentation of NK cell activity with various agents increases the capacity of the hosts to eliminate tumors (*654*).

However, few studies are available on control of primary tumor formation by NK cells—that is, tumor surveillance—that have only recently garnered attention (656). Probably the most systematic studies in a single experimental model involve fibrosarcoma development after subcutaneous methylcholanthrene challenge (*657–659*). In brief, NK cells collaborate with NKT cells in preventing fibrosarcomas through mechanisms involving perforin, TRAIL, and IFNγ. There is also evidence for involvement of NKG2D (*435*) and its ligands with respect to the immunoediting of tumors by NK cells (*437,438*).

NK Cells in Host Defense Against Pathogens

Although NK cells reportedly respond to a wide variety of microorganisms (*660*), the role of NK cells in infections is probably best illustrated by human patients with selective NK cell deficiencies (661,*662,663*,664). Although the molecular basis for most human NK cell deficiencies is unknown, several points can be gleaned: 1) NK cell deficiency is associated with a propensity for severe or recurrent virus infections, particularly herpes viruses. 2) Difficulty with tumors is not a common feature, except for virus-related lesions. 3) The disorder is rare, perhaps because patients succumb to overwhelming infection before the syndrome is recognized. 4) Defective NK cells can be found in other genetic and acquired immunodeficiency disorders that affect other immune components. For example, NK cell activity is significantly diminished in AIDS (*665,666*). NK cell infection with herpesvirus 6 induces *de novo* expression of CD4 rendering susceptibility to HIV-1 infection (*667*), perhaps accounting, in part, for increased susceptibility of AIDS patients to opportunistic infections, such as severe CMV (668). Immature NK cell number and function in the developing fetus may be clinically relevant to the classic "TORCH" syndrome, birth defects associated with maternal Toxoplasma, rubella, CMV, and herpesvirus infections (*669–671*). Thus, NK cells appear to be especially important in controlling infections, especially from herpes viruses.

In mouse models, detailed and ongoing evaluation of mouse NK cell responses, especially against viral and Listeria infections, have been especially revealing (summarized in *[672,673]*). For example, beige mice are susceptible to MCMV infections (674). *In vivo* antibody depletion of NK cells results in marked viral replication in internal organs (spleen, liver), and lethality with MCMV, vaccinia virus, or mouse hepatitis virus (675,676,677). A similar phenotype was observed in Tg mice lacking NK cells *(652,678)*. Interestingly, if depleting antibody was given to wild-type mice later in the infection, there was no untoward effect *(676)*. Thus, NK cells are significant in early, innate immunity to infections.

NK Cell Cytokine Responses and Production During Infection

During infection, NK cells can respond to several different cytokines resulting in production of other cytokines. In Listeriosis, the classic model for T cell–dependent resistance, *scid* mice achieve acute control of infection despite absence of T cells *(679)*, due to early NK cell production of IFNγ *(680)*. However, NK cells do not appear to respond directly to Listeria. Rather, macrophages produce IL-12 that then stimulate NK cell secretion of IFNγ and infection control (121,*681*). Further, TNF-α can synergize with IL-12 to induce NK cell production of IFNγ, whereas IL-10 is antagonistic (121). The increased susceptibility of mice lacking IL-12 receptor, IFNγ, or the IFNγ receptor signaling pathway *(682–685)* are consistent with macrophage production of IL-12 that stimulates NK cells to secrete IFNγ in Listeriosis.

While a similar IL-12-IFNγ pathway is also operational in MCMV infections *(673,678,686)*, IL-18 also contributes somewhat to NK cell control of MCMV *(687)*. However IL-12 appears to be more critical than IL-18 because uniform lethality was observed in IL-12p35$^{-/-}$ mice challenged with MCMV, while all IL-18$^{-/-}$ mice survived *(687)*. On the other hand, neutralization of IL-18 is a common feature of orthopoxviruses *(688)*. For example, ectromelia virus (EV, mousepox) contains an ORF for an IL-18 binding protein (IL18BP) that effectively neutralizes the effects of IL-18 on NK cells *(689)*. In addition to augmented IFNγ production, IL-18 enhances perforin-dependent cytotoxicity *(623,690,691)*.

Importantly, not all viral infections are controlled by NK cells. For example, NK cell depletion has little effect on lymphocytic choriomeningitis virus (LCMV) infections *(673,675,692)*. Yet many NK cell activities are stimulated by LCMV infection.

During infections, even with LCMV, cytotoxicity of NK cells is enhanced, and proliferation ensues. These events constitute systemic effects directly or indirectly mediated by cytokines, such as IL-12, IL-18, and IFNα/β *(693)*. However, IFNγ production is not seen in LCMV infections *(678,694)*. This apparent paradox is due to an inhibitory

effect of IFNα/β on IL-12–dependent IFNγ production *(694)*. Inhibition by IFNα/β is mediated through the STAT1 signaling pathway. In the absence of STAT1, IL-12 responsiveness is restored and IFNα/β induces IFNγ production. Although it remains to be determined how the IFNα/β response to LCMV differs from MCMV, these studies indicate that the NK cell cytokine response to infection varies with the pathogen even though many responses may appear to be similar.

A challenging area of investigation is the role of IL-15 in NK cell responses *in vivo (695)* because IL-15 and IL-15Rα–deficient mice lack NK cells (48,49). Nevertheless, NK cells can be stimulated during infection by IL-15 and control viral replication during *in vitro* cultures *(695–699)*. Moreover, IL-15 can provide protection to *Herpes simplex* viral infections *(699)*. Finally, IFNα/β can stimulate IL-15 production that can drive NK cell proliferation *(700)*.

NK cell responses to cytokines are also regulated by other innate lymphocytes. For example, in TCR$\delta^{-/-}$ mice, Listeria infection is enhanced compared to TCR$\beta^{-/-}$ mice and is associated with diminished production of IFNγ by NK cells, suggesting that γ/δT cells regulate NK cell responses *(701)*. Similarly, NKT cells can regulate NK cells because administration of α-galactosylceramide, a potent ligand for the TCR on NKT cells, results in nearly concomitant activation of NK cells, possibly due to release of IFNγ by the NKT cell (67). Inasmuch as NKT cells can recognize glycolipid antigens in Mycobacteria *(702,703)*, these studies indicate a potential physiologically important mechanism for NK cell activation in innate immunity to these organisms.

NK Cell Activation Receptors in Infection

There are several observations from studies of viral evasion indicating the importance of NK cell activation receptors in infection. Because viruses have evolved numerous strategies to down-regulate MHC-I molecules on infected cells to avoid MHC-I-restricted cytotoxic T lymphocytes *(139)*, virally infected cells should have enhanced susceptibility to NK cell lysis. However, viruses also encode proteins that interfere with natural killing (for recent review, see [704]).

In many cases, viral interference of natural killing is related to enhanced function of inhibitory MHC-I-specific NK cell receptors. For example, murine and rat CMV contain ORFs *m144* and *r144*, respectively, which encode molecules with sequence homology to MHC-I and enhance *in vivo* virulence, presumably by interacting with as yet unidentified NK cell inhibitory receptors (705,*706–708*). Human CMV (HCMV) encodes an MHC-I-like molecule (UL18) that interacts with LIR1 (ILT2), an Ig-like inhibitory receptor on NK cells (261,709). HCMV also encodes a peptide that binds and enhances expression of HLA-E that in turn binds CD94/NKG2A, a lectinlike NK cell inhibitory receptor (294,710). Another example is the

selective down-regulation of MHC-I by the human immunodeficiency virus, HIV-1 *(711)*. In this case, the virus downregulates HLA-A and B but not HLA-C or E; the former HLA molecules tend to be restricting elements for MHC-I-restricted CTLs, while the latter are selectively recognized by human KIRs and CD94/NKG2A. Therefore, viruses have evolved mechanisms to selectively engage inhibitory receptors that presumably prevent the action of NK cell activation receptors.

Viruses can also directly block triggering of NK cell activation receptors. For example, both human and mouse CMV block NKG2D recognition of its ligands with functional consequences *in vitro* and *in vivo* (discussed in greater detail earlier in this chapter) (405,*411,*442,*443–446,712*). More generally, the Kaposi's sarcoma–associated herpesvirus (KSHV) avoids NK cell activation through K5 that down-regulates expression of ICAM-1 and B7-2, ligands for NK cell coreceptors involved in target-induced stimulation *(713)*. Indeed, the interaction of LFA-1 on the NK cell with target ICAM-1 is critical for NK cell killing of targets *(714)*. Thus, viruses encode multiple proteins to specifically thwart NK cell responses through their activation receptors.

The viral evasion strategies implicate NK cell activation receptors that specifically recognize infected cells; these receptors are just beginning to be identified. Human NKp46 binds hemagglutinin of influenza virus and hemagglutinin-neuraminidase of parainfluenza virus, suggesting it may be involved in resistance to these viruses (501). However, this interaction is dependent on sialic acid residues that are widely expressed, and the *in vivo* significance of these findings is difficult to assess in humans. Nevertheless, recent studies in NKp46–deficient mice corroborate these findings *(504)*.

The autosomal dominant *Cmv1* gene in the NKC is responsible for resistance of certain mouse strains to MCMV (*476,477,715,716*); MCMV-resistant C57BL/6 mice are susceptible when depleted of NK cells *(717)*. Extensive genetic and immunological evidence established that *Ly49h* is responsible for genetic resistance to MCMV (*359,717,718–720*). A DAP12 signaling mutant mouse could not resist MCMV *(721)*, consistent with *in vitro* signaling studies showing that Ly49H signals through DAP12 (*358,718*). Thus, Ly49H is an NK cell activation receptor responsible for genetic resistance to MCMV.

The ligand for Ly49H is encoded by the *m157* ORF in MCMV (354,356). M157 has a predicted MHC-I fold, among 11 other MCMV molecules. Interestingly, in mice lacking adaptive immunity, m157 mutant MCMV clones emerge during MCMV infection, indicating selection pressure from Ly49H$^+$ NK cells result in escape mutant viruses (722). The reasons for maintenance of *m157* in the MCMV genome are still under investigation, but several observations suggest *m157* may be advantageous to the virus under certain circumstances: 1) m157 binds to an inhibitory

Ly49 receptor in certain mouse strains (356). 2) *m157*-deletion viruses cause a modest decrease in viral titers in mice lacking Ly49H, suggesting another immune evasion role *(723)*. 3) Host-virus coevolution often results in attenuated viruses *(724)*, and other MCMV proteins have positive effects on host responses *(725)*. 4) Finally, a unique aspect of herpesvirus biology is the capacity to become latent. If the virus kills the host during the acute viral replicative phase during which Ly49H mediates its control, then there will be no latent phase. Additional studies of m157 will be required to fully understand its biology.

Loci for resistance to other pathogens, such as mouse pox (ectromelia) virus and HSV, have also been genetically mapped to the NKC *(726,727)*. These loci are termed *Rmp1* and *Rhs1*, respectively, and C57BL/6 mice are resistant. However, recent studies have reported that *Rhs1* independently segregates from *Cmv1 (727)*. Nevertheless, the parallel phenotypes with *Cmv1* suggest that other NKC encoded NK cell activation receptors may be involved in NK cell–mediated resistance to other viruses.

In addition to target killing, NK cell activation receptors also trigger cytokine production *in vitro*. Although the relative contribution of this pathway of cytokine secretion to NK cell function in infection is currently unknown, Ly49H$^+$ NK cells can be selectively activated to produce IFNγ gnd chemokines within 6 to 8 hours after coincubation *in vitro* with MCMV-infected macrophages or m157 transfectants (354,*728*), and m157 itself is expressed soon after infection *(729)*, indicating that competent NK cells can respond within hours of recognizing virus-infected cells.

These findings, however, contrast with the relative "nonspecific" stimulation of NK cells found during early MCMV infection *in vivo* where IFNγ production was not confined to the Ly49H$^+$ NK cell subset (613). Moreover, while direct assessment of NK cell proliferation by FACS analysis of *in vivo* BrdU (bromo-deoxyuridine) incorporation (613) confirmed that infection stimulates NK cell proliferation *(730,731)*, it also revealed that early (days 1 to 2 postinfection) *in vivo* NK cell proliferation was nonselective with respect to Ly49H expression. This proliferation resembled the cytokine-driven "bystander proliferation" observed in T cells in response to viral infections or stimulation with IFNα/β *(732)*, suggesting that the initial phase of viral-induced NK cell proliferation represents a nonspecific response to pro-inflammatory cytokines (IL-12, IFNα/β) and proliferative cytokines such as IL-15. The nonselective proliferation phase was followed by a period of preferential proliferation of Ly49H$^+$ NK cells peaking at days 4 to 6 of MCMV infection (613). The selective phase of NK cell proliferation reflected the augmentation of pro-proliferative cytokine stimulation by Ly49H signaling mediated via DAP12 *(733)*. In vaccinia infection, the initial phase of nonspecific NK cell proliferation was found but

the later specific proliferation of Ly49H$^+$ NK cells was not (613). Thus, initial virus-specific NK cell responses may be masked by generic cytokine responses and only later are detectable.

NK AND DC INTERACTIONS

Given that both NK and DCs, when separately studied, are critical early responders in host immune defense, it is not surprising that these cells communicate in a bidirectional manner (734). In this "cross-talk," NK cells can respond to signals derived from DCs and vice versa (735,736,737, 738). Data support both cell contact-independent and -dependent pathways.

contact-independent pathways are perhaps better understood. Activated DCs can produce cytokines, including IFNα/β, IL-12, IL-15, and apparently IL-2 (27,739–742). As mentioned previously, all of these cytokines can stimulate NK cell production of other cytokines, such as IFNγ. Moreover, these cytokines enhance NK cell cytotoxicity by increasing expression of perforin and granzymes as well as perforin-independent cytotoxic pathways. The cytokines can also enhance signaling through ITAM-signaling chain-associated receptors (743). A variety of stimuli, such as certain TLR ligands (27,741,744), can activate DCs to produce cytokines that activate NK cells, although it remains to be established whether all DC stimuli are capable of similar effects. Nevertheless, TLR9-dependent activation of pDCs in MCMV infections is critical for appropriate NK cell control of infection (744).

Direct NK–DC cell–cell contact can also enhance NK cell activation (734). Several molecules have been implicated in this process, including cytokine-induced DC expression of ligands for human or mouse NKG2D (745,746). Human DCs can also activate resting NK cells via the NKp30 receptor (747). Other studies indicate that mouse NK cells can be activated by DCs in a TREM-2–dependent manner through the DAP12 signaling pathway (748).

Conversely, NK–DC interactions can induce DC maturation (738). For example, MHC-I-deficient targets can activate NK cells, which then induce DC maturation (749). NK–DC interactions also enhance TH1 polarization apparently through NK cell production of IFNγ (750). During MCMV infections, recognition of virus-infected cells by NK cells is critical for maintenance of DC subsets in the spleen (751). NK cells can also prime DCs to stimulate protective memory T cell responses against lymphomas (749). While NK–DC cell contact is also subject to inhibitory effects and even killing of DCs by NK cells (752,753), the capacity of NK–DC interactions to induce T cell responses (746,749,750,754) has led to interest in exploiting these interactions for therapeutic vaccines (755).

Although a hallmark of DC maturation is migration to a draining lymph node (LN), very few NK cells are present in the resting LN (647). Interestingly, however, deliberate introduction of DCs into the lymphatics leads to robust recruitment of activated NK cells (750). Real-time imaging indicates that NK cells contact DCs in the superficial regions of the LNs, where they are less motile and their interactions with DCs are more extensive than T cell motility and contacts with DCs (756). Leishmania infection led to NK cell secretion of IFNγ and migration to the paracortex where CD4 T cell activation occurred, indicating dynamic interactions in the LN not previously appreciated.

Recent evidence also suggest differences in LN NK cells in terms of capacity to be activated as compared to NK cells from conventional sources (peripheral blood, spleen) (740,757). For example in humans, nearly all NK cells in the LN are CD56^{bright}, whereas only ∼10% of peripheral blood NK cells are CD56^{bright} (649). Since CD56^{bright} NK cells have greater capacity to produce cytokines and lower cytotoxic capacity as compared to CD56^{dim} NK cells that dominate peripheral blood, LN NK cell populations appear to be particularly poised to stimulate subsequent immune responses. Moreover, LN NK cells appear to differ in capacity to respond to DCs (758).

Finally, NK cells express markers associated with DCs, such as CD11b (Mac-1, αM/β2, CD11b/CD18) and CD11c (p150/95, CD11c/CD18), that led to recent descriptions of cells with dual NK and DC phenotypes (759–761). However, whether such NK/DC cells are truly a distinct or overlapping lineage of cells, separable from conventional NK cells, remains to be established. In this regard, it is notable that NK cells frequently express markers originally thought to be exclusively found on other cells, such as B220 on B cells (9) and Mac-1.

NK CELLS AND MATERNAL–FETAL INTERACTIONS

One enigmatic area of continuing interest concerns NK cells in maternal–fetal interactions (summarized in [762,763,764]). Several observations are related: 1) Initially described as granulated metrial gland cells, maternal NK cells accumulate in the uterus, near the fetal trophoblast layer, in all mammalian species examined thus far. 2) Accumulation is related to local production of IL-15 (765). 3) Uterine NK cells more closely resemble CD56^{high} subpopulation, but there are still phenotypic differences, including expression of activation markers and different repertoire of MHC-specific receptors. 4) Human trophoblasts express the nonclassical MHC-I molecule, HLA-G, (766) but not other MHC-I or -II molecules. 5) Trophoblasts are sensitive to NK cells (767), but deficiencies of mouse NK cells are not associated with significant changes in fecundity. 6) Mice lacking NK cells show defects in placental blood vascular remodeling that appears to be IFNγ-dependent (768). 7) There are significant differences in the anatomy of the maternal–fetal interface that may limit

extrapolation of experimental results from one species to another (764). Nevertheless, uterine NK cells may provide important clues to understanding maternal–fetal interactions.

NK CELLS IN HUMAN DISEASE

Throughout this chapter, we have used human disorders involving NK cells to help illustrate their biology. In addition, NK cells are associated with autoimmune disorders *(769)*, such as multiple sclerosis, where they may regulate pro-inflammatory cells *(770)*. Interestingly, NK cell proliferative disorders are associated with both chronic viral infections (Epstein-Barr virus) and autoimmune phenomenon (8,*771*). NK cell malignancies can appear as lethal midline granuloma due to the propensity of NK lymphomas to present in the sinus and nasopharyngeal passages and be especially destructive *(772)*. NK cells are also associated with hydroa vacciniforme and hypersensitivity to mosquito bites *(773)*. Dysfunctional NK cells are found in patients with familial perforin deficiency *(774)* who typically demonstrate hemophagocytic lymphohistiocytosis that is also found in the macrophage activation syndrome and systemic-onset juvenile rheumatoid arthritis *(775)*.

Thus, as immunologists and physicians gain more appreciation for the molecular basis for NK cell biology, the future holds promise for insight into a number of enigmatic and unusual human diseases as well as common disorders, such as HCV and HIV infections, and exploitation of NK cells for immunotherapy.

NKT Cells and Other Innatelike T and B Lineages

Albert Bendelac

INTRODUCTION AND DEFINITION OF INNATELIKE LYMPHOCYTES

Characteristic features oppose innate and adaptive immunity in vertebrates. Innate immunity is an evolutionarily primitive, rapid arm of the immune response that relies on a set of germline-encoded receptors, some of which are conserved in plants and insects. These receptors are broadly expressed in body fluids, tissue cells, or mobile hemopoietic cells, and they generally recognize conserved self or pathogen structures to trigger effector mechanisms that are more or less tailored to the pathogen. In contrast, adaptive immunity evolved in vertebrates as a delayed arm of the response that relies on the expansion of rare lympho-

cytes expressing highly diverse, clonally restricted, antigen-specific receptors arising through random rearrangement of large families of gene segments encoded in specialized genetic loci. These receptors include leucine-rich-repeat domain receptors (variable lymphocyte receptor, VLR) in primitive fish and, in other vertebrates, the immunoglobulin domain receptors immunoglobulin (Ig) H/L, T-cell receptor (TCR) α/β or TCR γ/δ. Lymphocytes expanded after antigen encounter persist to form the basis of memory responses, another hallmark of adaptive immunity.

Some subsets of T and B lymphocytes, however, straddle the boundaries between innate and adaptive immunity. These "innatelike" lymphocytes express canonical
FIGURE 17.1 Specialized tissue niches and their resident innatelike lymphocytes. Left: Fluorescent NKT cells in CXCR6-GFP "knock-in" mice are "patrolling" the liver sinusoids. (Courtesy of Jessica Strid and Adrian Hayday, King's College, London, UK.)

germline-encoded antigen receptors that are specific for conserved self- and microbial ligands and are present at high frequency in specific tissues, suggesting that they function as immunologic sentinels and first line of defense in various strategic locations (Figure 17.1). With their memory/effector differentiation, they appear poised to mediate innatelike functions, which have been documented in a surprisingly broad range of conditions, from the regulation of autoimmunity and inflammation to antimicrobial defense and cancer rejection, as well as in homeostasis.

Innatelike lymphocytes include so-called B-1 B cells and a subset of marginal-zone B (MZB) cells; a fraction of $\gamma\delta$ T cells; subsets of $\alpha\beta$ T cells such as CD1d-restricted "NKT" cells and MR1-restricted mucosal-associated innate T cells ("MAIT cells") (Table 17.1). Studies have revealed common themes and principles in their development, antigen specificity, and function, although variations are found with individual subsets. Innatelike lymphocyte subsets are variably represented in different mammalian species. They represent a distinct host defense strategy, perhaps corresponding to an early phase of evolution of adaptive T- and B-cell immunity. With a particular focus on the well-studied NKT cell subset, this chapter will treat them as a group, using specific examples that illustrate similarities and differences.

CANONICAL GERMLINE-ENCODED ANTIGEN RECEPTORS

Antigen Receptor Structure

The most characteristic feature of innatelike lymphocytes is the expression by relatively large numbers of lymphocytes of so-called canonical and germline-encoded B- or T-cell receptors that are specific for conserved self- or foreign antigens. "Canonical" sequences are invariant sequences or motifs in the CDR3 regions of one or the two receptor chains, which are involved in antigen contact. The "germline" nature of these canonical receptors arises from nucleotide sequences that are entirely encoded in the genome, and do not require nontemplated N-nucleotide addition or mutation. Thus, these genetic elements could have been naturally selected for their protective value during the evolution of the immune system. For each of these canonical sequences, there are individual examples exhibiting nucleotide trimming and N additions. Because these changes are conservative—that is, they preserve the canonical amino acid sequence—they illustrate another important aspect of the biology of innatelike lymphocytes, which will be discussed later: antigen-driven cellular selection.

Some canonical receptors, such as the T15 antiphosphatidylcholine BCR (Table 17.2) and the Vγ5 [nomenclature according to Heilig and Tonegawa (1)] dendritic epidermal T-cell (DETC) TCR (Table 17.3) are made of invariant H/L or γ/δ pairs, and their production is generally limited to the fetal or neonatal period (2,3). Others appear to be "semi-invariant," as only one chain is invariant whereas the other exhibits diversity. For example, CD1d-restricted NKT cells express a canonical Vα14-Jα18 TCR α chain paired with β chains that use a limited set of Vβ8, Vβ7, Vβ2 families joined to variable DβJβ (4) (Table 17.4). Similarly, antiphosphatidylcholine-specific B1 B cells use invariant VH11 and VH12 heavy chains, with Vκ9 or Vκ4 light chains that are diverse in their Jκ usage (5,6). Other receptors exhibit relatively limited areas of sequence conservation or "motifs." In the case of γδ T cells specific for the MHC class I–like molecule T10/T22, a canonical sequence was not apparent until multiple T-cell clones were obtained and sequenced to suggest the importance of a W-(S)EGYEL motif, where W could be contributed by a Vδ or by Dδ1, SEGYE was from a Dδ2 segment, and L was encoded by a P nucleotide (7). The crystal structure of the TCR bound to T22 directly demonstrated that this canonical sequence contacts the antigen (8).

Ultimately, the canonical BCRs and TCRs functionally resemble innate receptors such as Toll-like receptors (TLR), for example, by their germline specificity for conserved antigens. Like TLRs, they can be monospecific or multispecific, recognizing related antigens or antigens of vastly different structure. The variable parts of these canonical receptors can modulate the affinity of antigen recognition, as shown for NKT cells (9–11) and for T10/T22-specific γδ T cells (7), perhaps affording greater plasticity for functional responses and for recognition of variant antigens.

Achieving a high frequency of canonical rearrangements is a prerequisite to contribute to innate responses. Depending on the canonical receptor, this requirement is met by diverse genetic strategies, by cellular selection, and, in some cases, by clonal expansion.

Genetic Mechanisms That Produce Canonical Antigen Receptors

Some genetic mechanisms operate early in fetal and newborn life, revealing distinct intrinsic properties of fetal progenitors, whereas others operate throughout newborn and adult life.

Programmed Rearrangements

In the fetal and neonatal periods, B and T lymphocytes show conspicuous tendencies to rearrange and express particular V(D)J gene segments encoding the canonical antigen receptors of some γδ T cells and B-1 B cells. This is particularly well illustrated for the sequential rearrangements that give rise to waves of TCR γδ T cells colonizing the skin and the other mucosal tissues in mice (2,12) and for the B-1 B cells that express the so-called T-15 idiotype (corresponding to the canonical portion of the antibody structure) (3). The molecular basis of these ordered rearrangements involves local as well as large-scale changes in chromatin structure that are still poorly understood (13). Nevertheless, signaling through the cytokine receptors for interleukin-7 (IL-7) or IL-15 involving Stat5 was shown to be essential for the expression of various B-1 and γδ TCR canonical receptors (14–17). IL-7 receptor signaling regulated histone acetylation and transcriptional activation of V$_H$558 genes through Stat5 binding the transcription factor Oct-1 (18). Interestingly, thymic

stromal-derived lymphopoietin (TSLP) can substitute for IL-7 and signal through IL-7Rα in fetal but not adult B-cell ontogenesis (19,20). These differences might explain intrinsic differences in BCR repertoire and possibly also other lineage characteristics of B cells produced in early life as compared to adult life.

Terminal Deoxynucleotidyl Transferase (TdT)

Low-level expression of TdT in the fetal and neonatal period favors germline canonical sequences by decreasing the frequency of nontemplated nucleotide addition (N diversity) at the joining end of the rearranging segments. Thus, genetic overexpression of TdT impairs, whereas abrogation favors, canonical rearrangements (21,22).

Short-Nucleotide-Homology-Mediated Rearrangements

The formation of canonical sequences is enhanced by regions of short homology that guide the recombination process (Tables 17.2 through 17.5). These short-homology regions are contributed sometimes by P nucleotides palindromic to the nucleotides at the end of V, D, or J elements (Tables 17.3 and 17.5). Suggested initially for the formation of T-15 antibody rearrangement (3), this general mechanism has been demonstrated *in vivo* for the fetal TCR γδ rearrangements that generate DETC cells (21).

Several canonical antigen receptors are produced continuously over the lifespan of the animal. This is the case, for example, for CD1d-restricted NKT cells, MR1-specific MAIT cells, phosphoantigen-specific Vγ9 T cells, and phosphatidylcholine-specific B-1 B cells. Because the Vα14 and Jα18 segments are distal, their recombination depends on the prolonged lifespan of double-positive thymocytes, which requires the induction of the antiapoptotic Bcl-xL protein by the transcription factor RORγt expressed at the double-positive stage of thymocyte development (23,24).

Antigen-driven Cellular Selection of Canonical Antigen Receptors

Although they were debated initially, there are now converging findings indicating that many innatelike lymphocyte subsets, including those that rely on programmed fetal rearrangements, undergo a phase of cellular selection driven by specificity for their self-ligand. Furthermore, as will be discussed in the section on lymphocyte development, these antigen-recognition events appear to be essential to initiate the peculiar signaling pathways that drive lineage differentiation.

Transgenic expression models have been generated for several canonical receptors and have usually demonstrated that receptor expression instructed the corresponding lineage differentiation for NKT cells (25,26) (Figure 17.2), DETC (27) and liver γδ T cells (28), B-1 B cells (29–32) (33), and MZB cells (34). Conversely, expression of

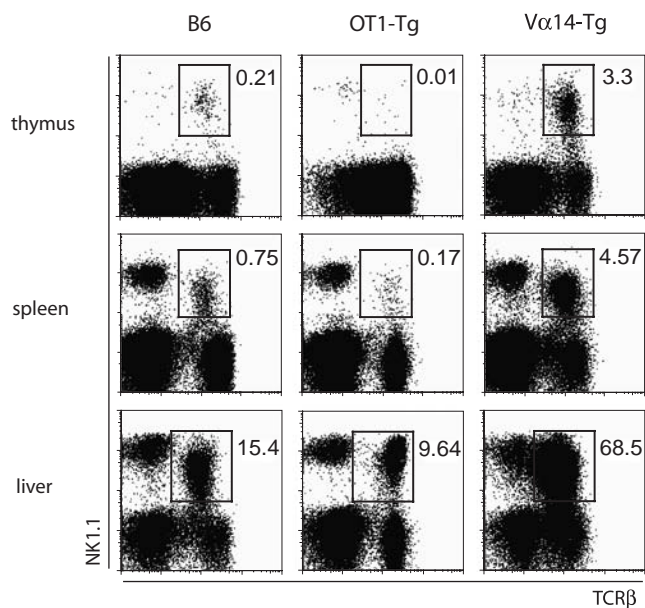

FIGURE 17.2 Developmental instruction of the NKT lineage by transgenic expression of the Vα18-Jα18 TCR α chain. In C57BL/6 mice, NKT cells labeled by anti-TCRβ and -NK1.1 are found in thymus and spleen but predominate among liver lymphocytes. Transgenic (Tg) mice expressing the Vα14-Jα18 Tg TCR α chain have increased NKT cell frequency, whereas mice expressing the MHC class I–restricted ovalbumin-specific TCR OT-1 are deprived of NKT cells. The NK1.1⁻ T cells in Vα14-Jα18 Tg mice include cells that express inappropriate Vβ families. The NK1.1⁺ T cells in OT-1 mice include cells that express endogenous Vα14-Jα18 TCR alpha chains.

"mainstream" αβ TCRs or BCRs prevented the development of NKT cells, B-1 B cells, and MZB cells, respectively. In cases where the self-ligand is known and could be deleted, development was interrupted, indicating that selection is based on antigen receptor/ligand interactions. Thus, ablation of CD1d (35–37), MR1 (38) specifically abrogated the development of TCR αβ NKT or MAIT cells, respectively. Beta 2-microglobulin–deficient mice did not support the development of T10/T22-specific KN6 γδ transgenic cells (39). B-1 B cells expressing an antibody specific for a carbohydrate determinant on the glycoprotein Thy-1 were not found in Thy1-deficient mice (40).

In the presence of a rearranged Vα14-Jα18 TCR α chain, TCRs using a Vβ8, Vβ7, or Vβ2 chain are the only ones that recognize the endogenous NKT ligand iGb3. This bias, which contrasts with the ability of Vα14-Jα18 to pair broadly with the entire Vβ repertoire, precisely matches the set of Vβs used by NKT cells, consistent with the notion of positive selection by this antigen (10).

Detailed analysis of the nucleotide sequences of canonical antigen receptors provide further unambiguous examples of antigen-driven selection. For example, a subset of the Vα14-Jα18 sequences of CD1d-restricted NKT cells ex-

hibit variations in nucleotides, but these variations preserve the canonical amino acid sequence (4). In the case of MR1-specific MAIT cells, the mouse Vα19-Jα33 nucleotide sequence is largely invariant, probably owing to a long stretch of nucleotide homology between Vα19 and Jα33 (Table 17.4), but the human Vα7.2-Jα33 sequences show junctional variations with N nucleotides. The length of the CDR3 loop and its canonical amino acid motif are well preserved, however (38,41). Similar examples of antigen-driven selection have been found for the VH11 and VH12 heavy chains of phosphatidylcholine-specific B1 B cells (31,42).

T10/T22specific γδ TCRs have a canonical CDR3δ motif W-(S)EGYEL that includes a W variably originating from Vδ6, Dδ1, or even P/N elements (7). Although this T10/T22-specific sequence is found at relatively high frequency among peripheral γδ T cells, it is unclear whether the corresponding cells have undergone antigen-driven selection *in vivo*, because the specificity is still expressed at high frequency in β2-microglobulin–deficient mice and a large fraction of the T10/T22-specific cells exhibit a naïve phenotype. However, memory-type cells do require T10/T22 expression.

In the case of DETC cells with tightly programmed Vγ5/Vδ1 rearrangements, Vγ5 gene-ablation experiments demonstrated that only select Vγ/Vδ TCRs could substitute for Vγ5/Vδ1. These substitutes exhibited reactivity to a skin-derived epidermal cell line, shared a conformational epitope (idiotype) with Vγ5/Vδ1 as detected by a monoclonal antibody, or used select Vδs, suggesting selection by the same self-ligand (43,44), perhaps expressed by thymic stromal cells (45).

Vγ9/Vδ2 TCRs exhibit a changing pattern of formation with age (46–48). Thus, canonical germline sequences are found in nearly all the Vγ9Vδ2 cells of the human fetal liver (Table 17.5). These cells already express a memory CD45RO⁺ phenotype. Later, in the perinatal period, substantial N-diversification is observed and a majority of the cells have a naïve phenotype, likely because they have lost specificity for self-antigen. Ultimately, antigen-driven selection becomes evident as the sequences accumulating in the adult repertoire retain the specificity of the germline fetal TCR and are associated with a memory phenotype. These observations illustrate both the importance of genetic mechanisms to increase the production of canonical sequences early in life and the presence of self-antigen–mediated selection at all stages of life.

Other, non–antigen-driven selection mechanisms have been proposed to narrow the antigen-receptor repertoire of future innatelike B-1 lymphocytes during early development. These include altered pairing with the surrogate light chain for pre-BCR signaling, which may have different consequences in fetal and adult precursors, or biased pairing with light chains (31,49,50).

Cellular Expansion of Innatelike Lymphocytes

Another mechanism contributing to the high frequency of some innatelike lymphocyte subsets is illustrated by the massive clonal expansion undergone by NKT cells during thymic development (51). Rounds of cell divisions occur in the thymus just after positive selection and before NKT cells emigrate to the periphery. These divisions, which increase the NKT cell frequency from $<10^{-4}$ among recently selected thymocytes to 2% to 5% among thymic emigrants, is independent of exposure to microbial or environmental antigens, as it is reproduced in fetal thymic organ culture *in vitro* and as NKT cell frequency is conserved in germ-free mice (52). It is not clear at present whether this expansion phase also applies to other subsets of innatelike lymphocytes. The "self-renewing" capacity ascribed to Ig-expressing B-1 B cells (53) may reflect the property of expansion post–BCR expression and/or increased survival compared with other B cells. This expansion is associated with the acquisition of a memory/effector phenotype that is a hallmark of many innatelike lymphocytes.

CONSERVED SELF- AND MICROBIAL ANTIGENS

General Considerations about Self- and Microbial Ligand Reactivities

The conservation of the invariant or semi-invariant BCRs and TCRs and their germline-encoded specificities are reminiscent of other innate immune receptors such as TLRs. Like TLRs, innatelike BCRs and TCRs appear to be monospecific or to recognize a restricted set of self- and microbial structures of particular evolutionary significance.

Autoreactivity

A quasi-universal feature of innatelike lymphocytes that has dominated the search for their ligands is their autoreactivity in various *in vitro* or *in vivo* assays against normal or transformed cells, or against soluble ligands. For example, NKT hybridomas or clones can be activated to secrete cytokines by fresh thymocytes, by DCs, and by various tumor cell lines (54–58), and $\gamma\delta$ T-cell clones kill stressed or transformed cells (59–62). TCR transfection or transgenic expression have established that these reactivities are linked to the TCR (25,63–65), although they could also be modulated by additional receptors such as NKG2D, for example (65,66). Many B-1- and MZB-cell–derived antibodies recognize senescent or apoptotic cell membranes (67–69); others recognize thymocytes (70).

Molecular identification of the self-ligands involved has been generally difficult and, in many cases, is still debated or in progress. This is because these ligands are often non-peptidic or are recognized in the context of more complex structures such as cell membranes, lipid particles, or antigen-presenting molecules. Redundancy and broad disturbances associated with genetic ablation of their synthesis pathways constitute further impediments to a definitive understanding of the basis of autoreactivity. Nevertheless, several ligands have been identified. They share the property of being full agonists, that is, they activate proliferation and effector functions of mature innatelike lymphocytes. They, therefore, differ from the "partial agonist" peptides that mediate positive selection of conventional thymocytes or promote survival of mature T cells.

How innatelike lymphocytes use these agonist ligands for positive selection yet escape negative selection, and how they avoid permanent activation and exhaustion in the periphery, are issues that have generally not been fully answered. It is also becoming apparent that the developmental signals initiated by encounter of these agonist ligands may be central to the instruction of innatelike lymphocyte commitment. Another emerging theme is that autoreactivity can be the basis of their activation during some of the antimicrobial immune responses in which innatelike lymphocytes are involved. Thus, autoreactivity constitutes a central feature of innatelike lymphocyte biology, and it appears to be by design rather than by accident (71). These aspects will be further addressed in the sections on development and function.

Dual Reactivity for Self- and Microbial Ligands

Systematic screening for responses to microbial extracts *in vitro* or studies of mutant mice lacking individual innatelike subsets *in vivo* have led to the discovery of microbial antigen targets and the demonstration that, at least in some conditions, innatelike lymphocytes can contribute substantially to the clearance of the corresponding pathogens. Two models have emerged to integrate the dual reactivity against self- and microbial ligands, each of which has received some support in different systems. In one model, microbial and mammalian cells express structurally related ligands, but the microbial ligands are recognized with very high affinity while the low affinity mammalian ligands require overexpression during transformation or infection to induce the full activation of innatelike lymphocytes. This is the proposed scenario for the microbial and mammalian phosphorylated isoprenoid metabolites recognized by human Vγ9 cells (72,73). A similar scenario governs the dual recognition of phosphorylcholine residues on Streptococcus *pneumoniae* carbohydrates by natural B-1 B-cell antibodies and of phosphatidylcholine in altered cell membranes or oxidized LDL (68,74). In another model illustrated by NKT cells, self- and microbial ligands are structurally very distinct (75–77) but they are

also recognized with different affinities by the canonical receptor.

Nonclassical MHC-like Ligands of Innatelike T Lymphocytes

The evolutionary significance and the functions of nonpolymorphic MHC class I–like molecules remained mysterious (78) until recent studies established that they function as ligands for multiple receptors, including those expressed by NK cells, which are true innate lymphocytes, or by the TCRs of innatelike $\alpha\beta$ and $\gamma\delta$ T cells. The MHC-like ligands of innatelike lymphocytes identified so far include CD1d (54) (NKT cells), MR1 (MAIT cells) (38), T10/T22 (79), CD1c (80), and MIC (65, 81) ($\gamma\delta$ T cells) (Figure 17.3).

CD1d

CD1d is a member of the CD1 family of β2-microglobulin–associated MHC class I–like molecules, which comprises five isotypes, CD1a–e (82). Although the mammalian CD1 genes are encoded in a locus outside the MHC, studies in chicken have suggested that they evolved from a precursor in the MHC locus (83,84). CD1a, b, c, and d are expressed on the cell surface of most antigen-presenting cells, including dendritic cells, macrophages, and B cells, as well as on cortical thymocytes (85,86). They bind lipid alkyl chains within hydrophobic channels buried in their groove and present their polar head to the TCR. Examples of CD1a-, b-, or c-restricted T cells include autoreactive or microbial lipid-specific human clones generated *in vitro*, whose $\gamma\delta$ or $\alpha\beta$ TCRs appear to be diverse. In contrast, CD1d, the only isotype found in mice and rats, is recognized by a prominent subset of T cells in both rodents and humans.

These T cells are dominated by innatelike NKT cells with canonical mVα14-Jα18/hVα24-Jα18 TCRs (87).

Vα14 NKT cells are autoreactive to CD1d-expressing cells in a manner that depends on CD1d endosomal trafficking (88,89), suggesting recognition of endosomal/lysosomal lipid antigens. Several glycolipid antigens require endosomal trafficking of CD1d for processing by glycosidases (90) or loading by glycolipid transfer proteins such as saposins (91–93) before recycling to the plasma membrane. Search for a lysosomally loaded self-ligand recognized by NKT cells has identified a trihexosylceramide, iGb3, first synthesized in the Golgi as an intermediate in the biosynthetic pathway of iGb4. In the lysosome, iGb4 is degraded into iGb3 by β-hexosaminidase AB, and then further degraded into LacCer, following established pathways of glycosphingolipid degradation. Mice that lacked β-hexosaminidase B lacked 95% of their NKT cells, a defect associated with the impaired ability of their thymocytes to stimulate autoreactive NKT hybridomas. Direct stimulation of mouse and human NKT cells with natural and synthetic iGb3, but not with any other known mammalian glycosphingolipids, indicated that iGb3 is a universal ligand of mouse and human NKT cells (75). Studies of Vα14-Jα18 transgenic T cells expressing a diverse Vβ repertoire showed that only those expressing the biased set of Vβ8, Vβ7 and Vβ2 chains normally found in mature NKT cells responded to iGb3 (10). The general functions of iGb3, like those of most glycosylceramides, remain largely unknown, and the regulation of iGb3 expression in different cell-types has not been studied yet. Thus, it is not clear why iGb3 may have been coopted by the NKT cell system.

Search for microbial ligands uncovered an interesting family of gram-negative lipopolysaccharide (LPS)-negative bacteria that use novel α-branched

FIGURE 17.3 MHC class I–like ligands of innatelike T lymphocytes. Ribbon-diagram structures of CD1d in complex with αGalCer (left), of MICA (center), and of H-2T22 (right). These MHC class I–like molecules serve as ligands of NKT cells, some Vδ1 T cells, and Dδ2 $\gamma\delta$ T cells, respectively. Note that the unliganded MICA has a disordered α2 helix. (Courtesy of Erin Adams, University of Chicago, Chicago, IL, USA.)
FIGURE 17.4 Lipid ligands of NKT cells. Note the structural similarities among foreign α-galactosylceramide (αGC) (derived from marine sponge), the *Sphingomonas* cell wall glycosphingolipid (GSL)-1, and *Borrelia burgdorferi* BbGl-IIc. All three lipids have a single carbohydrate with an α-anomeric linkage to the lipid. In contrast, the endogenous ligand iGb3 has a Galα1,3Galβ1,4Glc in a β-anomeric linkage to ceramide.

glycuronylceramides as substitute for LPS in the outer membrane of their cell wall (94). The best-studied example is *Sphingomonas*, a member of the class of α-proteobacteria and a ubiquitous bacterium found in marine and terrestrial environment that can infect dendritic cells and macrophages and activate NKT cells. Microbial α-glycuronylceramides are structurally very close to a previous NKT ligand isolated from marine sponge, α-galactosylceramide (95,96) (Figure 17.4). Because marine sponges are frequently colonized by α-proteobacteria including *Sphingomonas*, it is possible that the marine sponge ligand was of microbial origin. Another structurally related α-glycosylated lipid, α-galactosyldiacylglycerol, found in *Borrelia burgdorferi*, the agent of Lyme disease, was shown to activate mouse and human NKT cells (97).

The crystal structure of the α-branched glycosylceramide complexed to CD1d has been elucidated, showing the acyl and sphingosine chains buried in the A' and F' hydrophobic channels, respectively, and the carbohydrate sitting flat on top of the groove, anchored by a network of hydrogen bonds to amino acids on the α1 and α2 helices to form a rigid structure that is recognized nearly exclusively by the germline-encoded CDR3α of the canonical TCR (98–99a) (Figures 17.3, 17.5). Such α-branched glycosylceramides have not been reported in vertebrates, suggesting that they represent a pathogen signature that is equivalent in significance to LPS. Like TLR4, the canonical NKT TCR may have evolved to sense the predominant cell wall glycolipids of gram-negative bacteria. Indeed, α-glycosylceramide ligands can activate NKT cells at subnanomolar concentrations, and their Kd for the canonical TCR has been measured around 100 nM in mouse and 7 μM in human. In contrast, iGb3 is active at 100-fold higher concentration, and its affinity for the TCR appears to be lower than that of α-galactosylceramide (3).

FIGURE 17.5 Structural determinants of ligand recognition. Left: The rearranged TCR α chain of NKT cells exclusively use Jα18, shown as a thick tube in the structure of the human Vα24-Jα18/Vβ11 TCR. The CDR3α of the NKT TCRs are nearly identical in amino acid sequence between mouse and human and provide most of the contact points with CD1d complexed with an α-galactosylceramide ligand (99a). Right: $\gamma\delta$ T cells specific for the H-2T22 MHC class I molecule use a conserved amino acid motif (W.EGYEL) in their CDR3δ loop, shown as a thick tube in the structure of the G8 $\gamma\delta$ TCR in complex with H-2T22. These amino acids, which are encoded by the germline V region and D segments, contribute most of the contact points with H-2T22 (7). (Courtesy of Erin Adams, University of Chicago, Chicago, IL, USA.) (See color insert.)

T10/T22

$\gamma\delta$ T cells that are specific for the T10/T22 molecules constitute another well-studied system. T10 and T22 are β2-microglobulin–associated nonpolymorphic MHC class Ib molecules that are found in mouse, but not rat or human, and are upregulated by LPS or concanavalin A (79). Tetramers of empty T22 molecules stain 1% to 2% of $\gamma\delta$ T cells. Interestingly their TCRs appeared quite diverse until extensive sequence analysis uncovered a canonical sequence motif encoded mainly by the Dδ2 gene segment. A crystal structure of the G8 TCR complexed with T22 was generated (7), demonstrating that G8 binds empty T22 at a tilted angle through extensive, nearly exclusive contacts of Dδ with the exposed β-sheet floor and the α1 helix of T22 (Figure 17.5). Although residues flanking the canonical motif could influence the binding, the Kd of TCR/ligand interactions could be as high as the 10 nM range.

MR1

MR1 is a non–MHC-encoded, β2-microglobulin–associated MHC class I–like molecule conserved in mouse, human, and cow that is recognized by a subset of mucosal-associated invariant T (MAIT) lymphocytes that express a canonical hVα7.2/mVα19-Jα33 chain combined with diverse β chains (38). Although MR1 has yet to be detected at the cell surface of normal cells *in vivo*, it can be expressed upon transfection. Mutagenesis of residues putatively involved in peptide binding (based on modeling) influenced recognition by MR1-autoreactive hybridomas, suggesting ligand presentation rather than recognition of empty MR1 (100). The nature of these putative ligands remains mysterious. Selection of MAIT cells in mouse is independent of TAP or the invariant chain.

MIC

MICA and MICB are MHC-encoded glycoproteins expressed in conditions of stress by various epithelial and hemopoietic cells (101). Their MHC-like structure does not associate with β2-microglobulin and harbors the remnant of a peptide-binding groove reduced to a small, empty cavity (102) (Figure 17.3). MIC proteins can be recognized by the Vδ1 TCRs of some human T-cell clones (65,81), suggesting the possibility that dedicated TCR sequences akin to the ones associated with T10/T22 recognition may be involved. Interestingly, these $\gamma\delta$ T cells coexpress NKG2D,

another MIC-specific activating receptor, emphasizing the evolutionary importance of this specificity for distinct immune cell lineages.

CD1c

CD1c is recognized by some autoreactive $\gamma\delta$ T cells (80), but information on canonical recognition motif, lipid ligands, or the structure of CD1c is currently missing. Interestingly, CD1c can also present mycobacterial phosphoisoprenoids to T cells with apparently diverse $\alpha\beta$ TCRs (103).

DETC Ligand

The ligands of intraepithelial $\gamma\delta$ T cells such as DETC cells have remained totally elusive, although there is a strong likelihood that some unidentified MHC-like proteins could be involved.

Phosphorylated Metabolites of the Isoprenoid Pathway

The prominent subset of $V\gamma9$ T cells found in human peripheral blood show broad antimicrobial and antitumoral reactivities that have been ascribed to the recognition of metabolites of the isoprenoid biosynthetic pathways of microorganisms (1-deoxy-D-xylulose-5-phosphate [DOXP] pathway) and mammalian cells (mevalonate pathway) (72,73,104,105). These are small nonpeptidic phosphorylated compounds, with the microbial hydroxy-dimethyl-allyl-pyrophosphate (HDMAPP) being active at 0.1 nM concentrations and the mammalian isopentenylpyrophosphate (IPP) at 10,000-fold higher concentrations (Figure 17.6). Other activators such as aminobiphosphonates and alkylamines probably mediate their effect indirectly through inhibition of the mevalonate pathway leading to accumulation of IPP, whereas statins downregulate IPP levels (106,107). The requirement for cell–cell interactions in $V\gamma9$ T-cell activation and the lack of direct binding of these phosphoantigens to the TCR have suggested the existence of a more complex structure at the target cell surface. Recently, F1-ATPase, a mitochondrial enzyme that is translocated to the plasma membrane of hepatocytes and some tumor cell lines, was shown to be the target of $\gamma\delta$ T cells based on antibody-blocking experiments and direct binding to soluble TCR (108). Apolipoprotein A1 bound F1-ATPase and enhanced recognition. These findings could constitute a challenge to the previous model that phosphoisoprenoids are relevant or exclusive $\gamma\delta$ T-cell antigens. Conversely, they may indicate some interaction between the two pathways—for example, F1-ATPase may present the phosphoantigens to the $\gamma\delta$ TCR.
FIGURE 17.6 Phosphoantigens of human $V\gamma9$ T cells. Metabolites of the mammalian mevalonate pathway, isopentenyl-pyrophosphate (IPP), or of the microbial deoxyxylulose-phosphate (DOXP) pathway, hydroxydimethylallyl-PP (HDMAPP), and dimethylallyl-PP (DMAPP). Microbial HDMAPP activates $V\gamma9$ T cells at picomolar concentrations, whereas mammalian IPP requires 10,000-fold higher concentrations. Because $V\gamma9$ stimulation requires cell–cell contact and the $V\gamma9$ TCR does not bind these phosphoantigens in solution, it is assumed that the phosphoantigens are presented by some unidentified molecule, possibly F1-ATPase translocated at the plasma membrane.

B-1 and MZB Cell Ligands

B-1 and MZB cells produce a fraction of the so-called natural IgM antibodies that are present in unimmunized animals (109). Although some canonical recurrent antibodies have been ascribed to B cells of the B-1 or MZB lineages, the diversity and origins of other natural antibodies remain to be further investigated. For example, several natural antibodies against carbohydrate sequences (e.g., blood group) are elicited in a T-independent manner by the gut commensal flora from conventional B cells without germline canonical BCRs.

Membrane Phospholipids, Lipid Particles, Apoptotic Membranes, Microbial Cell Wall

One recurrent specificity group appears to be directed at phospholipids exposed in altered cell membranes or lipid particles. A significant fraction of B-1- or MZB-derived natural antibodies bind to apoptotic cells (34,68,110,111), a specificity shared by many other soluble membrane-bound innate receptors. Phosphorylcholine-specific T15 idiotype–bearing cells were found to be expanded in apolipoprotein E–deficient mice accumulating oxidized LDL particles. The B-1 cell–derived VH11/Vκ9, VH12/Vκ4 and the T15 idiotype–bearing antibodies, as well as the MZB-derived M167 idiotype–bearing antibodies all bind apoptotic cells and the phospholipid phosphatidylcholine, particularly after processing into lysophosphatidylcholine

(lysoPC) by phospholipase A2 (110). LysoPC, by virtue of lacking one of the two acyl chains that normally anchor phosphatidylcholine in the plasma membrane, is thought to expose its PC headgroup for recognition by natural antibodies. Natural IgM against autologous bromelain-treated red blood cells mainly include the VH11/Vκ9 and VH12/Vκ4 antibodies whose corresponding B-1 cells represent up to 10% of the peritoneal B-cell population based on staining with fluorescent liposome enriched in phosphatidylcholine (67). These antibodies cross-react onto lipoteichoic acid, a glycolipid component of the gram-positive bacterial cell wall of *Streptococcus pneumoniae,* whose carbohydrates are heavily decorated with PC headgroups (22,74).

Thymocyte Antigen

A minor subset of B-1 B cells uses VH3609 to produce natural antithymocyte antibodies (70). These B-1 BCRs are specific for a glycosylated epitope present on Thy1, a glycoprotein expressed by T cells and neural cells. Although the function of these antibodies is unknown, the system has been elegantly used to elucidate the role of self-antigen in development (40,112).

FUNCTIONS OF INNATELIKE LYMPHOCYTES

Functional Properties of Innatelike Lymphocytes

Many innatelike lymphocytes are memory/effector cells that reside or traffic in specific tissues and are endowed with specialized functional properties.

B-1 B cells, like MZB cells, express high-surface IgM and low IgD, a pattern that is characteristic of activated B cells. They are thought to be a major, though not exclusive, source of the natural IgM antibodies found in unimmunized mouse serum, which are produced in a T-independent manner (109). MZB cells respond faster and more strongly to stimulation than do conventional B cells (113). In addition, MZB cells express high levels of the complement receptor CD21, which considerably enhances their ability to detect and respond to blood-borne pathogens (114,115).

By virtue of their autoreactivity, NKT cells can reciprocally activate immature dendritic cells through CD40 ligand/CD40 interactions (76,116,117). This property can be further exploited by administering *in vivo* synthetic agonist ligands of NKT cells (α-galactosylceramide), which are efficiently presented by immature DCs to initiate a powerful cellular and molecular inflammatory network (118,119). Thus, after injection of 1 μg of the NKT li-

gand αGalCer, mice show an early and transient IL-4 response peaking in the first hour and a delayed but prolonged IFNγ and TNFα as well as various chemokines. DCs upregulate CD40, B7.1, B7.2, and IL12p40, which enhance NKT-cell activation and cytokine production. NK cells are also activated to release IFNγ and acquire cytolytic properties (120,121). These effects explain the superior effects of NKT ligands over TLR ligands as adjuvants of adaptive B- and T-cell responses, which is particularly important for CTL responses against nonreplicating, cross-presented antigens (122–124). Interestingly, synthetic phosphoantigens of Vγ9 T cells also elicit DC activation and exhibit adjuvant properties (125,126).

Massive Th1 and Th2 cytokine production within minutes of TCR activation (127), potent cytolytic functions mediated by granzyme and perforin as well as FasL/Fas that can be augmented by NKG2D cosignaling, help for B cell have been reported for both NKT and γδ T cells. Human Vγ9 γδ T cells can upregulate MHC class II and have been suggested to present antigen to CD4 T cells in some conditions (128). Th1 and Th2 properties have also been identified in unimmunized MAIT cells (129).

In line with their peculiar "sentinel" association with specific tissues, γδ T cells secrete growth factors such as keratinocyte growth factor-1 and insulin growth factor-1, which promote wound healing at mucosal barriers (130,131).

Natural Functions of Innatelike Lymphocyte Subsets in Physiology and Disease

Despite a very large body of literature dedicated to their functions in the context of host defense, inflammation and allergy, autoimmunity, and cancer rejection, the precise role of individual innatelike subsets is still partially understood and sometimes controversial.

NKT Cells

Microbial Infections. The best-characterized functions of NKT cells are related to antimicrobial immunity. Many micro-organisms elicit various networks of cellular and molecular interactions that involve NKT cells. Recent advances in identifying endogenous and exogenous NKT ligands have suggested the existence of two distinct pathways of antimicrobial defense (Figure 17.7).

A direct pathway is specifically recruited upon infection by micro-organisms that express NKT ligands in their cell wall. This is illustrated by the α-proteobacterium *Sphingomonas*. Though it is not a common pathogen in humans, *Sphingomonas* can cause severe infections, particularly in immunocompromised patients, and it is found

Late endosome / lysosome
FIGURE 17.7 Dual recognition of self- and foreign ligands by NKT cells. The gram-negative, LPS-negative cell wall of Sphingomonas activates NKT cells directly, through loading of glycosphingolipids onto CD1d in the lysosome and presentation at the plasma membrane. In contrast, the gram-negative, LPS-positive cell wall of *Salmonella* activates NKT cells indirectly, through TLR-mediated activation of DC and presentation of endogenous ligand iGb3 along with IL-12. It is unclear whether TLR signaling upregulates endogenous NKT ligands or only amplifies the consequences of basal TCR signaling by induction of IL-12, IL-15 or NK ligands.

by polymerase chain reaction (PCR) in the feces of healthy subjects (132). NKT cells are directly activated by infected antigen-presenting cells and function as an immediate innate source of help in a Toll-like receptor-independent manner, resulting in the rapid clearance of the pathogen (76,77). Thus, NKT cells substitute for TLR in the same way as their α-glycuronylceramide ligands substitute for LPS in the bacterial cell wall. A similar pathway appears to be elicited by another gram-negative, LPS-negative α-proteobacterium, *Ehrlichia muris*, a tickborne intracellular pathogen member of the *Rickettsiales* (76), although the chemical nature of the NKT ligands involved is unknown. Both *Sphingomonas* and *Ehrlichia* activate NKT cells after cellular infection in a CD1d-dependent and TLR-independent manner, and their clearance is severely impaired in CD1d$^{-/-}$ and Jα18$^{-/-}$ NKT-deficient mice (76,77). *Borrelia burgdorferi* expresses α-glycosyldiacylglycerols that can be recognized by mouse and human NKT cells (77). However, unlike *Sphingomonas* or *Ehrlichia*, antigen presenting cells exposed to *Borrelia* have not been shown to stimulate NKT cells, and the effect of NKT cell deficiency on bacterial clearance was modest (133).

Seropositivity against *Sphingomonas* proteins was specifically found in nearly all patients with primary biliary cirrhosis (PBC) (132). PBC is a chronic liver disease characterized by the destruction of small intrahepatic bile ducts and the presence of diagnostic antimitochondrial antibodies (134). In fact, these antimitochondrial antibodies were found to cross-react against an identical epitope on the homologous *Sphingomonas* enzyme PDC-E2 (132). Mitochondria are evolutionarily related to α-proteobacteria–like *Sphingomonas*, suggesting that PBC may be triggered or promoted by aberrant NKT cell responses to *Sphingomonas* infection. This intriguing hypothesis is supported by a report that NKT cells are increased in the liver of PBC patients and depleted in their blood (135).

Another, indirect pathway of NKT-cell activation is frequently elicited in many bacterial, viral, and parasitic infections. For example, in the presence of *Salmonella*, NKT cells produce substantial quantities of IFNγ, in a manner dependent on the IL-12 secreted by TLR-activated DCs (76,117). Contrary to initial beliefs, however, IL-12 is not sufficient to activate IFNγ secretion by NKT cells. Interactions with CD1d are required, as demonstrated by the interruption of NKT-cell activation in the presence of anti-CD1d antibody or CD1d-deficient DCs. Furthermore, contrasting with the direct activation pathway, NKT-cell activation was impaired in β-hexosaminidase B–deficient-mice with impaired lysosomal iGb3 production or by blocking with the lectin *Griffonia simplicifoliam,* specific for the terminal Galα1,3Gal of iGb3 alone or bound to CD1d (76). These findings suggest that NKT-cell responses can be based on the autoreactivity of NKT cells rather than on the recogni-

tion of specific microbial ligands. It is unclear at present whether iGb3 is induced in these conditions, or whether it is constitutive and low-level TCR signaling is amplified through activating NK lineage receptors such as NKG2D, the presence of IL-12, or the removal of influences from inhibitory NK lineage receptors, leading to IFNγ production. As might be expected from the diversity of cell types recruited to produce IFNγ early after this type of microbial infection, including NK cells and $\gamma\delta$ T cells, ablation of NKT cells does not detectably change the outcome. However, delayed clearance and alterations in granuloma formation have been reported for particular pathogens and in specific tissue locations. For example, NKT-deficient mice exhibited a transient but marked defect in secretion of macrophage inflammatory protein-2, attraction of neutrophils, and clearance of *Pseudomonas aeruginosa* in lungs (136).

Cancer Rejection. A role of NKT cells in cancer rejection has been suggested by studies in CD1d$^{-/-}$ and Jα18$^{-/-}$ NKT-deficient mice. The most striking observation reported an increased incidence of spontaneous fibrosarcomas after subcutaneous injection of methylcholanthrene (MCA) and also demonstrated a requirement for IL-12 and IFNγ (137). This report, however, has remained isolated, and other studies have examined the role of NKT cells in the setting of tumor transplants. NKT cells, particularly CD4$^-$CD8$^-$ cells, contributed to the prevention of liver metastasis after intravenous injection of fibrosarcoma cells. CD1d expression by host rather than tumor cells was essential, and the production of IFNγ by both NKT cells and other cell types, likely NK cells and CD8 T cells, was required. However, perforin expression was required only from non-NKT cells. These results suggested that activation of NKT cells was triggered by host-derived antigen-presenting cells, initiating a Th1 cascade involving NK cells and CD8 killer cells, and resulting in tumor elimination (138,139). In contrast, NKT cells suppressed the rejection of RMA/S transfected with CD1d (140). NKT cells may therefore recognize some undefined ligands either directly on the tumor or on antigen-presenting cells. Although Vα14 NKT cells represent $\sim$80% CD1d-restricted T cells in mice, non-Vα14 T cells exist and, based on the differential phenotypes of CD1d$^{-/-}$ and Jα18$^{-/-}$ mice, have been implicated in the IL-13-mediated suppression of other tumors.

MAIT Cells

MAIT cells accumulate in the lamina propria and the mesenteric lymph nodes of mouse and human (38,129). Their requirement for B cells, their dependence on the gut bacterial flora, and their ability to secrete various Th1 and Th2 cytokines have suggested a

role in intestinal immunity, perhaps in controlling IgA secretion.

γδ T Cells

Consistent with the autoreactivity of the canonical DETC TCR against keratinocytes undergoing stress and transformation (59,63) TCRδ$^{-/-}$ and Vγ5$^{-/-}$ mice exhibited a greater frequency of chemically induced skin cancer, which was reduced upon transfer of Vγ5 T cells (66,141). Mice lacking DETC cells also exhibited greater susceptibility to spontaneous or irritant-induced dermatitis (142,143). The secretion of keratinocyte growth factor-1 (130) and insulin growth factor-1 (131) and the induction of hyaluronan by neighboring epidermal cells (144) underlie a role in skin homeostasis and repair in mouse. Gut γδ T cells perform similar functions as well (145). Interestingly, DETC responses to stress and transformed keratinocytes is augmented by their expression of NKG2D, a NK lineage receptor specific for Rae1 ligands, which are also induced by stress and transformation (66).

Other subsets of γδ T cells, such as the human Vγ9 T cells, are likely to contribute to the rejection of primary and secondary cancers (146), but their importance and the precise mechanism involved have remained somewhat elusive. Likewise, there is abundant suggestion that γδ T cells are recruited in various infections, but their precise functions remain to be clarified (147).

B-1 and MZB Cells

Unlike NKT cells, MAIT cells and subsets of γδ T cells which have been specifically targeted by ablation of their ligands or of their TCR genes, B-1, and MZB cells, have not been properly "knocked out" of the mouse system.

Nevertheless, convergent findings suggest important functions for B-1 cell–derived natural IgM antibodies that share germline-encoded specificity to phosphatidylcholine, phosphorylcholine, oxidized LDL, and apoptotic cells. Through recognition of phosphorylcholine residues on microbial cell walls, such IgM antibodies can provide natural protection against infection by *Streptococcus pneumoniae* upon transfer into X-linked immunodeficiency (*Xid*) CBA/N mice (74). *Xid* mice have a missense mutation in the Bruton tyrosine kinase gene (*Btk*), which is essential for B-1 B cell development, but also for T-independent activation of conventional B cells. Thus, they do not represent a pure model of B-1 B cell deficiency. By virtue of their location in the marginal sinus of the splenic B-cell follicles and their expression of high levels of the complement receptor CD21, MZB cells can promptly detect and respond to blood-borne pathogens.

Natural IgM antibodies more generally provide protection at the early phase of infection by various bacterial, viral, and parasitic organisms (148,149). It is not always clear, however, whether the natural antibodies involved in particular conditions have germline-encoded specificities and originate from B-1 or MZB cells, or whether they have diverse non-germline–encoded sequences and originate from ongoing T-independent responses to various microbial polysaccharides (e.g., blood group or Galα1,3Gal epitopes). Conversely, natural antibodies and complement aggravate reperfusion injury after ischemia, likely through recognition of self-determinants exposed upon tissue ischemia (150).

DEVELOPMENT OF INNATELIKE LYMPHOCYTES

Innatelike lymphocytes comprise multiple lineages and sublineages that share a memory/effector differentiation but express quite diverse phenotypes, functional properties, and tissue locations. A cardinal principle underlying the diversity of these lineages is that they are instructed by the corresponding canonical antigen receptor during development, as a result of interaction with self-antigen. These self-antigens are often agonists that can fully activate the mature product of the lineage, explaining the autoreactive phenotype. The tight relationship between antigen receptor and lineage differentiation is abundantly illustrated by antigen-receptor transgenic experiments where each antigen receptor instructed differentiation according to the lineage of origin, including NKT cells (25,26) (Figure 17.2), DETC (27) and liver γδ T cells (28), B-1 B cells (29,30,32,33) and MZB cells (34). The production and selection of these canonical receptors have been examined in detail in the section on canonical germline-encoded antigen receptors. This section will therefore examine the cellular and molecular events driving lineage differentiation downstream of the expression of these receptors, using different examples in the NKT cell, mucosal γδ T cell, and B-1 B cell lineages.

One possible exception to this general scheme of production of differentiated memory/effector lineages is represented by the T10/T22-specific Dδ2 γδ T cells. T10/T22 are MHC-encoded β2-microglobulin–associated class Ib molecules that are expressed only in some MHC haplotypes. Self-ligand recognition is largely encoded in their Dδ2 segment, whose random usage in the absence of antigen (i.e., in β2-microglobulin—deficient mice) can explain the high frequency of reactivity to T10/T22 among naïve γδ T cells (7). However, there is also evidence of antigen selection for the KN6 TCR in transgenic mice, where the cells express a memory/effector differentiation in the presence of their ligand (151) and also depend on β2-microglobulin expression for development (39). Thus, antigen-independent naïve and antigen-experienced memory-type cells might coexist in this lineage.

Development of NKT Cells

Developmental Stages

The use of tetramers of CD1d-αGalCer specific for the canonical mVα14-Jα18/hVα24-Jα18 TCRs has revealed a previously unsuspected sequence of selection, expansion, and differentiation events preceding the terminally differentiated NK1.1$^+$ stage (51,152). As illustrated in Figure 17.8, NKT cells originate from mainstream thymocyte precursors that transit through the pre-TCRα/TCRβ stage to reach the CD4$^+$CD8$^+$ double-positive (DP) stage, where stochastic Vα-Jα rearrangements lead to expression of canonical Vα14-Jα18/Vβ8, Vβ7, or Vβ2 TCRs (153). These rearrangements involve distal gene segments and require prolonged cell survival mediated by RORγt and Bcl-xL (23,24). Studies of Vα14-Jα18 transgenic mice have demonstrated that whereas all Vβ families could pair with Vα14-Jα18, only the biased set of Vβs conferred specificity for the endogenous iGb3 ligand (10). The NKT precursors that are first detected are rare CD4$^+$CD8$^+$ double-positive and CD4$^+$ cells, both expressing high levels of CD24, a marker of immature cortical thymocytes, as well as CD69, a marker of positive selection (153). Early DP thymocytes that have not yet undergone positive selection are beyond the limits of detection because of the low frequency of Vα14-Jα18 rearrangements. As CD24^{high}CD4$^+$ cells mature into the next CD24^{low}CD4$^+$ stage, they undergo several rounds of cell divisions (51). This lineage expansion after thymic positive selection ensures the high copy number that is critical for innatelike functions. During this phase, a fraction of CD4$^+$ cells downregulates CD4 to become CD4$^-$CD8$^-$ double-negative (DN) T cells (153), which differ from CD4 cells by their more restricted Th1 and chemokine profile and their enhanced ability to reject tumors. Dividing cells acquire a CD44^{high} memory phenotype and sequentially activate their IL-4 and IFN-γ loci, which enables them to produce these cytokines explosively upon TCR triggering (51,152,154). Thus, unlike other $\alpha\beta$ T cells, NKT lineage cells undergo a sequence of events that is reminiscent of the antigen-driven activation, expansion, and effector differentiation of mature T cells but is independent of exposure to environmental or microbial antigens (52). Because this sequence immediately follows positive selection, it is presumably driven in part by the same set of TCR signals and cosignals involved in positive selection, as discussed in the following.

NKT lineage cells emigrate from the thymus to seed peripheral tissues as dividing, memory/effector-type cells. They represent 3% to 5% of recent thymic emigrants in the mouse spleen (51,155). Recent emigrants activate a program of expression of NK lineage receptors, including activating NK1.1 and NKG2D and inhibitory CD94/NKG2A, Ly49 A, C/I, and G2. A fraction of NKT thymocytes remains as permanent residents in the thymus, where they undergo the same terminal maturation program. These thymic residents appear to be absent in humans (156), and their role is unknown. NKT cells are found in the spleen but are most abundant in the liver, where they exhibit a dynamic pattern of patrolling the vascular sinusoid space with sudden arrest upon exposure to NKT ligand (157). This pattern is consistent with an intravascular function of NKT cells at sites of filtration of blood-borne pathogens. Although the factors controlling the specific migration and anatomic location of NKT cells are still unknown, their expression of CXCR6 was found to be critical for survival in the CXCL16-expressing sinusoid environment (157).

Cellular Interactions

Because TCR expression instructs NKT lineage commitment, the thymic cell types involved in presenting NKT ligands have been thoroughly investigated. Consistent with the prominent expression of CD1d, but not MHC class I or class II, on cortical thymocytes, and with the ability of cortical thymocytes to stimulate NKT hybridomas (55), bone marrow chimera experiments have demonstrated that NKT-cell development required CD1d expression by cortical thymocytes but not radioresistant stromal cells (158–160). This is radically different from conventional T-cell development, which is driven by MHC expression on thymic epithelial cells. Transgenic experiments using promoters for Lck, MHC class I, or MHC class II to redirect the expression of CD1d to various cell compartments in CD1d-deficient hosts have shown thymocyte expression to be necessary and sufficient for lineage development (161–164). Mixed-chimera experiments using pLck-CD1d transgenic TCR Cα-deficient bone marrow (where thymocyte development is arrested at the DP stage) as the sole source of CD1d expression demonstrated that recognition of CD1d on cortical thymocytes was sufficient for the long-range differentiation of NKT cells, including acquisition of NK-lineage receptors in the periphery (162). Peripheral expression of CD1d, however, significantly enhanced the transition between NK1.1-negative and -positive stages (155,162).

Signaling

The signals driving NKT cell lineage commitment are expected to differ from those involved in mainstream T-cell development. First, the autoreactive response of NKT hybridomas to cortical thymocytes (55), which is a result of the agonist nature of their iGb3 ligand (75), indicates that the TCR signals must differ from those of mainstream thymocytes seeing partial agonist MHC/peptide ligands. Second, the homotypic (DP-DP) cellular interactions involved in the presentation of the NKT ligand during development may recruit a different set of receptor/ligand interactions (162). In line with these expectations, various signaling mutants have demonstrated differential requirements for the development of NKT *versus* mainstream T lineages. In
FIGURE 17.8 Development of NKT cells. Lineage bifurcation between conventional T cells and NKT cells occurs at the double-positive (DP) thymic stage. Stochastic expression of the canonical Vα14-Jα18 TCR α chain at the DP stage requires prolonged survival through Bcl-xL induced by RORγt. Upon pairing with appropriate Vβ8, 7, or 2, a CD1d-reactive TCR is formed that interacts with other DP-expressing agonist ligands, such as iGb3 presented by CD1d. These homotypic DP–DP interactions enable the homophilic association of members of the SLAM family of receptors, such as SLAM and Ly108, resulting in signaling through the SLAM-associated protein (SAP) adaptor-mediated recruitment of the Src kinase Fyn. Because of the reciprocal pattern of expression of SLAM receptors and MHC molecules in the thymus, these homophilic signals are not available to conventional MHC-restricted thymocytes during positive selection by MHC ligands. Thus, a combination of agonist TCR signaling and SLAM-family receptor signaling defines the NKT lineage. After positive selection, and as they mature, NKT lineage cells undergo a massive expansion, acquire memory/effector differentiation, including expression of Tbet that induces IL-15Rβ, and sequential epigenetic changes in their *IL-4* and *IFN-γ* loci. Terminal NK differentiation occurs after emigration to peripheral tissues or, for a minor fraction of NKT cells that become thymic residents, directly in the thymus. NF-κB signaling is critical for survival of NKT cells during their expansion phase and may be elicited through TCR- and/or Fyn-mediated signaling and recruitment of PKCθ and Bcl-10.

particular, ablation of the Src kinase Fyn and its adaptor SLAM adaptor protein (SAP) severely impaired NKT-cell but not T-cell development (165–168). SAP associates with the cytoplasmic tail of several members of the SLAM family of homotypic self-associating receptors (169), which are prominently expressed on cortical thymocytes, suggesting that one or several SLAM family receptors may be recruited during the homotypic DP-DP interactions required for NKT-cell development. Signaling downstream of SAP and Fyn involves activation of the canonical NF-κB pathway and may account, in conjunction with TCR signaling, for the defective NKT-cell development in mice expressing a dominant negative IκBα transgene and those lacking NF-κBp50 (170,171). Development was arrested at the CD44^{high}NK1.1$^-$ stage and partially rescued by a Bcl-xL transgene, suggesting a survival role for NF-κB. Further, ablation of PKCθ and Bcl-10, which have been implicated in the signaling pathways downstream of SLAM and the TCR leading to NF-κB activation, induced partial defects in NKT-cell development (172,173). Thus, the current scenario suggests the importance of differential signaling through agonist ligand recognition by the TCR combined with SLAM family signaling for the bifurcation of the NKT lineage from mainstream T-cell development.

The downregulation of CD8β after exit from the DP stage remains a puzzling observation. One possible explanation in line with current models of CD4/CD8 coreceptor choice may be that strong, coreceptor-independent signaling maintains CD4 expression (174). Another, nonexclusive possibility is that CD8 binds CD1d and its persistence results in negative selection (158).

The induction of an NK program after the phase of clonal expansion constitutes a highly intriguing aspect of NKT-cell development. The transcription factor T-bet induces expression of the IL2Rβ component of the IL-15 receptor, which is critical for the survival of NKT cells during their expansion phase (175,176). A similar role was reported for CD8 T cells and NK cells. Whether Tbet exerts a more general role in the NK differentiation program remains to be investigated. Interestingly, studies have suggested that the Tec family kinases Itk and Rlk downstream of the TCR play a central role in regulating the decision between conventional and "NKT-like" lineages (177,178). Thus, conventional CD8 T cells lacking these kinases upregulated both eomesodermin, a Tbet homolog, and the IL15 receptor to differentiate into NKT-like T cells. Like true NKT cells, these NK-like T cells recognized their ligand on bone marrow–derived cells rather than epithelial cells. These findings suggest that Tec kinases are critical to transduce the positive selection signals mediated by partial agonist antigens. In their absence, cells that can see ligands on bone marrow–derived cells and induce eomesodermin would differentiate into NK-like T cells, perhaps with critical signaling from the SLAM/SAP/Fyn pathway.

Together, these observations suggest that a fundamental bifurcation between T cells and NKT cells may occur as a result of ligand recognition expressed on different cell types, namely, epithelial cells and thymocytes. Conventional T cells require Tec kinases to undergo positive selection by partial agonists, whereas NKT cells require agonist recognition and SLAM family member interactions. The coexpression of high levels of SLAM family members and CD1d on bone marrow–derived cells favors the NKT lineage, whereas the restricted expression of MHC class I or II on epithelial cells ensures their development in the absence of "cognate" SLAM signaling.

Development of MAIT Cells

The rarity of MAIT cells in mouse, which contrasts with their relative abundance in humans, has impeded studies of their development. MAIT cells are thymus-dependent, CD4$^-$CD8$^-$ double-negative T cells with a memory phenotype that coexpress their invariant mVα19/hVα7.2 TCR α chain with variable Vβ6 and Vβ8 in mouse, Vβ2 and Vβ13 in human. They require MR1 expression by bone marrow–derived cells rather than thymic epithelium for thymic development (38). Thus, they resemble mVα14/hVα24 NKT cells in many respects. They exhibit considerably different properties, however, which are recapitulated in a TCRα transgenic model (129). MAIT cells express the α4β7 intestinal homing integrin receptor and selectively accumulate in the lamina propria in mouse and human (38). Importantly, JH$^{-/-}$ mice lacking the immunoglobulin heavy-chain joining region and therefore B cell–deficient also lacked MAIT cells in the gut lamina propria. In contrast, μMT$^{-/-}$ mice lacking the transmembrane region of immunoglobulin μ, which harbor IgA-expressing B cells in their intestine, have lamina propria B cells. Strikingly, unlike any other innatelike lymphocyte studied to date, MAIT cells were undetectable in germ-free mice. Together, these findings have suggested a role of the commensal flora and IgA-secreting intestinal B cells in MAIT cell expansion or survival (38).

Development of Skin $\gamma\delta$ T Cells

Developmental Stages

The development of antibodies specific for the canonical Vγ5Vδ1 TCR has allowed the analysis of the stages of DETC development in the fetal thymus (Figure 17.9). Like Vα14-Jα18 NKT cells, Vγ5/Vδ1 thymocytes undergo a thymic activation process whereby CD122, the IL15 receptor β chain that is essential for survival (179), is induced along with several NK receptors including inhibitory CD94/NKG2 and Ly49E as well as activating NKG2D (44,180) and with CCR10, a skin-homing chemokine receptor. Because there is evidence of antigen-driven selection
FIGURE 17.9 Development of DETC cells. Genetically programmed rearrangements in the fetal thymus lead to expression of canonical Vγ5-Jγ1/Vδ1-Dδ2-Jδ2 TCRs. As the CD24^{high} DETC precursors mature to become CD24^{low}, they undergo cellular activation leading to memory/effector differentiation, expression of NK lineage receptors, and the skin-homing receptor CCR10. Intrathymic activation requires interaction with epithelial stromal cells, perhaps involving recognition of an as yet unidentified agonist ligand (depicted as black star). In the skin epidermis, DETC cells are activated upon induction of an unidentified agonist ligand of their Vγ5/Vδ1 TCR (possibly identical to the thymic ligand) on stressed or transformed keratinocytes to release cytokines and growth factors that contribute to wound healing. Additional signals through NKG2D and its inducible Rae1 ligands contribute to the DETC response.

of the DETC TCR (27,44), these findings suggest the existence of an as yet unidentified selecting antigen recognized by DETC in the thymus.

Cellular Interactions

Consistent with this antigen-mediated activation hypothesis, a recent study identified a substrain of FVB mice in which Vγ5/Vδ1 thymocytes were arrested at a naïve, pre-

activation stage and failed to colonize the skin (45). Genetic analysis suggested a single recessive gene, whereas fetal thymic reaggregation cultures demonstrated that the defect resided at the level of stromal, nonhemopoietic cells. These findings are therefore compatible with the notion that Vγ5/Vδ1 thymocytes recognize a self-antigenic ligand on thymic stromal cells, which may be identical to their ligand expressed on stressed or transformed keratinocytes. The nature of this self-antigen,

possibly a nonclassical MHC-like molecule independent of β2-microglobulin, remains to be characterized. Because previous studies had indicated that stromal cells of adult thymus could not sustain the development of DETCs from fetal hemopoietic precursors (181), this ligand may be downmodulated in the adult period. An unexpected level of crosstalk between the development of $\gamma\delta$ T cells and that of $\alpha\beta$ T cells was recently uncovered with the observation that lymphotoxin/lymphotoxin β–receptor interactions between CD4$^+$CD8$^+$ double-positive (DP) cortical thymocytes (mainly $\alpha\beta$ lineage) and stromal cells shaped the functional differentiation of $\gamma\delta$ T cells (182). Absence of this crosstalk in the fetal period when DP cells are absent could be a determining factor of DETC functional differentiation (183).

These recent findings have revealed a sequence of cellular and molecular interactions triggered by ligand recognition and resulting in the instruction of a highly specialized effector differentiation and tissue migration program. This appears to be a central theme of innatelike lymphocyte development, as previously illustrated in the case of NKT cells and their endogenous ligand iGb3. Unlike NKT cells, however, in which the presence of CD1d ligands is absolutely required for development, both Vγ5Vδ1 T cells in mouse and Vγ9Vδ2 T cells in humans may be able to develop and survive in the absence of TCR engagement by self-antigen, i.e., in the absence of positive selection, although they fail to acquire the cardinal differentiation and migration features of their antigen-selected memory/effector-type counterparts.

Development of B-1 B Cells and Marginal-Zone B Cells

Although there are intrinsic features of the fetal B-cell precursors and their environment that favor the expression of canonical B-cell receptors and the development of B-1 B cells (184), as reviewed in the section on canonical germline-encoded antigen receptors, adult precursors also give rise to B-1 cells expressing canonical germline-encoded BCRs, although their phenotypes may be somewhat different from their fetal counterparts, for example, by lacking CD5 expression (so-called B-1b cells).

Signaling the B-1 and MZB Fates

This section focuses on the mechanisms instructing the bifurcation between B-1 and conventional B-2 cells that revolve around signaling through the BCR and other pathways as a consequence of self-ligand recognition. The compelling rationale for these studies is that transgenic expression of a BCR derived from B-1 cells usually recapitulates B-1 B cell development, whereas transgenic expression of a B-2 BCR excludes B-1 development (29–33). Further, removal of the B-1 B cell ligand Thy1 abrogated

the development of B-1 cells of the corresponding specificity (40).

Thus, the transitional B-cell stage is thought to represent the bifurcation point where BCR signaling and other factors instruct innatelike differentiation. The agonist nature of the self-antigens has been noted and, in experiments in which the density of the B-1 BCR was decreased by dilution with a second BCR transgene, reversion to the conventional B-2 phenotype was observed, suggesting that exquisite signaling thresholds regulate lineage differentiation (29,30,33).

In direct support of a contribution of BCR signaling, genetic alterations of components of the BCR signaling complex selectively perturbed the development of B1 B cells. Thus, *motheaten* mice with defective SHP-1 phosphatase, a negative regulator of BCR signaling, had increased frequency of CD5$^+$ B-1–like cells, but their repertoire excluded canonical B-1 BCRs such as the phosphatidylcholine-specific VH11 and VH12 BCRs, suggesting a general shift in the BCR avidity threshold of B-1 development leading to the negative selection of canonical BCRs and positive selection of other conventional B-2 BCRs (67). Likewise, mice lacking the negative regulators Lyn (185) and CD22 (186) exhibited hyperreactive B cells and increased B-1 B–like cells. *Xid* mice with a missense mutation of *Btk* or *Btk*$^{-/-}$ mice selectively lacked natural IgM antibodies and B-1 B cells (74,187) and mice lacking CD19 (188,189) also exhibited a striking reduction of B-1 B cells. A more precise evaluation of Btk in the context of a B-1 BCR transgene revealed differentiation toward the conventional B-2 lineage in the absence of Btk, further supporting a BCR signaling instruction model at a common precursor stage (190). Low level expression of LMP2a, an Epstein–Barr virus gene, allowed BCR-independent generation of mature CD19$^+$ cells resembling follicular and marginal-zone B cells, whereas high-level expression converted all cells to the B1 lineage (191,192).

Together, these observations have suggested a generally accepted model whereby a higher level of BCR signaling nearing the threshold of negative selection is an essential component of the instructive mechanisms leading to the B-1 B cell fate (Figure 17.10). With some exceptions (193), there is evidence that differentiation toward conventional B-2 B cells, marginal-zone B cells and B-1 B cells is determined by an increasing level of BCR signaling during development (34,69). Such a model is elegantly supported by transgenic experiments in which changing the level of autoantigen from absent to moderate to high induced development into B-2, MZB, and B-1 B cells, respectively (112).

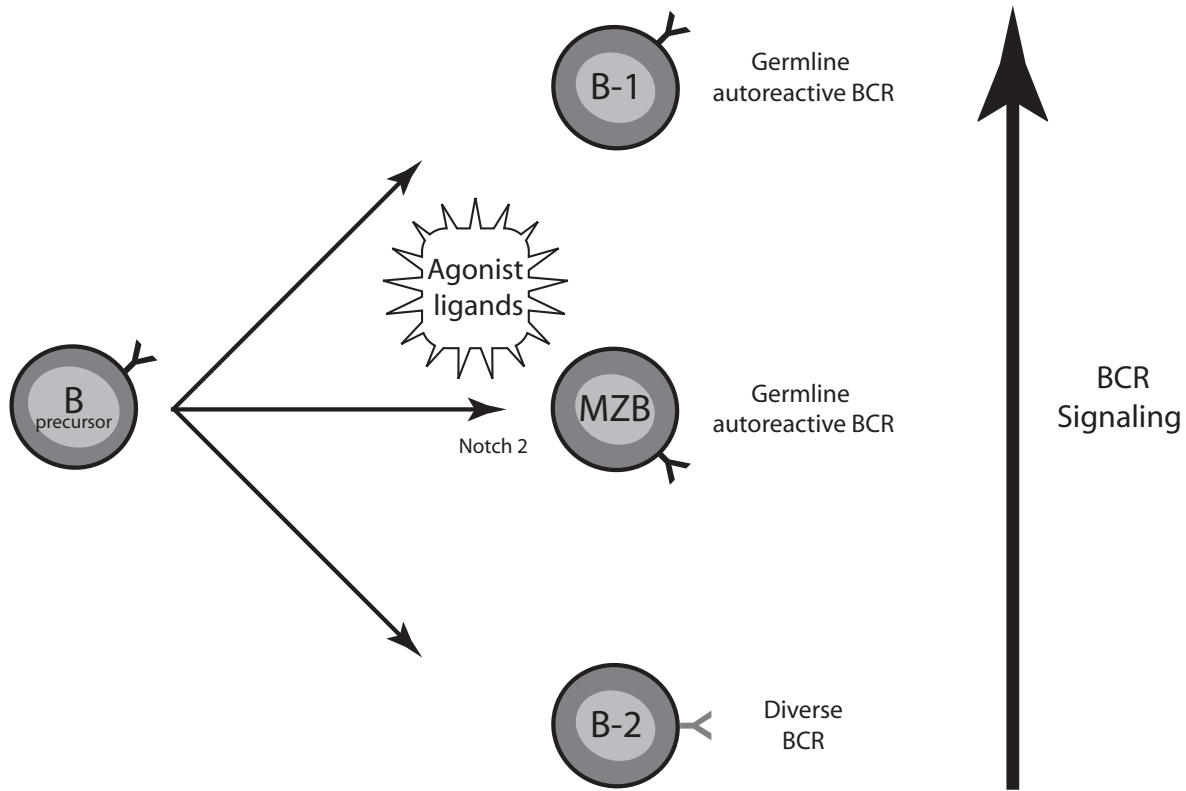
Differentiation into the various B-cell lineages also involves differences in chemokine receptor and integrin expression that dictate residence in the follicle, marginal zone, or peritoneum. B1 B cells require CXCL13 for


FIGURE 17.10 A signal-strength model of B-1 and MZB cell development. Interactions between germline-encoded canonical BCR sequences and endogenous agonist ligands such as apoptotic membrane phospholipids lead to the development of MZB and B-1 B cells. Exquisite signaling thresholds set by the affinity and the density of BCR and antigen and by signaling components such as Btk and SHP-1 are essential for proper lineage commitment. Additional differentiation signals are involved in this complex lineage decision scheme, including age-associated factors for some B-1 B cells and Notch2 for MZB cells.

peritoneal homing and natural antibody production (194), whereas MZB cells are retained in the marginal zone through high-level expression of the integrins LFA1 and $\alpha4\beta1$ and signaling through the S1P receptor to overcome CXCL13-mediated recruitment to the follicules (195,196). How chemokine receptor induction is coordinated with BCR signaling during development remains to be determined. Nevertheless, the process is reminiscent of the specialized induction of skin-homing or liver-homing properties of DETC and NKT cells, respectively, during development. Additional signals involving Notch2 for MZB cells have been demonstrated (197), perhaps indicative of microenvironmental interactions with cellular partners that remain to be elucidated.

In conclusion, the exquisite role of BCR signaling for the development of B-1 and MZB cells is now well established. Further studies combining individual BCR transgenes with various mutations are warranted to develop a more precise understanding of signaling in B-cell lineage development. Current knowledge, however, strongly supports the notion that the B-1 and MZB cell fates are specified primarily through their evolutionarily selected germline-encoded specificity and affinity for a select group of conserved self-ligands.

CONCLUSION

Harnessing Autoreactivity

The demonstrated autoreactivity of nearly all canonical antigen receptors and their germline nature support the notion that autoreactivity is by evolutionary design rather than by accident (71). Indeed, the type of agonist signaling associated with autoreactivity appears to be essential both for lineage commitment and, in many cases, for function as well.

It is envisioned that reactivity to self-ligands may serve to form an expanded pool of memory/effector cells with innate protective value against cross-reactive microbial pathogens. However, there are also examples of conditions in which recognition of the self-ligands themselves,

whether constitutive or inducible, serves a protective function. More generally, dual reactivity to self- and foreign ligands is a hallmark of nearly all innate receptor systems, from soluble C-reactive protein to surface-bound scavenger receptors and TLRs. This may reflect the evolutionary advantage of receptors that detect multiple components of the same aggression event, for example, antigenic structures associated with the pathogen, as well as consequences of pathogenic aggression such as tissue damage.

This autoreactivity raises several issues. First, are innatelike lymphocytes resistant to negative selection? Several experiments suggest that this is not the case. Rather, the affinities of canonical antigen receptors are precisely tuned to their self-antigens. For example, the endogenous ligand iGb3 exclusively activates the Vα14-Jα18 TCRs that use Vβ7, Vβ8, and Vβ2, the biased Vβ set normally expressed by mature NKT cells with a Vβ7>Vβ8>Vβ2 hierarchy of affinity that precisely matches the relative enrichment of these Vβs after thymic selection (10). Transgenic overexpression of CD1d decreased the relative frequency of the high-affinity Vβ7$^+$ cells, likely through negative selection, whereas very low CD1d levels increased their relative representation (9,10,163,198). These observations suggest that the levels of ligand expression and TCR affinity are naturally set for optimal selection of NKT cells.

Second, how is autoreactivity controlled to prevent overt reactivity and exhaustion of innatelike lymphocytes? One possibility is that endogenous ligands are only induced under some conditions in the periphery. This could be the case for the apoptotic material that stimulates B-1 B cells, for example, or for the T10/T22 ligands of $\gamma\delta$ T cells. Another possibility is that endogenous ligands are constitutively expressed but autoreactivity is controlled by a balance of inhibitory and activating receptors. Thus, inhibitory and activating NK receptors expressed by NKT cells and $\gamma\delta$ T cells have been shown to control autoreactive TCR responses (199–201). In addition, induction of NKG2D ligands such as Rae1 family members by transformed epidermal cells triggered NKG2D signaling to promote cytolysis by DETCs (66). There are also indications that CD5 may have inhibitory functions on BCR signaling (202). Importantly, B-1 B cells have not been found to engage naturally in antigen-driven somatic hypermutation, which could lead to uncontrollable autoimmunity, perhaps because their phospholipid antigens do not elicit concomitant T-cell help or, alternatively, because of intrinsic inhibition.

Finally, the dual reactivity to self- and microbial antigens exhibited by various canonical antigen receptors raises issues of specificity and sensitivity of recognition. In the case of Vγ9Vδ2 T cells, endogenous isoprenoid antigens are 10,000-fold less stimulatory than their microbial counterparts. In the case of NKT cells, iGb3 also appears to be much less stimulatory than the microbial α-glycuronylceramides. Thus, it may be that self-antigens alone seldom stimulate innatelike lymphocytes but will do so only when combined with factors associated with infection or inflammation that activate costimulatory pathways, for example, IL-12 released by TLR-activated DCs or NKG2D induced by IL-15.

Evolving Canonical B- and T-Cell Receptors

Genetic Basis of Specificity

Because each TCR or BCR is made of the pairing of chains that themselves originate from several gene segments, the evolution of these canonical specificities is difficult to understand. Of note, the specificities of several canonical antigen receptors rely largely on one rather than two canonical chains, as is the case for the Vα14-Jα18 invariant chain combined with a set of variable Vβ chains, or the VH11 heavy chain combined with variable Vκ9. Recent observations further suggest that a single junctional segment can confer most of the specificity to antigen. For example, low-affinity clones specific for the NKT ligand αGalCer were found to use the canonical Jα18 combined with Vαs other than Vα24 (203,204). The T10/T22-specific $\gamma\delta$ T cells also illustrate at the structural level the predominant contribution of the Dδ2 segment to antigen binding (7,8). It is possible, therefore, to envision that, starting from one low-affinity gene segment, a higher-affinity canonical receptor can be built over evolutionary time through the selection of additional V, D, or J gene segments.

Inter- and Intraspecies Variations

Whereas some canonical antigen receptors and their corresponding innatelike lymphocyte subsets are represented in multiple mammalian species, others appear to be restricted. For example, NKT cells have been identified in humans, mice, and rats (86) and MAIT cells in humans, mice, and cows (38). Skin DETCs, however, are not found in humans, and phosphoantigen-specific Vγ9Vδ2 T cells are absent in mice (205). From an evolutionary standpoint, these findings suggest that different canonical specificities may have different protective value in different species and thus may have been independently added or removed from the mammalian genome during evolution.

Intriguingly, there is also a wide polymorphism of expression of these innatelike lymphocyte subsets within species. For example, NKT-cell frequencies vary widely among humans, in which high expressors can express up to 100 times more NKT cells than low expressors (206). These frequencies are under tight genetic control, as shown by identical-twins studies (206). Similarly, there are up to 10-fold variations in NKT-cell frequencies among common

inbred mouse strains (127,207). Some mouse substrains, such as FVB/tac, have lost expression of skin DETCs and, as a consequence, show heightened responses to inflammatory stimuli (45). Thus, while the genetic basis of these extraordinary variations is under investigation, it is tempting to speculate that such balanced polymorphism could reflect the "ying and yang" of innatelike lymphocytes, which serve protective functions in some conditions or environments but may be deleterious in others.

Other "Innatelike" Lymphocytes

This chapter has focused on expanded lymphocyte subsets that carry *germline-encoded specificities* and are endowed with functional innatelike properties. There are, however, additional populations of T and B lymphocytes that do not express canonical germline-encoded receptors, yet share some features of innatelike lymphocytes. For example, exposure to gut-flora carbohydrate antigens is thought to trigger the production of the natural IgM antibodies that cause rejection of incompatible red blood cells. Likewise, natural IgM antibodies against Galα1,3Galβ1,4GlcNAc epitopes probably derived from the gut flora, are found in the human species because humans lack Galα1,3 transferase and are therefore not tolerant of Galα1,3Galβ1,4GlcNAc. These antibodies are the basis of the abrupt rejection of xenotransplants carrying this carbohydrate epitope on their glycoproteins (208). Although they are absent in wild-type mice, which express the Galα1,3Galβ1,4GlcNAc epitopes on their glycoproteins, the antibodies are observed in "humanized" Galα1,3 transferase knockout mice, in which they are found mainly in the spleen and express an intermediate IgM^{high}CD5$^-$Mac1$^-$CD43$^+$ phenotype partially overlapping with B-1 cells (209,210). Importantly, however, neither anti-Gal nor anti–blood group antibodies have been reported to express canonical receptors.

CD8$\alpha\alpha$ TCR$\alpha\beta$ intraepithelial lymphocytes are found in the mouse intestine (though they are absent in humans) and are often referred to as "innate" based on their effector differentiation with transcriptionally active *IFNγ* gene (154,211), their expression of NK-lineage receptors (212), and their specificity for unidentified, nonclassical MHC class I–like ligands (213,214). Exposure to agonist antigens in a fetal thymic reaggregation culture system recapitulated the CD8$\alpha\alpha$ lineage (215). However, although the population is made of expanded clones, their $\alpha\beta$ TCRs are diverse and noncanonical (216).

Like CD1d-restricted NKT and MR1-restricted MAIT cells, MHC class Ib–restricted T cells acquire a memory/effector phenotype in the thymus by interaction with bone marrow–derived rather than epithelial cells (217). These properties enable H-2M3–restricted T cells, for example, to jump-start the CTL response to *Listeria monocytogenes* infection (218). However, studies so far have not documented the presence of recurrent canonical or germline-encoded TCRs among these cells.

Future Challenges

Comparative Immunology

Studies are needed to search for additional canonical germline-encoded receptors in B-1 and MZB populations of mice and humans. Likewise, comparative studies in more distant species should provide a broader picture of the array of innatelike BCRs and TCRs selected over evolutionary time and their species- or environment-specific protective value.

Antigens and Functions of Innatelike Lymphocytes

Several gaps remain in our knowledge of the antigen specificity of innatelike lymphocytes. The nonpeptidic nature of many ligands hinders their identification and complicates the interpretation of genetic ablation experiments. The functional redundancy of individual subsets prevents a definitive assessment of their role in physiologic and pathologic conditions. Thus, future identification of the self-ligand of DETCs, clarification of the respective roles of F1-ATPase and small phosphoantigens in Vγ9-cell activation, understanding of the regulation of iGb3 and other NKT ligands, and elucidation of the MAIT ligands associated with MR1 will be needed, along with new strategies for specific ablation of ligands and receptors. Novel approaches such as live imaging microscopy should prove particularly useful in studying the specialized functions of innatelike lymphocytes in their tissue context, for example, in the liver for NKT cells (157), skin for DETCs, peritoneum for B-1 B cells, and marginal zone for MZB cells.

Structural Biology of Innate Immune Recognition

As suggested by the unusual mode of recognition of T10/T22 by the $\gamma\delta$ TCR, the crystal structures of other innatelike receptor/ligand complexes will provide important information about the structural basis of innatelike receptor recognition. The phospholipidic and glycolipidic nature of several ligands, and their association with the membrane lipid bilayer or with proteins such as CD1d, complicate the studies, but their recognition by antibodies and TCRs likely involve novel structural solutions of great immunologic interest.

Lymphocyte Lineage Decisions

The instructional mechanisms involved in the differentiation of conventional and innatelike lineage differentiation are based on specific sets of receptors that signal the

transcriptional and epigenetic control of lineage commitment. Current studies indicate that, in addition to the strength of antigen, additional cofactors recruited through the topology and the timing of antigen expression contribute essential steps in the differentiation of specialized lineage subsets. Because these signals underlie a developmental bifurcation between "conventional" and "innatelike" B- and T-cell lineages, their studies should provide important insights into a general understanding of lymphocyte lineage development.

Therapeutics

As a follow-up to basic studies investigating the conserved antigens of innatelike lymphocytes, several synthetic NKT- and $\gamma\delta$ T-cell ligands have now been designed, and some have shown promising value in preclinical trials, particularly for their effects as adjuvants in anticancer and microbial vaccines (122,124,219). The interplay among these and other adjuvant pathways mediated by TLRs, NODs, and NALPs provides exciting new avenues of research and development.

Macrophages and Phagocytosis

Siamon Gordon

INTRODUCTION

Macrophages (Mϕ) represent a family of mononuclear leukocytes that are widely distributed throughout the body within and outside of lymphohemopoietic organs. They vary considerably in life span and phenotype, depending on their origin and local microenvironment. Mature Mϕ are highly phagocytic, relatively long-lived cells that are adaptable in their biosynthetic responses to antigens and microbial stimuli. The functions of Mϕ within tissues are homeostatic, regulating the local and systemic milieu through diverse plasma membrane receptors and varied secretory products. They react to, and themselves generate, signals that influence growth, differentiation, and death of other cells, recognizing and engulfing senescent and abnormal cells. These activities contribute substantially to recognition and defense functions against invading microorganisms, foreign particulates, and other immunogens. Innate immune functions of Mϕ complement their contributions to acquired humoral and cellular immunity, in which they regulate activation of T and B lymphocytes; this is achieved in part through their specialized derivatives, dendritic cells (DCs) of myeloid origin. Mϕ, with or without DCs, process and present antigen, produce chemokines and cytokines such as interleukin-1 (IL-1), IL-6, IL-12, IL-18, IL-23, tumor necrosis factor-α (TNFα), and IL-10, and phagocytose apoptotic and necrotic cells. Acting directly or under the influence of other immune cells, Mϕ capture extra- and intracellular pathogens, eliminate invaders, and deliver them to appropriate subcompartments of lymphoid organs. As key regulators of the specific as well as the natural immune response, Mϕ boost as well as limit induction and effector mechanisms of the specific immune response by positive and negative feedback.

The properties and roles of DCs are described in detail elsewhere in this volume. Here we focus on other members of the Mϕ lineage, consider their interrelationship, and outline specialized properties that underlie their roles in the execution and regulation of immune responses. A number of books deal with the history and broad aspects of Mϕ immunobiology (1–10).

SOME LANDMARKS IN THE STUDY OF MACROPHAGES

Our understanding of Mϕ developed in parallel with the growth of immunology as an experimental science. Metchnikoff, a comparative developmental zoologist, is widely credited for his recognition of phagocytosis as a

fundamental host defense mechanism of primitive, as well as highly developed, multicellular organisms (1–3). He clearly stated the link between capture of infectious microorganisms by the spleen and subsequent appearance of reactive substances (antibodies) in the blood, although mistakenly ascribing their production to the phagocytes themselves. The importance of systemic clearance of particles by Mϕ, especially Kupffer cells in liver and other endothelial cells, was enshrined in the term reticuloendothelial system (RES). Although it was rejected by influential investigators in the field in favor of the term mononuclear phagocyte system (MPS), the appreciation that sinuslining Mϕ in liver and elsewhere share common properties with selected endothelial cells is worth preserving (4). Earlier studies by Florey and his students, including Gowans, established that circulating monocytes give rise to tissue Mϕ. Van Furth and his colleagues investigated the life history of Mϕ by kinetic labeling methods; subsequently, the development of membrane antigen markers facilitated a more precise definition of specialized Mϕ subpopulations in tissues such as brain (5). The appearance and potential importance of Mϕ during development also became evident as a result of sensitive immunocytochemical methods. Morphologic and functional studies by Humphrey and many others drew attention to striking diversity among Mϕ-like cells in secondary lymphoid organs, especially within the marginal zone of the spleen, where complex particulates and polysaccharides are captured from the circulation (6,7).

The era of modern cell biology impinged on Mϕ studies following the studies of Cohn, Hirsch, and their colleagues (8). Their work touched on many aspects of cell structure and function, including phagocytosis (the zipper mechanism of Silverstein), fluid- and receptor-mediated endocytosis, secretion, and antimicrobial resistance. Isolation and *in vitro* culture systems became available for cells from mice and humans, especially after the identification of specific growth and differentiation factors such as colony-stimulating factor-1 (CSF-1; M-CSF) (9). It is perhaps fitting that the earliest known natural knockout (ko) affecting macrophages, a natural mutation in the op gene in the osteopetrotic mouse, should involve CSF-1 (9,10). Cell lines retaining some but not all features of mature Mϕ have been useful for many biochemical and cellular studies (11). Macrophages and dendritic cells can be readily derived from embryonic stem (ES) cells by growth in appropriate culture conditions.

The role of Mϕ as antigen-processing cells able to initiate adaptive immune responses had false trails ("immunogenic RNA" was thought to be involved at one time) and encompassed early genetic strategies (Mϕ of mice selected for high anti–sheep erythrocyte antibody responses by Biozzi and colleagues displayed enhanced degradative properties; adherent cells from defined guinea pig strains were shown to play an important role in major histocompatibility complex (MHC) Ia–restricted antiinsulin responses. For many years the antigen presenting cell (APC) functions of adherent cells were highly controversial as promoted by Unanue, who concentrated on intracellular processing by Mϕ, and Steinman, who discovered the specialized role of "dendritic cells" in antigen presentation to naive T lymphocytes. The importance of Mϕ as effector cells in immunity to intracellular pathogens such as *Mycobacterium tuberculosis* was recognized early by Lurie and Dannenberg. Mackaness used *Listeria monocytogenes* and bacille Calmette-Guérin (BCG) infection in experimental models and developed the concept of Mϕ activation as an antigen-dependent but immunologically nonspecific enhancement of antimicrobial resistance. The subsequent delineation of T lymphocyte subsets and characterization of interferon-γ (IFNγ) (12) as the major cytokine involved in macrophage activation, including MHC II induction, merged with increasing knowledge of the role of reactive oxygen and, later, nitrogen metabolites as cytotoxic agents (13). The role of virus-infected Mϕ as MHC I–restricted targets for antigen-specific CD8$^+$ killer cells was part of the initial characterization of this phenomenon by Zinkernagel and Doherty. D'Arcy Hart was an early investigator of the intracellular interactions between Mϕ and invaders of the vacuolar system, especially mycobacteria, which survive within Mϕ by inhibiting acidification and phagosome–lysosome fusion, thus evading host resistance mechanisms (14). Mouse breeding studies by several groups defined a common genetic locus involved in resistance to BCG, *Leishmania*, and *Salmonella* organisms. The host phenotype was shown to depend on expression in Mϕ and, many years later, the gene (termed N-ramp for natural resistance-associated membrane protein) was identified by positional cloning by Skamene, Gros, and their colleagues (15). Positional cloning by Beutler and associates led to the identification of the gene responsible for lipopolysaccharide (LPS) resistance in particular mouse strains (16). Together with studies by Hoffmann and his colleagues on the Toll pathway in *Drosophila* (17), this work resulted in an explosion of interest in the identification of mammalian Toll-like receptors (TLRs) and their role in innate immunity to infection (18,19). At the same time it became apparent that some malignant tumors contain macrophage populations that may favor their growth (20).

This brief survey concludes with the identification of Mϕ as key target cells for infection, dissemination, and persistence of HIV (21), tropic for macrophages by virtue of their expression of CD4, chemokine coreceptors, and DC-SIGN, a C-type lectin also expressed by DCs (22). Although Mϕ had been implicated by earlier workers such as Mims as important in antiviral resistance generally, their role in this regard was neglected before the emergence of HIV as a major pathogen.

Many molecules have been identified as important in Mϕ functions in immunity and serve as valuable markers

to study their properties in mice and humans. These include Fc (23) and complement (24) receptors, which are important in opsonic phagocytosis, killing, and immunoregulation; scavenger receptors implicated in foam cell formation and atherogenesis by Brown and Goldstein (25); nonopsonic lectin receptors, such as the mannose receptor (MR) (26) and β-glucan receptor (BGR) (27); and secretory products such as lysozyme (28), neutral proteinases, TNFα (29), chemokines, and many other cytokines. A range of membrane antigens (ag) expressed by human and rodent mononuclear phagocytes has been characterized and reagents made available for further study of Mϕ in normal and diseased states (5). Recently, the role of DNA-binding transcription factors including members of the nuclear factor (NF)-κB and ETS (Pu-1) families has received increased attention in the study of differential gene expression by Mϕ (30,31). Gene inactivation has confirmed the important role of many of these molecules within the intact host, and use has been made of cell-specific or conditional ko to uncover the role of Mϕ in immunologic processes (32). Naturally occurring inborn errors in humans such as the leukocyte adhesion deficiency syndrome and chronic granulomatous disease have contributed to the analysis of important leukocyte functions, including those of Mϕ, in host resistance to infection. Mutations in a monocyte-expressed gene (NOD-2), involved in cytosolic sensing of microbial products and NF-κB activation, have been implicated in a subset of individuals with an enhanced susceptibility to Crohn's disease (33). The validity of murine ko models for human genetic deficiencies has been confirmed for key molecules involved in Mϕ activation, such as IFNγ and IL-12 (34). *N*-Ethyl *N*-nitrosourea mutagenesis has begun to reveal new macrophage innate immune functions (35).

PROPERTIES OF MACROPHAGES AND THEIR RELATION TO IMMUNE FUNCTIONS

Introduction

Mϕ participate in the production, mobilization, activation, and regulation of all immune effector cells. They interact reciprocally with other cells while their own properties are modified to perform specialized immunologic functions. As a result of cell surface and auto- and paracrine interactions, Mϕ display marked heterogeneity in phenotype (5,36,37), a source of interest and considerable confusion to the investigator. Increasing knowledge of cellular and molecular properties of Mϕ bears strongly on our understanding of their role in the immune response. These will be reviewed briefly, with emphasis on functional significance, and draw attention to unresolved and controversial issues.

Growth and Differentiation: Life History and Turnover

In contrast with T and B lymphocytes, monocytes from blood give rise to terminally differentiated Mϕ that cannot recirculate or reinitiate DNA replication except in a limited way; DCs may represent specialized migratory derivatives of mononuclear cells. Unlike other myeloid granulocytic cells, Mϕ can be long lived and retain the ability to synthesize RNA and protein to a marked extent, even when in a relatively quiescent state, as "resident" cells. These are distributed throughout the tissues of the body and constitute a possible alarm-response system, but they also mediate poorly understood trophic functions. Following inflammatory and immune stimuli, many more monocytes can be recruited to local sites and give rise to "elicited" or "immunologically activated" Mϕ with altered surface, secretory, and cytotoxic properties. The origins of Mϕ from precursors are well known; from yolk sac (and possibly earlier paraaortic progenitors), migrating to fetal liver, then spleen and bone marrow, before and after birth (38). In the fetus, mature Mϕ proliferate actively during tissue remodeling in developing organs. In the normal adult, tissue Mϕ do not self-renew extensively except in specialized microenvironments such as lung epidermis or, the pituitary; after injury there can be considerable further replication at local sites of inflammation. Growth and differentiation are tightly regulated by specific growth factors and their receptors (e.g., IL-3, CSF-1, granulocyte-macrophage [GM]-CSF, IL-4, IL-13) and inhibitors (e.g., IFNα/β, transforming growth factor-β [TGFβ], leukemia inhibitory factor), which vary considerably in their potency and selectivity. These processes are modulated by interactions with adjacent stromal and other cells (e.g., through c-kit/ligand and Flt-3/ligand interactions). The growth-response of the target cell to an extrinsic stimulus decreases progressively and markedly (from 10^8 or more to 10^0) during differentiation from stem cell to committed precursor to monoblast, monocyte, and Mϕ, yet even the most terminally differentiated Mϕ such as microglial cells can be "reactivated" to a limited extent by local stimuli (39). Elicited/activated Mϕ respond more vigorously than resident Mϕ to growth stimuli *in vivo* and *in vitro*, but the molecular basis for their enhanced proliferation is unknown.

Although the general picture of blood monocyte-to-tissue Mϕ differentiation has been clear for some time as a result of parabiosis, adoptive transfer, and irradiation-reconstitution experiments, there are still major unsolved issues. Are all "monocytes" equivalent, or is there heterogeneity in the circulating mononuclear cell pool corresponding with the ultimate tissue localization of their resident, constitutively distributed progeny? Our understanding of DCs and osteoclast differentiation is compatible with a relatively simple model (Figure 18.1) in which major Mϕ populations in tissues can be characterized by selected ag
FIGURE 18.1 Differentiation of mononuclear phagocytes based on antigen markers FA-11 (macrosialin, murine CD68) and F4/80. See text for detailed discussion.

markers such as F4/80 (Emr1, a member of a new family of EGF-TM7 molecules) (40) and macrosialin (CD68), a pan-Mϕ endosomal glycoprotein related to the lysosome-associated membrane protein (LAMP) family (41). The DCs of myeloid origin (see elsewhere in this volume) can be viewed as products of Langerhans-type cells in nonlymphoid organs such as skin and airway epithelium, which may undergo further differentiation and migrate to secondary lymphoid organs in response to an antigenic stimulus (42). Circulating precursors of DCs and recirculating progeny are also normally present in the mononuclear fraction of blood in small numbers and may be already "marked" for distribution to peripheral sites as Langerhans cells. Monocytes that have crossed the endothelium may be induced to "reverse migrate" into the circulation by selected stimuli in tissues (43).

Circulating mononuclear precursors for osteoclasts are less defined and differentiate into mononucleate cells in bone and cartilage, where they fuse to form multinucleate bone-resorbing osteoclasts (44). Local stromal cells, growth factors such as CSF-1, steroids (vitamin D metabolites), and hormones (e.g., calcitonin, for which osteoclasts express receptors) all contribute to local maturation. Osteoprotegerin, a naturally occurring secreted protein with homology to members of the TNF-receptor family, interacts with TRANCE, a TNF-related protein, to regulate osteoclast differentiation and activation *in vitro* and *in vivo*.

Use of ag markers such as CD34 on progenitors, CD14 and CD16 (45) on monocytes, and chemokine receptors (46) and multichannel fluorescein-activated cell sorter (FACS) analysis makes it possible to isolate leukocyte subpopulations and study their progeny and differential responses (see later discussion). The mononuclear fraction of blood may contain precursors of other tissue cells, including "fibrocytes" (47) thought to be hemopoietic yet able to synthesize matrix proteins such as collagen, and some endothelial cells. Perhaps the mysterious follicular dendritic cells (FDCs) with mixed hemopoietic and mesenchymal properties fall in this category.

The large-scale production of immature and mature DC-like cells from bulk monocytes in cytokine-supplemented culture systems (IL-4, GM-CSF, TNFα) has revolutionized the study of these specialized APCs (48,49). Individually, the same cytokines give rise to Mϕ-like cells, and early during *in vitro* differentiation, the cellular phenotype is reversible. Later, when mature DCs with high MHC II, APC function, and other characteristic markers are formed, differentiation is irreversible. This process is independent of cell division, although earlier progenitors in bone marrow and G-CSF–mobilized blood mononuclear cells can be stimulated to multiply, as well as differentiate, *in vitro*. These examples of terminal differentiation observed with DCs and osteoclasts may extend to other specialized, more obvious Mϕ-like cells. Mature Mϕ

can be derived by growth and differentiation in steroid-supplemented media in Dexter-type long-term bone marrow cultures that contain stromal fibroblasts and hemopoietic elements. These Mϕ express adhesion molecules responsible for divalent cation–dependent cluster formation with erythroblasts (EbR) (50). This receptor, possibly related to V-CAM, cannot be induced on terminally differentiated peritoneal Mϕ if these are placed in the same culture system. This contrasts sharply with the ready adaptation of many tissue Mϕ to conventional cell culture conditions, when the cells often adopt a common, standard phenotype. Irreversible stages of Mϕ differentiation may therefore occur in specialized microenvironments *in vitro* or *in vivo*.

Little is known about determinants of Mϕ longevity and turnover. Growth factors such as CSF-1 enhance Mϕ survival and prevent induction of an apoptotic program. The expression of Fas-L and Fas on Mϕ has been less studied than on lymphocytes; they and other members of the TNF and its receptor family may play a major role in determining Mϕ survival, especially in induced populations, where cell turnover is markedly enhanced. Tissue Mϕ vary greatly in their life span, from days to months. Apart from inflammatory and microbial stimuli, local and systemic environmental factors such as salt loading and hormones, including estrogen, are known to influence Mϕ turnover.

Tissue Distribution and Phenotypic Heterogeneity of Resident Macrophages in Lymphoid and Nonlymphoid Organs

The use of the F4/80 plasma membrane ag made it possible to detect mature Mϕ in developing and adult murine tissues and define their anatomic relationship to other cells in endothelium, epithelium, and connective tissue, as well as the nervous system (5,51). Subsequently, other membrane antigens (52) [macrosialin (41), sialoadhesin (53,54)] were identified as useful markers for Mϕ *in situ* (Table 18.1). Mϕ subpopulations in different tissues display considerable heterogeneity in expressing these and selected receptor antigens, for example, CR3 (55) and SR-A (56), drawing attention to unknown mechanisms of homing, emigration, and local adaptation to particular microenvironments. From the viewpoint of immune responses, a few aspects deserve comment.

Fetal Liver and Bone Marrow

Mature Mϕ form an integral part of the hemopoietic microenvironment and play a key role in the production, differentiation, and destruction of all hemopoietic cells (57). The fetal liver is a major site of definitive erythropoiesis from midgestation. The bone marrow becomes

▶ **TABLE 18.1 Selected Differentiation Antigens Used to Study Murine Macrophage Heterogeneity**

Ab	Ag	Structure	Ligands	Cellular Expression	Function	Comment
F4/80	F4/80 (EMR1)	EGF-TM7	?	Mature Mϕ, absent T areas	Peripheral tolerance	Useful marker development, CNS
FA-11	Macrosialin (CD68)	Mucin-LAMP	OX-LDL	Pan-Mϕ, DC	Late endosomal	Glycoforms regulated by inflammation and phagocytosis
5C6	CR3 (CD11b, CD18)	β2-integrin	iC3b, ICAM	Monocytes, microglia, PMN, NK cells	Phagocytosis, adhesion	Important in inflammatory recruitment, PMN apoptosis
2F8	SR-A (I, II)	Collagenous, type II glycoprotein	Polyanions, LTA, LPS, bacterial proteins		Adhesion, endocytosis	Protects host against LPS-induced shock
		Isoforms differ, cysteine-rich domain	Modified proteins β-amyloid Apolipoprotein A, E	Mϕ, sinusoidal Endothelium	Phagocytosis of apoptotic cells and bacteria	Promotes atherosclerosis
SER-4 3D6	Sn (Siglec-1)	Ig superfamily	Sialyl glycoconjugates e.g., CD43	Subsets Tissue Mϕ	Lectin	Strongly expressed Marginal zone metallophils in spleen and subcapsular sinus of lymph nodes

Ab, antibody; Ag, antigen; CNS, central nervous system; DC, dendritic cells; ICAM, intercellular adhesion molecule; Ig, immunoglobulin; LAMP, lysosome-associated membrane protein; LPS, lipopolysaccharide; LTA, lipoteichoic acid; Mϕ, macrophages; NK, natural killer cells; PMN, Sn, sialoadhesin; SR-A, type A scavenger receptor.
FIGURE 18.2 Associations of tissue macrophages with other hemopoietic cells to illustrate variations on a common theme. See text for details.

active in the production of hemopoietic cells from shortly before birth, and Mφ are a prominent component of the hemopoietic stroma throughout adult life. Mature "stromal" Mφ in fetal liver and adult bone marrow express nonphagocytic adhesion molecules such as sialoadhesin (Sn), an immunoglobulin (Ig)-superfamily sialic acid–binding lectin (53,54) (Table 18.1), and the EbR referred to previously (50), which is also involved in adhesion of developing myeloid and possibly lymphoid cells (Figure 18.2). VLA-4 has been implicated as a ligand for EbR. Ligands for Sn include CD43 on developing granulocytes (58) and on lymphocyte subpopulations. Sialoadhesin clusters at sites of contact between stromal Mφ and myeloid but not erythroid cells. Chemokines are able to induce polarized expression of adhesion molecules such as intercellular adhesion molecules (ICAMs) and CD43 in leukocytes, but the significance of altered ligand distribution for interactions between Mφ and bound hemopoietic cells is unknown. Adhesion of immature cells to stromal Mφ may play a role in regulating their intermediate stages of development before release into the bloodstream, whereas fibroblasts in the stroma associate with earlier progenitors, as well as with Mφ. Discarded nuclei of mammalian erythroid cells are rapidly engulfed by stromal Mφ, but the receptors involved in their binding and phagocytosis are unknown. Mφ also phagocytose apoptotic hemopoietic cells generated in bone marrow, including large numbers of myeloid

and B cells. We know little about the plasma membrane molecules and cytokine signals operating within this complex milieu, but it is clear that stromal Mφ constitute a neglected constituent within the hemopoietic microenvironment.

Thymus

Apart from their remarkable capacity to remove apoptotic thymocytes, the possible role of Mφ in positive and negative selection of thymocytes has been almost totally overlooked; more attention has been given to local DCs and their specialized properties. Mature Mφ with unusual features are also present in cortex and medulla. Clusters of viable thymocytes and Mφ can be isolated from the thymus of young animals by collagenase digestion and adherence to a substratum (Figure 18.2). The nonphagocytic adhesion receptors responsible for cluster formation are more highly expressed by thymic than other Mφ, but their nature is unknown (N. Platt, unpublished observations). These Mφ also express MHC class II antigens and other receptors such as the class A scavenger receptor (SR-A) (see later discussion), which contributes to phagocytosis of apoptotic thymocytes *in vitro* (59) but is redundant *in vivo* (60); other markers, such as the F4/80 ag, are poorly expressed *in situ* but can be readily detected after cell isolation. A striking difference between thymic and several other tissue
FIGURE 18.3 Microheterogeneity of macrophages in spleen, resting, and antigen-stimulated lymph nodes. See text for markers and details.

Mϕ subpopulations is their independence of CSF-1; the CSF-1–deficient *op/op* mouse lacks osteoclasts and some Mϕ populations, including monocytes, peritoneal cells, and Kupffer cells, but contains normal numbers of thymic Mϕ, as well as DCs and selected Mϕ in other sites (61). Factors involved in constitutive recruitment of thymic Mϕ are unknown; following death of thymocytes induced by ionizing radiation or glucocorticoids, intensely phagocytic Mϕ appear in large numbers; it is not known what proportion arises locally and by recruitment.

Spleen

From the viewpoint of the Mϕ, the spleen is perhaps the most complex organ in the body (6,7). It contributes to hemopoiesis, which persists postnatally in some species or can be induced by increased demand, and to the turnover of all blood elements at the end of their natural life span. In addition, the spleen filters a substantial proportion of total cardiac output, captures particulate and other antigenic materials from the bloodstream, and plays an im-

portant role in natural and acquired humoral and cellular immunity. The organ is rich in subpopulations of Mϕ that differ in microanatomic localization, phenotype, life history, and functions (Figure 18.3). Mϕ are central to antigen capture, degradation, transport, and presentation to T and B lymphocytes and contribute substantially to antimicrobial resistance. Because other hemopoietic and secondary lymphoid organs can replace many of these functions after maturation of the immune system, the unique properties of the spleen have been mainly recognized in the immature host and in immune responses to complex polysaccharides. Splenectomy in the adult renders the host susceptible to infection by pathogenic bacteria such as pneumococci that contain saccharide-rich capsular antigens; the marginal zone of the spleen in particular may play an essential role in this aspect of host resistance.

The properties of Mϕ in the unstimulated mature mouse spleen are very different according to their localization in red or white pulp and the marginal zone. Mϕ are intimately associated with the specialized vasculature. Species differences in splenic anatomy and phenotype

are well recognized (62–64), although Mϕ display broadly common features in humans and rodents. Subpopulations of Mϕ, DCs, and cells with mixed phenotypes have been characterized by *in situ* analysis by ag markers, liposome- or diphtheria toxin–depletion studies, various immunization and infection protocols, and cytokine and receptor gene ko models in the mouse. The results raise questions about the dynamics and molecular basis of cell production, recruitment, differentiation, emigration, and death within each distinct splenic compartment. Cell isolation methods are still primitive in correlating *in vitro* properties with those of Mϕ subpopulations *in vivo* and remain an important challenge. Detailed aspects of splenic architecture, DC origin and function, and T and B lymphocyte induction and differentiation are described elsewhere in this volume. Here I highlight some features of Mϕ in the normal and immunoreactive organ.

Marginal Zone Macrophages

The marginal zone of spleen consists of a complex mixture of resident cells (reticular and other fibroblasts, endothelium), Mϕ, DCs, and lymphoid cells, including subpopulations of B lymphocytes (7). It constitutes an important interface with the circulation that delivers cells, particulates, or soluble molecules directly into the marginal sinus or via the red pulp. Resident Mϕ are present as specialized metallophilic cells in the inner marginal zone, and other Mϕ are found in the outer zone; the latter may be more phagocytic. Sialoadhesin is very strongly expressed by the marginal metallophils, compared with only weak expression in red pulp and virtual absence in the white pulp (65). Sialoadhesin-positive cells appear in this zone 2 to 4 weeks postnatally in the mouse as the white pulp forms (66). Liposomes containing clodronate, a cytotoxic drug, can be delivered systemically and deplete Sn$^+$ cells and other Mϕ; regeneration of different Mϕ subpopulations in spleen occurs at different times, and this procedure has been used to correlate their reappearance with distinct immunologic functions. Marginal zone Mϕ lack F4/80 but may express an undefined ligand for F4/80 on circulating activated DCs, which mediates peripheral tolerance to anterior chamber or gut-derived antigens (67). Marginal zone Mϕ express phagocytic receptors, such as SR-A (68), which is more widely present on tissue Mϕ, as well as MARCO, a distinct collagenous scavenger receptor (69), which is almost exclusively present on these Mϕ in the normal mouse (70). The structures and possible role of these pattern recognition receptors in uptake of microbes are discussed later. *In vivo* studies have shown that a Mϕ lectin, the MR, may be involved in transfer of mannosylated ligands to the site of an immune response in the white pulp (26,71–73). The MR contains a highly conserved cysteine-rich domain, not involved in mannosyl recognition, that reacts strongly with ligands on a subset of marginal metallophilic Mϕ (73a), sulfated glycoforms of Sn, and CD45, among oth-

ers; this has been demonstrated with a chimeric probe of the cysteine-rich domain of the MR and human Fc (CR-Fc) and by immunochemical analysis of tissue sections and affinity chromatography of spleen ligands. After immunization, this probe additionally labels undefined cells in the FDC network of germinal centers, as well as tingible body Mϕ. It is possible that marginal zone Mϕ can be induced to migrate into white pulp as described after LPS injection; alternatively, they may shed complexes of soluble MR-glycoprotein ligand for transfer to other CR-Fc$^+$ cells, which may be resident, or newly recruited mononuclear cells. Finally, the marginal metallophilic Mϕ population depends on CSF-1 for its appearance (61) and on members of the TNF receptor family (74), as shown with *op/op* and experimentally produced ko mice.

White Pulp Macrophages

The F4/80 ag is strikingly absent on murine white pulp Mϕ, which do express FA-11 (macrosialin), the murine homolog of CD68. Actively phagocytic Mϕ express this intracellular glycoprotein in abundance compared with DCs. After uptake of a foreign particle (e.g., sheep erythrocytes or an infectious agent, such as BCG or *Plasmodium yoellii*), white pulp Mϕ become more prominent, although it is not known whether there is migration of cells into the white pulp or transfer of phagocytosed material and reactivation of previous resident Mϕ. Tingible body Mϕ appear to be involved in uptake and digestion of apoptotic B lymphocytes.

Red Pulp Macrophages

These express F4/80 ag and MR (75) strongly and in the mouse include stromal-type Mϕ involved in hemopoiesis. Extensive phagocytosis of senescent erythrocytes results in accumulation of bile pigments and ferritin. The role of various phagocytic receptors in clearance of host cells and pathogens by red pulp Mϕ requires further study.

There is no evidence that Mϕ, other than interdigitating DCs, associate directly with CD4$^+$ T lymphocytes in the normal spleen. Following infection by BCG, for example, or by other microorganisms such as *Salmonella*, there is massive recruitment and local production of Mϕ, many of which associate with T lymphocytes. Newly formed granulomata often appear first in the marginal zone (focal accumulations of activated Mϕ and activated T cells. As infections spread into the white and red pulp, the granulomata become confluent and less localized, obscuring and/or disrupting the underlying architecture of the spleen. The possible role of activated Mϕ in T cell apoptosis and clearance in spleen has not been defined.

Lymph Nodes

F4/80 ag is relatively poorly expressed in lymph node (Figure 18.3), but many macrosialin (CD68)$^+$ cells are present. The subcapsular sinus is analogous to the marginal zone

and contains strongly Sn$^+$ cells; this is the site where afferent lymph enters, containing antigen and migrating DCs derived from Langerhans cells. The medulla contains Sn$^+$, CD68$^+$ Mϕ, which also express high levels of SR-A. As in the spleen marginal zone, subcapsular sinus Mϕ are strongly labeled by the CR-Fc probe. Following primary or secondary immunization, the staining pattern moves deeper into the cortex and eventually becomes concentrated in germinal centers. The kinetics of this process strongly suggests a transport process by Mϕ-related cells resembling antigen transport cells described previously. CR-Fc$^+$ cells can be isolated by digestion of lymph nodes and form clusters with CR-Fc$^-$ lymphocytes. Adoptive transfer has shown that FACS-isolated CR-Fc$^+$ cells resemble DCs in their ability to home to T cell areas and to present antigen to naive T and B cells (76). Overall, there is considerable heterogeneity in the population of migratory APCs involved in antigen capture, transport, and delivery to T and B cells, and it may turn out that specialized tissue Mϕ as well as myeloid-type DCs can migrate in response to immunologic stimuli, especially TLR ligands (73).

Peyer's Patch

Although less studied, the Mϕ in Peyer's patch resemble the CD68$^+$, F4/80$^-$ cells described in spleen and white pulp and in other T cell–rich areas. They are well placed to interact with gut-derived antigens and pathogens taken up via specialized epithelial M cells in the dome, and deliver antigens to afferent lymphatics, as myeloid DCs. These cells are distinct from abundant F4/80$^+$ cells in the lamina propria found all the way down the gastrointestinal tract and may play a role in the induction of mucosal immunity.

Nonlymphoid Organs

Regional F4/80$^+$ and CD68$^+$ Mϕ are well described in liver (Kupffer cells), dermis, neuroendocrine and reproductive organs, and serosal cavities, where they are able to react to systemic and local stimuli. In the lung, alveolar Mϕ are strongly CD68$^+$ but only weakly F4/80$^+$ and are distinct from interstitial Mϕ and intraepithelial DCs. In the lamina propria of the intestine, macrophages display a downregulated phenotype, ascribed to TGFβ of local origin (77). In addition, resident Mϕ are found throughout connective tissue and within the interstitium of organs, including heart, kidney, and pancreas. These cells vary greatly depending on their local microenvironment; for example, in the central nervous system, microglia within the neuropil differ strikingly from Mϕ in the meninges or choroid plexus. Perivascular Mϕ in the brain can be distinguished from resident microglia by their expression of endocytic receptors, for example, the SR-A and MR, and of MHC I and II antigens. Microglia are highly ramified, terminally differ-

entiated cells of monocytic origin, and many Mϕ markers are downregulated; their phenotype is influenced by the blood–brain barrier, normally absent in circumventricular organs, and disrupted by inflammatory stimuli. Microglia can be reactivated by local LPS and neurocytotoxins, and they are then difficult to distinguish from newly recruited monocytes, which acquire microglial features once they enter the parenchyma of the brain (51). Resting microglia are unusual among many tissue Mϕ in that they constitutively express high levels of CR3 and respond to CR3 ligands, such as mAb, by induced DNA synthesis and apoptosis (39). In other sites, such as lung and liver, CR3 expression is a feature of recent myeloid recruitment, including monocytes. Resident Kupffer cells lack constitutive CR3 but express a novel CR implicated in clearance function (78).

Enhanced Recruitment of Monocytes by Inflammatory and Immune Stimuli: Activation *in vivo*

In response to local tissue and vascular changes, partly induced by resident Mϕ during (re)activation by inflammatory and immunologic stimuli, monocytes are recruited from marrow pools and blood in increased numbers; they diapedese and differentiate into Mϕ with altered effector functions as they enter the tissues. These Mϕ are classified as "elicited" when cells are generated in the absence of γ-interferon and as "immunologically activated" after exposure to γ-interferon. Enhanced recruitment can also involve that of other myeloid or lymphoid cells; selectivity of the cellular response depends on the nature of the evoking stimulus (immunogenic or not), the chemokines produced, and the receptors expressed by different leukocytes. Mϕ and other cells produce a range of different chemokines and express multiple seven-transmembrane, G protein–coupled chemokine receptors. The chemokines can also act in the marrow compartment, especially if anchored to matrix and glycosaminoglycans, may display other growth regulatory functions, and can control egress. Locally bound or soluble chemokines induce the surface expression and activity of adhesion molecules on circulating white cells, as well as directing their migration through and beyond endothelium. Feedback mechanisms from periphery to central stores and within the marrow stroma may depend on cytokines and growth factors such as macrophage inflammatory protein-1α and GM-CSF, which inhibit or enhance monocyte production, respectively. The adhesion molecules involved in recruitment of monocytes, originally defined by studies in humans with inborn errors and by use of inhibitory antibodies in experimental animal models, overlap with those of polymorphonuclear neutrophils (PMNs) and lymphocytes and include L-selectin, β_2-integrins, especially CR3, CD31, an Ig-superfamily molecule, and CD99 (79); additional
FIGURE 18.4 Distinct monocyte subsets give rise to inflammatory and resident macrophages and dendritic cells. The origin of different resident subpopulations is not clear. See text for further details.

monocyte adhesion molecules for activated endothelium include CD44, vascular cell adhesion molecules, β_1-integrins, and newly described receptors such as EMR2 and CD97, members of the EGF-TM7 family (37,40). The mechanisms of constitutive entry of monocytes into developing and adult tissues, in the absence of an inflammatory stimulus, are unknown.

By contrast with the uncertain precursors of resident Mϕ and DC populations, distinct monocyte subsets have been implicated in the enhanced mobilization and turnover in response to inflammatory, infectious, and metabolic stimuli (37,46,80) (Figure 18.4). Differential expression of fractalkine receptor, CCR2, and other chemokine receptors, together with antigen markers (Gr-1 in mouse and CD14 in human), have made it possible to define monocyte heterogeneity (81,82). Although such subsets seem to be conserved across several species, their properties may reflect stages of cell activation along a continuous spectrum rather than true differentiation.

The migration and differentiation of newly recruited monocytes once they have left the circulation are poorly understood. They are able to enter all tissues, undergoing alterations in membrane molecules and secretory potential under the influence of cytokines and surface interactions with endothelial cells, leukocytes, and other local cells. Phenotypic changes mentioned in the following section have been characterized by a range of *in vitro* and *in vivo* studies. Well-studied examples include murine peritoneal Mϕ—resident, elicited by thioglycollate broth or biogel polyacrylamide beads, and immunologically activated by BCG infection. The latter provides a useful model of granuloma formation in solid organs but does not fully mimic the human counterpart associated with *M. tuberculosis* infection. Granuloma Mϕ vary in their turnover and immune effector functions and display considerable het-

erogeneity; lesions contain recently recruited monocytes, mature, epithelioid Mϕ (described as secretory cells), and Langhans giant cells. Interactions with T lymphocytes, other myeloid cells, DCs, fibroblasts, and microorganisms yield a dynamic assembly of cells as the granuloma evolves, heals, and resolves (Figure 18.2). Apoptosis and necrosis of Mϕ and other cells contribute to the balance of continued recruitment and local proliferation. The emigration of Mϕ rather than DCs from sites of inflammation is less evident, although it has become clear that elicited Mϕ within the peritoneal cavity, for example, migrate actively to draining lymph nodes.

Gene ko models have confirmed the role of molecules previously implicated in recruitment, activation, and granuloma formation. These include the adhesion molecules listed previously, their ligands, such as ICAM-1, and key cytokines such as γ-interferon, IL-12, and TNFα, as well as their receptors. Antimicrobial resistance and Mϕ cytotoxicity resulting from production of reactive oxygen and nitrogen metabolites are now accessible to study in knockouts of the phagocyte oxidase and inducible nitric oxide synthase (iNOS) (83). Knockouts of membrane molecules of immunologic interest expressed by Mϕ and other cells include MHC class II and I, CD4, and CD40L, other accessory molecules such as B7-1 and B7-2, and the Mϕ-restricted intracellular molecule N-ramp.

The use of knockouts and/or antibodies or soluble receptors has brought insight into essential, nonredundant contributions of molecules that regulate Mϕ activation, immunopathology syndromes such as septic shock, and autoimmunity. Examples include myeloid antigens such as TREM-1 (84), associated with DAP-12, receptor–ligand pairs such as CD200/CD200 receptor (85,86), and suppressors of cytokine signaling (SOCS) proteins (87). TNFα is essential for host resistance to infection (88), and also

contributes to immunopathology. Highly effective anti-TNFα therapy for chronic inflammatory diseases such as rheumatoid arthritis (89) can result in reactivation of latent tuberculosis.

The potential for Th1- and Th2-type regulation of Mϕ demonstrated *in vitro*, and discussed later, can result in highly complex, often coexistent, heterogeneity of Mϕ phenotype *in situ* (90) (Figure 18.4). Although almost all granuloma Mϕ express lysozyme (28), only minor subpopulations express cytokines such as IL-1β, IL–6, and TNFα. Pro- and antiinflammatory cytokines, IL-12, IL-18, IL-10, and TGFβ, produced by Mϕ themselves and other cells, modulate the phenotype of Mϕ *in vivo*.

Apart from the local interactions outlined, Mϕ regulate systemic host reactions to immune and infectious stimuli by producing circulating cytokines such as IL-6 and arachidonate- and other lipid-derived metabolites, including resolvins, that contribute to the resolution of acute inflammation (91). These also act on neural and endocrine centers, crossing the blood–brain barrier, or are generated locally by reactive microglia and Mϕ. Glucocorticosteroids are powerful immunomodulators (92) and form part of a network that regulates monocyte recruitment and Mϕ functions through circulating mediators such as MIF (migration inhibition factor). Mϕ contain potent enzymes involved in steroid biosynthesis and catabolism.

Although the immunologic relevance of Mϕ-induced responses may seem evident, many aspects remain unclear. For example, do Mϕ actively suppress or destroy activated T lymphocytes, thus contributing to regulation of immune responses and peripheral tolerance, or are Mϕ only passive removers of dying cells; do Mϕ contribute to recruitment, differentiation, and death of DCs at sites of inflammation before their migration to secondary lymphoid organs; do adjuvant-stimulated Mϕ interact with B lymphocytes, directing their migration into germinal centers; are interactions of activated Mϕ with antibody and complement, through different Fc and complement receptors, implicated in fine-tuning humoral responses; are activated Mϕ themselves cytocidal for infected host cells, and to what extent do they in turn interact with and provide targets for attack by natural killer (NK) cells and cytotoxic T lymphocytes? Study of a range of experimental models and disease processes *in vivo* should yield new insights, as well as extend and confirm mechanisms already defined *in vitro*.

Phagocytic Recognition and Intracellular Infection

The initiation and localization of an immune response depend on recognition by Mϕ and other cells of particulate agents or soluble proteins that are foreign or modified-self. Phagocytic and endocytic recognition by Mϕ and DCs depends on opsonic (mainly antibody, complement) and nonopsonic pattern recognition receptors that inter-

act with a range of related ligands (93–95). Innate and acquired responses are thus interlinked. Different FcR are involved in uptake and destruction of targets as well as in negative regulation of effector functions (23). Complement receptors are also heterogeneous; CR3 interacts with C3-derived ligands formed by activation of the classical, alternate, or lectin pathways and mediate phagocytosis, cell migration, and cell activation. Other ligands include I-CAM. CR3 functions are modulated by fibronectin, via integrins, other adhesion molecules, and inflammatory stimuli. FcR ligation and cross-linking activates tyrosine kinases such as syk that are essential for phagocytosis (96); CR3 signaling is less defined and may not trigger a respiratory burst or arachidonate release, unlike FcR, thus favoring pathogen entry (97). Antibody-mediated uptake targets an organism or soluble antigen to a different, degradative compartment (Figure 18.6A) and usually results in its neutralization and destruction, although enhancement of infection can also occur in Mϕ. For example, flavivirus infection in the presence of specific antibody can result in the Dengue hemorrhagic shock syndrome (98). Immune complexes, with or without complement, localize antigens to FDCs and other FcR$^+$ CR$^+$ cells (99). Mϕ themselves are able to produce all components of the complement cascade in significant amounts at local sites, which may be less accessible to circulating proteins made by hepatocytes.

Nonopsonic receptors reacting directly with ligands on microorganisms (95) include CR3, lectins, especially the MR (26) and β-glucan receptor (27), the scavenger receptors SR-A (100) and MARCO, and the family of TLRs (19). MRs are present on Mϕ, DCs, and sinusoidal endothelium. They mediate phagocytosis and endocytosis, including macropinocytosis, and structurally resemble another multilectin, Dec 205, present on DCs as well as tissue Mϕ and epithelial cells in thymus; carbohydrate recognition by the latter has not been demonstrated (101). The MR has eight C-type lectin domains, homologous to the mannose-binding protein (MBP), a circulating hepatocyte-derived, acute-phase reactant. MBP, also known as mannose-binding lectin (MBL), contains a single lectin domain per polypeptide, which oligomerizes like other collectins to achieve multivalent interactions and activate complement via associated serine proteases. MR expression on Mϕ is selectively down- and upregulated by IFNγ and IL-4/13 (90,102), respectively. The possible role of the cysteine-rich domain in transport of immunogenic glycopeptides within secondary lymphoid organs has been noted.

The β-glucan receptor, previously reported as Dectin 1, is related to C-type lectins and is responsible for phagocytic recognition of unopsonized zymosan and for Mϕ activation (103). It contains an ITAM-like motif in its cytoplasmic domain that is essential for phagocytosis and induced secretory responses (e.g., TNFα). It cooperates with TLR2 and synergizes with other TLRs in cell activation.
FIGURE 18.5 Macrophage activation. Role of microbial stimuli and cytokines. See text for details.

It is essential for resistance to a range of fungal particles *in vivo*, as shown by studies with knockout mice (104). The SR-A mediates endocytosis of modified proteins (e.g., acetylated lipoproteins) and selected polyanions, such as LPS and lipoteichoic acid (LTA). In addition, it can serve as an adhesion molecule (56) and contributes to phagocytic clearance of apoptotic thymocytes (59) and gram-negative as well as gram-positive bacteria (105). MARCO, a related

TABLE 18.2 Toll-Like Receptors and Their Selected Ligands

Receptor	Ligands
TLR2/6 or unknown	Peptidoglycan (gram-positive), LPS (*Leptospira*, *Porphyromonas gingivalis*)
	Bacterial lipoprotein, lipoarabinomannan, zymosan, GPI anchor (*Trypanosoma cruzi*)
TLR3	Double-stranded RNA
TLR4	LPS (gram-negative), taxol (plant), F protein (respiratory syncytial virus), heat shock protein 60 (host), fibronectin fragments
TLR5	Flagellin
TLR9	CpG DNA

collagenous receptor, mediates cell adhesion and phagocytosis of bacteria but is independently regulated (106), as discussed later. The report of a phosphatidylserine (PS) receptor implicated in the recognition of novel lipid ligands expressed on the surface of apoptotic cells has not been confirmed (107). CD36 (thrombospondin receptor) (108), vitronectin receptors, CD91, and CD44 have all been implicated in the uptake of senescent PMNs by Mϕ. Other opsonins for apoptotic cell clearance include milk fat globule protein (lactadherin) (109). A role for Mϕ SR-A in immune induction has not been demonstrated, but studies in SR-A ko mice have revealed an important inhibitory role in limiting TNFα production by immunologically activated Mϕ (109a). Wild-type, BCG-primed mice produce granulomata rich in SR-A$^+$ Mϕ; SR-A ko mice restrict growth of this organism and form normal granulomata containing activated, MHC II$^+$ Mϕ; on additional challenge with LPS, the ko mice die approximately 10-fold more readily than wild-type animals. TNFα levels in the circulation rise markedly because of unopposed triggering via CD14, a receptor for the LPS-binding protein, and contribute to septic shock, because blocking anti-TNF mAb protects these mice (110).

The family of TLRs consists of homo- or heterodimeric transmembrane molecules related to the IL-1 receptor, which are involved in innate immunity to microbial

FIGURE 18.6 Phagocytic pathway in macrophages. **A:** Heterophagy. Fc receptor–mediated phagocytosis. (a) Microbes are coated with a variety of opsonins, including complement, pentraxin 3, and antibodies. A number of receptors are involved in initial recognition of microbes and induction of proinflammatory signaling (e.g., the Toll-like receptors [TLRs], and especially TLRs 2, 4, and 5), but these receptors are not phagocytic. Receptors involved in phagocytosis include the complement receptors, Fc receptors, and others. (b) Fc receptor ligation initiates a signaling cascade that results in actin polymerization and extension of the plasma membrane. Phagocytosis mediated by this method occurs via the "zipper" mechanism (i.e., sequential binding between the Fc receptors and their ligands along the length of the microbe). (c) Fusion with the early endosome results in a slight drop in pH that results in the uncoupling of receptors with their ligands. Receptor recycling is facilitated by the Rab proteins, which also confer the ability to undergo subsequent fusion. The developing phagosome now contains MHC class II and TLRs, including those that signal from within the developing endosome (e.g., TLR9). (d) Fusion with the late endosome results in the addition of the LAMP proteins, the accumulation of acid-resistant phospholipids, and a subsequent drop in pH. (e) On fusion with lysosomes the low pH results in the activation of a number of proteolytic enzymes. These are necessary for both direct antimicrobial activity and the creation of peptides for presentation via MHC class II. The phagolysosome is a highly oxidative environment, exposing the pathogen to destructive reactive oxygen and reactive nitrogen intermediates. (f) Under certain circumstances the phagosome may contain markers specific for the endoplasmic reticulum (ER). The ER may contribute directly to the creation of the phagocytic membrane in some circumstances (e.g., phagocytosis of latex beads), or ER-derived vacuoles may contribute MHC class I and other molecules to the endosomes or the developing phagolysosome. For further information see refs. 97, 121, 122, and 138. (*continued*)
FIGURE 18.6 (*CONTINUED*) **B:** The autophagy pathway. Autophagy is a homeostatic process that can be further enhanced in macrophages in the presence of interferons or by starvation. Cytosolic proteins and organelles are found in ER-derived cytoplasmic vesicles. These vesicles fuse with lysosomes, and the proteins and organelles are degraded and recycled. Conventional wisdom states that endogenous and cytoplasmic proteins are presented by MHC class I molecules, whereas exogenous peptides are presented by MHC class II molecules; however, it has become clear that peptide presentation is altered considerably on induction of autophagy. The presentation of peptides from intracellular and lysosomal source proteins is increased on MHC-II. For further information see refs. 139–141.

constituents and activation of Mφ responses (Table 18.2) (19,111–113). Downstream signaling depends on association with other soluble and membrane molecules, as well as with intracellular proteins. MyD88, for example, has been implicated in many but not all TLR-induced signaling resulting in transcription factor regulation, cell activation, or apoptosis.

Naturally occurring microbial ligands for these nonopsonic receptors are still poorly defined; individual receptors mediate microbial binding and uptake of microorganisms, although each contributes only part of total binding (Figure 18.6A) (105). Particle uptake involves the cytoskeleton, bulk membrane flow, and remodeling, as well as multiple plasma membrane receptors (97). Phagosome formation and maturation resemble endocytic uptake, initiating Mφ vesicle trafficking and recirculation, fusion with lysosomes, acidification, ion fluxes, and digestion. Table 18.3 lists immunologic and other markers used to identify intracellular compartments (114). GTP-binding proteins and complex signaling cascades play an important role in these dynamic events. A key issue that needs to be resolved is how cell and receptor functions are modulated so that microbial phagocytosis or invasion induces inflammatory responses, unlike the uptake of apoptotic cells (115). The MHC II biosynthesis and subcellular localization and proteolytic processing of peptide antigens in

▎**TABLE 18.3 Membrane or Content Markets Used to Identify Phagosomes as Resembling a Given Endocytic Compartment or the Endoplasmic Reticulum**

Compartment	Markers
Early endosome	Membrane markers: TfR, Rab5, annexins, I, II, and III
	Proteases: immature cathepsin D
Late endosome	Membrane markers: M6PR, Rab7, LAMP1, LAMP2, CD63, CD68
	Hydrolases: acid phosphatase, aryl sulfatase, trimetaphosphatase
	Proteases: cathepsin B, D, H, dipeptidyl peptidase I and II
	Phospholipid: LBPA
Lysosome	Membrane markers: LAMP1, LAMP2, CD63
	Hydrolases: acid phosphatase, aryl sulfatase, trimetaphosphatase
	Proteases: cathepsin B, D, H, dipeptidyl peptidase I and II
ER	Membrane markers: calnexin, calreticulin
	Enzyme: glucose-6-phosphatase

LAMP, lysosome-associated membrane protein; LBPA, lysobisphosphatidic acid; M6PR, mannose-6-phosphate receptor; TfR, transferrin receptor.

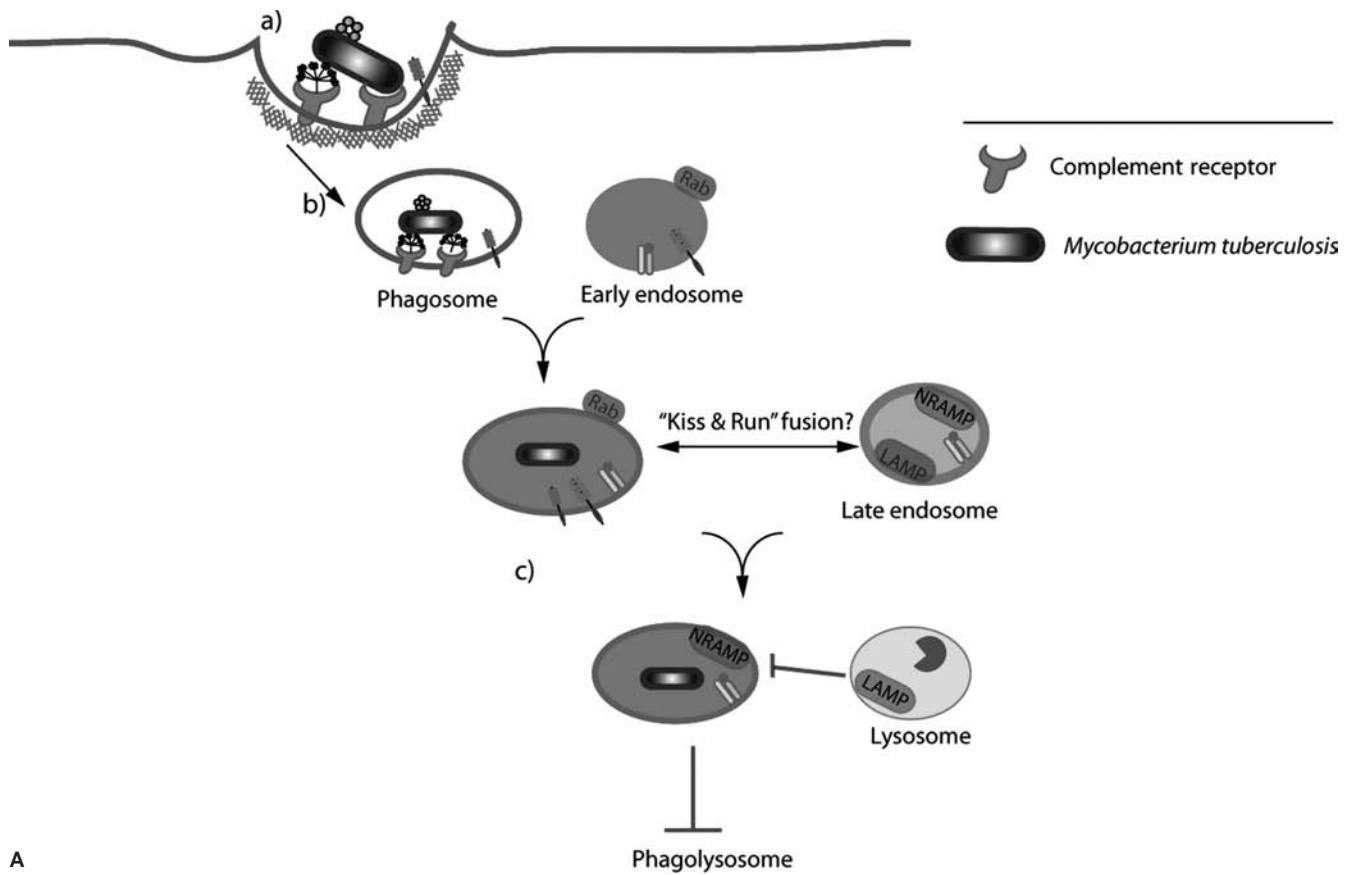

FIGURE 18.7 Interactions of selected intracellular pathogens with the phagocytic pathway. **A:** *Mycobacterium tuberculosis* evades destruction by subverting normal phagolysosome maturation. (a) Phagocytosis of *M. tuberculosis* occurs via the complement pathway (although it may not require direct binding of complement to the bacterium) and is characterized by (b) "sinking" phagocytosis (i.e., very little filopodia formation or actin polymerization). (c) The *M. tuberculosis*–containing vacuoles contain markers of the early and late endosomes such as Rab5 and Nramp1 but are devoid of most lysosomal markers, including the LAMP proteins, and do not undergo normal acidification. It has been proposed that the colocalization of some but not the normal allotment of endosomal markers can be explained by the concept of "Kiss & Run" fusion. This implies that the early and late endosomes may have transient contact with the *M. tuberculosis*–containing vacuoles, and there may be a selective transfer of markers rather than a complete fusion. The high pH of the *M. tuberculosis*–containing vacuole (pH 6.2) does not allow optimum loading of major histocompatibility complex class II molecules, and thus they remain loaded with nonmycobacterial peptides. Elevated pH also inhibits production of inducible nitric oxide synthase, which is required for killing. In the presence of interferon-γ (IFNγ), normal acidification may be restored, resulting in destruction of the pathogen (142). (*continued*)

vacuolar and cytosolic compartments of APC are discussed elsewhere in this volume. Cytokines, especially IL-4/13, IL-10, and IFNγ, influence endocytosis via MR-dependent and -independent pathways and selectively alter vesicle dynamics.

Pathogens vary in using Mϕ plasma membrane molecules for entry and modify the composition of the resultant phagosome membrane (Figure 18.7) (116). Mycobacteria, for example, employ a range of mechanisms to evade killing by Mϕ, including delayed maturation of phagosomes and inhibition of fusion with lysosomes and acidification (Figure 18.7A). *Listeria monocytogenes* es-

capes into the cytosol by disruption of the phagosome membrane, whereas *Leishmania* multiplies in phagolysosomes. Humoral (antibody, complement) and cellular (γ-interferon) mechanisms overcome parasitization of Mϕ by diversion to lysosomes or induce killing via O/N-dependent and other mechanisms.

Entry of microbial constituents such as muramyldipeptide from vacuolar compartments to the cytosol can result in sensing by NOD-like receptors (NLRs), inflammasome assembly, activation of caspase-1, and processing and release of IL-1β (117). Nucleic acid recognition results in cytoplasmic and mitochondrial-associated protein signaling
FIGURE 18.7 (*CONTINUED*) **B:** *Mycobacterium tuberculosis*–containing phagosomes are targeted to the autophagy pathway on treatment with IFNγ. IFNγ treatment can both restore the normal process of acidification and alter the expression of a number of endoplasmic reticulum proteins, the result of which is the targeting of *M. tuberculosis*–containing phagosomes to the autophagosomes. The fusion between the *M. tuberculosis*–containing phagosomes and lysosomes results in an autolysosome with low pH that destroys *M. tuberculosis* and results in *M. tuberculosis* peptides being presented via MHC class II (143).

responsible for type 1 interferon gene expression (118). It has recently become clear that induction of autophagy and apoptosis by intracellular pathogens, including *Mycobacterium tuberculosis*, provides important host-protective responses (119,120) (Figures 18.6B, 18.7A, B).

Although the "canonical" entry pathway described here and illustrated in Figure 18.6A is used and modified by many pathogens, recent evidence has shown that organisms such as *Legionella pneumophila* (Figure 18.7C, D) and *Brucella abortus* induce vacuoles with novel membrane components or colonize compartments derived from the Golgi apparatus and the endoplasmic reticulum (121). The relative contributions of plasma membrane and endoplasmic reticulum (Figure 18.6A) to vacuole formation can thus vary considerably, depending on the nature of the phagocytic cargo or invading pathogen (122–124). Opsonins such as antibody are able to divert the cargo to lysosomes. Interferon-γ can induce GTP-binding proteins that associate with vacuoles inhabited by a range of intracellular pathogens (e.g., *Toxoplasma gondii*), thus marking them for destruction within the macrophage (125).

Clearance of proteinase–inhibitor complexes (e.g., by CD91) and of haptoglobin–hemoglobin complexes by the Mϕ-receptor CD163 are essential homeostatic functions of tissue Mϕ, limiting potentially injurious extracellular molecules (126).

Major unsolved questions remain concerning phagocytosis, intracellular infection, and immune responses. How do particulate antigens and microbial agents induce T cell responses, and what are the relative contributions to this process of Mϕ and DCs, abundant and sparser professional phagocytes, respectively; what is the role of the receptors mediating entry in subsequent adaptive immunity? Does TLR engagement within vacuoles determine the kinetics of phagosome maturation as well as induce local intracellular responses? What determines the balance between total antigen degradation and loading of MHC molecules; what interactions take place between intracellular pathogens and host Mϕ, especially in regard to nutritional requirements of the organism; what is the role of pathogen-derived secretory products in the vacuolar milieu, in recruitment of organelles such as endoplasmic reticulum and mitochondria, and in effects on host cell biosynthesis; what are the intracellular killing mechanisms, and how can organisms survive, or become latent, within Mϕ? Finally what receptor-mediated signals induce the secretion of Mϕ molecules such as IL-12 and IL-23 that direct the resultant specific immune response?
FIGURE 18.7 (*CONTINUED*) **C:** *Legionella pneumophila* survives intracellularly by subverting phagosome maturation at an early stage. (a) The recognition and uptake of *L. pneumophila* are not well characterized, but phagocysis occurs via a "spiral" mechanism. (b) Once inside the cell, *L. pneumophila* uses a specialized secretion system (i.e., Dot/Icm secretion system) to secrete proteins directly into the cytosol. These proteins alter the morphology of the vacuole in a number of ways, for example, by actively recruiting vesicles in transit from the ER to the Golgi apparatus and inhibiting the fusion of lysosomes. (c) The *L. pneumophila*–containing vacuole thus has many similarities to the Golgi apparatus and ER and is rich in peptides, the primary carbon source for *L. pneumophila*. (*continued*)

Gene Expression and Secretion

Knowledge of Mφ gene expression and protein synthesis is growing rapidly from the application of gene array and proteomic technologies (e.g., 127,128). After surface and endocytic stimulation the mature Mφ is able to secrete a very large range of high– and low–molecular weight products. These include enzymes involved in antimicrobial resistance (lysozyme), neutral proteinases and arachidonate metabolites that contribute to inflammation and tissue repair, cytokines such as IL-1 and TNFα that modulate the activities of other leukocytes and endothelium, and reactive oxygen and nitrogen intermediates implicated in host defense (129). Proinflammatory cytokines account for part of the effects of immune adjuvants in promoting, broadening, and sustaining humoral responses. The ability to release these products depends on the prior history of the Mφ—whether resident, recruited, or activated (primed), its encounters with microbial wall products, including LPS acting via TLR, or with apoptotic cells, and exposure to cytokines and other immunomodulatory molecules in its immediate environment. Ligation of specific receptors induces various signaling pathways and is able to alter gene expression in the Mφ selectively. Transcription factors such as the NF-κB, Pu-1, and interferon regulatory factor families contribute to Mφ-restricted or activation-dependent changes in gene expression. Product expression depends further on translational regulation, posttranslational modification such as proteolytic processing, intracellularly or at the cell surface, and coexpression of inhibitors such as IL-10. mRNA turnover varies greatly for different products due to the presence or absence of specific 3′ instability sequences. Many Mφ products are labile and act close to the cell surface; overproduction results in tissue catabolism and systemic effects associated with widespread infection or chronic inflammation, often as a result of an immunologically driven disease process.

Whereas most bioactivities have been defined *in vitro*, there is evidence that expression of Mφ secretory activities may be quite different *in situ*; lysozyme production is characteristic of all Mφ in culture but is downregulated on most resident cells *in vivo*, and its expression by
FIGURE 18.7 (*CONTINUED*) **D:** Macrophages enhance autophagy in response to *Legionella pneumophila*. A consequence of residing in a vacuole that so closely resembles the ER is that it is subject to autophagy. *L. pneumophila*–containing phagosomes fuse with lysosomes, resulting in destruction of the pathogen and antigen presentation. Factors secreted from *L. pneumophila* cause macrophages to increase the number of autophagosomes, although autophagosomes containing *L. pneumophila* mature more slowly, and thus it is believed that the bacteria encode factors to delay normal progression. For more information see ref. 144.

granuloma Mϕ, for example, depends on induction by immune or phagocytic stimuli (28). 5′ promoter sequences of human lysozyme (130) and CD68 (131) transgenes have been used to target tissue- and Mϕ activation-specific expression of reporter molecules *in vivo*. The promoters of these and other Mϕ-restricted molecules may, in due course, make it possible to direct Mϕ biosynthetic activities precisely, to boost or inhibit immune responses.

Modulation of Macrophage Activation *in vitro*

Our understanding of Mϕ activation derives from studies of induction of MHC II and costimulatory antigens of effector functions such as proteinase, TNFα, reactive oxygen intermediate and reactive nitrogen intermediate release, expression of membrane receptors such as MRs, and resistance to infectious agents, for example, *Mycobacteria*, *Listeria*, *Candida*, and HIV. Generalizations can be made, but it must be remembered that organisms vary considerably in their ability to evade or survive Mϕ restriction mechanisms, and they interact with Mϕ in individual ways. Various inhibitory cell surface molecules (e.g., CD200 and SIRPα) (132) are known to regulate Mϕ activation through interactions with other activating plasma membrane receptors. Receptors including FcRγ (23) and C-type lectins

(133) use paired ITAM and ITIM intracellular signaling motifs.

Figure 18.4 and Table 18.4 illustrate various pathways and markers of Mϕ activation that result from microbial, cellular, and cytokine interactions. Knowledge is based mainly on *in vitro* experiments and *in vivo* challenge of selected animal models. Innate activation depends on direct stimulation by microbial products, independent of cytokines, although often enhanced by concomitant stimulation (e.g., by IFNγ). Newly discovered markers of innate activation of mouse peritoneal macrophages include upregulation of MARCO, a type A SR, via a TLR pathway, and of CD200, a more widely expressed IgSF membrane glycoprotein. Induction of MARCO, a phagocytic receptor for a range of bacteria, represents an adaptive innate immune response to microbial contact (106). Analysis of the actions of individual cytokines (IFNγ, IL-10, IL-4/13) on defined Mϕ targets (murine peritoneal Mϕ and human monocyte–derived Mϕ) reveals three characteristic and distinctive *in vitro* phenotypes across a spectrum of activation. IFNγ and its production and amplification via IL-12, IL-23, or IL-18 play a central role in MHC II induction, enhanced antimicrobial resistance, and proinflammatory cytokine production, characteristic of Th1-type responses; conversely, IL-10 suppresses markers of activation while inducing selective expression of other Mϕ genes. A

▶ **TABLE 18.4 Modulation of Macrophage Phenotype**

Category	Stimulus	Selected Marker Changes	Function
Innate activation	Microbial products (e.g., LPS, other TLR ligands)	Costimulatory molecule expression, MARCO upregulation	Phagocytosis
Classic activation	Interferon γ	MHC II upregulation, proinflammatory cytokine secretion, inducible NO synthase	Adaptive immunity, Cell-mediated immunity, e.g., intracellular pathogens
Alternative activation	IL-4/IL-13	Upregulation of MHC II, arginase, mannose receptor, Ym1, FIZZ1 (resistin-like), production of selected chemokines, macrophage fusion	Parasitic and allergic immunity, repair
Innate and acquired deactivation	Apoptotic cells, IL-10, glucocorticoids, TGFβ, PGE2	Various surface and secretory markers, e.g., anti-TNFα actions	Antiinflammatory and altered immunity

IL, interleukin; LPS, lipopolysaccharide; MHC, major histocompatibility complex; NO, nitric oxide; PGE2, prostaglandin E2; TGFβ, transforming growth factor-β; TLR, Toll-like receptor; TNFα, tumor necrosis factor-α.

comparable link between Mϕ/APC and the induction of Th2-type responses has proved elusive to identify. IL-4/IL-13 have closely overlapping functions and induce an alternative activation phenotype in Mϕ consistent with increased APC function and humoral responses in allergy and parasitic infection as well as giant cell formation (Table 18.3) (134). It is important to distinguish modulation of Mϕ immunologic properties by IL-4/IL-13 from marked deactivation and inhibition of proinflammatory and cytotoxic functions by IL-10 and glucocorticosteroid (92). Immune complexes are also able to induce an analogous alternative activation pathway, which overlaps with but differs from IL-4/IL-13– and IL-10–induced phenotypes. By extension, M-CSF, glucocorticosteroids, TGF-β, and type I IFN all modulate Mϕ gene expression with individual signatures.

The interplay of cytokines derived from Mϕ themselves, from activated T and B lymphocytes, and from other cells (NK, endothelial cells) results in reciprocal positive or negative interactions and time-dependent changes in activating and inhibitory signals. Some predictions from *in vitro* studies can be extended to the intact host. For example, IFNγ, IL-12, and IL-23 deficiency results in inability to restrict opportunistic organisms in murine models and in humans, and i-NOS is important for resistance to a range of infectious agents. IL-10 deficiency, on the other hand, results in overactive Th1-dependent inflammation, for example, in gut (135). IL-4 deficiency by itself has little effect on Mϕ phenotype *in vivo* because IL-13 mimics many of its actions. These cytokines share a common receptor subunit, and its targeted genetic ablation makes it possible to study Mϕ that lack the ability to respond to both IL-4 and IL-13 (32).

The foregoing analysis is oversimplified. Combinations of cytokines *in vitro* have different effects on Mϕ than the sum of the parts. For example, the combination of IL-4 and GM-CSF induces differentiation of human monocytes into immature DCs, whereas each alone induces cells with distinctive Mϕ properties. Furthermore, a particular "Th2-type" cytokine such as IL-10 can display radically different effects on antimicrobial (i-NOS dependent) killing, which is markedly suppressed, and anti-HIV activities of Mϕ, which are enhanced (136). Whereas IFNγ and IL-4 may have opposing actions on MR expression and phagocytosis of yeasts, in combination they synergize to enhance uptake markedly. Other combinations of cytokines, such as IFN$\alpha\beta$ and IFNγ, can antagonize each other, presumably by competition for signaling pathways. Although extrapolations with predictive value can be made in some situations, a great deal remains to be learned about Mϕ behavior in complex immune environments *in vivo*.

CONCLUSIONS AND SOME REMAINING ISSUES

Mϕ influence and respond to all other cells involved in immunity, during both the afferent and efferent limbs. Many of the molecules that mediate particular functions are now defined, but their role within the Mϕ and in intercellular interactions is often poorly understood. Mϕ developed during the evolution of multicellular organisms before immunologically specific, clonotypic responses of B and T lymphocytes emerged. Mϕ themselves diversified in parallel with T helper lymphocytes, generating DCs as specialized APCs for naïve T lymphocytes and yielding a range of effector cell phenotypes in response to diverse activated T cells, both CD4$^+$ and CD8$^+$. Mϕ and their derivatives cluster with differentiating hemopoietic cells in fetal liver and bone marrow, with developing thymocytes, with naïve CD4$^+$ T lymphocytes and antigen during immune induction, and with activated T cells and microbial pathogens in granuloma formation (Figure 18.2). In addition, they associate with antigen-stimulated B lymphocytes during cell expansion, diversification, and apoptosis. A major challenge will be to define the role of specific and accessory

surface molecules by which Mφ discriminate between live and dying cells and to uncover the intrinsic and extrinsic factors that control Mφ activities within these diverse immune cell interactions.

Our understanding of the multiple roles of Mφ and DCs in immunoregulation is also evolving as we better appreciate their specializations and adaptations. Central issues in the immunobiology of Mφ remain obscure and interesting topics for further investigation. These include the following.

Mφ display broad functions in homeostasis, beyond host defense and immunity, which may be special instances of a more general role in preserving host integrity, comparable to that of the central nervous and endocrine systems. Their dispersion, plasticity, and responsiveness raise obvious questions for the biologist. In particular, what are their roles in development and in trophic interactions within different organs?

The Mφ lies at the heart of the classic immunologic question of recognition of altered or non-self, especially of particulates. What are the actual ligands recognized by the diverse range of plasma membrane receptors capable of direct discrimination, and what determines whether uptake of a target is immunologically silent or productive? How can this information be harnessed for vaccine development?

The delineation of further subsets of CD4+ T lymphocytes (TH17, regulatory T cells) suggests that it will be useful to define the effects on the Mφ phenotype of contact- and cytokine-dependent interactions with these cells. It is likely that further distinctive type 2 activation pathways of Mφ will be discovered by microarray and protein analysis.

Once activated, Mφ change their ability to recognize and destroy targets, directly or in concert with antibody, complement, and other less-defined opsonins. Can Mφ directly kill virus-infected and other immunologically activated cells? If so, do they use MHC matching, even in a limited way, and do they contribute to tolerance and, by implication, autoimmunity by failure to perform such a suppressive function?

A special case in which Mφ are present in large numbers at a site of "failure" to respond immunologically is the fetoplacental unit. CSF-1 is produced locally at high levels; does this deactivate Mφ or make them switch to perform a trophic role? Do tumors that are rich in Mφ adopt a similar strategy? Catabolism of tryptophan by Mφ enzymes has been put forward as another mechanism for preventing local destruction of an allogeneic fetus (137).

Although Mφ express a large number of genes involved in household functions and share expression of others with a limited range of cell types, they also express highly restricted molecules responsible for unique functions. Can these be harnessed for Mφ-specific gene targeting at selected microanatomic sites to deliver functionally precise signals at predetermined times? Techniques are becoming available for at least part of this fantasy, and they should provide new insights into the multiple roles of the Mφ an immunity.

Major Histocompatibility Complex (MHC) Molecules: Structure, Function, and Genetics

David H. Margulies, Kannan Natarajan, Jamie Rossjohn, and James McCluskey

INTRODUCTION

Not only because of their profound immunologic importance as cell surface receptors that mediate recognition of infected, tumor, or foreign cells by T lymphocytes, but also because they are encoded by the immunoregulatory genes identified first, the set of molecules commonly referred to as the major histocompatibility complex or MHC molecules is central to understanding both the phenomenon and mechanism of immune recognition. The sophistication of our knowledge of MHC molecules and their function reflects the steady improvement of our understanding of the details of molecular mechanism and also outlines a conceptual framework for appreciating the elegance of nature's solutions to complicated cellular and ultimately molecular problems. MHC molecules play a crucial role in defense of the host against bacterial and viral pathogens and recognition of tumors. Our approach in this chapter will be first to give a cursory view of function and then to explore the structural solutions to functional requirements posed by the complexities of immune recognition. We will consider key features of the molecular skeletons, subunit organization, and surface shape and charge of representative members of the MHC family and correlate these structures with their known functions. We will progress to a more critical investigation of the role of these molecules with respect to their cellular biosynthesis and assembly, and their contribution to immunologic cell communication. We will continue with a status report on the genetics of MHC molecules, focused on both mouse and human, and will conclude with a contemporary view of the evolution of this broad gene family. Speculation on the coevolution of these molecules with their host ligands as well as viral homologs will finish the

chapter, providing the reader with a factual and conceptual foundation with which to address current literature. Along the way, important structural and functional aspects of MHC molecules as they relate to human disease will be discussed. The story of MHC molecules is incomplete, not only because our database is incomplete, but also because the pathogens and tumors with which both the adaptive and innate immune systems wrestle continue to change. Like human families, the MHC gene family expands, contracts, and adapts to changing environments and to emerging requirements and opportunities.

We cannot, in the allotted space, provide a complete historical background and the didactic aspects of mouse genetics offered in earlier editions of this book. We can only strongly suggest that the student explore the important history of the development of inbred mouse strains and the contemporary view of detailed genetic analysis that has been previously summarized elsewhere. The power of Internet Web sites for seeking some of this information should not be overlooked, but we raise a necessary note of caution because such sources of information may not be expertly curated and may be erroneous or inaccurate.

The molecular focus of the immune system consists of MHC molecules—those cell surface receptors that govern, by interaction with membrane-expressed molecules on crucial cells of the innate and adaptive immune systems, the initiation, perpetuation, and regulation of cellular activation in response to infection and neoplasia. MHC molecules are not static surface receptors that merely bind another set of receptors to indicate their presence and number, but are structurally and conformationally dynamic—they modulate their structure by incorporating peptides derived from degraded self- and foreign proteins expressed in the same cell; and they sense the presence of proteins from viruses and other cellular pathogens that affect the nature or efficiency of the MHC molecules' cell surface expression. Molecules encoded by the major histocompatibility complex (*Mhc*) represent a microcosm of complex molecular, cellular, and organismic biology. Members of the family of *Mhc*-encoded molecules interact extensively with a number of other molecules, during both their biosynthesis and intracellular trafficking. When poised at the cell surface as ligands for specific molecules on T cells and natural killer (NK) cells, they control the response of these immunoeffectors. MHC genes have also been purloined by some viruses that have exploited these to encode immunoevasins—molecules that either counter-regulate host MHC expression or that deceptively bind NK receptors to allow viral escape from the immune response. Understanding the MHC molecules in detail, then, provides a foundation for comprehending the layers of complex regulation to which the immune system is servant. The genetics of the *Mhc* offers a groundwork for understanding immunologic selection, and also reveals living footprints of molecular genetic evolution.

Although an earlier view was that the *Mhc*-encoded molecules were uniquely involved as recognition elements for T cells, it is now overwhelmingly clear that MHC molecules interact with receptors on NK cells as well. As the strict definitions of MHC molecules based purely on the location of their encoding genetic loci have given way to looser groupings based on similarities of the protein structures or on functional relationships, we now appreciate that a larger family of genes, molecules, and functions should be included in this chapter. The *Mhc* provides a genetic link from immune responsiveness to autoimmune disease—those well-known strong associations of particular *Mhc* genes with particular human diseases, and we will outline the molecular basis for some such associations.

The *Mhc* is a set of linked genes, located on chromosome 6 of the human, chromosome 17 of the mouse, chromosome 20 of the rat, and cluster I of the chicken, that was first identified by its effects on tumor or skin transplantation and control of immune responsiveness (1,2,3). More recently, in part because of evolutionary interest and in part because of the importance of *Mhc* loci in species that serve as models for human disease, particularly human immunovirus (HIV) infection, extensive information has been gathered on the *Mhc* genes of several primate species (4). The *Mhc* also plays a role in resistance to infection. Early observations indicated an *Mhc*-linked control of immune responsiveness (5–8,9) and have culminated in a molecular understanding of the critical details of genetically encoded cellular recognition in the immune system. The control of transplantation and the immune response are the phenotypic consequences of the function of molecules encoded in the *Mhc*. Therefore, we gain a deeper understanding of the *Mhc* as we explore it in molecular and cellular terms. MHC molecules are cell surface receptors that bind antigen fragments and display them to various cells of the immune system, T cells that bear $\alpha\beta$ receptors (10,11,12), NK cells (13–15), T cells that express $\gamma\delta$ receptors (16), and NKT cells (17–19,20). Molecules that are structurally similar to MHC-I molecules but are encoded beyond the strict genetic bounds of the *Mhc*, and in some cases lacking the full complement of MHC-I domains, are now known to be expressed on particular subsets of somatic cells, some tumors, and cells of the placenta. Thus, we have witnessed a transition in knowledge from that of mysterious genetic entities with ill-defined mechanisms but distinct immunologic functions and genetic locations to a biochemical understanding of specific molecules with known structures, biosynthetic pathways, biophysical parameters of interaction, and temporal expression that convey specific signals between and within cells, and that map precisely to defined regions of the chromosome. The study

of the *Mhc* has also made a transition, from that of genetics and cellular immunology to detailed molecular mechanisms.

The focus of this chapter is the *Mhc*, and our primary goal will be to outline the general principles of molecular organization and function both of the genetic regions that encode MHC molecules as well as of the functional cell surface molecules themselves. Human disease associations, molecular typing of MHC molecules and *Mhc* genes, and relevant functional polymorphisms will complete our explication of these markers of immunologic function.

A Note on Nomenclature

Students have frequently been confused by *Mhc* nomenclature. Like language, nomenclature evolves, and our attempts at standardization are inevitably only partially successful. Current usage differs from species to species, journal to journal, and writer to writer, although there are standards of which the informed scientist should be aware. For the mouse and rat *Mhc*, these have been set down by an international committee and are available at the Jackson Laboratory home page (www.informatics.jax.org/mgihome/nomen). For the human *Mhc*, there is a standard World Health Organization (WHO) nomenclature that is periodically evaluated and revised (17). By convention, genes or genetic loci are indicated in italics and the encoded protein products or phenotypic descriptions are shown in a standard font. For the genes of the human *Mhc* this convention is often overlooked, whereas for those of the mouse and other species it is frequently followed. The mouse *Mhc* is referred to as *H2* because it was the second genetic locus involved in control of expression of erythrocyte antigens to be identified by Gorer (18,19). Now, the *Mhc* is known to consist of many loci, and the extended genetic region is referred to as the complex; thus, the general term used for all species is the *Mhc* or *MHC*. The *Mhc* in the rat is known as *RT1*, the human locus is known as *HLA* (for Human Leucocyte Antigen). *DLA* for the dog, *GPLA* for the guinea pig, *SLA* for the swine, and *RLA* for the rabbit are the common usages. For other species, the taxonomic name forms the basis for the designation, contributing the first two letters of the genus and the first two of the species to name the locus. Thus we have *Patr* for the chimpanzee, *Pan troglodytes, Gogo* for the gorilla, *Gorilla gorilla, Mamu* for the Rhesus macaque, *Macacca mulatta,* and *Papa* for the Bonobo, *Pan paniscus.*

We now know of over 400 genes that map to the human or mouse *Mhc*, and though technically they are all "*Mhc*" genes, the "MHC" molecules refer specifically to the MHC class I (MHC-I) or MHC class II (MHC-II) molecules that are related in structure and function. Other *Mhc*-encoded molecules with distinct structure and function are referred to by their more specific names.

Particular *Mhc* genes are designated by a letter (or letters) for the locus (e.g., *H2K, H2D, H2L, H2IA*, in the mouse; and *HLA-A, HLA-B, HLA-C, HLA-E, HLA-F, HLA-G, HLA-H, HLA-J, HLA-K, HLA-L, HLA-DR, HLA-DQ, HLA-DO*, and *HLA-DP* in the human). *HLA-H, -J*, *-K*, and *-L* are pseudogenes. Allelic genes (and their expressed cell surface protein products) have been denoted in the mouse by the addition of a superscript (e.g., $H2K^b$ and $H2K^d$ are distinct alleles at the same locus). In the human, a letter and a number distinguish serologically defined MHC allotypes (*HLA-A2* and *HLA-A3* are allotypes of *HLA-A*; whereas *HLA-B8* and *HLA-B27* are allotypes of *HLA-B*). Precise designation of human genes uses a nomenclature including a four-digit (or longer) number following the locus (e.g., HLA-A*0101 and HLA-A*0201 are alleles of *HLA-A*; see Table 19.1 for clarification of the nomenclature of the HLA alleles). Clarity in understanding the human designations requires a conversion table to align the older allotype nomenclature based on definition of gene products by serology (often encompassing families of allelic gene products) with the more recent one based on DNA typing (Tables 19.2, 19.3).

For the *Mhc* class II genes, the designation in the human is *HLA-D* (including *-DM, -DO, -DP, -DQ*, and *-DR*), whereas in the mouse *H2-IAa, H2-IAb, H2-IEa*, and *H2-IEb* are used, frequently shortened to *IAa, IAb, IEa*, and *IEb*, respectively. *a* and *b* refer to the *a-* or *α-* (alpha) and *b-* or *β-*) chain encoding genes, respectively. Current usage tends to employ the Roman letter for the gene designation and the Greek for the encoded protein chain. The MHC-II molecules are often referred to as IA or IE with a superscript denoting the haplotype (i.e., IA[b], IA[d], or IE[d]). Several murine MHC-II–like genes, originally named *H2-Ma*, *H2-Mb1*, and *H2-Mb2*, which are homologs of the human *HLA-DMA* and *HLA-DMB* genes, are now called *H2-DMA*, *H2-DMB1*, and *H2-DMB2* in an effort to emphasize their structural and functional similarity to the human *HLA-DMA* and *-DMB* genes, as well as to distinguish them from the *H2-M* genes that lie most distal on chromosome 17 (*20*). Another complication that demands the precise use of gene and encoded protein names is that the number of genes in a particular homologous genetic region can differ between strains or between individuals. In the mouse, whereas some strains have only a single gene at the MHC-I *H2-D* locus (*H2-D*[b], for instance), other strains may have as many as five genes in the homologous regions (*H2-D*[d], *H2-D2*[d], *H2-D3*[d], *H2-D4*[d], and *H2-L*[d] (*21*).

An important description commonly used is "haplotype," which refers to the linked constellation of particular alleles at distinct loci that occur as a group on a parental chromosome (*22*). The concept of haplotype is important in typing the *HLA* loci in the human, where the linked *Mhc* genes of one chromosome of one parent will generally segregate as a linkage group to the children. When alleles at linked loci segregate more commonly together than

▶ **TABLE 19.1 Nomenclature of HLA Loci and Alleles[a]**

Nomenclature	Definition
HLA	The HLA (human leukocyte antigen) region and prefix for an HLA gene
HLA-DRB1	A particular HLA locus, i.e., DRB1
HLA-DRB1*13	A group of alleles that encode the DR13 antigen defined serologically by microlympho-cytotoxicity or by mixed lymphocyte reactivity (MLR)
HLA-DRB1*1301	A specific HLA allele
HLA-DRB1*1301N	A null allele (i.e., nonexpressed)
HLA-DRB1*130102	An allele that differs by a synonymous mutation (i.e., identical amino acid encoded by a different codon)
HLA-DRB1*13010102	An allele that contains a mutation outside the coding region
HLA-A*2409N	A null allele
HLA-A*3014L	An allele encoding a protein with significantly reduced or "low" cell surface expression
HLA-A*24020102L	An allele encoding a protein with significantly reduced or "low" cell surface expression, where the mutation is found outside the coding region
HLA-B*44020102S	An allele encoding a protein that is expressed as a "secreted" molecule only
HLA-A*3211Q	An allele that has a mutation that has previously been shown to have a significant effect on cell surface expression, but for which this has not been confirmed and its expression remains "questionable"

[a] In addition to the unique allele number, there are additional optional suffixes that may be added to an allele to indicate its expression status. Alleles that have been shown not to be expressed, "null" alleles, have been given the suffix "N." Those alleles that have been shown to be alternatively expressed may have the suffix "L," "S," "C," "A," or "Q." The suffix "L" is used to indicate an allele that has been shown to have "low" cell surface expression when compared to normal levels. The "S" suffix is used to denote an allele specifying a protein that is expressed as a soluble "secreted" molecule but is not present on the cell surface. A "C" suffix indicates an allele product that is present in the "cytoplasm" but not on the cell surface. An "A" suffix indicates "aberrant" expression, where there is some doubt as to whether a protein is expressed. A "Q" suffix is used when the expression of an allele is "questionable," given that the mutation seen in the allele has previously been shown to affect normal expression levels.

predicted by chance, this is called linkage disequilibrium, a phenomenon that leads to the presence of well-recognized MHC haplotypes in unrelated individuals. Individual haplotypes of the *Mhc* in the mouse are referred to by a lowercase letter superscript *as $H2^b$, $H2^d$*, or *$H2^k$*. Thus, the $H2^k$ haplotype refers to the full set of linked genes, *$H2$-K^k, $H2$-IA^k, $H2$-IE^k, $H2$-D^k*, and extends to the genes of the Q and T regions as well (23,24). (Some haplotype designations, such as *$H2^a$*, refer to natural recombinants and thus have some of the linked genes from one haplotype and some from another). Table 19.4 summarizes the haplotypes of common mouse strains.

In parallel with the genetic nomenclature system, a system has developed that focuses on the expressed proteins rather than on the genes, and by its use emphasizes both structural and functional differences. The main distinction of MHC molecules is between the MHC class I (MHC-I) and MHC class II (MHC-II) molecules. (MHC class III molecules have also been included in a group originally characterized as serum molecules involved in the complement system (C4/C2/Bf) but now also include products of the genetically linked loci mapping between the class I and class II regions of the *Mhc*). MHC-I molecules all consist of a heavy chain (also called an α chain), which is noncovalently assembled with a monomorphic (genetically invari-

ant, or almost so) light chain known as β2-microglobulin (β2m), encoded by the *B2m* gene. MHC-I molecules are subclassified into the MHC class Ia and MHC class Ib groups, distinctions made based on amino acid sequence differences as well as gene location (25,26). Recently, genes of members of the herpesvirus families have been shown to encode proteins that are structurally related to MHC-I molecules and are designated "MHC-Iv," as virus-encoded molecules (27). MHC-II molecules are heterodimeric, consisting of noncovalently assembled α and β chains. The bulk of the serologically defined differences in HLA-DR molecules reside in the β chain. The heterodimers usually consist of the assembled products of the linked genes encoding the two chains. In the mouse the products of the *IAa* (also known as *IAα*) and *IAb* (or *IAβ* genes) assemble to form the IA heterodimer, and similarly, the products of the *IEa* (*IEα*) and *IEb* (*IEβ* genes assemble to form IE. IA and IE are often referred to as "isotypes." The allelic forms are usually referred to as *IA^b, IA^d*, or *IA^k*. Under some circumstances, mixed heterodimers, which may be of immunologic importance, are observed (28–33). Thus, when one refers to a mixed heterodimer consisting of the α chain of IE^d and the β chain of IA^d, one must use the more precise but cumbersome description IAβ^dEα^d (IAb^{d}Ea^d). In the human, particularly in referring to MHC-II molecules,

[a]This table summarizes the designations of the human MHC-I HLA gene products as they are known based on serology, and as they have been assigned by nucleotide (and thus inferred amino acid) sequences. Current serologic designations are given in the "Serology" column, with older (broader) serologic assignments listed in parentheses. Serologic assignments are usually based on reactivity with alloantisera in a microlymphocytotoxicty assay. Some of the most recently identified HLA polymorphisms and products of nonclassical loci (e.g., HLA-E and HLA-G) have no historical serologic designation. Note that the serologically defined HLA B15 antigen comprises some 128 allelic members (B*1501–1599 and B*9501–9529), and HLA A2 comprises 115 members (A*0201–0299 and A*9201–9216) as of April 2007. The table is based on a listing of alleles maintained by the WHO Nomenclature Committee for Factors of the HLA System. All new and confirmatory sequences are generally submitted directly to the committee via the IMGT/HLA Database using the sequence submission tool provided. The IMGT/HLA Database may be accessed via the World Wide Web at: www.ebi.ac.uk/imgt/hla.

DRB9	DRB9*0101						

[a]The table is based on a listing of alleles maintained by the WHO Nomenclature Committee for Factors of the HLA System as of April 2007. All new and confirmatory sequences are generally submitted directly to the committee via the IMGT/HLA Database using the sequence submission tool provided. The IMGT/HLA Database may be accessed at www.ebi.ac.uk/imgt/hla. Note that the serologic assignments of HLA class II molecules do not always correlate with the DNA nomenclature. This is particularly true for some of the DRB1*11/12/13/14 alleles. Serological assignment of HLA-DR molecules is largely determined by the DRB1 gene product, whereas assignment of DQ molecules reflects serologic contributions from both DQA1 and DQB1 gene products. As new alleles of DR and DQ have been identified, original assignments have been "split," and these relationships are indicated in brackets. Thus DR15 and DR16 are splits of DR2, DR11 and DR12 are splits of DR5, and DQ3 includes the serologically determined DQ7, DQ8, and DQ9 antigens. The "w" designations (for HLA-C and HLA-DP) are "workshop" assignments because serologic and cellular assignments are sometimes imprecise. The DPw cellular assignments (e.g., DPw1, etc) generally, but not always, correlate with the same numbers used for allele assignments (e.g., DPB1*0101). Some null alleles and alleles with synonymous mutations are omitted. In addition to those serologic designations listed in the table, Bw4 and Bw6 specificities group the following: Bw4: B5, B5102, B5103, B13, B17, B27, B37, B38(16), B44(12), B47, B49(21), B51(5), B52(5), B53, B57(17),B58(17), B59, B63(15), B77(15), and A9, A23(9), A24(9), A2403, A25(10), A32(19); Bw6: B7, B703, B8, B14, B18, B22, B2708, B35, B39(16), B3901, B3902, B40, B4005, B41, B42, B45(12), B46, B48, B50(21), B54(22), B55(22), B56(22), B60(40), B61(40), B62(15), B64(14), B65(14), B67, B70, B71(70), B72(70), B73, B75(15), B76(15), B78, B81 (www.anthonynolan.org.uk/HIG/data.html).

the distinctions between molecules identified by antibodies and those identified by DNA sequence typing must be made (Tables 19.2, 19.3).

The Immunologic Functions of MHC Molecules

MHC molecules are a molecular reflection of the health of either the cell that synthesizes them (for MHC-I molecules) or of the local environment in which the cell resides (for MHC-II). The structure of the MHC molecule reflects not only the amino acid sequence of the two polypeptide chains (α and β for MHC-II; and heavy [or α] and β2m for MHC-I) that form the bulk of the complex, but also of a variable bound peptide (generally from 8 to 15 amino acids in length) that forms an integral part of the trimer. The MHC molecule, governed by the sequence of the encoding structural genes for *Mhc-I* heavy chain and the *Mhc-II*

α and β chains, as well as other genes involved in antigen processing and presentation that map to the *Mhc*, must satisfy at least two distinct recognition functions: the binding of peptides or in some cases nonpeptidic molecules, and the interaction with either T or NK cells via their respective receptors. The T-cell receptor (TCR) may augment its interaction with the MHC molecule by virtue of interaction of a T-cell–expressed coreceptor (CD8 for MHC-I and CD4 for MHC-II). Evidence now suggests that some NK receptors, when expressed on T cells, may also serve as coreceptors (*34*). The binding of peptides by an MHC-I or MHC-II molecule is the initial selective event that permits the cell expressing the MHC molecule (the antigen-presenting cell, APC) to sample fragments derived either from its own proteins (for MHC-I–restricted antigen presentation) or from those proteins ingested from the immediate extracellular environment (for the case of MHC-II).

In particular, cell surface MHC class I glycoproteins gather from the cell's biosynthetic pathway fragments of proteins derived from infecting viruses, intracellular parasites, or self-molecules, either expressed normally or in a dysregulated fashion as a result of tumorigenesis, and then display these molecular fragments, in complex with the mature MHC-I molecule, at the cell surface (*12,35,36,37,38*). Here, the cell-bound MHC-I/β2m/peptide complex on the APC is exposed to the extracellular milieu and is available for interaction with T cells or NK cells. A T cell bearing an $\alpha\beta$ receptor recognizes the particular MHC/peptide complex (MHC/p) by virtue of a specific physical binding interaction. Each mature T cell bears a unique TCR encoded by somatically rearranged TCR genetic elements. T cells bearing $\alpha\beta$ receptors are first selected for weak reactivity with one or other self-MHC/p complexes in the thymus (a process known as positive selection), and then TCRs that bind strongly are deleted (negative selection) so that only a small proportion of T cells that develop in the thymus ultimately reach peripheral lymphoid organs such as lymph nodes and spleen. A particular TCR is therefore selected to bind only a limited set of MHC/p complexes based on this bias for self-recognition. The recognition by T cells is thus described as "MHC-restricted" in that TCR interact preferentially with self-MHC molecules. However, T cells are also "antigen-specific" in that a particular T cell sees a particular peptide. For any given T-cell clone, single amino acid substitutions of either the MHC or the peptide may severely diminish, or even obliterate, TCR recognition of the MHC/p complex. The MHC-I system draws its spectrum of peptides from proteins in the cytosol that are degraded by the multiproteolytic proteasome complex. These peptides that are transported from the cytosol to the endoplasmic reticulum via the intrinsic membrane peptide transporter, the transporter associated with antigen processing (TAP), are then trimmed at their amino terminus and cooperatively folded within the peptide loading complex to form an in-

strinsic component of the newly synthesized MHC-I molecule (*39*).

MHC-II molecules, in contrast to MHC-I, are expressed on a more limited set of somatic cells—B cells, macrophages, dendritic cells, activated but not resting T cells in the human—and have a somewhat more specific function in peptide selection and presentation. In general, they bind peptides derived from the degradation of proteins ingested by the antigen-presenting cell (APC), as well as endogenous cytosolic and endosomal proteins. They then sort their MHC-II molecules into endosomal cellular compartments, where the degraded peptides are generated and catalytically transferred to the binding site of the MHC-II. The MHC-II antigen-presentation pathway is based on the initial assembly of the MHC-II $\alpha\beta$ heterodimer with a dual-function molecule, the invariant chain (Ii). Ii serves as both a chaperone to direct the $\alpha\beta$ heterodimer to an endosomal, acidic protein-processing location, where it encounters antigenic peptides, and also protects the antigen-binding site of the MHC-II molecule so that it will be preferentially loaded with antigenic peptides in this endosomal/lysosomal location (*40,41–43*). The loading of the MHC-II molecule with antigenic peptide, a process dependent on the release of the Ii-derived "CLIP" (class II–associated invariant chain peptide), in part dependent on the MHC-II–like molecules, HLA-DM and HLA-DO in the human, and H2-DM and H2-DO in the mouse (*44,45*), then leads to the cell surface expression of MHC-II peptide complexes. HLA-DM functions by interacting directly with an acidic face of the MHC-II molecule (*46*) to catalyze the exchange of the CLIP peptide with an antigenic peptide in the endosomal compartment. HLA-DO modulates HLA-DM function by altering the repertoire of MHC-II/peptide complexes observed in DO-expressing cells (*47,48*). The MHC-II–recognizing T cells then secrete lymphokines and may also be induced to proliferate or to undergo programmed cell death. Such MHC-restricted lymphokine production that facilitates and augments the recruitment of additional inflammatory cells as well as antigen-presenting cells and antibody-producing cells is a key component of what was historically referred to as "T-cell help."

Distinct from the recognition of MHC molecules by TCRs, a number of activating and inhibitory NK cell receptors bind MHC-I molecules, whereas several NK receptors interact with MHC-I–like molecules (49). In general, the NK/MHC-I interaction, as compared to the TCR/MHC interaction, shows considerably less peptide specificity, although the interaction is peptide-dependent, and in some cases may exhibit clear-cut peptide preferences (13,50,*51,52*). The functional purpose of the MHC-I or MHC-I–like molecule in NK-cell recognition appears to be more subtle than that in T-cell recognition. The NK cell is tuned by a balance of inhibitory and activating signals conveyed to it via MHC interaction, and in its

resting state the inhibitory signals predominate. MHC-I is a sensor of the biosynthetic and metabolic state of the cell in which it is synthesized—when dysregulated by tumorigenesis or viral infection, the altered level of MHC-I can be detected by the NK cell. This ability of the NK cell to sense altered levels of MHC-I on target cells is the basis of the "missing-self hypothesis," which explains that NK cells detect and lyse those cells that are defective in MHC-I expression as a result of the loss of the inhibitory signal that results from engagement of NK receptors by MHC-I (53–55). The prototype NK receptor is the mouse NK inhibitory receptor, Ly49A, a C-type lectinlike molecule that delivers an inhibitory signal to the cell, expressing it as a result of its interaction with normally expressed MHC-I molecule, H2-D^d (56). Distinct clones of NK cells differ in the combinatorial expression of different NK receptors that have different MHC preferences. Thus, in the mouse, each distinct NK clone may express a different combination of NK-inhibitory receptors such as Ly49A, Ly49C, Ly49G2, and Ly49I (57). Because each inhibitory molecule may exhibit slight differences in its MHC-I and/or peptide preference and specificity, this kind of combinatorial variation of NK activity provides a breadth of specificity toward different potential target cells. The interaction of MHC-I on the NK cells themselves with an NK inhibitory receptor, such as Ly49A or Ly49C (i.e., a "cis" interaction), plays an important role in the priming of NK cells (58). The interaction of the NK-activating receptor, NKG2D, with MHC-I–like molecules induced by stress in the target cell results in the activation of the NK cell and follows distinct molecular rules of recognition (34).

MHC-I and MHC-II molecules, because of differences in the cellular compartments that they traverse from biosynthesis to maturation, reveal strong preferences for the origin of the proteins that they sample for antigen presentation (59,60). The MHC-I antigen-presentation pathway in nondendritic cells is most easily thought of as an "inside-out" pathway by which protein fragments of molecules synthesized by the cell are delivered to and bound by the MHC-I molecule during its biosynthesis. Certain specialized dendritic cells can acquire exogenous antigen and present this via the MHC-I pathway. In contrast, the MHC-II antigen-presentation pathway is best visualized as both an "inside-out" pathway and an "outside-in" one, in which endogenous and ingested proteins are degraded by enzymes in the endosomal/lysosomal system and are delivered to MHC-II molecules in that degradative compartment (12,38,61–64). The processes of antigen processing and presentation are described in more detail elsewhere in this volume. The biochemical steps involved in the production of antigen fragments from large molecules are known collectively as "antigen-processing," whereas those that concern the binding of antigen fragments by MHC molecules and their display at the cell surface are known as "antigen-presentation."

Our understanding of the complexities of antigen processing and presentation continues to improve. Not only do we now recognize the importance of proteasome components in controlling the specificity of the degradation of proteins in the cytoplasm (37), we also are aware of contributions made by the chaperone tapasin (48,65), by ubiquitination (37,66), by amino-terminal trimming of peptides in the endoplasmic reticulum (ER) (67), and the role of disulfide interchange as controlled by the resident ER proteins ERp57 and/or protein disulfide isomerase (PDI) in peptide loading during MHC-I assembly (68,69). MHC-II peptide loading is controlled in part by the multifunctional chaperone/groove protector, Ii, as well as by the important catalytic machinery of the endosomes, molecules known as HLA-DM and -DO in the human, and H2-DM and H2-DO in the mouse (48).

In addition to showing preference for distinct pathways of antigen presentation, the MHC-I and MHC-II molecules also show preferential presentation to T cells of the CD8- or CD4-bearing subsets, respectively. This is related to the observation that CD8 binds to the nonpolymorphic α3 domain of MHC-I molecules (70–72,73), whereas CD4 interacts with membrane proximal domains of MHC-II (74,75,76,77,78). The CD8 and CD4 molecules serve as "coreceptors" on the surface of the T lymphocyte, providing both adhesion (avidity increase) and specific activating signals that modulate the avidity of the T cell in a time-dependent manner (79,80). The precise location of the site of interaction of the CD8$\alpha\alpha$ homodimer with the MHC-I α3 domain has been determined crystallographically for both human and murine molecules (81,82). The CD8$\alpha\beta$ molecule, expressed on peripheral T cells bearing $\alpha\beta$-TCR and on thymocytes, presumably has a similar site of interaction, but has not yet been directly visualized by structural methods. In addition, the amino-terminal two immunoglobulinlike domains of human CD4 complexed with a murine MHC-II molecule, IA^k, have been visualized crystallographically (78). The numerous interactions of MHC molecules with other cellular components as well as with the wide variety of peptides and of various immunologic receptors reflect the robust potential of the MHC structure as a molecular sensor and as a master regulator of immune responses. These molecular interactions then orchestrate different cell trafficking and signaling functions. Table 19.5 summarizes some of these interactions, emphasizing the similarities and differences between MHC-I and MHC-II molecules.

THE MAJOR HISTOCOMPATIBILITY COMPLEX

Mhc Genetic Maps

The major histocompatibility complex is an extended region of the genome that spans some 4 million base pairs (Mb) on the short arm of human chromosome 6 in the

▶ **TABLE 19.5 Comparison of MHC-I and MHC-II Molecules**

	MHC-Ia, Ib, and Iv	**MHC-II**
Genetics	Multiple heavy-chain loci, many linked to the MHC. Light chain, β2-m, is genetically unlinked.	Several heavy and light chain loci, α- and β-chain genes linked to each other.
Polymorphism	Highly polymorphic MHC-Ia heavy chain. Few alleles of β2m. Polymorphism of MHC-Ib and Iv variable.	β chain most polymorphic. α chain shows some allelic diversity.
Tissue-specific expression	MHC-Ia, ubiquitous. MHC-Ib on various cell subsets. MHC-Iv encoded by viruses.	MHC-II on B cells, macrophages. In human, also found on T cells and many activated cell types.
Molecular structure	Heavy chain/light chain form heterodimer. Obligate cell surface molecule. Heavy chain has three extracellular domains, α1, α2, and α3. α1/α2 form peptide-binding site. α3 and β2-m are Ig-like. Only heavy chain is membrane bound; β2-m is noncovalently assembled. (Some MHC-Ib, like MICA, not β2-m–associated; MHC-Iv may or may not be β2-m–associated.) Some MHC-Ib and MHC-Iv, unique disulfide bonds.	α and β chains form heterodimer of four domains; α1/β1 form peptide-binding site; α2 and β2 are Ig-like. Both chains are membrane-bound. Association of nascent MHC-II with invariant chain.
Site of peptide acquisition	In endoplasmic reticulum during biosynthesis. Role of Erp57 oxidoreductase in peptide loading. At cell surface when exposed to exogenous peptides.	In endosome or lysosome, where degraded products of ingested proteins are encountered; assistance of DO and DM for peptide exchange and loading.
Nature of peptides bound	MHC-Ia Preference for 8- to 10-mers; though longer peptides can be bound. "Motif" residues for particular MHC I molecules. MHC-Ib CD1 capable of binding lipid antigens. MICA, RAE-1, HL-60, MULT1, FcRn, no peptide-binding cleft. MHC-Iv m144, m153, no peptide-binding cleft.	Longer peptides are acceptable.
Rules for peptide binding	Defined termini. Anchor residues crucial.	Core motif of 9 residues may be extended variably at either N or C terminus. Anchors more subtle. Role for backbone interactions.
T-cell recognition	Primarily CD8$^+$.	Primarily CD4$^+$.
NK-cell recognition	Interaction with both NK-activating and NK-inhibitory receptors.	No known binding by NK receptors.
Associated molecules	β2-microglobulin. TAP. Tapasin. Calnexin.	Ii—invariant chain. H2-DM, (HLA-DM), H2-DO, HLA-DO.

region of 6p21.3. A recent analysis (*83*) suggests that the extended *Mhc* covers as much as 8 Mb. Although *Mhc* genes were among the first to be mapped here, it is now clear that many genes with function unrelated to immune recognition also reside in this region. The interested reader is referred to the continually updated maps and linkages available at various Web sites, including www.ebi.ac.uk/imgt/hla, and the MHC haplotype project at www.sanger.ac.uk/HGP/Chr6.

Figure 19.1 shows schematically a map of some of the major genes of the human (*84*), mouse, and rat *Mhc*, which includes those that encode MHC-I and MHC-II proteins. These comparative maps are not drawn to scale and do not show every gene identified in the region. Three markers, *Ke2*, *Bat1*, and *Mog*, serve to define the gross collinearity of the MHC of the three species (*85*), though there are clearly major differences between strains and even detectable differences between individuals within a species. *Bat1* and *Mog* define the boundaries of the MHC-I regions in all three species. The mapping and sequence information now available for the human MHC is more extensive than that available for the mouse and the rat, though

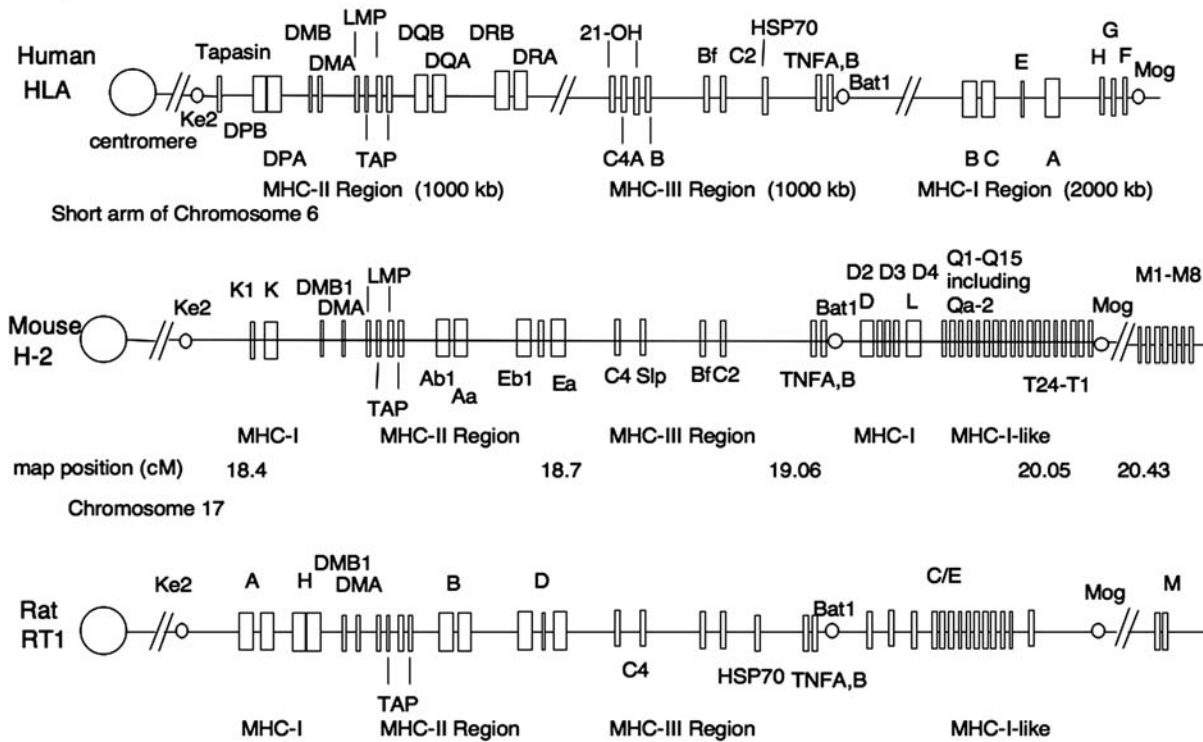
Map of the MHC


FIGURE 19.1 Genetic maps of the *Mhc*. Comparative map of the human, mouse, and rat *Mhc*. This schematic map is not complete, nor drawn to scale, and is derived from maps available elsewhere (*85,86,141,151,502–505*). The centromere and major genes are indicated.

data on these are improving rapidly. A database of the human *Mhc* is available (www.hgmp.mrc.ac.uk) (*86*). The homology of the *Mhc* region of mouse chromsome 17 to that region on human chromosome 6 can be found at www.ncbi.nlm.nih.gov/Homology, and extensive maps of syntenic regions of the human and mouse are available there.

The human MHC map reveals clusters of genes grouped roughly into an *Mhc* class II region covering about 1,000 kilobases (kb), an *Mhc* class III region of about 1,000 kb, and an *Mhc* class I region spanning 2,000 kb (Figure 19.1). *HLA-DP* genes (*DPA* encoding the α chain and *DPB* encoding the β chain) are proximal to the centromere on the short arm of the chromosome and are linked to the genes encoding the related HLA-DM molecule (*DMB* and *DMA*). Between these and the *DQ* genes lie *LMP* [for low-molecular-weight proteins (*87–90*)] and *TAP* (*91,92– 94,95,96*) genes. *LMP* and *TAP* genes encode molecules that are involved in peptide generation in the cytosol and peptide transport across the endoplasmic reticulum membrane, respectively. LMPs are subunits of the multicatalytic proteolytic proteasome complex that regulate the specificity of cleavage of proteins and thus modulate the repertoire of peptides available for MHC-I–restricted antigen presentation (*97–100*). The *TAP* genes encode a

two-chain intrinsic membrane protein that resides in the endoplasmic reticulum of all cells and functions as an ATP-dependent transporter that pumps peptides generated in the cytosol into the lumen of the ER (*101,102*). The selective transport of cytoplasmically generated peptides by different TAP proteins in the rat demonstrates that the spectrum of MHC/peptide complexes expressed at the cell surface can be significantly altered by differences in the antigen-presentation pathway (*103*,104,*105*), although there is little evidence for this phenomenon in humans (106).

The major *Mhc-II* genes of the human are *HLA-DRA* and *HLA-DRB*, which encode the chains that form the HLA-DR molecule, a major antigen-presentation element. Genetic mapping of the human DRB region now indicates that several alternative arrangements of DRB loci explain the varied serotypes and genotypes observed among different individuals (Figure 19.2). Because these are carried as sets of genes in linkage disequilibrium, they are frequently referred to as "haplotypes." The *Mhc-III* region is important in immunologic terms for several reasons—the structural genes for several complement components map here, as well as the structural genes for 21-hydroxylase (CYP21A2) (*107,108*), an enzyme that is critical to the biosynthesis of glucocorticoids, a deficiency of which can lead to the

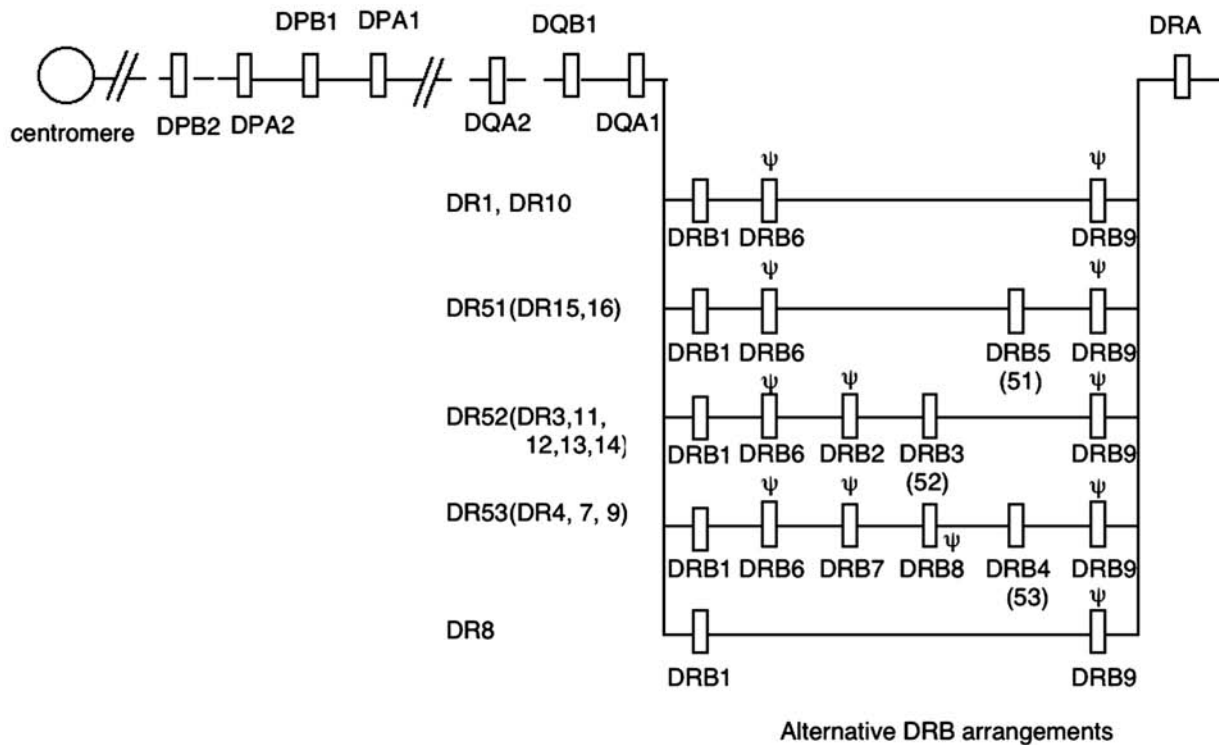
MHC Class II Region (~1 Megabase)


FIGURE 19.2 Genetic basis of structural variation in HLA class II haplotypes. All HLA class II haplotypes contain DPA1, DPB1, DQA1, DQB1, DRA, and DRB1 loci; however, there is variation in the number of additional DRB loci found on different haplotypes. The DRB9 pseudogene (labeled with a ψ) is common to all haplotypes; however, a DRB3 locus product is also expressed on halotypes containing any of the serologic DRB1 specificities DR3, DR5 (11,12) or DR6 (13,14). The DRB3 β-chain forms a cell surface heterodimer with the DRA α-chain and creates the serologic specificity DR52. These haplotypes also contain DRB6 and DRB2 loci that are pseudogenes. The DRB5 locus is found on most haplotypes containing the serologic DRB1 specificity, DR2, but occasionally this gene product is also expressed on other DRB1 haplotypes (*506*).

genetic disease congenital adrenal hyperplasia. Also located in the *Mhc-III* region are the structural genes for tumor necrosis factors A and B (TNF-A and TNF-B), which are lymphokines made by activated T cells (*109–111*). TNF-B is also known as lymphotoxin α.

The more distal region of the *Mhc* encodes other MHC molecules. In humans, the cluster of the major *Mhc-I* genes lies here, spanning 2 Mb, including the genes encoding HLA-B, HLA-C, HLA-E, and HLA-A, as well as HLA-H, HLA-G, and HLA-F. HLA-A, HLA-B, and HLA-C are the major MHC-I molecules of humans. (A summary of the serologic and genetic identification of these is in Table 19.2). Serologic identification of HLA-C molecules has been difficult and imprecise, however, HLA-C molecules interact directly with NK receptors of the KIR2D family. Direct binding studies have analyzed the kinetics of the interaction of the KIR2 Ig-like NK receptors (*112*,113,*114*), and three-dimensional structures of KIR2DL2 in complex

with HLA-Cw3 and KIR2DL1 complexed with HLA-Cw4 have been published (115,116). The precise functions of HLA-E, HLA-F, and HLA-G are not yet clear. HLA-E and its murine analog Qa-1 bind the hydrophobic leader peptides derived from some MHC-I molecules, forming a complex that is recognized by the C-type lectinlike NK receptor CD94/NKG2 (*117–121*). This implies an important function for HLA-E, because these molecules are expressed on placental trophoblast cells and would be expected to bind the inhibitory NK receptor, CD94/NKG2A, preventing NK-mediated rejection of the fetus (*122,123*). HLA-E has been shown to serve as a recognition element for some T cells as well, so it seems capable of a classical as well as a unique functional role (*120,124,125*). Some evidence now also supports an antigen-presentation function of HLA-F, and -G l (*126,127*), and the tissue-restricted expression of HLA-G as well as the observation that a soluble form leads to apoptosis of CD8$^+$ T cells suggest that this

molecule may be involved in the mother's immunologic tolerance of the fetus (*128*). *HLA-H* (*129*) is a pseudogene that maps to this region. This should not be confused with the more distantly related *HLA-HFE*, an *Mhc-Ib* gene erroneously called *HLA-H* by some authors (*130,131*), which controls hereditary hemochromatosis by virtue of the interaction of its encoded protein with the transferrin receptor (*132–137*). The observations that extravillous trophoblast cells express an unusual combination of HLA-C, HLA-E, and HLA-G molecules, that uterine NK cells express NK-inhibitory receptor (KIR) molecules known to interact with HLA-C allelic products, and the relationship among different complex genotypes and the clinical relationship with pre-eclampsia all raise the possibility that not only this complex medical condition, but also important aspects of fetal rejection and clinical infertility, may be related to MHC recognition by NK cells in the placenta (138).

Comparison of the mouse, rat, and human *Mhc* maps reveals several interesting differences (*139–142*). The *Mhc* genes proximal to the centromere of the mouse and rat belong to the *Mhc-I* family, rather than to the *Mhc-II* family, as they do in the human. This mapping has suggested that an intrachromosomal recombination event that occurred in some common rodent ancestor relocated some of the *Mhc-I* genes from a more distal location to the proximal site (143). Inspection of the current human, mouse, and rat maps clearly indicates similarities in the relative locations and organization of *Mhc-II*, *Mhc-III*, and the distal *Mhc-I* genes (*141*). Various genetic expansions and contractions (144) are obvious as well. In particular, the mouse *Q* and *T* regions have expanded the pool of *Mhc-I* genes, of which there are relatively few in the human and the rat. Early studies of congenic mouse strains mapped multiple genes to the *Q* and *T* regions (145,146,*147*), and recent evidence suggests significant differences in the number of genes of this region in different strains. The mouse has some *MHC-Ib* genes that seem to be relatively unique in function. In particular, the *H2-M3* gene (not to be confused with the *Mhc-II H2-Ma* and *H2-Mb* genes, which encode the homologs of the human HLA-DMA and HLA-DMB proteins), which maps distal to the *Q* and *T* regions, encodes a protein that exhibits a preference for binding peptides that have N-formyl amino-terminal modifications. This antigen-presentation function may be geared to bacterial, protozoal, and mitochondrial antigens (*148–150*). Rat homologs of the mouse *H2-M3* and *H2-M2* genes have also been identified (*151*).

Mhc Polymorphism

The *Mhc*'s function in immune responsiveness is also reflected in its genetic polymorphism. Polymorphism is the presence at any given time of a larger than expected number of genetic variants in a population. As populations change and evolve, we expect that genetic variants should arise, but because of the selection exerted on most gene products, relatively few of these genetic variants will persist. A genetic locus that exhibits variant alleles at a frequency of more than 1% is considered "polymorphic." A polymorphic locus or gene is one that has a high frequency (not raw number) of genetic variants (1). A genetic locus that is relatively invariant is often referred to as "monomorphic," even if more than one allele is recognized. *HLA* genes exhibit a high degree of polymorphism, and a number of different mechanisms may contribute to the generation and maintenance of polymorphism. Among these are the selective advantage of a heterozygous pool of antigen-presenting elements in a given individual that might allow the binding and presentation of antigenic peptides derived from a wide variety of environmental pathogens. Limited polymorphism would make the entire population susceptible to a chance infectious agent for which all individuals would be unable to respond, whereas widespread polymorphism would be expected to allow the antigen-presenting cells of at least a proportion of the population to bind and present antigens derived from invading pathogens effectively (*152,153*). Although such a view was originally based on HLA molecules as presenting elements for pathogen-derived peptide fragments to T cells and their antigen-specific T-cell receptors, recent studies suggest an additional role for MHC-I–related resistance to viral infection via NK cell–mediated recognition (*154*,155) and altered antigen-presentation pathway (156).

The human *Mhc-I* and *Mhc-II* genes are clearly polymorphic, with more than 100 alleles at each of the *HLA-A*, *HLA-B*, and *HLA-DRB* loci identified (17,*157*) (Tables 19.2, 19.3). It is more difficult to demonstrate polymorphism in terms of population genetics in experimental animals, although typing of wild mice has confirmed the existence of natural polymorphism predicted from the analysis of inbred strains and their mutants (*158*,159). The polymorphism of *Mhc-I* and *Mhc-II* genes, so evident in human and mouse, has also been documented in analyses of cichlid fishes, animals that diverged from the line leading to mammals at least several hundred million years ago (*160–163*).

Mhc Evolutionary Mechanisms

As both an extended genetic region and a group of genes with many belonging to the immunoglobulin supergene family (164,165), the *Mhc* has served as a prototype for elucidating mechanisms that contribute to the evolution of a multigene family and that add to the polymorphism that is such a dominant characteristic of the classical MHC molecules (*142*). The analysis of mutations in the mouse, mostly those of *Mhc-I* genes, has led to the understanding of the mechanisms that give rise to polymorphism. The mutations have been identified in mice based on

screening of large numbers of animals by skin grafting among siblings. Both induced and spontaneous mutations affecting skin-graft acceptance or rejection have been identified, and many of these have been mapped to the *Mhc*. Gross recombinational events have been documented in the *Mhc* (*166,167*), as well as more subtle mutations, many of which are multiple amino acid substitutions in a relatively small part of the protein that seem to derive from nonreciprocal recombinational events. Such recombination that occurs over short sequences is known as "gene conversion" because of its similarity to the phenomenon that occurs in yeast (*166,167*,168,*169,170*,171,*172,173*).

The mechanism of gene conversion in mice is now better understood because nucleotide sequence analysis and oligonucleotide-specific hybridization have been used to characterize the mutations that have occurred and the genes that serve as donors of the mutant sequences. Although the precise enzymatic details are not clear, we now understand gene conversion as a genetic event that allows the copying or transposition of short sequences from a donor gene to a recipient. Some of the polymorphisms of *Mhc* genes that have been identified clearly reflect point mutations (17). Recently, structural studies have shown that the profound immunologic effects of mutations of the *H2* genes *H2K*^{bm1} and *H2K*^{bm8} result from minimal detectable changes that may affect thermostability (*174*). In addition to such mouse mutants, a number of somatic cell variants and mutants, some resulting from major deletions or regulatory defects, others clearly point mutants of structural genes, have been described (*175*). An effort to identify the donor gene for the *H2K*^{bm3}, *H2K*^{bm23}, and *H2D*^{bm23} mutations leads to the conclusion that these complex mutations must have arisen by the contribution of at least two different donor genes acting either in sequence or in synergy (*175*).

The *Mhc* and Transplantation

Although the early description of the genes of the *Mhc* was based on identification of loci involved in tumor and allograft rejection (the rejection of grafts from genetically disparate donors of the same species), and although these genes clearly play a role in such complex phenomena, a contemporary understanding of the function of *Mhc* genes in immunology requires little understanding of the rules of transplantation. The early history of transplantation is chronicled extensively in several books (1,3) and reflects a developing interest in tumor immunology and congenic mouse strains. The most extensively studied species for tumor, tissue, and organ transplantation has been the mouse, so a brief description of some relevant principles is in order. Comprehensive manuals and reviews are available (176). Propagation of a mouse strain by repeated matings of brothers and sisters leads to the establishment of an inbred strain, a group of animals that is genetically identical

at all loci. More complete descriptions of the process by which brother–sister mating leads to homozygosity at all loci are given elsewhere (1,3). The probability of fixation of all loci (P_{fix}) as a function of the number of generations, n, is given by $P_{fix} = 1 - (7/8)^{n-1}$. Thus, after five generations of brother $\times$ sister matings, the probability of all loci being identical is 0.414; after 10 generations it is 0.7, after 15 generations ir is 0.85, and after 20 generations it is 0.91.

"Congenic" mouse strains, also known as "congenic resistant" or "CR" strains, are those derived by first crossing two inbred strains that differ in a histocompatibility phenotype such as resistance to a transplantable tumor or ability to reject a skin graft. These are then successively backcrossed to one parental strain, and the resistance phenotype is preserved. Following at least 10 backcross generations (N10), a point at which $(1/2)^9 = 0.002$, of the genes of the selected strain should be present, the new strain is propagated by brother $\times$ sister mating. From such breeding schemes, a number of strains critical to genetic studies of the *Mhc* have been derived. Several relevant inbred and congenic mouse strains are listed in Table 19.4 along with their *H2* designations.

The availability of numerous polymerase chain reaction (PCR)–based genetic markers throughout the mouse genome allows the direct identification of those progeny that have a greater proportion of the desired background at each generation. Selective backcrossing, taking advantage of the genotype of a large number of such genetic markers distributed widely throughout the genome, a process known as "speed congenics," can hasten the process of establishing a homogeneous background for a particular mutant or knock-in trait (*177–179*). Because strains obtained by brother $\times$ sister matings may reveal genetic drift as spontaneous mutations accumulate in the strain, it is crucial to keep track of the stock from which the animals were derived and the number of generations that they have been propagated without backcrossing to founder stock. This has been of particular concern in recent years as various lines of embryonic stem cells derived from different lines of strain 129 have been used for genetic manipulation (gene knockout experiments) (*180*), and there are clearly differences in histocompatibility (*181*).

The early rules of transplantation were determined by observation of the ability of either transplantable tumors or of allografts (usually from skin) to survive in a particular inbred mouse-strain host. The graft-rejection phenomenon is an extremely sensitive and specific bioassay that permits the detection of genetic differences as small as a single amino acid in an MHC protein. It has been particularly valuable in assessing spontaneous and induced mutants (see earlier discussion) and remains the absolute experimental discriminator of "histocompatibility."

In addition to the *Mhc* genes, we should not overlook the genes that encode minor histocompatibility antigens.

In the mouse, these were originally identified as genetic loci responsible for graft rejection after extended periods of time. More recently, several minor histocompatibility loci have been identified as those that encode polymorphic proteins that give rise to peptides presented by MHC molecules (*182–186*), and we now can understand the complexities of transplantation tolerance not only in terms of *Mhc* genes but also in terms of numerous proteins that may give rise to variant peptides for T-cell recognition. Not only can peptides derived from polymorphic genes throughout the genome serve as minor histocompatibility antigens, also defective translation products, or peptides resulting from transcription of introns or alternate coding strands of DNA may also produce immunologically significant peptides that, bound by self-MHC molecules, may stimulate T cells (187,188). Whether such defective newly synthesized proteins seve as a major source of MHC-I–bound peptides remains controversial (189). Minor antigens that are confined to hematopoietic cells can be recognized as targets by antitumor cytolytic cells and may explain the lower incidence of relapse in hematopoietic stem cell (HSC) transplant recipients who experience graft-versus-host disease (*190*).

The *Mhc* and Clinical Transplantation

Processed foreign antigen complexed to HLA class I or class II molecules is recognized by a specific clonally distributed TCR for antigen on the surface of T lymphocytes. The T cell bearing an $\alpha\beta$ receptor is capable of recognizing the unitary structure of the HLA molecule itself coordinately with the exposed parts of the peptide antigen. Co-recognition of HLA and peptide antigen means that TCRs are highly specific and genetically restricted to recognizing HLA molecules of the individual from which they were derived. Thus, a killer (cytotoxic) T cell raised against an influenza virus peptide in an individual expressing HLA-A2 will not recognize influenza-infected HLA-A1. This concept is known as "MHC restriction" and was first described by Shevach and Rosenthal for recognition of alloantigens (7), by Zinkernagel and Doherty (8) for recognition of viral antigens, and by Shearer for recognition of altered self-ligands (6). Given that T cells are MHC-restricted, it is difficult to understand why they should ever recognize a foreign HLA type. However, in practice they do, and data indicate that such alloreactive T cells arise with remarkably high frequency. Estimates of between 1/10 to 1/1,000 activated clonally distinct T cells are capable of responding to any random allogeneic HLA molecule (*191–194*). Given the number of T cells in the human lymphoid system, this represents a striking tendency for T cells that are normally restricted to recognizing self-HLA molecules complexed to foreign peptides to cross-react on allogeneic HLA molecules. This cross-reaction can arise from direct recognition of the allogeneic HLA/peptide complex, which usually depends on the peptide antigen as well as the allogeneic HLA molecule. Alternatively, allorecognition by T cells can occur indirectly (*195,196*). In such cases, peptides derived from the allogeneic HLA molecules are presented as nominal antigen after processing by the host cells bearing self-HLA molecules. In the normal course of events, T-cell alloreactivity is an in vitro curiosity, although it is still not entirely clear why the fetal "allograft" does not stimulate the maternal immune system. However, it is the clinical transplantation of organs and hematopoietic stem cells across HLA compatibility barriers that produces graft rejection or graft-versus-host disease due to T-cell alloreactivity. Fully allogeneic transplants theoretically expose the recipient immune system to up to 12 non–self-HLA allele products expressed by the allograft. Moreover, the "self-peptides" constitutively presented by allogeneic HLA molecules are likely to be quite distinct from those presented by syngeneic HLA molecules, because the polymorphisms of the peptide antigen-binding cleft of the MHC-I molecule that distinguish HLA alleles alter the spectrum of selected peptides. Allogeneic HLA/peptide complexes probably stimulate powerful T-cell responses because of the high density of unusual determinants and the diversity of new peptide ligands presented by the allogeneic HLA/peptide complexes. Because there are many MHC-linked genes encoding a host of proteins, many lacking known immunologic function, it is likely that polymorphisms in these molecules contribute significantly to the alloresponse (see earlier discussion of *Mhc* genetic maps). Accordingly, many studies have demonstrated an incremental improvement in long-term graft survival with progressively higher levels of HLA matching at HLA-A, -B, and -DR loci. For this reason, HLA matching is essential in allogenic HSC transplantation, and highly desirable in solid-organ transplantation. The degree of HLA matching usually required for renal transplantation is shown in Figure 19.3 and for bone marrow transplantation in Table 19.6. The effect of HLA matching on solid-organ transplantation has been monitored by the Collaborative Transplant Study since 1982 (see www.ctstransplant.org/public/introduction.html).

In addition to the allogeneic cellular response, the antibody response to HLA molecules and ABO blood groups can also cause rejection of certain grafts, especially where these antibodies are preformed and therefore present at the time of organ transplantation. Antibodies to ABO blood-group antigens react with these determinants on vascular endothelium, and therefore ABO-incompatible solid organs can be rapidly rejected by humoral mechanisms. In patients who have been transfused or previously transplanted, or in multiparous females, exposure to allogeneic HLA molecules can also result in the production of anti-HLA class I antibodies. These preformed antibodies can lead to acute and hyperacute rejection of grafts expressing the particular HLA molecules recognized by these

antibodies. Therefore for solid-organ transplants, individuals are not only matched as closely as possible for their HLA types to avert cellular rejection, it is also necessary to ensure ABO compatibility and to exclude preformed antidonor HLA antibodies in the host.

Paradoxically, some patients who have received multiple blood transfusions prior to transplantation appear to develop some form of T-cell tolerance to allogeneic donor HLA alleles, and renal graft survival is actually enhanced in these individuals. This is known as the "transfusion effect," and in some centers, pretransplant transfusion and even donor-specific transfusions are routinely carried out. Transfusion of potential renal transplant recipients carries the risk, however, of inducing undesirable anti-HLA antibodies in the patient.

Testing for anti-HLA antibodies is known as the "crossmatch." In practice, many laboratories crossmatch only for anti-HLA class I antibodies. Crossmatch compatibility to exclude anti-HLA class I antibodies is essential in renal transplantation and is widely practiced in heart/lung transplantation. Crossmatching for liver transplantation is practiced at only some centers, and the evidence that a positive crossmatch predicts allogeneic liver graft rejection has not convinced everyone of its importance in routine matching. Patients awaiting renal transplantation are usually monitored regularly for anti-HLA class I antibodies, because the level and specificity of these antibodies can change with time. This monitoring involves regular crossmatching of patient serum against a panel of randomly selected cells bearing different HLA types. The percentage of positively reacting cells is known as the "panel reactivity." When carrying out a crossmatch between a patient's serum and donor cells, many centers test the current as well as "historical peak" serum from the patient. The "historical peak" is defined as the patient serum sample giving the highest panel reactivity throughout the monitoring period and is thought to be a sensitive reflection of previous HLA sensitization. Many centers now prescreen patients on transplant waiting lists for anti-HLA antibodies using MHC-coated beads as a source of antigen and a highly sensitive flow cytometry technology for their detection. In highly sensitized patients with multiple host antidonor antibodies, these unwanted antibodies can sometimes be functionally eliminated using B-cell ablation therapies (anti-CD20 mAb), plasmapharesis, and intravenous gamma-globulin infusions, thus allowing successful transplantation.

The role of antibody crossmatching in allogeneic HSC transplantation is less clear, and many centers do not take the class I or class II crossmatch into account when

▶ TABLE 19.6 MHC Matching versus Success of Bone Marrow Transplantation

MHC Compatibility	Risk of Graft Rejection (%)	Risk of Acute Graft-versus-Host-Disease (%)	Survival (3 y) (%)
Share two haplotypes (HLA-identical sibling)	2	40	50
Share one haplotype plus:			
Phenotypically identical	7	40	50
1 HLA mismatch	9	70	50
>2 HLA mismatches	21	80	15
Share zero haplotypes (unrelated):			
"Matched"	3	80	35
"Mismatched"	5	95	35

identifying a bone marrow transplant donor. On the other hand, some large centers place considerable importance on a positive crossmatch as a predictor of bone marrow rejection, and it is therefore advisable to crossmatch bone marrow donor–recipient pairs when there is a high risk of rejection (e.g., aplastic anemia). Crossmatching is also used to detect anti-HLA antibodies that caused refractoriness to platelet transfusion with random platelets.

Family Studies in Histocompatibility Testing

The linkage of HLA loci on chromosome 6 means that individuals will usually inherit a set of nonrecombined HLA alleles encoded at linked HLA loci from each parent. This set of genes (the haplotype) is often identifiable in family studies, where all the alleles present on one chromosome cosegregate. In identifying donors for hematopoietic stem cell transplantation, testing of family members is essential to determine haplotypes accurately (*197,198*). This is because sharing of HLA antigens from different haplotypes is

quite common in families, so mismatches within HLA subtypes (i.e., allele-level mismatches) are easily overlooked as a result of mistaken haplo-identity of siblings or other family members. Because unrecognized HLA mismatching is poorly tolerated in hematopoietic stem cell transplantation, high-resolution sequence-based DNA matching (or its equivalent) is required to avoid graft-versus-host disease (*199–201*). Although allogeneic HSC transplantation can be carried out across single-locus mismatches, there is little correlation with the magnitude of a given mismatch and the subsequent immune response. Donor–recipient MHC differences of just a single amino acid can provoke strong alloresponses comparable to reactions between vastly different MHC products (*202*). An example of haplotyping in a family study is shown in Figure 19.4. Added complexity of the kinds of cell surface molecules that are expressed as a result of the codominant expression of molecules encoded by the human MHC-I and MHC-II loci is illustrated in Figure 19.5.

The role of HLA-DP in allogeneic stem cell transplantation is still unclear, so testing for this locus is not
FIGURE 19.4 Segregation of HLA haplotypes in a family. From (*507*), with permission.
FIGURE 19.5 Codominant expression of HLA gene products encoded by the major histocompatibility complex. The *HLA-A, -B,* and *-C* class I loci, and the linked *HLA-DR, -DQ,* and *-DP* class II loci are located the short arm of chromosome 6 (6p21), and the class I light-chain locus, $\beta 2M$, is encoded on chromosome 15. HLA genes and their respective proteins are shaded to reflect the different loci encoding these proteins and the inheritance of different alleles from the two parental chromosomes. The separate HLA class II α- and β-chain loci are also shown. The products of both maternal and paternal chromosomes are codominantly expressed on the surface of antigen-presenting cells, resulting in expression of up to six distinct class I allotypes. The number of expressed class II gene products can be even greater, because some haplotypes have extra DRB loci that produce additional β chains capable of assembling with DRα. In addition, pairing of certain DQα molecules from the DQA locus encoded on one chromosome, with DQβ chains derived from the other chromosome, can result in expression of new DQ cis–trans isotypes. The HLA class I and class II loci are separated by the class III region of the major histocompatibility complex (not shown). HLA class II molecules are constitutively expressed only on B cells, macrophages, and dendritic cells, whereas class I molecules are found on nearly all nucleated cell types.

routinely carried out clinically except when several donors are available and a rational choice of the best donor has to be made (*203,204*). [Note that some recent studies suggest a contribution of HLA-DP to graft success in both stem cell and renal transplantation (*205,206*)]. Typically, an HLA typing laboratory will test for HLA-A, -B, -DRB1, -DRB3, -DRB4, -DRB5, and -DQ loci (207). In the family study shown in Figure 19.4, the mother and father are mismatched at both haplotypes. Among the children, John and Andrew are haploidentical (and therefore phenotypically identical). Jane and Jim share a single haplotype, as do Tom and Jim. Jane's paternal haplotype is a recombinant involving a crossover event between HLA-A and -B. Re-

combination is observed between HLA-A/B and HLA-B and HLA-DR in about 1% of meiotic events. The implications of this family study are that Andrew and John would be ideal bone marrow donors for each other. However, none of the other siblings would be suitable as a donor for these brothers. Even though there is sharing of a single haplotype between Tom and both Andrew and John, the complete mismatch in the second haplotype would make Tom unsuitable as a donor for hematopoietic stem cell transplantation, which requires very close matching of HLA. On the other hand, haplotype mismatching is common in renal transplantation, in which perfect HLA matching is not absolutely required or routinely achievable (because

of the narrow time frame for acquisition of acceptable cadaver donor grafts). However, for renal and other solid-organ transplantation, ABO blood group compatibility is essential, because these determinants are expressed on vascular endothelium, where recognition by isohemagglutinins leads to rapid intravascular coagulation and organ failure.

When a matched sibling donor does not exist for a patient requiring allogeneic hematopoietic stem cell transplantation (70% of cases), searching of the extended family or unrelated bone marrow registries is indicated. The National Marrow Donor Panel (NMDP; www.marrow.org) has several million potential donors suitable for unrelated stem cell transplantation, and these donors are used in the United States and worldwide. Bone marrow donor registries also exist in Europe, Australia, Hong Kong, and Japan, and these registries often provide donors for patients in other parts of the world. Mobilization of stem cells in the blood following administration of hematopoietic growth factors is now widely used to avoid the need for marrow collections from donors.

Cord blood banks have also been established around the world (*208,209,*210). However, cord blood donation of stem cells is often unsuitable for adult transplantation because of limitations in the volume of cord blood collections. Cord bloods offer the advantage of finding donors faster than adult unrelated registries (*211*) and theoretically providing banked stem cells from ethnic minority groups that are not well represented in bone marrow donor registries (*212*). Cord blood transplants induce less graft-versus-host disease than bone marrow or peripheral blood stem cell transplants, but posttransplant engraftment is slower (*213*).

Functional Tests of HLA Compatibility

Testing for HLA identity at all HLA loci is a daunting task for most laboratories because of the very large number of alleles present in the population. Moreover, in renal transplantation, some mismatches appear to be well tolerated and are associated with long-term graft survival, whereas other mismatches of similar genetic disparity are poorly tolerated and are associated with early rejection (*214*). Reliable methods for predicting these "taboo" mismatches are not readily available. Similarly, high-resolution HLA typing does not predict all graft-versus-host disease (GVHD) when selecting suitable unrelated donors for hematopoietic stem cell transplantation (*200,215*). Therefore, there has been a great deal of interest in developing functional or in vitro cellular tests of overall donor–recipient compatibility. Unfortunately, none of the tests so far developed provides convincing predictability of impending graft rejection or, more important, GVHD. Among the tests used historically for assessing functional compatibility are the mixed lymphocyte reactivity (MLR)

test and allogeneic T-helper or CTL precursor studies. The MLR or MLC (C = culture) involves measuring T-cell proliferation of host T cells in response to donor lymphocytes and vice versa. In a one-way MLR, the stimulating lymphocytes are irradiated to prevent their proliferation; whereas in the two-way MLR, both stimulator and responder cells are allowed to proliferate. In MLR studies, it is necessary to include controls showing that responder cells can all respond and that stimulator cells can all stimulate across an appropriate barrier such as third-party donor cells. Responses can vary widely, and individual laboratories use their own cutoff values to define negative (i.e., nonreactive) and positive (reactive) MLR results (*215*). Unfortunately, known HLA mismatches can be present in a negative MLR, and a positive MLR can be obtained between phenotypically HLA-identical individuals. Because the MLR is biased toward measuring HLA class II discrepancies and is notoriously irreproducible (*215*), many laboratories have abandoned this test in favor of implementation of high-resolution PCR-based HLA class II typing.

Measurement of allogeneic CTL or helper T-cell precursor frequencies is carried out at specialized bone marrow transplant centers but is not universally accepted as being predictive of GVHD (*216,217*). The test is labor-intensive and requires a skilled technician for reproducibility. Precursor frequencies are estimated by limiting dilution analysis or Elispot of donor-versus-host lymphocytes (i.e., T cells expected to cause GVHD). High precursor frequencies (up to 1 in 10^4 cells) are thought to be associated with a greater risk of acute GVHD (*218*). It is possible that precursor studies detect major and minor incompatibilities and so, theoretically, they might give a broad measure of the transplant barrier, but technical improvements will be required before this test is widely adopted in clinical practice (*219*).

The *Mhc* and Disease

In addition to the control of transplant acceptance or rejection and immune responsiveness, the *Mhc* in the human plays an important role in the etiology of a number of diseases, many of which are autoimmune in nature (144,220–222). Several human diseases are associated with the *Mhc* class III genes, because some of the structural genes for enzymes involved in the adrenal steroid biosynthetic pathway (i.e., 21-hydroxylase, CYP21A2) map to this region. More than 40 diseases have well-established genetic linkages to the *Mhc* (144,221,222,*223*); the most important are summarized in Table 19.7. Recent genome-wide association studies confirm the importance of the HLA-DRB1 locus in rheumatoid arthritis and type 1 diabetes (224). The precise mechanisms underlying the association of most of these diseases with the particular *Mhc* haplotypes are unknown, but several models have been proposed, including the cross-reactivity of antimicrobial antibodies

▌**TABLE 19.7 Some HLA Disease Associations**

Disease	*MHC-I*	*Strength of Association*[a]
Ankylosing spondylitis	HLA-B27	+++
Reiter disease	HLA-B27	++
Psoriasis	HLA-Cw6	+
Abacavir drug hypersensitivity	HLA-B*5701	+++
Behcet disease	HLA-B51	+
Birdshot retinopathy	HLA-A29	+++
	MHC-II	
Narcolepsy	HLA-DQB1*0602	++
Insulin-dependent diabetes mellitus	HLA-DQ8	++
	HLA-DQ2	+
	HLA-DR2	−
Rheumatoid arthritis	HLA-DR4	+
Celiac disease	HLA-DQ2	+++
	HLA-DQ8	+
Multiple sclerosis	HLA-DR2	+

[a]+++ = very strong association that is clinically useful as a diagnostic tool.
++ = strong association with likely primary involvement in disease pathogenesis.
+ = clear association with likely role in disease pathogenesis.
− = negative or protective influence on disease probability.
For a more detailed summary of MHC and disease associations, see (144).

with particular MHC molecules (*225*) and the molecular mimicry of viral antigens that might induce T-cell responses to self-antigens (226,*227–232*). The very high incidence of some diseases associated with certain *HLA* genes assists in the diagnosis as well as the counseling of patients and their families. Several of these diseases are of particular note. Because virtually 100% of patients with narcolepsy have *HLA-DQB1*0602* (associated with *HLA-DR2*) (*233,234*), HLA typing can be used as a test of disease exclusion. Thus, a diagnosis of narcolepsy can be excluded with reasonable certainty if the patient does not have HLA-DQB1*0602. On the other hand, the presence of HLA-DQB1*0602 is of little predictive value in diagnosis of narcolepsy, because this HLA type is relatively common in many populations and occurs frequently in the absence of disease.

Ankylosing spondylitis is so strongly associated with the *Mhc-I* allele *HLA-B27* and the presence of some bacterial pathogens that it is a popular hypothesis that ankylosing spondylitis is due to the stimulation of particular T cells by HLA-B27–presented bacterial antigens that cross react on self-tissues. These T cells are then thought to initiate an inflammatory cascade. Despite the strong association of HLA with spondyloarthropathy, critical evaluation of the literature brings a postinfectious etiology into question, and certainly more studies are indicated (*235*). The tendency of HLA-B27 to form disulfide-linked covalent dimers raises the question whether the resulting cellular pathology related to poor cell surface expression of this MHC-I molecule may be related to the inflammation of joints that is characteristic of this disease (236,*237*).

Hereditary hemochromatosis (HH) is one of the most common genetic disorders in Caucasian populations (with a prevalence of 1/300 to 1/400), and the gene controlling this condition (HFE) is MHC-linked, mapping approximately 3Mb telomeric to the HLA-A locus (*134*). The HFE protein is a class I–like molecule, the structure of which is now solved (*238,239*). The HFE protein assembles with β2m and is expressed in the intestinal mucosa and placenta, where it plays a role in regulating iron uptake and transport (*240,241*). Mice that are homozygous for an induced defect of β2m as well as those with targeted inactivation of the *HFE* gene suffer from iron overload, hemochromatosis (*242*) (*515–517*), although there are mutations at loci other than β2m or *HFE* that also lead to the same disease phenotype (*137*). HFE regulates the affinity of the transferrin receptor for transferrin, resulting in an alteration of the efficiency of iron transport. The most common molecular defect associated with hereditary hemochromatosis involves a point mutation that results in a Cys282Tyr substitution in the α3 domain of this class I–like molecule (*134*). This mutation accounts for >80% of patients with hereditary hemochromatosis (*243*). The disruption of the disulfide bond in the α3 domain at this site prevents efficient folding of the molecule and impairs assembly with β2m, resulting in improper HFE protein expression. This leads to a failure to downregulate the affinity of the transferrin receptor for its ligand, transferrin, presumably causing increased iron uptake by cells and tissue damage as a result of iron overload. A second common *HFE* mutation, 187G, results in a His63Asp substitution and a very slight increase in susceptibility

to developing hereditary hemochromatosis, depending on the genotype of the individual (*244*). Incomplete penetrance of even the high-risk Cys282Tyr *HFE* genotypes can be partly explained by natural iron deficiency from limited dietary intake and menstrual losses in women.

As summarized in Table 19.7 and discussed earlier, there are a number of autoimmune diseases associated with particular alleles of HLA class II loci, especially with DR and DQ (*245*). These diseases include type 1 (insulin-dependent) diabetes mellitus, rheumatoid arthritis, multiple sclerosis, systemic lupus erythematosus, thyrogastric autoimmunity, Sjogren syndrome, and many others. Rheumatoid arthritis is strongly associated with HLA-DR4 subtypes that share a common sequence motif within the DRβ chain (*246*), suggesting preferential antigen presentation of self-epitopes by these molecules. The relative risk of severe rheumatoid arthritis is increased in DR4 homozygotes, particularly compound heterozygotes with high-risk alleles (*247,248*), indicating a gene dose effect in susceptibility to autoimmune inflammation.

Although the number of different *HLA* class I and class II alleles that are associated with insulin-dependent diabetes mellitus (type 1 diabetes) clearly indicates that this relatively common disease has a complex etiology, the identification of a novel *Mhc-II* haplotype in the mutant NOD (nonobese diabetic) mouse (*249–253*), and the recognition that particular TCRs can mediate disease (*254*), suggest that a cross-reactive response to a common self- or environmental antigen may play an important role in the etiology of this disease as well. In human type 1 diabetes, the incidence of disease is significantly increased in Caucasians with *HLA-DR3-DQ2* and *DR4-DQ8* haplotypes (*255,256*). These haplotypes impart a synergistically increased relative risk when they occur as a heterozygous combination compared to the risk of disease conferred by either haplotype alone (*245,255,256*). This raises the possibility of trans-complementation of *HLA-DQ* gene products producing new molecules involved in antigen presentation (*257*). Analysis of large cohorts of patients in genome-wide marker studies offers a promising approach to identify additional genetic factors that act synergistically with HLA-allelic linkages in raising the odds of disease susceptibility (224). Online genomic maps and correlations of associations with particular loci further augments our ability to understand the relative contributions of MHC-linked and unlinked genes in autoimmune diseases such as type 1 diabetes (*258*).

In addition to recent progress in recognizing *Mhc* associations with a variety of autoimmune and immune deficiency conditions, further analysis has identified relationships of HLA-linked markers with susceptibility and prognosis in a number of infectious diseases. Among the most striking has been the recognition that delayed progression of HIV infection to acquired immunodeficiency syndrome (AIDS) correlates with possession of HLA-B

Bw4 alleles that express a molecule with isoleucine at position 80 along with a gene for the NK-cell receptor KIR3DS1. This observation suggested that KIR3DS1 offered protection early in HIV infection for those patients bearing the appropriate Bw4 allele (155). More recent observations indicate that patients with such a KIR3DS1/Bw4 ile80 genotype also exhibit resistance to late opportunistic infections (*259*). Other studies now show that particular *HLA-DRB* alleles as well as *MHC-I* alleles significantly influence hepatitis B and C virus susceptibility, persistence, and response to treatment (*260*).

Mutations at the *H2* Locus

Mutations at the *H2* locus have been identified in animals screened by skin grafting in extensive experiments carried out over a 25-year period (*261,262*). By grafting tail skin of siblings to and from each other, spontaneous or induced mutant animals that displayed either a "gain," "loss," or "gain plus loss" transplantation phenotype were identified. Gain mutants are those that express a new transplantation antigen—thus, their skin is rejected by their nonmutant siblings; loss mutants have lost a transplantation antigen—thus, they recognize the skin of their siblings as foreign and reject that graft. Gain-plus-loss mutations give effects in both directions—they reject the skin of their siblings, and their skin is rejected by their siblings as well. In a classic series of experiments over an extended period of time, Melvold, Kohn, and their colleagues screened a large number of mouse progeny. Both homozygous inbred and F1 animals were examined, yielding a total of 25 *H2* mutations identified at *K*, *D*, *L*, and *Ab* loci, and an additional 80 mutations of non-*H2* histocompatibility genes. Although earlier studies suggested that all *H2* genes might be hypermutable, a more complete retrospective evaluation of the available data suggests that with the exception only of the *H2K^b* gene, the spontaneous mutation rate for *H2* genes was comparable to that for non-*H2* genes. The characterization of these mutant animals, first based on peptide maps and amino acid sequences of the H2 proteins (*263,264*,265,266), later based on the nucleotide sequences of the cloned cDNAs or genes (171), provided some of the basic biochemical information on which later studies of structure and function and mechanism of gene evolution were based. Recently, x-ray structure determination of the H2-K^bm1^ and H2-K^bm8^ mutants suggest explanations for the differences in T-cell recognition that result from what might appear to be subtle amino acid substitutions (*174*).

Expression of MHC Molecules

MHC molecules, synthesized in the endoplasmic reticulum and destined for cell surface expression, are controlled at many checkpoints before their final disposition as receptors available for interaction with either T cells

or NK cells. The MHC-I molecules should be viewed as trimers, consisting of the polymorphic heavy chain, the light-chain β2m, and the assembled self-peptide. A number of steps in biosynthesis and expression are inhibited by virus-encoded proteins. The first level of control of MHC-I expression is genetic; that is, the genes for a particular chain or key components of the peptide loading complex must be present for the trimer to be expressed. This is particularly relevant for β2m, which is the obligate light chain for the complex. Induced β2m-defective animals ($B2m^{o/o}$) (267,268) lack normal levels of MHC-I expression. The next level of MHC-I expression control is transcriptional, and interferon-γ (IFN-γ)-dependent regulation is particularly important (*269*). For the most part, MHC-Ia molecules are ubiquitously expressed, and expression is dependent on a complex trans-regulatory process that coordinately controls the transcription of both MHC-I and β2m (*270–272*). The basis of the more limited tissue-specific expression of MHC-Ib molecules is of interest because of the potential importance in the role of some of the MHC-Ib molecules in tolerance to the placenta. HLA-E and HLA-G, expressed on placenta, and HLA-F, another MHC-Ib with limited tissue-specific expression, have been examined in considerable detail (*273–277*). The rest of the MHC-I biosynthetic pathway is dependent on proper generation of cytosolic peptides by the proteasome and delivery to the endoplasmic reticulum by TAP, appropriate core glycosylation in the ER, transport through the Golgi, and arrival at the plasma membrane (*278*). A number of persistent viruses have evolved mechanisms for subverting this pathway of expression (*279*). The herpes simplex virus encodes a protein, infected cell peptide 47 (ICP47) (*280–282*), that blocks the activity of the peptide transporter TAP (*283*). Several proteins encoded by the human cytomegalovirus (HCMV), unique short-region proteins 2 and 11 (US2 and US11), cause rapid protein degradation of MHC-I molecules (*284*). Another HCMV protein, unique long-region protein 18 (UL18), which has sequence similarity to MHC-I molecules, may affect normal MHC-I function by limiting β2m availability. The biologic effect may be related to functional inhibition of NK recognition of viral-infected cells (*285–288*). Other molecules that assist the large DNA viruses in evading either the T-cell or NK-cell immune response include HCMV UL142 (*289*). Murine cytomegalovirus (290) encodes a number of open reading frames considered MHC-I homologs that may function to deceive NK cells into the perception of normal MHC-I expression (291,*292,293*). Adenovirus 2 (*294,295*) also has genes that function in blocking the transfer of folded assembled MHC-I molecules from the ER to the Golgi.

MHC-II molecules are also susceptible to regulation at multiple steps. The clear-cut tissue dependence of MHC-II expression—MHC-II molecules are generally found on cells that have specific antigen-presentation functions, such as macrophages, dendritic cells, Langerhans cells, thymic epithelial cells, and B cells, and can also be detected on activated T cells of the human and rat—suggests that transcriptional regulation plays an important role. Extensive studies of the promoter activities of *Mhc-II* genes have defined a number of specific transcriptional regulatory sequences (*296*), and one transcriptional activator, MHC class II transcriptional activator (CIITA) clearly plays a major role (*270,296–298*). Considerations of differential expression of MHC-II molecules in different tissues, MHC-II deficiency diseases known as "bare lymphocyte syndromes" (*298,299,*300,*301,302,*303), and current views of the role of the balance of Th1 and Th2 T-lymphocyte subsets, have led to a provocative hypothesis that suggests that the contribution of MHC-II differential expression and the resulting balance of Th1- and Th2-derived lymphokines are critical in the control of autoimmune disease (159,304,*305,306*).

A unique aspect of MHC-II regulation is the need to protect its peptide-binding site from loading of self-peptides in the ER, and the requirement to traffic to an acidic endosomal compartment where antigenic peptides, the products of proteolytic digestion of exogenous proteins, can be obtained. These two functions are provided by the type II membrane protein, invariant chain, Ii (40,*307–309*), which forms a nine-subunit complex (consisting of three Ii and three $\alpha\beta$ MHC-II heterodimers). The region of Ii that protects the MHC-II peptide-binding groove, CLIP, is progressively trimmed from Ii, and is ultimately released from the MHC-II by the catalytic action of HLA-DM in the endosome to allow exchange for peptides generated there. HLA-DO regulates the repertoire of bound peptides, presumably by modulating the catalytic activity of the DM exchange reaction. The important role of Ii in regulating MHC-II expression has been emphasized by the behavior of induced mutant mice lacking normal Ii (*310–312*), which exhibit a profound defect in MHC-II function and expression.

STRUCTURE OF MHC MOLECULES

There is nothing that living things do that cannot be understood from the point of view that they are made of atoms acting according to the laws of physics.

RICHARD FEYNMAN (*313*)

So central are *Mhc* genes and their encoded molecules to both the regulation and the effector function of the immune system that it has been apparent almost since their discovery that an understanding of their structure and structural interactions would be fundamental to a comprehension of their physiologic effects. Structural relationships of MHC molecules came first from understanding serologic differences, then from cellular immunologic analysis, and subsequently from biochemical studies of the MHC-I and MHC-II chains. Amino acid

sequence comparisons suggested a domain structure for the MHC-I molecules. With the identification of first cDNA and then genomic clones of those genes encoding MHC molecules, it became routine to determine the encoded protein sequences of a large number of molecules. We now have available high-resolution three-dimensional structures of >200 different MHC/peptide, MHC/peptide/TCR, MHC/peptide/coreceptor, and MHC/peptide/NK receptor complexes that allow an understanding of the function of these molecules in a detailed structural context (*314*). The details of these structures also pose a number of questions that may only be addressed by additional functional experiments in whole animals complemented by biophysical methods applied in vitro. The molecular biologic, functional, and structural studies have led to the development of the use of MHC multimers as extremely powerful tools for imaging specific T cells as well as NK cells. The goal of this section of this chapter is to summarize these developments with an eye toward explanation of function by structure, and in hopes of revealing some of the current quandaries that continue to confound our understanding of the function of the *Mhc*.

Amino Acid Sequences—Primary Structure

Before the cloning of *Mhc* genes, the biochemical purification and amino acid sequence determination of the human MHC-I molecules, HLA-A2 and HLA-B7, and of the mouse molecule H2-K^b (*315*,316) indicated that the MHC molecules showed similarities to immunoglobulins in their membrane proximal regions. Early concerns were to identify the differences between allelic gene products as well as the differences between MHC proteins encoded at different loci. With the cloning of cDNAs and genomic clones for MHC-I molecules (168,317,*318*,*319*) and then for MHC-II molecules (*320–322*), the encoded amino acid sequences of a large number of MHC molecules of a number of species quickly became available. The comparison of gene and cDNA structures gave an indication of the exon/intron organization of the genes and explained the evolution of the MHC molecules as having been derived from primordial single-domain structures of a unit size of a single Ig domain (such as the light chain β2m), which duplicated to form the basic unit of the MHC-II chains (two extracellular domains) and the MHC-I chain (three extracellular domains) (*142*). The canonical MHC-I molecule has a heavy chain that is an intrinsic type I integral membrane protein with amino-terminal domains called α1, α2, and α3, is embedded in the cell membrane by a hydrophobic transmembrane domain, and extends into the cytoplasm of the cell with a carboxyl-terminal tail. The light chain of the MHC-I molecule, β2m, is a single-domain soluble molecule.

The MHC-II molecule consists of two chains inserted in the membrane, an α chain and a β chain. The α and β chains consist of two major extracellular domains, α1 and α2, and β1 and β2, respectively, each linked to a transmembrane domain and cytoplasmic sequences. Thus, both MHC-I and MHC-II molecules are noncovalently assembled heterodimers consisting of four extracellular domains, the two membrane proximal domains (α3 and β2m for MHC-I and α2 and β2 for MHC-II) of each molecule are Ig-like, while the two amino terminal domains (α1 and α2 of MHC-I and α1 and β1 of MHC-II) are not. The α1 domains of both MHC-I and MHC-II lack the intradomain disulfide-bond characteristic of the other extracellular domains. The cytoplasmic domain of MHC-I molecules can be regulated by splicing and differential phosphorylation or other modification, and is likely to play a role in cell surface stability and cycling between the cell surface and other intracellular compartments (*323–327*). However, analysis of directed mutants of MHC-I in some systems indicates that the cytoplasmic domain is not required for cytoskeletal association or surface recycling (*328*). The MHC-II transmembrane and cytoplasmic domains have clear effects on the level of cell surface expression, the efficiency of antigen presentation, and the rate of lateral diffusion of the molecules in the cell membrane (*329,330*). Amino acid sequence alignments of MHC-I and MHC-II proteins, particularly of the human molecules, are available in a number of databases, such as www.ebi.ac.uk/imgt/hla and www.ebi.ac.uk/ipd/mhc. Both *Mhc-I* and *Mhc-II* genes, like many other mammalian genes, reflect the protein structure by an exon/domain correspondence (*331*).

Identification of Peptides Bound by MHC Molecules

Many different lines of evidence coalesced over a short period of time to demonstrate that MHC molecules function by binding peptides. From functional experiments, MHC-II–restricted T-cell responses to protein antigens were shown to be dependent on peptide fragments (*332*). The first direct evidence of MHC–peptide interactions came from the demonstrations that purified MHC-II proteins could bind synthetic peptides in a specific, saturable, and stable manner (*333,334*) with measurable affinity, and remarkably slow dissociation rate (*334*). For MHC-I molecules, the results were at first less clear, but the realization that some cell lines defective in MHC-I surface expression could be induced to express higher levels of surface MHC-I molecules by exposure to the appropriate peptides (*335,336*) led the way for direct measurement of MHC-I peptide binding (*337*).

Several laboratories succeeded in developing methods for the partial purification and identification of the peptides that copurified with MHC molecules. One approach for identifying the peptide derived from a virus that was bound by the MHC-I molecule H2-K^b involved recovering

[a] Peptide-binding motifs for the indicated MHC-I molecules are shown in the single amino acid code. Position refers to the amino acid position of the peptide from the amino terminus. Only the most common residues are shown. Assignments in parentheses are less common than the others. These motifs are taken from the more extensive summary of http://syfpeithi.bmi-heidelberg.com/ and from the extensive description (*477*). Also see www.cancerimmunity.org/peptidedatabase/differentiation.htm and www.immuneepitope.org/home.do.

MHC molecules from infected cells, fractionating the bound peptides chromatographically, identifying a peak of functional biological activity in a cytotoxic T-cell assay, and determining the amino acid sequence of the recovered peptide by radiochemical techniques (338). Another method that was useful for identifying both viral-derived peptides as well as the "motif" of self-peptides by particular MHC-I molecules involved first the isolation of a large amount of detergent-solubilized MHC-I using appropriate antibodies, the elution of the bound peptides, their partial purification as pools by reverse-phase high-pressure liquid chromatography, and the determination of the amino acid sequence of the bound peptides by classic Edman degradation of the peptide pools (339,*340,341*). The unpredictable and surprising result obtained from these studies of MHC-I–derived peptides was that specific amino acid residues were favored at particular positions of the sequence, depending on the MHC-I molecule from which the peptides were obtained, and that the length of the bound peptides was well defined and short, ranging from 8 to 10 amino acids. From such experiments, a number of peptide "motifs" of peptides bound to particular MHC-I molecules and allelic products were identified. Often, specific amino acids were identified at particular Edman degradation steps, indicating a common, highly preferred residue at the same spacing from the amino terminus of the peptide. Thus, the peptide "motif" could be determined even from heterogeneous pools of peptides eluted

from particular MHC-I molecules. Further refinements in methodology included the application of mass spectrometry to the identification of individual peptides and their sequencing (*342,343*). Alternative approaches for identifying peptide motifs include the use of soluble analogs of MHC-I molecules to ease the purification (*344,345*) or the use of peptide display libraries to identify those peptides that can bind the MHC (*346,347*). A summary of MHC-I peptide motifs is given in Table 19.8. An online database that is regularly maintained is available (http://syfpeithi.bmi-heidelberg.com) (*348*). Antigenic peptides that represent those observed as tumor antigens, and available for recognition by T cells, are summarized at www.cancerimmunity.org/peptidedatabase/differentiation.htm. In addition, the immune epitope database (www.immuneepitope.org) (*349*) offers a regularly updated and curated Web site that describes MHC motifs, allows evaluation of new proteins for MHC epitopes, and provides new computational tools for such evaluation. An algorithm that allows the prediction of candidates for MHC-I–restricted peptides based on the amino acid sequence of the protein of interest is also available (www-bimas.dcrt.nih.gov/molbio/hla_bind/index.html) (*350*). The distinction between "motif" residues of an MHC-restricted peptide and "anchor" residues is an important one. "Motif" refers to those amino acid residues that are identified based on the sequences of self- or antigenic peptides that have been demonstrated to bind or copurify with

[a] MHC-II peptide-binding motifs. These are drawn from the more extensive summary of (477) and from http://syfpeithi.bmi-heidelberg.com.

[b] As indicated, the peptide positions are relative, with i being the amino acid residue that is thought to be situated in pocket P1, I + 1, P2, and so forth.

[c] No motif assigned because of great variation in alignment possibilities.

[d] Motif assigned based on structural similarity to IEd and IEk (478).

a particular MHC molecule. "Anchor" implies a biophysical function of the particular amino acid residue as interacting specifically with a particular part of the MHC molecule itself. The designation of a residue as an anchor residue may be inferred by analysis of binding to peptide variants in the context of the parental peptide. Alternatively, anchors can be defined from a knowledge of the x-ray structure of the peptide complexed to the MHC-I molecule, and predictions of likely peptide motifs for MHC molecules whose sequence is known but whose structure has not yet been determined can be made by comparison to known structures.

The identification of MHC-II–bound self- or antigenic peptides by biochemical methods similar to those employed for MHC-I molecules has proved more difficult, because the MHC-II molecules do not have the rigorous requirement for a defined amino terminus or the restricted length that MHC-I molecules need. Whereas MHC-I molecules bind peptides with a particular motif residue at a specific position as defined by the amino terminus, resulting in the ability to identify the dominant residue at a particular step in the Edman degradation, even amidst a pool of peptides, MHC-II molecules bind peptides with "ragged ends," and little information is obtained from the sequencing of pools of peptides (351–354). Identification of MHC-II peptide-binding motifs by bacteriophage display is also possible (355). In accord with the view that MHC-II molecules present peptides derived from an "outside-in" pathway, many of the peptides that copurify with MHC-II molecules represent molecules derived from the extracellular milieu of the medium in which the cells were grown. Analysis of MHC-II/peptide complexes with cloned T cells and monoclonal antibodies with

MHC/peptide specificity reveals that, in part because of the ability of MHC-II molecules to accommodate peptides with extensions at their amino and carboxyl termini, and in part because of the smaller role that anchor residues seem to play in peptide binding by MHC-II molecules, occasionally even a unique peptide can bind a particular MHC-II molecule in more than one frame (356–358). As a result of structural studies (summarized later) and compilation of peptide sequences of those peptides bound by particular MHC-II molecules, the general conclusion is that MHC-II molecules all have binding pockets identifiable for the particular allelic product. For some alleles, such as HLA-DR1 and IA[d], these pockets are spaced at position P1, P4, P6, and P9 (or i, i + 3, i + 5, i + 9). Because of the complexity and potential degeneracy of peptide motifs for MHC-II molecules, more elaborate schemes have been devised for prediciting those peptides that may bind to particular MHC-II molecules (359). A summary of identified peptide-binding motifs for MHC-II molecules is given in Table 19.9.

High-Resolution Crystallographic Structures

MHC-I Molecules

The most graphic description of the relationship of form and function of the MHC molecule was first made by Bjorkman and colleagues, who determined the three-dimensional structure of the human MHC-I molecule, HLA-A2, by x-ray crystallography (360,361). The extracellular, soluble portion of the membrane-associated molecule was cleaved from the surface of tissue culture

cells by papain and further purified. At the time, there was not a clear appreciation of the role of peptide either in the assembly of the molecule or of the nature of the recognition of the MHC molecule by TCRs or, for that matter, NK receptors. Despite the fact that the first purified HLA-A2 molecules possessed a heterogeneous mixture of bound peptides, protein from these preparations crystallized readily, and electron density maps calculated from the diffraction data were interpretable, allowing modeling of the backbone molecular structure. The most important insight in the interpretation of the electron density map derived was that part of the density, and thus part of the structure, was due to a heterogeneous collection of peptides bound tightly by the molecule, and that this density could not be modeled based on the known amino acid sequence of HLA-A2.

This first MHC-I structure clarified several important aspects of the mechanism by which the MHC-I molecule carries out its peptide-binding function. The amino-terminal domains ($\alpha1$ and $\alpha2$) form a unitary binding site for peptide. This domain unit consists of a floor of eight strands of antiparallel β-pleated sheet, which supports two α-helices, one contributed from the $\alpha1$ domain and one from the $\alpha2$ domain, aligned in an antiparallel orientation. The membrane-proximal $\alpha3$ domain has an immunoglobulin C-type fold (27), and pairs asym-

metrically with the other immunoglobulin domain of the molecule contributed by $\beta2$m. The nature of recognition by T cells was suggested by comparing the location of those amino acid residues that had been characterized as being strong elements in T-cell recognition, residues that distinguished closely related allelic gene products and amino acid residues that had been identified as those that were responsible for the transplant rejection of the mutants of the *H2-K*[b] series (361). Amino acid residues of the MHC-I molecule responsible for T-cell recognition were most clearly classified into one of two categories, or an overlapping set: those residues that were "on the top of the molecule," exposed to solvent and available for direct interaction with the TCR, and those residues whose side chains pointed into the peptide-binding groove and might be considered crucial in the peptide-binding specificity of the particular MHC molecule. The original publications, based on a structure determined to a resolution of 3.5 Å, focused mainly on the structural outline of the molecule. More recent structures have been determined of HLA-A2 complexed with specific peptides at higher resolutions. Ribbon diagrams of HLA-A2 as seen from the side (Figure 19.6A) and from the top (Figure 19.6B) indicate how the entire structure of the molecule is designed: the peptide-binding site is supported by the β-sheet floor, and the floor in turn is supported by the two
FIGURE 19.6 Structure of HLA-A*0201. **A:** Ribbon representation of HLA-A2 heavy chain (green), $\beta2$m light chain (cyan), and bound peptide (yellow). **B:** Ribbon representation of the peptide-binding groove. **C:** Surface representation of the binding groove, with pockets labeled. **D:** Surface representation of binding groove with peptide shown in stick illustration. immunoglobulinlike domains, the α3 domain of the heavy chain and the β2m light chain.

The comparison of this structure and higher-resolution refinement of it to that of the closely related human MHC-I molecule, HLA-Aw68 (now known as HLA-A68 or, more accurately, HLA-A*68011; see Table 19.2), suggested that surface depressions in the groove of the MHC-I molecule, now known as pockets A through F, would be available for interactions with some of the side chains of the bound peptide (*362,363*). These six pockets are illustrated in Figure 19.6C and with bound peptide in Figure 19.6D. These MHC-I structures were determined of molecules purified from tissue culture cells and containing a heterogeneous spectrum of self-peptides. Concurrently with the structural studies, a number of laboratories developed methods to identify the motifs of peptides bound by particular MHC-I molecules (see earlier discussion of MHC-bound peptides). Concomitant with the determination of the x-ray structure of the human MHC-I molecule, HLA-B*2705 (*364*), the motif of the peptides that were recovered from this molecule was determined, permitting the more precise modeling of the bound peptide in the cleft of the MHC-I (*365*). For HLA-B27 this was of particular interest because the bound peptides had a strong overrepresentation of arginine at position 2, and scrutiny of the HLA-B27 structure suggested that the amino acid residues lining the B pocket, particularly glutamic acid at position 45 as well as cysteine 67, were complementary to the long, positively charged arginine side chain of the peptide amino acid at that position (*364*). These structural studies supported a view of MHC-I/peptide binding in which the side chain of the carboxyl-terminal residue of the bound peptide sits deep in the F pocket. In addition, the amino-terminal amino group forms strong hydrogen bonds with the hydroxyl groups of conserved amino acids tyrosine 59 and tyrosine 171. A hydrogen bond from the amino group of conserved tryptophan 147 to the backbone carbonyl oxygen of the penultimate peptide amino acid (usually position 8) also seems to be important, as do charge interactions and hydrogen bonds of the free carboxyl group at the carboxyl terminus of the peptide with tyrosine 84, threonine 143, and lysine 146.

Other structures of MHC-I molecules were determined of complexes produced with homogeneous peptide, assembled either in vitro from bacterially expressed proteins with synthetic peptide (*366*), or exploiting MHC proteins expressed in insect cells (*367,368*). The structures determined with homogeneous peptide confirmed the impression obtained from the structures obtained from molecules with heterogeneous self-peptides. The structures of the H2-K^{b} molecule complexed with synthetic peptides derived either from Sendai virus, vesicular stomatitis virus, or chicken ovalbumin revealed that the same MHC molecule can bind peptides of different sequences, lengths, and structures by virtue of their conserved motif residue side

chains. Although small conformational changes of the MHC are detectable on binding the different peptides, the main distinction in the recognition of different peptides bound by the same MHC molecule is a result of the location, context, size, and charge of amino acid side chains of the peptide displayed when bound by the MHC molecule.

The most consistent rule learned from the first x-ray structures and complemented by peptide recovery and early binding studies was that MHC-I–bound peptides were required to embed the side chain of their carboxyl-terminal amino acid into the F pocket. However, with further studies, it became clear that MHC-I molecules could bind longer peptides that extended beyond the residue anchored in the F pocket (*369*), a view that was confirmed by a crystallographic structure (*370*). More recently, the lack of an absolute requirement for a free C-terminal amino acid has been exploited in the engineering of a single-chain peptide, β2m, H2-K^{b} molecule that shows unusual stability and is an effective MHC/peptide immunogen (371). An additional variation on the theme of MHC-I–binding peptides based on particular anchor residues includes the demonstration that glycopeptides, bound to the MHC-I via amino acid side chains and termini, can expose their carbohydrate moieties to solvent and be available for TCR interaction (*372–374*). An example of a 13-residue peptide bound to its MHC-I–presenting element, the rat MHC-I molecule, RT1-Aa, was crystallized and shown to produce a peptide/MHC complex with a large central bulge. Two different complexes consisting of the same MHC and peptide reveal significantly different conformations in this central bulge region (*375*). Bulged viral peptides have also been characterized in complex with human MHC-I structures of HLA-B35 allotypes complexed with 13-mer and 11-mer peptides (*376,377*). TCR recognition of "bulged" peptides can involve conformational adjustments of the TCR in recognizing fairly rigid bulged peptide (*378*) or "crumplings" of the bound peptide by a largely rigid face of the TCR upon binding the MHC-I/p complex (*379*).

MHC-II Structures

Before any MHC-II structure had been determined experimentally, a model was constructed based on the alignment of amino acid sequences and the available MHC-I three-dimensional structure (*380*). This model made several valid predictions that were borne out by the subsequent x-ray structure determination of HLA-DR1 (*381*). MHC-II clearly showed similarity to MHC-I and formed its binding groove by the juxtaposition of the α1 and β domains. The position of the electron density representing the heterogeneous peptide that copurified with the HLA-DR1 was identified. Figures 19.7A and C show a ribbon diagram of HLA-DR1 with a homogeneous bound peptide. In comparison to the MHC-I structure (Figure 19.6), the peptides bound to the MHC-II molecule extend through the
FIGURE 19.7 Color ribbon representation of HLA-DR1. **A:** Side view; α chain is in green, β chain is in blue, peptide in stick representation is in yellow. **B:** Top view. **C:** Top view with bound peptide (PKYVKQNTLKLAT) visualized. The illustration was made with PyMol (*509*) based on the protein data bank (*508*) coordinates of 1DLH. (See color insert.)

binding groove, rather than being anchored in it at both ends.

A comparison of the α-carbon backbone of the peptide-binding region of an MHC-I structure with that of an MHC-II structure is shown in Figure 19.8. It is remarkable that the structures are so similar, whether the binding domain is built of the $\alpha 1$ and $\alpha 2$ domains from the same chain (for MHC-I) or of the $\alpha 1$ and $\beta 1$ domains that derive from two chains (for MHC-II). The location of polymorphic residues can be determined by variability plots based on multiple sequence alignments as originally suggested by Kabat and Wu (*382*). Comparative ribbon diagrams (Figure 19.9), in which the locations of the amino acid residues that are polymorphic for the human MHC-I and MHC-II chains are indicated, show that the bulk of the polymorphism derives from amino acid variability in regions that line the peptide-binding groove. This suggests that MHC polymorphism is required to allow the MHC molecules, and as a result, the organism and its species, to respond to a changing antigenic environment.

As with MHC-I, a further understanding of the details of the interactions of peptides with the MHC-II molecule came from crystallographic studies of molecules prepared
FIGURE 19.8 Superposition of the α-carbon backbones of an MHC-I [PDB (*508*)], 3HLA (*363*), and an MHC-II [1DLH (*383*)] molecule. The backbone tracings were displayed and superposed with QUANTA 97 (Molecular Simulations, Inc). MHC-I is shown in blue, MHC-II in red. Amino termini are labeled N. (See color insert.)

FIGURE 19.9 Location of polymorphic amino acid residues in MHC-I and MHC-II molecules. Variability plots were calculated according to the method of Kabat and Wu (*382*) and the level of variability illustrated on ribbon diagrams. Generated in QUANTA 2000 (Accelrys) of 3HLA (*363*) (HLA-class I), 1DLH (*383*) (HLA-DR), and 1JK8 (*510*) (HLA-DQ), where greatest variability is red, intermediate is green, and least is blue. (See color insert.)
FIGURE 19.10 Location of pockets in HLA-DR1 based on the cocrystal of HLA-DR1 with a peptide derived from the influenza hemagglutinin. The surface representation of the molecule, looking into the cleft, is shown colored based on electrostatics—red, acidic; blue, basic. Numbering of the major binding pockets of HLA-DR1 is according to (383). (See color insert.)

FIGURE 19.11 Ribbon diagram of the structure of HLA-DR1 showing the dimer of dimers and the individual domains of the protein. α chains are in blue and *I*, β chains are in red and green. Peptide is in red. The illustration was generated from 1DLH (383) in MOLSCRIPT (*511*) and rendered in RASTER3D (*512*). (See color insert.)

with homogeneous peptide, in the first case HLA-DR1 complexed with an antigenic peptide derived from the hemagglutinin of influenza virus (383). Figure 19.7 shows side (panel A) and top (panels B and C) views of HLA-DR1 bound to an influenza peptide. Based on this structure, a set of pockets was initially designated, numbered for the peptide position that is bound. For the influenza peptide studied in this example, the major interactions were from peptide positions 1, 4, 6, 7, and 9, which are indicated in Figure 19.10. The deep P1 pocket accommodates the tyrosine (the third position of the peptide PKYVKQNTLKLAT) and the pockets indicated by 4, 6, 7, and 9 fit the Q, T, L, and L residues, respectively. The MHC-II is similar in its mode of binding to MHC-I but reveals key differences: the lack of requirement for free amino and carboxyl termini of the peptide, the binding of the peptide in a relatively extended conformation (like that of a type II polyproline helix), and a number of hydrogen bonds between conserved amino acids that line the binding-cleft main-chain atoms of the peptide.

Among the most provocative observations from the first MHC-II structures was that the molecule was visualized as a dimer of dimers, and this moved a number of investigators to consider the possibility that activation of the T cell via its receptor might require the dimerization or multimerization of the TCR, an event thought to be dependent on the propensity of the MHC/peptide complex to self-dimerize. The simple elegance of this dimer of dimers is illustrated in Figure 19.11. Several arguments support the dimerization hypothesis: the finding of a dimer of dimers in the crystals of HLA-DR that formed in sev-

eral different space groups (*381*,383), the observation that a TCR Vα domain formed tight dimers and in its crystals formed dimers of the dimers (*384*), the demonstration of the ability to immunoprecipitate MHC-II dimers from B cells (*385*), the apparent requirement for purified MHC-I dimers for stimulation of a T cell in an in vitro system (*386*), and the finding that MHC-II/peptide/TCR complexes could form higher-order multimers in solution as detected by quasi-elastic light scattering (*387*). However, a number of strong counterarguments draw this hypothesis into question. MHC-II molecules other than HLA-DR1 that have been crystallized do not seem to form the same kind of dimer of dimers in their crystals (*388,389*). None of the MHC-I molecules that have been examined by x-ray crystallography shows dimers in the same orientation as the MHC-II ones reported. A different Vα domain fails to dimerize even at high concentration (*390*). The reported x-ray structures of TCR/MHC/peptide complexes (*391,392,393,394*) fail to show dimerization. Despite the simple elegance of the dimer hypothesis, it is clear that additional experimentation will be required to understand the topologic requirements for T-cell activation through the $\alpha\beta$ TCR.

Recent additions to the library of MHC-II structures include the I-A^{g7} molecule, a unique MHC-II that provides one link in the susceptibility to insulin-dependent diabetes in the mouse model (*395,396*). Although the structure fails to provide direct evidence to explain the linkage to diabetes, it suggests that the novel repertoire of peptides

bound by this MHC-II molecule reflects unique features of its wider peptide-binding groove and resulting relatively low-affinity interaction with peptide.

MHC-Ib Molecules

H2-M3

To this point, our description of MHC-I molecules has focused on the classical molecules, represented by HLA-A, HLA-B, and HLA-C in the human and by H2-K, H2-D, and H2-L in the mouse. Several MHC-Ib molecules, for which three-dimensional structures have been determined, are of particular interest: the CD1 molecules (*397,398*), H2-M3 (*399,400*), MICA (*401,402*), nFcR (*403*), Rae-1 (*404*), H-60 (*186*), MULT1 (*405*), and MR1 (406). H2-M3 is of particular note because of its ability to bind and present peptide antigens that contain amino-terminal N-formyl groups. H2-M3 was originally identified as the MHC-Ib molecule that presents an endogenous peptide derived from the mitochondrially encoded protein ND1 that has been called MTF (maternally transmitted factor) (*150,407*). Thus, it was of interest to understand in structural terms how this molecule binds such N-formylated peptides (*400*,408). The crystal structure of H2-M3 complexed with an N-formylated nonamer peptide, fMYFINILTL, revealed that the structure of the A pocket, highly conserved among MHC-Ia molecules, which have tyrosine 7, tyrosine 59, tyrosine 159, tryptophan 167, and tyrosine 171, is quite different, so that it can accommodate the N-formyl group in the A pocket. In particular, H2-M3 has hydrophobic residues, leucine at 167 and phenylalanine at 171, and because of the side-chain orientation of leucine 167, the A pocket is dramatically reduced in size, causing the amino-terminal nitrogen of the formylated peptide to be positioned where the peptide position 2 amino nitrogen would lie in a MHC-Ia molecule. Thus, the unique peptide selectivity of H2-M3 is explained in structural terms.

CD1

Another MHC-Ib molecule of great interest is CD1, representative of a class of MHC-I molecules that map outside of the MHC, that have limited tissue specific expression, and that seem capable of interaction with both $\alpha\beta$ and $\gamma\delta$ T cells (*409*). In the human, there are two clearly distinct groups of CD1 molecules: one consisting of CD1a, CD1b, CD1c, and CD1e; and another of CD1d alone (*410*). CD1a, CD1b, and CD1c are capable of binding and presenting various nonpeptidic mycobacterial cell wall components such as mycolic acid–containing lipids and lipoarabinomannan lipoglycans (*411,412*). A minor subset of $\alpha\beta$-bearing T cells, believed to be an independent lineage, and defined by the expression of the NK1.1 marker and known as NKT cells, is restricted to CD1 recognition (*413*). The crystal structure of mouse CD1d1, which corresponds to human CD1d, has been determined (*397*), revealing a classic

MHC-I structure with a basic α-carbon fold and β2m association quite similar to that of the MHC-Ia molecules. Remarkably, this molecule was purified without the addition of either exogenous lipid or peptidic antigen, but the crystallographic structure revealed some poorly defined electron density in the binding-cleft region. Consistent with its apparent biologic function of binding hydrophobic lipid-containing molecules, its binding groove is somewhat narrower and deeper than that of either MHC-Ia molecules or MHC-II molecules. The backbone configuration of the α1 α2 domain structure of CD1 is shown in Figure 19.12, where it is compared to the homologous region of H2-K^b, HLA-DR1, and another MHC-Ib molecule, FcRn, a neonatal Fc receptor. To get a three-dimensional understanding of the shape and charge distribution of the peptide-binding grooves of several examples of MHC-Ia, MHC-Ib and MHC-II molecules, Zeng et al. (*397*) displayed a surface representation of the binding regions with electrostatic potentials mapped to that surface (Figure 19.13). Despite the narrowness of the entrance to the groove resulting from the distance between the α helices, the CD1-binding groove, because of its depth, has the largest volume. The depth of the groove results from the merging of pockets to form what have been termed the A′ and F′ pockets in place of the MHC-Ia A through F pockets (see Figure 19.6C). This A′ pocket is about the size of the binding site of a nonspecific lipid-binding protein. For comparison, the groove of H2-M3, with a small charged A pocket, and deep B and F pockets, is shown. An example of an MHC-Ia molecule, H2-D^b (*414*), shows how different charge distribution occurs in molecules of this group, and the depiction of HLA-DR1 reveals the depth of side-chain pockets there. The very narrow groove of FcRn (see later) appears to lack sufficient space to accommodate a conventional peptide antigen.

In an effort to understand more precisely how CD1 molecules bind lipid antigens, Gadola et al. crystallized human CD1b complexed with either phosphatidylinositol (PI) or ganglioside GM2 (GM2) and determined their x-ray structures (*398*). The structures were essentially identical for the CD1b heavy chain and β2m in the two complexes and revealed a network of four hydrophobic channels at the core of the α1 α2 domain, which accommodates four hydrocarbon chains of length from 11 to 22 carbon atoms. These channels are called A′, C′, and F′ for the three analagous to the A, C, and F pockets of the MHC-Ia molecules, and a fourth, termed T′, which is a distinct tunnel. An illustration of the binding groove with the bound alkyl chains is given in Figure 19.14, which shows orthogonal views of the binding pocket of CD1b (panel A) and compares these with the pocket of CD1d with the hydrocarbon chains superposed (panel B). These features illustrate quite elegantly how the binding site of a classical MHC-I molecule may have evolved from (or to) the binding site of a molecule such as CD1 to provide antigen selectivity for
FIGURE 19.12 Comparison of the α-carbon backbone tracings and size of the potential peptide-bindng cleft of MHC-I molecule H2-K^b, MHC-II HLA-DR1, and MHC-Ib molecules CD1d, and FcRn. (From (*397*), with permission.) (See color insert.)
FIGURE 19.13 Shape, size, and charge of the binding groove of CD1d compared with those of several other MHC molecules and with a lipid-transport protein. Surface representation of the ligand-bindng cleft is displayed with acidic regions in red, basic regions in blue, and hydrophobic regions in green. (From (*397*), with permission.) (See color insert.)

a distinct set of molecules that would be common to a set of important mycobacterial pathogens.

FcRn

Another example of an MHC-Ib molecule, noteworthy because it serves as an example of a novel function of MHC molecules, is the neonatal Fc receptor. Originally described in the rat as a molecule of the intestinal epithelium that is involved in the transport of colostral immunoglobulin from the lumen to the bloodstream (*415,416*), homologs in the mouse and human have also been described (*417–419*), and the structure of the rat molecule has been determined crystallographically (*403*) (Figure 19.15). As suggested by the amino acid sequence similarity of the FcRn to MHC-I proteins, the three-dimensional structure revealed considerable similarity to MHC-Ia molecules (*403*). Specifically, $\alpha 1$ and $\alpha 2$ domains have similar topology to the MHC-I molecule, although, as we discussed earlier, what would be the peptide-binding groove in the MHC-Ia molecules is

closed tightly and lacks space sufficient for a ligand. The most provocative feature of the structure of the FcRn/Fc complex is that the MHC-I–like FcRn interacts with the Fc through contacts from the $\alpha 2$ and $\beta 2m$ domains to interact with the Fc $C\gamma 2$–$C\gamma 3$ interface. As compared to the structure of the unliganded Fc, the complex reveals both conformational changes in the Fc and the presence of several titratable groups in the interface that must play a role in the pH-dependent binding and release of Ig molecules from the FcRn. The FcRn has taken the MHC-I fold and diverted its function to an interaction with the Fc of the immunoglobulin. Amino acids at what would classically be considered the "right-hand side" of the peptide-binding groove make contact with the Fc interface that lies between the $C\gamma 2$ and $C\gamma 3$ domains. The FcRn serves as an excellent example of similar structures in the immune system being diverted for an alternative purpose. The importance of the FcRn has been underscored by the recent observations of differences in the serum half-life of immunoglobulin in

FIGURE 19.15 Structure of the FcRn complexed with Fc. Ribbon diagram of the FcRn (purple), $\beta 2m$ (green) interacting with the Fc (magenta and brown) heterodimer consisting of the wild-type (wt) and nonbinding (nb) engineered chain. For comparison, the homodimer of the nbFc is shown on the right. These are PDB (*508*) files, 1I1A and 1I1C (*513*), respectively. (From (*513*), with permission.) (See color insert.)
animals that, as a result of an induced deletion of β2m, lack the normal expression FcRn as well, and seem to metabolize serum immunoglobulin aberrantly (*420*).

MHC-Iv Molecules

MHC and structurally related molecules are produced not only by vertebrates but also by cytomegaloviruses, large DNA viruses of the β-herpesvirus family that have coevolved with their vertebrate hosts over millennia and are exquisitely adapted to survive and persist in the face of host immune responses. Viral MHC-I–like molecules have been identified bioinformatically from amino acid sequences of the open reading frames predicted from genome sequence data. In some cases, such as the UL18 protein of human cytomegalovirus (HCMV) and the m144 protein of mouse cytomegalovirus (MCMV), the sequence homology to bonafide MHC-I molecules is sufficiently strong to identify them unambiguously as MHC-I–like. However, in most cases, such as with the m145 family of MCMV, the sequence homology to MHC-I is very weak and relatedness to MHC-I is based on structure prediction algorithms alone. We term these virally encoded MHC-I–like molecules MHC-Iv to reflect their distinct evolutionary history, their structural deviation from typical MHC-I molecules in some cases, and their role in evading host immune responses. A survey of DNA sequences of 11 genes obtained from 26 wild murine cytomegalovirus isolates and laboratory strains indicated that several of the *MHC-Iv* genes (m144, m145, and m155) revealed significant sequence variation, consistent with the view that this variation may offer some immune-evasive benefit to the virus (*421*).

Structural characterization of MHC-Iv molecules begins with an evaluation of the requirement for β2m and/or peptide for stable expression. UL18 is associated with both β2m and peptide, whereas m144 is associated only with β2m. The structure of m144 has been reported (27), revealing the preservation of all structural elements of the MHC-I fold (Figure 19.16). The cleft of m144 does not seem capable of binding peptides, as the groove is narrow and critical tyrosine residues are not conserved. A unique disulfide anchors the α1 helix to the β sheet. Recently, the structure of m157, a cytomegalovirus MHC-I–like immunoevasin that binds the Ly49H activation receptor of C57BL/6 mice and the Ly49I inhibitory receptor of 129/J mice, has been reported (422). This β2m-independent, peptide-free MHC-Iv molecule reveals the major features of the MHC-I fold with some unique aspects. How it binds its Ly49 ligands remains unclear. The m153 protein of MCMV, also a member of the m145 family, reveals novel adaptations of the MHC-I fold (*423*). The m153 protein does not require β2m or peptide and, in contrast to other MHC-I molecules, is a noncovalent dimer. The monomers are associated in a head-to-tail fashion. An extended unstructured N terminus contains a unique disulfide that anchors it to the α3 domain. The m153 structure hints tantalizingly of more surprises to come as structures of other MHC-Iv molecules become available.
In those cases where functions have been elucidated, MHC-1v molecules have been shown to act as immunoevasins that inhibit NK cells to enable virus survival and persistence in the host. Both UL18 and UL142 inhibit human NK function, the former by binding to the inhibitory receptor LIR-1. The mode of action of UL142 remains to be determined. The m157 binds to the inhibitory receptor Ly49I in mouse strains that are susceptible to viral infection. The m144 protein has also been shown to inhibit NK activation, but the ligand remains to be identified.

Mill MHC–like Molecules

A novel set of MHC-Ib–like genes designated *Mill* (MHC class I–like located near the l̲eukocyte receptor complex) has recently been identified in both mice and rats (*424–426*). These encode MICA/B-like glycophosphatidylinositol-linked cell surface molecules that are associated with β2m and do not require TAP for cell surface expression. Their function remains unclear.

Complexes of MHC Molecules with Ligands

Our structure/function survey will be completed by brief descriptions of the interactions of MHC-I and MHC-II molecules with $\alpha\beta$ TCRs, with the T-cell coreceptors CD8 and CD4, and of MHC-I molecules interacting with NK receptors. MHC-I molecules, MHC-Ia, MHC-Ib, and MHC-Iv, offer a unique challenge to the student and investigator to keep track of which MHC molecule binds which other receptor and with what function. Although a complete description of these many interactions is beyond the scope of this chapter, Table 19.10 offers a compilation of the human MHC-I and MHC-I–like molecules and their known cognate receptors. A description of interactions of MHC-II molecules with superantigen follows. Each of these

FIGURE 19.16 Structure of the MHC-Iv molecule, m144 (27), is shown. Heavy chain is in magenta, β2m light chain is in blue. (See color insert.)

structural studies complements a host of biologic experiments that have led to an appreciation of the importance of understanding the structural basis of these immune reactions.

MHC/TCR Interactions

Perhaps the most exciting of the recent structural observations has been the solution of x-ray structures of MHC molecules complexed with both specific peptides and TCR. This has been accomplished in several systems (391,392,*393,427,428*). The first examples were of MHC-I–restricted TCR, one from the mouse (392) and one from the human (391). The mouse MHC-I molecule H2-K^b was analyzed in complex with a self-peptide, dEV8, and a TCR known as 2C (392,429), and the human HLA-A2 complexed with the Tax peptide was studied with its cognate TCR derived from a cytolytic cell known as A6 (391). These structures offered a consistent first glimpse at the orientation of the TCR on the MHC/peptide complex, but additional structures, including one involving a murine MHC class II–restricted TCR, suggest that more molecular variations may exist. As a canonical example of the MHC/peptide/TCR complex, we include an illustration of the H2-K^b/dEV8/2CTCR complex (429) (Figure 19.17). Another view of this mouse TCR as mapped onto its cognate MHC/peptide complexes is illustrated in Figure 19.18. This illustration shows that the complementarity-determining regions (CDRs) of the TCR (labeled 1α2α3α for CDRs of Vα and 1β2β and 3β for the CDRs of Vβ, respectively) sit symmetrically on the MHC/peptide complexes. For the 2C/H2-K^b/dEV8 complex (Figure 19.18), the region contacted by the CDRs of the Vα domain of the TCR lies to the left and that contacted by the CDRs of the Vβ domain lies to the right. The regions contacted by CDR3, labeled 3α and 3β, are at the center of the bound peptide, while the regions contacted by CDR1 and CDR2 of both Vα and Vβ lie peripherally. Footprints of other TCRs have been reviewed elsewhere (314).

With the publication of additional MHC/peptide/TCR structures (314), several additional points have emerged: (a) There is considerable variability in the orientation of the TCR Vα and Vβ domains with respect to the MHC/peptide complex. Although the first MHC-II/peptide/TCR structure suggested that an orthogonal disposition, in which Vβ makes the great majority of contacts with the MHC-II α1 domain and the Vα interacts predominantly with the β1 domain, might be the preference for MHC-II/TCR interactions (*393*), additional MHC-II/peptide/TCR structures (*394,427*) suggest that this disposition is not indicative of MHC-I as compared to MHC-II but rather reveals the wide variety of possibilities. (b) Considerable plasticity in the conformation of the CDR loops of the TCR, particularly long CDR3 loops, is observed in the comparison of TCRs free or bound to their cognate MHC/peptide ligands (429,*430*). A striking example of this is illustrated

by the structure of the KB5-C20 TCR alone as compared to its complex with H2-K^b/peptide (Figure 19.19).

Recent Structural Insights into Alloreactivity

During T-cell development, TCRs destined to be useful to the host are selected for weak reactivity with one or more self-peptides complexed with cell surface host major histocompatibility (MHCp) molecules. TCR selection is customized in each individual because of extensive polymorphism in MHC molecules that is designed to diversify peptide repertoire and optimize immune responsiveness. Thymic selection and MHC polymorphism combine to generate antimicrobial T-cell responses that are genetically restricted to recognizing host MHC molecules while retaining Ag specificity. MHC-restriction has been a central paradigm of T-cell immunity and was the basis for the 1996 Nobel Prize awarded to Peter Doherty and Rolf Zinkernagel.

Unfortunately for transplant clinicians and their patients, the rule of MHC restriction is violated when T cells are exposed to allogeneic MHC/p complexes. Remarkably, up to 10% of naive T cells react strongly against allogeneic MHC/p in vitro (mixed lymphocyte reaction) and in vivo, leading to allograft rejection and graft-versus-host disease. This reaction, known as T-cell alloreactivity, is why MHC molecules were initially called transplantation or histocompatibility molecules and has puzzled immunologists for decades.

There are two main historical theories to explain the high frequency of alloreactive T cells. The first, proposed in 1977 by Matzinger and Bevan, postulated that a single allogeneic MHC molecule could give rise to multiple binary complexes with cell surface molecules, creating "neoantigenic" determinants recognized by clonally distinct T cells. This has been reinterpreted in a "peptide-centric" hypothesis whereby a single MHC molecule presents disparate peptides recognized by multiple different T-cell clones. The "multiple binary complex" model implies that the TCR interacts with a set of amino acids shared by self- and allogeneic MHC molecules, so the cross-reaction depends crucially on the peptide antigen. However, Bevan later suggested that alloreactive T cells might focus on polymorphic residues exposed on the allogeneic MHC molecule itself, the "high determinant density" model in which the TCR focus is "MHC-centric" and the peptide is largely irrelevant.

Recently, Garcia and colleagues have solved the structure of the 2C TCR in complex with its known allogeneic ligand, H2-L^d-QL9 and then compared it to the structure of 2C in complex with its positively selecting ligand, H2-K^b-dEV8, and thus were able to provide important insight into the structural basis of alloreactivity (431). These two TCR footprints were typical of known TCR-MHC/p structures but differed from each other in a number of ways. For instance, each chain of 2C made contact with one MHC

α-helix of H2-L^d-QL9, whereas both chains contacted both α helices in H2-K^b-dEV8. The geometry of 2C adopted a more perpendicular orientation on H2-L^d-QL9 and there was a relative rotation of H2-K^b-dEV8 by 20 degrees. The alloreactive complex reveals that both peptide-centric and MHC-centric interactions underpin direct T-cell allorecognition by the 2C receptor, but with a heavy emphasis on MHC-centric interactions. Most surprising, however, was the small number of shared contacts between the two structures, implying a limited role for mimicry between cognate and allogeneic MHC/p. H2-K^b and H2-L^d have 31 amino acid differences and there is no sequence similarity between the H2-K^b–restricted octamer self-peptide dEV8 and the H2-L^d–restricted nonamer QL9. Given these differences, it was a fair bet that the cross-reactivity of 2C on H2-K^b-dEV8 and H2-L^d-QL9 would depend on plasticity in the CDR3 regions of the TCR as documented in comparisons of bound and free TCRs, including 2C. Surprisingly, this was not the case, as the TCR actually adopted very similar conformations in the two structures.

The role of molecular mimicry and the relative importance of "peptide-centric" versus "MHC-centric" bias in T-cell allorecognition is likely to vary in different systems. Hence, it is likely that the nature of the polymorphisms between cognate and allogeneic MHC allotypes will affect TCR focus. Thus, closely related MHC allotypes that differ by as little as one amino acid (e.g., H2-K^b mutants in mice; HLA-A2, B44, and B27 families in humans) are set up for MHC mimicry to be a key component of T-cell allorecognition, where *specificity* is likely to be "peptide-centric."

For example, HLA-B*4402 and B*4403 allotypes differ by only a single amino acid and yet stimulate strong mutual allogeneic T-cell responses. Indeed, the potency of T-cell alloresponses between closely related MHC allotypes probably occurs because positive selection of host T cells is purposely designed to create a repertoire responsive to subtle changes in peptide display. Therefore, closely related MHC allotypes, with differences in both peptide repertoire and MHC/p conformation of a shared repertoire, play straight into nature's design for T-cell recognition.

HLA-A2 heavy chain, red, β2m, orange, and peptide (ball-and-stick) are shown in complex with the CD8$\alpha\alpha$ homodimer (red and blue). MOLSCRIPT (*511*) illustration based on the PDB (*508*) file 1AKJ (*82*). (See color insert.)

MHC/Coreceptor Interactions

The major coreceptors for recognition by $\alpha\beta$ TCRs are CD8, which interacts with MHC-I molecules, and CD4, which interacts with MHC-II. Coreceptor function likely plays a role in signaling the T cell in addition to or distinct from any contribution the coreceptor MHC interaction may provide in increasing apparent avidity between the MHC/peptide and the TCR complexes. CD8, the coreceptor on MHC-I–restricted $\alpha\beta$ T cells, exists as a cell surface homodimer of two α chains or a heterodimer of α and β chains and plays an important role both in the activation of mature peripheral T cells as well as in the thymic development of MHC-I–restricted lymphocytes (*432,433*). The three-dimensional structures of human and mouse MHC-I/CD8$\alpha\alpha$ complexes have been reported (81,82). These structures have localized the binding site of the CD8 immunoglobulinlike $\alpha\alpha$ homodimer to a region beneath the peptide-binding platform of the MHC, focusing an antibodylike combining site on an exposed loop of the MHC-I α3 domain. This interaction is illustrated in Figure 19.20, which shows the flexible loop of residues 223 to 229 clamped into the CD8 combining site.

The T-cell coreceptor associated with cells restricted to MHC-II antigens, CD4, has also been the subject of detailed structural studies, in part because of its role as a receptor for attachment and entry of the human immunodeficiency virus, HIV (*434*). The x-ray structure determination of the complete extracellular portion of the molecule (domains D1 through D4) indicates that there is segmental flexibility between domains D2 and D3, and both crystallographic and biochemical data suggest that dimerization of cell surface CD4 occurs (*435*). These results have been interpreted to support a role for CD4-mediated, MHC-II–dependent dimerization in facilitating TCR dimerization and signaling. The geometry that facilitates the CD4/MHC–II/TCR interaction has been suggested by a crystal structure of an MHC-II/CD4 D1D2 complex and the superposition mod-

eling of this with both a TCR/MHC structure and the full structure of the D1–D4 homodimer (78) (Figure 19.21).
MHC/NK Receptor

A cellular system that parallels T cells in recognition of cells altered by oncogenesis or pathogens is that of the innate immune system. The crucial cells that perform
FIGURE 19.21 Model of TCR/MHC-II/peptide complex interacting with CD4. Superposition of MHC-II/CD4 D1D2 structure with that of a complete D1-D4 CD4 structure results in this model suggesting how MHC-II may contribute to multimerization of a TCR/CD4 complex. (From (*78*), with permission.) (See color insert.)

this recognition function are NK cells, and their NK receptors interact with either classical MHC-I molecules on their targets or their structural relatives. In the past several years, not only has our appreciation of the complexity of NK/MHC recognition increased, we have also learned some of the structural and functional details by which different NK receptors identify potentially harmful cells (13,49). In addition to their expression on NK cells, some of the NK receptors are now known to be expressed on subsets of T cells and other hematopoietic cells. The NK receptors in general fall into two major functional categories, activating receptors and inhibitory receptors. In general, each of these classes of NK receptors also falls into two different structural groups, the Ig-like receptors and the C-type lectinlike receptors. Because of their functional interactions with MHC-I and MHC-I–like molecules, and because several different systems have evolved to recognize MHC-I molecules differently, it is worthwhile to examine the recently determined structures of several MHC-I/NK receptor complexes.

In the human, the major NK receptors are known as KIRs, for killer-cell immunoreceptors. These molecules are of the immunoglobulin superfamily and are distinguished by the number of their extracellular domains (classified as KIR2D or KIR3D for those with two or three extracellular domains, respectively), as well as the amino acid sequence and length of their transmembrane and cytoplasmic domains. The short KIRs (e.g., KIR3DS and KIR2DS molecules) are considered activating because they have the potential to interact with the DAP12 (KARAP12) signal-transducing molecule, and the long KIRs (e.g., KIR3DL and KIR2DL) are inhibitory because they have cytoplasmic domains that contain ITIMs (immunoreceptor tyrosine-based inhibitory motifs).

The KIR2DL1 and KIR2DL2 molecules have been studied extensively. They interact with the human MHC-I molecules HLA-Cw4 and HLA-Cw3, respectively, and show some preferences for MHC-I molecules complexed with particular peptides. Among the polymorphic amino acid residues that distinguish HLA-Cw3 and HLA-Cw4 are Asn80 of -Cw3 and Lys80 of -Cw4. Thus, it was of interest when the structures of KIR2DL2/HLA-Cw3 (115) and KIR2DL1/HLA-Cw4 complexes were reported (116). These structures are illustrated in Figure 19.22. The important
FIGURE 19.22 Interactions of KIR2D molecules with their HLA-Cw ligands. KIR2DL2 **(A, C)** and KIR2DL1 **(B, D)** are shown (magenta) in complex with their respective HLA-Cw3 and HLA-Cw4 ligands. (From (13), with permission.) (See color insert.)

conclusions from these structures is that the recognition of the MHC-I is via amino acid residues of the elbow bend joining the two immunoglobulinlike domains of the KIR and that residues that vary among different KIRs determine the molecular specificity of the interaction with the particular allelic product of HLA-C. In addition, the interaction of the KIR with the HLA-C is also modulated by the particular bound peptide, explaining the results of binding/peptide specificity studies.

The mouse exploits a set of NK receptors of a different structural family to provide the same function. In particular, the predominant, and best studied, mouse NK receptors are those of the Ly49 family, and Ly49A is the best studied. Functional experiments had demonstrated that Ly49A interacts with the MHC-I molecule, H2-D^d, and also that, for appropriate interaction, the H2-D^d needs to be complexed with a peptide. In contrast to human NK recognition, however, surveys of H2-D^d–binding peptides reveal little if any peptide preference or specificity. This would explain the function of the NK-inhibitory receptor, in that they are at baseline chronically stimulated by normal MHC-I on somatic cells, turning off the NK cell. When MHC-I is dysregulated by tumorigenesis or by pathogenic infection, the lower level of surface MHC-I diminishes the NKIR-mediated signal, and the NK cell is activated. The structure of the mouse Ly49A–inhibitory receptor in complex with its MHC-I ligand, H2-D^d (Figure 19.23), reveals several crucial features of the interaction: (a) the Ly49A C-type lectinlike molecule is a homodimer; (b) the Ly49A molecule makes no direct contact with residues of the MHC-bound peptide; and (c) in the x-ray structure, there are two potential sites for Ly49A interaction with the MHC molecule—site 1 at the end of the α1 and α2 helices, and site 2, an extensive region making contact with the floor of the peptide binding groove, the α3 domain of the MHC-I molecule, and the β2m domain as well. The ambiguity sug-
FIGURE 19.23 H2-D^d interactions with the C-type lectinlike receptor, Ly49A. The crystallographic determination of two distinct sites of H2-D^d interacting with the Ly49A homodimer is shown. Extensive mutagenesis and binding studies suggest that the functional site of interaction is site 2. (From (13), with permission.) (See color insert.)

gested by the x-ray structure has been resolved by extensive mutagenesis studies that are consistent with the view that site 2 is functionally significant (*436*,437). Recently, several other NK receptors have been studied structurally. These include the Ly49I inhibitory receptor, which interacts functionally with H2-K^b, which has been crystallized without a ligand, revealing a basic fold similar to that of Ly49A, but with a somewhat different dimeric arrangement (438). Ly49C, another murine NK-inhibitory receptor, has been examined in complex with its H2-K^b ligand (439). Differences between H2-K^b/Ly49C and H2-D^d/Ly49A suggest different modes of NK-receptor binding to MHC-I, depending on whether the interaction is "cis" (i.e., between the NK receptor and the MHC-I on the same NK cell) or "trans" (between the NK receptor on the NK cell and the MHC-I on its target). Both human and mouse NKG2D C-type lectinlike activation receptors have been examined by crystallography as well. The human NKG2D molecule forms a complex with an MHC-I–like molecule, MICA, which is expressed on epithelial cells and a wide variety of epithelial tumors (*401*). The murine NKG2D molecule has been crystallized in complex both with RAE-1β (*404*), a distantly related MHC-I–like molecule that lacks the α3 and β2m domains of the classical MHC-I molecules, and with another MHC-I–like α1 α2-domain molecule, ULBP3 (*440*). The general lesson learned from the studies of NKG2D interactions are that: (a) this C-type lectinlike receptor, unlike Ly49A, binds to MHC-like molecules spanning the α1 and α2 domains of the MHC-I–like ligands; and (b) NKG2D has considerable plasticity in its ability to interact with several different molecules while maintaining the same general docking orientation (441).

MHC-II Superantigen

Superantigens are molecules, frequently toxic products of bacteria, that bind MHC molecules on the cell surface and are then presented to a large subset of T cells, usually defined by the expression of a particular family of TCR V regions (*442*). Most of the known superantigens bind MHC-II molecules, though one, the agglutinin from *Urtica dioica*, the stinging nettle, can be bound by both MHC-I and MHC-II molecules and presented to T cells of the Vβ8.3 family (*443*). Its structure in complex with carbohydrate ligand has been reported (*444*,445). MHC-II interactions with superantigens, such as those derived from pathogenic bacteria, are the first step in the presentation of the multivalent array of the APC-bound superantigen to T cells bearing receptors of the family or class that can bind the superantigen (*442*). A number of structural studies examining the interaction of superantigen, both with their MHC-II ligands and with TCRs, have been reported (*446*). Structural analysis of crystals derived from staphylococcal enterotoxin B (SEB) complexed with HLA-DR1 (*447*) and from toxic shock syndrome toxin-1 (TSST-1) complexed with HLA-DR1 (*448*) revealed that the two toxins bind to an overlapping site, primarily on the MHC-II α chain, and

A   MHC–SEB–TCR   B   MHC–SpeC–TCR
FIGURE 19.24 Different superantigens, **(A)** SEB and **(B)** SpeC, interact differently with TCR and MHC-II. (From (*514*), with permission.)

indicated that the SEB site would not be expected to be influenced by the specific peptide bound by the MHC, although the TSST-1 site would. Recently, the view that superantigens exert their biologic effects by interaction with conserved regions of the MHC-II molecule as well as conserved regions of the TCR has been challenged by the determination of two structures, that of *Staphylococcus aureus* enterotoxin H complexed with HLA-DR1 (*449*), and that of streptococcal pyrogenic toxin C in complex with HLA-DR2a (*450*). Both of these studies indicate that these superantigens can interact with the MHC-II β chain through a zinc-dependent site that includes superantigen contacts to bound peptide. Looking at models for the complete complex of MHC-II/SEB/TCR and MHC-II/SpeC/TCR based on these structures, a sense of the biologic variety available for superantigen presentation to TCRs was developed. These models are shown in Figure 19.24.

MOLECULAR INTERACTIONS OF MHC MOLECULES

Physical Assays

Whereas the crystal stuctures provide a vivid static illustration of the interactions of MHC molecules with their peptide, FcRn, CD8, CD4, superantigen, NK receptor, and TCR ligands, the dynamic aspects of these binding steps can be approached by a variety of biophysical methods (451). It is important to note that affinities and kinetics of interaction of MHC/peptide complexes for TCR have been determined by several methods in a variety of systems (*452–454*,455,*456–459*). In addition, MHC interactions with NK receptors (*112*,113,460,*461*) have been quantified by simi-

lar techniques. Although there are clear differences in the affinity and kinetics of binding of different TCR and NK receptors for their respective cognate MHC/peptide complexes, the generally consistent findings are that the affinities are low to moderate (i.e., $K_d = 5 \times 10^{-5}$ to 10^{-7} M) and are characterized by relatively rapid dissociation rates (i.e., $k_d = 10^{-1}$ to 10^{-3} s^{-1}).

Multivalent MHC/Peptide Complexes

A major development in the past several years has been the engineering and application of multivalent MHC/peptide complexes for the identification, quantification, purification, and functional modulation of T cells with particular MHC or MHC/peptide specificity. Two general approaches have been exploited: one based on the enzymatic biotinylation of soluble MHC/peptide molecules generated in bacterial expression systems that are then multimerized by binding of the biotinylated molecules to the tetravalent streptavidin (*462*); and another based on the engineering of dimeric MHC/immunoglobulin fusion proteins (*463*). These reagents can be used in flow cytometric assays that permit the direct enumeration of MHC/peptide-specific T cells taken directly ex vivo. In either of these methods, multivalent MHC/peptide complexes are generated and the relatively weak intrinsic affinity of the MHC/peptide complex for its cognate TCR is effectively magnified by the gain in avidity obtained by the increase in valency. For MHC-I molecules, the technology has been so reliable in producing multivalent (tetrameric) molecules loaded homogeneously with synthetic peptides that a wide variety of specific peptide/MHC-I multimers are available either from a resource facility sponsored

by the National Institute of Allergy and Infectious Diseases (www.niaid.nih.gov/reposit/tetramer/index.html) or from commercial suppliers that offer either the tetramer or the immunoglobulin multimer. The MHC-I/peptide multimers have also been exploited for identification of specific populations of NK cells and for assignment of various NK-receptor specificities (*117,464–466*). For some MHC-II molecules, similar success has been achieved in the production of such multimers, using insect cell or mammalian cell expression systems for molecules produced by either the tetramer or the immunoglobulin chimera strategy (*467–471*). Despite many reports of successful application of these MHC class II multimers for identification of specific MHC-II/peptide–directed T cells, the technology at the present time seems less predictable than for MHC-I molecules. No doubt, further methodologic improvements will be needed (*472*).

CONCLUSION

We have surveyed the *Mhc* as a genetic region and a source for molecules that are crucial to immune regulation and immunologic disease. These genes reflect the panoply of mechanisms involved in the evolution of complex systems and encode cell surface proteins that interact via a complex orchestration with small molecules, including peptides and glycolipids, as well as with receptors on T cells and NK cells. The MHC-I molecules provide the immune system with a window for viewing the biologic health of the cell in which they are expressed, and MHC-II molecules function as scavengers to taste and display the remnants of the cellular environment. Viruses and bacterial pathogens contribute enormously to the genetic dance—they modulate and compete in the control of MHC expression— and the host, by adjusting its T-cell and NK-cell repertoire on the time scale of both the individual organism and the species, resists the push to extinction. The immune system, dynamically, resourcefully, creatively, provides, through the concerted action of its MHC molecules, TCR, NK receptors, and antibodies, as well as a host of other regulatory molecules, an organ system that is vital not only to the survival of the individual but to the success of the species. As we understand better the molecular functions of the MHC, we should better understand rational approaches to manipulating the immune system in the prevention, diagnosis, and treatment of immunologic and infectious diseases.

Cell Biology of Antigen Processing and Presentation

Lélia Delamarre and Ira Mellman

To be recognized by T lymphocytes, antigens must be bound to antigen-presenting molecules, which are displayed at the cell surface. Classically, antigen-presenting molecules—class I and class II major histocompatibility complex (MHC) molecules—bind peptides derived from intracellular proteins and from proteins captured by the antigen-presenting cells (APCs), respectively, whereas CD1 MHC-like molecules bind lipid antigens. Antigen recognition by T lymphocytes primarily depends on the ability of APCs to process protein antigens into peptides, load them onto MHC molecules, and finally display the MHC–peptide complexes at the cell surface. In this chapter we begin by giving a brief overview of the different types of APCs, concentrating on their properties that both facilitate and modulate the processing and presentation of antigens. We then discuss the mechanisms of antigen processing and loading onto MHC molecules, and transport of the MCH–antigen complexes to the cell surface for each of the major antigen-presenting molecules MHC I, MHC II, and CD1.

I presentation pathway, and it allows CD8[+] T cells to monitor the contents of the cells, identify and eliminate cells infected by viruses or intracellular pathogens, and possibly tumor cells. In contrast, MHC II and CD1 molecules present respectively peptides and lipids derived primarily from captured exogenous antigens to CD4[+] T cells and natural killer T cells. MHC II and CD1 molecules are expressed mainly on a limited subset of cells, called professional APCs (pAPCs), which are to varying degrees involved in the initial presentation of antigens to naive T cells. pAPCs include B lymphocytes, macrophages (Mϕ), and especially dendritic cells (DCs). As we discuss later, pAPCs can also present peptides derived from exogenous antigens on MHC I to activate naive CD8[+] T cells and prime an immune response by a process called cross-presentation. pAPCs vary in their capacity to capture, process, and present antigens on MHC molecules. They also differ in the level expression of the costimulatory molecules and released cytokines required for activating naive T cells.

ANTIGEN-PRESENTING CELLS

Almost all nucleated cells constitutively display at their surface MHC I molecules presenting peptides derived from intracellular proteins. This process is called the classic MHC

B Lymphocytes

The ability of B cells to internalize antigen is very limited because they do not exhibit a marked capacity for endocytosis. For example, B cells are generally not capable of

phagocytosis of large particles, and therefore they are unable to capture and present antigens derived from invading microorganisms. B cells do, however, efficiently bind and internalize soluble antigens that bind specifically to their unique surface immunoglobulins. Because they express high levels of MHC II and costimulatory molecules, B cells are highly efficient at presenting only their cognate antigens, generating peptide–MHC class II complexes that are presented to CD4[+] T cells. Not only does presentation by B cells serve to stimulate T cell proliferation, CD4[+] T cells return the favor and facilitate the proliferation and differentiation of B cells into antibody-secreting B cells and plasma cells (see Chapters 8 and 9).

Macrophages

Macrophages exhibit an exceptional capacity for endocytosis and thus have the ability to capture a broad spectrum of antigens by fluid-phase endocytosis, receptor-mediated endocytosis (e.g., via Fcγ receptors, various lectins such as mannose receptor), and phagocytosis of large particles (see Chapter 18). However, Mϕ express relatively low levels of MHC and costimulatory molecules. Upon activation by inflammatory stimuli, Mϕ upregulate the expression of MHC II and costimulatory molecules, although their level of expression is still substantially lower than in B cells and DCs. On the other hand, Mϕ exhibit an exceptional capacity for lysosomal digestion, unlike B cells or DCs (1). This allows for a rapid clearance of the captured antigens but may limit the generation of antigenic peptides by premature destruction and thus affect MHC presentation. Together, these results suggest that although Mϕ can initiate innate immune responses and were once thought to be essential for initiating adaptive immunity, they are suboptimal for efficient MHC presentation.

Dendritic Cells

DCs are believed to play a primary role in priming T cell–mediated immune responses (2,3) (see also Chapter 15). Their efficiency stems not only from their location in tissues, high endocytic capacities, migratory properties in response to inflammatory stimuli, and high surface expression of MHC and costimulatory molecules, but also from their capacity to developmentally regulate these functions (4). Immature DCs mainly reside in peripheral tissues, where they act as sentinels, capturing a wide spectrum of antigens via various mechanisms. Like Mϕ, DCs have a capacity for multiple forms of endocytosis. While in their immature state, however, DCs are poor at antigen presentation, expressing low levels of surface MHC and costimulatory molecules. MHC II molecules accumulate inside lysosomal compartments together with internalized intact antigens. After receiving an inflammatory stimulus, peripheral DCs begin to mature and migrate to

secondary lymphoid organs, where they present processed antigens to T cells. DC maturation is accompanied by a dramatic structural reorganization of the cells. DCs acquire the capacity to process captured antigens, load immunogenic peptides onto MHC II molecules, and selectively transfer the MHC II/peptide complexes from lysosomes to the plasma membrane together with costimulatory molecules. Not all mature DCs, however, are functionally equivalent. It is now clear that different maturation stimuli produce mature DCs with different abilities for T cell stimulation and other functions (5). In addition, several DC subsets have been identified that appear to have distinct abilities to prime immune responses (6,7).

MHC I PRESENTATION

To protect the host effectively, the immune system must be constantly surveying for signs of infection. Because many pathogens have evolved to enter a host's cells and replicate intracellularly, the immune system has developed the means to detect the presence of not only extracellular but also intracellular infections. This is the primary function of the MHC I system. Peptides derived from intracellular antigens (both pathogen encoded and host derived) are loaded onto MHC I molecules, which then traffic to the plasma membrane for recognition by CD8[+] T cells (Figure 20.1). It has been estimated that any given cell presents hundreds of thousands of such peptides. All nucleated cells express MHC I products.

Classic Pathway of MHC I Antigen Processing

Source of Antigenic Peptides for MHC I Presentation

It had long been thought that proteins at the end of their life span were the source of peptides for MHC I presentation, probably because inhibitors of the proteasome altered protein turnover as well as antigen presentation by MHC I molecules (8). More recently, however, it has been shown that most antigenic peptides (approximately 70%) originate from newly synthesized polypeptides. These are likely to largely consist of premature termination products and misfolded full-length proteins, called defective ribosomal products (DRIPs) (9–11). Thus, peptide presentation on MHC I molecules appears to depend on the rate of protein translation rather than the rate of protein turnover or the total amount of the protein. This process favors the rapid presentation of newly synthesized viral proteins early during viral infection.

Soon after the induction of DC maturation, DRIPs transiently accumulate as aggregates in the cytosol, suggesting that the generation of antigenic peptides and their presentation by MHC I might be regulated (12).
FIGURE 20.1 Overview of the major histocompatibility complex (MHC) I classic pathway. MHC I peptides derive from various sources of endogenous proteins, including (1) cytosolic proteins, (2) proteins retrotranslocated from the endoplasmic reticulum (ER), (3) defective ribosomal products, and (4) cryptic translation products. Polyubiquinated polypeptides are degraded by the proteasome in the cytosol and further processed by cytosolic proteases. The resulting peptides are then translocated into the ER by the transporter associated with antigen processing (TAP), where further trimming by the ER aminopeptidase associated with antigen processing (ERAAP) can occur. The newly synthesized MHC I heavy chain (HC) initially associates with the chaperone calnexin, which assists its folding and binding to β_2-microglobulin (β_2m) in the endoplasmic reticulum. The HC–β_2m complex is then incorporated into the loading complex composed of TAP, tapasin, calreticulin, ERp57, and protein disulfide isomerase (PDI). The role of the loading complex is to help the binding of HC–β_2m complexes to high-affinity peptides and enhance HC–β_2m–peptide complex stability. The peptide-loaded MHC I complexes then leave the ER and are transported to the cell surface via the Golgi apparatus. (Adapted from Trombetta ES and Mellman I. Cell biology of antigen processing in vitro and in vivo. *Annu Rev Immunol* 2005;23:975, with authorization)

In addition to conventional translation products, a small fraction of antigenic peptides can also be generated from cryptic translation products, including introns, intron/exon junctions, untranslated regions, and alternate reading frames (13,14).

Peptide Generation

Peptides presented on MHC I molecules are generated primarily by the ubiquitin-proteasome pathway in the cytosol, whose primary function is to rapidly degrade proteins to amino acids (15). Indeed the peptides produced by this pathway range in size from 2 to 25 amino acids, most of which (approximately 70%) are too short to bind to MHC I molecules (16,17). To be recognized by the degradation machinery, most substrate proteins must be first conjugated to ubiquitin (18). This process is adenosine triphosphate (ATP) dependent and requires multiples enzymes (19). How protein substrates are recognized by the ubiquitin machinery, however, remains elusive. It has been proposed that the same chaperones that usually promote the folding of nascent polypeptides and misfolded proteins can also facilitate polyubiquitination if folding is unsuccessful. It has recently been shown that the knockdown of the chaperone Hsp90 and CHIP, a ubiquitin ligase E3 that interacts with heat shock proteins and ubiquitinates their bound substrates, results in the reduced presentation of MHC I–peptide complexes (20).

The ubiquitinated proteins are then targeted to the proteasome for degradation. The 26S constitutive proteasome is composed of the 20S-core particle responsible for substrate proteolysis and the 19S-regulator complex responsible for substrate recognition and access to the 20S core (21). The 20S core is a cylindrical structure made up of 28 subunits arranged in four stacked heptameric rings. The two inner rings are each composed of homologous but distinct β-subunits, which surround a central chamber where proteolysis occurs. Eukaryotic proteasomes contain

two sites that cleave after hydrophobic residues, two after acidic residues, and two after basic residues; thus they can cut most types of peptide bonds, although with different efficiencies depending on the residues that flank the cleavage sites. The two outer rings are each composed of homologous but distinct α-subunits and are arranged to form a central gate that controls the access of substrates to the catalytic chamber. This gate is normally closed, and access is controlled by the 19S particle. The 19S particle consists of two functionally distinct entities: the base and the lid. The base contains ATPases that have the ability to unfold the substrate and to open the gate and thus promote its translocation into the inner chamber of the 20S core, whereas the lid binds and deubiquitinates protein substrates before they access the 20S core.

On interferon γ (IFNγ) stimulation, as occurs during inflammation, new catalytic subunits are incorporated into the proteasome to generate the immunoproteasome (β1, β2, and β5 of the constitutive proteasome are replaced by the IFNγ-inducible homologs LMP2 [β1i], MECL-1 [β2i], and LMP7 [β5i], respectively) (22). The replacement of the three catalytic subunits in the immunoproteasome does not affect the rate at which proteins are degraded, but it alters the cleavage specificity, favoring cleavage behind basic and hydrophobic residues that preferentially bind MHC I molecules, and thus it often enhances the generation of antigenic peptides (23,24). In rare cases, immunoproteasome can also destroy MHC I epitopes normally generated by the constitutive proteasome (25). Of interest, *in vitro* studies have suggested that compared to the constitutive proteasome, the immunoproteasome produces greater amounts of N-extended versions of a dominant antigenic peptide derived from ovalbumin. Thus, antigenic peptides can be generated by further trimming by peptidases in the cytosol and/or the endoplasmic reticulum (ER) rather than being completely degraded to amino acids (26). However, studies with other protein substrates are needed to determine whether this is a general feature of the immunoproteasome.

IFNγ also stimulates the expression of an additional regulator complex called PA28 that can bind both ends of the 20S proteasome (27). Its function in antigen processing is unclear. Although PA28 modifies the profile of peptides produced by the proteasome *in vitro* (28), it does not seem to be essential for MHC I presentation of most antigens *in vivo* (29).

As mentioned earlier, although the proteasomes can generate peptides 8 to 10 amino acids in length that are capable of stably binding MHC I molecules (see Chapter 19), they more frequently produce longer peptides requiring further trimming to potentially become MHC I epitopes (28,30). *In vivo* studies using proteasome inhibitors have shown that additional proteases can be involved in peptide processing (31–33). However, the proteasome must generate the final C-terminus of MHC I–binding peptides. In

contrast, N-extended precursors generated by the proteasome can be further processed by aminopeptidases and endopeptidases in the cytosol (34–37,37a). Further trimming can also occur in the ER. The ER aminopeptidase associated with antigen processing (ERAAP/ERAP1) has been recently identified as being a major player in this process (38,39). In ERAAP/ERAP1-deficient mice, cell surface expression of some but not all MHC I alleles is significantly decreased. The presentation of peptides also appears to be differentially affected, with expression of some peptides unchanged, whereas expression of others is either enhanced or absent (40,41). Furthermore, ERAAP-deficient cells present many peptides with N-terminal extensions (42). This suggests that a significant amount of N-extended peptides are translocated from the cytosol into the ER. As for the proteasome, one has to keep in mind that the major role of most these proteases is most likely to hydrolyze peptides to amino acids for cellular homeostasis, a process that would normally contribute to the destruction of MHC I epitopes, although clearly they can sometimes also favor their production (43,44).

Peptides derived from signal sequences of proteins translocated into the ER have also been shown to bind MHC I in an antigen-processing defective cell line (45). How and where these peptides are generated, in the ER or in the cytosol in a proteasome-dependent manner, and whether this phenomenon occurs under normal conditions remain to be determined. The same applies to MHC I–binding peptides that are derived from the membrane anchors of integral membrane proteins.

Peptide Transport into the Endoplasmic Reticulum

As mentioned, peptides generated in the cytosol must be translocated across the ER membrane in order to bind MHC I molecules. This is achieved by the *transporter associated with antigen processing* (TAP) localized in the ER and *cis*-Golgi (46). TAP belongs to the large family of ATP-binding cassette (ABC) transporters, which translocate a variety of solutes across membranes in an ATP-dependent fashion (47). TAP is a heterodimer composed of two subunits, TAP1 and TAP2, both of which are essential and sufficient for peptide translocation (48,49). Each subunit comprises an N-terminal transmembrane domain containing the peptide-binding pocket and a C-terminal cytosolic domain containing the ATP-binding and hydrolysis sites. Peptide transport into the ER lumen is a multistep process: (a) ATP and peptide binding, (b) ATP hydrolysis, and (c) peptide translocation. TAP most efficiently binds and transports peptides 8 to 12 amino acids in length. The binding affinity depends on the three N-terminal and the C-terminal residues (50). Of interest, it is the C-terminal residue preferentially produced by the immunoproteasome that also binds preferentially TAP and MHC I molecules, suggesting a coevolution of these

molecules. However, the TAP preferences for the three N-terminal residues and the length of the peptides does not always correspond to those of MHC I molecules confirming that further trimming might be required for some peptides in the ER (see previous section). Nevertheless, it is clear that the TAP affinity for peptides has a substantial impact on the range of peptides presented by MHC I (51,52).

MHC I/Peptide Assembly

MHC I/peptide assembly occurs in the ER. This complex process requires a number of chaperones, which help with the folding of the MHC I heavy chain (HC), its binding to β_2-microglobulin (β_2m), and the peptide loading (53–55). Once formed, the MHC I complexes are transported to the cell surface to present peptides to CD8$^+$ T cells.

The HC is cotranslationally translocated into the ER; it is glycosylated and associates successively with the chaperones BIP and calnexin (56,57), which assist HC folding and the recruitment of disulfide isomerase ERp57 to facilitate disulfide bond formation (58). Toward the end of the folding process, HC binds to β_2m and dissociates from calnexin (56,59); the newly formed complex HC–β_2m is incorporated into an ensemble of accessory molecules called the loading complex, composed of TAP, the transmembrane protein tapasin (TAP-associated glycoprotein), calreticulin, ERp57, and the protein disulfide isomerase (PDI) (59–62). In mice, the loading complex also contains calnexin. Most HC–β_2m complexes are held in association with the loading complex until they stably assemble with a peptide (63,64). The peptide-loaded MHC I complexes then leave the ER and are transported to the cell surface via the Golgi apparatus.

Although it is clear that the role of the loading complex is to help the binding of HC–β_2m complexes with high-affinity peptides and enhance HC–β_2m–peptide complex stability, the precise function of each of the components of the peptide-loading complex is far from completely understood. Each of the components is essential to the MHC I pathway. Deficiency in any of them leads to a similar phenotype, although with various degrees of severity: impaired peptide association with MHC I molecules and reduced MHC I surface expression (48,49,62,65–69). TAP is indispensable for peptide transport into the ER, as mentioned in the previous section. Tapasin appears to have multiple critical roles: (a) stabilizing TAP and thus enhancing peptide translocation in the ER (70,71), (b) recruiting MHC I molecules to the peptide-loading complex by forming a bridge between TAP and HC–β_2m (65), and (c) facilitating and optimizing peptide loading (72,73). ERp57 is also crucial for the recruitment of MHC I molecules into the peptide-loading complex (69). PDI stabilizes a peptide-receptive site by regulating the oxidation state of the disulfide bond in the MHC peptide-binding groove. In addition, PDI binds efficiently to peptides and thus could also help

peptide delivery (62). Calreticulin appears to be important in the optimization of peptide loading. but its precise contribution remains to be determined (68).

Cross-presentation: Presentation of Exogenous Antigens by MHC I Molecules

Although MHC I molecules classically present peptides derived from proteins of endogenous origin, exogenous antigens can also enter the MHC I pathway in a process called "cross-presentation" (74,75) (Figure 20.2). This process is likely to be crucial in the initial phase of an immune response because naive CD8$^+$ T cells can only be stimulated by antigens presented on the MHC I molecules of pAPCs. If the pAPC does not synthesize a given antigen, then it must acquire the antigen exogenously. The resulting stimulation of the CD8$^+$ T cell response *in vivo* is called cross-priming.

Cross-presenting APCs

In vitro, Mϕ and DCs are the principal cells able to present peptides derived from exogenous antigens on MHC I molecules, although DCs do it far more efficiently (76). Recently it has also been suggested that B cells can cross-present antigens (76a,76b). By contrast, *in vivo*, DCs seem to be the key players in cross-priming CD8-dependent responses: Ablation of CD11$^+$ DCs in mice abrogates T cell cross-priming (77).

In addition, a new mechanism of antigen transfer has been identified and suggests that cross-presentation might not be limited to pAPCs. Peptides can be transferred through gap junctions from the cytosol of one cell directly into the cytosol of neighboring cells, either innocent bystander cells or pAPCs (78). The physiologic role of this mechanism remains to be elucidated.

Source and Nature of the Cross-presented Antigens

In vitro, virtually any form of antigen (soluble, particulate, aggregated, cell associated, bacterial, protozoan) can be cross-presented. However, under physiologic conditions, it is possible that cross-presented peptides are most often generated from cell-associated antigens captured by phagocytosis.

Cell remnants contain three potential pools of peptides for cross-presentation by MHC I molecules—stable proteins, chaperone-associated peptides, and MHC I–associated peptides. Which of these sources actually contributes to cross-presentation remains controversial. Using different approaches, recent reports showed that stable intact proteins derived from dying cells are the predominant source of cross-presented antigens *in vivo* (79–81), whereas others suggested that fully processed peptides can also be transferred to pAPCs and directly cross-presented

FIGURE 20.2 Mechanisms of cross-presentation of exogenous antigens by major histocompatibility complex (MHC) I molecules. Exogenous antigens enter the classic MHC I pathway through various potential routes: (1) Peptides are transferred through gap junctions from the cytosol of one cell directly into the cytosol of neighboring cells. (2) Antigens can gain access to the classic MHC I pathway after endocytosis. This process requires their transfer from the endosomal compartments to the cytosol. How antigens reach the cytosol is unclear. One possibility is that endosomal vesicles simply leak or rupture, delivering their content into the cytosol. Alternatively, internalized antigens are selectively transported from the endocytic compartments to the cytosol via specific transporter molecules. (3) It was recently suggested that cross-presentation could involve direct fusion of phagosomes or macropinosomes with the endoplasmic reticulum (ER). As a consequence, endocytosed proteins would gain access to the ER-associated degradation machinery required for their release into the cytosol. Once in the cytosol, the exogenous antigens are degraded by the proteasome, and the resulting peptides are transported by the transporter associated with antigen processing (TAP) into the ER or the ER/phagosome and loaded onto MHC I molecules. (4) Some endocytosed antigens appear to be processed and loaded onto MHC I molecules in endocytic compartments independent of the proteasome and TAP. ERAAP, ER aminopeptidase associated with antigen processing; PDI, protein disulfide isomerase.
on MHC I (82). The use of different antigens might be the explanation for these discrepancies, although it is certainly possible that both mechanisms contribute. Notably, these results suggest that the requirements for proteins to be presented by MHC I in the classic pathway and in the cross-presentation pathway are different, and thus the repertoire of peptides presented by MHC I might be influenced by the pathway that is followed.

Mechanisms of Cross-presentation

How the antigens captured by APCs reach the MHC I pathway for cross-presentation is the subject of intense debate (83). Two major mechanisms have been described based on their sensitivity to proteasome inhibitors and their dependence on TAP molecules. One pathway involves antigen proteolysis and peptide loading on MHC I molecules in the endocytic compartments and is thus proteasome and TAP independent. Alternatively, captured antigens are transferred (by an as-yet-unknown mechanism) to the cytosol for proteasomal proteolysis and therefore reach the

MHC I via the classic pathway. The choice of the pathway might depend on the nature of the antigen and its intracellular fate after capture. For example, soluble or latex bead-bound ovalbumin is cross-presented in a proteasome- and TAP-dependent manner. The same antigen incorporated into microsphere composed of biodegradable copolymer, however, is cross-presented by a TAP-independent pathway (84). It is important to note that the use of proteasome inhibitors or TAP-deficient cells also directly affects the expression of MHC I molecules, which strongly relies on both TAP and proteasome activities. It is thus likely that the proteasome- and TAP-independent cross-presentation pathway has been largely underestimated.

The Proteasome- and TAP-independent Pathway

The precise mechanism of this pathway, also called the vacuolar pathway, is poorly understood and has been largely characterized as being insensitive to proteasome inhibitors and independent of TAP. Recent work, both *in vitro* and *in vivo*, has shown that the lysosomal protease cathepsin S is required for the generation of the antigenic

peptides (84). Whether other lysosomal proteases also contribute to this pathway remains to be determined. It is also unclear how MHC I molecules sample or bind the peptides generated in the endocytic compartments, which are generally devoid of the panoply of chaperones involved in peptide–MHC I formation in the ER.

This mechanism also implies that MHC I molecules are sorted to the endocytic compartment, a feature most likely mediated through a tyrosine-based signal in their cytoplasmic tail (85). Indeed, elimination of this tyrosine-based signal decreases cross-presentation in mouse DCs.

The Proteasome- and TAP-dependent Pathway

This pathway requires the transfer of captured antigens from the endosomal compartments to the cytosol. How antigens reach the cytosol is unclear. One possibility is that endosomal vesicles simply leak or rupture, delivering their content into the cytosol. Experimental rupture of endocytic vesicles has long been known to induce cross-presentation of internalized antigens (86). Another possibility is the selective export of exogenous antigens from the endocytic compartments to the cytosol via specific transporter molecules (87).

More recently it was proposed that cross-presentation involves direct fusion of phagosomes or macropinosomes with the ER (88–91). As a consequence, endocytosed proteins would gain access to the ERAD (ER-associated degradation) machinery required for their release into the cytosol, and therefore the MHC I processing machinery (92). However, other studies could not detect a significant contribution of the ER to the formation of phagosomes in Mϕ or DCs (93). If ER components are present in endocytic organelles, they are therefore present in trace amounts relative to the ER proper, making it difficult to understand how they might work. Alternatively, it is possible that small amounts of internalized antigen reach the lumen of the ER proper. That this can occur has been demonstrated by the fact that endocytosis in caveolae can lead to direct delivery to the ER, avoiding conventional endosomes and lysosomes (94).

Internalized antigens have to survive the harsh environment of endosomes/lysosomes before being delivered to the cytosol. Lysosomes contain proteases the primary function of which is to degrade proteins to amino acids. Indeed, limiting lysosomal protease activity by artificially reducing acidification of the endosomal compartments increases the transfer of endocytosed antigens to the cytosol and enhances their cross-presentation (95). Similarly, it has been recently shown in DCs that phagosomes recruit the nicotinamide adenine dinucleotide phosphate oxidase NOX2 to neutralize the phagosomal pH and promote cross-presentation (96). Antigen targeting to protease-poor recycling endosomes also may favor cross-presentation, probably by sequestering antigens away from lysosomal degradation (97).

After exposure to inflammatory stimuli, such as microbial products or inflammatory cytokines, surface MHC I expression increases in pAPCs. In DCs, this reflects at least partially an increase in synthesis and posttranslational stability (98–100). In addition, the cross-presentation pathway is regulated in DCs independently of the endogenous MHC I pathway (100–102).

MHC II PRESENTATION

Source of Antigenic Peptides for MHC II Presentation

Whereas MHC I molecules present mainly peptides derived from endogenous proteins, MHC II molecules typically associate with peptides generated from exogenous proteins internalized by the APCs. B cells internalize antigens mainly through their B cell receptor. Although this is an efficient mechanism of capture, it essentially limits B cells to the internalization of a single type of antigen. B cells also express Fcγ receptors that in principle could allow any immune complex to be taken up and presented. However, alternative mRNA splicing ensures that the Fcγ receptors expressed by B cells are incapable of efficient endocytosis for antigen presentation (103,104).

In contrast, both Mϕ and immature DCs endocytose avidly through a wide array of mechanisms (including Fcγ receptors), allowing them to internalize a broad spectrum of antigens (105). Different types of antigens use different routes of internalization, which determine the intracellular organelles to which antigens are delivered, which in turn may affect their processing and loading onto MHC II molecules.

Endocytosis falls into two major categories: phagocytosis and pinocytosis (106,107). Phagocytosis involves the capture of large particles, such as bacteria or cell debris, and is likely to be the most physiologically relevant mode of antigen uptake *in vivo* (107a) (see also Chapter 18). Phagocytosis is typically triggered by the binding of particulate antigens to specific surface receptors, which in turn transduce the signals for particle engulfment. Pinocytosis includes fluid-phase uptake by macropinocytosis and receptor-mediated endocytosis. In most DC subsets (Langerhans cells being a notable exception), macropinocytosis plays a major role in internalization of soluble antigen, at least *in vitro*. Greater efficiency of endocytosis can be achieved when antigens are captured by specific high-affinity receptors, such as the mannose receptor, which binds glycosylated ligands, Fcγ receptors, which bind immunoglobulin G–antigen complexes, or scavenger receptors, which bind a wide variety of ligands.

In DCs macropinocytosis is regulated during maturation. Immediately after receiving maturation stimuli, there is a brief increase in macropinocytosis, followed by its complete downregulation. This is believed to boost the

capture of the pathogens responsible for inducing maturation (108–111). Paradoxically, because macropinocytosis is largely responsible for endocytosis *in vitro*, it is commonly believed that all forms of endocytosis are shut down in mature DCs. However, this question has never been properly addressed, and the various mechanisms involved in antigen endocytosis may not be affected in the same way during DC maturation. Indeed, the number of clathrin-coated structures is unchanged in immature and mature mouse bone marrow–derived DCs, suggesting that receptor-mediated endocytosis still occurs in mature DCs (109).

MHC II molecules can also present peptides derived from endogenous proteins. How cytoplasmic and nuclear proteins gain access to this antigen presentation pathway remained elusive until recently. Autophagy is now believed to be the main mechanism responsible for the delivery of cytoplasmic proteins to lysosomes (112). Two main autophagic pathways have been identified—macroautophagy and chaperone-mediated autophagy. In macroautophagy, aggregate-prone, long-lived cytosolic and nuclear proteins get preferentially incorporated into autophagosomes, which then fuse with endosomal/lysosomal compartments. Proteins from the autophagosome are then degraded by lysosomal proteases and the generated peptides loaded onto MHC II molecules (113,114). Macroautophagy is a constitutive pathway in DCs and B cells *in vitro* (114). In chaperone-mediated autophagy, cytosolic proteins are believed to be directly translocated into late endosomes/lysosomes by a process somehow dependent on the lysosomal membrane glycoprotein Lamp-2a (115). This process is facilitated by the chaperone protein hsc70. The efficiency of the autophagic pathways in the presentation of cytosolic proteins by MHC II molecules in primary APCs remains to be established.

MHC II Assembly in the ER and Transport to the Endosomal Pathway

Unlike MHC I molecules, the assembly of MHC II molecules and peptide association occurs in two distinct and independent steps (Figure 20.3). The initial assembly of the MHC II molecules with the chaperone-invariant chain (Ii) takes place in the ER. The MHC II–Ii complexes are then targeted through the Golgi apparatus to the endosomal compartment, where the Ii chain is degraded and peptide loading occurs. The newly formed MHC II–peptide complexes are then transported to the cell surface.

MHC II molecules are heterodimers of two variable-transmembrane glycoproteins–α chain and β chain. They are synthesized and assembled in the ER with the help of the chaperone Ii chain and form a nine-chain structure consisting of three α–β dimers associated with an Ii chain trimer (116). The Ii chain is a transmembrane type II glycoprotein. In mice, two splicing forms of the Ii chain have been identified—p33 and p41—based on their molecular weight. p41 contains an additional domain that can bind the lysosomal protease cathepsin L, although its physiologic significance is unclear (117). In humans, there are two additional forms of Ii chain—p35 and p43—resulting from alternative initiation of translation. As a consequence, p35 and p43 possess an additional 15 amino acids containing an ER retention signal (118).

MHC II association with Ii chain has multiple functions. The ER retention signal prevents premature transport of the MHC II molecules before they are properly assembled and folded. This signal is overridden when the MHC II–Ii chain assembly is complete, allowing the export of the complex to the Golgi apparatus (119). The second function of Ii chain is to prevent premature peptide loading of MHC II in the ER (120,121). The Ii chain contains a domain called MHC II–associated invariant chain peptide (CLIP) that protects the peptide-binding groove until the MHC II–Ii complex enters the endocytic pathway. Finally, targeting signals contained in the cytoplasmic domain of Ii chain drive the MHC II–Ii complexes into the endosomal pathway where the peptide loading occurs (122–124).

MHC II–Peptide Assembly

Two major steps take place in the endocytic pathway: The Ii chain is degraded, liberating the peptide-binding site of MHC II molecules, and antigens are processed into peptides associating with MHC II molecules. Newly formed MHC II–peptide complexes are then transported to the cell surface. This process is believed to occur largely in late endosomes/lysosomes–like structures where proteases are the most active and intracellular MHC II molecules accumulate (125). However, lysosomes have classically been considered a degradative dead end, from which very few proteins escape. This consideration led to the idea that APCs might have developed specialized MHC II–containing compartments (MIICs) devoted to antigen processing and peptide loading. However, recent studies instead suggest that DCs have developed the unique capacity to modify the features of otherwise conventional late endosomes/lysosomes to overcome their inherent limitations of strictly degradative organelles, as discussed later.

Ii Degradation

As they progress through the endocytic pathway toward lysosomes, MHC II–Ii complexes are exposed to increasingly acidic environments, causing the activation of endosomal/lysosomal proteases. Perhaps as a result, Ii chain undergoes cleavages directionally from the C-terminus to the N-terminus involving multiple proteases after delivery to late endocytic compartments, although the process may well begin even in early compartments (117). *In vitro* studies have suggested the participation of several endosomal/
FIGURE 20.3 Overview of the major histocompatibility complex (MHC) II pathway in dendritic cells. **A:** MHC II peptides are mainly derived from exogenous proteins endocytosed by dendritic cells (DCs) through a wide array of mechanisms, including phagocytosis, macropinocytosis, and receptor-mediated endocytosis. The captured antigens eventually reach endosomal/lysosomal compartments. Endogenous proteins can also be imported into lysosomes by autophagy for loading onto MHC II molecules. Newly synthesized MHC II molecules associate with the invariant chain (Ii) in the ER. The MHC II–Ii complexes are then targeted through the Golgi apparatus to the endosomal/lysosomal compartments. In immature DCs, internalized antigens and Ii chain are poorly degraded, and MHC II–peptide complex generation is thus relatively inefficient. Upon DC maturation, some lysosomal proteases are converted into their active mature forms, expression of protease inhibitors is downregulated, and, perhaps most important, there is acidification of the endosomes/lysosomes, which induces nonspecific activation of most proteases. As a result, Ii chain removal, antigen processing, and peptide loading onto MHC II are enhanced. The newly formed MHC II–peptide complexes are then transported to the cell surface. (From Trombetta ES, Mellman I. Cell biology of antigen processing *in vitro* and *in vivo*. *Annu Rev Immunol* 2005;23:975, with permission.) **B:** Another mechanism for regulating surface expression of MHC class II molecules in DCs is polyubiquination. In immature DCs, ubiquitination of the cytoplasmic tail of MHC II-β chain limits surface expression of MHC II molecules by inducing their clearance from the cell surface by endocytosis and possibly their sequestration in the endosomal/lysosomal compartments. In mature DCs, ubiquitination of MHC II molecules is suppressed.

lysosomal proteases in Ii degradation, but the use of protease-deficient mice largely failed to confirm a critical role for most proteases tested. This suggests that there may be large redundancy among these proteases. However, the terminal stages of Ii processing seem to be differentially dependent on the cysteine protease cathepsin S, at least in some MHC II haplotypes. Cathepsin S–deficient B cells and DCs show accumulation of the processing intermediate p10 (126–128).

Ultimately, only the end product, CLIP, remains in the MHC II peptide groove. CLIP is subsequently exchanged for antigenic peptides in a reaction favored by acidic pH and facilitated by the MHC II–like chaperone DM (also called HLA-DM in humans and H2-DM or H2-M in mice)

(129). The current model is that the association of DM with the MHC II–CLIP complex induces a conformational change of the peptide-binding groove, decreasing its affinity for CLIP and thus facilitating its dissociation (130,131). DM also catalyzes the dissociation of any peptide from MHC II molecules. Thus, by enhancing the rate of peptide exchange, DM favors the presentation of high-affinity peptides with slower intrinsic rates of dissociation (132–134).

In B cells and some DC subsets, there is an additional MHC II–like molecule DO (also called HLA-DO in humans and H2-O in mice) (135). Its intracellular trafficking is dependent on DM, with which DO is tightly associated. In human B cells, DO inhibits DM activity. DO-transfected cells express increased surface levels of MHC II-CLIP (136).

However, after antigen internalization via the B cell receptor (BCR), DO dissociates from DM (135). These results suggest that DO promotes MHC II presentation of antigens recognized by the BCR while it inhibits the presentation of antigens from endogenous origin or those taken up nonspecifically.

Antigen Processing

Antigenic peptides presented on MHC II molecules are produced by endosomal/lysosomal proteases (117,137). However, a requirement for specific proteases in the processing of most antigens has been difficult to establish. Some proteases may regulate MHC II presentation by exerting a dual effect on both protein antigen processing and Ii-chain degradation. In addition, most endosomal/lysosomal proteases have redundant activities, with few exceptions. The IFNγ-induced lysosomal thiol reductase (GILT) is the only lysosomal reductase known, and it does play a role in the degradation of protein antigens containing disulfide bonds (138); however, even GILT is dispensable. An example in which a single enzyme does play a unique and necessary role is the asparaginyl cysteine endoprotease (AEP) (also called legumain), which controls the processing of tetanus toxoid (139). Conversely, AEP limits the presentation of myelin basic protein (MBP) by destroying its immunodominant peptide (140). Cathepsin L and cathepsin S expression can also positively or negatively affect the generation of some antigenic peptides (141). In conclusion, it is likely that the redundancy of degradative activities in late endosomes and lysosomes ensures that a single protease is rarely required for antigen processing in general.

The late endosomal/lysosomal compartment is a hostile environment for proteins. Its primary function is to degrade proteins into amino acids. How antigenic peptides survive such an environment remains elusive. It has been suggested that intact or partially processed protein antigens rapidly bind the MHC II groove before destruction and that processing happens on each side of the groove after binding (142). Consistent with this idea, it was found that large protein fragments are associated with MHC II molecules (143–149).

Another way in which to reduce epitope destruction is to limit protease activity. DCs and B cells contain low levels of proteases, resulting in a limited capacity for antigen degradation (1). DCs further limit proteolysis by expressing protease inhibitors (150,151). Limited proteolysis also allows DCs to sequester captured antigens for up to several days, providing a source of antigens for sustained processing and presentation by DCs within secondary lymphoid organs. Conversely, limiting susceptibility to lysosomal proteolysis enhances protein antigen presentation by MHC II molecules and antigen immunogenicity (152). In contrast to DCs and B cells, Mϕ express exceptionally high levels of lysosomal proteases and rapidly degrade captured proteins. These low protease levels, together with relatively low MHC II expression, help to explain why, compared to DCs and B cells, Mϕ are better adapted for the clearance of the captured pathogens than for their presentation to T cells.

Regulation of Antigen Processing and MHC II Pathway in DCs

In response to inflammatory and microbial stimuli, DCs enhance their capacity to form and present MHC II–peptide complexes (4,153,154), in part by controlling their lysosomal proteolytic activities through multiple mechanisms. In immature DCs, internalized antigens are degraded slowly, with MHC II–peptide complex generation or accumulation thus being relatively inefficient (155,156). Upon DC maturation, the lysosomal proteases AEP and cathepsin L are converted into their active mature forms (157,158), expression of cystatin C, a cathepsin S/B inhibitor, is downregulated (150), and, perhaps most important, there is acidification of the endosomes/lysosomes, which induces nonspecific activation of most proteases (158,159). DC maturation enhances activation of vacuolar proton ATPase, which lowers endosomal/lysosomal pH and favors antigen processing and the formation of MHC II–peptide complexes (158).

DCs also control MHC II presentation by tightly regulating MHC II trafficking during maturation. In immature DCs, MHC II molecules accumulate in late endosomes/lysosomes, whereas in mature DCs, MHC II molecules accumulate at the cell surface (160,161). In immature DCs, most of the newly synthesized MHC II–Ii complexes are targeted from the Golgi apparatus to the endosomal pathway (161). As discussed earlier, in immature DCs the attenuated activity of endosomal/lysosomal proteases limits Ii degradation and the generation of antigenic peptides, thus leading to the retention and eventually the degradation of MHC II molecules in the lysosomes. There is also a significant portion of MHC II molecules that reach endosomes/lysosomes following endocytosis from the plasma membrane. Recent data indicate that MHC II clearance from the surface of immature DCs is triggered by ubiquitination of the cytoplasmic tail of MHC II-β chain (162–164). Upon maturation, general endosomal/lysosomal proteolytic activity increases, resulting in the rapid maturation and peptide loading of the newly synthesized MHC II molecules, which are then targeted to the plasma membrane. Ubiquitination of MHC II molecules no longer occurs, causing their accumulation at the cell surface (163,164).

It is remarkable that MHC II–peptide complexes can escape the late endosomal/lysosomal compartments in DCs, because lysosomes are conventionally considered inefficient sites of membrane recycling to the plasma membrane. DC maturation elicits the formation of lysosomal tubules, which move in a retrograde manner to fuse directly with the plasma membrane (165–167). In the

presence of specific T cells, the tubules may even be selectively targeted to the DC–T cell interface (166), thus facilitating antigen presentation to T cells.

MHC II molecules exhibit a unique distribution at the surface of DCs. They appear to be organized into clusters (156). The discontinuous distribution is at least in part mediated by lateral association of MHC II molecules with the tetraspan molecule CD9 and could facilitate T cell recognition (168).

CD1 PRESENTATION

CD1 molecules are MHC-like proteins that bind and present lipid antigens (169,170). Compared to the MHC I and MHC II presentation pathways, little is known about the intracellular pathways leading to lipid presentation by CD1 molecules. In humans, five CD1 isoforms have been identified, and two classes can be distinguished: The first group, containing CD1a, CD1b, and CD1c molecules, presents bacterial lipid antigens to conventional $\alpha\beta$ T cells. The second group, composed of CD1d molecules, mainly presents self-lipid antigens to a specialized population of T cells, named NKT cells, expressing an invariant TCR α chain. The function of CD1e molecules is poorly understood. CD1e molecules appear to remain intracellular, apparently never reaching the plasma membrane, which would exclude a direct role in lipid antigen presentation to T cells (171). It was recently proposed that CD1e might instead be involved in lipid antigen processing, as discussed later. In mice, only the CD1d isoform is expressed. CD1a, b, c, e isoforms are expressed mainly by DCs, whereas the CD11d isoform is also expressed in other tissues. Like MHC I molecules, CD1 molecules consist of one transmembrane heavy chain that associates with β_2m. Unlike MHC I molecules, however, CD1 molecules are targeted to the endocytic pathway, where they bind lipid antigens.

Source and Nature of Antigens for CD1 Presentation

A wide variety of lipid antigens from microbial and self-origin have been found to bind CD1 molecules. Most of the identified foreign lipid antigens are constituents derived from the cell wall of mycobacteria. Some of these are shed and might therefore be readily available for loading onto CD1 molecules. Others are covalently attached to the bacterial cell wall and require processing in the endosomal pathway before association to CD1 molecules. The characterized self-lipids capable of binding CD1 molecules include glycolipids, phospholipids, and lipopeptides (172,173).

A comparison of the structures of the known CD1 ligands has revealed a large flexibility both in the type of hydrophobic tail that can bind the CD1 molecules and in the hydrophilic region that interacts with TCR (174).

The mechanisms of exogenous lipid antigen capture have been poorly scrutinized. It is likely that protein antigens and lipid antigens, both associated with bacteria or cell debris, are internalized through the same routes (see section on MHC II presentation). In addition, pathways specific to lipid antigen recognition and internalization have been developed by APCs. The lipid transporter apolipoprotein E mediates the delivery of serum-borne lipid antigens to the endocytic pathway in a receptor-dependent manner, leading to their efficient presentation (175).

Assembly and Intracellular Trafficking of the CD1 Molecules

CD1 molecules are synthesized in the ER, where they assembled with β_2m in a process requiring the chaperones calnexin, calreticulin, and ERp57, analogous to MHC I molecules (176) (Figure 20.4). The CD1b and CD1d molecules, and probably the other CD1 isoforms, associate with the self antigen phosphatidylinositol (PI) in the ER (177), suggesting that PI plays a role similar to the Ii in the MHC II pathway by facilitating CD1 assembly and possibly protecting the binding groove until the CD1 molecules enter the endocytic pathway. This hypothesis has yet to be verified. Microsomal triglyceride transfer protein (MTP), an ER-resident protein, associated with CD1d *in vitro*, is essential to lipid antigen presentation, and was proposed to assist in loading of lipids onto nascent CD1d proteins (178,179). However, recent studies suggest instead a distal role of MTP at a later stage in the recycling of CD1d from the lysosomes to the plasma membrane (180). CD1d has also been shown to associate with Ii chain alone or in complex with MHC II molecules *in vitro*, suggesting that the intracellular trafficking of CD1d may be altered in presence of Ii and MHC II molecules (181,182). However, a potential role of the Ii chain in the intracellular trafficking of CD1d was not confirmed *in vivo* (183).

The newly assembled CD1 complexes are transported from the ER to the cell surface via the Golgi apparatus, although an endosomal intermediate remains possible. In any event, targeting signals contained in the cytosolic tails of the various CD1 isoforms induce their internalization via diverse mechanisms and their traffic through different portions of the endocytic pathway (184–188). CD1a molecules traffic only within the recycling early endosomes, whereas CD1b and CD1d molecules accumulate in the late endosomes/lysosomes. CD1c molecules are equally distributed in the early endosomes and the late endosomes/lysosomes at steady state.

During DC maturation, intracellular distribution and trafficking of the CD1a, b, c isoforms does not appear to be dramatically affected (189). However, certain features
FIGURE 20.4 Overview of the CD1 pathway. CD1 molecules are major histocompatibility complex (MHC)–like proteins that bind lipid antigens from endogenous and exogenous origin. The newly synthesized CD1 heavy chain (HC) assembles with β_2-microglobulin (β_2m) in a process analogous to MHC I and requires the chaperones calnexin, calreticulin, and ERp57 in the endoplasmic reticulum (ER). The CD1b and CD1d molecules, and probably the other CD1 isoforms, then associate with the self-antigen phosphatidylinositol (PI) in the ER, possibly with the help of the microsomal triglyceride transfer protein (MTP). The antigen-loaded CD1 complexes then leave the ER and are transported to the cell surface via the Golgi apparatus. From the plasma membrane, CD1 isoforms traffic to different endocytic compartments, where they bind lipid antigens (CD1a molecules traffic to early endosomes, whereas CD1b and CD1d are targeted to the late endosomes/lysosomes). In lysosomes, sphingolipid activator proteins (SAPs) facilitate lipid extraction from the membranes and loading onto CD1 molecules. The lipid-loaded CD1 molecules are then transported to the cell surface for presentation to T cells.

of the CD1 presentation pathway may be regulated during DC maturation without affecting CD1 distribution. For example, it is unknown whether immature and mature DCs present a similar repertoire of lipid antigens. Of interest, CD1e molecules relocalize from the Golgi apparatus to the lysosomes, where they are cleaved into a stable soluble form upon DC maturation (171). CD1e molecules have been shown to be involved in the generation of glycolipid antigens presented by CD1b molecules (190). Thus, by regulating the intracellular distribution of CD1e molecules,

DCs might regulate the processing of glycolipid antigens and their presentation by CD1 molecules.

Antigen Processing and Loading on CD1 Molecules

Lipid ligand selection is probably controlled by the intracellular distribution and the binding groove specificities of the CD1 isoforms. According to their intracellular localization, it is likely that CD1a molecules bind lipid antigens in

the early endosomes, whereas CD1b and CD1d molecules are loaded in the late endosomes/lysosomes. Consistent with this idea, lipid binding to CD1b but not CD1a depends on endosomal acidification (186).

Antigen Processing

How are lipid antigens processed and loaded onto CD1 molecules? Few details are known. The lysosomal glycosidases α-galactosidase A, β-hexosaminidase β, and α-mannosidase have been shown to be involved in the trimming of glycolipid antigens (190–192). In lysosomes, soluble CD1e molecules are also involved in glycolipid degradation (190). The proposed model suggests that CD1e molecules are primarily involved in the editing of glycolipid antigens by binding glycolipids in a mode similar to that of other CD1 isoforms and facilitating carbohydrate degradation.

Antigen Loading onto CD1 Molecules

In vitro, lipids can directly associate with CD1b and CD1d molecules in absence of chaperones in a reaction favored by acidic pH (193–195). Within the cell, however, lipids tend to insert into the membrane bilayer, suggesting that accessory molecules may be required to facilitate lipid extraction from the membranes and loading on CD1 molecules. Sphingolipid activator proteins (SAPs), including saposins and the GM2-activator protein, and the Niemann-Pick type C2 (NPC2) are essential for loading lipid antigens onto CD1b and CD1d molecules in late endosomes/lysosomes (196–200). SAPs are believed to have multiples functions: (a) they extract lipids from the lysosomal membrane, making them available for processing by lysosomal enzymes or direct loading onto CD1 molecules and (b) they interact with CD1 molecules and exchange the lipids bound to CD1 molecules. By analogy with the chaperones, tapasin in the MHC pathway, and DM in the MHC II pathway, SAPs may serve an editing function by binding to and removing antigens that are weakly bound to CD1 molecules.

Cathepsin L–deficient mice exhibit a defect in CD1d presentation (201), although the underlying mechanism remains to be elucidated. Cathepsin L may be required for the conversion of the saponin precursor, or other unknown enzymes involved in the CD1 pathway, into mature active forms. Alternatively, cathepsin L may be directly involved in the processing of antigens that bind CD1d molecules.

The newly lipid-loaded CD1 molecules are then transported to the cell surface, where they present lipid antigens to T cells. CD1a molecules loaded in early endosomes reach the plasma membrane via the recycling endosomal pathway. How CD1b and CD1b molecules escape the late endosomes/lysosomes has not been characterized. One possibility is that they use the same pathway as MHC II molecules (see section on MHC II presentation), although CD1 and MHC II trafficking appear to be differentially regulated in DCs.

Regulation and Effector Functions of the Immune Response

Immunogenicity and Antigen Structure

Jay A. Berzofsky and Ira J. Berkower

THE NATURE OF ANTIGENIC DETERMINANTS RECOGNIZED BY ANTIBODIES

Haptens

In the antigen–antibody-binding reaction, the antibody-binding site is often unable to accommodate the entire antigen. The part of the antigen that is the target of antibody binding is called an *antigenic determinant*, and there may be one or more antigenic determinants per molecule. To study antibody specificity, we need to have antibodies against single antigenic determinants. Small functional groups that correspond to a single antigenic determinant are called *haptens*. For example, these may be organic compounds, such as trinitrophenyl or benzene arsonate, a mono- or oligosaccharide such as glucose or lactose, or an oligopeptide such as pentalysine. Although these haptens can bind to antibody, immunization with them

usually will not provoke an antibody response (for exceptions, see online ref. *1*). Immunogenicity often can be achieved by covalently attaching haptens to a larger molecule, called the *carrier*. The carrier is immunogenic in its own right, and immunization with the hapten–carrier conjugate elicits an antibody response to both hapten and carrier. However, the antibodies specific for hapten can be studied by equilibrium dialysis using pure hapten (without carrier) or by immunoprecipitation using hapten coupled to a different (and non–cross-reacting) carrier, or by inhibition of precipitation with free hapten.

This technique was pioneered by Landsteiner *(2)* and helped to elucidate the exquisite specificity of antibodies for antigenic determinants. For instance, the relative binding affinity of antibodies prepared against succinic acid–serum protein conjugates shows marked specificity for the maleic acid analog, which is in the *cis* configuration, as compared to the fumaric acid (*trans*) form *(3)*. Presumably, the immunogenic form of succinic acid corresponds to the *cis* form *(3)*. This ability of antibodies to distinguish *cis* from *trans* configurations was re-emphasized in later studies measuring relative affinities of antibodies to maleic and fumaric acid conjugates *(4)* (Table 21.1A). Table 21.1B shows the specificity of antibodies prepared against *p*-azobenzene arsonate coupled to bovine gamma globulin *(5)*. Since the hapten is coupled through the *p*-azo group to aromatic amino acids of the carrier, haptens containing bulky substitutions in the para position would most resemble the immunizing antigen. In fact, *p*-methyl-substituted benzene arsonate has a higher binding affinity than unsubstituted benzene arsonate. However, methyl substitution elsewhere in the benzene ring reduces affinity, presumably because of interference with the way hapten fits into the antibody-binding site. Thus, methyl substitutions can have positive or negative effects on binding energy, depending on where the substitution occurs. Table 21.1C shows the specificity of antilactose antibodies for lactose versus cellobiose *(6)*. These disaccharides differ only by the orientation of the hydroxyl attached to C4 of the first sugar ei-

ther above or below the hexose ring. The three examples in this table, as well as many others *(1)*, show the marked specificity of antibodies for *cis–trans*, *ortho–meta-para*, and stereoisomeric forms of the antigenic determinant.

Comparative binding studies of haptens have been able to demonstrate antibody specificity despite the marked heterogeneity of antibodies. Unlike the antibodies against a multideterminant antigen, the population of antibodies specific for a single hapten determinant is a relatively restricted population, because of the shared structural constraints necessary for hapten to fit within the antibody-combining site. However, the specificity of an antiserum depends on the collective specificities of the entire population of antibodies, which are determined by the structures of the various antibody-binding sites. When studying the cross-reactions of hapten analogs, some haptens bind all antibodies, but with reduced K_A. Other hapten analogs reach a plateau of binding because they fit some antibody-combining sites quite well but not others (see discussion of cross-reactivity in Chapter 5). Antibodies raised in different animals may show different cross-reactivities with related haptens. Even within a single animal, antibody affinity and specificity are known to increase over time following immunization under certain conditions *(7)*. Thus, any statements about the cross-reactivity of two haptens reflect both structural differences between the haptens that affect antigen–antibody fit and the diversity of antibody-binding sites present in a given antiserum.

Carbohydrate Antigens

The antigenic determinants of a number of biologically important substances consist of carbohydrates. These often occur as glycolipids or glycoproteins. Examples of the former include bacterial cell wall antigens and the major blood group antigens, whereas the latter group includes "minor" blood group antigens such as Rh. In addition, the capsular polysaccharides of bacteria are important for virulence and are often targeted by protective antibodies.

▌**TABLE 21.1 Exquisite Specificity of Antihapten Antibodies**

Hapten	Structure	K_{rel} of Antibody Specific for	
A.		Maleic (cis)	Fumarlc (trans)

A number of spontaneously arising myeloma proteins have been found to show carbohydrate specificity, possibly reflecting the fact that carbohydrates are common environmental antigens. In the days prior to hybridoma technology, these carbohydrate-specific myeloma proteins provided an important model for studying the reaction of antigen with a monoclonal antibody.

Empirically, the predominant antigenic determinants of polysaccharides often consist of short oligosaccharides (one to five sugars long) at the nonreducing end of the polymer chain *(8)*. This situation is analogous to a hapten consisting of several sugar residues linked to a large nonantigenic polysaccharide backbone. The remainder of the polysaccharide is important for immunogenicity, just as the carrier molecule was important for haptens. In addition, branch points in the polysaccharide structure allow for multiple antigenic determinants to be attached to the same macromolecule. This is important for immunoprecipitation by lattice formation, as discussed in Chapter 5. Several examples illustrating structural studies of oligosaccharide antigens are given later.

The technique used most widely to analyze the antigenic determinants of polysaccharides is called *hapten inhibition (8)*. In this method, the precipitation reaction between antigen and antibody is inhibited by adding short oligosaccharides. These oligosaccharides are large enough to bind with the same affinity and specificity as the polysaccharide, but because they are monomeric, no precipitate forms. As more inhibitor is added, fewer antibody-combining sites remain available for precipitation. Using antiserum specific for a single antigenic determinant, it is often possible to block precipitation completely with a short oligosaccharide corresponding to the nonreducing end of the polysaccharide chain. Besides showing the "immunodominance" of the nonreducing end of the chain, this result also shows that the structure of the antigenic determinant of polysaccharides depends on the sequence of carbohydrates and their linkage, rather than their conformation. For inhibition by hapten to be complete, the antigen–antibody system studied must be made specific for a single antigenic determinant. For optimal sensitivity, the equivalence point of antigen and antibody should be used.

We illustrate the types of carbohydrate antigens encountered by examining three classic examples in more detail: the salmonella O antigens, the blood group antigens, and dextrans that bind to myeloma proteins.

Immunochemistry of Salmonella O Antigens

The antigenic diversity among numerous salmonella species resides in the structural differences of the lipopolysaccharide (LPS) component of the outer membrane *(9)*. These molecules are the main target for antisalmonella antibodies. The polysaccharide moiety contains the antigenic determinant, whereas the lipid moiety is responsible for endotoxin effects. The chemical structure of LPS can be divided into three regions (Figure 21.1). Region I contains the antigenic O-specific polysaccharide, usually made up of repeated oligosaccharide units, which vary widely among different strains. Region II contains an oligosaccharide "common core" shared among many different strains. Failure to synthesize region II oligosaccharide or to couple completed region I polysaccharide to the growing region II core results in R (rough) mutants, which have "rough" colony morphology and lack the O antigen. Region III is the lipid part, called *lipid A*, which is shared among all salmonellae and serves to anchor LPS on the outer membrane. Early immunologic attempts to classify the O antigens of different salmonellae revealed a large number of cross-reactions between different strains. These were detected by preparing antiserum to one strain of salmonella and using it to agglutinate bacteria of a second strain. Each cross-reacting determinant was assigned a number, and each strain was characterized by a series of O antigen determinants (in aggregate, the "serotype" of the strain) based on its pattern of cross-reactivity. Each strain was classified within a group, based on sharing a strong O determinant. For example, group A strains share determinant 2, whereas group B strains share determinant 4 (Table 21.2). However, within a group, each strain possesses additional O determinants, which serve to differentiate it from other members of that group. Thus, determinant 2 coexists with determinants 1 and 12 on *Salmonella paratyphi A*.

This problem of cross-reactivity based on sharing of a subset of antigenic determinants is commonly encountered in complex antigen–antibody systems. The problem may be simplified by making antibodies monospecific for individual antigenic determinants. To do this, antibodies are absorbed to remove irrelevant specificities, or cross-reactive strains are chosen that share only a single determinant with the immunizing strain. The reaction of each determinant with its specific antibody can be thought of as an antigen–antibody system. Thus, for the strains shown in Table 21.2, antiserum to *Salmonella typhi* (containing anti-9 and anti-12 antibodies) may be absorbed with *S. paratyphi A* to remove anti-12, leaving a reagent specific for antigen 9 (21.2). Alternatively, the unabsorbed antiserum may be used to study the system antigen 12–anti-12 by allowing it to agglutinate *Salmonella paratyphi B*, which shares only antigen 12 with the immunogen. Because the other determinants on *S. paratyphi B* were absent from the immunizing strain, the antiserum contains no antibodies to them.

Once the antigen–antibody reaction is made specific for a single determinant, a variety of oligosaccharides can be added to test for hapten inhibition. Because the O antigens contain repeating oligosaccharide units, it is often possible to obtain model oligosaccharides by mild chemical or enzymatic degradation of the LPS polysaccharide itself. Once the most inhibitory oligosaccharide is found,

FIGURE 21.1 Structure of *Salmonella (S.)* lipopolysaccharide. Region I contains the unique O-antigen determinants, which consist of repeating units of oligosaccharides. These are attached to lipid moiety through the core polysaccharide. Three examples of oligosaccharide units are shown (9). (Part A adapted from ref. *8*, with permission; part B based on ref. *9*.)

its chemical structure is determined. Alternatively, a variety of synthetic mono-, di-, tri-, and oligosaccharides are tested for hapten inhibition of precipitation. For example, as shown in Table 21.3, antigen 1–anti-1 antibody precipitation is inhibited by methyl-αD-glucoside. Therefore, various disaccharides incorporating this structure were tested,

of which αD-Glu$(1\rightarrow6)$D-Gal was the most inhibitory. Then various trisaccharides incorporating this sequence were tested. The results indicate the sequence and size of the determinant recognized by anti-1 antibodies to be a disaccharide with the structure shown here. The test sequences can be guessed by analyzing the oligosaccharide

breakdown products of the lipopolysaccharide, which include tetramers of D-Glu-D-Gal-D-Man-L-Rham.

The results in Table 21.3 also suggest that the difference between determinants 1 and 19 is the length of oligosaccharide recognized by antibodies specific for each determinant. This hypothesis is supported by the observation that determinant 1 is found in some strains with, and in other strains without, determinant 19; whereas determinant 19 is always found with determinant 1. As shown in the table, determinant 19 requires the full tetrasaccharide for maximal hapten inhibition, including the sequence coding for determinant 1. Besides identifying the antigenic structures, these results indicate that there is variation in the size of different antigenic determinants of polysaccharides.

Blood Group Antigens

The major blood group antigens A and B were originally detected by the ability of serum from individuals lacking either determinant to agglutinate red blood cells bearing them (for reviews, see refs. *8* and *10–12*). In addition, group O individuals have an H antigenic determinant that is distinct from A or B types, and individuals in all three groups may have additional determinants such as the Lewis (Le) antigens. Although the ABH and Le antigenic determinants are found on a carbohydrate moiety, the carbohydrate may occur in a variety of biochemical forms. On cell surfaces, they are either glycolipids that are synthesized within the cell (AB and H antigens) or glycoproteins taken up from serum (Le antigens). In mucinous secretions, such as saliva, they occur as glycoproteins. Milk, ovarian cyst fluid, and gastric mucosa contain soluble oligosaccharides containing blood group reactivity. In addition, these antigens occur frequently in other species, including about half of the bacteria in the normal flora of the gut *(10)*. This widespread occurrence may account for the ubiquitous anti-AB reactivity of human sera, even in people never previously exposed to human blood group substances through transfusion or pregnancy.

The immunochemistry of these antigens was simplified greatly by the use of oligosaccharides in hapten inhibition studies. Group A oligosaccharides, for example, would inhibit the agglutination of group A red blood cells by anti-A antibodies. They could also inhibit the immunoprecipitation of group A-bearing glycoproteins by anti-A antibodies. Because the oligosaccharides are monomeric, their reaction with antibody does not form a precipitate but does block an antibody-combining site.

The inhibitory oligosaccharides from cyst fluid were purified and found to contain D-galactose, L-fucose, *N*-acetyl galactosamine, and *N*-acetylglucosamine. The most inhibitory oligosaccharides for each antigen are indicated in Figure 21.2. As can be seen in the figure, the ABH and Le antigens all share a common oligosaccharide core sequence, and the antigens appear to differ from each other by the sequential addition of individual sugars at the end or at branch points. Besides hapten inhibition, other biochemical data support this relationship among the different determinants. Enzymatic digestion of A, B, or H antigens yields a common core oligosaccharide from each. This product cross-reacts with antiserum specific for pneumococcal polysaccharide type XIV, which contains structural elements shared with blood group determinants, as shown at the bottom of Figure 21.2. In addition, this structure, known as *precursor substance*, has been isolated from ovarian cyst fluid.

Starting from precursor substance, the H determinant results from the addition of L-fucose to galactose, whereas Lewis[a] antigen (Le[a]) determinant results from the addition of L-fucose to *N*-acetylglucosamine, and Le[b] from the addition of L-fucose to both sugars. Addition of *N*-acetylgalactosamine to H substance produces the A determinant, whereas addition of galactose produces the B determinant, in each case blocking reactivity of the H determinant.

The genetics of ABH and Le antigens is explained by this sequential addition of sugars via glycosyltransferases. The allelic nature of the AB antigens is explained by the addition of *N*-acetylgalactosamine, galactose, or nothing to the H antigen. The rare inherited trait of inability to synthesize the H determinants from precursor substance (Bombay phenotype) also blocks the expression of A and B antigens, because the A and B transferases lack an
FIGURE 21.2 Oligosaccharide chain specificity. Structure of the ABH and Lewis (Le) blood group antigens, as determined by hapten inhibition studies (*8,11*). There are two variants of each of these determinants. In type 1, the Gal-GNAc linkage is $\beta(1 \to 3)$, whereas in type 2, the Gal-GNAc linkage is $\beta(1 \to 4)$. In addition, there is heterogeneity in the A and B antigens with respect to the presence of the Le fucose attached to the GNAc. In the molecules that contain the extra fucose, when the Gal-GNAc linkage is $\beta(1 \to 3)$ (type 1), the fucose must be linked $\alpha(1 \to 4)$, whereas the type 2 molecules, with the $\beta(1 \to 4)$ Gal-GNAc linkage, contain $\alpha(1 \to 3)$-linked fucose. The *asterisks* indicate the sites of this variability in linkage.

acceptor substrate. However, the appearance of the Le[a] on red cells is independent of H antigen synthesis. Its structure, shown in Figure 21.2, can be derived directly from precursor substance without going through an H antigen intermediate. Comparing different individuals, the appearance of Le[a] antigen on red blood cells correlates with its presence in saliva, because the Le[a] antigen is not an intrinsic membrane component but must be absorbed from serum glycoproteins, which, in turn, depend on secretion. In addition to the independent synthetic pathway, the secretion of Le[a] antigen is also independent of the secretory process for ABH antigens. Therefore salivary nonsecretors

of ABH antigens (which occur in 20% of individuals) may still secrete Le[a] antigen if they have the fucosyl transferase encoded by the Le gene. In contrast, salivary secretion of ABH is required for red blood cells to express Le[b].

Dextran-Binding Myeloma Proteins

Because polysaccharides are common environmental antigens, it is not surprising that randomly induced myeloma proteins were frequently found to have carbohydrate specificities. Careful studies of these monoclonal antibodies support the clonal expansion model of antibody diversity: heterogeneous antisera behave as the sum of many individual clones of antibody with respect to affinity and specificity. In the case of the IgAκ myeloma proteins W3129 and W3434, both antibodies were found to be specific for dextrans containing α-glu $(1 \to 6)$glu bonds *(12)*. Hapten inhibition with a series of mono- or oligosaccharides of increasing chain length indicated that the percentage of binding energy derived from the reaction with one glucose was 75%, two glucoses 95%, three 95% to 98%, and four 100%. This suggests that most binding energy between antidextran antibodies and dextran derives from the terminal monosaccharide, and that oligosaccharides of chain length 4 to 6 commonly fill the antibody-combining site. Human antidextran antisera behaved similarly, with tetrasaccharides contributing 95% of the binding energy. These experiments provided the first measure of the size of an antigenic determinant, 4 to 6 residues *(13,14)*. In addition, as was observed for antisera, binding affinity of myeloma proteins was highly sensitive to modifications of the terminal sugar and highly specific for $\alpha(1 \to 6)$ versus $\alpha(1 \to 3)$ glycosidic bonds. However, modification of the third or fourth sugar of an oligosaccharide had relatively less effect on hapten inhibition of either myeloma protein or of antisera reacting with dextran.

Studies with additional dextran-binding myeloma proteins *(15)* revealed that not all antipolysaccharide monoclonal antibodies are specific for the nonreducing end, as exemplified by QUPC 52. Competitive inhibition with mono- and oligosaccharides revealed that less than 5% of binding energy derived from mono- or disaccharides, 72% from trisaccharides, 88% from tetrasaccharides, and 100% from hexasaccharides, in marked contrast to other myeloma proteins. A second distinctive property of myeloma protein QUPC 52 was its ability to precipitate unbranched dextran of chain length 200. Because the unbranched dextran has only one nonreducing end, and because the myeloma protein has only one specificity, lattice formation due to cross-linking between the nonreducing ends is impossible, and precipitation must be explained by binding some other determinant. Therefore, QUPC 52 appears to be specific for internal oligosaccharide units of 3 to 7 chain length. W3129 is specific for end determinants and will not precipitate unbranched dextran chains.

Antibodies precipitating linear dextran were also detected in six antidextran human sera, comprising 48% to 90% of the total antibodies to branched chain dextran. Thus antidextrans can be divided into those specific for terminal oligosaccharides and those specific for internal oligosaccharides; monoclonal examples of both types are available, and both types are present in human immune serum. Cisar et al. *(15)* speculated as to the different topology of the binding sites of W3129 or QUPC 52 necessary for terminal or internal oligosaccharide specificity. Both terminal and internal oligosaccharides have nearly identical chemical structures, differing at a single C–OH or glycoside bond. Perhaps the terminal oligosaccharide specificity of W3129 is due to the shape of the antibody-combining site—a cavity into which only the end can fit; whereas the internal oligosaccharide-binding site of QUPC 52 could be a surface groove in the antibody, which would allow the rest of the polymer to protrude out at both ends. A more definitive answer depends on x-ray crystallographic studies of the combining sites of monoclonal antibodies with precisely defined specificity, performed with antigen occupying the binding site (see below).

With the advent of hybridoma technology, it became possible to produce monoclonal antibodies of any desired specificity. Immunizing mice with nearly linear dextran (the preferred antigen of QUPC 52), followed by fusion and screening (with linear dextran) for dextran-binding antibodies, yielded 12 hybridomas *(16)*, all with specificity similar to QUPC 52. Oligosaccharide inhibition of all 12 monoclonals showed considerable increments in affinity up to hexasaccharides, with little affinity for disaccharides and only 49% to 77% of binding energy derived from trisaccharides *(17)*. Second, all 12 monoclonals had internal $\alpha(1\rightarrow6)$ dextran specificity because they could all precipitate linear dextran. Third, 9 of 11 BALB/c monoclonals shared a cross-reactive idiotype with QUPC 52, whereas none shared idiotype with W3129 *(18)*. These data support the hypothesis that different antibodies with similar specificity and similar groove-type sites may be derived from the same family of germline V_H genes bearing the QUPC 52 idiotype *(18)*.

The large number of environmental carbohydrate antigens and the high degree of specificity of antibodies elicited in response to each carbohydrate antigen suggest that a tremendous diversity of antibody molecules must be available, from which some antibodies can be selected for every possible antigenic structure. Studies of a series of 17 monoclonal anti-$\alpha(1\rightarrow6)$ dextran hybridomas *(19,20)* have investigated whether the binding sites of closely related antibodies were derived from a small number of variable region genes, for both heavy and light chains, or whether antibodies of the same specificity could derive from variable region genes with highly divergent sequences. Each monoclonal had a groove-type site that could hold six or seven sugar residues (with one exception), based on inhibition

of immunoprecipitation by different-length oligosaccharides. Thus, unlike monoclonals to haptenated proteins, the precise epitope could be well characterized and was generally quite similar among the entire series.

Studies of the V_κ sequences revealed that only three V_κ groups were used in these hybridomas. Use of each V_κ group correlated with the particular antigen used to immunize the animals, whether linear dextran or short oligosaccharides, so that 10 of the monoclonals from mice immunized the same way all used the same V_κ.

In contrast, the 17 V_H chains were derived from at least five different germline genes from three different V_H gene families *(21)*. The two most frequently used germline V_H genes were found in seven and five monoclonals, respectively, with minor variations explainable by somatic mutations. The remarkable finding is that very different V_H chains (about 50% homologous) can combine with the same V_κ to produce antibody-binding sites with nearly the same size, shape, antigen specificity, and affinity. Even when different V_H sequences combine with different V_κ sequences, they can produce antibodies with very similar properties. Dextran binding depends on the antigen fitting into the groove and interacting favorably with the residues forming the sides and bottom of the groove. The results indicate that divergent variable region sequences, both in and out of the complementarity-determining regions, can be folded to form similar binding site contours, which result in similar immunochemical characteristics. Similar results have been reported in other antigen–antibody systems, such as phenyloxazolone *(22)*.

Additional studies of carbohydrate binding monoclonal antibodies have revealed significant information about how the antibody variable regions can bind a carbohydrate structure with high affinity and specificity. Several examples are now available of crystal structures of carbohydrates bound to antibodies.

For example, monoclonal antibody Se155-4 is specific for the group B determinant of the Salmonella O antigen, which consists of the sugars Gal- Abequose- Man (23,24). The crystal structure of antibody bound to the polysaccharide shows that one hexose, abequose, fits into the binding pocket, while the rest of the interactions occur along the surface of the antibody, similar to the groove-type sites previously described. Binding energy depends on hydrogen bonds formed between the protein residues and the hydroxyl groups of the carbohydrate. The protein residues include aromatic amines, such as His 32, Trp91, and Trp 96 of the light chain, as well as His 97 and His 35 of the heavy chain. In addition, one of the sugars is hydrogen bonded via a water molecule bridge to the amide bonds of the protein backbone. About three fourths of all sugar hydroxyl groups are involved in hydrogen bonds with the protein. Although each H bond is relatively weak by itself, the combined effect of eight hydrogen bonds results in high affinity binding. Antibody specificity derives from the fact that the

carbohydrate fits into a binding pocket, where H bond formation depends on precise interactions with amino acid residues that are oriented about the pocket. Surprisingly, most of these bonds are formed between sugar hydroxyls and aromatic amino acids that are neither charged nor very polar at neutral pH.

Similarly, monoclonal antibody BR96 and the humanized monoclonal hu3S193 are specific for the Lewis Y antigen, which resembles the Le b antigen described in Figure 21.2, except that the Fucose-*N* Acetyl Glucosamine bond is beta 1→3 instead of beta 1→4. The Le Y antigen is commonly expressed on tumor cells of epithelial origin. The crystal structures have revealed the sources of the binding energy that results in affinity and specificity for this carbohydrate antigen (25,26). These two monoclonals bind Le Y antigen in a large, deep pocket, which accommodates all four hexoses and corresponds to the cavity-type binding site predicted by Kabat (*15*). The terminal Fucose goes in first, while the other three sugars are hydrogen-bonded to amino acid side chains lining the pocket, including Tyr 33, Tyr 35, and Gln 52 of the heavy chain, and His 27 of the light chain. Once again, hydrogen bonds between hydroxyl groups of the sugars and aromatic amines (Trp and Tyr) of the protein play a dominant role in determining affinity and specificity of binding. A smaller number of H bonds depend on amide groups of the protein backbone.

A third example is provided by human monoclonal 2G12, which has neutralizing activity against a broad spectrum of HIV isolates. This antibody binds the mannose-rich oligosaccharide side chains that form a protective surface, called a *glycoshield*, on the envelope glycoprotein gp120. The crystal structure shows that the two terminal mannose sugars of each oligosaccharide bind end-on into a deep pocket of the antibody, in a cavity-type site (27,28). Twelve hydrogen bonds form between the two terminal mannose residues and the protein, depending mainly on the amide groups of the protein backbone. Additional hydrogen bonds form between the third mannose residue and the side chain of Asp 100 of the heavy chain and between the fourth mannose residue and Tyr 94 of the light chain and Tyr 56 of the heavy chain. A unique feature of this antibody is the cross over of variable regions between heavy and light chains, so that each binding site is made up of the V_H from one HL pair combining with the V_L chain of the opposite pair. This arrangement allows the antibody to bind one branch of an oligosaccharide and the opposite branch of a nearby oligosaccharide and makes it ideally suited for cross-linking the densely clustered oligosaccharides of gp120.

Immunogenicity of Polysaccharides

Capsular polysaccharides are the main target of protective antibodies against bacterial infection, and, as such, are important vaccine antigens. In adults, the chain length of the polysaccharide is an important determinant of immunogenicity, and the polysaccharides induce a T-independent response that cannot be boosted on repeat exposure. In young children, whose maternal antibodies wane by 6 months of age and who most need immunity to pathogens such as *Haemophilus influenzae* type b and *Streptococcus pneumoniae* of multiple serotypes, the T-independent response to these polysaccharides is weak, regardless of chain length. To immunize children, the polysaccharides were coupled to a protein carrier to create a new T-dependent antigen that gained immunogenicity from T-cell help and boosted antibody titers with each successive dose. This strategy has produced highly successful conjugate vaccines against *H. influenzae* type b *(29)* resulting in a markedly reduced incidence of meningitis caused by this agent in immunized children (30,31) and evidence of herd immunity even among unimmunized children. The same strategy has produced an effective vaccine against invasive disease (32) and otitis media (33) caused by the most prevalent serotypes of *Strep. pneumonia*.

Protein and Polypeptide Antigenic Determinants

Like the proteins themselves, the antigen determinants of proteins consist of amino acid residues in a particular three-dimensional array. The residues that make contact with complementary residues in the antibody-combining site are called *contact residues*. To make contact, of course, these residues must be exposed on the surface of the protein, not buried in the hydrophobic core. Because the complementarity-determining residues in the hypervariable regions of antibodies have been found to span as much as 30 to 40 Å × 15 to 20 Å × 10 Å (D. R. Davies, personal communication, 1982), these contact residues comprising the antigenic determinant may cover a significant area of protein surface, as measured by x-ray crystallography of antibody–protein antigen complexes (*34–36,37*). The size of the combining sites has also been estimated using simple synthetic oligopeptides of increasing length, such as oligolysine. In this case, a series of elegant studies *(38–40)* suggested that the maximum length of chain a combining site could accommodate was six to eight residues, corresponding closely to that found earlier for oligosaccharides *(13,14)*, discussed previously.

Several types of interactions contribute to the binding energy. Many of the amino acid residues exposed to solvent on the surface of a protein antigen will be hydrophilic. These are likely to interact with antibody contact residues via polar interactions. For instance, an anionic glutamic acid carboxyl group may bind to a complementary cationic lysine amino group on the antibody, or vice versa; or a glutamine amide side chain may form a hydrogen bond with the antibody. However, hydrophobic interactions can also play a major role. Proteins cannot exist in aqueous solution

as stable monomers with too many hydrophobic residues on their surface. Those hydrophobic residues that are on the surface can contribute to binding to antibody for exactly the same reason. When a hydrophobic residue in a protein antigenic determinant or, similarly, in a carbohydrate determinant *(8)*, interacts with a corresponding hydrophobic residue in the antibody-combining site, the water molecules previously in contact with each of them are excluded. The result is a significant stabilization of the interaction. A thorough review of these aspects of the chemistry of antigen–antibody binding is in reference 41.

Mapping Epitopes: Conformation versus Sequence

The other component that defines a protein antigenic determinant, besides the amino acid residues involved, is the way these residues are arrayed in three dimensions. Because the residues are on the surface of a protein, we can also think of this component as the topography of the antigenic determinant. Sela *(42)* divided protein antigenic determinants into two categories, sequential and conformational, depending on whether the primary sequence or the three-dimensional conformation appeared to contribute the most to binding. On the other hand, because the antibody-combining site has a preferred topography in the native antibody, it would seem *a priori* that some conformations of a particular polypeptide sequence would produce a better fit than others and therefore would be energetically favored in binding. Thus, conformation or topography must always play some role in the structure of an antigenic determinant.

Moreover, when one looks at the surface of a protein in a space-filling model, one cannot ascertain the direction of the backbone or the positions of the helices (contrast Figs. 21.3A, B) *(43–47)*. It is hard to recognize whether two residues that are side by side on the surface are adjacent on the polypeptide backbone or whether they come from different parts of the sequence and are brought together by the folding of the molecule. If a protein maintains its native conformation when an antibody binds, then it must similarly be hard for the antibody to discriminate between residues that are covalently connected directly and those connected only through a great deal of intervening polypeptide. Thus, the probability that an antigenic determinant on a native globular protein consists of only a consecutive sequence of amino acids in the primary structure is likely to be rather small. Even if most of the determinant were a continuous sequence, other nearby residues would probably play a role as well. Only if the protein were cleaved into fragments before the antibodies were made would there be any reason to favor connected sequences.

This concept was analyzed and confirmed quantitatively by Barlow et al. *(48)*, who examined the atoms lying within spheres of different radii from a given surface atom on a protein. As the radius increases, the probability that all the atoms within the sphere will be from the same continuous segment of protein sequence decreases rapidly. Correspondingly, the fraction of surface atoms that would be located at the center of a sphere containing only residues from the same continuous segment falls dramatically as the radius of the sphere increases. For instance, for lysozyme, with a radius of 8 Å, fewer than 10% of the surface residues would lie in such a "continuous patch" of surface. These are primarily in regions that protrude from the surface. With a radius of 10 Å, almost none of the surface residues fall in the center of a continuous patch. Thus, for a contact area of about 20 Å × 25 Å, as found for a lysozyme–antibody complex studied by x-ray crystallography, none of the antigenic sites could be completely continuous segmental sites (see following discussion and Fig. 21.4).

Antigenic sites consisting of amino acid residues that are widely separated in the primary protein sequence but brought together on the surface of the protein by the way it folds in its native conformation have been called *assembled topographic* sites *(49,50)* because they are assembled from different parts of the sequence and exist only in the surface topography of the native molecule. By contrast, the sites that consist of only a single continuous segment of protein sequence have been called *segmental* antigenic sites *(49,50)*.

In contrast to T-cell recognition of "processed" fragments retaining only primary and secondary structures, the evidence is overwhelming that most antibodies are made against the native conformation when the native protein is used as immunogen. For instance, antibodies to native staphylococcal nuclease were found to have about a 5,000-fold higher affinity for the native protein than for the corresponding polypeptide on which they were isolated (by binding to the peptide attached to Sepharose) *(51)*. An even more dramatic example is that demonstrated by Crumpton *(52)* for antibodies to native myoglobin or to apomyoglobin. Antibodies to native ferric myoglobin produced a brown precipitate with myoglobin, but did not bind well to apomyoglobin, which, without the heme, has a slightly altered conformation. On the other hand, antibodies to the apomyoglobin, when mixed with native (brown) myoglobin, produced a white precipitate. These antibodies so strongly favored the conformation of apomyoglobin, from which the heme was excluded, that they trapped those molecules that vibrated toward that conformation and pulled the equilibrium state over to the apo form. One could almost say, figuratively, that the antibodies squeezed the heme out of the myoglobin. Looked at thermodynamically, it is clear that the conformational preference of the antibody for the apo versus native forms, in terms of free energy, had to be greater than the free energy of binding of the heme to myoglobin. Thus, in general, antibodies are

made that are very specific for the conformation of the protein used as immunogen.

Synthetic peptides corresponding to segments of the protein antigen sequence can be used to identify the structures bound by antibodies specific for segmental antigenic sites. To identify assembled topographic sites, more complex approaches have been necessary. The earliest was the use of natural variants of the protein antigen with known amino acid substitutions, where such evolutionary variants exist *(49)*. Thus, substitution of different amino acids in proteins in the native conformation can be examined. The use of this method, which is illustrated later, is limited to studying the function of amino acids that vary among homologous proteins, that is, those that are polymorphic. It may now be extended to other residues by use of site-directed mutagenesis. A second method is to use the antibody that binds to the native protein to protect the antigenic site from modification *(53)* or proteolytic degradation *(54)*. A related but less sensitive approach makes use of competition with other antibodies *(55–57)*. A third approach, taking advantage of the capability of producing thousands of peptides on a solid-phase surface for direct binding assays *(58)*, is to study binding of a monoclonal antibody to every possible combination of six amino acids *(58)*. If the assembled topographic site can be mimicked by a combination of six amino acids not corresponding to any continuous segment of the protein sequence but structurally resembling a part of the surface, then one can produce a "mimotope" defining the specificity of that antibody *(58)*.

Myoglobin also serves as a good model protein antigen for studying the range of variation of antigenic determinants from those that are more sequential in nature to those that do not even exist without the native conformation of the protein (Fig. 21.3). A good example of the first, more segmental type of determinant, is that consisting of residues 15 to 22 in the amino terminal portion of the molecule. Crumpton and Wilkinson *(59)* first discovered that the chymotryptic cleavage fragment consisting of residues 15 to 29 had antigenic activity for antibodies raised to either native or apomyoglobin. Two other groups *(44,60)* then found that synthetic peptides corresponding to residues 15 to 22 bind antibodies made to native sperm whale myoglobin, even though the synthetic peptides were only 7 to 8 residues long. Peptides of this length do not spend much time (in solution) in a conformation corresponding to that of the native protein. On the other hand, these synthetic peptides had a several hundred-fold lower affinity for the antibodies than did the native protein. Thus, even if most of the determinant was included in the consecutive sequence 15 to 22, the antibodies were still much more specific for the native conformation of this sequence than for the random conformation peptide. Moreover, there was no evidence to exclude the participation of other residues, nearby on the surface of myoglobin

but not in this sequence, in the antigenic determinant[1] *(61–64)*.

A good example of the importance of secondary structure is the case of the loop peptide (residues 64 to 80) of hen egg-white lysozyme *(65)*. This loop in the protein sequence is created by the disulfide linkage between cysteine residues 64 and 80 and has been shown to be a major antigenic determinant for antibodies to lysozyme *(65)*. The isolated peptide 60 to 83, containing the loop, binds antibodies with high affinity, but opening of the loop by cleavage of the disulfide bond destroys most of the antigenic activity for antilysozyme antibodies *(65)*.

At the other end of the range of conformational requirements are those determinants involving residues far apart in the primary sequences that are brought close together on the surface of the native molecule by its folding in three dimensions, called *assembled topographic determinants (49,50)*. Of six monoclonal antibodies to sperm whale myoglobin studied by Berzofsky et al. *(43,66)*, none bound to any of the three cyanogen bromide cleavage fragments of myoglobin that together span the whole sequence of the molecule. Therefore, these monoclonal antibodies (all with affinities between 2×10^8 and 2×10^9 M^{-1}) were all highly specific for the native conformation. These were studied by comparing the relative affinities for a series of native myoglobins from different species with known amino acid sequences. This approach allowed the definition of some of the residues involved in binding to three of these antibodies. Two of these three monoclonal antibodies were found to recognize topographic determinants, as defined previously. One recognized a determinant including Glu 4 and Lys 79, which come within about 2 Å of each other to form a salt bridge in the native molecule (Fig. 21.3A,B). The other antibody recognized a determinant involving Glu 83, Ala 144, and Lys 145 (Fig. 21.3A). Again, these are far apart in the primary sequence but are brought within 12 Å of each other by the folding of the molecule in its native conformation. Similar examples have been reported for monoclonal antibodies to human myoglobin *(67)* and to lysozyme (37,55).

Other examples of such conformation-dependent antigenic determinants have been suggested using conventional antisera to such proteins as insulin *(68)*, hemoglobin *(69)*, tobacco mosaic virus *(70)*, and cytochrome c *(71)*. Moreover, the crystallographic structures of

---

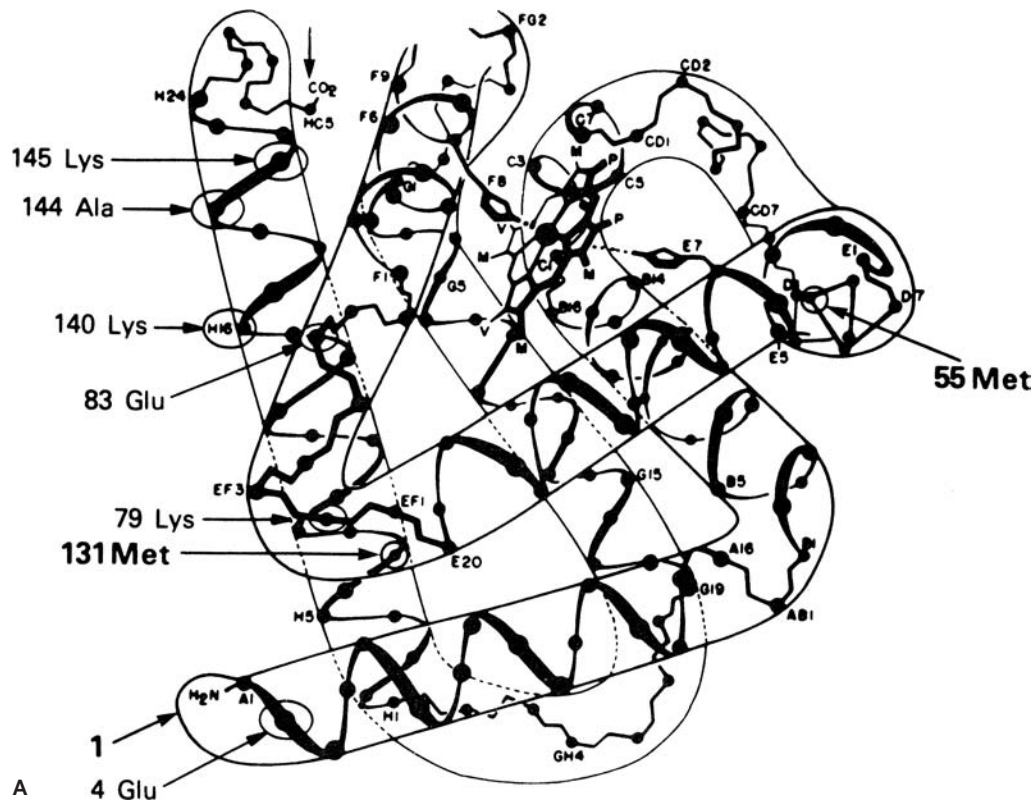
[1] This is the only segmental antigenic determinant of myoglobin that has clearly been confirmed by more than one independent group of investigators. Crumpton and Wilkinson *(59)* did measure antigenic activity for a chymotryptic fragment 147-153 that overlaps one of the other reported sequential determinants *(61)*. However, two of the other reported sequential determinants *(61)*, corresponding to residues 56 to 62 and 94 to 100, have not been reproducible when tested with other antisera, even raised in the same species *(62)*. For related studies, see refs. *63* and *64*.


FIGURE 21.3 A: Artist's representation of the polypeptide backbone of sperm whale myoglobin in its native three-dimensional conformation. The α helices are labeled A through H from the amino terminal to the carboxyl terminal. Side chains are omitted, except for the two histidine rings (F8 and E7) involved with the heme iron. Methionines at positions 55 and 131 are the sites of cleavage by cyanogen bromide (CNBr), allowing myoglobin to be cleaved into three fragments. Most of the helicity and other features of the native conformation are lost when the molecule is cleaved. A less-drastic change in conformation is produced by removal of the heme to form apomyoglobin, because the heme interacts with several helices and stabilizes their positions relative to one another. The other labeled residues (4 Glu, 79 Lys, 83 Glu, 140 Lys, 144 Ala, and 145 Lys) are residues that have been found to be involved in antigenic determinants recognized by monoclonal antibodies (*43*). Note that cleavage by CNBr separates Lys 79 from Glu 4 and separates Glu 83 from Ala 144 and Lys 145. The "sequential" determinant of Koketsu and Atassi (*44*) (residues 15 to 22) is located at the elbow, lower right, from the end of the A helix to the beginning of the B helix. (Adapted from ref. *45*, with permission.) **B:** Stereoscopic views of a computer-generated space-filling molecular model of sperm whale myoglobin, based on the Takano (*46*) x-ray diffraction coordinates. This orientation, which corresponds to that in Panel A, is arbitrarily designated the *front view*. The computer method was described by Feldmann et al. (*47*). The heme and aromatic carbons are shaded darkest, followed by carboxyl oxygens, then other oxygens, then primary amino groups, then other nitrogens, and finally side chains of aliphatic residues. The backbone and the side chains of nonaliphatic residues, except for the functional groups, are shown in white. Note that the direction of the helices is not apparent on the surface, in contrast to the backbone drawing in Panel A. The residues Glu 4, Lys 79, and His 12 are believed to be part of a topographic antigenic determinant recognized by a monoclonal antibody to myoglobin (*43*). This stereo pair can be viewed in three dimensions using an inexpensive stereoviewer such as the "stereoscopes" sold by Abrams Instrument Corp., Lansing, MI, or Hubbard Scientific Co., Northbrook, IL. (Adapted from ref. *43*, with permission.)
FIGURE 21.4 Assembled topographic sites of lysozyme illustrated by the footprints of three nonoverlapping monoclonal antibodies. Shown are the α carbon backbones of lysozyme in the center and the Fv portions of three antilysozyme monoclonal antibodies D1.3, HyHEL-5, and HyHEL-10. The footprints of the antibodies on lysozyme and lysozyme on the antibodies (i.e., their interacting surfaces) are shown by a dotted representation. Note that the three antibodies each contact more than one continuous loop of lysozyme and so define assembled topographic sites. (Reproduced from ref. *37*, with permission.)

lysozyme–antibody (*34,36,37*) and neuraminidase–antibody *(35)* complexes show clearly that, in both cases, the epitope bound is an assembled topographic site. In the case of the three monoclonal antibodies binding to nonoverlapping sites of lysozyme (Fig. 21.4), it is clear that the footprints of all three antibody-combining sites cover more than one loop of polypeptide chain and thus each encompasses an assembled topographic site (37). This result beautifully illustrates the concept that the majority of antibody-combining sites must interact with more than a continuous loop of polypeptide chain and thus must define assembled topographic sites *(48)*. Another important example is represented by neutralizing antibodies to the HIV envelope protein that similarly bind assembled topographic sites (72,73); see also the discussion at the end of this section.

How frequently are antibodies specific for topographic determinants compared with those that bind consecutive sequences when conventional antisera are examined? This question was studied by Lando et al. *(74)*, who passed goat, sheep, and rabbit antisera to sperm whale myoglobin over columns of myoglobin fragments, together spanning the whole sequence. After removal of all antibodies binding to the fragments, 30% to 40% of the antibodies remained that still bound to the native myoglobin molecule with high affinity but did not bind to any of the fragments in solution by radioimmunoassay. Thus, in four of four antimyoglobin sera tested, 60% to 70% of the antibodies could bind peptides and 30% to 40% could bind only native-conformation intact protein.

On the basis of studies such as these, it has been suggested that much of the surface of a protein molecule may be antigenic *(49,75)* but that the surface can be divided up into antigenic domains *(43,63,64,67)*. Each of these domains consists of many overlapping determinants recognized by different antibodies.

An additional interesting point is that in three published crystal structures of protein antigen–antibody complexes, the contact surfaces were broad, with local complementary pairs of concave and convex regions in both directions (*34–36,37*). Thus, the concept of an antigen binding in the groove or pocket of an antibody may be oversimplified, and antibodies may sometimes bind by extending into pockets on an antigen.

Further information on the subjects discussed in this section is available in the reviews by Sela *(42)*, Crumpton *(52)*, Reichlin *(76)*, Kabat *(77)*, Benjamin et al. *(49)*, Berzofsky *(50)*, Getzoff et al. *(41)*, and Davies et al. (37).

Conformational Equilibria of Protein and Peptide Antigenic Determinants

There are several possible mechanisms to explain why an antibody specific for a native protein will bind a peptide fragment in random conformation with lower affinity. Of course, the peptide may not contain all the contact residues of the antigenic determinant, so that the binding energy would be lower. However, for cases in which all the residues in the determinant are present in the peptide, several mechanisms still remain. First, the affinity may be lower because the topography of the residues in the peptide may not produce as complementary a fit in the antibody-combining site as the native conformation would. Second, the apparent affinity may be reduced because only a small fraction of the peptide molecules are in a nativelike conformation at any time, assuming that the antibody binds only

to the native conformation. Because the concentration of peptide molecules in native conformation is lower than the total peptide concentration by a factor that corresponds to the conformational equilibrium constant of the peptide, the apparent affinity is also lower by this factor. This model is analogous to an allosteric model. A third, intermediate hypothesis would suggest that initial binding of the peptide in a nonnative conformation occurs with submaximal complementarity and is followed by an intramolecular conformational change in the peptide to achieve energy minimization by assuming a nativelike conformation. This third hypothesis corresponds to an induced-fit model. The loss of affinity is due to the energy required to change the conformation of the peptide, which in turn corresponds to the conformational equilibrium constant in the second hypothesis. To some extent these models could be distinguished kinetically because the first hypothesis predicts a faster "on" rate and a faster "off" rate than does the second hypothesis *(78)*.

Although not the only way to explain the data, the second hypothesis is useful because it provides a method to estimate the conformational equilibria of proteins and peptides (*51–71,72,73,74–79*). The method assumes the second hypothesis, which can be expressed as follows:

$$P_n \xrightleftharpoons{K_{conf}} P_r \quad (1)$$
where A is antibody, P_n is native peptide, and P_r is random conformation peptide, so that

$$K_{apparent} = K_{conf} K_{native} \quad (2)$$

Thus, the ratio of the apparent association constant for peptide to the measured association constant for the native molecule should give the conformational equilibrium constant of the peptide. Note the implicit assumption that the total peptide concentration can be approximated by $[P_r]$. This will generally be true because most peptide fragments of proteins demonstrate little native conformation; that is, $K_{conf} = [P_n]/[P_r]$ is much less than 1. Also note that if the first hypothesis (or third) occurs to some extent, this method will overestimate K_{conf}. On the other hand, if the affinity for the peptide is lower because it lacks some of the contact residues of the determinant, this method will underestimate K_{conf} (by assuming that all the affinity difference is due to conformation). To some extent, the two errors may partially cancel out. When this method was used to determine the K_{conf} for a peptide staphylococcal nuclease, a value of 2×10^{-4} (unitless because it is a ratio of two concentrations) was obtained *(51)*. Similarly, when antibodies raised to a peptide fragment were used, it was possible to estimate the fraction of time the native nucle-

ase spends in nonnative conformations *(79)*. In this case, the K_{conf} was found to be about 3,000-fold in favor of the native conformation.

Antipeptide Antibodies that Bind to Native Proteins at a Specific Site

In light of the conformational differences between native proteins and peptides and the observed K_{conf} effects shown by antibodies to native proteins when tested on the corresponding peptides, it was somewhat surprising to find that antibodies to synthetic peptides show extensive cross-reactions with native proteins *(80,81)*. These two types of cross-reactions can be thought of as working in opposite directions: the binding of antiprotein antibodies to the peptide is inefficient, while the binding of antipeptide antibodies to the protein is quite efficient and commonly observed. This finding is quite useful because automated solid-phase peptide synthesis has become readily available. This has been particularly useful in three areas: exploitation of protein sequences deduced by recombinant DNA methods, preparation of site-specific antibodies, and the attempt to focus the immune response on a single protein site that is biologically important but may not be particularly immunogenic. This section focuses on the explanation of the cross-reaction, uses of the cross-reaction, and the potential limitations with regard to immunogenicity.

The basic assumption is that antibodies raised against peptides in an unfolded structure will bind the corresponding site on proteins folded into the native structure *(81)*. This is not immediately obvious because antibody binding to antigen is the direct result of the antigen fitting into the binding site. Affinity is the direct consequence of "goodness of fit" between antibody and antigen, while antibody specificity is the result of the inability of other antigens to occupy the same site. How then can the antipeptide antibodies overcome the effect of K_{conf} and still bind native proteins with good affinity and specificity? The whole process depends on the antibody-binding site forming a three-dimensional space and the antigen filling it in an energetically favorable way.

Because the peptides are randomly folded, they rarely occupy the native conformation, so they are not likely to elicit antibodies against a conformation they do not maintain. If the antibodies are specific for a denatured structure, then, like the myoglobin molecules that were denatured to apomyoglobin by antibody binding *(52)*, the cross-reaction may depend on the native protein's ability to assume different conformational states. If the native protein is quite rigid, then the possibility of its assuming a random conformation is quite small; but if it is a flexible three-dimensional spring, then local unfolding and refolding may occur all the time. Local unfolding of protein segments may permit the immunologic cross-reaction with antipeptide antibodies because a flexible segment could

assume many of the same conformations as the randomly folded peptide *(81)*.

In contrast, the proteins' ability to crystallize (a feature that allows the study of their structure by x-ray crystallography) has long been taken as evidence of protein rigidity *(82)*. In addition, the existence of discrete functional states of allosteric enzymes *(83)* provides additional evidence of stable structural states of a protein. Finally, the fact that antibodies can distinguish native from denatured forms of intact proteins is well known for proteins such as myoglobin *(52)*.

However, protein crystals are a somewhat artificial situation because the formation of the crystal lattice imposes order on the components, each of which occupies a local energy minimum at the expense of considerable loss of randomness (entropy). Thus, the crystal structure may have artificial rigidity that exceeds the actual rigidity of protein molecules in solution. On the contrary, we may attribute some of the considerable difficulty in crystallizing proteins to disorder within the native conformation. Second, allosterism may be explained by two distinct conformations that are discrete without being particularly rigid. Finally, the ability to generate antiprotein antibodies that are conformation-specific does not rule out the existence of antipeptide antibodies that are not. All antibodies are probably specific for some conformation of the antigen, but this need not be the crystallographic native conformation in order to achieve a significant affinity for those proteins or protein segments that have a "loose" native conformation.

Antipeptide antibodies have proved to be very powerful reagents when combined with recombinant DNA methods of gene sequencing *(81,84)*. From the DNA sequence, the protein sequence is predicted. A synthetic peptide is constructed, coupled to a suitable carrier molecule, and used to immunize animals. The resulting polyclonal antibodies can be detected with a peptide-coated enzyme-linked immunosorbent assay plate (see Chapter 5). They are used to immunoprecipitate the native protein from a ^{35}S-labeled cell lysate and thus confirm expression of the gene product in these cells. The antipeptide antibodies can also be used to isolate the previously unidentified gene product of a new gene. The site-specific antibodies are also useful in detecting posttranslational processing, because they bind all precursors and products that contain the site. In addition, because the antibodies bind only to the site corresponding to the peptide, they are useful in probing structure–function relationships. They can be used to block the binding of a substrate to an enzyme or the binding of a virus to its cellular receptor.

Immunogenicity of Proteins and Peptides

Up to this point, we have considered the ability of antibodies to react with proteins or peptides as antigens. However, immunogenicity refers to the ability of these compounds to elicit antibodies following immunization. Several factors limit the immunogenicity of different regions of proteins, and these have been divided into those that are intrinsic to protein structure itself versus those extrinsic to the antigen that are related to the responder and vary from one animal or species to another *(50)*. In addition, we consider the special case of peptide immunogenicity as it applies to vaccine development. The features of protein structure that have been suggested to explain the results include surface accessibility of the site, hydrophilicity, flexibility, and proximity to a site recognized by helper T cells.

When the x-ray crystallographic structure and antigenic structure are known for the same protein, it is not surprising to find that a series of monoclonal antibodies binding to a molecule such as influenza neuraminidase choose an overlapping pattern of sites at the exposed head of the protein *(85)*. The stalk of neuraminidase was not immunogenic, apparently because it was almost entirely covered by carbohydrate.

Beyond such things as carbohydrate, which may sterically interfere with antibody binding to protein, accessibility on the surface is clearly a sine qua non for an antigenic determinant to be bound by an antibody specific for the native conformation, without any requirement for unfolding of the structure *(50)*. Several measures of such accessibility have been suggested. All these require knowledge of the x-ray crystallographic three-dimensional structure. Some have measured accessibility to solvent by rolling a sphere with the radius of a water molecule over the surface of a protein *(86,87)*. Others have suggested that accessibility to water is not the best measure of accessibility to antibody and have demonstrated a better correlation by rolling a sphere with the radius of an antibody-combining domain *(88)*. Another approach to predicting antigenic sites on the basis of accessibility is to examine the degree of protrusion from the surface of the protein *(89)*. This was done by modeling the body of the protein as an ellipsoid and examining which amino acid residues remain outside ellipsoids of increasing dimensions. The most protruding residues were found to be part of antigenic sites bound by antibodies, but usually these sites had been identified by using short synthetic peptides and so were segmental in nature. As previously noted, for an antigenic site to be contained completely within a single continuous segment of protein sequence, the site is likely to have to protrude from the surface, as otherwise residues from other parts of the sequence would fall within the area contacting the antibody *(48)*.

Because the three-dimensional structure of most proteins is not known, other ways of predicting surface exposure have been proposed for most antigens. For example, hydrophilic sites tend to be found on the water-exposed surface of proteins. Thus, hydrophilicity has been proposed as a second indication of immunogenicity *(90–92)*.

This model has been used to analyze 12 proteins with known antigenic sites: the most hydrophilic site of each protein was indeed one of the antigenic sites. However, among the limitations are the facts that a significant fraction of surface residues can be nonpolar *(86,87)* and that several important examples of hydrophobic and aromatic amino acids involved in the antigenic sites are known *(42,70,93,94)*. Specificity of antibody binding likely depends on the complementarity of surfaces for hydrogen bonding and polar bonding as well as van der Waals contacts *(95)*, while hydrophobic interactions and the exclusion of water from the interacting surfaces of proteins may contribute a large but nonspecific component to the energy of binding *(95)*.

A third factor suggested to play a role in immunogenicity of protein epitopes is mobility. Measurement of mobility in the native protein is largely dependent on the availability of a high-resolution crystal structure, so its applicability is limited to only a small subset of proteins. Furthermore, it has been studied only for antibodies specific for segmental antigenic sites; therefore, it may not apply to the large fraction of antibodies to assembled topographic sites. Studies of mobility have taken two directions. The case of antipeptide antibodies has already been discussed, in which antibodies made to peptides corresponding to more mobile segments of the native protein were more likely to bind to the native protein *(81,96)*. This is not considered just a consequence of the fact that more mobile segments are likely to be those on the surface and therefore more exposed, because in the case of myohemerythrin (which was used as a model), two regions of the native protein that were equally exposed but less mobile did not bind nearly as well to the corresponding antipeptide antibodies *(97)*. However, as is clear from the earlier discussion, this result applies to antibodies made against short peptides and therefore is not directly relevant to immunogenicity of parts of the native protein. Rather, it concerns the cross-reactivity of antipeptide antibodies with the native protein and therefore is of considerable practical importance for the purposes outlined in the section on antipeptide antibodies.

Studies in the other direction—that is, of antibodies raised against native proteins—would be by definition more relevant to the question of immunogenicity of parts of the native protein. Westhof et al. *(98)* used a series of hexapeptides to determine the specificity of antibodies raised against native tobacco mosaic virus protein and found that six of the seven peptides that bound antibodies to native protein corresponded to peaks of high mobility in the native protein. The correlation was better than could be accounted for just by accessibility because three peptides that corresponded to exposed regions of only average mobility did not bind antibodies to the native protein. However, when longer peptides—on the order of 20 amino acid residues—were used as probes, it was found that an-

tibodies were present in the same antisera that bound to less mobile regions of the protein *(99)*. They simply had not been detected with the short hexapeptides with less conformational stability. Thus, it was not that the more mobile regions were necessarily more immunogenic but rather that antibodies to these were more easily detected with short peptides as probes. A similar good correlation of antigenic sites with mobile regions of the native protein in the case of myoglobin *(98)* may also be attributed to the fact that seven of the nine sites were defined with short peptides of six to eight residues *(61)*. Again, this result becomes a statement about cross-reactivity between peptides and native protein rather than about the immunogenicity of the native protein. (For reviews, see Van Regenmortel *[100]* and Getzoff et al. *[41]*).

To address the role of mobility in immunogenicity, an attempt was made to quantitate the relative fraction of antibodies specific for different sites on the antigen myohemerythrin *(101)*. The premise was that, although the entire surface of the protein may be immunogenic, certain regions may elicit significantly more antibodies than others and therefore may be considered immunodominant or at least more immunogenic. Because this study was done with short synthetic peptides from 6 to 14 residues long based on the protein sequence, it was limited to the subset of antibodies specific for segmental antigenic sites. Among these, it was clear that the most immunogenic sites were in regions of the surface that were most mobile, convex in shape, and often of negative electrostatic potential. The role of these parameters has been reviewed *(41)*.

These results have important practical and theoretical implications. First, to use peptides to fractionate antiprotein antisera by affinity chromatography, peptides corresponding to more mobile segments of the native protein should be chosen when possible. If the crystal structure is not known, it may be possible to use peptides from amino or carboxyl termini or from exon–intron boundaries, as these are more likely to be mobile *(96)*. Second, these results may explain how a large but finite repertoire of antibody-producing B cells can respond to any antigen in nature or even artificial antigens never encountered in nature. Protein segments that are more flexible may be able to bind by induced fit in an antibody-combining site that is not perfectly complementary to the average native structure *(41,50)*. Indeed, evidence from the crystal structure of antigen–antibody complexes *(102–103,*104) suggests that mobility in the antibody-combining site as well as in the antigen may allow both reactants to adopt more complementary conformations on binding to each other, that is, a two-way induced fit. A very nice example comes from the study of antibodies to myohemerythrin *(103)*, in which the data suggested that initial binding of exposed side chains of the antigen to the antibody promoted local displacements that allowed exposure and binding of other, previously buried residues that served as contact residues. The

only way this could occur would be for such residues to become exposed during the course of an induced-fit conformational change in the antigen *(41,103)*. In a second very clear example of induced fit, the contribution of antibody mobility to peptide binding was demonstrated for a monoclonal antibody to peptide 75-110 of influenza hemagglutinin, which was crystallized with or without peptide in the binding site and analyzed by x-ray crystallography for evidence of an induced fit (104). Despite flexibility of the peptide, the antibody-binding site probably could not accommodate the peptide without a conformational change in the third complementarity determining region (CDR3) of the heavy chain, in which an asparagine residue of the antibody was rotated out of the way to allow a tyrosine residue of the peptide to fit in the binding pocket of the antibody (104).

With regard to host-limited factors, immunogenicity is certainly limited by self-tolerance. Thus, the repertoire of potential antigenic sites on mammalian protein antigens such as myoglobin or cytochrome c can be thought of as greatly simplified by the sharing of numerous amino acids with the endogenous host protein. For mouse, guanaco, or horse cytochrome c injected into rabbits, each of the differences between the immunogen and rabbit cytochrome c is seen as an immunogenic site on a background of immunologically silent residues *(49,71,105)*. In another example, rabbit and dog antibodies to beef myoglobin bound almost equally well to beef or sheep myoglobin *(106)*. However, sheep antibodies bound beef but not sheep myoglobin, even though these two myoglobins differ by just six amino acids. Thus, the sheep immune system was able to screen out those clones that would be autoreactive with sheep myoglobin.

Ir genes of the host also play an important role in regulating the ability of an individual to make antibodies to a specific antigen *(107)*. These antigen-specific immune response genes are among the *MHC* genes that code for transplantation antigens. Structural mutations, gene transfer experiments, and biochemical studies *(107)* all indicate that *Ir* genes are actually the structural genes for major histocompatibility complex (MHC) antigens. The mechanism of action of the MHC antigens works through their effect on helper T cells (described later). There appear to be constraints on which B cells a T cell of a given specificity can help *(108,109)*, a process called *T–B reciprocity (110)*. Thus, if *Ir* genes control helper T-cell specificity, they will in turn limit which B cells are activated and thus which antibodies are made.

The immunogenicity of peptide antigens is also limited by intrinsic and extrinsic factors. With less structure to go on, each small peptide must presumably contain some nonself structural feature in order to overcome self-tolerance. In addition, the same peptide must contain antigenic sites that can be recognized by helper T cells as well as by B cells. When no T-cell site is present, three approaches may be helpful: graft on a T-cell site; couple the peptide to a carrier protein; or overcome T-cell nonresponsiveness to the available structure with various immunologic agents, such as interleukin (IL-2).

An example of a biologically relevant but poorly immunogenic peptide is the asparagine–alanine–asparagine–proline (NANP) repeat unit of the circumsporozoite (CS) protein of malaria sporozoites. A monoclonal antibody to the repeat unit of the CS protein can protect against murine malaria *(111)*. Thus, it would be desirable to make a malaria vaccine of the repeat unit of *Plasmodium falciparum* $(NANP)_n$. However, only mice of one MHC type $(H-2^b)$ of all mouse strains tested were able to respond to $(NANP)_n$ *(112,113)*. One approach to overcome this limitation is to couple $(NANP)_n$ to a site recognizable by T cells, perhaps a carrier protein such as tetanus toxoid *(114)*. In human trials, this conjugate was weakly immunogenic and only partially protective. Moreover, as helper T cells produced by this approach are specific for the unrelated carrier, a secondary or memory response would not be expected to be elicited by the pathogen itself.

Another choice might be to identify a T-cell site on the CS protein itself and couple the two synthetic peptides together to make one complete immunogen. The result with one such site, called *Th2R*, was to increase the range of responding mouse MHC types by one, to include $H-2^k$ as well as $H-2^b$ *(115)*. This approach has the potential advantage of inducing a state of immunity that could be boosted by natural exposure to the sporozoite antigen. Because CS-specific T and B cells are both elicited by the vaccine, natural exposure to the antigen could help maintain the level of immunity during the entire period of exposure.

Another strategy to improve the immunogenicity of peptide vaccines is to stimulate the T- and B-cell responses artificially by adding IL-2 to the vaccine. Results with myoglobin indicate that genetic nonresponsiveness can be overcome by appropriate doses of IL-2 *(116)*. The same effect was found for peptides derived from malaria proteins (*117*; K. Akaji, D. T. Liu, and I. J. Berkower, unpublished results).

One of the most important possible uses of peptide antigens is as synthetic vaccines. However, even though it is possible to elicit with synthetic peptides anti-influenza antibodies to nearly every part of the influenza hemagglutinin *(80)*, antibodies that neutralize viral infectivity have not been elicited by immunization with synthetic peptides. This may reflect the fact that antibody binding by itself often does not result in virus inactivation. Viral inactivation occurs only when antibody interferes with one of the steps in the life cycle of the virus, including binding to its cell surface receptor, internalization, and virus uncoating within the cell. Apparently, antibodies can bind to most of the exposed surface of the virus without affecting these functions. Only those antibodies that bind to certain "neutralizing" sites can inactivate the virus. In addition, as in the case of the VP1 coat protein of poliovirus, certain neutralizing sites are found only on the native protein and not

on the heat-denatured protein *(118)*. Thus, not only the site but also the conformation that is bound by the antibodies may be important for the antibody to inactivate the virus. These sites may often be assembled topographic sites not mimicked by peptide segments of the sequence. Perhaps binding of an antibody to such an assembled site can alter the relative positions of the component subsites so as to induce an allosteric neutralizing effect. Alternatively, antibodies to such an assembled site may prevent a conformational change necessary for activity of the viral protein.

One method of mapping neutralizing sites is based on the use of neutralizing monoclonal antibodies. The virus is grown in the presence of neutralizing concentrations of the monoclonal antibody, and virus mutants are selected for the ability to overcome antibody inhibition. These are sequenced, revealing the mutation that permits "escape" by altering the antigenic site for that antibody. This method has been used to map the neutralizing sites of influenza hemagglutinin *(119)* as well as poliovirus capsid protein VP1 *(120)*. The influenza escaping mutations are clustered to form an assembled topographic site, with mutations distant from each other in the primary sequence of hemagglutinin but brought together by the three-dimensional folding of the native protein. At first, it was thought that neutralization was the result of steric hindrance of the hemagglutinin binding site for the cell surface receptor of the virus *(121)*. However, similar work with poliovirus reveals that neutralizing antibodies that bind to assembled topographic sites may inactivate the virus at less than stoichiometric amounts, when at least half of the sites are unbound by antibody *(122)*. The neutralizing antibodies all cause a conformational change in the virus, which is reflected in a change in the isoelectric point of the particles from pH 7 to pH 4 *(120,123)*. Antibodies that bind without neutralizing do not cause this shift. Thus, an alternative explanation for the mechanism of antibody-mediated neutralization is the triggering of the virus to self-destruct. Perhaps the reason that neutralizing sites are clustered near receptor-binding sites is that occupation of such sites by antibody mimics events normally caused by binding to the cellular receptor, causing the virus to prematurely trigger its cell entry mechanisms. However, in order to transmit a physiologic signal, the antibody may need to bind viral capsid proteins in the native conformation (especially assembled topographic sites), which antipeptide antibodies may fail to do. Antibodies of this specificity are similar to the viral receptors on the cell surface, some of which have been cloned and expressed without their transmembrane sequences as soluble proteins. The soluble recombinant receptors for poliovirus (124) and HIV-1 *(125–127)* exhibit high-affinity binding to the virus and potent neutralizing activity *in vitro*. The HIV-1 receptor, CD4, has been combined with the human immunoglobulin heavy chain in a hybrid protein CD4–Ig *(128)*, which spontaneously assembles into dimers and resembles a mono-

clonal antibody, in which the binding site is the same as the receptor-binding site for HIV-1. In these recombinant constructs, high-affinity binding depends on the native conformation of the viral envelope glycoprotein gp120.

For HIV-1, two types of neutralizing antibodies have been identified. The first type binds a continuous or segmental determinant, such as the "V3 loop" sequence between amino acids 296 and 331 of gp120 *(129–131)*. Antipeptide antibodies against this site can neutralize the virus *(129)*. However, because this site is located in a highly variable region of the envelope, these antibodies tend to neutralize a narrow range of viral variants with nearly the same sequence as the immunogen. Even for this highly variable site, more broadly neutralizing antibodies can be obtained that recognize conserved conformations (132–134). The second type of neutralizing antibody binds conserved sites on the native structure of gp120, allowing them to neutralize a broad spectrum of HIV-1 isolates. These antibodies are commonly found in the sera of infected patients *(135)*, and a panel of neutralizing monoclonals derived from these subjects has been analyzed.

These monoclonals can be divided into three types. One group, possibly the most common ones in human polyclonal sera, bind at or near the CD4 receptor-binding site of gp120 (136–140). A second type of monoclonal, called *2G12*, binds a conformational site on gp120 that also depends on glycosylation, but has no direct effect on CD4 binding (141). A third type, quite rare in human sera, is represented by monoclonal antibody 2F5 (142) and binds a conserved site on the transmembrane protein gp41. Although this site is contained on a linear peptide ELDKWA, antibodies like 2F5 cannot be elicited by immunizing with the peptide, again suggesting the conformational aspect of this site (143,144).

These monoclonals neutralize fresh isolates, as well as laboratory-adapted strains, and they neutralize viruses tropic for T cells or macrophages (145), regardless of the use of CXCR4 or CCR5 as second receptor. These monoclonals, which target different sites, act synergistically. A cocktail combining all three types of monoclonals can protect monkeys against IV challenge or vaginal challenge with an SIV/HIV hybrid virus, indicating the potential for antibodies alone to prevent HIV infection (146,147). Because each of the three conserved neutralizing determinants depends on the native conformation of the protein (148), a prospective gp120 vaccine (or gp160 vaccine) would need to be in the native conformation to be able to elicit these antibodies.

ANTIGENIC DETERMINANTS RECOGNIZED BY T CELLS

Studies of T-cell specificity for antigen were motivated by the fact that the immune response to protein antigens is regulated at the T-cell level. A hapten, not immunogenic by

itself, will elicit antibodies only when coupled to a protein that elicits a T-cell response in that animal. This ability of the protein component of the conjugate to confer immunogenicity on the hapten has been termed the *carrier effect*. Recognition of the carrier by specific helper T cells induces the B cells to make antibodies. Thus, the factors contributing to a good T-cell response appear to control the B-cell response as well.

"Nonresponder" animals display an antigen-specific failure to respond to a protein antigen, both for T cells and antibody responses. The "high responder" phenotype for each antigen is a genetically inheritable, usually dominant trait. Using inbred strains of mice, the genes controlling the immune response were found to be tightly linked to the MHC genes (*107*,149). MHC-linked immune responsiveness has been shown to depend on the T-cell recognition of antigen bound within a groove of MHC antigens of the antigen-presenting cell (APC) (discussed later; see also Chapters 19 and 20). The recognition of antigen in association with MHC molecules of the B cell is necessary for carrier-specific T cells to expand and provide helper signals to B cells.

In contrast to the range of antigens recognized by antibodies, the repertoire recognized by helper and cytotoxic T cells appears to be limited largely to protein and peptide antigens, although exceptions such as the small molecule tyrosine–azobenzene arsonate *(150)* exist. Once the antigenic determinants on proteins recognized by T cells are identified, it may be possible to better understand immunogenicity and perhaps even to manipulate the antibody response to biologically relevant antigens by altering the helper T cell response to the antigen.

Defining Antigenic Structures

Polyclonal T-Cell Response

Significant progress in understanding T-cell specificity was made possible by focusing on T-cell proliferation *in vitro*, mimicking the clonal expansion of antigen specific clones *in vivo*. The proliferative response depends on only two cells: the antigen-specific T cell and an APC, usually a macrophage, dendritic cell, or B cell. The growth of T cells in culture is measured as the incorporation of [^{3}H]thymidine into newly formed DNA. Under appropriate conditions, thymidine incorporation increases with antigen concentration. This assay permits the substitution of different APCs and is highly useful in defining the MHC and antigen-processing requirements of the APCs.

Using primarily this assay, several different approaches have been taken to mapping T-cell epitopes. First, T cells immunized to one protein have been tested for a proliferative response *in vitro* to the identical protein or to a series of naturally occurring variants. By comparing the sequences of stimulatory and nonstimulatory variants, it was possible to identify potential epitopes recognized by T cells. For example, the T-cell response to myoglobin was analyzed by immunizing mice with sperm whale or horse myoglobin and testing the resulting T cells for proliferation in response to a series of myoglobins from different species with known amino acid substitutions *(151)*. Reciprocal patterns were observed in T cells from mice immunized with sperm whale or horse myoglobin. The response to the cross-stimulatory myoglobins was as strong as to the myoglobin used to immunize the mice. This suggested that a few shared amino acid residues formed an immunodominant epitope and that most substitutions had no effect on the dominant epitope. A comparison of the sequences revealed that substitutions at a single residue could explain the pattern observed. All myoglobins that cross-stimulated sperm-whale-immune T cells had Glu at position 109, while all that cross-stimulated horse-immune T cells had Asp at 109. No member of one group could stimulate T cells from donors immunized with a myoglobin of the other group. This suggested that an immunodominant epitope recognized by T cells was centered on position 109, regardless of which amino acid was substituted. Usually, this approach has led to correct localization of the antigenic site in the protein *(151–153)*, but the possibility of long-range effects on antigen processing must be kept in mind (see "Antigen Processing"). Also, this approach using natural variants is limited in that it can focus on the correct region of the molecule but cannot define the boundaries of the site. Site-directed mutagenesis may therefore expand the capabilities of this approach.

A second approach is to use short peptide segments of the protein sequence, taking advantage of the fact that T cells specific for soluble protein antigens appear to see only segmental antigenic sites, not assembled topographic ones *(107,154–158)*. These may be produced by chemical or enzymatic cleavage of the natural protein (*156–163*,164), solid-phase peptide synthesis *(163,165–168)*, or recombinant DNA expression of cloned genes or gene fragments *(169)*. In the case of class I MHC molecule-restricted cytotoxic T cells, viral gene deletion mutants expressing only part of the gene product have also been used (*170,171*,172).

In the case of myoglobin-specific T cells, mapping of an epitope to residue Glu 109 was confirmed by use of a synthetic peptide 102–118, which stimulated the T cells *(167,173)*. The T cells elicited by a myoglobin with either Glu or Asp 109 could readily distinguish between synthetic peptides containing Glu or Asp at this position. Similar results were obtained with cytochrome c, where the predominant site recognized by T cells was localized with sequence variants to the region around residue 100 at the carboxyl end of cytochrome *(152)*. Furthermore, the response to cytochrome c peptide 81 to 104 was as great as the response to the whole molecule. This indicated that a 24-amino acid peptide contained an entire antigenic site recognized by T cells. The T cells could distinguish between synthetic

peptides with Lys or Gln at position 99, although both were immunogenic with the same MHC molecule *(174–176)*. This residue determined T-cell memory and specificity and so presumably was interacting with the T-cell receptor. A similar conclusion could be drawn for residue 109 of myoglobin. However, this type of analysis must be used with caution. When multiple substitutions at position 109 were examined for T-cell recognition and MHC binding, residue 109 was found to affect both functions (177). The ultimate use of synthetic peptides to analyze the segmental sites of a protein that are recognized by T cells was to synthesize a complete set of peptides, each staggered by just one amino acid from the previous peptide, corresponding to the entire sequence of hen egg lysozyme, HEL (178). Around each immunodominant site, a cluster of several stimulatory peptides was found. The minimum "core" sequence consisted of just those residues shared by all antigenic peptides within a cluster, while the full extent of sequences spanning all stimulatory peptides within the same cluster defined the "determinant envelope." These two ways of defining an antigenic site differ, and one interpretation is that each core sequence corresponds to an MHC binding site, while the determinant envelope includes the many ways for T cells to recognize the same peptide bound to the MHC.

In each case, the polyclonal T-cell response could be mapped to a single predominant antigenic site. These results are consistent with the idea that each protein antigen has a limited number of immunodominant sites (possibly one) recognized by T cells in association with MHC molecules of the high responder type. If none of the antigenic sites could associate with MHC molecules on the APCs, then the strain would be a low responder, and the antigen would have little or no immunogenicity.

Monoclonal T Cells

Further progress in mapping T-cell sites depended on the analysis of cloned T-cell lines. These were either antigen-specific T-cell lines made by the method of Kimoto and Fathman *(179)* or T-cell hybridomas made by the method of Kappler et al. *(180)*. In the former method, T cells are allowed to proliferate in response to antigen and antigen-presenting cells, rested, and then restimulated again. After stimulation, the blasts can be cloned by limiting dilution and grown from a single cell in the presence of IL-2. In the second method, enriched populations of antigen-specific T cells are fused with a drug-sensitive T-cell tumor, and the fused cells are selected for their ability to grow in the presence of the drug. Then the antigen specificity of each fused cell line must be determined. The key to determining this in a tumor line is that antigen-specific stimulation of a T-cell hybridoma results in release of IL-2 even though proliferation is constitutive. T cells produced by either method are useful in defining epitopes, measuring their MHC

associations, and studying antigen-processing requirements.

Monoclonal T cells may be useful in identifying which of the many proteins from a pathogen are important for T-cell responses. For instance, Young and Lamb *(181)* have developed a way to screen proteins separated by SDS–polyacrylamide gel electrophoresis and blotted onto nitrocellulose for stimulation of T-cell clones and have used this to identify antigens of *Mycobacterium tuberculosis (182)*. Mustafa et al. *(183)* have even used T-cell clones to screen recombinant DNA expression libraries to identify relevant antigens of *Mycobacterium leprae*. Use of T cells to map epitopes has also been important in defining tumor antigens (*184*,185–189).

Precise mapping of antigenic sites recognized by T cells was made possible by the fact that T cells would respond to peptide fragments of the antigen when they contain a complete antigenic determinant. A series of overlapping peptides can be used to walk along the protein sequence and find the antigenic site. Then, by truncating the peptide at either end, the minimum antigenic peptide can be determined. For example, in the case of myoglobin, a critical amino acid residue, such as Glu 109 or Lys 140, was found by comparing the sequences of stimulatory and non-stimulatory myoglobin variants and large CNBr cleavage fragments *(190)* as previously discussed, and then a series of truncated peptides containing the critical residue was synthesized with different overlapping lengths at either end *(163,167)*. Because solid-phase peptide synthesis starts from a fixed carboxyl end and proceeds toward the amino end, it can be stopped at various positions to produce a nested series of peptides that vary in length at the amino end. In this way, it was found that two of the Glu 109-specific T-cell clones responded to synthetic peptides 102 to 118 and 106 to 118 but not to peptide 109 to 118 *(167)*. One clone responded to peptide 108 to 118, and the other did not. Thus, the amino end of the peptide recognized by one clone was Ser 108, and the other clone required Phe 106 and/or Ile 107. Similar fine specificity differences have been observed with T-cell clones specific for the peptides 52 to 61 and 74 to 96 of hen egg lysozyme *(160,191,192)*, the peptide 323 to 339 of chicken ovalbumin *(161)*, and the peptide 81 to 104 of pigeon cytochrome c *(166)*: the epitopes recognized by several T-cell clones overlap but are distinct. In addition, nine T-cell clones recognized a second T-cell determinant in myoglobin located around Lys 140, and each one responded to the cyanogen bromide cleavage fragment 132 to 153 *(193)*. Further studies with a nested series of synthetic peptides showed that the stimulatory sequence is contained in peptide 136 to 145 *(163)*.

These findings can be generalized to characterize a large number of epitopes recognized by T cells from a number of protein antigens (Table 21.4) *(190–205)*. What these studies and others demonstrated about epitopes recognized by

▎**TABLE 21.4** **Examples of Immunodominant T-Cell Epitopes Recognized in Association with Class II MHC Molecules**

Protein	T-Cell Antigenic Sites (ref.)	Amphipathic Segments
Sperm whale myoglobin	69–78 (148)	64–78
	102–118 (*159*)	99–117

Sequential Steps that Focus the T-Cell Response on Immunodominant Determinants

In contrast to antibodies that bind all over the surface of a native protein *(49)* (see "Protein and Polypeptide Antigenic Determinants"), it has been observed that T cells elicited by immunization with the native protein tend to be focused on one or a few immunodominant sites *(208,209–*210). This is true whether one deals with model mammalian or avian proteins such as cytochrome c *(157)*, myoglobin *(156,158)*, lysozyme *(160,192,211,212)*, insulin *(165,197)*, and ovalbumin *(161)*, or with bacterial, viral, and parasitic proteins from pathogens, such as influenza hemagglutinin *(195)* or nucleoprotein *(206)*, staphylococcal nuclease *(213)*, or malarial circumsporozoite protein *(115,214)*. Because the latter category of proteins shares no obvious homology to mammalian proteins, the immunodominance of a few sites cannot be attributed simply to tolerance for the rest of the protein because of homologous host proteins. Moreover, immunodominance is not simply the pre-emption of the response by a single clone of predominant T cells, because it has been observed that immunodominant sites tend to be the focus for a polyclonal response of a number of distinct T-cell clones recognizing overlapping subsites within the antigenic site or having different sensitivities to substitutions of amino acids within the site *(160,161,166,167,*178,*191,192,*215).

Immunodominant antigenic sites appear to be qualitatively different from other sites. For example, in the case of myoglobin, when the number of clones responding to different epitopes after immunization with native protein was quantitated by limiting dilution, it was observed that the bulk of the response to the whole protein in association with the high-responder class II MHC molecules was focused on a single site within residues 102 to 118 *(173)* (Fig. 21.5). When T cells in the (high × low responder) F1 hybrid restricted to each MHC haplotype were compared, there was little difference in the responses to nondominant epitopes, and all the overall difference in magnitude of response restricted by the high versus low responder MHC could be attributed to the high response to the immunodominant determinant in the former and the complete absence of this response in the latter (Fig. 21.5). Similar results were found for two different high-responder and two different low-responder MHC haplotypes *(173)*. Why did not the response to the other sites compensate for the lack of response to the immunodominant site in the low responders? The greater frequency of T cells specific for the immunodominant site may in part be attributed to the large number of ways this site can be recognized by different T-cell clones, as mentioned previously, but this only pushes the problem back one level. Why is an immunodominant site the focus for so many different T-cell clones? Because the answer cannot depend on any particular T cell, it must depend on other factors, primarily involved in the steps in antigen processing and presentation by MHC molecules.

It has also been observed that some peptides may be immunogenic themselves, but the T-cell response they elicit is specific only for the peptide and does not cross-react with the native protein, nor do T cells specific for the native protein recognize this site *(216,217,*218). These are called

T cells is that in each case, the entire site is contained on a short peptide. MHC class I-restricted antigens also follow this rule *(206)*, even when the protein antigen is normally expressed on the surface of infected cells. This applies to viral glycoproteins, such as influenza hemagglutinin, that are recognized by cytolytic T cells after antigen processing *(207)* (see "Antigen Processing"). These peptides consist of no more than about 12 to 17 amino acid residues for class II MHC or 8 to 10 residues for class I. Within this size, they must contain all the information necessary to survive processing within the APC, associate with the MHC antigen, and bind to the T-cell receptor, as discussed in the next sections.

FIGURE 21.5 Frequency of high- and low-responder major histocompatibility complex (MHC)-restricted T cells in F1 hybrid. High responsiveness may be accounted for by the response to a single immunodominant epitope. Lymph node T cells from [low-responder (H-2^k) × high-responder (H-2^d)]F1 hybrid mice immunized with whole myoglobin were plated at different limiting dilutions in microtiter wells with either high- or low-responder presenting cells and myoglobin as antigen. The cells growing in each well were tested for responsiveness to whole myoglobin and to various peptide epitopes of myoglobin. The frequency of T cells of each specificity and MHC restriction was calculated from Poisson statistics and is plotted on the ordinate. Most of the difference in T-cell frequency between high- and low-responder restriction types (*solid bars*) can be accounted for by the presence of T cells responding to the immunodominant site at residues 102 to 118, accounting for more than two thirds of the high-responder myoglobin-specific T cells, in contrast to the absence of such T cells restricted to the low-responder MHC type. (Based on the data in ref. *173*.)

cryptic determinants (218). The reasons for these differences may involve the way the native protein is processed to produce fragments distinct from but including or overlapping the synthetic peptides used in experiments, and also the competition among sites within the protein for binding to the same MHC molecules, as discussed further in a later section. To understand these factors that determine dominance or crypticity, one must understand the steps through which an antigen must go before it can stimulate a T-cell response.

Unlike B cells, T-cell recognition of antigen depends on the function of another cell, the APC *(219)*. Antigen must pass through a number of intracellular compartments and survive processing and transport steps before it can be effectively presented to T cells. Following antigen synthesis in the cell (as in a virally infected cell) or antigen uptake via phagocytosis, pinocytosis, or, in some cases, receptor-mediated endocytosis, the subsequent steps include (a) partial degradation ("processing") into discrete antigenic fragments that can be recognized by T cells,

(b) transport of these fragments into a cellular compartment where MHC binding can occur, (c) MHC binding and assembly of a stable peptide-MHC complex, and (d) recognition of that peptide-MHC complex by the expressed T-cell repertoire. At each step, a potential antigenic determinant runs the risk of being lost from the process, for example, by excessive degradation or failure to meet the binding requirements needed for transport to the next step. Only those peptides that surmount the four selective hurdles will prove to be antigenic for T cells. We will now consider each step in detail, for its contribution to the strength and specificity of the T-cell response to protein antigens.

A. Antigen Processing

Influence of Antigen Processing on the Expressed T-Cell Repertoire

Several lines of evidence indicate that antigen processing plays a critical role in determining which potential antigenic sites are recognized and therefore what part of the potential T-cell repertoire is expressed on immunization with a protein antigen. Because the T cell does not see the native antigen but only the products of antigen processing, it is not unreasonable that the nature of these products would at least partly determine which potential epitopes could be recognized by T cells.

One line of evidence that processing plays a major role in T-cell repertoire expression came from comparisons that were made of the immunogenicity of peptide versus native molecule in the cases of myoglobin *(216)* or lysozyme *(217)*. In the case of myoglobin, a site of equine myoglobin (residues 102 to 118) that did not elicit a response when H-2^k mice were immunized with native myoglobin nevertheless was found to be immunogenic when such mice were immunized with the peptide (*216*). Thus, the low responsiveness to this site in mice immunized with the native myoglobin was not due to either of the classical mechanisms of Ir gene defects—namely, a hole in the T-cell repertoire or a failure of the site to interact with MHC molecules of that strain. However, the peptide-immune T cells responded only poorly to native equine myoglobin *in vitro*. Thus, the peptide and the native molecule did not cross-react well in either direction. The problem was not simply a failure to process the native molecule to produce this epitope, because (H-2^k × H-2^s)F1-presenting cells could present this epitope to H-2^s T cells when given native myoglobin but could not present it to H-2^k T cells. Also, because the same results applied to individual T-cell clones, the failure to respond to the native molecule was apparently not due to suppressor cells induced by the native molecule.

Similar observations were made for the response to the peptide 74 to 96 of hen lysozyme in B10.A mice *(217)*. The peptide, not the native molecule, induced T cells specific for this site, and these T cells did not cross-react with the native molecule. With these alternative mechanisms

excluded, we are left with the conclusion that an appropriate peptide was produced but it differed from the synthetic peptide in such a way that a hindering site outside the minimal antigenic site interfered with presentation by presenting cells of certain MHC types. Further evidence consistent with this mechanism came from the work of Shastri et al. *(220)*, who found that different epitopes within the 74 to 96 region of lysozyme were immunodominant in H-2^b mice when different forms of the immunogen were used.

Another line of evidence came from fine specificity studies of individual T-cell clones. Shastri et al. *(221)* observed that H-2^b T-cell clones specific for hen lysozymes were about 100-fold more sensitive to ring-necked pheasant lysozyme than to hen lysozyme. Nevertheless, they were equally sensitive to the cyanogen bromide cleavage fragments containing the antigenic sites from both lysozymes. Thus, regions outside the minimal antigenic site removable by cyanogen bromide cleavage presumably interfered with processing, presentation, or recognition of the corresponding site in hen lysozyme. Similarly, it was observed that a T-cell clone specific for sperm whale myoglobin, not equine myoglobin, responded equally well to the minimal epitope synthetic peptides from the two species *(216)*. Here too, residues outside the actual site must be distinguishing equine from sperm whale myoglobin. Experiments using F1-presenting cells that can clearly produce this epitope for presentation to other T cells proved that the problem was not a failure to produce the appropriate fragment from hen lysozyme *(217)* or equine myoglobin *(216)*. Thus, these cases provide evidence that a structure outside the minimal site can hinder presentation in association with a particular MHC molecule.

Such a hindering structure was elegantly identified in a study by Grewal et al. (222) comparing hen egg lysozyme peptides presented by strains C57BL/6 and C3H.SW that share H-2^b but differ in non-MHC genes. After immunization with whole lysozyme, a strong T-cell response was seen to peptide 46-61 in C3H.SW mice but not at all in C57BL/6 mice. Because the F1 hybrids of these two strains responded, the lack of response in one strain was not due to a hole in the T-cell repertoire produced by self-tolerance. It was found that peptide 46-60 bound directly to the I-A^b class II MHC molecule, whereas 46-61 did not, indicating that the C-terminal Arg at position 61 hindered binding. Evidently, a non-MHC–linked difference in antigen processing allowed this Arg to be cleaved off the 46-61 peptide in C3H.SW mice, in which the peptide was dominant, but not in C57Bl/6 mice, in which the peptide was cryptic.

Even a small peptide that does not need processing may nevertheless be processed, and that processing may affect its interaction with MHC molecules. Fox et al. *(223)* found that substitution of a tyrosine for isoleucine at position 95 of cytochrome c peptide 93 to 103 enhanced presentation with Eβ^b but diminished presentation with Eβ^k when live APCs were used but not when the APCs were

fixed and could not process antigen. Therefore, the tyrosine residue was not directly interacting with the different MHC molecule but was affecting the way the peptide was processed, which in turn affected MHC interaction.

Besides the mechanisms suggested here, Gammon et al. *(217)* and Sercarz et al. *(224)* have proposed the possibility of competition between different MHC-binding structures ("agretopes") within the same processed fragment. If a partially unfolded fragment first binds to MHC by one such site already exposed, further processing may stop, and other potential binding sites for MHC may never become accessible for binding. Such competition could also occur between different MHC molecules on the same presenting cell *(217)*. For instance, BALB/c mice, expressing both A^d and E^d, produce a response to hen lysozyme specific for 108 to 120, not for 13 to 35 *(217)*, and this response is restricted to E^d. However, B10.GD mice that express only A^d respond well to 13 to 35 when immunized with lysozyme. BALB/c mice clearly express an A^d molecule, so the failure to present this 13 to 35 epitope may be due to competition from E^d, which may preempt by binding the 108 to 120 site with higher affinity and preventing the 13 to 35 site from binding to A^d. Competition between different peptides binding to the same MHC molecule could also occur.

All these results, taken together, indicate that antigen processing not only facilitates interaction of the antigenic site with the MHC molecule and/or the T-cell receptor but also influences the specificity of these interactions and in turn the specificity of the elicited T-cell repertoire. The molecular mechanisms behind such effects are just now being elucidated, as described in the next sections.

Processing of Antigen for T Cells Restricted to Class II MHC Molecules

It has long been known that T-cell responses such as delayed hypersensitivity *in vivo* or T-cell proliferation *in vitro* to exogenous proteins can be stimulated not only by the native protein but also by denatured protein *(154)* and fragments of native protein *(197)*. Indeed, this feature, along with the requirement for recognition in association with class II MHC molecules, distinguishes T- from B-cell responses. In a number of cases, the site recognized by cloned T cells has been located to a discrete synthetic peptide corresponding to a segment of the primary sequence of the protein. Examples include insulin *(165,197)*, cytochrome c *(166)*, lysozyme *(160,191)*, and myoglobin *(156,163,167)*. In each case, the stimulatory peptide must contain all the information required for antigen presentation and T-cell stimulation. The lack of conformational specificity does not indicate a lack of T-cell receptor specificity. Rather, it results from antigen processing into peptide fragments that destroys conformational differences prior to binding the T-cell receptor. One way to accomplish this is via antigen processing, which involves the partial

FIGURE 21.6 Steps in antigen presentation by class II major histocompatibility complex (MHC) molecules. Soluble antigen enters the presenting cell by phagocytosis, pinocytosis, or receptor-mediated endocytosis. It is partially degraded to peptide fragments by acid-dependent proteases in endosomes. Antigenic peptides associate with MHC class II molecules (I-A or I-E in the mouse) to form an antigenic complex that is transported to the cell surface. Before an MHC class II molecule can bind the peptide, it must release the class II-associated invariant chain peptide fragment of invariant chain from the binding groove, which is catalyzed by HLA-DM. Binding of T-cell receptors to the peptide/MHC complex triggers T-cell proliferation, resulting in clonal expansion of antigen-specific T cells.
degradation of a protein antigen into peptide fragments (Fig. 21.6).

Evidence of processing came from the fact that a single protein antigen could stimulate T cells to different epitopes, each specific for a different MHC antigen. For example, when a series of myoglobin-specific T-cell clones were tested for both antigen specificity and MHC restriction, six clones were specific for a site centering on amino acid Glu 109, and all six recognized the antigen in association with I-A^d. Nine additional T-cell clones were specific for a second epitope centered on Lys 140 and were restricted to a different MHC antigen, I-E^d. Thus, the antigen behaved as if it was split up into distinct epitopes, each with its own ability to bind MHC *(193)*.

That T cells recognize processed antigen was demonstrated by the fact that inhibitors of processing can block antigen presentation. Early experiments by Ziegler and Unanue *(225)* showed that processing depends on intracellular degradative endosomes because drugs like chloroquine and NH$_4$Cl, which raise endosomal pH and inhibit acid-dependent proteases, could block the process. However, prior degradation of proteins into peptide fragments allows them to trigger T cells even in the presence of these inhibitors of processing *(226)*. For example, T-cell clone 14.5 recognizes the Lys 140 site of myoglobin equally well on the antigenic peptide (residues 132 to 153) as on the native protein (Fig. 21.7). The difference between these two forms of antigen is brought out by the presence of processing inhibitors. Leupeptin, for example, inhibits lysosomal proteases and blocks the T-cell responses to native myo-

globin but not to peptide 132 to 153. Thus, native myoglobin cannot stimulate T cells without further processing, whereas the peptide requires little or no additional processing *(227)*.

Why is antigen processing necessary? For class II MHC molecules, experiments suggest that antigen processing may uncover functional sites that are buried in the native protein structure. For example, a form of intact myoglobin that has been partially unfolded through chemical modification can behave like a myoglobin peptide and can be presented by APC even in the presence of enough protease inhibitor or chloroquine to completely block the presentation of native myoglobin *(227)*. Denatured lysozyme could also be presented without processing to one T-cell clone *(162)*. This result suggests that the requirement for processing may simply be a steric requirement, that is, to uncover the two sites needed to form the trimolecular complex between antigen and MHC and between antigen and T-cell receptor. Thus, unfolding may be sufficient without proteolysis, and proteolysis may simply accomplish an unfolding analogous to Alexander's approach to the Gordian knot.

The importance of antigen unfolding for T-cell recognition and the ability of unfolding to bypass the need for antigen processing apply to a range of polypeptide sizes from small peptides to extremely large proteins. At one extreme, Lee et al. *(228)* found that even fibrinogen, of Mr 340,000, does not need to be processed if the epitope recognized is on the carboxy terminal portion of the α chain, which is naturally unfolded in the native molecule. At the other
FIGURE 21.7 Inhibition of antigen presentation by the protease inhibitor leupeptin: differential effect on presentation of the same epitope of native myoglobin or peptide 132 to 153 to the same monoclonal T-cell population. Splenic cells from nonimmunized B10.D2 mice, as a source of antigen-presenting cells, were incubated with leupeptin at the concentration indicated for 15 minutes prior to and during exposure to 2-μM native myoglobin or 1-μM peptide fragment, washed, irradiated, and cultured at 400,000 cells/well with 10,000 T cells of clone 14.5; thymidine incorporation was measured after 4 days of culture. (See ref. *227*.)

extreme, even a small peptide of only 18 amino acid residues, apamin, requires processing unless the two disulfide bonds that hold it in the native conformation are cleaved artificially to allow unfolding *(229)*. Therefore, large size does not mandate processing, and small size does not necessarily obviate the need for processing, at least for class II presentation. The common feature throughout the size range seems to be the need for unfolding. This evidence, taken together with the earlier data on unfolding of myoglobin and lysozyme, strongly supports the conclusion that unfolding, rather than size reduction, is the primary goal of antigen processing and that either antigen presentation by MHC molecules or T-cell receptor recognition frequently requires exposure of residues not normally exposed on the surface of the native protein. This conclusion is supported by recent studies of peptides eluted from class II MHC molecules, and the crystal structures of class II MHC-peptide complexes, which show that longer pep-

tides can bind with both ends extending beyond the two ends of the MHC groove (230–232) (see "Antigen Interaction with MHC Molecules").

Besides proteolysis, unfolding may require the reduction of disulfide bonds between or within protein antigens. A gamma interferon-inducible lysosomal thiol reductase, called *GILT*, is expressed in antigen-presenting cells and localizes to the late endosomal and lysosomal compartments where MHC class II peptide loading occurs (233). Unlike thioredoxin, this enzyme works at the acid pH of endosomes and uses Cys but not glutathione as a reducing agent. Antigen-presenting cells from GILT knockout mice were tested for the ability to present hen egg lysozyme to HEL-specific T-cell lines (234). For two epitopes, the T-cell response was insensitive to the GILT defect, even though they involved a disulfide bond in the native protein. But for one epitope, located between disulfide bonds, the T-cell response was completely inhibited when the antigen-presenting cells lacked GILT reductase. In this case, reduction of disulfide bonds was an essential step for antigen presentation, presumably needed to generate free peptides for MHC class II binding.

Processing of Antigen for T Cells Restricted to Class I MHC Molecules

Early studies on class I-restricted T cells, such as cytolytic T cells (CTLs) specific for virus-infected cells, assumed that they responded mainly to unprocessed viral glycoproteins expressed on the surface of infected cells. However, since the mid-1980s, it has been clear that CTLs, like other T cells, recognize processed antigens. For example, influenza nucleoprotein (NP) was a major target antigen for influenza-specific CTLs, even though NP remains in the nucleus of infected cells and none is detectable on the cell surface *(235)*. Further support came from the finding that target cells that take up synthetic NP peptide 366 to 379 were lysed by NP-specific CTLs *(206)*. This constitutes evidence that antigen presented in association with class I molecules requires processing into antigenic fragments. Also, the demonstration that synthetic peptides could sensitize targets for CTLs introduced a powerful tool for mapping and studying CTL epitopes.

Even for influenza hemagglutinin, which is expressed on the surface of infected cells, surface expression was not required for antigenicity, implying that it is the processed antigen that stimulates a T-cell response. Target cells expressing leader-negative hemagglutinin, which is not transported to the cell surface but remains in the cytosol, were lysed equally well as those with surface hemagglutinin *(207)*. Similar conclusions were drawn from anchor-negative mutants *(236)*. Indeed, studies of HIV-1 gp160 genes with or without a leader sequence suggest that removal of the leader sequence can increase the amount of protein that is retained in the cytosol and is available for processing and presentation through the class I MHC

processing pathway (237). The explanation may be that the signal peptide results in cotranslational translocation of the growing peptide chain into the endoplasmic reticulum, whereas proteins without a signal peptide remain in the cytosol, where they are accessible to the processing machinery of the class I pathway (see later discussion). This cytosolic protein-processing machinery consists primarily of the 26S proteasomes (238,239). The specificity of such proteasomes to cleave at certain positions in a protein sequence thus provides the first hurdle that a potential epitope must surmount to be presented by class I MHC molecules, to be cut out correctly but not destroyed by the proteasome.

In the standard proteasome, 14 distinct subunits assemble to form a high-molecular-weight complex of about 580 kD with three distinct protease activities, located on different subunits. The proteasome is a barrel-shaped structure, with the protease activities arrayed on the inner surface, and unfolded proteins are believed to enter the barrel at one end, leaving as peptides at the other end. The different proteases cut preferentially after aromatic or branched chain amino acids (chymotrypticlike activity of the β5 subunit), basic amino acids (trypsinlike activity of the β2 subunit), or acidic residues (glutamate preferring activity of the β1 subunit) (240,241). Protease activity is increased against misfolded proteins, such as senescent proteins, which are tagged with ubiquitin and directed to the proteasome. In addition, viral proteins produced during infection and proteins synthesized with artificial amino acids are particularly susceptible to degradation by proteasomes. The products of protease digestion are peptides ranging from to 3 to 14 amino acids in length, including nine-mers, of just the right size for MHC binding. The chymotryptic- and trypsinlike activities may be particularly important for antigenic peptides because many peptides that naturally bind MHC end in hydrophobic or basic residues (242).

The proteasome is the major processing machinery of the nonendosomal processing pathway. This is shown by the effect of proteasome inhibitors on MHC class I assembly and antigen presentation and by the effect of LMP-2 and LMP-7 mutations on antigen processing. A family of proteasome inhibitors have been described (240,241,243) which consist of short peptides, three to four amino acids in length, ending in an aldehyde, such as Ac-Leu Leu norLeu-al, carbobenzoxy-Leu Leu norVal-al (241), or nonpeptides such as lactacystin (244). Although the peptides appear to be directed primarily at the chymotrypsinlike protease activity, as false substrates, in fact they inhibit all three types of protease activity.

By inhibiting antigen processing, these inhibitors induce a phenotype of reduced expression of MHC class I and inability to present antigen to class I-restricted CTL (241). The MHC class I heavy chains remain in the endoplasmic reticulum (ER), as shown by failure to become resistant to endoglycosidase H (245), which occurs in the Golgi. They are also unable to form stable complexes with β_2-microglobulin because of a lack of peptides. These effects are specific for the protease function because the inhibitors do not block presentation of synthetic peptides, which also rescue MHC class I expression, and because inhibition is reversible when inhibitor is removed. These results suggest that proteasomes are the primary supplier of antigenic peptides for class I because other pathways are unable to compensate. However, it is also possible that the inhibitors could block other potential processing enzymes as well. An alternative processing pathway that bypasses the proteasome is provided by signal peptidase. As signal peptides are cleaved from proteins entering the endoplasmic reticulum, these hydrophobic peptides can bind MHC class I (246). Particularly for MHC molecules like HLA-A2, which prefer hydrophobic sequences, this peptidase can be an alternative source of antigenic peptides that are independent of proteasomes and TAP-1/2 transport (see "Transport") because they are formed inside the ER.

The proteins destined for proteasomal processing include some normally short-lived proteins with a half-life of about 10 minutes, which constitute about 25% of the proteins in the cell. The rest arise from long-lived proteins, with a half-life of about 1 day, which may be synthesized incorrectly. These defective ribosomal products, or DRiPs, are ubiquitinated and marked for rapid degradation in proteasomes (247,248). In a normal cell, these can arise from errors in RNA transcription, protein translation, assembly, folding, or targeting. But in a virally infected cell, misfolded viral proteins provide a ready supply of antigenic peptides for antigen presentation and T-cell recognition almost as soon as the virus starts to produce new viral proteins. Similarly, incorporation of amino acid analogues, such as canavanine in place of arginine, creates misfolded proteins that are rapidly processed and more efficiently presented via the proteasomal pathway (249).

Interestingly, the MHC itself encodes, near the class II region, three proteins, known as LMP-2 and LMP-7 for "low-molecular-weight protein," and MECL1, for "multicatalytic endopeptidase complexlike 1," that contribute to the proteasome structure. The LMP-2, MECL-1, and LMP-7 subunits are upregulated by interferon-γ, and substitute for the subunits β1, β2, and β5, respectively, forming what has been dubbed an *immunoproteasome*, present in professional antigen-presenting cells. All complexes with LMPs contain proteasome proteins, but only 5% to 10% of proteasomes contain LMP-2 and LMP-7. The ones without LMPs are called *constitutive proteasomes*.

These MHC-encoded subunits of the immunoproteasome shift the preference of proteasomes for cleaving after certain sequences, resulting in the production of different peptide fragments (250–252). Proteasomes lacking LMP-2 through mutation or gene knockout have the same affinity, but decreased cleavage rate, for sequences ending in hydrophobic or basic amino acids. The effect is specific

for these proteolytic sites because the activity against sequences containing acidic amino acids actually increased (251). Despite the shift in specific peptides released, the overall level of MHC class I expression was reduced only slightly in LMP-7 knockouts (252) and not at all in the LMP-2 knockouts. However, presentation of specific epitopes of the male H-Y antigen or of influenza nucleoprotein was reduced by three- to fivefold in these knockouts. Toes et al. (253) quantitatively compared the cleavage fragments produced by standard proteasomes and immunoproteasomes, and defined the prevalence of different amino acids on each side of the cleavage site. Consistent with the earlier studies, there is a strong preference for both to cleave after leucine, and also to a lesser extent after other hydrophobic residues, both aliphatic and aromatic. However, the immunoproteasomes have a stronger tendency to cleave after such hydrophobic residues and a much reduced cleavage frequency after acidic residues, Asp and Glu, than standard or constitutive proteaseomes. This shift in specificity is concordant with the observation that class I MHC molecules tend to bind peptides with C-terminal hydrophobic or basic residues, not acidic ones. Thus, the immunoproteasomes in professional antigen-presenting cells may be more effective at generating antigenic peptides that can be presented by MHC molecules (250,253). Protein degradation by proteasomes is processive, so the peptides released after 5% digestion are the same as the fragments released after 90% digestion. This suggests that intact proteins may enter the barrel, but they are not released at the other end until processing is complete.

Immunoproteasomes were shown to be essential for production of a hepatitis B virus core antigenic epitope (254), and to increase production of epitopes from adenovirus (255) and lymphocytic choriomeningitis virus (256). Similarly, certain epitopes of latent membrane protein 2 of Epstein-Barr virus depended on immunoproteasomes (257). In that case, the requirement for immunoproteasomes depended on the context of the peptide within the native protein. Incomplete protein synthesis due to puromycin, or expression of the epitope surrounded by protein fragments with fewer membrane-spanning domains, allowed epitope generation by constitutive proteasomes.

On the other hand, some epitopes are generated more effectively by the constitutive proteasome than the immunoproteasome (253,258). When the repertoire of seven defined class I MHC-restricted epitopes was compared in an elegant quantitative study in LMP2-deficient or wild-type C57BL/6 mice, it was found that responses to the two epitopes that are immunodominant in wild-type mice were greatly reduced in the LMP2-deficient mice, that lack immunoproteasomes, and two normally subdominant epitopes became dominant (259). However, from adoptive transfer experiments in both directions, it was found that the reduced response to one normally dominant epitope was due to decreased production without immunoprotea-

somes, but that to the other was due to an altered T-cell repertoire in the LMP2-deficient mice, presumably from alterations in the peptides presented in the thymus. Further, the increased response to one of the subdominant determinants was related to increased production of this peptide by the constitutive proteasomes compared to the immunoproteasomes. Thus, the immunoproteasome specificity plays a significant role in determining the repertoire of epitopes presented, and in selecting those that are immunodominant, as well as regulating the CD8+ T-cell repertoire generated in the thymus.

Another protein associated with proteasomes is the proteasome activator PA28, which assembles into 11s structures (260). Like LMP-2 and 7 (250), PA28 is inducible by interferon-γ, and its induction causes a shift in proteasome function that may lead to the production of greater amounts of and different repertoires of antigenic peptides. For example, synthetic substrates were designed to test the ability of proteasomes to generate authentic MHC binding peptides. These substrates contained the MHC-binding ligand flanked by the natural sequence as found in the original protein.

To generate the MHC-binding ligand, the proteasome would have to cleave the substrate twice (261). By itself, the 20s proteasome was able to produce singly cleaved fragments, but with added PA28, doubly cut peptides were generated preferentially. Thus, PA28 favored the production of antigenic peptides, possibly by keeping the peptide in the proteasome until processing was complete. Alternatively, PA28 may coordinate the proteolytic activity of two adjacent sites to generate doubly cut peptides of just the right length (8 to 9-mers) to fit in the MHC groove. The distance between these nearby sites would determine the size of the peptides produced. PA28 has been shown to increase generation of a dominant lymphocytic choriomeningitis virus epitope independently of the presence of the other interferon-γ–inducible components LMP2, LMP7, and MECL-1 (262).

The specificity of this proteasomal processing system determines the first step in winnowing the number of protein segments that can become CTL epitopes, by selectively producing some peptide fragments in abundance and destroying others. Thus, it is probably not just coincidental that the C-terminal residues produced by proteasomal cleavage often serve as anchor residues for binding class I MHC molecules, or that the lengths of peptides produced are optimal for class I MHC binding (250,263). Better understanding of the specificity of proteasomes will contribute to the new methods to predict dominant CD8+ T cell epitopes (210).

Additional downstream processing steps, after the proteasome, are known to be important for generation of antigenic peptides. One of these occurs in the cytoplasm, prior to TAP transport, and others occur after transport into the ER. The proteasome creates a first draft of the peptides, which are then selected and trimmed to produce the final

pool of antigenic peptides of optimal size and sequence for MHC binding, while protecting the nascent peptides from degradation before they can bind MHC.

Recent studies have revealed that most peptides are released from the proteasome when they still need further processing to become antigenic peptides (264,265). In the cytoplasm, the major proteolytic activity comes from an enzyme called *tripeptidyl amino peptidase II*, or TPPII, which is located on a large particle. It has amino peptidase activity, which can remove one to three amino acids at a time, and is useful for peptides of 15 amino acids or less. It also has endopeptidase activity that can cut in the middle of peptides larger than 15 amino acids, with the release of fragments of at least 9 amino acids. These are a significant source of 9-mers with new carboxyl ends, and this may be the only way to generate carboxyl ends other than the proteasome itself.

The importance of TPPII activity for antigen processing is shown by the fact that a specific inhibitor, butabindide, can prevent peptide loading of MHC, resulting in reduced surface expression. The most likely path for most protein antigens is to enter the proteasome and emerge as peptides of 15 amino acids or larger. These are then trimmed by TPPII, resulting in peptides ready for TAP transport. Longer peptides are trimmed internally by TPPII endoprotease, which may generate carboxyl ends needed for TAP binding. The resulting peptides are then transported by TAP into the ER, where they may be trimmed further to prepare them for MHC binding. An additional role of TPPII is shown by the generation of unique epitopes that are not produced by proteasomes. For example, an important T-cell epitope of the Nef protein of HIV requires TPPII processing. Proteasomal inhibitors have no effect on it, but butabindide prevents its processing and presentation to HLA-A3 or A11 restricted T cells (266). This pathway seems particularly important for generating epitopes ending in lysine groups, which bind these two MHC types but are rarely generated by proteasomes alone. TPPII can act in parallel with proteasomes or in tandem with them to release this epitope from intact protein or its partially degraded fragments.

B. Transport into a Cellular Compartment where MHC Binding Can Occur

The second hurdle a potential epitope must surmount is to be transported into the cellular compartment for loading onto MHC molecules. These compartments are different for class I and class II molecules, as noted earlier.

Transport Pathways Leading to MHC Class I Presentation

The second hurdle for peptide presentation by class I MHC molecules is to get from the cytosol, where the peptides are produced, to the ER, where the newly synthe-sized class I MHC molecules are assembled and loaded with peptide. The discovery of a specific active transporter suggested that specificity of transport could further restrict the repertoire of peptides available to load onto class I MHC molecules. Genetic analysis of mutant cell lines that failed to load endogenous peptides onto class I molecules revealed homozygous deletions of part of the MHC class II region near the DR locus. Molecular cloning of DNA from this region revealed at least 12 new genes, of which two, called *TAP-1* and *TAP-2*, for "transporter associated with antigen processing," showed a typical sequence for ABC transporter proteins (267–269). Their function is to transport processed peptides from the cytosol to the ER. Once in this compartment, peptides are handed off by TAP to newly formed MHC class I molecules and stabilize a tri-molecular complex with β_2-microglobulin. This complex is then transported to the cell surface, where antigen presentation occurs. Without the peptide transporters, empty dimers of MHC class I with β_2-microglobulin form, but these are unstable. Excess free peptide would rescue MHC class I by stabilizing the few short-lived empty complexes that reach the surface, as shown by Townsend et al. *(270)* and Schumacher et al. (271). Thus MHC-linked genes coding for proteolysis, peptide transport, and presentation at the cell surface have been identified. In effect, the MHC now appears to encode a complex system of multiple elements devoted to the rapid display of foreign protein determinants on the surface of an infected cell. By continuously sampling the output of the protein-synthesizing machinery, this system permits rapid identification and destruction of infected cells by CTL before infectious virus can be released.

In an infected cell, as soon as viral proteins are made, peptide fragments generated by the proteasome become available to the TAP-1 and TAP-2 transporter proteins (Fig. 21.8). These transport the peptide fragments into the ER for association with newly formed MHC class I molecules, which would carry them to the cell surface for antigen presentation, all within 30 minutes. Indeed, the finding of a physical association between TAP and the nascent class I heavy chain/β_2-microglobulin complex suggests that the peptide may be directly handed off from TAP to the new MHC molecule without being free in solution (272,273). If TAP transport is highly selective, then some cytosolic peptides may fail to enter the ER for presentation with class I, but if it is promiscuous, then some peptides may be transported that were better off not presented, such as those leading to autoimmunity.

The idea that other proteins may control accessibility of MHC class I binding sites for peptides originally came from the observation that two rat strains with the same MHC type (RT1.A^a) were nevertheless not histocompatible, and CTL could recognize the difference between them *(274)*. The difference, called a *cim* effect, for class I modification, occurred because different peptides were binding the same MHC in the two strains (275,276). The
FIGURE 21.8 Cytoplasmic antigen-processing pathway leading to major histocompatibility complex (MHC) class I presentation. Cytoplasmic antigen is degraded in the proteasome to fragments, which are transported into the endoplasmic reticulum (ER) by the transporter associated with antigen processing (TAP). Peptide supplied by TAP forms a stable complex with MHC class I heavy chains and β_2-microglobulin, and the complex is transported through the Golgi, where it achieves mature glycosylation, and out to the cell surface for presentation to class I-restricted T cells. Additional processing options by tripeptidyl amino peptidase II in the cytoplasm and endoplasmic reticulum aminopeptidase I (ERAP 1) in the ER, before and after TAP transport, allow greater flexibility in meeting the requirements of binding both TAP and MHC molecules.

rat has two alleles for a peptide transporter supplying peptides to MHC. The one called TAP2A has peptide specificity matching that of RT1.A^a and delivers a broad set of peptides for MHC binding. The other transporter allele, called TAP2B, supplies a different set of peptides that are discordant with RT1.A^a, so fewer types of peptides are bound. Although RT1.A^a would prefer to bind peptides with Arg at position 9, it has to settle for peptides with hydrophobic termini as provided by TAP2B (277), thereby accounting for the apparent histocompatibility difference. Thus, the specificity of TAP transport was shown to provide a selective step in narrowing the potential repertoire of CTL epitopes.

To measure TAP specificity in other species, a transportable peptide bearing an N-linked glycosylation site was added to cells permeabilized by treatment with streptolysin. If the peptide was transported by TAP, it would enter the ER and *cis*-Golgi, where it would be glycosylated (278–280). The extent of glycosylation served as a measure of TAP function. When competitor peptides were added as well, TAP-mediated transport of the reporter peptide decreased, indicating saturation of peptide binding sites. In this way, a series of related peptides could be tested for the ability to compete for TAP binding and transport in order to identify the requirements for TAP binding and transport.

TAP binding and transport depended strongly on peptide length (280,281). Mouse TAP was shown to have a strong preference for peptides of nine residues or longer (281). For human TAP, peptides shorter than seven amino acids long were not transported, regardless of sequence (280). Peptides 8 to 11 amino acids long were almost all transported, with some variation in binding affinities depending on sequence. Peptides 14 to 21 amino acids in length were transported selectively, while those longer than 24 amino acids were almost never transported intact. Thus, human TAP transport selected against peptides less than 7 or more than 24 amino acids in length, regardless of sequence. Unlike the rat, human and mouse TAP do not show allelic differences in peptide transport.

Although TAP can and must transport a wide variety of peptides, it may still have preferences for which peptides are transported most efficiently and which MHC types are provided with the peptides they need. For example, a self-peptide that naturally binds HLA B27 was modified slightly to produce an N-linked glycosylation site, resulting in the sequence RRYQNSTEL (280). Using the glycosylation of this peptide to measure transport, saturation of TAP by homologous peptides occurred with a 50% inhibitory concentration of less than 1 μM. Other peptides with unrelated sequences also inhibited, often with equally high affinity.

Not only did natural HLA-binding peptides compete, but so did peptide variants lacking the MHC binding motif at positions 2 and 9 (see later discussion). Clearly, peptides binding different MHC types were transported by the same TAP protein, and even peptides that bound mouse MHC were transported by human TAP. In another example, using rat TAP proteins, peptides with Pro at position 2, 6, or 9 were found to be poor competitors for transport of a reference peptide (279).

In a different approach, using a baculovirus system overexpressing TAP proteins in microsomes, the affinity of TAP binding was determined for a wide variety of synthetic peptides, allowing mapping of the important residues (282,283). Binding, rather than transport, appears to be the major step determining TAP peptide selectivity (284). Indeed, artificial neural networks have been developed to predict peptide binding to human TAP (285). Using this scheme, it was found that peptides eluted from three different human class I molecules had higher predicted affinities for TAP than a control set of peptides with equal binding to those class I MHC molecules, supporting the hypothesis that TAP specificity contributes to the selection of the subset of peptides able to bind a class I molecule that actually binds *in vivo* (285). Unlike MHC class I, there were no anchor positions at which a specific amino acid was required. However, there were several positions where substituting the wrong amino acid caused a marked reduction in TAP binding. In a typical MHC class I binding 9-mer, the strongest substitution effects were observed at position 9 (P9), followed by substitutions at P2 and P3, followed by P1. At the carboxy terminal P9 position, the preferred residues were Tyr and Phe (as well as Arg and Lys), while Glu was worst, causing a 3 log reduction in binding. Similarly, substituting Pro at P2 caused a 1.5 to 2 log reduction in binding, as compared with preferred residues Arg, Val, and Ile. TAP preferences such as these would selectively transport some peptides more than others from cytoplasm to ER. Use of combinatorial peptide libraries independently confirmed that the critical residues influencing TAP transport were the first three N-terminal residues and the last C-terminal residue (286).

Interestingly, these preferred residues are many of the same ones forming the MHC class I binding motifs (P2 and P9). However, because the MHC binding motifs differ from each other, it is not possible for TAP preferences to match them all. For example, the TAP preference for Arg at P2 and Phe, Tyr, Leu, Arg, or Lys at P9 overlaps with the binding motif of HLA-B27 and may favor the transport of peptide ligands for this MHC type. Remarkably, the variant B2709, which does not prefer Tyr or Phe at P9, is not associated with autoimmune disease as in the more common form of HLA-B27. In contrast, HLA-B7 requires a Pro at P2, which greatly decreases TAP binding. Similarly, some peptides binding HLA-A2 have hydrophobic residues unfavorable for TAP binding, suggesting suboptimal com-

patibility between TAP and the most common HLA class I allele. Measurements with a series of naturally presented peptides from HLA-A2 and B27 indicated a mean 300-fold higher affinity of TAP for the B27 peptides than for those from A2, and some of the A2 peptides did not bind TAP at all (285). How are these low-affinity peptides delivered to MHC? One suggestion is that peptide ligands for HLA-A2 and B7 may be transported as a larger precursor peptide containing the correct amino acids, which are then trimmed off to fit the MHC groove.

A series of studies support this mechanism, showing that longer peptide precursors are trimmed at the N-terminus by aminopeptidases in the ER to form HLA-binding peptides (287). The ability to transport larger peptides, followed by trimming, could increase the range of permissible antigenic peptides, by facilitating transport of nonantigenic peptides, followed by trimming to the size and specificity needed for MHC binding. For example, following hepatitis B virus infection, certain peptide epitopes that are frequently recognized by CTL are nevertheless not bound or transported by TAP. By extending these peptides by one or two amino acids of the natural sequence at the amino end, their TAP binding was greatly enhanced, but at the expense of reduced MHC binding. When tested on permeabilized cells, the overall effect of the extended peptides was to increase MHC binding. Apparently, by improving TAP transport, these peptides were able to increase peptide delivery into the ER, where they were trimmed to produce peptides compatible with MHC binding (288).

Similarly, it is known that peptides with a Pro at position 2, needed to bind to certain MHC molecules but poorly transported, are produced from longer precursors that are transported by N-terminal trimming in the ER by aminopeptidases (289). In fact, the inability of the aminopeptidase to cleave beyond a residue preceding a Pro naturally leads to trimming of peptides to produce ones with a Pro at position 2. Alternatively, some of these peptides may derive from signal peptides and enter the ER in a TAP-independent manner. The ER trimming enzyme has been identified as endoplasmic reticulum aminopeptidase I (ERAP I) (290–292). This enzyme is a 106-kD zinc metalloproteinase, and it is the major ER protease with broad specificity. It is inducible by interferon-γ and inhibited by the aminopeptidase inhibitor leucinethiol. Down-regulation of ERAP I with siRNA results in decreased expression of MHC class I, indicating that ERAP I contributes to the supply of peptides. ERAP I prefers peptides of 9 or 10 amino acids or longer and ignores peptides of 8 amino acids or fewer, which may allow it to generate antigenic peptides for MHC binding without degrading them beyond recognition. The aminopeptidase provides a way to relax the requirement for proteasomes to generate ends that can simultaneously bind TAP and MHC. In contrast, the fact that a comparable carboxypeptidase has not been identified

suggests that carboxyl ends generated by proteasomal processing must be suitable for TAP transport and compatible with MHC binding. This requirement is quite stringent because the carboxyl terminal residue is the most important for TAP binding, and it is frequently an anchor residue for MHC as well.

The significance of selective peptide transport may be to limit immunity to self-peptides. If the match between HLA-B27 and TAP specificity is too good, it may contribute to the increased incidence of autoimmune disease associated with HLA- B27 (282). An effect of human TAP specificity in loading of peptides in viral infection has confirmed the biological significance of TAP specificity (288). TAP binding specificity also limited the repertoire of alloantigenic peptides presented by HLA-B27 (293).

By combining the selectivity of proteasomal processing, TAP transport, and MHC binding, it has been possible to generate models that correlate with known antigenic peptides (294,295). These can be used to analyze the sequence of any given protein and to predict epitopes that may be recognized by T cells restricted to MHC class I. These may be important for analyzing the T-cell response to viral or neoplastic antigens and for generating synthetic vaccines capable of eliciting a T-cell response to these antigens.

The importance of TAP proteins to antiviral immunity is shown by the fact that herpesviruses have targeted TAP-1 function as a way to interfere with antigen presentation to $CD8^+$ CTL. A herpes simplex virus (HSV-1) immediate early viral protein called ICP47 binds to TAP and inhibits its function, causing reduced expression of new MHC class I molecules on the cell surface and inability to present viral or other antigens with MHC class I (296–298). As a way to evade immune surveillance, this strategy could contribute to viral persistence in chronic infection and viral activation in recurrent disease, as frequently occurs with HSV-1 and -2. These findings also raise the possibility of making a live attenuated ICP47-defective HSV vaccine that would be more immunogenic than natural infection.

Transport Pathways Leading to MHC Class II Presentation

Unlike the class I pathway, which delivers peptides to MHC, the MHC class II pathway transports MHC molecules to the endosomal compartment, where antigenic peptides are produced. During transport, the peptide binding groove must be kept free of endogenous peptides. The cell uses one protein, called *invariant chain* (and its processed fragment CLIP), to block the binding site until needed, and another protein, HLA-DM, to facilitate release of CLIP peptides and their exchange for antigenic peptides as they become available.

MHC class II molecules assemble in the ER, where alpha and beta chains form a complex with invariant chain (*299*–301). Invariant chain binds MHC and blocks the peptide-binding groove, so endogenous peptides transported into the ER, for example by TAP, cannot bind (300,*302*,303–307). The complex of alpha, beta, and invariant chains, consisting of nine polypeptide chains in all (308), is transported via the Golgi and directed by signals on invariant chain into endosome/lysosomelike vesicles called MHC class II compartments. The compartments contain acid-activated proteases capable of digesting foreign proteins into antigenic peptides. In addition, they degrade invariant chain to a fragment called *CLIP*, corresponding to amino acids 80–103. As long as CLIP remains in the binding groove, antigenic peptides cannot bind, so the rate of CLIP release limits the capacity of MHC to take up antigenic peptides.

Peptide loading can be measured by its effect on MHC structure. When an MHC class II molecule binds a peptide, it changes conformation, and certain monoclonal antibodies are specific for the peptide-bound conformation (309). Also, the alpha-beta complex becomes more stable after peptide binding, which can be detected by running the MHC on an SDS gel without boiling. The peptide bound form runs on gels as a large alpha-beta dimer, while MHC without peptides (but still bound to CLIP) is unstable under these conditions and falls apart to give alpha and beta chain monomers on SDS gels (310).

Mutant cell lines have been generated with a deletion between *HLA-DP* and *HLA-DQ* genes on chromosome 6 (309,311–313). These cells express normal levels of MHC class II structural proteins, HLA-DQ and DR, but fail to present protein antigens (313). Some of their class II MHC proteins appear on the cell surface, but more are retained in the MHC class II compartments. Biochemically, they still contain CLIP peptides (314), rather than peptide antigens, and they have not achieved the conformation (309) or SDS stability of peptide-binding MHC class II complexes (315). The defect was discovered to be due to loss of either of the two chains of a class II molecule, HLA-DM, and the phenotype can be corrected by adding back the missing gene (316). In the presence of normal HLA-DM, MHC releases CLIP and binds antigenic peptides for presentation to T cells.

The importance of HLA-DM function for T-cell help *in vivo* was studied in H2-DM knockout mice (317). These mice have reduced numbers of T cells, their class II MHC molecules reach the cell surface bearing high levels of CLIP peptide, and their B cells are unable to present certain antigens, such as ovalbumin, to T cells. When H2-DM knockout mice were immunized with 4-hydroxy 5-nitrophenyl acetyl ovalbumin, specific IgG antibodies were reduced 20-fold, as compared with wild type. Germinal center formation and class switching were greatly reduced, and affinity maturation was not observed. The phenotype was more pronounced for some MHC types, such as I-A^b, than for others, such as I-A^k. Because of tighter binding of CLIP peptides, these MHC types may be more dependent on H2-DM to

▶ **TABLE 21.5 Effect of HLA-DM on Peptide on Rates and Off Rates for Binding to HLA-DR1**

Peptide	HLA-DM	Half-Life for Binding	Half-Life for Release
CLIP (80–103)	−	60 min	11 hr
	+	9 min	0.3 hr
MBP (90–102)	−	62 min	86 hr
	+	9 min	1 hr
HA (307–319)	−	67 min	144 hr
	+	10 min	144 hr

CLIP, class II-associated invariant chain peptide; HA, hemagglutinin; HLA, human leukocyte antigen; MBP, myelin basic protein.

The on (association) and off (dissociation) rates of biotinylated peptide from purified soluble HLA-DR1 were measured by fluorescence assay, in the presence or absence of HLA-DM. The on rates of all three peptides are increased similarly in the presence of HLA-DM and probably reflect the rate-limiting dissociation of the bound CLIP fragment of the invariant chain. In contrast, once the peptides are bound, the off rates differ as a result of differences in affinity. Thus, HLA-DM catalyzes release of more weakly binding peptides and allows stable binding of higher affinity peptides. In effect, this is an editing function of HLA-DM.

Adapted from the data of Sloan et al. (298).

maintain empty class II molecules in a peptide receptive state.

In vitro studies with purified MHC class II molecules and biotin-labeled peptides have shown that HLA-DM can accelerate loading of exogenous peptides into HLA-DR binding sites (318,319). For example, loading of myelin basic protein fragment 90–102 was accomplished in 9 minutes with HLA-DM versus 60 minutes without it (Table 21.5). Other peptides were also loaded at the same rate, suggesting that the rate-limiting step was the same for each: removal of CLIP peptides to expose the peptide binding sites on HLA-DR. The kinetic effect was optimal between pH 4.5 and 5.8, which is typical of the endosomal/lysosomal compartment where HLA-DM operates. HLA-DM did not affect the affinity, as measured by half-maximal binding, but it had a marked effect on the kinetics of binding.

Conversely, when biotinylated peptides were allowed to saturate HLA-DR binding sites overnight, and then free peptides were removed, the off rate could be measured over time (318,319). As shown in Table 21.5 (adapted from ref. 318), the off rate for different peptides could be compared in the absence or presence of HLA-DM. The half-life for CLIP peptides was reduced from 11 hours to 20 minutes by adding HLA-DM. This could explain the enhanced loading of all other peptides because they must wait for CLIP to come off. In the case of antigenic peptides, myelin basic protein 90–112 was released 80-fold faster in the presence of DM than in its absence. However, another peptide, influenza hemagglutinin 307–319, was not affected at all. The differential effect on these antigenic peptides suggests that HLA-DM can serve a potential role in editing which peptides stay on MHC long enough to be presented

and which are removed (318). By releasing MBP preferentially and not the HA peptide, HLA-DM would favor the stable MHC binding and presentation of HA peptides over MBP peptides. The affinity of each peptide is determined by the fit between peptide and MHC groove, not by HLA-DM. However, DM can amplify the impact of the difference in affinity (i.e., signal-to-noise ratio), by facilitating release of low-affinity peptides and allowing the high-affinity ones to remain. This editing function could have an important effect on which peptides get presented and elicit a T-cell response, and which do not. HLA-DM could contribute to immunodominance of a peptide binding MHC with high affinity by releasing its lower affinity competitors. Alternatively, HLA-DM could contribute to self-tolerance by releasing self-peptides of low affinity before they could stimulate self-reactive T cells.

C. MHC Binding and Assembly of a Stable Peptide-MHC Complex

Antigen Interaction with MHC Molecules

Perhaps the most selective step a potential antigenic site must pass is to bind with sufficiently high affinity to an appropriate MHC molecule.

The response of T cells to antigens on APCs or target cells provided a number of hints that antigen interacts directly with MHC molecules of the APCs. First, genes coding for immune responsiveness to a specific antigen are tightly linked to genes for MHC-encoded cell surface molecules (*107,149*). Second, it became apparent that T-cell recognition of antigen is the step at which MHC restriction occurs (*107,157,197,320*). For example, *in vitro* T-cell responses to small protein and polypeptide antigens were found to parallel *in vivo* responses controlled by *Ir* genes, and T cells were exquisitely sensitive to differences in MHC antigens of the APC in all their antigen recognition functions. This observation *in vitro* made it possible to separate the MHC of the T cell from that of the APC. The T-cell response to antigenic determinants on each chain of insulin depended on the MHC antigens of the APC. This was particularly apparent when T cells from an (A × B)F1 animal responded to antigen presented by APCs of either the A or B parental MHC type (*197,321*). Neither parental APC stimulated an allogeneic response from (A × B)F1 T cells, and the response to antigen was now limited by the MHC of the APC. This ability of the APC to limit what could be presented to the T cells was termed *determinant selection (197,321)*. It became obvious that even in a single (A × B)F1 animal, distinct sets of antigen-specific T cells exist that respond to each antigenic determinant only in association with MHC type A or type B (*322*).

Experiments on the fine specificity of antigen-specific T cell clones suggested that the MHC of the APC could influence the T-cell response in more subtle ways than just allowing or inhibiting it. Determinant selection implied

that a given processed peptide should contain both a site for MHC interaction and a distinct functional site for T-cell receptor binding. Thus, a protein with multiple determinants could be processed into different peptides, each with a different MHC restriction, consistent with the independent *Ir* gene control of the response to each antigenic determinant on the same protein *(159)*. For example, T-cell clones specific for myoglobin responded to different antigenic determinants on different peptide fragments of myoglobin *(193)*: those specific for one of the epitopes were always restricted to I-A, while those specific for the other were always restricted to I-E. The simplest interpretation was that each antigenic peptide contained an MHC association site for interacting with I-A or I-E. At the level of *Ir* genes, mouse strains lacking a functional I-E molecule could respond to one of the sites only, and those with neither I-A nor I-E molecules capable of binding to any myoglobin peptide would be low responders to myoglobin.

Evidence for a discrete MHC association site on peptide antigens came from studies with pigeon cytochrome c. The murine T-cell response to pigeon cytochrome c and its carboxy terminal peptide (*81–103*,104) depends on the I-E molecules of the APCs *(157)*. However, distinct structural sites on the synthetic peptide antigen appear to constitute two functional sites: an epitope site for binding to the T-cell receptor and an "agretope" (for "antigen-restriction-tope") site for interacting with the MHC molecule of the APC *(157,174–176)*. Amino acid substitutions for Lys at position 99 on the peptide destroyed the ability to stimulate T-cell clones specific for the peptide, while the difference between Ala and a deletion at position 103 determined T-cell stimulation in association with some MHC antigens but not others, independent of the T-cell fine specificity. In addition, immunizing with the peptides substituted at position 99 elicited new T-cell clones that responded to the substituted peptide but not the original and showed the same pattern of genetic restriction, correlated with the residue at position 103, as the clones specific for the original peptide. These results implied that the substitutions at position 99 had not affected the MHC association site but independently altered the epitope site that interacts directly with the T-cell receptor. In contrast, position 103 was a likely subsite for MHC interaction, without altering the T-cell receptor binding site.

It remained to be shown that MHC molecules without any other cell surface protein were sufficient for presentation of processed peptide antigens. This was demonstrated by Watts et al. *(323)*, who showed that glass slides coated with lipid containing purified I-A molecules could present an ovalbumin peptide to an ovalbumin-specific T-cell hybridoma. This result meant that no other special steps were required other than antigen processing and MHC association. Likewise, Walden et al. *(324)* specifically stimulated T-cell hybridomas with liposomes containing nothing but antigen and MHC molecules. Second, Norcross et al. *(325)*

transformed mouse L cells with the genes for the I-A α and β chains and converted the fibroblasts (which do not express their own class II molecules) into I-A-expressing cells. These cells were able to present several antigens to I-A-restricted T-cell clones and hybridomas *(325)*, and similar I-E transfectants presented to I-E–restricted T cells *(193)*. Thus, whatever processing enzymes are required are already present in fibroblasts, and the only additional requirement for antigen-presenting function is the expression of I-A or I-E antigens.

The planar membrane technique has been applied to determine the minimum number of MHC–antigen complexes per antigen-presenting cell necessary to induce T-cell activation (326). After pulsing the presenting cells with antigen, the cells were studied for antigen-presenting activity, and some of the cells were lysed to produce a purified fraction containing MHC charged with antigenic peptides. These MHC–peptide complexes were used to reconstitute planar membranes, and their potency was compared with a reference MHC preparation pulsed with a high peptide concentration *in vitro* and presumed to be fully loaded. In this way, the relative peptide occupancy of MHC binding sites corresponding to any level of antigen presentation could be determined. For B cells and macrophages, the threshold of antigen loading necessary for triggering T cells was 0.2% of I-E^d molecules occupied by peptide, corresponding to about 200 MHC–peptide complexes per presenting cell. For artificial presenting cells, such as L cells transfected with I-E^d, the threshold was 23 times greater, or 4.6% of MHC occupied by peptide. Similarly, when MHC–peptide binding was measured directly, using radiolabeled peptide to determine the minimum level of MHC–peptide complexes required for T-cell triggering, B cells were capable of presenting antigen with as few as 200 to 300 MHC–peptide complexes per cell (327). A similar number of peptide–MHC class I molecule complexes was reported to be required on a cell for recognition by CD8$^+$ cytotoxic T cells (328). These results explain how newly generated peptide antigens can bind enough MHC molecules to stimulate a T-cell response, even in the presence of competing cellular antigens, because a low level of MHC occupancy is sufficient. In addition, this threshold of presentation may explain how multivalent protein antigens, such as viral particles, with 100 to 200 protein copies each, can be more than 10^3-fold more immunogenic than the same weight of protein monomers *(329,330,331)*. Studies of the number of T-cell receptors needed for triggering, based on titrating peptide and recombinant soluble class I MHC molecules on plastic, suggested that interaction of three to five T-cell receptors with peptide-MHC complexes was sufficient, consistent with several T cells interacting with one APC (332,333).

Biochemical evidence for the direct association between processed peptide and MHC molecules was demonstrated by competition between peptides for antigen

presentation *(203,334–337)* and then more directly by equilibrium dialysis *(338)*, molecular sieve chromatography *(339)*, or affinity labeling *(340)*. Equilibrium dialysis was performed by incubating detergent-solubilized class II molecules with fluoresceinated or radioactive antigenic peptides, followed by dialysis against a large volume of buffer. Peptide can pass in or out of the dialysis bag, but the class II molecules are trapped inside. In the absence of binding by class II molecules, the labeled peptide would distribute itself equally between the inside and outside of the dialysis chamber. However, when the appropriate class II molecules were added to the chamber, extra peptide molecules were retained inside it due to formation of a complex with MHC class II. In this way, direct binding of antigen and MHC was shown, and an affinity constant was determined *(338,339)*.

A second approach was to form the antigen–MHC complex over 48 hours, followed by rapid passage over a Sephadex G50 sizing column. The bound peptide came off the column early because it is the size of class II molecules (about 58 kD), while free peptide was usually included in the column and eluted later because it is only approximately 2 kD *(339)*. Peptide bound to specific and saturable sites on MHC. Competitive binding showed that different peptide antigens with the same MHC restriction bind to the same site on the MHC class II molecule *(341,342)*. For example, Table 21.6 shows the results with peptide antigens that are known to be presented with I-A or I-E antigens of the d or k haplotype. We observe that Ova peptide 323 to 339, which is presented with I-A^d, also binds well to purified I-A^d, while nonradioactive peptide competes for the peptide binding sites of the I-A^d molecule. Similarly, the other I-A^d-restricted peptide, myoglobin 106–118, competes with Ova 323–339 for the same site. However, myoglobin 132–153, which is not restricted to I-A^d, does not compete for it but does compete for its own restriction element, I-E^d. Similarly, pigeon cytochrome c competes best for its restriction element I-E^k rather than I-A^k or I-E^d, which do not present cytochrome. Conversely, recombinant Eβ genes have been used to map separate sites on a class II MHC molecule for binding to peptide antigen and to the T-cell receptor *(343)*.

Using these two biochemical methods, it has been possible to explain major losses of peptide antigenicity resulting from amino acid substitutions in terms of their adverse effect on epitope or agretope function. For example, the response of each of two ovalbumin-specific T-cell clones was mapped to peptide 325 to 335 by using a nested set of synthetic peptides. Five substitutions were made for each amino acid in the peptide, and the resulting 55 different peptides were each tested for the ability to stimulate the clone *(344)*. Presumably, those peptides that failed to stimulate could be defective at an epitope or an agretope functional site. In fact, only two amino acids (Val 327 and Ala 332) were essential for MHC interaction, and changes at either of these resulted in a loss of antigenicity for the clone. Seven other amino acids were critical for T-cell stimulation but did not affect MHC binding. Thus, these must be part of the functional epitope. Interestingly, certain substitutions for His 328, Ala 330, and Glu 333 had effects on MHC binding, while others had effects on T-cell stimulation without affecting MHC binding. These amino acids might participate in both agretope and epitope functional sites, or, alternatively, the substitutions may affect the conformation of the peptide as it binds, thus indirectly affecting T-cell recognition (345) (see later discussion). The fact that substitutions at 9 of 11 amino acids could be tolerated without affecting MHC binding is consistent with the determinant selection hypothesis in that multiple antigenic peptides are capable of interacting with the same antigen binding site on the MHC molecule.

Similarly, by using a T-cell clone specific for peptide 52–61 of hen egg lysozyme, substitutions at each amino acid were analyzed for the ability to bind to I-A^k and stimulate the clone *(346)*. Four of 11 amino acid residues were silent, while substitutions at three positions resulted in reduced binding to I-A^k. Substitutions at the remaining three positions resulted in decreased T-cell stimulation without affecting MHC association. The epitope was very sensitive to substitutions, even conservative ones such as changing Leu 56 to Ile, norLeu, or Val. The results in both of these studies confirmed by competitive binding that the MHC molecule contains a single saturable site for peptide

▎**TABLE 21.6 Correlation between MHC Restriction and Binding to MHC Molecules**

Competitor Peptide		*Ova + A^d*	*Myo + E^d*	*HEL + A^k*	*Cyto + E^k*

binding. This site must be capable of binding a broad range of antigenic peptides. In binding the MHC groove, antigenic peptides assume the extended conformation that exposes the epitope for recognition by the T-cell receptor.

Although a full set of general principles explaining the specificity of antigen presentation and T-cell recognition has not yet emerged, it is studies such as these, combined with complementary structural studies characterizing the antigen-interacting portions of MHC molecules (*192*,231,232,*343*,*347–349*,350–352,*353*,*354*) (see Chapters 19 and 20) and of T-cell receptors (*355–358*,359–361) (see Chapter 10) that will ultimately lead to an understanding of these principles.

One observation that came out of this type of structure–function study was that a single peptide can bind to a class II MHC molecule in more than one way, and thus be seen by different T cells in different orientations or conformations (345,*362*) The same conclusion can be reached from an entirely different type of study, in which mutations are introduced into the MHC molecule. Mutations in the floor of the peptide-binding groove, which cannot directly interact with the T-cell receptor, can differentially affect recognition of a peptide by one clone and not another (*363,364*,365). In a particularly thoroughly studied case, it was clear that the quantitative level of peptide binding was not affected by the mutation, but rather the change in the floor of the groove imposed an altered conformation on the peptide that differentially affected recognition by different T cells (365). If indeed the T-cell receptor cannot detect the mutation in the MHC molecule except indirectly by its effect on the peptide conformation, then one is forced to conclude that different T cells have preferences for different conformations of the same peptide bound to (what appears to the T cell as) the same MHC molecule.

Another general observation to come from this type of study is that substitution of amino acids often affects presentation by MHC and recognition by T cells through introduction of dominant negative interactions or interfering groups, whereas only a few residues are actually essential for peptide binding (366). Both for class II binding (366,*367,368,369*) and for class I MHC binding (370), most residues can be replaced with Ala or sometimes Pro without losing MHC binding, as long as a few critical residues are retained. Of course, T-cell recognition may require retention of other residues. If many of the amino acid side chains are not necessary for binding to the MHC molecule, then one might expect side chains of noncritical amino acids to occasionally interfere with binding, either directly or through an effect on conformation. That is exactly what was observed for a helper epitope from the HIV-1 envelope protein when a heteroclitic peptide—that is, one that stimulated the T cells at much lower concentrations than did the wild-type peptide—was obtained by replacing a negatively charged Glu with Ala or with Gln, which has the same size but no charge (366). An Asp, negatively charged

but smaller, behaved like the Glu. Thus, this residue was not necessary for binding to the class II MHC molecule, but a negatively charged side chain interfered with binding to the MHC molecule as measured by competition studies. Information about residues that interfere with binding has allowed the refinement of sequence motifs for peptides binding to MHC molecules to permit more reliable prediction of binding (371) (see later discussion).

This observation also provides a novel approach to make more potent vaccines by "epitope enhancement," the process of modifying the internal sequence of epitopes to make them more potent, for example, by increasing affinity for an MHC molecule or T-cell receptor (TCR), or able to induce more broadly cross-reactive T cells specific for multiple strains of a virus (372–375). Proof of principle that this approach can make more potent peptide vaccines has recently been obtained (375). The modified "enhanced" helper T-cell epitope from the HIV-1 envelope protein described previously (366), with Ala substituted for Glu, was shown to be immunogenic at 10- to 100-fold lower doses for *in vivo* immunization than the wild-type HIV-1 peptide to induce a T-cell proliferative response specific for the wild-type peptide. Further, when a peptide vaccine construct using this helper epitope coupled to a CTL epitope (376,377) was modified with the same Glu-to-Ala substitution, it was more potent at inducing CD8$^+$ CTL specific for the CTL epitope than was the original vaccine construct, even though the CTL epitope was unchanged (Fig. 21.9) (375). The increased potency of the vaccine construct was shown to be due to improved class II MHC-restricted help by genetic mapping using congenic strains of mice expressing the same class I MHC molecule to present the CTL epitope and the same background genes, but differing in class II MHC molecules (375). Thus, class II-restricted help makes an enormous difference in induction of class I-restricted CTL, and epitope enhancement can allow construction of more potent vaccines, providing greater protection against viral infection (378). Further, the improved help was found to be qualitatively, not just quantitatively, different, skewed more toward Th1 cytokines (378). The mechanism was found to involve greater induction of CD40-ligand on the helper T cells, resulting in greater IL-12 production by the antigen-presenting dendritic cells, which in turn polarized the helper cells toward Th1 phenotype (378). The dendritic cells conditioned with the helper T cells and the higher affinity peptide and then purified were also more effective at activating CD8$^+$ CTL precursors in the absence of helper cells, supporting a mechanism of help mediated through activation of dendritic cells (379–381). This study showed also that such help was mediated primarily through up-regulation of IL-12 production and CD80 and CD86 expression on the dendritic cell (378). Understanding this mechanism of epitope enhancement may contribute to the design of improved vaccines.
FIGURE 21.9 Enhancement of immunogenicity of a peptide vaccine for induction of class I major histocompatibility complex (MHC)-restricted cytotoxic T lymphocytes by modification of the class II MHC-binding portion to increase CD4+ T-cell help. Peptide vaccine PCLUS3-18 IIIB contains a class II MHC binding helper region, consisting of a cluster of overlapping determinants from the human immunodeficiency virus (HIV)-1 envelope protein gp160, and a class I MHC-binding cytotoxic T-cell (CTL) epitope, P18 IIIB. Modification of the helper epitope to remove an adverse negative charge by replacement of a Glu with an Ala residue was shown to increase binding to the class II MHC molecule (366). Here, introduction of the same modification of the helper epitope, to produce PCLUS3(A)-18IIIB, is shown to greatly increase immunogenicity *in vivo* for induction of CTL to the class I-binding P18IIIB portion. Immunization of A.AL mice with 5 nmol of either vaccine construct subcutaneously in montanide ISA 51 adjuvant, and stimulation of resulting spleen cells with P18IIIB for 1 week in culture, resulted in 33-fold more lytic units for lysing targets coated with P18IIIB when mice were immunized with the modified second-generation vaccine than when they were immunized with the original construct with the natural sequence. Thus, class II-restricted CD4+ T-cell help has a major impact on induction of class I-restricted CTL, and this process of "epitope enhancement" can be used to make vaccines more potent than the natural viral antigens. Targets: BALB/c 3T3 fibroblasts with P18IIIB (*solid lines*) or no peptide (*dashed lines*). (Modified from ref. 375 with permission.)

Similar epitope enhancement has been carried out for class I MHC-binding viral or tumor peptides as well (382,383,384), and in one case has been found to result in greater clinical efficacy of a melanoma vaccine used for human immunotherapy (385). These results emphasize the importance of affinity for MHC molecules vaccine efficacy (386), and suggest that rational design of vaccines with higher affinity epitopes may produce more effective second-generation vaccines (387,388). To that end, the discovery of sequence motifs predicting MHC molecule bind-

ing, and the development of bioinformatics strategies to predict peptide affinity, have proven a great impetus to the field (389).

In the case of class I MHC molecules, results defining sequence-binding motifs generalize the conclusion that only a few critical "anchor" residues determine the specificity of binding to the MHC molecule (Table 21.7) (242,370,390–394). These motifs were defined by a detailed study of one peptide–MHC system (392), by sequencing the mixture of natural peptides eluted from a class I MHC molecule and finding that at certain positions in the sequence a single residue predominated within the pool of peptides (390), and by separating and sequencing individual natural peptides eluted from a class I molecule and finding a conserved residue at certain positions (391). The latter two studies also made the important observation that the natural peptides eluted from class I MHC molecules were all about the same length, eight or nine residues, and this was confirmed for a much larger collection of peptides eluted from HLA-A2 and analyzed by tandem mass spectrometry (393). This finding was consistent with other studies demonstrating that a minimal nonapeptide was many orders of magnitude more potent than longer peptides in presentation by class I molecules to T cells (395,396). This conservation of length was critical to the success of the approach of sequencing mixtures of peptides eluted from a class I molecule (390), because such a method requires that the conserved anchor residues all be at the same distance from the N terminus. The fact that Falk et al. (390) could find a single amino acid at certain positions, such as a Tyr at position 2 in peptides eluted from K^d, implies not only that most or all of the peptides bound to K^d had a Tyr that could be aligned, but also that the peptides were already aligned as bound to the MHC molecule, with each one having just one residue N terminal to the Tyr. This result implies that the position of the N-terminal residue is fixed in the MHC molecule. It is this fact that has made the identification of motifs for binding to class I molecules much more straightforward than finding motifs for binding class II molecules.

This conclusion has not only been confirmed but also explained by the x-ray crystallographic data on class I peptide–MHC complexes (350–352). It appears that both the N-terminal α amino group and the C-terminal carboxyl group are fixed in pockets at either end of the MHC groove, independent of what amino acids are occupying those positions, and that the rest of the peptide spans these fixed points in a more or less extended conformation. The minimum length that can span the distance between these pockets is 8 residues, but 9 or 10 residues can be accommodated with a slight bulge or β turn in the middle of the peptide, explaining the narrow restriction on length. Between these ends, one or two pockets in the groove can accommodate the side chain of an amino acid, usually either at position 2 binding in the B pocket, or at position 5 binding in

▎**TABLE 21.7 Examples of Motifs for Peptides Binding to Class I and II MHC Molecules**

MHC Molecule	Residue Number

MHC, major histocompatibility complex.
Data from refs. 234, 350, and 370–374.

the C pocket, depending on the particular MHC molecule. Additionally the side chain of the C-terminal residue serves as an anchor in the F pocket at the end of the groove. These residues that fit into pockets correspond exactly to the "anchor" residues, at positions 2 or 5, and 8, 9, or 10, defined by the sequence motifs, and appear to be the primary determinants of specificity for peptide binding because the rest of the interactions are largely with peptide backbone atoms, including the α amino and carboxyl groups, and therefore do not contribute to sequence specificity. This finding can explain both the breadth of peptides that can bind to a single MHC molecule because most of the binding involves only backbone atoms common to all peptides, and also the exquisite specificity of binding is determined by the anchor residues that account for the *Ir* gene control of responsiveness.

In contrast, when natural self-peptides were eluted from class II MHC molecules (230,397), the lengths were much more variable, ranging from 13 to 18 residues, and sev-

eral variants of the same peptide were found with different lengths of extra sequence at one end or the other ("ragged ends"). This finding suggested that both ends of the peptide-binding groove of class II MHC molecules are open, in contrast to class I, so that additional lengths of peptide can hang out either side, and trimming does not have to be precise. However, a corollary is that the peptides eluted from class II molecules would not be aligned in a motif starting from the exact amino terminus, and that was indeed what was found. Although a moderately conserved motif was found in some of the peptides eluted from the murine class II molecule I-A^d, consistent with the motif defined based on known antigenic peptides binding to I-A^d *(398)*, the motif was neither so clearly defined nor so highly conserved as in the class I case, and required aligning of sequences to identify a core motif of about 9 amino acid residues (397). Subsequently, a number of motifs for peptides binding to human class II MHC molecules have been defined (242,399–404). Unlike peptides eluted from

MHC class I grooves, these class II binding peptides may locate the core binding motif at various distances from the amino or carboxyl end of the peptide.

The crystal structure of a peptide bound to a human class II MHC molecule, DR1, revealed that indeed the ends of the groove are open and the peptide can extend beyond the groove in either direction (232,405). In addition, the more broadly defined class II motifs in Table 21.7 can be explained by less stringent requirements for amino acid side chains to interact with binding pockets in class II. In general, the MHC class II binding pockets are shallower than for class I, and a selected peptide derives less binding energy from each pocket. In fact, they form fewer H-bonds with the peptide side chains, and more H-bonds are directed at the peptide backbone, allowing a variety of different peptides to bind. Rather than requiring a specific amino acid at each position, the shallow binding pockets of MHC class II tend to exclude peptides based on unfavorable interactions, such as side chains too large to fit the binding pocket. Even one amino acid side chain that binds strongly to an MHC pocket is sufficient to anchor the peptide to MHC class II and set the frame for the interaction of the rest of the peptide with the MHC groove.

For example, binding of three peptides to the class II molecules I-A in mice or HLA-DQ in humans are shown in Figure 21.10. The first residue of the peptide motif is designated P1, the next is P2, and so on. The alpha-helical walls and beta-sheet floor of the MHC class II groove (Chapter 19) are peeled away to reveal the peptide backbone and side chains in relation to MHC binding pockets. For the ovalbumin peptide $Ova_{323-329}$ binding to I-A^d, residues P1, P4, and P9 all point down into the binding pockets (406). The best fit is between Val 327 and the P4 pocket, which creates mainly hydrophobic interactions with MHC, and serves as the anchor residue. Residues P5 (His 328) and P8 (His 331) project upward for binding to the TCR. The shallow P4 pocket can tolerate only small hydrophobic side chains, such as Val, so it dictates which peptides can bind here. The other MHC pockets, P1 and P9, accommodate many different residues, so they have little effect on which peptides can be presented by I-A^d.

For hen egg lysozyme peptide HEL_{50-62} binding to I-A^k, interactions with MHC are observed for P1, P4, P6, and P9 (407). The P1 interaction is very different from I-A^d because the P1 pocket is a perfect fit for Asp and has an arginine at the end of the tunnel to neutralize charge. This structure explains why nearly all peptides presented by I-A^k must have Asp at this position. In contrast, the P4 and P9 pockets are partially filled and will tolerate a number of different side chains at these positions. The P6 pocket requires a Glu or Gln here, even though the MHC residues deep in the pocket are acidic. It is presumed that one of the Glu residues must be protonated to allow Glu binding at this position. This arrangement of the peptide leaves P2,
FIGURE 21.10 Interaction of peptides with the binding groove of major histocompatibility complex (MHC) class II, as determined by x-ray crystallography. Anchor residue side chains fill binding pockets to a greater or lesser extent, supplemented by H-bonds to the peptide backbone. Examples include: I-A^d with ovalbumin peptide 323-334 (**top**) (406), I-A^k with hen egg lysozyme 52-60 (**middle**) (407), and HLA-DR3 with class II-associated invariant chain peptide (**bottom**) (408).

P5, and P8 exposed to solvent in the crystal structure and to the TCR during antigen presentation.

For the CLIP peptide binding to HLA-DR3, deep pockets at P1 and P9 are more fully occupied by the peptide side chains (408). pH-dependent binding is important because CLIP must be stable at neutral pH and unstable at acid pH in the presence of HLA-DM in order to perform its function.

Based on affinity for MHC, these interactions explain the peptide-binding motifs for MHC class II that select which peptides can be presented to T cells. In addition, these interactions orient the peptide in the MHC groove and determine which residues are accessible for recognition by the TCR.

D. T-Cell Receptor Recognition

The last hurdle that a potential antigenic determinant must surmount is recognition by a TCR within the repertoire of the individual responding. This repertoire may be limited

by the availability of combinations of V, D, and J genes in the genome that can combine to form an appropriate receptor, given the lack of somatic hypermutation in TCRs in contrast to antibodies *(357,409)*, and then by self-tolerance, as mediated by thymic or peripheral negative selection, or by limits on the repertoire that is positively selected in the thymus on existing self-peptide–MHC complexes. The available repertoire may also be influenced by prior exposure to cross-reactive antigens. In general, however, it has been hard to find holes in the repertoire *(410)*. Indeed, studies examining large panels of peptides binding to particular class I molecules for correlations between peptide affinity for MHC and T-cell responses have failed to find high-affinity peptides for which no T-cell response can be raised, whereas not all lower affinity peptides elicit a response (411,412). These results suggest that if the peptide can bind well enough to the MHC molecule, there is virtually always a T cell that can see the complex. However, the array of other MHC molecules present can influence the breadth of the T-cell repertoire (413). Furthermore, when TCR repertoires of mice and humans were compared for peptides presented by HLA-A2.1, they seemed to be capable of seeing the same spectrum of peptides (414). Eleven peptides from HCV proteins, each of which had a motif for binding to HLA-A2.1, were tested for recognition by CTL from HLA-A2.1 transgenic mice and human HLA-A2.1–positive patients infected with HCV. The same four peptides that were recognized by the T cells from the mice were the ones recognized by the human T cells, whereas the others were not recognized well by either murine or human T cells. The selection of which peptides were recognized seemed to be determined by binding to the HLA-A2.1 molecule, rather than by the availability of T cells. Thus, despite the differences in *TCR* genes in mice and humans, the repertoires are plastic enough that if a peptide passes the other three hurdles of processing, transport, and binding to MHC molecules, T cells can be elicited to respond to it in either species (414). Likewise, no hole in the helper T-cell repertoire could be found to explain low responders to the recombinant hepatitis B vaccine (415).

On the other hand, evidence exists that MHC binding is not the whole story. Schaeffer et al. *(416)* examined 14 overlapping peptides covering the sequence of staphylococcal nuclease with different class II MHC molecules, constituting 54 different peptide-MHC combinations. Clearly, MHC binding plays a major role because 12/13 immunogenic peptides were high or intermediate binders to MHC molecules, whereas only one of 37 poor binders were immunogenic. Of high-affinity binders, 5/5 peptides were immunogenic. However, for intermediate-affinity MHC-binding peptides, only 7/12 were immunogenic. Similar results were found for the class I MHC molecule HLA-B0702, in which it was found that 7/7 high-affinity binders but only 9/12 intermediate affinity binders were immunogenic

(412). Thus, MHC binding alone is not sufficient to ensure immunogenicity. The T-cell repertoire was one factor suggested that might limit the spectrum of immunogenic peptides.

Indeed, examples for selection at the level of the TCR repertoire exist. A particularly elegant example described by Moudgil et al. (417) is one in which a peptide *(46–61)* of mouse lysozyme presented by I-A^k is recognized T cells from CBA/J and B10.A mice, expressing I-A^k and I-E^k, but not by T cells from B10.A(4R) mice expressing only I-A^k, even though the APC from B10.A(4R) mice can present the peptide to T cells from the other strains. T cells from the B10.A(4R) mice can respond to variant 46–61 peptides in which the C-terminal Arg is replaced by Ala, Leu, Phe, Asn, or Lys, indicating that the C-terminal Arg is hindering recognition, but not binding by I-A^k, and in this case, not processing because the B10.A(4R) APC can present the peptide. It appears that the hindrance interferes with recognition by TCRs available in B10.A(4R) mice, but not TCRs available in B10.A or CBA/J mice, or in (B10.A[4R] × CBA/J)F1 mice. Because the B10.A mice are congenic with the B10.A(4R) mice, the difference is not one of non–MHC-linked genes such as TCR structural genes or non-MHC self-antigens producing self-tolerance. Further, because the F1 mice respond, the difference is not due to a hole in the repertoire produced by a self-antigen of the B10.A(4R) mice. It was concluded that the CBA/J and B10.A mice contain an additional repertoire, positively selected on I-E^k or possibly an H-2D/L class I molecule, in which these strains differ, that can recognize the 46–61 peptide despite the hindering Arg at the C-terminus.

An alternative related explanation is that strains that express I-E^k or D^k or D^d/L^d have an additional repertoire of TCRs positively selected on I-A^k presenting self-peptides from processing of these other MHC molecules in the thymus. This example illustrates a case in point that subtle differences in TCR, presumably caused in this case by positive selection, can lead to responsiveness or nonresponsiveness to a determinant that has already passed all of the three earlier hurdles: processing, transport, and MHC binding. Of course, there are some holes related to self-tolerance, primarily related to the loss of response to dominant determinants (418) and especially loss of high-avidity T cells (419–422). Interestingly, not only is there no loss of response to cryptic determinants, but also T cells recognizing cryptic determinants of mouse lysozyme can be positively selected on other nonmouse lysozyme self-ligands in a lysozyme knockout mouse (418). The selective loss of high-avidity T cells to immunodominant determinants has suggested a strategy to apply epitope enhancement to modify subdominant lower affinity tumor antigen peptides to increase their affinity for MHC molecules and thereby make them more immunogenic in order to take advantage of a repertoire not already crippled by loss of the high-avidity clones (423).

Another elegant example of T-cell repertoire limitations on immunodominance comes from a study of mice deficient in LMP2, and so unable to make immunoproteasomes. Reduced response to one normally immunodominant influenza epitope was found by T-cell adoptive transfer studies to be due to an alteration in the T-cell repertoire, presumably because of altered processing of self-peptides in the thymus (259).

A recent study found another mechanism by which the T-cell repertoire contributes to immunodominance. It was found that the relative immunodominance of a dominant determinant of the HIV envelope protein among different strains of H-2^d mice all presenting the same peptide–H-2D^d complex correlated with the avidity of the T cells responding in those strains (423a). The mechanism found was that high-avidity T cells proliferate faster than low-avidity ones when exposed to antigen, and therefore dominate the response. This mechanism differs from those at earlier steps that progressively constrain the response and thereby narrow the repertoire to dominant epitopes, whereas this mechanism selectively expands the dominant repertoire. This mechanism may also explain other recent findings such as the higher affinity of dominant compared with subdominant TCRs specific for human cytomegalovirus (424). Because high-avidity T cells are better able to clear virus infection (425,426), a recent study even suggests that the driving force for MHC polymorphism is to create a large enough repertoire to select for high-avidity T cells (427).

As more is understood about the molecular basis of TCR recognition, with crystallographic data now available (360,361,428), it becomes possible to apply epitope enhancement in a rational way to the affinity of the peptide-MHC complex to the TCR, as was previously described for the peptide affinity for MHC molecules. Sequence modifications in the peptide that increase the affinity for the TCR were shown to be more effective at expanding *in vivo* the T cells specific for tumor antigens (429–431). Most of these modifications were found empirically, but a systematic study of substitutions throughout a number of peptides revealed a pattern in which peptides with conservative substitutions at positions 3, 5, or 7 were most likely to yield increased TCR affinity, narrowing the candidate list of peptides that require empirical screening (432). This strategy provides a second type of epitope enhancement, derived from basic immunologic principles, to produce more effective vaccines.

Defining the Role of Individual Amino Acids and Effects of Altered Peptide Ligands

Once an antigenic peptide is identified, the next step is to map key amino acid residues by making a series of variant peptides, each of which differs from the native sequence by a single amino acid substitution, as described in section C.

One approach, called an *alanine scan*, substitutes Ala for the natural amino acid at each position in the peptide, or uses Ser or Gly to replace naturally occurring Ala. Ala is used because the side chain is only a methyl group, so it replaces whatever functional side chain is present with the smallest one other than that of Gly, which is not used because of its effects on conformation. Thus, one can ask whether loss of the naturally occurring side chain affects function, without the introduction of a new side chain that might itself affect function. Generally, each peptide will have several amino acids wherein Ala substitution destroys antigenicity. Some of these correspond to contact residues for the TCR, while others are contact residues for MHC. In many cases, the MHC binding residues can be determined by testing the substituted peptides in a competitive MHC binding assay (previously discussed). The amino acid substitutions that knock out T-cell proliferation but not MHC binding are presumed to be in the epitope recognized by the TCR directly, and these can be studied with additional substitutions. For example, this technique was used to compare the residues interacting with the MHC molecule or TCR when the same HIV-1 V3 loop peptide P18 (residues 308–322) was presented by three different MHC molecules, a human class I molecule, a mouse class I molecule, and a mouse class II molecule (Fig. 21.11) (433,434). Interestingly, there was a striking concordance of function of several of the residues as presented by all three MHC molecules (Fig. 21.11). For example, Pro and Phe interacted with the MHC in all three cases, and the same Val interacted with the TCR in all three cases. Also, the same Arg in the middle of the peptide interacted with both the mouse class I and the mouse class II molecules, and the C-terminal Ile was an anchor residue for both human and murine class I molecules (433,434).

In the case of autoimmune T cells, these techniques have been used to study the number and variety of epitopes recognized by self-reactive T cells. In the diabetic NOD mouse, the B chain of insulin is a major target of T cells recovered from pancreatic islets (435). Alanine scanning of B chain peptide 9 to 23 revealed two patterns of T-cell recognition for the same peptide. Some T cells recognize peptide 9–16, and others respond to peptide 13–23. Each epitope appears to have distinct sites for MHC and TCR binding, even though they come from the same peptide chain. Similarly, in systemic lupus erythematosus, human T cells specific for the Sm antigen are narrowly restricted to a few epitopes that are found on a small group of proteins (436). On the Sm-B antigen, three epitopes were recognized. On Sm-D antigen, there were two. In each case, alanine scans showed that the same epitopes were recognized by distinct T-cell clones. These results are consistent with the hypotheses that the autoimmune response to insulin or to Sm antigen may be induced by abnormal exposure of a very few cryptic epitopes, or they may depend on

HLA-A2

H-2D^d

I-A^d
FIGURE 21.11 Comparison of the major histocompatibility complex (MHC)-interacting ("agretopic") and T-cell receptor interacting ("epitopic") residues of the same human immunodeficiency virus (HIV)-1 envelope V3 loop peptide as it is presented by human class I, murine class I, and murine class II MHC molecules to CD8[+] cytotoxic T cell (CTL) and CD4[+] helper T cells. Shown is the sequence of the optimal binding portion of peptide P18 IIIB from the HIV-1 envelope protein V3 loop for each MHC molecule, in single-letter amino acid code. *Arrows pointing up* indicate residues determined to interact with the T-cell receptor, and *arrows pointing down* indicate residues determined to interact with the MHC molecule. Mapping of residue function for binding to the human class I MHC molecule HLA-A2.1 was described in ref. 434, and binding to the murine class I molecule H-2D[d] and the murine class II molecule I-A[d] was described in ref. 433. Note the common use of the Pro and Phe for binding all three MHC molecules, and the use of the key Val residue for binding all the T-cell receptors. Also, the murine MHC molecules both use the central Arg residue as a contact residue, whereas both class I molecules use the C-terminal Ile residue as an anchor residue. Thus, there is a surprising degree of concordance.

selective loss of tolerance for a limited number of epitopes shared by a small subset of self-proteins.

TCRs may distinguish different chemical classes of amino acid side chains. An example of structural differences between amino acid side chains recognized by the TCR comes from an analysis of non–cross-reactive CTL that distinguish homologous peptides from the V3 loop of different strains of HIV-1 envelope protein. The residue at position 8 in the minimal determinant was identified as a key "epitopic" TCR contact residue in both strain IIIB, which has a Val at this position, and strain MN, which has a Tyr at this position (433,437,*438*). CTL specific for strain IIIB do not recognize the MN sequence, but will recognize peptides identical to MN except for the substitution of any aliphatic amino acid at that position, such as

Val, Leu, or Ile (374). In contrast, CTL specific for the MN strain do not recognize the IIIB sequence, but will recognize the IIIB peptide if the Val at this position is replaced by a Tyr (437). Moreover, they will see any MN variant in which the Tyr is replaced by another aromatic amino acid, such as Phe, Trp, or His (374). Thus, the two non–cross-reactive TCRs see similar peptides but discriminate strongly between peptides with amino acids with aliphatic versus aromatic side chains. On the other hand, they do not distinguish strongly among different aliphatic residues or among different aromatic residues. Interestingly, however, in each category, the least active is the bulkiest member of the category, Ile and Trp, respectively, suggesting that these residues must fit into a pocket of limited size in the TCR.

However, many T cell receptors can distinguish even conservative substitutions. The interaction of peptide ligand with TCR can be studied by introducing single substitutions of conservative amino acids at these contact residues, such as Glu for Asp, Ser for Thr, or Gln for Asn. The TCR readily distinguishes among peptides with these minor differences at a single residue, and the results have been revealing. Depending on affinity for the TCR, closely related (altered) peptides can elicit very different responses in T cells. Thus, although a substituted peptide may be very weak or nonstimulatory by itself, it may still act as a partial agonist, or even a strong antagonist of an ongoing T-cell response. Antagonistic peptides can be demonstrated by pulsing antigen-presenting cells with native peptide antigen first, so that one is not measuring competition for binding to MHC molecules, followed by pulsing with a 10-fold or greater excess of the antagonist, before adding T cells. In the case of influenza hemagglutinin peptide 307-319 presented with HLA-DR1, peptide analogues such as Gln substituted for Asn 313 inhibited the proliferation of a human T-cell clone, even though they did not stimulate the clone. Anergy was not induced, and the antagonist peptide had to be present throughout the culture to inhibit the response (439,440). Thus, lack of antagonist activity is another feature of the interaction between peptide (in complex with MHC molecule) and TCR that is required for the peptide to be a stimulatory antigenic determinant.

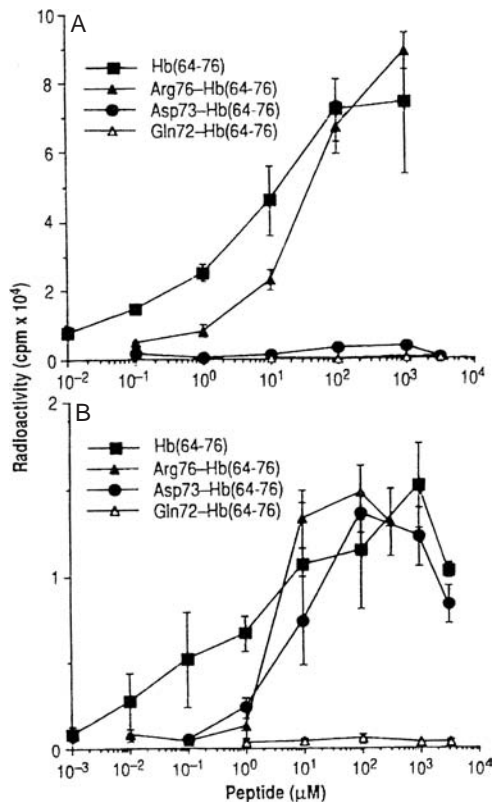
Partial agonists were first demonstrated using T-cell clones specific for an allelic form of mouse hemoglobin. These T cells were from CE/J mice, which express the Hb[s] allele of mouse hemoglobin, after immunization with the Hb[d] allele. The minimum antigenic peptide corresponds to amino acids 67-76 of the Hb[d] sequence and differs from Hb[s] at positions 72, 73, and 76 *(441)*. Peptides substituted at each residue from amino acid 69 to 76 were tested for T-cell proliferation and cytokine release. Some substitutions, such as Gln for Asn at position 72, blocked T-cell stimulation completely in both assays. Other substituted peptides, such as Asp for Glu at position 73, lost T-cell proliferation, but still stimulated IL-4 release, and these are considered


FIGURE 21.12 Differential effect of altered peptide ligands on the response to peptide 64 to 76 from hemoglobin. **A:** Proliferative response of a T-cell line incubated with antigen-presenting cells and the natural Hb (64-76) peptide or with peptides substituted at positions 72, 73, or 76. **B:** Interleukin 4 (IL-4) release by the T-cell line under the same conditions. The peptide substituted with Asp for Glu at position 73 is unable to induce T-cell proliferation, but it can still induce production of IL-4, so it is a partial agonist. In contrast, substitution of Gln for Asn at position 72 knocks out both responses equally. (Modified from ref. 442, with permission.)

partial agonists (Fig. 21.12) (442). Lack of stimulation was not due to failure to bind MHC because both substituted peptides gave reasonable binding in a competitive binding assay (443). Similar alteration of cytokine profile by altering the peptide ligand can be seen in other systems (440,444,445).

For one of the Hb 64-76–specific T-cell clones, PL.17, substitutions at amino acids 70, 72, 73, or 76 reduced antigenic potency by 1,000-fold or more, even though conservative amino acids were substituted. Although substitution of Ser for Ala 70 prevented T-cell stimulation in both assays, there was clearly some response to this peptide because it induced expression of the IL-2 receptor (446). In addition, once T cells were exposed to the Ser 70 peptide, they became unresponsive to subsequent exposure to the natural Hb^d peptide. This phenomenon closely resembled T-cell anergy and persisted for a week or more. The Ser 70 substitution alters a contact residue of the peptide for the TCR of clone PL.17 and affects its affinity. Other T-cell

clones, however, can respond to this peptide presented on the same MHC molecule (I-E^k). Other Hb^d peptides substituted at this position, such as Met and Gly 70, also induced anergy but not proliferation, while nonconservative substitutions such as Phe, Asn, Asp, and His 70 induced neither (447)

Another well-studied example is influenza hemagglutinin peptide 306-318 as presented on human HLA-DR1. Based on the known crystal structure of the peptide-MHC complex (231) amino acid substitutions could be targeted to contact residues for the TCR, at positions 307, 309, 310, 312, 315, and 318 (448). At each position, nonconservative substitutions often rendered the peptide inactive, while conservative substitutions at several sites either gave full antigenicity, or gave progressively lower stimulatory activity, down to 1,000-fold less than native peptide, while retaining the ability to induce anergy. For example, substituting His or Gly for Lys 307 gave 1,000-fold reduced stimulation of T-cell proliferation, but full ability to induce tolerance. Similarly, substituting His for Lys 315 gave complete loss of stimulation, but nearly full anergy-inducing activity. As before, induction of the IL-2 receptor (CD25) was a sign of T-cell activation by these altered peptide ligands, even when they did not induce proliferation. Unlike these peptides, the antagonists do not induce interleukin receptors or secretion, and they do not cause long-lasting tolerance. Overall, a number of altered peptide ligands have now been identified that, in appropriate complexes with MHC molecules, induce anergy or act as antagonists of the TCR and block activation by agonist ligands by delivering an abortive signal (440).

Several methods have been found to anergize T cells to a specific antigen for up to a week, and all have the common theme of delivering a partial signal via the TCR, resulting in tolerance rather than stimulation. The first method was to expose the T cells to peptide plus antigen-presenting cells treated with the carbodiimide cross-linker ECDI *(449)*. This treatment may prevent accessory molecules on the presenting cell from interacting with the TCR complex, or costimulatory signals from contributing to T-cell activation. The second method was to present peptide on presenting cells with mutated I-E molecules (450,451). The third method was to use altered peptide ligands that act as TCR antagonists as previously described (440,447,448). The final method was to block CD4 function with a monoclonal antibody, which would delay the recruitment of CD4 to the engaged TCR (452). Because generation of a complete stimulatory signal requires the interaction of TCR and accessory molecules, modifications that affect either component can block signaling. An altered peptide ligand, with decreased affinity for the TCR, may form an unstable complex, which cannot stay together long enough to recruit accessory molecules and generate a complete signal (452,453). Altered peptide ligands with low affinity for the TCR can also act as partial agonists that can compete

with optimal agonists and reduce T-cell stimulation based on a similar mechanism (short dwell time of peptide-MHC complex on the TCR) (177).

Abnormal TCR signaling can be demonstrated by following the activity of protein kinases. Normal signaling produces phosphorylation of TCR subunits, such as ζ chain, as well as phosphorylation and activation of receptor-associated tyrosine kinases, such as ZAP-70. These kinases generate the downstream signal needed for T-cell activation. However, in each case studied, partial antigen signaling resulted in ζ chain phosphorylation without phosphorylation or activation of ZAP-70 (447,451,452), so downstream activation did not occur. This abnormal pattern occurred regardless of the method of anergy induction.

Partial signaling may be important for T-cell survival during negative selection in the thymus or in maintaining peripheral tolerance. By responding to self-antigens as if they were altered ligands presented in the thymus, T cells could use anergy induction as a successful strategy for avoiding clonal deletion. Similarly, peripheral tolerance may be an important mechanism for preventing autoimmune disease. Immunotherapy with altered peptide ligands could be envisioned as a way to block an ongoing response or induce tolerance to a specific antigen, such as the synovium in arthritis, or foreign MHC antigens in allograft rejection. However, a potential pitfall is that different T cells recognize the same peptide differently, so a peptide that is seen as an altered peptide ligand by some T-cell clones may be seen as a complete antigen by others. In addition, the choice of peptide would vary with MHC type. To be effective, an altered peptide ligand should antagonize or anergize polyclonal T cells and should work with each patient's MHC type.

A similar mechanism may be invoked to explain the generally weak immunogenicity of tumor antigens. According to this hypothesis, the only T cells capable of responding to self-antigens on tumors may have low-affinity receptors for them. In effect, the natural sequence is the altered ligand that induces tolerance. In some cases, this anergy can be overcome with modified peptides that have greater affinity for the TCR and induce a full stimulatory signal, resulting in an effective immune response to the tumor antigens (429), as described previously.

Prediction of T-Cell Epitopes

The fact that T cells recognize processed fragments of antigens presented by MHC molecules leads to the ironic situation that T-cell recognition of antigen, which is more complex than antibody recognition because of the ternary complex needed between TCR, antigen, and MHC molecule, may actually be focused on simpler structures of the antigen than those seen by most antibodies specific for native protein antigens. In contrast to the assembled topographic antigenic sites seen by many antibodies (49,50), T cells specific for processed antigens are limited to seeing short segments of continuous sequence (155,211). Therefore the tertiary structure of the protein plays little if any role in the structure of the epitope recognized by T cells, except as it may influence processing. However, the structure of the T-cell antigenic site itself must be limited to primary (sequence) and secondary structure, the latter depending only on local rather than long-range interactions. This limitation greatly simplifies the problem of identifying structural properties important to T-cell recognition because one can deal with sequence information, which can now be obtained from DNA without having a purified protein, and with the secondary structure implicit therein without having to obtain an x-ray crystallographic three-dimensional structure of the native protein, a much more difficult task.

Because the key feature necessary for a peptide to be recognized by T cells is its ability to bind to an MHC molecule, most approaches for predicting T-cell epitopes are based on predicting binding to MHC molecules. These approaches, which have been reviewed (389,454), can be divided into those that focus on specific individual MHC molecules one at a time, such as motif-based methods, and those that look for general structural properties of peptide sequences. We shall discuss first the methods based on general properties, and then those directed to individual MHC molecules.

The first structural feature of amino acid sequences found associated with T-cell epitopes that remains in use today is helical amphipathicity (205,455–458) which is statistically significant independent of the tendency to form a helix per se (456). Because the x-ray crystallographic structures of both MHC class I (350–352,459) and class II molecules (231,408) have consistently shown peptides to be bound in extended, not alpha helical conformation, helicity per se has been abandoned as an associated structural feature of T-cell epitopes. However, as discussed later, other explanations of amphipathic structures have been discovered that do not require the peptide to be bound to the MHC molecule as an alpha helix. Amphipathicity is the property of having hydrophobic and hydrophilic regions separated in space. It was observed that the immunodominant T-cell epitopes of myoglobin and cytochrome c corresponded to amphipathic helices (163,167,460). DeLisi and Berzofsky (455) developed an algorithm to search for segments of protein sequence that could fold as amphipathic helices, based on the idea that the hydrophobicity of the amino acids in the sequence must oscillate as one goes around an amphipathic helix. For the hydrophobic residues to line up on one side and the hydrophilic residues on the other, the periodicity of this oscillation must be approximately the same as the structural periodicity of the helix, about 100 degrees per residue (360 degrees per 3.6 residues per turn) (Fig. 21.13).
FIGURE 21.13 Plot of hydrophobicity of each amino acid in sperm whale myoglobin 102 to 118, according to the scale of Fauchère and Pliska (*529*), as a function of amino acid sequence, showing least-squares fit of a sinusoidal function to the sequence of hydrophobicities from 107 to 117. (From ref. *158*, with permission.)

A microcomputer program implementing this analysis was published *(458)*. Margalit et al. *(205)* optimized the original approach *(455)*, correctly identifying 18 of the 23 immunodominant helper T-cell antigenic sites from the 12 proteins in an expanded database ($p < .001$) *(205)* (Table 21.4). Indeed, when the database was expanded to twice and then 4 times its original size, the correlation remained highly significant, and the fraction of sites predicted remained relatively stable (34/48 sites = 71%, $p < .003$; 61/92 sites = 66%, $p < .001$) (*461,462*). A similar correlation was found for 65% of peptides presented by class I MHC molecules (462). A primary sequence pattern found in a substantial number of T-cell epitopes by Rothbard and Taylor *(463)* was consistent with one turn of an amphipathic helix. Also, another approach, called the *strip-of-the-helix* algorithm, that searches for helices with a hydrophobic strip down one face, found a correlation between amphipathic helices and determinants presented by both class II and class I MHC molecules *(457,464)*.

Newer data suggest at least two explanations, not mutually exclusive, for this correlation in the absence of helical structure found in the peptides bound to MHC molecules (465). First, crystal structures of peptides bound to class II MHC molecules have found that the peptides are bound in an extended conformation, but with a −130-degree twist like that of a type II polyproline helix (231,408), and can be quite amphipathic because of this twist (231). Although the -130-degree twist is distinct from that of an alpha helix, it gives a periodicity similar enough to be detected. Second, it was observed that spacing of the anchor residues in the motifs for peptides binding to class I and II MHC molecules was consistent with the spacing of turns of an alpha helix, for example, at positions 2 and 9 (7 residues apart like two turns of a helix) or at positions 5 and 9 (spaced like one turn of a helix) (465). Because the anchor residues are most often hydrophobic, this pattern resulted in an amphipathic periodicity pattern like that of an amphipathic alpha helix for just the anchor residues alone, seen in the majority of motifs (465). Thus, if the other residues have a random pattern, the anchor residue spacing alone, which is enforced by the spacing of the pockets in the MHC molecules that bind these anchor residues, will produce the amphipathic helical signal, even though the peptide is bound in an extended conformation. This amphipathic helical periodicity has held up as a correlate for peptides defined as T-cell epitopes (465), and has continued to be a useful predictive tool for identifying potential epitopes, successful in a number of studies, when one does not want to focus on individual MHC alleles or wants to find regions of high epitope density.

Other approaches to predicting T-cell epitopes are generally based on sequences found to bind to specific MHC molecules (389,454). The simplest approach is to apply standard sequence search algorithms to known protein sequences to locate motifs for peptides binding to particular MHC molecules, using collections of motifs identified in the literature (242). This approach showed early success for epitopes in proteins from *Listeria monocytogenes* (466) and malaria (467), but it also became apparent that only about 30% of sequences bearing motifs actually bound to the corresponding MHC molecules (466,468,469). This discrepancy may relate to adverse interactions created by nonanchor residues (366,371,470), and could be overcome to some extent by generating extended motifs taking into account the role of each residue in the sequence (371,470).

To determine whether one could locate regions of proteins with high densities of motifs for binding multiple MHC molecules, Meister et al. (471) developed the algorithm Epimer, which determined the density of motifs per length of sequence. A surprising result was that the motifs were not uniformly distributed, but clustered. This clustering may reflect the fact that many motifs are related, and that the same anchor residues are shared by several motifs, perhaps because MHC molecules are also related and their variable segments that define some of the binding pockets are sometimes exchanged by gene-conversion events *(472)*. This hypothesis has now been confirmed and extended by studies showing that each anchor pocket can be grouped into families of MHC molecules sharing similar pockets and therefore anchor residues, but the families for the B, C, and F pockets do not coincide, so there is a reassortment between pockets (473,474). These observations allow prediction of motifs for additional MHC molecules. In the case of HIV, the densities of motifs for class I MHC binding were anomalous at both the low and high ends of the spectrum (475). Clustering at the high end may be due to anchor sharing, and showed no correlation with conserved or variable regions of the sequence. However, at the low end, long stretches with low motif density occurred

preferentially in variable regions, suggesting that the virus was mutating to escape the CTL immune system (475). This clustering may be useful in vaccine development, because identification of sequences containing overlapping motifs for multiple MHC molecules may define promiscuously presented peptides that would elicit responses in a broad segment of the population (471).

Another type of MHC allele-specific approach is the use of matrices defining the positive or negative contribution of each amino acid possible at each position in the sequence toward binding to an MHC molecule. A positive or negative value is assigned to each of the 20 possible amino acids that can occur at each position in a peptide sequence, and these are summed to give the estimated potential of that peptide for binding. The values in the matrix are derived from either experimental binding studies using peptide panels with single positions substituted with each possible amino acid (404,476–478), or from comparisons of peptides known to bind in a compilation of the literature, if the number known is sufficiently large (454,479). Davenport et al. (480,481) also developed a motif method based on Edman degradation sequencing of pooled peptides eluted from MHC molecules. All of these methods have had some success in predicting peptides binding to particular MHC molecules (454), but they all require the assumption that each position in a peptide must be acting independently of its neighbors, which is a reasonable first approximation, but exceptions are known (482). The more experimental data that go into generating the matrix, the more reliable the predictions. Therefore, the predictive success may be greater for some of the more common HLA molecules for which more data exists. This matrix approach has been used for both class I and class II MHC molecules. Current predictive matrix algorithms, compared with experimental screening, have been found to detect most CD8$^+$ T-cell epitopes detected experimentally, for example, in vaccinia virus, in which the top-ranked 300 peptides using 4 different algorithms predicted 40/49 epitopes found (483).

A potentially very useful observation is the finding that HLA class I molecules can be grouped into families (HLA supertypes) that share similar binding motifs (403,476,484,485). The broader motifs that encompass several MHC molecules have been called *supermotifs*. For example, HLA-A0301, A1101, A3101, A3401, A6601, A6801, and A7401 all fall into the HLA-A3 superfamily (484). A peptide that carried this supermotif should be active in a broader range of individuals than one that was presented by a single HLA molecule. Moreover, because several HLA supertypes have been defined, it should be possible to design a vaccine effective in a large fraction of the population with only a limited number of well-selected antigenic determinants (486).

Another approach for predicting peptides that bind to MHC molecules is based on free energy calculations of pep-

tides docked into the groove of a known MHC structure, for which the crystallographic coordinates are known, or on structural modeling of the MHC molecule by homologous extension from another MHC molecule, when the crystal structure is not known, followed by peptide docking calculations (487,488) It is important to use free energy rather than energy because the latter alone cannot find the most stable orientation of a side chain and cannot correctly rank order different side chains at the same position. This approach correctly predicts the structure of several known peptide–MHC complexes when starting with the crystal structure of a different complex, in each case to within 1.2 to 1.6 Å all-atom root-mean square deviation (488). Using this structural modeling can allow one to extend motifs to nonanchor positions for cases in which only anchor residue motifs are known, and can allow one to predict new motifs for MHC molecules whose motifs have not yet been determined.

Another approach to predicting MHC binding sequences uses a technique called *threading* that has been developed for predicting peptide secondary structure, based on threading a sequence through a series of known secondary structures, and calculating the energies of each structure. Altuvia et al. (489,490) showed that threading could be applied to peptides in the groove of MHC molecules, because when several peptides that bind to the same MHC molecule are compared crystallographically, the conformation of the peptides is fairly similar, as for example in several peptides crystallized bound to HLA-A2.1 (459). In testing the threading approach, Altuvia et al. (489,490) showed that known antigenic peptides are highly ranked among all peptides in a given protein sequence, and the rank order of peptides in competitive binding studies could be correctly predicted. The advantage of this approach is that it is independent of known binding motifs, and can identify peptides that bind despite lack of the common motif for the MHC molecule in question. It can also be used to rank a set of peptides all containing a known motif.

Finally, artificial neural networks (ANN) can be trained on a set of peptides that bind to a given MHC molecule to recognize patterns present in binding peptides (491). When the predictions of the ANN are tested, the results can be used to further train the ANN to improve the predictive capability in an iterative fashion.

Recently, predictive algorithms for proteasomal cleavage sites (492) and TAP-transported peptides (294) have been developed. Combining these into approaches to predict epitopes based on all the steps a peptide must pass through, cleavage, transport, and MHC binding, (except for TCR binding), has led to the most recent comprehensive algorithms for epitope prediction, which can achieve up to 62% sensitivity (295,493–497).

As all these methods are further developed and refined, they promise to allow accurate prediction of peptides that

will bind to different MHC molecules and thus allow the design of vaccines without empirical binding studies until the end of the process. Further, localization of clusters of adjacent or overlapping binding sequences in a short segment of protein sequence can also be useful for selecting sequences that will be broadly recognized.

RELATIONSHIP BETWEEN HELPER T-CELL EPITOPES AND B-CELL EPITOPES ON A COMPLEX PROTEIN ANTIGEN

As we have seen, the factors that determine the location of antigenic sites for T cells and for B cells, with the possible exception of self-tolerance, are largely different. Indeed, if B cells (with their surface antibody) bind sites that tend to be especially exposed or protruding—sites that are also more accessible and susceptible to proteolytic enzymes—then there is reason to think that T cells may have a lower probability of being able to recognize these same sites, which may be more likely to be destroyed during processing. Certainly, assembled topographic sites will be destroyed during processing. On the other hand, there are examples in which T cells and antibodies seem to see the same, or very closely overlapping, sites on a protein *(43,163,193,498–500)*, although fine specificity analysis usually indicates that the antibody and T-cell fine specificities are not identical. The question dealt with here is whether there are any functional or regulatory factors in T cell–B cell cooperation that would produce a relationship between helper T-cell specificity and B-cell specificity for the same protein antigen.

Early evidence that helper T cells might influence the specificity of the antibodies produced came from a number of studies showing that *Ir* genes, which appeared to act through effects of T-cell help, could influence the specificity of antibodies produced to a given antigen *(159,501–508)*. It was hard to imagine how MHC-encoded *Ir* genes could determine which epitopes of a protein elicit antibodies, when such antibodies are generally not MHC-restricted. One explanation suggested was that the *Ir* genes first select which helper T cells are activated, and these in turn influence which B cells, specific for particular epitopes, could be activated *(110)*. Because, for cognate help, the B cell has to present the antigen in association with an MHC molecule to the helper T cell, the *Ir* gene control of antibody specificity must operate at least partly at this step by selecting which helper T cell can be activated by and help a given B cell. Conversely, if the helper T cell selects a subset of B cells to be activated on the basis of their antibody specificity, then there is a reciprocal interaction between T and B cells influencing each other's specificity. Therefore, this hypothesis was called *T–B reciprocity (110)*. Steric constraints on the epitopes that could be used by helper T cells to help a B cell specific for another particular epitope

of the same protein were also proposed by Sercarz et al. *(509)*.

The concept was first tested by limiting the fine specificity of helper T cells to one or a few epitopes and then determining the effect on the specificities of antibodies produced in response to the whole molecule. This was accomplished by inducing T-cell tolerance to certain epitopes *(510)* or using T cells from animals immune to peptide fragments of the protein *(108,511,512)*. In each case, the limitation on the helper T-cell specificity repertoire influenced the repertoire of antibodies produced.

One purpose of the B-cell surface immunoglobulin is to take up the specific antigen with high affinity, which is then internalized by receptor-mediated endocytosis and processed like any other antigen *(513–520)*. Therefore, the explanation was proposed that the surface immunoglobulin, which acts as the receptor to mediate endocytosis, sterically influences the rate at which different parts of the antigen are processed, because what the B cell is processing is not free antigen but a monoclonal antibody–antigen immune complex *(110)*. This concept presupposes that many antibody–antigen complexes are stable near pH 6 in the endosome and that what matters is the kinetics of production of large fragments, rather than the products of complete digestion, when both the antigen and the antibody may be degraded to single amino acids. Such protection from proteolysis of antigen epitopes by bound antibody can be demonstrated at least *in vitro (54)*. The effect of antigen-specific B-cell surface immunoglobulin on the fragments produced by proteolytic processing of antigen was elegantly demonstrated by Davidson and Watts *(521)*. They demonstrated that the pattern of fragmentation of tetanus toxoid, as measured by SDS–polyacrylamide gel electrophoresis, produced during processing by B lymphoblastoid clones specific for tetanus toxoid, varied among B-cell clones depending on their specificity for different epitopes within the antigen. Binding to the antibody may also influence which fragments are shuttled to the surface and which are shunted into true lysosomes for total degradation. Thus different B cells bearing different surface immunoglobulin would preferentially process the antigen differently to put more of some potential fragments than others on their surface, in contrast to nonspecific-presenting cells that would process the antigen indifferently. By this mechanism, it is proposed that B-cell specificity leads to selective antigen presentation to helper T cells and therefore to selective help from T cells specific for some epitopes more than from T cells specific for others *(110)*.

To test this hypothesis, Ozaki and Berzofsky *(109)* made populations of B cells effectively monoclonal for purposes of antigen presentation by coating polyclonal B cells with a conjugate of monoclonal antimyoglobin coupled to anti-IgM antibodies. B cells coated with one such conjugate presented myoglobin less well to one myoglobin-specific

T-cell clone than to others. B cells coated with other conjugates presented myoglobin to this clone equally well as to other clones. Therefore, the limitation on myoglobin presentation by this B cell to this T-cell clone depended on the specificity of both the monoclonal antibody coating the B cell and the receptor of the T-cell clone. It happened in this case that both the monoclonal antibody and the T-cell clone were specific for the same or closely overlapping epitopes. Therefore, it appears that the site bound by the B-cell surface immunoglobulin is less well presented to T cells. This finding is also consistent with a study of chimeric proteins in which one or more copies of an ovalbumin helper T-cell determinant were inserted in different positions (522). Although the position of the ovalbumin determinants did not affect the antibody response to one epitope, the position did matter for antibody production to an epitope of the chimeric protein derived from insulinlike growth factor I. An ovalbumin determinant inserted distal to this epitope was much more effective in providing help than one inserted adjacent to the same epitope, when both constructs were used as immunogens, even though both constructs elicited similar levels of ovalbumin-specific T-cell proliferation in the presence of nonspecific presenting cells *in vitro*, as a control for nonspecific effects of flanking residues on processing and presentation of the helper T-cell determinants. However, circumstantial evidence from the *Ir* gene studies mentioned previously suggests that T cells may preferentially help B cells that bind with some degree of proximity to the T-cell epitope, as there was a correlation between T cell and antibody specificity for large fragments of protein antigens under *Ir* gene control *(107,110,159,504,505,508)*. Therefore, antibodies may have both positive and negative selective effects on processing.

Further studies on presentation of *β*-galactosidase–monoclonal antibody complexes by nonspecific APCs suggest similar conclusions *(523,524)*. Presumably, the conjugates are taken up via immunoglobulin fragment c (Fc) receptors on the presenting cells and processed differentially according to the site bound by the antibody, so that they are presented differentially to different T-cell clones. Thus, non–B-presenting cells can be made to mimic specific B-presenting cells. This also suggests that circulating antibody may have a role in the selection of which T cells are activated in a subsequent exposure to antigen.

The issue of whether bound antibody enhanced or suppressed presentation of specific determinants to T cells was explored further by Watts and Lanzavecchia (525) and their coworkers (Simitsek et al. [526]). They first found that a particular tetanus-toxoid–specific Epstein-Barr virus-transformed human B-cell clone 11.3 failed to present the tetanus-toxoid epitope 1174-1189 to specific T cells, whereas it presented another epitope as well as did other B cells, and another B-cell clone presented the 1174-1189 epitope well. Moreover, the free 11.3 antibody

also inhibited presentation of this epitope to T cells at the same time that it enhanced presentation of other epitopes by Fc receptor facilitated uptake (525). They subsequently found that the same 11.3 B cell and antibody actually enhanced presentation of another epitope of tetanus toxoid, 1273-1284, by about 10-fold, even though both epitopes were within the footprint of the antibody, as determined by protection from proteolytic digestion (526). The enhancement could be mediated also by free antibody as well as Fab fragments thereof, indicating that the mechanism did not involve Fc receptor-facilitated uptake. Further, the 11.3 antibody had no effect on presentation of another determinant in the same tetanus toxoid C fragment, 947-967, that was not within the footprint of the antibody, and another antibody to the C fragment did not enhance presentation of 1273-1284. The authors conclude that the same antibody or surface immunoglobulin can protect two determinants from proteolysis, but sterically hinder the binding of one to class II MHC molecules while facilitating the binding of the other (526). The facilitation may involve protection from degradation. This antibody-mediated enhancement of presentation of selected epitopes to helper T cells can greatly lower the threshold for induction of a T-cell response, and may thereby elicit responses to otherwise subdominant epitopes. It can also contribute to epitope spreading, for example, in autoimmune disease, in which an initial response to one dominant determinant leads to a subsequent response to other subdominant determinants, perhaps by helping for antibody production, which in turn facilitates presentation of the other determinants.

Taken together, these results support the concept of T–B reciprocity in which helper T cells and B cells each influence the specificity of the other's expressed repertoire *(110)*. This mechanism may also provide an explanation for some of the cases in which *Ir* genes have been found to control antibody idiotype *(527,528)*. These relationships probably play a significant role in regulating the fine specificity of immune response of both arms of the immune system. Therefore, they will also be of importance in the design of synthetic or recombinant fragment vaccines that incorporate both T- and B-cell epitopes to elicit an antibody response.

CONCLUSION

Overall, antibodies and T cells recognize different structural features in different contexts or environments, and thus complement each other to detect the spectrum of foreign (or self) antigens encountered. Antibodies recognize three-dimensional structures on the exposed surface of molecules either in solution or on a cell surface. Therefore, they are very dependent on the conformation of the antigen and can recognize structures that are assembled on the surface of the antigen molecule by the way it folds

but that are not contiguous in the primary sequence. However, they do not generally recognize structures buried within protein molecules or inside cells. In contrast, T cells are designed to recognize short segments of primary amino acid sequence of protein antigens, and thus are not dependent on the conformation of the original protein, unless it affects processing. Furthermore, T cells particularly provide internal surveillance of proteins inside cells, recognizing peptide fragments of these presented by MHC molecules that carry these fragments to the cell surface.

This surveillance of intracellular proteins requires a number of hurdles including proteolytic processing of the antigen into fragments, transport of these into the compartments where they are loaded onto MHC molecules, binding with appropriate specificity to the combining site of specific MHC molecules, and then finally recognition by an appropriate T-cell receptor. These hurdles limit the number of amino acid sequences that can be recognized and account in part for immunodominance. Furthermore, the two major subsets of T cells also complement each other by recognizing exogenous and endogenous proteins processed and transported through different pathways and presented by difference classes of MHC molecules. Thus, the two major classes of T cells complement the types of structures and the locales surveyed by antibodies. For example, in the case of viruses, antibodies can detect intact virions and shed viral proteins in solution as well as viral proteins expressed on the surface of infected cells, CD4$^+$ T cells can recognize viral proteins taken up by antigen-presenting cells and processed in an endosomal pathway, and CD8$^+$ T cells can detect proteins synthesized within the infected cell, whether or not they are ever expressed intact on the cell surface or secreted. Together, they provide the immune system with a strategy to detect all forms of foreign invaders as well as to protect the host through different effector mechanisms.

Fc Receptors and Their Role in Immune Regulation and Inflammation

Jeffrey V. Ravetch and Falk Nimmerjahn

HISTORICAL BACKGROUND

Cellular receptors for immunoglobulins were anticipated by the description of cytophilic antibodies of the immunoglobulin (Ig) G class, identified by Boyden and Sorkin in 1960 (1). These antibodies conferred on normal cells, like macrophages, the capacity to specifically absorb antigen. Using sheep red blood cells (RBCs) as the antigen resulted in rosette formation between the cytophilic anti–sheep RBC antibodies and macrophages and provided a convenient means of visualization of the binding of cytophilic antibodies with normal cells. Subsequent studies by Berken and Benacerraf (2) suggested that the crystallized fragment (Fc) of the cytophilic antibody interacted with a cell surface receptor on macrophages. Similar studies on B lymphocytes extended the generality of these receptors and led to the term *Fc receptor* (FcR) to denote the surface molecules on lymphoid and myeloid cells that are capable of interacting with the Fc of immunoglobulin molecules (3). Studies on IgE, IgM, and IgA also demonstrated the existence of distinct receptors for those isotypes

various immune cell types. Detailed biochemical characterization of Fc receptors was inaugurated by the studies of Kulczycki et al. (4) on the high-affinity IgE FcR of mast cells, revealing a heterooligomeric $\alpha\beta\gamma_2$ subunit structure. A distinction between FcRs for the IgE and IgG isotypes emerged with the observation of the very high (10^{10} M^{-1}) binding affinity of IgE for its receptor in comparison with the low binding (10^6 M^{-1}) of IgG1 to its receptor. This distinction led to the realization that the functional IgG1 ligand was exclusively in the form of an immune complex, whereas IgE binding occurred through monomer interaction with its receptor. This difference in binding affinity had significant functional implications for the structures of these receptors and mechanisms by which each isotype activated its target cell. Determination of the structure of these receptors was facilitated by their molecular cloning, beginning with the IgG FcRs (5,6) and followed by the IgE FcR (7). Two distinct types of IgG receptors differing in their transmembrane and cytoplasmic sequences, were identified, which thus offered a molecular explanation for the apparent contradictory activation and inhibitory

activities attributed to IgG FcRs. The primary structure of the subunits of the high-affinity IgE FcR revealed homology in the ligand-binding α subunit to its IgG counterparts. However, the extent of similarity between these receptors became apparent with the observation that the γ-chain subunit was common to both IgG and IgE FcRs, providing both assembly and signaling functions to these activation receptors (8,9). This common structure suggested a functional link between immune complex diseases and allergic reactions, a prediction that was confirmed through mouse knockout studies of IgG FcRs (10,11). The FcRs, through their dependence on the immunoreceptor tyrosine-based activation motif (ITAM) pathway of cellular activation, belonged to the family of immunoreceptors that included the antigen receptors on B cells and T cells. Three-dimensional crystal structures have been solved for the low-affinity IgG FcRs (12,13) and the high-affinity IgE FcR (14) alone and in complex with their immunoglobulin ligands (15,16), further establishing the close structural link between these immunoglobulin receptors.

The functional roles of IgG FcRs were suggested by the distribution of these receptors on both lymphoid and myeloid cells (17). On myeloid cells, they were presumed to mediate effector cell activation, resulting in phagocytosis, antibody-dependent cellular cytotoxicity (ADCC), and release of inflammatory mediators. However, the well-known ability of the classic pathway of complement to generate activated fragments in response to immune complexes capable of inducing inflammatory responses by myeloid cells complicated the interpretation of the physiologic role of IgG FcRs. Thus, the contribution of IgG FcRs to the mechanism of immune complex–mediated inflammation, as distinct from the role of complement, remained uncertain. Insight into this distinction was gained through the generation of mouse strains specifically deficient or blocked in either FcRs (10,18–20) or components of the classic complement pathway (21). Studies on immune complex–mediated inflammatory responses in these animals, such as the Arthus reaction, led to the realization that IgG FcRs and not the classic pathway of complement activation were the functional mediators of inflammatory responses triggered by immune complexes (20,22,23). The situation for IgE was less confounding, and the identification and characterization of a high-affinity receptor for this isotype on mast cells offered a plausible explanation for many of the inflammatory features of allergic reactions (24), validated later by mouse knockouts of this receptor. IgG immune complexes had also been observed to mediate suppression of B cell responses; thus, the presence of an IgG FcR activity on B cells provided a possible but uncharacterized mechanism for this inhibitory activity. Molecular characterization of this inhibitory activity for the B cell FcR, FcRIIB, resulted in the first detailed description of an inhibitory motif, now termed the immunoreceptor tyrosine-based inhibitory motif (ITIM) (25,26), and the

signaling pathway by which it abrogates ITAM-triggered activation. The ITIM mechanism is now recognized as ubiquitous and has resulted in the recognition of a large family of inhibitory receptors on immune cells that function to maintain proper thresholds for activation and abrogate activation responses to terminate an immune reaction (27).

FcRs are now recognized as central mediators of antibody-triggered responses, coupling the innate and adaptive immune responses in effector cell activation (28). In addition to these specialized roles, the IgG FcRs have served as an example of the emerging class of balanced immunoreceptors, in which activation and inhibition are tightly coupled in response to ligand binding. Perturbations in either arm of the response have been shown to lead to pathologic consequences and have been taken as a paradigm of how these systems are likely to work for those paired immunoreceptors with unknown ligand-binding functions. The newly described roles for FcRs in maintaining peripheral tolerance, shaping the antibody repertoire, regulating antigen-presenting cell (APC) maturation, and promoting mast cell survival indicate the diversity of functions that these receptors possess and their central role in modulating both afferent and efferent responses in the immune response.

This chapter focuses primarily on the IgG and IgE FcRs, for which substantial data are available on their structure, function, regulation, and role in a variety of physiologic and pathologic conditions. The similarity in structure and signaling between those receptors and other members of this family, such as the IgA FcR, is also discussed. In addition, a brief overview of the recently discovered and rapidly expanding family of FcR homologous proteins is given. Other immunoglobulin receptors with specialized functions in the transport of immunoglobulins, such as the FcRn (29) and the poly-Ig FcR (30), are discussed elsewhere in this volume.

STRUCTURE AND EXPRESSION

Molecular Genetics

Two general classes of FcRs are now recognized: the activation receptors, characterized by the presence of a cytoplasmic ITAM sequence associated with the receptor, and the inhibitory receptor, characterized by the presence of an ITIM sequence. These two classes of receptors function in concert and are usually found coexpressed on the cell surface. Thus, coengagement of both signaling pathways is the rule, setting thresholds for and ultimately determining the physiologic outcome of effector cell responses. Among the factors that determine this threshold level are the actual affinities of the individual activating and inhibitory receptors for a specific IgG ligand and the expression level of the

receptor pairs on immune effector cells. It is important to note that the affinity of different antibody isotypes and subclasses for their respective activating and inhibitory FcRs varies significantly, which explains the differential activity of antibody isotypes *in vivo* (20,31,32). In addition, alleles of specific FcRs have been described that alter their affinity for individual subclasses, thus accounting for the variable responses seen in a population to an antibody (see later discussion).

Subunit Composition

FcRs are typically type I integral membrane glycoproteins consisting of, at the least, a ligand recognition α subunit that confers isotype specificity for the receptor. The α subunits for IgG, IgE, and IgA have been described (17,33). These subunits typically consist of two extracellular domains of the immunoglobulin V type superfamily: a single transmembrane domain and a relatively short intracytoplasmic domain. In activation FcRs, a signaling subunit of the γ family is often found, resulting in an $\alpha\gamma_2$ complex. The inhibitory FcRIIB molecule, in contrast, is expressed as a single-chain receptor. The α subunits have apparent molecular weights of between 40 and 75 kDa and share significant amino acid sequence homology in their extracellular domains. Alternatively spliced forms of FcγRIIB modify the intracytoplasmic domain of this molecule. For example, the B2 form lacks sequences that inhibit internalization and thus demonstrates enhanced internalization of immune complexes in comparison with RIIB1. However, all the splice variants contain the ITIM motif, a necessary and sufficient domain for mediating inhibitory signaling. The conservation of this sequence in mice and humans, its presence in all splice variants, and the hyperresponsive phenotypes generated in mice deficient in this receptor all support inhibition as the central function of RIIB. The specific structures of the α subunits are shown in Figure 22.1. The notable exceptions to the general structure just outlined are seen for the high-affinity FcγRIα subunit, which has three extracellular domains; the activation FcγRIIAα subunit, which does not require additional subunits for assembly or signaling; and the glycosyl-phosphatidylinositol (GPI)–linked FcγRIIIB, which attaches to the cell surface through a GPI linkage rather than through a transmembrane domain.

The γ subunit is found associated with activation of IgG, IgE, and IgA FcRs, as well as with non-FcR molecules, such as paired immunoglobulin-like receptor A (PIR-A) and natural killer (NK) cell cytotoxicity receptors (34–36). It is required for assembly of the α subunits of these receptors by protecting them from degradation in the endoplasmic reticulum. The γ chain is found as a disulfide-linked homodimer with a short extracellular domain containing the cysteine involved in dimerization, a transmembrane domain, and an intracytoplasmic domain containing the

ITAM. An aspartic acid residue found in the transmembrane domain is often associated with a basic amino acid residue in the transmembrane domain of the α subunit. The γ subunit belongs to a gene family that includes the T cell receptor–associated ζ chain and the NK receptor DAP-10– and DAP-12–associated molecules (37). FcγRIIIA can associate with the ζ chain, resulting in the $\alpha\zeta_2$ complex found in human NK cells.

A third subunit is found associated with the activation of FcRs, FcεRI, and FcγRIII, the β subunit. This 33-kDa subunit has four transmembrane-spanning domains and amino and carboxy intracytoplasmic domains, belonging to the CD20 family of tetraspan molecules (24). An ITAM sequence is found in the intracytoplasmic carboxy domain. In mast cells and basophils, the β chain assembles into an $\alpha\beta\gamma_2$ complex, with the α chain belonging to either FcγRIII or FcεRI. Its presence is required for assembly of FcεRI in rodents. In humans, however, $\alpha\gamma_2$ complexes of FcεRI are found in monocytes, Langerhans cells, and dendritic cells, in addition to the $\alpha\beta\gamma_2$ complexes found in mast cells and basophils. The ITAM motif found in the β subunit is not an autonomous activation sequence but functions as a signaling amplifier of the ITAM found in the γ subunits (38).

Gene Organization, Linkage, and Polymorphisms

All α subunits share a common gene organization, which indicates that the evolution of this family of receptors resulted from gene duplication from a common ancestor (39). Sequence divergence then resulted in the acquisition of distinctive specificities for these related sequences. Most of the genes belonging to the FcR family, including the recently identified group of FcR-homologous or -like (FCRL) proteins, are found on the long arm of chromosome 1, including the γ chain and the α chains of FcγRI, FcγRII, FcγRIII, and FcεRI (Figure 22.2) (40–42). This region is syntenic with a comparable region on mouse chromosome 1; however, FcγRIα and several FCRLs are found on mouse chromosome 3. In humans, the α subunit of the IgA receptor is found on chromosome 19, and the β subunit is on chromosome 11. The FcγRII–FcγRIII locus on chromosome 1 is further linked to a variety of lupus susceptibility genes found in that region, including the *Sle1* cluster (43). A locus linked to atopy has been identified at 11q12–13 and further delineated polymorphisms of the β chain (I181V and V183L) that are associated with a heightened risk of atopy. However, a direct functional association of these polymorphisms with the known biological activities of the β chain has not been found (44).

Polymorphisms in the α chains of the FcγRs have been described, most notably in FcγRIIA and FcγRIII; these polymorphisms result in differences in binding affinity to specific IgG subclasses (45). For example, a histidine at

position 131 in FcγRIIA results in higher-affinity binding to IgG2 and IgG3 than does an arginine at that position. Similarly, FcγRIIIA with valine at position 158 of the α chain has a higher binding affinity for IgG1 and 3 than does the polymorphic form with phenylalanine at that position. This polymorphism translates into a more robust ADCC response for the val/val haplotype *in vitro* and has been positively correlated with the degree of an *in vivo* response to a B cell–depleting, anti-CD20 antibody (46). Four amino acids are polymorphic for FcγRIIIB at positions 18, 47, 64, and 88, which contributes to the neutrophil antigen polymorphisms for this receptor. Several studies have attempted to link specific FcR polymorphisms to autoimmune diseases, specifically to systemic lupus erythematosus (SLE). Recent studies have reported associations in susceptibility to SLE in both murine and human populations with levels of RIIB expression or alleles of RIIB (47). Reduced expression of RIIB on activated B cells, such as

memory cells, has been seen in lupus populations and is associated with a promoter polymorphism. In mouse strains that develop a spontaneous, lupus-like disease, restoring the level of RIIB expression on their B cells to a wild-type level reverses disease (48). A higher incidence of an allele of RIIB has been reported in several populations with autoimmune disease. This allele, found in the transmembrane domain of the receptor, is suggested to result in a hypomorphic phenotype, similar to the reduced expression observed.

Species Comparisons

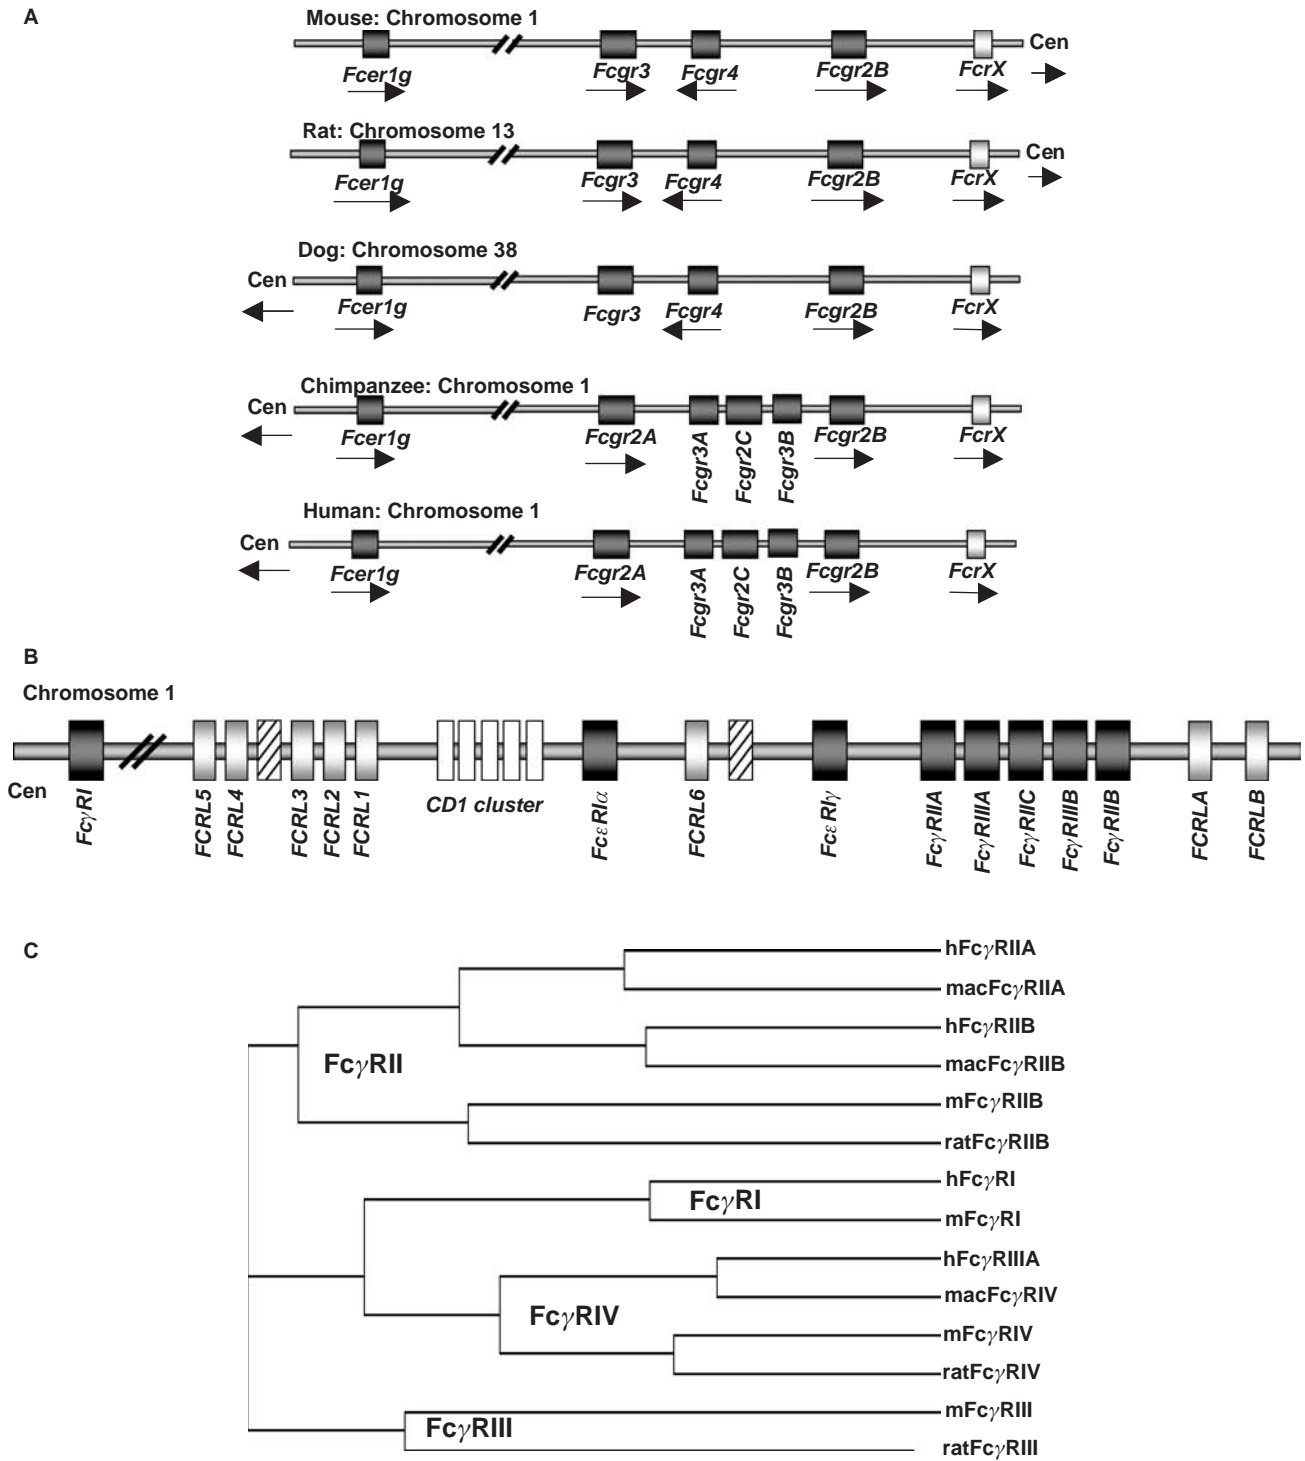
Detailed comparisons between FcRs in mice and humans have revealed several notable differences in both structure and expression of these molecules (Figures 22.1 to 22.3). Whereas IgG and IgE FcRs are conserved in these species, IgA FcRs are not. A murine homolog for the IgA


FIGURE 22.2 Chromosomal organization of FcR and FCRL genes. **A:** Localization of FcR genes in different species. **B:** The human FcR locus on chromosome 1. Classic FcR genes are shown in dark gray, FCRL genes as light gray, and the CD1 gene cluster on chromosome 1 as white boxes. Pseudogenes are indicated as hatched boxes. FIGURE 22.3 Comparison of the human and mouse Fcγ-receptor protein family. In both species FcγRs can be distinguished by their affinity for the antibody Fc portion (high or low affinity) and by the signaling pathways they trigger (activating versus inhibitory).

FcR has not been identified. In general, murine and human IgG FcRs display comparable degrees of heterogeneity and complexity (39,49). Specific differences, however, have been noted. For example, FcγRI is encoded by a single gene in the mouse and three genes in the human (41). Two genes for activation FcRs, FcγRIIA and C, are found in humans and not rodents, which is notable because of their unusual single-chain activation structure (50). Both mice and humans encode a gene referred to as FcγRIIIA, although recent studies have identified a novel mouse FcR with higher homology to the human FcγRIIIA called FcγRIV (31,49,51). As mentioned previously, FcγRIIIB is unique among FcRs in being expressed as a GPI-anchored protein. Its expression is limited to human neutrophils, in contrast with FcγRIIIA, which is expressed widely on cells of the myeloid lineage, such as macrophages, NK cells, mast cells, and dendritic cells. Finally, both mice and humans have only a single gene encoding the inhibitory FcγRIIB molecule.

The genes for the IgE FcR are conserved in mice and humans. The difference that is observed relates to the requirement for the β chain to achieve surface expression in mice, precluding the expression of the $\alpha\gamma_2$ complex (24). In humans, this form of the receptor is widely expressed on monocytes, Langerhans cells, and dendritic cells and is likely to be found on mast cells and basophils as well. This difference in FcεRI subunit composition is likely to result in functional differences as well. Although these specific interspecies differences are important, the fundamental organization of the FcR system, with activation and inhibitory signaling through a shared ligand specificity coupled to opposing signaling pathways, is well conserved. Thus, conclusions regarding the function of this system in immunity by the analysis of murine models are relevant to

an understanding of the role of these receptors to human immunity as well.

Expression

FcRs are expressed widely on cells of the myeloid lineage, including monocytes, macrophages, dendritic cells, mast cells, basophils, neutrophils, eosinophils, and NK cells (17,33). In addition, B cells and follicular dendritic cells (FDCs) express the inhibitory FcRIIB receptor, whereas T cells are generally negative for FcR expression. Of interest, the majority of FCRL proteins are expressed during varying stages of B cell development. Despite their homology to the classic FcRs, however, the FCRL proteins seem not to bind to immunoglobulins, rendering FcγRIIB the only IgG-binding FcR on B cells. The specific expression pattern for each Fc-receptor varies; these patterns are summarized in Figure 22.1. Because FcRs represent a balanced system of activation and inhibition, the general rule of coexpression of FcRs of these classes is maintained. B cells use the B cell antigen receptor as the activation coreceptor for FcRIIB, whereas NK cells appear to use NK inhibitory receptors to modulate FcγRIIIA activation. The decoy FcγR, FcγRIIIB, is expressed exclusively on human neutrophils, on which it functions to concentrate and focus immune complexes without directly triggering cell activation, perhaps also playing a role in neutrophil recruitment (52). The FcγRIIA–FcγRIIB pair functions on neutrophils to modulate immune complex activation. FcεRI can be modulated by FcγRIIB, as demonstrated both *in vitro* and *in vivo*; mice deficient in FcγRIIB display enhanced IgE-triggered anaphylaxis (53) by virtue of the ability of IgE to bind with high affinity to FcεRI and with low affinity to FcγRIIB. Other mast cell inhibitory receptors, such as glycoprotein

49B1, modulate mast cell sensitivity to IgE: Mice deficient in this molecule display enhanced anaphylactic responses to IgE stimulation (54). Expression of the common γ chain is broad: It has been found on all myeloid and lymphoid cells examined. In contrast, the β chain appears to be quite restricted in its expression: It has been found only on mast cells and basophils.

Regulation of FcR expression can occur at several levels. In general, cytokines involved in activation of inflammatory responses induce expression of activation FcγRs, whereas inhibitory cytokines downregulate these activation receptors. Transcriptional regulation of α chain levels has been documented for a variety of cytokines, including interferon-γ, interleukin-4 (IL-4), and transforming growth factor-β (55,56). In addition, complement component C5a binding to its receptor, C5aR, results in the induction of expression of activation FcγRs (57). Induction of FcγRI, FcγRIIA, and FcγRIIIA α and γ chains in myeloid cells occurs on interferon-γ treatment: IL-4 generally inhibits expression of these activation receptors but induces expression of the inhibitory FcγRIIB. Administration of intravenous γ-globulin, a widely used treatment for inflammatory diseases, has been shown to induce expression of the inhibitory FcγRIIB on effector macrophages (58–60). This induction is not direct but is likely mediated through another, noncanonical Fc receptor pathway (60). The situation in B cells is likely to be more complex, whereby regulation of FcγRIIB is critical for the maintenance of peripheral tolerance. Germinal center B cells downregulate FcγRIIB, perhaps in response to IL-4 production by T cells. Regulation of FcR expression has also been documented to occur on binding of ligand. IgE reg-

ulates the expression of FcεRI by stabilizing the intracellular pool of receptor on receptor engagement (61). Thus, high IgE levels result in the induction of surface expression of FcεRI. However, this same mechanism of regulation is not seen for FcγRs: Mice deficient in IgG have FcγR levels comparable with those of wild-type animals. Competition for limiting subunits also contributes to regulation of receptor expression. In mast cells, it appears that the level of γ chain is limiting. Competition between α chains for the limiting concentration of γ chain has been documented in mouse knockouts, whereby levels of one receptor increase if the α chain of the other receptor is reduced (62). This type of reciprocal regulation is likely to be significant in the cross-regulation of FcRs by different isotypes of immunoglobulin.

Three-Dimensional Structure

The crystal structures of FcγRIIA, FcγRIIB, FcγRIIIA, and FcεRI have been solved, along with the cocrystals of FcγRIIIA–IgG1 Fc and FcεRI–IgE Fc (63) (Figure 22.4). These studies demonstrate that the receptors have a common structure in which the two extracellular immunoglobulin domains fold in a strongly bent overall structure arranged into a heart-shaped domain structure. A 1:1 stoichiometry between the receptor and ligand is observed, with the receptor inserted into the cleft formed by the two chains of the Fc fragment (Cγ2 or Cε3). The binding region of the FcR to Fc fragments consists mainly of rather flexible loops that rearrange on complex formation. Only domain 2 and the linker region connecting domains 1 and 2 interact in the complex with different regions of both
FIGURE 22.4 Ribbon diagram of crystallizable fragment (Fc) receptor III–immunoglobulin G1 (IgG1) Fc structure. The carbohydrate moiety has been removed from the IgG1 Fc fragment in this visualization, although it is present in the crystal structure. The extracellular domains of Fc receptor III are shown, together with the Fc fragment of IgG1. Some of the contact residues are shown for the binding interface. See text for details. (Adapted from Sondermann P, Huber R, Oosthuizen V, et al. The 3.2-A crystal structure of the human IgG1 Fc fragment-Fc gammaRIII complex. *Nature*. 2000;406(6793):267, with permission.)

chains of the Fc. Conserved tryptophans located on the FcRs interact with proline to form a "proline sandwich." A solvent-exposed hydrophobic residue at position 155 is conserved among all FcRs and represents a binding site for the important IgG1 residue Leu 235 (not found in IgE). Specificity is generated among the receptor–ligand pairs in a variable region connecting the two extracellular domains that is in contact with the lower hinge region of the Fc fragment (residues 234 to 238), a region not conserved among the IgGs and IgE. The binding region of FcRs to their immunoglobulin ligands does not overlap with other Fc-binding molecules such as protein A, protein G, and FcRn.

The structure of the FcR bound to their ligand reveal that the antigen-binding fragment (Fab) arms are quite sharply bent and may adopt a perpendicular orientation toward the Fc. This arrangement would give the Fab arms maximal flexibility to bind antigen when the Fc fragment is oriented parallel to the membrane of the FcR-expressing cell. The asymmetric interaction of the two Fc chains with a single FcR prevents a single antibody molecule from triggering dimerization of receptors and initiating signaling. Instead, dimerization is initiated by the interaction of antigen with the Fab arms, thus linking adaptive responses to effector cell triggering.

IN VITRO ACTIVITY

Binding Properties

As outlined in Figures 22.1 and 22.3, immunoglobulin binding to FcRs falls into either a high- or a low-affinity binding class. The high-affinity binding class is typified by FcεRI, with a binding affinity of 10^{10} M^{-1} for IgE, which ensures a monomeric interaction between IgE and its receptor. FcγRI binds with relatively high affinity for IgG1 and IgG3 (human) and IgG2a (mouse), with an affinity constant of 10^8 M^{-1}. In contrast to these high-affinity FcRs, the low-affinity receptors, such as the human FcγRIIA, FcγRIIB, FcγRIIIA, FcγRIIIB, and FcαRI and the mouse FcγRIIB, FcγRIII, and FcγRIV bind with affinities ranging from 5×10^5 M^{-1} (FcγRIII) to 2×10^7 M^{-1}. This low-affinity binding ensures that these receptors interact with immune complexes and not monomeric ligands. As described later, this dependence on high-avidity and low-affinity interactions ensures that these receptors are activated only by physiologically relevant immune complexes and not by circulating monomeric immunoglobulin, thus avoiding inappropriate activation of effector responses. In general, low-affinity FcγRs bind IgG1 and IgG3 preferentially; binding to IgG2 and IgG4 is observed at even lower affinities. As mentioned previously, polymorphisms in FcγRIIA and FcγRIIIA affect binding to IgG2 and IgG1, respectively, which may have significance *in vivo* in pre-

dicting responses to specific cytotoxic antibodies (Table 22.1). The isolated consideration of the affinity of antibody isotopes to their activating FcRs is not sufficient, however, to explain the differences in *in vivo* activity. More important, the ratio of the affinity of an antibody isotype to the activating FcRs compared to its affinity to the inhibitory FcγRIIB (the A/I ratio) predicts antibody activity more consistently (20,49). Thus, antibody isotypes with a high A/I ratio, such as mouse IgG2a and IgG2b, show a greater activity than counterparts with a lower ratio (Table 22.1). Binding has been observed between aglycosyl FcRs and immunoglobulin, with K_a values similar to those observed for the glycosylated forms. In contrast, the sugar moiety of the antibody Fc portion is essential for FcR binding, and the presence or absence of certain sugar residues can significantly affect antibody–FcR binding (20,64–66). The absence of fucose, for example, will selectively increase the affinity of human IgG1 or mouse IgG2b to FcγRIIIa or mouse FcγRIV, respectively. In contrast, the presence of terminal sialic acid on the N-linked Fc glycan reduces affinities for FcRs by an order of magnitude with a concomitant reduction in *in vivo* activity (66). Subunit interactions have also been reported to influence affinity for ligand, as demonstrated for the common γ chain associating with FcγRIIIA (67). Its affinity for IgG1 is higher than the GPI-anchored form of this receptor, FcγRIIIB.

The crystal structures of IgG1-FcγRIIIA and IgE-FcεRI reveal similarities in the binding properties of these two complexes. Of significance is the 1:1 stoichiometry of the complexes, which ensures that a single receptor binds to a single immunoglobulin molecule (15,16). This property in turn ensures that activation occurs on cross-linking of receptor complexes by multivalent ligands. Two binding sites on the receptor interact asymmetrically with two sites on the Fc molecule. The FcR inserts into the cleft formed by the two chains of the Fc molecule, burying a binding surface of 895 Å for each binding site. Alterations in the Fc structure that reduce the cleft, such as deglycosylation of IgG, inhibit FcR binding. Four distinct regions have been defined in the Fc domains involved in FcR interactions. For IgE, this includes residues 334 to 336, 362 to 365, 393 to 396, and 424. The homologous regions for IgG are residues 234 to 239, 265 to 269, 297 to 299, and 327 to 332, respectively. Interactions of these residues occur with the carboxy-terminal domain 2 of the respective FcRs. In view of the similarities of these complexes and the homologies among the receptors and their ligands, an obvious question that arises concerns the molecular basis for specificity. Attempts to resolve that question have relied on mutagenesis studies of the ligands and domain exchanges between receptors. For example, exchange of the FG loop in domain 2 of Fcε to Fcγ receptors confers detectable IgE binding; similarly, variation in this loop in FcγRs may provide interactions that determine IgG specificity for these receptors. Mutagenesis of IgG1 revealed that a common set of

A/I, ratio of activating to inhibitory binding; h, human; Ig, immunoglobulin; m, mouse.
Binding constants were obtained by surface plasmon resonance (SPR) analysis with immobilized antibodies (fluorescein isothiocyanate–isotype switch variants) and soluble FcRs produced by transient transfection in 293T cells.
n.b., No detectable binding, or binding that is too low to be evaluated.
n.d., No SPR or other quantitative data are available.
+, Detectable but very low binding that did not allow determination of exact binding constants by SPR.
[a]Paetz et al. (137).
[b]Okazaki et al. (138), Maenaka et al. (139).
[c]The two numbers indicate the A/I ratios for the low- and high-affinity alleles of FcγRIIIA, respectively.
[d]Due to the low affinity of IgG2 to FcγRIIB, the values are approximate.

residues is involved in binding to all FcγRs, but FcγRII and FcγRIII also use distinct residues (68). Several IgG1 residues not found at the IgG–FcR interface by crystallographic determination had a profound effect on binding, which indicates the greater complexity of these interactions in solution.

The implications of these structural studies are that the Fc domain of IgG may be selectively mutated to direct its binding to specific FcγRs. Fc mutants that selectively engage activation FcRs (IIIA and IIA) while minimally interacting with inhibitory and decoy FcRs (IIB and IIIB) would confer optimal cytotoxic potential for tumoricidal applications. Indications that such Fc engineering is possible are suggested by IgG mutants with selective binding to FcRIII or FcRII.

Effector Cell Activation

The critical step in triggering effector cell response by FcRs is mediated by the cross-linking of these receptors by immunoglobulin. This can occur either by interactions of low-affinity, high-avidity IgG immune complexes or of IgG opsonized cells with activation FcγRs or by the cross-linking of monomeric IgG or IgE bound to FcγRI or FcεR, respectively, by multivalent antigens binding to the Fab of the antibody. Cross-linking of ITAM-bearing FcRs results in common cellular responses, determined by the cell type, rather than the FcR. Thus, for example, FcεRI or FcγRIII cross-linking of mast cells results in degranulation of these cells, whereas cross-linking of macrophage-expressed FcαRI or FcγRIII by opsonized cells triggers phagocytosis. These functions underlie the functional similarity of activation FcRs in which cross-linking mediates cellular responses by ITAM-mediated tyrosine kinase cascades. In addition to degranulation and phagocytosis, activation FcR cross-linking has been demonstrated to induce ADCC, the oxidative burst, and the release of cytokines and other inflammatory cell mediators. A sustained calcium influx is associated with these functions, as is transcription of genes associated with the activated state.

Cellular activation initiated by ITAM-bearing activation FcRs can be enhanced by coengagement with integrin and complement receptors. Although the ability of these receptors to mediate phagocytosis, for example, is modest, synergistic interactions with FcRs result in sustained activation and enhancement. Synergistic interactions between activation FcRs and Toll receptors, mannose receptors, and other pattern-recognition molecules have also been reported *in vitro* and suggest that interplay between the innate and adaptive effector mechanisms of an immune response are involved in mediating efficient protection from microbial pathogens.

In contrast to the activation of effector cell responses triggered by cross-linking of ITAM-bearing FcRs *in vitro,* cross-linking of an ITIM-bearing inhibitory receptor to an ITAM-bearing receptor results in the arrest of these effector responses. Homoaggregation of FcRIIB by its cross-linking on effector cells by immune complexes does not result in cellular responses; rather, it is the coengagement of ITAM- and ITIM-bearing receptors that results in the functional generation of an inhibitory signal. *In vitro,* it is possible to ligate any ITAM-bearing receptor to any ITIM-bearing receptor with a resulting inhibitory response. This activity is used functionally to define putative ITIMs and has proved to be a useful device in dissecting the signaling pathways induced by ITAM–ITIM coligation.

B Lymphocyte Suppression

B cell stimulation through the B cell antigen receptor can be arrested by the coligation of FcγRIIB to the B cell receptor (BCR). This occurs naturally when immune complexes retained on FDCs in the germinal center interact with both the BCR and FcγRIIB during the affinity maturation of an antibody response. *In vitro* suppression of B cell activation has been demonstrated by coligation of BCR and FcγRIIB, resulting in arrest of calcium influx and proliferative responses triggered by the BCR (25,69), the result of recruitment of the SH2-containing inositol 5′-phosphatase (SHIP)–1 (70). Calcium release from the endoplasmic reticulum is not affected, and there is thus an initial rise in intracellular calcium; however, this calcium flux is not sustained because SHIP recruitment blocks calcium influx by uncoupling of the capacitance channel. Homoaggregation of FcγRIIB by immune complexes can trigger apoptosis in B cells, as demonstrated in the DT40 B cell line and in murine splenocyte preparations (71). This activity is retained in ITIM mutants and depends on the transmembrane sequence of FcγRIIB. The *in vivo* relevance of this activity remains to be determined.

SIGNALING

Immunoreceptor Tyrosine-Based Activation Motif Pathways

The general features of signal transduction through ITAM receptors are conserved among all members of this family, including T cell receptors, BCRs, and various FcRs. The 19–amino acid–conserved ITAM is necessary and sufficient to generate an activation response, as demonstrated by the analysis of chimeric receptors. With a single exception, FcRs associate with accessory subunits that contain these signaling motifs. As described previously, the common γ chain contains an ITAM and is associated with FcεRI, FcγRI, FcγRIII, FcγRIV, and FcαRI. In addition, both FcεRI and FcγRIII may associate with the β subunit in mast cells. The ITAM found in the β chain does not function as an autonomous activation cassette, as has
FIGURE 22.5 Signaling by activation and inhibitory FcRs. **A:** FcRIII signaling in natural killer cells is shown as an example of the activation class of FcRs. Cross-linking by an immune complex initiates the signaling cascade. The specific Src family kinase varies, depending on the cell type. **B:** FcR signaling in macrophages is shown as an example of simultaneous triggering of activation and inhibitory Fc receptors.

been found for most other ITAMs. Instead, it functions to amplify the activation response generated by the γ chain ITAM by increasing the local concentration of Lyn available for activation on aggregation of the receptor (38). FcγRIIA contains an ITAM in the cytoplasmic domain of its ligand recognition α subunit and is thus able to activate in the absence of any associated subunit.

On sustained receptor aggregation, Src-family kinases that may be associated with the receptor in an inactive form become activated and rapidly tyrosine-phosphorylate the ITAM sequences, creating SH2 sites for the docking and subsequent activation of Syk kinases. Ligands that become rapidly dissociated from the receptors result in nonproductive signaling complexes that fail to couple to downstream events and behave as antagonistic ligands (72). The specific Src kinase involved for each FcR depends on the receptor and cell type in which it is studied. Thus, Lyn is associated with the FcεRI pathway in mast cells, Lck is associated with FcγRIIIA in NK cells, and both of these kinases as well as Hck are associated with FcγRI and FcγRIIA in macrophages. After activation of the Src kinase, tyrosine phosphorylation of the ITAM motif rapidly ensues, leading to the recruitment and activation of Syk kinases. This two-step process is absolutely necessary to transduce the aggregation signal to a sustainable intracellular response.

Once activated, Syk kinases lead to the phosphorylation or recruitment of a variety of intracellular substrates, including PI3K, Btk and other Tec family kinases, phospholipase C-γ (PLCγ), and adaptor proteins such as SLP-76 and BLNK. The Ras pathway is also activated through Sos bound to Grb2 that is recruited on phosphorylation of Shc. Ras phosphorylates Raf, which in turn leads to MEK kinase and MAP kinase activation. A summary of these intracellular pathways is shown in Figure 22.5A. A crucial step in this sequential activation cascade occurs with the activation of PI3K by Syk. By generating phosphatidylinositol polyphosphates such as PIP$_3$, PI3K leads to the recruitment of pleckstrin homology (PH) domain–expressing proteins such as Btk and PLCγ, which in turn leads to the generation of inositol triphosphate (IP3) and diacylglycerol (DAG), intermediates crucial to the mobilization of intracellular calcium and activation of protein kinase C (PKC), respectively.

Immunoreceptor Tyrosine-Based Inhibitory Motif Pathways

The inhibitory motif, embedded in the cytoplasmic domain of the single-chain FcγRIIB molecule, was defined as a 13–amino acid sequence AENTITYSLLKHP, shown to be both

necessary and sufficient to mediate the inhibition of BCR-generated calcium mobilization and cellular proliferation (25,26). Of significance, phosphorylation of the tyrosine of this motif was shown to occur on BCR coligation and was required for its inhibitory activity. This modification generated an SH2 recognition domain that is the binding site for the inhibitory signaling molecule SHIP (70,73). In addition to its expression on B cells, where it is the only IgG FcR, FcγRIIB is widely expressed on macrophages, neutrophils, mast cells, dendritic cells, and FDCs, absent only from T and NK cells. Studies on FcγRIIB provided the impetus to identify similar sequences in other surface molecules that mediated cellular inhibition and resulted in the description of the ITIM, a general feature of inhibitory receptors.

FcγRIIB displays multiple inhibitory activities. Coengagement of FcγRIIB to an ITAM-containing receptor leads to tyrosine phosphorylation of the ITIM by the Lyn kinase, recruitment of SHIP, and the inhibition of ITAM-triggered calcium mobilization and cellular proliferation (Figure 22.5B) (70,74,75). These two activities result from different signaling pathways; calcium inhibition requires the phosphatase activity of SHIP to hydrolyze PIP$_3$ and the ensuing dissociation of PH domain–containing proteins such as Btk and PLCγ (76). The net effect is to block calcium influx and prevent sustained calcium signaling. Calcium-dependent processes such as degranulation, phagocytosis, ADCC, cytokine release, and proinflammatory activation are all blocked. Arrest of proliferation in B cells also depends on the ITIM pathway, through the activation of the adaptor protein Dok and subsequent inactivation of MAP kinases (77,78). The role of SHIP in this process has not been fully defined, inasmuch as it can affect proliferation in several ways. SHIP, through its catalytic phosphatase domain, can prevent activation of the PH domain survival factor Akt by hydrolysis of PIP$_3$ (79,80). SHIP also contains PTB domains that could act to recruit Dok to the membrane and provide access to the Lyn kinase that is involved in its activation. Dok-deficient B cells are unable to mediate FcγRIIB-triggered arrest of BCR-induced proliferation while retaining their ability to inhibit a calcium influx, which demonstrates the dissociation of these two ITIM-dependent pathways.

Another inhibitory activity displayed by FcγRIIB is independent of the ITIM sequence and is displayed on homoaggregation of the receptor. Under these conditions of FcγRIIB clustering, a proapoptotic signal is generated through the transmembrane sequence. This proapoptotic signal is blocked by recruitment of SHIP, which occurs on coligation of FcγRIIB to the BCR because of the Btk requirement for this apoptotic pathway (71). This novel activity has been reported only in B cells and has been proposed to act as a means of maintaining peripheral tolerance for B cells that have undergone somatic hypermu-

tation. The *in vivo* relevance of this pathway remains to be proven.

IN VIVO FUNCTIONS

Fcγ Receptors in the Afferent Response

The ability of IgG immune complexes to influence the afferent response has been known since the 1950s and can be either enhancing or suppressive, depending on the precise combination of antibody and antigen and the mode of administration (81). Investigators have attempted to define the molecular mechanisms behind these activities with the availability of defined mouse strains with mutations in activation or inhibitory FcRs and through the use of specific blocking antibodies to individual receptors. Direct effects on B cells stem from the ability of the inhibitory FcγRIIB molecule to influence the state of B cell activation and survival Because antigen is retained in the form of immune complexes on FDCs, it can interact with B cells by coengaging FcγRIIB with BCR, modulating the activation state of the cell. Mice deficient in this inhibitory receptor develop anti-DNA and anti-chromatin antibodies and die of a fatal, autoimmune glomerulonephritis at 8 months of age. The phenotype is strain dependent and is not seen in BALB/c or 129 strains of mice (82). Combining FcγRIIB deficiency with defects in other inhibitory receptor pathways, such as PD-1, results in autoantibodies with different specificities and distinct pathologic presentation. Thus, PD-1–deficient BALB/c mice develop cardiomyopathy resulting from anti–cardiac myosin antibodies. PD-1/RIIB double-deficient BALB/c mice develop antiuroepithelial antibodies and hydronephrosis (83). FcγRIIB thus acts as a modifier of autoimmune disease, a conclusion further supported by studies that determined the contribution of the C57B6 background to the spontaneous lupuslike disease observed in those mice. The B6 background, by virtue of an incomplete light chain editing pathway, provides a source of autoreactive B cells in the periphery, which, when combined with defects in the inhibitory RIIB pathway, lead to the accumulation of autoantibodies, pathogenic immune complexes, and disease (84). Further support for this conclusion is provided by the observations that autoimmune disease–prone strains of mice, such as New Zealand black (NZB), BXSB, SB/Le, MRL, and nonobese diabetic (NOD) strains, have reduced surface expression of FcγRIIB on activated B cells, attributed to DNA polymorphisms in the promoter region of the gene encoding this receptor (85,86). This reduced expression of FcγRIIB is thus suggested to contribute to the increased susceptibility of these animals to the development of autoantibodies and autoimmune disease. Direct evidence that this is indeed the case comes from studies in which FcγRIIB expression levels have been restored by retrovirus-mediated gene transfer in

BXSB, NZM, and FcγRIIB knockout animals. These mice had dramatically reduced levels of autoreactive antibodies and were protected from the development of fatal autoimmune disease (48).

Moreover, if FcγRIIB indeed functions *in vivo* to maintain peripheral tolerance, then its loss should allow for the emergence of autoantibodies when otherwise resistant animals are challenged with potentially cross-reactive antigens. This hypothesis has been validated in models of collagen-induced arthritis and Goodpasture's syndrome. FcγRIIB-deficient mice, with the nonpermissive H-2^b haplotype, develop arthritis when immunized with bovine type II collagen (87). The loss of FcγRIIB thus bypasses the requirement for the specific H-2^q and H-2^r alleles previously demonstrated to be necessary in this model by allowing FcγRIIB-deficient autoreactive B cell clones to expand and produce pathogenic autoantibodies. When the permissive DBA/1 strain (H-2^q) is made deficient in FcγRIIB, autoantibody development is augmented and disease is greatly enhanced. In a similar manner, immunization of H-2^b mice deficient in FcγRIIB with bovine type IV collagen results in cross-reactive autoantibodies to murine type IV collagen, with dramatic pathogenic effects (87,88). These mice develop hemorrhagic lung disease and glomerulonephritis with a "ribbon deposition" pattern of immune complexes in the glomeruli. These characteristics are indicative of Goodpasture's syndrome, a human disease not previously modeled in an animal species.

Expression of the inhibitory FcγRIIB on B cells thus provides a mechanism for the suppressive effects of immune complexes on antibody production. Although FcγRIIB is expressed throughout peripheral B cell development, recent data suggest that it represents a late checkpoint controlling the expansion of autoreactive IgG-positive plasma cells. In contrast, deficiency of the inhibitory receptor did not affect the generation of autoreactive IgM antibodies (84). Given the considerably higher pathogenic potential of IgG compared to IgM antibodies, this late stage of FcγRIIB-mediated regulation seems to be sufficient to prevent severe autoreactive processes.

The enhancing property of immune complexes on the afferent response is likely to arise from the expression of FcRs on APCs, such as dendritic cells (89–91). Dendritic cells express all three classes of IgG FcRs as well as FcεRI. Although *in vitro* studies have suggested that triggering of activation FcRs can induce dendritic cell maturation, the *in vivo* significance of this pathway has not been established (92). The ability of FcRs, particularly FcγRI, to internalize immune complexes could provide a mechanism for enhanced presentation and augmented antibody responses, whereas the presence of the inhibitory FcγRIIB molecule appears to reduce the enhancing effect. Mice deficient in FcγRIIB display enhanced antibody responses to soluble antibody–antigen complexes, in some cases dramatically so, which is likely to result from enhanced pre-sentation (93,94). In addition, *in vitro* studies suggest that internalization through specific FcRs on APCs may influence the epitopes presented and T cell response generated as a result. A growing body of data suggests that FcRs are indeed involved in enhancement of the afferent response by influencing antigen presentation and cognate T cell interactions. FcγRIIB-deficient dendritic cells pulsed *ex vivo* with antigen in the form of immune complexes (ICs) induce a strong and protective cytotoxic immune response after transfer into naïve mice (95). In contrast, wild-type DCs induce a much smaller and nonprotective response, indicating that the threshold set by co-cross-linking of the inhibitory and activating Fc receptors prevents complete DC maturation. Moreover, blocking of IC binding to FcγRIIB on human DCs with an FcγRIIB-specific antibody resulted in spontaneous maturation of the cells by ICs present in low amounts in human serum (96,97). Taken together these data indicate that the inhibitory receptor is an important regulator of DC activation. Because the DC maturation state will determine whether an activating or a tolerogenic signal will be delivered to T cells, FcRs might be important factors for the maintenance of peripheral tolerance in the cellular immune system. Transiently blocking FcγRIIB activity with monoclonal antibodies *in vivo* might thus be an interesting strategy for optimizing immunotherapeutic and vaccination approaches. Further defining the precise role of each FcR expressed on APCs will require conditional knockouts of these molecules on specific dendritic cell populations to resolve the contribution of these systems to the generation of an appropriate antibody response.

Fcγ Receptors in the Efferent Response

The first FcR knockout to be described was for the common activation subunit, the γ chain, which resulted in the loss of surface assembly and signaling of FcγRI, FcγRIII, and FcγRIV as well as FcεRI (10). Mice deficient in the common γ chain were systematically studied in diverse models of inflammation and found to be unable to mediate IgG-triggered inflammatory responses for cytotoxic or immune complex reaction; attributed to low-affinity activation receptors, the high-affinity FcγRI played a minimal role in the *in vivo* inflammatory response triggered by IgG (22,98–100). The results were further confirmed by comparisons of mice deficient or blocked for FcγRI, FcγRIII, or FcγRIV (19,20,32,101). The loss of FcεRI ablated IgE-mediated anaphylaxis; this was demonstrated independently by gene disruption in the α subunit of that receptor (11). Subsequent studies on mice deficient in the inhibitory FcγRIIB molecule established the opposing action of this receptor, in which mice deficient in that receptor displayed enhanced B cell responses, autoimmunity, and augmented IgG-mediated inflammation in a subclass- and effector cell–dependent manner (18,20,32,100,102).

The general finding, which is discussed in detail later, illustrates that IgGs initiate their effector responses *in vivo* through coengagement of activating and inhibitory FcRs. The physiologic response is thus the net of the opposing activation and inhibitory signaling pathways that each receptor triggers and is determined by the level of expression of each receptor and the selective avidity of the IgG ligand (Table 22.1). This also explains the longstanding observation that different IgG isotypes have a differential activity *in vivo* (Figure 22.6A). The absence of a murine homolog for FcαRI has precluded similar studies for that recep-

tor. Studies on mice bearing a human transgene of FcαRI suggest that this receptor is involved in IgA nephropathy (Berger's disease) (103).

Type I: Immediate Hypersensitivity

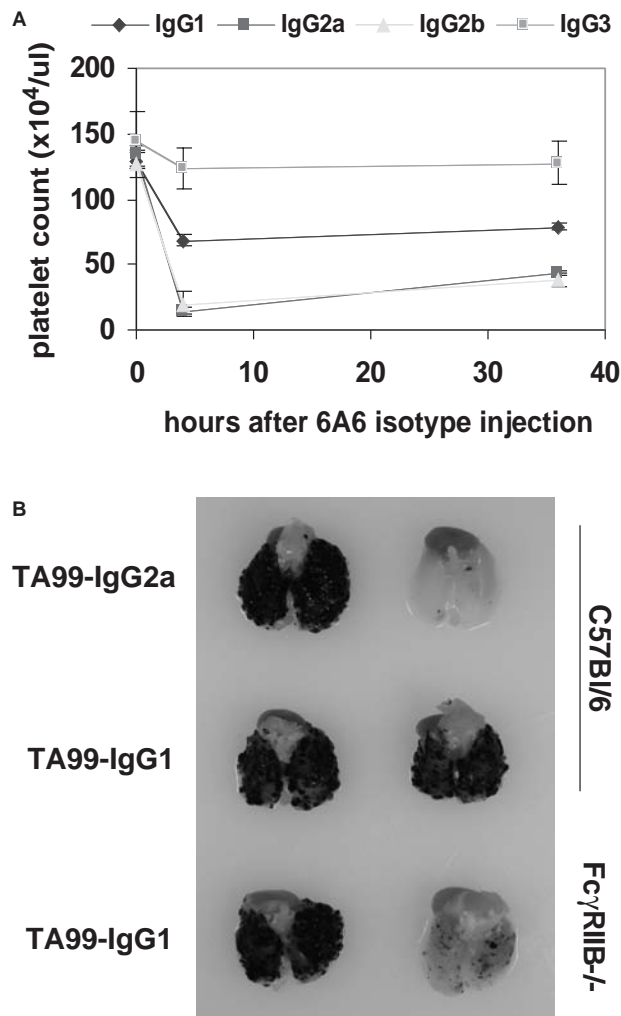
Both cutaneous and systemic models of passive anaphylaxis induced by IgE were studied in FcRγ chain–deficient mice and were found to be absent, a finding fully consistent with the observations obtained in FcεRI-deficient mice and confirming the role of the high-affinity IgE receptor in mediating IgE-induced anaphylactic responses (10,11,38,104). FcγRIIB-deficient mice challenged in this model displayed an unexpected enhancement of IgE-mediated anaphylaxis, which suggests a physiologic interaction between this inhibitory receptor and FcεRI (53). The molecular basis for this modulation of FcεRI signaling by FcγRIIB has not been determined, although previous studies indicated that IgE can bind with low affinity to FcγRII/FcγIII, which suggests that there exists a mechanism for coengagement of these receptors. Deletion of the mast cell inhibitory receptor glycoprotein 49B1 also results in enhanced IgE-induced anaphylaxis (54). In addition to FcεRI, mast cells also express the IgG FcRIIB and FcRIII but not FcγRIV. Passive systemic anaphylaxis induced by IgG was attenuated in FcRγ chain–deficient and FcγRIII-deficient mice, which indicates the capacity of IgG and FcγRIII to mediate mast cell activation *in vivo*. FcγRIIB-deficient mice displayed enhanced IgG-induced anaphylaxis. Active anaphylaxis, induced by immunization with antigen in alum, was enhanced in FcεRI-, FcγRIIB-, and glycoprotein 49B1–deficient mice and attenuated in FcRγ- and FcγRIII-deficient mice. All of these animals displayed antigen-specific antibodies for IgE and IgGs, which indicates that the active anaphylaxis seen was attributed primarily to IgG antibodies. The reason for the enhancement of anaphylactic responses in FcεRI-deficient animals resulted from the increased expression of FcγRIII on mast cells in these mice, normally limited by competition of α chains for the available pool of the common γ chain (62). In the absence of FcεRI α chain, FcRγ chain is available to associate with FcγRIII α chain and assemble on the cell surface as a functional signaling receptor. These studies indicated the importance of the γ chain in regulating the level of surface expression of FcεRI and FcγRIII. Because γ chain is also associated with other members of the activation/inhibition paired receptors expressed on mast cells, such as PIR-A/PIR-B, the intracellular competition between these diverse α subunits and the common γ chain determines the level of surface expression of individual receptors and thus their ability to respond to specific biological stimuli. The absolute level of surface expression of FcRs on mast cells is clearly of therapeutic significance in both IgE- and IgG-mediated inflammatory responses; modulation of γ chain expression could thus represent a


FIGURE 22.6 Antibody activity is determined by activating and inhibitory FcRs. **A:** Mice were injected with the same amount of different 6A6 antibody isotypes, which recognize an integrin on mouse platelets and lead to FcR-dependent clearance of platelets from the blood as observed by the drop in platelet count after antibody injection. **B:** Wild-type or FcγRIIB knockout mice were injected intravenously with B16 melanoma cells on day 0 and with IgG1 and IgG2a isotype switch variants of the monoclonal antibody TA99 on alternate days. Lungs were harvested on day 14. (Adapted from Nimmerjahn F, Ravetch JV. Divergent immunoglobulin g subclass activity through selective Fc receptor binding. *Science*. 2005;310(5753):1510, with permission.)

new therapeutic avenue for intervention in diseases such as anaphylaxis and asthma.

Type II Inflammation: Cytotoxic Immunoglobulin G

Cytotoxic IgGs are found in a variety of autoimmune disorders and have been developed for therapeutic indications in the treatment of infectious and neoplastic diseases. The mechanisms by which these antibodies trigger cytotoxicity *in vivo* have been investigated in FcR knockout mice. Anti-RBC antibodies trigger erythrophagocytosis of IgG-opsonized RBCs in an FcR-dependent manner; γ chain–deficient mice were protected from the pathogenic effect of these antibodies, whereas complement C3–deficient mice were indistinguishable from wild-type animals in their ability to clear the targeted RBCs (105,106). FcγRIII plays the exclusive role in this process for the mouse IgG1 isotype. Murine IgG2a anti-RBC antibodies use primarily the FcγRIV receptor pathway despite the singular ability of murine IgG2a antibodies to bind as monomers to FcγRI. These and other studies suggest that the role of the high-affinity FcγRI in IgG-mediated inflammation is likely to be restricted to augmenting the effector response (determined by FcγRIII and IV) in situations that involve high concentrations of murine IgG2a antibodies that are found at localized inflammatory sites where FcγRI expression is induced on recruited macrophages.

Experimental models of immune thrombocytopenic purpura (ITP) in which murine IgG1 antiplatelet antibodies trigger thrombocytopenia yielded results similar to those of the anti-RBC studies cited previously. The specific FcγR involved depended on the subclass of antibody used. IgG1 antibodies mediated their activity exclusively through FcγRIII, whereas IgG2a and 2b were RIV dependent. In contrast, FcγRI- or C3-deficient mice were fully susceptible to antibody-induced thrombocytopenia (20,31). FcγRIIB-deficient mice showed an isotype-specific enhancement of antibody-mediated platelet depletion, with the strongest impact on IgG1 and much smaller increases for IgG2a and IgG2b isotypes. This is consistent with the affinities of these isotypes for their specific activating and the inhibitory receptor, which will determine antibody activity *in vivo* (Table 22.1). In a passive protection model of *Cryptococcus neoformans*–induced disease, passive immunization with mouse IgG1, IgG2a, and IgG2b antibodies resulted in protection in wild-type animals but not in FcRγ chain–deficient animals (107).

IgG antibodies raised to murine glomerular basement membrane preparations induce acute glomerulonephritis in a model of Goodpasture's disease in wild-type but not FcRγ- or FcγRIV-deficient animals (59,108,109). FcγRIIB-deficient animals displayed enhanced disease in this model, which indicates that the effector cells involved were constitutively expressing significant levels of FcγRIIB. Similar results were obtained when DBA/1 animals were immunized with bovine type II collagen to in-

duce arthritis. Deficiency of FcRγ chain protected these mice from the pathogenic effects of the anticollagen antibodies that were generated (110). As mentioned previously, deficiency of FcγRIIB in the DBA/1 collagen-induced arthritis model resulted in enhanced disease through increased autoantibody production and elevated effector responses.

A dramatic example of the importance of these pathways in determining the *in vivo* activity of cytotoxic antibodies was obtained in models of antitumor antibody response. In a syngenic murine model of metastatic melanoma, a murine IgG2a antimelanocyte antibody was able to reduce tumor metastasis in wild-type animals but was ineffective in FcRγ- or FcγRIV-deficient mice (20,111). In the absence of FcγRIIB, the activity of an IgG1 antibody, matched in its antigen-binding domain, was enhanced, which indicates that the *in vivo* cytotoxic activity of the antibody was the net of activation and inhibitory receptor engagement (20,102) (Figure 22.6B). These studies, together with similar studies performed with antiplatelet antibodies or defucosylated antibodies, demonstrated that the *in vivo* activity of a cytotoxic antibody could be predicted by a simple equilibrium binding model in which the ratio of the monomeric affinity constants for the activation and inhibitory Fc receptors (A/I ratio) are the dominant parameters, as demonstrated for TCR–MHC interactions (112). Xenograft models of human tumors transplanted into nude mice demonstrated, for a variety of tumors and cytotoxic antibodies, the requirement for FcR effector activity. For example, human breast carcinoma or lymphoma lines transplanted into nude mice and treated with either the humanized IgG1 or chimerized IgG1 antibodies trastuzumab (Herceptin) and rituximab (Rituxan), respectively, revealed that the ability of these antibodies to modulate tumor growth was abrogated in FcRγ chain–deficient mice. A point mutation that eliminated FcR binding of the anti-Her2/neu murine IgG1 antibody 4D5 abolished the *in vivo* cytotoxic activity of the antibody against a human xenograft but did not affect the *in vitro* growth-inhibitory activity; this again illustrates the difference between *in vivo* and *in vitro* mechanisms. Similar results were obtained for T cell lymphoma xenograft models and anti-CD2 antibodies, among others (113,114). The general conclusions that can be drawn from these studies support a dominant role for the low-affinity activating FcγRs in mediating cytotoxicity by IgG antibodies. FcγRIIB restricts the effector response for those antibodies with low A/I ratios and in situations in which the effector cell expresses this inhibitory molecule.

The relevance of these murine *in vivo* studies to the treatment of human populations with antitumor cytotoxic antibodies has been demonstrated in two studies that investigated the differential responses of patients treated with anti-CD20 (Rituximab) for lymphoma (115,116). Both studies demonstrated a highly significant correlation between patient response, as measured by the time to relapse,

and alleles of FcγRIIIA. In patients with an allele of this low-affinity activation receptor (158V) that confers higher binding affinity for human IgG1 Fc, improved outcome was observed as compared to those with a lower-binding allele of this receptor (158F). In addition, lymphoma patients with the high-affinity allele showed a significantly better clinical response after receiving antiidiotype vaccination (117).

Type III Responses: Immune Complex–mediated Inflammation

The classic example of this reaction, the Arthus reaction, has been studied in a variety of FcR- and complement-deficient animals. The initial studies were performed by using the cutaneous reverse passive Arthus reaction in which antibody was injected intradermally and antigen was given intravenously. An inflammatory response, characterized by edema, hemorrhage, and neutrophil infiltration, developed within 2 hours. This reaction was elicited in a variety of complement- and FcR-deficient animals. The results from several independent studies confirmed the initial observations: IgG immune complexes triggered cutaneous inflammatory reactions even in the absence of complement but displayed an absolute requirement for FcγR activation (22). FcγRIIB modulated the magnitude of the response, with enhanced Arthus reactions observed in FcγRIIB-deficient strains (18). The effector cell in the cutaneous reaction was determined to be the mast cell, as demonstrated by the use of mast cell–deficient strains and by mast cell reconstitution studies (104). The generality of this result was demonstrated in similar reactions performed in the lung, illustrating the FcR dependence and relative complement independence of this response (88). Thus, all studies have demonstrated an absolute dependence on FcR expression in the Arthus reaction. One model for immune complex–induced arthritis, the KRN/NOD model, in which IgG1 anti-GPI antibodies are responsible for IC deposition in the synovium (118), has been shown to depend on both FcRIII and C3 but not on components of the classic pathway, such as C1q and C4; transfer of serum to animals deleted for FcRIII or C3 prevented the development of disease (119,120). Deficiency in the late components of complement, such as C5a or its receptor, have also been reported to result in a partial reduction in the magnitude of the response in immune complex–induced lung inflammation (121) and a result in a complete block in the KRN/NOD arthritis model. The likely mechanism by which C5a exerts its effects is through upregulation of activating FcγRs, resulting in an amplification loop (57). C5a is generated in this system as a result of FcR activation of effector cells and is independent of the classic, alternative and MBP pathways. Binding of C5a to the C5aR results in upregulation of activation receptors on these effector macrophages, thus augmenting the inflammatory response triggered by FcRs. These studies have led to a revision of the hypotheses about the mechanism of immune complex–mediated inflammation, typified by the Arthus reaction, in which there is an absolute requirement for activating FcγRs in initiating mast cell activation by immune complexes. FcγR activation is, in turn, modulated by the inhibitory receptor FcγRIIB. The A/I value of a specific IgG antibody and the densities of these opposing signaling receptors determine the concentration threshold for immune complex activation and the magnitude of the effector response that can be obtained. The classic pathway of complement activation is not required; however, C5a activation, through the FcγR pathway, may enhance the response under some circumstances through an amplifying loop. These release of inflammatory mediators such as vasoactive amines, chemokines, and cytokines leads to the hallmarks of this reaction: edema, hemorrhage, and neutrophil infiltration at the site of immune complex deposition.

The significance of the FcR pathway in initiating immune complex inflammation in autoimmune disease was further established by investigating a spontaneous murine model of lupus, the B/W F1 mouse. The Arthus reaction results predicted the absolute requirement of activation FcγR in initiating inflammation and tissue damage in immune complex diseases such as lupus. The FcRγ chain deletion was backcrossed onto the NZB and New Zealand white strains for eight generations, and the intercrossed progeny were segregated into B/W FcR$\gamma^{-/-}$ and FcR$\gamma^{+/-}$. Anti-DNA antibodies and circulating immune complexes developed in all animals; immune complex and complement C3 deposition was similarly observed in all animals. However, mice deficient in the common γ chain showed no evidence of glomerulonephritis and had normal life expectancy, despite comparable levels of circulating immune complexes and glomerular deposition of these complexes along with complement C3. Mice heterozygous for the γ chain mutation were indistinguishable from B/W F1 animals with wild-type γ chains in developing glomerulonephritis and displaying reduced viability (99). This spontaneous model supports the conclusions stated previously about the absolute requirement for FcRIII in the activation of inflammatory disease by immune complexes: In the absence of this receptor, deposited immune complexes and C3 are not sufficient to trigger effector cell activation, which indicates that it is possible to uncouple pathogenic immune complexes from inflammatory disease by removing activating FcR engagement. Similar conclusions were reached in a murine model of Goodpasture's disease in which immune complex deposition, composed of mouse IgG2b antibodies, resulted in a fulminant glomerulonephritis (59). Blocking the relevant activation FcR, FcRIV, with a monoclonal antibody protected the animals from fatal disease. These results further indicate that intervention in the effector stage of immune complex diseases, such as lupus and rheumatoid arthritis, would be accomplished by blocking activation FcγRs to prevent initiation of effector cell responses.

Fc Receptor Homologs

The family of FcR-homolog or FcR-like (FCRL) proteins was initially discovered by database searches based on a conserved motif in the Fc-binding region of classic FcRs. In humans the FCRL family consists of eight family members, termed FCRL1 to 6 and FCRLA, B (122). All the FCRL genes are located in close proximity to the classic FcRs on chromosome 1q21-23 (Figure 22.2B). A similar, although smaller family of FCRL proteins exists in mice also closely linked to classic FcRs on chromosomes 1 and 3 (42,123). In addition, the mouse has a unique FcR-like protein, called FCRLS, with a C-terminal type B scavenger receptor cysteine-rich domain. The majority of FCRL proteins consist of an extracellular domain of variable size, a transmembrane domain, and an intracellular portion that contains ITIM or ITAM motifs. The only exceptions are FCRLA, B, which lack a transmembrane domain and therefore represent intracellular or secreted proteins (122,123). The FCRL proteins do not depend on the common signaling γ chain, which is the crucial signaling adaptor for classic FcRs. Moreover, the FCRLs are predominantly expressed on B cells, with significant variation during B cell development and activation state. The ITAM-containing receptor FCRL1, for example, is widely expressed throughout B cell development starting from the pre-B cell stage (123,124). On activation, however, it is downregulated, and expression is restored on differentiation into memory but not into plasma cells. In contrast, FCRL4, which contains two ITIM motifs in its cytosolic domain, shows a more restricted expression pattern on a subpopulation of memory B cells (125). Co-cross-linking of FCRL4 with the BCR has been shown to dampen activating signals triggered by the BCR via recruitment of SHP-1 and SHP-2 (126). A functional variant of FCRL3 has recently been linked to rheumatoid arthritis and other autoimmune disorders in a group of Japanese patients (127). Despite significant sequence homology in some of the extracellular domains of FCRL proteins to classic FcRs, however, attempts to show binding to antibody Fc-portions have failed. Thus, the ligands of this interesting new family of proteins remain to be identified. More important, this renders the inhibitory FcγRIIB the only bona fide Fc receptor on B cells.

DISEASE ASSOCIATIONS

Autoimmunity and Tolerance

In view of their functional capacity to link autoantibodies to effector cells, FcRs have naturally been considered to have a pathogenic role in the development of autoimmune diseases. Several studies have attempted to correlate specific polymorphisms in FcRIIA, FcRIIIA, or FcRIIIB with incidence or severity of lupus or rheumatoid arthritis (128). In view of the heterogeneity of these diseases, it is perhaps not surprising that inconsistent results have been obtained. Alleles that increase the ability of FcRIIA to bind IgG2 or FcRIIIA to bind IgG1 might be expected to correlate with disease severity in some populations. Indeed, these types of associations have been reported in some studies but not in others. These variable results have often been explained as an indication that other genes may be in linkage disequilibrium with the FcR alleles under investigation. This is a plausible explanation when viewed in light of the autoimmunity susceptibility genes mapping in or near the region of the FcR genes, chromosome 1q21-24 (129). This region of chromosome 1 has been implicated in a variety of human and murine linkage studies. For example, the *Sle1* alleles derived from NZB flank the FcRIIB gene and form a linkage group with the ability to break tolerance to nuclear antigens, resulting in production of antichromatin antibodies. Epistatic interactions between FcRIIB and lupus susceptibility genes have been demonstrated in the murine lupus model of B6.RIIB. Crossing the *yaa* gene to this strain accelerates the development of disease; 50% survival is decreased from 8 months to 4 months, with 100% fatality by 8 months. This increase in severity correlates with a change in the specificity of the autoantibodies, from diffuse antinuclear antibodies to antibodies that stain with a punctate, nucleolar pattern on antinuclear antibody staining. Recently, it has been shown that the *yaa* susceptibility locus contains a duplication of the Toll-like receptor 7 (TLR7) gene in the pseudoautosomal region of the Y chromosome (130). Moreover, TLR7 and TLR9, with their ability to recognize potential self antigens such as RNA or DNA, respectively, were shown to be important components in the generation of pathogenic autoreactive antibodies (131,132).

Recent studies have identified two types of polymorphisms in the FcRIIB gene that are associated with SLE. Promoter polymorphisms have been described resulting in reduced expression of RIIB on activated B cells in both mouse and human SLE populations (85,133). In addition, a polymorphism in the transmembrane domain of FcRIIB has been identified that is associated with susceptibility to SLE in Japanese populations. This polymorphism results in an RIIB protein with reduced ability to enter lipid rafts and thus behaves as a hypomorphic allele for inhibitory function.

Together, these studies point to FcRIIB as a susceptibility factor in the development of autoimmunity, with the ability to interact with other susceptibility factors to modify both the afferent and efferent limbs of the autoimmune response

Inflammation

Antibody-mediated inflammatory diseases have been clearly demonstrated to involve the coupling of pathogenic autoantibodies or immune complexes to cellular FcRs.

Therapeutics targeted to disrupt these interactions are in development, beginning with a monoclonal antibody to human IgE that functions to reduce IgE binding to its high-affinity receptor and thereby prevent allergic and anaphylactic reactions (134). Because IgE is required for the survival of mast cells as well as in the regulation of FcεRI expression, reduction in IgE has synergistic effects on the ligand, receptor, and effector cell. The success of this approach will undoubtedly lead to other approaches that target the receptor or its signaling pathway. Blocking FcγRIIIA or IIA is expected to mimic the phenotype of FcRγ-deficient animals in models of IgG-induced disease. Early attempts to use this approach in ITP were promising but limited by the cross-reactivity to receptors on neutrophils, which led to neutropenia and the development of immune response to the murine antibody (135). Development of second-generation anti-FcRIIIA antibodies with greater specificity and reduced toxicity now appears to be a viable approach for the treatment of autoimmune diseases.

An alternative approach to limiting the activation of FcRs is to use the endogenous inhibitory pathway to abrogate IgE or IgG activation of their cognate receptors through coligation to FcγRIIB. This mechanism has been proposed to explain the ability to induce desensitization for the treatment of allergic diseases (33,136). Inducing production of IgG antibodies to an allergen may facilitate cross-linking of FcγRIIB to FcεRI. The ability to exploit the inhibitory pathway to reduce the activity of activation FcγRs has been demonstrated to account for some of the anti-inflammatory activity associated with high-dose intravenous γ-globulin (IVIG), which consists of the pooled IgG fraction of serum from thousands of donors (58). The use of IVIG for the treatment of ITP and other autoimmune diseases is well established, although the mechanism of action has been elusive. In murine models of ITP, arthritis, and nephritis, it has been demonstrated that protection by IVIG depends on the presence of FcRIIB; deletion of FcRIIB or blocking FcRIIB by a monoclonal antibody eliminates the ability of IVIG to protect the animal against an inflammatory response (58,60,66). IVIG was demonstrated to lead to the *in vivo* induction of FcRIIB on splenic effector macrophages, which would raise the threshold required for platelet clearance by FcRIII on these cells (60). Recently it has become clear that the sialic acid–rich fraction of IgG antibodies in the IVIG preparation is responsible for the antiinflammatory activity and FcγRIIB upregulation (66). Together with previous data on the dependence of FcRIIB upregulation on effector macrophages on CSF-1–dependent, so-called sensor macrophages, this suggests a two-cell model for the mechanism of IVIG activity (Figure 22.7). In this model, sialic acid–rich IVIG binds to a receptor on sensor macrophages, which in turn induces upregulation of FcRIIB on effector macrophages, thereby raising the threshold for activation. In addition, inducing expression of FcRIIB might be a clinically feasible approach and could be effective at modulating pathogenic autoantibodies from activation effector cell responses through activating FcRs.

Studies on the FcαRI receptor have demonstrated a role for this molecule in the pathogenesis of IgA nephropathy, in which circulating macromolecular complexes are deposited in the mesangium, resulting in hematuria and eventually leading to renal failure. Soluble FcαRI is found in the circulating IgA complexes, which suggests a role for the receptor in the formation of these pathogenic complexes. A transgenic mouse expressing FcαRI spontaneously develops IgA nephropathy resulting from the interaction of polymeric mouse IgA and the human FcαRI receptor to release soluble receptor–IgA complexes, which leads to deposition in the mesangium and the sequelae of IgA neuropathy.

SUMMARY AND CONCLUSIONS

Receptors for the Fc of immunoglobulins provide an essential link between the humoral and adaptive response, translating the specificity of antibody diversity into cellular responses. These receptors mediate their biological responses through the coupling of Fc recognition to ITAM/ITIM-based signaling motifs. A diverse array of biological responses depends on the FcR system, influencing both the afferent and efferent limbs of the immune response. Detailed biochemical, structural, and molecular biological data have provided a thorough understanding of how these receptors are regulated, are assembled, bind their ligand, and transduce specific cellular signals. FcRs play a significant role *in vivo* in maintaining peripheral tolerance by limiting the accumulation of autoreactive B cells that escape central tolerance checkpoints, such as light-chain editing, or that potentially arise during somatic hypermutation in germinal centers, in modulating T-cell responses by regulating both antigen presentation and maturation by dendritic cells, and in mediating the coupling of antigen recognition to effector cell activation. They are the primary pathways by which pathogenic IgG and IgE antibodies trigger inflammatory responses *in vivo*. Allergic reactions, cytotoxic IgG responses, and immune complex–mediated inflammation are all critically dependent on FcR cross-linking and have resulted in a fundamental revision of the mechanisms underlying such classic immunologic responses as the Arthus reaction. Blocking of these receptors uncouples the pathogenic potential of autoantibodies and represents an important new therapeutic target for the development of anti-inflammatory therapeutic agents. Central to the correct functioning of these responses is the balance that is maintained through the pairing of

FIGURE 22.7 Two-cell model for the antiinflammatory activity of intravenous γ-globulin (IVIG). Sialic acid–rich antibodies in the IVIG preparation bind to an as-yet-unknown cell surface receptor on CSF-1–dependent sensor macrophages. This leads to the upregulation of the inhibitory FcγRIIB on effector macrophages, which results in a higher threshold for cell activation and thus inhibits the release of inflammatory mediators and tissue destruction. activation and inhibitory receptors that coengage the IgG ligand; perturbations in either component can result in pathologic responses. The study of FcRs defined the ubiquitous inhibitory motif, the ITIM, and provided a paradigm for how these pathways modulate ITAM-based activation responses. Studies in mice deficient in individual FcRs have provided the necessary insights for defining comparable activities in human autoimmune diseases and suggest ways in which manipulation of the IgG–FcR interaction may lead to new classes of therapeutics for the treatment of these diseases. Modulation of the inhibitory response, a novel activity associated with IVIG to account for some of its anti-inflammatory activity *in vivo,* represents a novel approach to the regulation of immunoglobulin-mediated inflammation and suggests that therapeutic agents based on those pathways are likely to be effective. Conversely, engineering of therapeutic antibodies targeted to eliminate infectious or neoplastic disease will probably benefit from optimization of their Fc domains for interaction with specific FcRs.

Type I Cytokines and Interferons and Their Receptors

Warren J. Leonard

OVERVIEW AND ISSUES OF NOMENCLATURE

Cytokines are proteins that are secreted by cells and exert actions on either the cytokine-producing cell (autocrine actions) or on other target cells (paracrine actions) by binding to and transducing signals through specific cell surface receptors. From this operational type of description, it is clear that the distinction among cytokines, growth factors, and hormones is imprecise, even though all are secreted proteins. As a generalizaiton, cytokines and growth factors are similar, except that the term *cytokine* typically refers to a molecule involved in host defense that has actions on white blood cells (leukocytes), whereas the term *growth factor* more often refers to molecules acting on other somatic cell types. Cytokines generally act locally. For example, in the interaction between a T cell and an antigen-presenting cell, cytokines are produced and usually exert potent actions locally, with rather limited biologic half-lives in the circulation. In contrast, hormones are released and then disseminated via the bloodstream throughout the body, with actions on many distal target organs. Nevertheless, this distinction between cytokines and hormones is not absolute, with certain cytokines acting at longer distances as well.

In the immune system, terms such as *monokines* and *lymphokines* were originally devised to identify the cellular source for cytokines (1). Specifically, monokines included molecules such as interleukin-1 (IL-1), which was first recognized as being produced by monocytes, and lymphokines included molecules such as IL-2, which was first described as a T-cell growth factor produced by T lymphocytes. The monokine/lymphokine nomenclature has obvious limitation when a cytokine is synthesized by more than one type of cell. This resulted in the adoption of the term *cytokine,* as proposed by Stanley Cohen in 1974 (2,3). The term *cytokine* refers to a protein made by a cell ("cyto") that acts on target cells. Cytokines can have very broad ranges of actions, including effects on cell growth, cell differentiation, cytolytic activity of effector cells, apoptosis, and chemotaxis.

Many cytokines are referred to as *interleukins,* a term that refers to molecules that are produced by one leukocyte and act on another (4). Analogous to the inadequacy of the terms *monokine* and *lymphokine,* however, some interleukins (e.g, IL-1 and IL-6) are additionally produced by cells other than leukocytes and/or can exert actions on other cell types extending beyond the immune system. IL-7 is not ideally named, as it is a cytokine that is produced by stromal/epithelial cells rather than by typical leukocytes. Furthermore, nomenclature has also been inconsistent. For example, IL-7 is highly related to another cytokine that is denoted as thymic stromal lymphopoietin (TSLP) rather than as an interleukin (both are discussed later). Indeed, both are stromal factors that share a receptor component and have overlapping actions on T and B cells, but their very different types of names obscures these facts. The more descriptive name TSLP correctly describes its production by thymic stroma but obcures its production by skin epithelial cells and that major target cells include dendritic cells and CD4$^+$ T cells.

Among the many different cytokines, the "type I" cytokines share a similar four–α-helical–bundle structure, as detailed later, and correspondingly, their receptors also share characteristic features that have led to their description as the cytokine receptor superfamily, or type I cytokine receptors (5,6,7,8). Although many interleukins are type I cytokines, this is not true for all. For example, two of the major "proinflammatory cytokines," IL-1 and IL-6, are interleukins, but IL-6 is a type I cytokine whereas IL-1 is not (IL-1 is discussed in Chapter 24). TUF (see Chapter 25) is yet another very different type of proinflammatory cytokine. One interleukin, IL-8, is a CXC-family chemokine (see Chapter 26), an entirely different type of molecule involved in chemotaxis. Moreover, as discussed later, IL-10, IL-19, IL-20, IL-22, IL-24, IL-26, IL-28, and IL-29 are more similar to interferons and are denoted as type II cytokines.

In summary, the term inter*leuk*in indicates a relationship to *leuk*ocytes, whereas the identification of a cytokine as a type I or type II cytokine indicates general properties of the three-dimensional structure of the cytokine. Knowing that a molecule is a type I cytokine is instructive,

as it indicates a likely general structure for the cytokine receptor as well as the mechanism of signal transduction. In contrast, the identification of a molecule as an interleukin provides little information other than that it typically, but not always, is a type I or type II cytokine of immunologic interest.

In addition to molecules that are primarily of immunologic interest, other extremely important proteins, such as growth hormone, prolactin, erythropoietin (Epo), thrombopoietin (Tpo), and leptin, are also type I cytokines and their receptors are type I cytokine receptors. Despite having major actions outside the immune system, these cytokines nevertheless share important signal transduction pathways with type I cytokines whose actions are primarily of immunologic interest. By focusing on type I cytokines and their receptors, this chapter necessarily focuses on cytokines that are evolutionarily related and that share common signaling pathways, instead of focusing on common functions per se. For example, although IL-6 has overlapping actions with IL-1 and TNF-α, these latter proinflammatory cytokines are discussed elsewhere because they are not type I cytokines, and the signaling pathways they use are distinct from those used by IL-6. This illustrates the important concept that similar end functions can be mediated via more than one type of signaling pathway. This is not to minimize the observation that many type I cytokines in fact do have similar/overlapping functions, as detailed later, in the section on cytokine redundancy.

The field of interferon (IFN) research is older than the cytokine field, but both fields more recently have developed in parallel. In fact, one should perhaps simply consider the IFNs to be the first cytokines that were identified. IFN was originally discovered as an antiviral activity in 1957. This turned out to be type I IFN (IFN-α/β). Type II IFN (IFN-γ) was discovered in 1965. Over time, it was recognized that type I cytokines and IFNs/type II cytokines share a number of common features. It is noteworthy that a number of years ago, the International Interferon Society changed its name to the International Society of Interferon and Cytokine Research and that the International Cytokine Society focuses on the IFNs as well as cytokines, underscoring the common features, both in basic science and clinically, of IFNs and cytokines.

TYPE I CYTOKINES AND THEIR RECEPTORS

Type I Cytokines—Structural Considerations

Type I cytokines typically share only limited amino acid sequence identity, but strikingly, all type I cytokines whose structures have been solved by nuclear magnetic resonance (NMR) and/or x-ray crystallographic methods are known to achieve similar three-dimensional structures
FIGURE 23.1 Schematic of four–α-helical–bundle cytokines. Schematic drawing showing typical short-chain and long-chain four-helical-bundle cytokines. Although these both exhibit an "up-up-down-down" topology to their four α helices, note that in the short-chain cytokines, the AB loop is behind the CD loop, whereas in the long-chain cytokines the situation is reversed. See text. The figure was provided by Dr. Alex Wlodawer, National Cancer Institute.

(5,6,7,8). Moreover, type I cytokines whose structures have not yet been solved also appear, based on modeling and comparison to the solved structures, to achieve similar three-dimensional structures (5,6,7,8). Type I cytokines contain four α helices and thus are designated as four–α-helical–bundle cytokines (Figure 23.1). Within their structures, the first two and last two α helices are each connected by long-overhand loops. This results in these cytokines achieving an "up-up-down-down" topologic structure, as the first two helices (A and B) can be oriented in an "up" orientation and the last two helices (C and D) can be oriented in a "down" orientation, as viewed from the NH$_2$- to COOH-terminal direction. As shown in Figure 23.1, the N and C termini of the cytokines are positioned on the same part of the molecule.

Type I cytokines fall into two groups, known as "short-chain" and "long-chain" four–α-helical–bundle cytokines, based on the lengths of the α helices (8). Some of the short-chain cytokines include IL-2, IL-3, IL-4, IL-5, GM-CSF, IL-7, IL-9, IL-13, IL-15, IL-21, M-CSF, SCF, and TSLP, whereas long-chain cytokines include growth hormone, prolactin, erythropoietin, thrombopoietin, leptin, IL-6, IL-11, leukemia-inhibitory factor (LIF), oncostatin M (OSM), ciliary neurotrophic factor (CNTF), cardiotrophin-1 (CT-1), novel neurotrophin-1/B cell-stimulating factor-3/cardiotrophinlike factor (NNT-1/BSF-3/CLC), and G-CSF (Table 23.1) (8,9). The α helices are approximately 15 amino acids long in short-chain helical cytokines and 25 amino acids long in long-chain cytokines. Additional differences include differences in the angles between the pairs of helices, and the AB loop is "under" the CD loop in the short cytokines, but "over" the CD loop in the long cytokines

▶ **TABLE 23.1 Four-Helical-Bundle Cytokines**

Short-Chain Cytokines	*Long-Chain Cytokines*
IL-2	IL-6
IL-4	IL-11
IL-7	Oncostatin M
IL-9	Leukemia-inhibitory factor
IL-13	CNTF
IL-15	Cardiotropin-1
IL-21	NNT-1/BSF-3
TSLP	
IL-3	Growth hormone
IL-5[a]	Prolactin
GM-CSF	Erythropoietin
	Thrombopoietin
M-CSF[a,b]	Leptin
SCF[b]	G-CSF

[a]Dimers.
[b]Different from the other four-helical-bundle cytokines in that the M-CSF and SCF receptors (CSF-1R and c-kit, respectively) have intrinsic tyrosine kinase activity and are not type I cytokine receptors.

(Figure 23.1) (7,8,10). Moreover, short-chain cytokines have β structures in the AB and CD loops, whereas long-chain cytokines do not.

The division of type I cytokines into short-chain and long-chain cytokines has evolutionary considerations and also correlates with grouping of receptor chains for these two subfamilies of type I cytokines. An analysis of short-chain cytokines has revealed that 61 residues comprise the family framework, including most of the 31 residues that contribute to the buried inner core. The similarities and differences in the structures of IL-2, IL-4, and GM-CSF have been carefully analyzed (5). Among these cytokines, there is considerable variation in the intrachain disulfide bonds that stabilize the structures. For example, IL-4 has three intrachain disulfide bonds, GM-CSF has two, and IL-2 has only one. In IL-4, the first disulfide bond (between Cys 24 and Cys 65) connects loop AB to BC, the second disulfide bond (between Cys 46 and Cys 99) connects helix B and loop CD, and the third disulfide bond (between Cys 3 and Cys 127) connects the residue preceding helix B with helix D. In GM-CSF, the N terminus of helix B and the N terminus of β-strand CD are connected by one disulfide bond, whereas the other disulfide bond connects the C terminus of helix C and a strand following helix D. In IL-2, a single essential disulfide bond between Cys 58 and Cys 105 connects helix B to strand CD. Thus, each cytokine has evolved distinctive disulfide bonds to stabilize its structure, although it is typical that helix B is connected to the loop between helices C and D. The structures formed by helices A and D are more rigorously conserved than those formed by helices B and C, primarily because of the interhelical angles; helix D and the connecting region are the most highly conserved elements among the three cytokines (5).

This is of particular interest because the regions of type I cytokines that are most important for cytokine receptor interactions (based on analogy to the growth-hormone receptor structure, see later), include helices A and D and residues in the AB and CD loops, whereas helices B and C do not form direct contacts (5).

Certain variations on these typical four–α-helical–bundle structures can occur. For example, IL-5 is unusual in that it is a dimer positioned in a fashion so that the ends containing the N and C termini are juxtaposed *(11)*. Helix D is "exchanged" between the two covalently attached monomers so that helix D of each molecule actually forms part of the four-helix bundle of the other *(11)*. M-CSF is also a dimer, but no exchange of helix D occurs (10).

The interferons form related albeit distinctive structures from type I cytokines and are designated as type II cytokines *(8)*. IFN-β has an extra helix that is positioned in place of the CD strand *(12)*. IFN-γ is a dimer, each of which consists of six α helices *(13)*, as can be seen in Figure 23.2. Two of these helices are interchanged, including one from each four–α-helical bundle (10,13). IL-10, which is closely related to IFN-γ, has a similar structure *(14)*, and it can be predicted that more recently identified IL-10–like molecules, including IL-19, IL-20, IL-22, IL-24, IL-26, IL-28, and IL-29, have similar structures. Interestingly, although not universally the case, the majority of four α-helical cytokines have four exons, with helix A in exon 1, helices B and C in exon 3, and helix D in exon 4 *(7)*. A related organization is found for IFN-γ, as well as for the long-chain helical cytokines, growth hormone and G-CSF. However, there are exceptions; for example, IL-15 is divided into nine exons, whereas the IFN-α and IFN-β are encoded by single exons.
FIGURE 23.2 Structure of the IFN-γ receptor. Shown are ribbon diagrams of the structures of the IFN-γ/IFN-γ receptor complex as an example of a type II cytokine/cytokine receptor. In the IFN-γ receptor, only IFNGR-1 complexed to the IFN-γ dimer is shown, as the full structure with IFNGR-2 is not available. See text for discussion of the structure. The IFN-γ-IFNGR-1 structure is from (287). The figure was provided by Dr. Alex Wlodawer, National Cancer Institute.

Receptors for Type I Cytokines

The first report suggesting that type I cytokines interacted with receptors with similar features identified similarities in the sequences of the erythropoietin receptor and the IL-2 receptor β chain *(15)*, and subsequent analysis of a large number of type I cytokine receptors much more clearly established the existence of these receptors as a superfamily (16). Type I cytokine receptors are generally type I membrane-spanning glycoproteins (N terminus extracellular, C terminus intracellular). The only exceptions are proteins such as the CNTF receptor α chain (see later), which lacks a cytoplasmic domain and instead has a GPI anchor; however, the orientation of this protein is otherwise similar to that of a type I membrane protein. In their extracellular domains, a number of conserved features have been noted (Table 23.2). These include four conserved cysteine residues that are involved in intrachain disulfide bonding, and a tryptophan residue, located two amino acids C-terminal to the second conserved cysteine. In addition, a membrane-proximal region WSXWS (Trp-Ser-X-Trp-Ser) motif is generally conserved, although again exceptions exist: for example, in the growth hormone receptor, the motif is a substantially different YGEFS (Tyr-Gly-Glu-Phe-Ser) sequence, and in the IL-23R, it is a more similar WQPWS (Trp-Gln-Pro-Trp-Ser) motif. In some cases, such as the common cytokine receptor β chain, β_c, shared by the IL-3, IL-5, and GM-CSF receptors (see later), the extracellular domain is extended, with a duplication of the domains containing the four conserved cysteines and the WSXWS motif. Another shared feature of type I cytokine receptors is the presence of fibronectin type III domains.

The two pairs of conserved cysteine residues are typically encoded in two adjacent exons, and the exon containing the WSXWS motif is typically just 5′ to the exon encoding the transmembrane domain. Although serines can be encoded by six different codons (i.e, sixfold degeneracy in codon usage), only two of these (AGC and AGT) dominate as the codons used for the serines in WSXWS. All of these features indicate a common ancestral type I cytokine receptor.

Cytoplasmic Domain
1. Box 1/Box 2 regions—The Box 1 region is a proline-rich region that is involved in the interaction of Janus family tyrosine kinases.

Overall, analogous to limited sequence identity between type I cytokines, there is only limited sequence identity among type I receptor molecules. Nevertheless, they appear to form similar structures, based on the known structures for the receptors for growth hormone, prolactin, erythropoietin, IL-4, and IL-2 (17,*18–20,*21), and the modeling of other cytokine receptor molecules based on the known structures. The cytokines and their receptors have presumably coevolved, with the differences in amino acid sequences between different cytokines allowing for their distinctive interactions with their cognate receptor chains. Despite amino acid differences, there are several sets of cytokines that coevolved to interact with shared receptor chains, thus forming type I cytokine and cytokine receptor subfamilies *(8)*.

In addition to the above-noted similarities in the extracellular domains, there are sequence similarities that are conserved in the cytoplasmic domain of cytokine receptors. In particular, membrane-proximal "Box 1/Box 2" regions are conserved (Table 23.2), with the proline-rich Box 1 region being the most conserved *(22)*. This will be discussed in greater detail later, related to its role in the binding of Jak kinases.

Type I Cytokine Receptors Are Homodimers, Heterodimers, or Higher-order Receptor Oligomers

The first cytokine receptor structure solved was that for growth hormone (Figure 23.3) (17). Prior to the x-ray crystallographic analysis, it was believed that growth hormone bound to its receptor with a stoichiometry of 1:1. Remarkably, however, the x-ray crystal solution structure revealed that a single growth hormone molecule interacted with a
FIGURE 23.3 Structure of the growth hormone receptor. Shown are ribbon diagrams of the structure of the growth hormone receptor as an example of a type I cytokine receptor. For growth hormone, both growth hormone receptor monomers are shown. See text for discussion of the structures. The growth hormone/growth hormone receptor structure is from (17). The figure was provided by Dr. Alex Wlodawer, National Cancer Institute.

dimer of the growth hormone receptor, in which each receptor monomer contributes a total of seven β strands. Perhaps the most striking finding was that totally different parts of the growth hormone molecule interacted with the same general region of each receptor monomer. The three-dimensional x-ray crystal structure for the growth hormone/growth hormone receptor complex is shown in Figure 23.3. Solving the structure also clarified the basis for the assembly of the growth hormone receptor complex (17). Growth hormone appears first to interact with one receptor monomer via a relatively large and high-affinity interaction surface (site I), spanning approximately 1,230 Å^2. A second receptor monomer then interacts with the growth hormone/growth hormone receptor complex via two contact points—one on growth hormone (spanning approximately 900 Å^2) (site II), and the other on the first receptor monomer (spanning approximately 500 Å^2) (site III), located much more proximal to the cell membrane. Thus, a total of three extracellular interactions are responsible for the formation and stabilization of the growth hormone/growth hormone receptor complex. Mutations in critical residues in site I should prevent growth hormone binding to its receptor, whereas inactivating mutations in site II can be predicted to prevent dimerization and signal transduction. These considerations indicate a basis by which different classes of antagonists might be identified.

The growth hormone/growth hormone receptor structure revealed that the growth hormone receptor extracellular domain is composed of two fibronectin type III modules, each of which is approximately 100 amino acids long and contains seven β strands, resulting in the formation of an immunoglobulinlike structure. The contact surface between ligand and receptor occurs in the hinge region that separates these two fibronectin type III modules. Analysis of a growth hormone/prolactin receptor complex revealed the anticipated similar structure for the prolactin receptor *(18)*.

The growth hormone/growth hormone receptor structure was not only of great importance for the growth hormone field, it also served as a paradigm for the structures of other type I cytokine receptors. As a receptor homodimer, it immediately served as a model for other homodimers, such as the erythropoietin receptor, whose structure was solved *(19)* using a small protein mimetic (20-amino acid–long peptide) of erythropoietin *(23)*. The erythropoietin receptor structure is similar to that of the growth hormone receptor, although the "site III" stem region interaction surface in the erythropoietin receptor is much smaller than that in the growth hormone receptor, comprising only 75 Å^2 *(19)*.

In addition to the structural similarities for the growth hormone and erythropoietin receptors and perhaps other homodimeric type I cytokine receptors, a similar structure was achieved by the heterodimeric growth hormone/

growth hormone receptor/prolactin receptor structure *(18)*, in which one of the growth hormone receptor monomers is replaced by a prolactin receptor molecule. Thus, the growth hormone/growth hormone receptor system is one in which two surfaces of growth hormone interact either with two identical monomers of growth hormone or with two nonidentical monomers in the case of the growth hormone receptor/prolactin receptor heterodimer.

It can be hypothesized that cytokine receptor systems with a homodimeric receptor are evolutionarily older than those with heterodimeric receptors, and that the coordination of two different receptor chains in heterodimeric receptors would have evolved in order to allow higher levels of specialization. In this regard, it is interesting that growth hormone and erythropoietin, whose actions are vital for growth and erythropoiesis, bind to receptors that are both homodimers, whereas the heterodimeric structures that typify the immune system are perhaps more "specialized" functions that arose later in evolution.

Interestingly, all type I cytokines known to interact with homodimers (growth hormone, prolactin, erythropoietin, and G-CSF) are long-chain helical cytokines, although other long-chain helical cytokines (e.g, the cytokines whose receptors contain gp130; see later) interact with heteromeric receptors. The short-chain cytokines that signal through homodimers are stem cell factor (SCF) and M-CSF, but in these cases the receptors (c-kit and CSF-1R, respectively) are different from type I cytokine receptors in that they contain intrinsic tyrosine kinase domains. Thus, SCF and M-CSF are not typical type I cytokines, and all other short-chain cytokines signal through heterodimers or more complex receptor structures (e.g, IL-2 and IL-15 receptors have three components).

Heterodimeric receptors are involved when site II on a cytokine has evolved to a point at which it interacts with a different receptor molecule than site I. This latter situation is the case for many cytokines, including all short-chain type I cytokines except for SCF and M-CSF. Overall, several sets of type I cytokines fall into distinct groups, wherein each group shares at least one common receptor component. This phenomenon is observed for certain sets of both short-chain and long-chain four–α-helical–bundle cytokines, and depending on the set of cytokines, the shared chain interacts either with site I or with site II.

The structures of the low- and high-affinity forms of the IL-2 receptor have now been solved (21,24). These are valuable structures in that they include the first complete structure for a short-chain cytokine/receptor complex (25). Moreover, they are of added interest in that the low-affinity receptor involves the interaction of IL-2 with IL-2Rα, which is not a type I cytokine receptor protein but instead is a distinctive sushi domain–containing protein, whereas the high-affinity receptor includes not only IL-2Rα but also IL-2Rβ and γ_c, which are both type I cytokine receptor proteins that are shared either with
FIGURE 23.4 Structure of the high-affinity IL-2 receptor. This is the first structure for a short-chain type I cytokine complexed to its complete receptor. It is particularly interesting in that it includes the sushi domain containing the IL-2Rα chain as well. Reprinted from (21) with permission of Dr. Garcia and *Science* magazine.

IL-15 (IL-2Rβ) or with IL-4, IL-7, IL-9, IL-15, and IL-21(γ_c) (26), as discussed later. In the structure of IL-2 bound to its high-affinity receptor (Figure 23.4), there is a long peptide connecting the IL-2Rα globular head and transmembrane segment, allowing the binding site on this protein to extend relatively far from the cell surface in order to bind the dorsal surface of IL-2. Both the IL-2/IL-2Rα and IL-2/IL-2Rβ contacts are independent, and IL-2Rα does not appear to contact either IL-2Rβ or γ_c; however, IL-2 and IL-2Rβ together form a composite surface with γ_c, somewhat analogous to the composite surface formed by growth hormone and one growth hormone receptor monomer for binding to a second monomer. As anticipated, the surface interaction between IL-2 and γ_c is smaller than that between IL-2 and either of the other chains.

TYPE I CYTOKINE RECEPTOR FAMILIES AND THEIR RELATIONS

Cytokines That Share the Common Cytokine Receptor γ Chain (IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21)

The receptors for six different immunologically important cytokines, IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21, share the common cytokine receptor γ chain, γ_c (CD132) (27–29, 30,31,32,33,34,35; reviewed in 26,36). These cytokines are all short-chain four–α-helical–bundle cytokines; basic features of these cytokines are summarized in Table 23.3. In the following, the properties of these cytokines and their unique receptor chains are summarized, followed by a discussion of the discovery that they share a common receptor component and the implications thereof.

Mature IL-2 is a 133-amino acid–long peptide that is produced by activated CD4$^+$ T lymphocytes and is the major T-cell growth factor, in keeping with its original discovery as a T-cell growth factor (TCGF) (37). IL-2 has other

important actions as well (Table 23.3) (25). For example, it can increase immunoglobulin synthesis and J-chain transcription in B cells *(38–40)*, potently augment the cytolytic activity of natural killer (NK) cells (41,42,*43*) and induce the cytolytic activity of lymphokine-activated killer (LAK) cells, promote the elimination of auto-reactive cells in a process known as antigen-induced (or activation-induced) cell death (AICD; see Chapter 27) (25,*40*,44), promote the differentiation of regulatory T cells (T$_{reg}$ cells) (45) (see Chapter 30), cells that suppress inappropriate responses and are important for immunologic tolerance (see Chapter 29), and it is important for proper T-helper cell differentiation. Interestingly, IL-2 can also prime CD8$^+$ T cells during a primary response to undergo enhanced proliferation in vivo during a secondary response *(46,47)*.

IL-2 is particularly important historically, as it is the first type I cytokine that was cloned (48), the first type I cytokine for which a receptor component was cloned (49,*50*), and was the first short-chain type I cytokine whose receptor structure was solved (21). Many general principles have been derived from studies of this cytokine, including its being the first cytokine demonstrated to act in a growth factor–like fashion through specific high-affinity receptors, analogous to the growth factors being studied by endocrinologists and biochemists *(40,51)*.

Although IL-2 is not produced by resting T cells, its production is rapidly and potently induced following antigen encounter with resting T cells. As a result, transcription and synthesis of IL-2 are often used as indicators of successful T-cell receptor–mediated cellular activation. Although the antigen determines the specificity of the T-cell immune response, the interaction of IL-2 with high-affinity IL-2 receptors regulates the magnitude and duration of the subsequent response, based on the amount of IL-2 produced, the levels of high-affinity receptors expressed, and the duration of IL-2 production and receptor expression. IL-2 can act in either an autocrine or paracrine fashion, depending on whether the producing cell is also the

▶ **TABLE 23.3 Features of Cytokines Whose Receptors Share γ_c**

Cytokine	Major Source	Size[a]	Actions	Chromo. Location (h/m)	Genomic Org
IL-2	Activated T cells (Th1 cells)	h153 aa/20aa m169aa/20aa 15.5 kDa	T-cell growth factor B-cell growth, Ig production, J-chain expression Induce LAK activity Induce tumor-infiltrating lymphocyte activity Augment NK activity Critical role in antigen-induced cell death (AICD) Stimulate macrophage/monocyte antitumor effects	4q26-27/3	4 exons
IL-4	Activated T cells (Th2 cells) CD4$^+$NK1.1$^+$ natural T cells	h153/24 aa m140 aa/20 aa 18 kDa	B-cell proliferation Ig class switch—IgG1, IgE production Augment MHC II, Fcε receptors IL-4Rα and IL-2Rβ expression Th2 cell differentiation Antitumor effects	5q31.1/11	4 exons
IL-7	Stromal cells	h177 aa/25aa m154aa/25aa 17–25 kDa	Thymocyte growth T-cell growth Pre-B cell growth in mice but not humans Survival and growth of peripheral T cells	8q12-13/3	6 exons
IL-9	Activated helper T cells	h144aa/18aa m144aa/18aa 14 kDa	Th-helper clones Erythroid progenitors B cells Mast cells Fetal thymocytes	5q31-35/13	5 exons
IL-15	Monocytes and many cells outside the immune system[b]	h162aa/48aa m162aa/48aa 14–15 kDa	Mast-cell growth NK-cell development and activity T-cell proliferation	4q31/8	9 exons
IL-21	Activated CD4$^+$ T cells T$_{FH}$ cells NKT cells Th17 cells	h162aa/31 aa m146aa/24 aa	Comitogen for T-cell proliferation Inhibits B-cell proliferation to anti-IgM + IL-4 Augments B-cell proliferation to anti-CD40 Conflicting reports related to NK cells Cooperates with IL-7 and IL-15 to expand CD8 cells Antitumor effects Drives terminal B-cell differentiation to plasma cells Proapoptotic for B and NK cells	4q67-27	

[a]h and m refer to human and murine, respectively. The number of amino acids refers to the length of the open reading frame/length of signal peptide. The number of amino acids in the mature protein is therefore the difference between these numbers. Note that for IL-15, residues 1–29 have been identified as a signal peptide and residues 30–48 as a propeptide.

[b]More IL-15 mRNA is produced in skeletal muscle, kidney, placenta, and lung than in thymus or spleen. It is important to note, however, that IL-15 mRNA is widely expressed without concomitant production of IL-15 protein, so the source of biologically meaningful IL15 may be more limited.

responding cell or whether the responding cell is a non-producing cell. The gene encoding IL-2 is located on chromosome 4 *(52)*, and, like many other helical cytokines, its gene consists of four exons *(7)*.

IL-2 binds to three different classes of receptors. These are formed by different combinations of three different chains, IL-2Rα (49,*50,53*), IL-2Rβ (54,55,*56*,57), and a protein initially called IL-2Rγ (27) but now known as the common cytokine receptor γ chain, γ_c (26,28). The different classes of IL-2 receptors are discussed in the following.

Like IL-2, IL-4 is produced primarily by activated CD4$^+$ T cells (58). IL-4 is also produced by CD4$^+$NK1.1$^+$

"natural" T cells, denoted as NKT cells *(59)*, and by mast cells and basophils (58). IL-4 is the major B-cell growth factor, and it promotes immunoglobulin class switch, enhancing the production and secretion of mouse IgG1 (human IgG4) and being essential for the production of IgE (58). IL-4 is involved in the physiologic response to parasites, including helminths, and for allergen sensitization. IL-4 induces expression of class II major histocompatibility complex (MHC) molecules and increases cell surface expression of the CD23 (the low-affinity IgE receptor) on B cells. In addition to its actions on B cells, IL-4 can also act as a T-cell growth factor, inducing proliferation in both human and murine T cells, and is critical for normal differentiation of Th2 cells (discussed later). When combined with PMA, IL-4 is also a potent comitogen for thymocytes. Importantly, IL-4 can inhibit certain responses of cells to IL-2 *(60)*. Moreover, IL-4 can exert actions on macrophages, hematopoietic precursor cells, stromal cells, and fibroblasts *(61)*. The gene encoding IL-4 is located on human chromosome 5 (5q23.3-31.2) and mouse chromosome 11 *(61,62)*, in the same region as IL-3, IL-5, IL-13, and GM-CSF. The type I IL-4 receptor expressed on T cells and other hematopoietic cells consists of the 140-kDa IL-4Rα protein (58,*63–65*) and γ_c (29,*30*). Expression of IL-4Rα tends to be quite low, and cells that respond potently to IL-4 often express only a few hundred receptors per cell. In addition to the type I IL-4 receptor, an alternate form of the receptor, containing IL-4Rα and IL-13Rα (now denoted IL-13Rα1), although it is not expressed on mature T cells, is expressed on many other cell types and can transduce IL-4 signals into these cells. For example, IL-13Rα1 is expressed on neonatal Th1 cells, and the type II IL-4R has been implicated as mediating apoptosis of these cells *(66)*.

IL-7 is not a lymphokine (i.e, it is not produced by lymphocytes) but instead is a 152-amino acid–long cytokine that is produced by stromal cells (67,*68*). Its major role is to enhance thymocyte survival, growth, and differentiation (*69,70*,71–73), as well as low-affinity peptide-induced proliferation, and thus it promotes homeostatic proliferation of naïve and memory CD8$^+$ T cells (73,*74*,75). Additionally, IL-7 can regulate homeostasis of CD4$^+$ memory T cells (76,77) and also can stimulate the growth of mature T cells (26,73,*78*,79). It is vital for the growth of murine pre-B cells (*65*,67,71,72,79), and transient IL-7 signaling can inhibit immunoglobulin heavy-chain gene rearrangements *(80)*. In contrast to the mouse situation as underscored by the normal B-cell development in patients with defective IL-7 signaling (patients with X-linked severe combined immunodeficiency [SCID], Jak3-deficient SCID, and IL-7Rα-deficient SCID, see later), human B cells can develop normally in the absence of IL-7 responsiveness, demonstrating that in humans, IL-7 is not vital for the growth of human pre-B cells (26,*81*), and it remains unknown whether IL-7 plays any important role for B-cell biology in humans. The gene encoding IL-7 is located on human chromosome 8q12-13 *(82)* and mouse chromo-

some 3. The functional IL-7 receptor contains the 75-kDa IL-7Rα *(83)* and γ_c (28,*31*). Based on chemical cross-linking experiments and Scatchard analyses, there is a suggestion, however, that the receptor may contain a still-unidentified third component as well (28).

IL-9 was originally described as a murine T-cell growth factor (84) that is produced by activated T cells and can support the growth of T-helper clones but not of cytolytic clones *(85)*. In contrast to IL-2, its production is delayed, suggesting its involvement in later, perhaps secondary signals. In the mouse, IL-9 can exert proliferative effects on erythroid progenitors, B cells, B1 cells, mast cells, and fetal thymocytes. IL-9 is identical to mast cell growth-enhancing activity (MEA), a factor present in conditioned medium from splenocytes *(86)*, and synergizes with IL-3 for maximal mast cell proliferation. The action of IL-9 on thymocytes in vitro is interesting in view of the development of thymomas in IL-9 transgenic mice coupled to the observation that IL-9 is a major antiapoptotic factor for thymic lymphomas (87). Nevertheless, IL-9 knockout mice do not have a defect in T-cell development (88). Instead, they exhibit a defect in pulmonary goblet cell hyperplasia and mastocytosis following challenge with *Schistoma manoni* eggs, a synchronous pulmonary granuloma formation model; however, there was no defect in eosinophilia or granuloma formation (88). Mice in which an IL-9 transgene is expressed in the lung exhibit airway inflammation and bronchial hyperresponsiveness; nevertheless, IL-9$^{-/-}$ mice exhibit normal eosinophilia and airway hyperreactivity in an ovalbumin-induced inflammatory model (*89,90*,91). Thus, although IL-9 can contribute to allergic/pulmonary responses, there are compensatory cytokines that substitute for IL-9 in at least certain settings. Although murine IL-9 is active on human cells, human IL-9 is not biologically active on murine cells (the opposite situation from that for IL-2). Human IL-9 is located on chromosome 5 in the 5q31-35 region *(92)*, which is also the location of the genes encoding IL-3, IL-4, IL-5, IL-13, and GM-CSF. In contrast, mouse IL-9 is "isolated" on chromosome 13, while IL-3, IL-4, IL-5, IL-13, and GM-CSF are clustered on chromosome 11. IL-9 binds to the 64-kDa IL-9Rα–binding protein, which is similar in size to γ_c *(93)*, and the functional IL-9 receptor consists of IL-9Rα plus γ_c (26,32,*33*).

IL-15 was identified as a novel T-cell growth factor that also unexpectedly was expressed in the supernatants of an HTLV-I–transformed T-cell line (94,*95*). Although IL-15 mRNA is produced by a range of nonlymphocytic cell types, it is difficult to detect physiologic levels of IL-15 protein (96). Its main site of synthesis appears to be dendritic cells and monocytes, and unlike IL-2, it is not produced by activated T cells (97). IL-15 receptors are widely expressed, but IL-15 is most important for the development of NK cells (*98,99*,100) and CD8$^+$ memory T cells (99,*100*). Interestingly, it also regulates the T-cell receptor repertoire of $\gamma\delta$ intraepithelial lymphocytes (101) and cross-talk

between different types of dendritic cells (102). The receptor for IL-15 on T cells contains IL-2Rβ (34,96,*103*), γ_c (34) and one unique protein, IL-15Rα. IL-15Rα shares a number of structural similarities with IL-2Rα, including that it is a sushi domain–containing protein (IL-2Rα has two sushi domains, whereas IL-15Rα has one) *(104)*, and the *IL2RA* and *IL15RA* genes are closely positioned on human chromosome 10p14 *(105)*. What is distinctive about IL-15 signaling is that it signals substantially by a process called *trans presentation*, wherein IL-15Rα on the surface of dendritic cells or monocytes will trans-present IL-15 to responding cells such as CD8$^+$ T cells or NK cells that express IL-2Rβ + γ_c (97,106). The very high affinity of IL-15Rα for IL-15 is explained by a large number of ionic interactions mediated by the sushi domain *(107)*. Note that these responding cells can also express IL-15Rα. In contrast to IL-2, which is a growth factor as well as a mediator of AICD and promoter of T$_{reg}$ differentiation, the role of IL-15 appears to be more focused on growth of CD8$^+$ T cells *(108)*, maintaining long-lasting, high-avidity T-cell responses to foreign pathogens (i.e, CD8$^+$ T-cell memory) (97,109). This ability has suggested that it could have potential as a vaccine adjuvant *(110)*.

IL-21 is the most recently identified member of the IL-2 family of cytokines (reviewed in 110a). IL-21 can bind to specific receptors and exert actions on T, B, asnd NK cells. It augments T-cell proliferation as a comitogen (111), can cooperate with IL-7 or IL-15 to drive the expansion of freshly isolated murine CD8$^+$ T cells, and can augment the antitumor activity of CD8$^+$ T cells (112). Its actions on B cells are particularly complex. It augments B-cell proliferation when combined with anti-CD40 or lipopolysaccharide (LPS) but inhibits proliferation in response to anti-IgM + IL-4 (111), but this inhibition is reversed if anti-CD40 is additionally provided. It induces apoptosis of incompletely activated B cells but drives terminal differentiation to plasma cells of more fully activated cells. Strikingly, IL-21 can drive plasma cell differentiation of both peripheral memory B cells and cord-blood B cells, at least in part explained by its ability to induce expression of Blimp1 (113,*114*). In IL-21R knockout mice, following immunization, IgG1 is diminished related to a role for IL-21 in class switching to IgG1 and IgG3, whereas IgE is elevated, related to the ability of IL-21 to inhibit Cε transcription (115). IL-21R/IL-4 double-knockout mice have revealed that IL-21 cooperates with IL-4 to globally regulate immunoglobulin production in that it causes a pan-hypogammaglobulinemia, mimicking the T-cell phenotype in humans with XSCID (116). IL-21 can also cooperate with IL-15 and Flt-3 ligand to increase development of NK cells (111), and augment antitumor activity (117), but yet it was also reported to oppose the actions of IL-15 (118) and it can also direct NK cell apoptosis. Interestingly, elevated IL-21 levels have been reported in the BXSB-*Yaa* mouse model of systemic lupus erythematosus (SLE) (113) and, moreover, elevated IL-21 levels have been found in a subset of humans with SLE (P. Lipsky, personal communication). Moreover, elevated IL-21 has also been associated with other autoimmune processes, including in the NOD mouse (reviewed in 115). More recently, IL-21 has been shown to be vital for the differentiation of Th17 cells (115a, 115b, 115c) and to be able to prime cells in vitro for antitumor effects in vivo following adoptive transfer in a melanoma tumor model (115d). The receptor for IL-21 consists of IL-21R plus γ_c (*35*; reviewed in 26). IL-21R is most related to IL-2Rβ, and like IL-2Rβ, its expression is induced following cellular stimulation with anti-CD3 or phytohemagglutinin, and in addition, its expression is augmented in T cells following transformation with HTLV-I (119). Both human and murine IL-21 can act on cells of the other species. IL-21 is on human chromosome 4q26-27, while its receptor is on chromosome 16p11, immediately downstream of the *IL4R* gene.

Thus, IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21 collectively exhibit partially overlapping roles related to T cells, NK cells, B cells, and mast cells, and together would be expected to play vital roles for normal development and/or function of these cellular lineages. The fact that these six cytokines share γ_c is of particular interest given that the gene encoding this protein is mutated in the most common form of severe combined immunodeficiency in humans.

X-Linked Severe Combined Immunodeficiency Disease (XSCID) Results from Mutations in γ_c

The γ chain was originally identified as a third component of the IL-2 receptor (27), after it became clear that IL-2 receptor α and β chains alone were not sufficient to transduce an IL-2 signal. The hypothesis that the γ chain was a shared component of receptors in addition to the IL-2 receptor was motivated from a comparison of the clinical phenotypes in humans that result from defective expression of IL-2 versus the γ chain. In 1993, it was reported that the γ chain was defective in patients with X-linked severe combined immunodeficiency (XSCID; the disease is formally designated as SCIDX1) (26,120) (see also Chapter 46). XSCID is characterized by profoundly diminished numbers of T cells and NK cells (26,*36*,120,*121*,*122*,123,124), (Table 23.4). Although

▎ **TABLE 23.4 Features of XSCID**

1. Absent or profoundly diminished numbers of T cells and mitogen responses.
2. Absence of NK cells
3. Normal numbers of B cells, but defective B-cell responses.
4. IgM can be normal, but greatly diminished immunoglobulins of other classes.
5. XSCID carrier females exhibit nonrandom X-inactivation patterns in their T cells and NK cells; the X-inactivation pattern is random in surface IgM-positive B cells but nonrandom in more terminally differentiated B cells

the B cells are normal in number, they are nonfunctional, apparently because of a lack of T-cell help as well as an intrinsic B-cell defect (*36,123,125*). In contrast to the profoundly decreased number of T cells in patients with XSCID, IL-2–deficient patients *(126,127)* and mice *(128)* have normal numbers of T cells (the phenotypes of mice deficient in type I and type II cytokines and their receptor, Jak kinases, and STAT proteins are summarized later, in Table 23.15). This observation minimized the possibility that a component of the IL-2 receptor was defective in XSCID, making the finding that the γ chain was mutated in XSCID all the more unexpected. Thus, the conundrum was why a defect in a component of a receptor would be more severe than a defect in the corresponding cytokine. This led to the hypothesis that the γ chain was part of other immunologically important cytokine receptors as well (120). In this model, defective IL-2 signaling either did not contribute to the defects in XSCID or these defects were explained by the simultaneous inactivation of multiple signaling pathways, rather than from a selective IL-2 signaling defect (*36,120*). Initially, it was shown that the γ chain was also an essential functional component of both the IL-4 and IL-7 receptors on T cells (28,29,*30,31*), leading to it being renamed as the common cytokine receptor γ chain, γ_c (28,29). IL-9, IL-15, and IL-21 were subsequently also shown to share γ_c (26) (Figure 23.5).

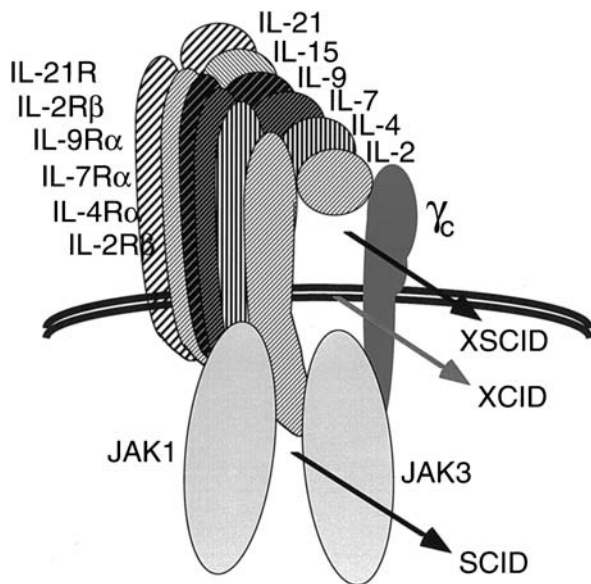
The sharing of γ_c by six different cytokine receptors revealed XSCID to be a disease of defective cytokine signaling. The major deficiencies in XSCID can be attributed


FIGURE 23.5 Schematic of the receptors for IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21, showing interactions with Jak1 and Jak3. The cartoon shows that IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21 all share γ_c. IL-2Rα and IL-15Rα are not shown. Whereas the distinctive chains associate with Jak1, γ_c associates with Jak3. Mutations in γ_c cause XSCID or more moderate forms of X-linked immunodeficiency (XCID). Mutations in Jak3 cause an autosomal recessive form of SCID (see text).

to defects related to different cytokines. Based on the dramatically diminished T-cell development not only in IL-7–deficient (72) or IL-7Rα–deficient mice (71), but also in *IL7R*-deficient humans with $T^-B^+NK^+$ SCID (129,*130*), yet normal T-cell development in mice deficient in either IL-2 *(128)*, IL-4 *(131,132)*, both IL-2 and IL-4 *(133)*, IL-9 (88), IL-15 *(100)*, IL-15Rα (99), and IL-21R (116,118), most if not all of the defect in T-cell development in patients with XSCID can be attributed to defective IL-7 signaling (26). In addition to profoundly diminished numbers of T cells, humans with XSCID lack NK cells. As discussed previously, NK-cell development is defective in IL-15– and IL-15Rα–deficient mice, indicating that it is defective IL-15 signaling that is responsible for the defective NK-cell development in XSCID (26).

In contrast to the greatly diminished number of T cells and absent NK cells in XSCID patients, B-cell numbers are normal. This is in marked contrast to the greatly diminished numbers of B cells in γ_c-deficient mice (134,135) and mice deficient in either IL-7 or IL-7Rα, indicating that IL-7 is not required for pre–B-cell development in humans and underscoring a major difference for IL-7 in human versus mouse biology. Indeed, *IL7R*-deficient SCID patients have a $T^-B^+NK^+$ form of SCID (129,*130*). Although B cells develop in XSCID patients, they are nonfunctional. This is due in part to a lack of T-cell help (given the near absence of T cells in XSCID), but a variety of data have suggested an intrinsic B-cell defect as well (26). As discussed earlier, analysis of IL-4/IL-21R double-knockout mice indicated that defective signaling by IL-4 and IL-21 appear to explain the intrinsic B-cell defect in XSCID.

Rationale for the Sharing of γ_c

Why should there have been evolutionary pressure to maintain the sharing of γ_c, given the obvious increased risk associated with sharing a receptor component when it is mutated? There are at least two different types of models *(36,136)*. First, given that IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21 can each act as T-cell growth factors, at least in vitro, it is possible that γ_c might couple to signal-transducing molecule(s) that promote T-cell growth. The second type of model is diametrically different, and suggests that the sharing of γ_c is a means by which one cytokine using γ_c can modulate the signals of the others. To understand this model, it is important to emphasize that, in contrast to antigen receptor complexes, cytokine receptor components are targeted individually to the cell surface, and the formation/stability of receptor complexes is dependent on ligand binding. This was suggested earlier in the discussion of the growth hormone receptor, wherein the second receptor monomer recognizes the combined surface of growth hormone and the first growth hormone receptor monomer (17) or for the IL-2 receptor where γ_c "sees" a combined IL-2/IL-2Rβ surface (21), consistent with γ_c originally having been identified in coprecipitates with IL-2Rβ in the

presence but not in the absence of IL-2 *(137)*, and dimerization of IL-2Rβ and γ_c is known to be required for efficient signaling (138,139). Thus, receptor heterodimerization at a minimum is stabilized by the cytokine and physiologically may be absolutely dependent on the presence of the cytokine. In the absence of stable preformed cytokine receptor complexes between γ_c and the other receptor chains, one can envision that γ_c might be differentially recruited to different receptors based on the relative amount of a cytokine or its binding efficiency. In a situation where γ_c is limiting, a cytokine might then not only induce its own action but could also simultaneously inhibit the action of another cytokine that was less efficient at recruiting γ_c to its cognate receptor complex.

An analysis of mice deficient in IL-2 *(128)*, IL-2Rα (140), IL-2Rβ (141), and γ_c (134, 135) provides the interesting observation that although the mice lacking γ_c have defective signaling in six different cytokine pathways, mice deficient in IL-2, IL-2Rα, and IL-2Rβ appear to be less healthy than the γ_c knockout mice with activated T cells and autoimmunity that is not evident in γ_c-deficient mice. This perhaps is explained by the fact that IL-2–deficient mice lack regulatory T cells and thus develop autoimmune disease, whereas γ_c-deficient mice lack T cells as a result of defective IL-7 signaling and thus lack effector T cells. These and other data indicate that γ_c plays a major role in regulating lymphoid homeostasis as originally indicated *(142)*.

Cytokines Whose Receptors Share the Common β Chain, β_c (IL-3, IL-5, and GM-CSF)

The hematopoietic cytokines, IL-3, IL-5, and GM-CSF (Table 23.5) are all synthesized by T cells and exert effects on cells of hematopoietic lineage (*143*,144,145). These cytokines are vital for proliferation as well as differentiation of myeloid precursor cells. Of these three cytokines, IL-3 is the most pluripotent (144) and historically was also called multi-CSF, reflecting the large number of lineages on which it can act. It can act to promote proliferation,

survival, and development of multipotent hematopoietic progenitor cells and of cells that have become dedicated to a range of different lineages, including granulocyte, macrophage, eosinophil, mast cell, basophil, megakaryocyte, and erythroid lineages. IL-3 also can exert end-function effects, such as enhancing phagocytosis and cytotoxicity. GM-CSF is mainly restricted to the granulocyte and monocyte/macrophage lineages, but its actions are nevertheless still quite broad *(143)*. It is both a growth and a survival factor. In addition, it can expand the number of antigen-presenting cells, such as dendritic cells, and thereby may greatly expand the ability of the host to respond to antigen. Whereas IL-3 and GM-CSF can act on eosinophils, they act at much earlier stages than IL-5, presumably expanding the number of eosinophil-committed precursors cells. IL-5 stimulates the eosinophilic lineage and eosinophil release from the bone marrow and is essential for expanding eosinophils after helminth infections *(146,147)*, and it can mediate the killing of *Schistosoma mansoni*. IL-5 can also induce immunoglobulin production in B cells activated by contact with activated Th cells in murine systems, and IL-5 and IL-5Rα knockout mice have diminished CD5$^+$ B1 cells and decreased thymocytes until approximately 6 weeks of age *(146,147)*.

On cells that express receptors for more than one of these cytokines, such as eosinophilic progenitors that express receptors for IL-3, IL-5, and GM-CSF, or on murine pre-B cells, which express receptors for IL-3 and IL-5, the signals induced are indistinguishable (144,145). Thus, the different lineage specificities of these cytokines are determined by the cellular distribution of their receptors rather than by fundamental differences in the signals that are induced by each cytokine. These observations are explained by studies demonstrating that each of these three cytokines has its own unique 60- to 80-kDa α chain (i.e, IL-3Rα, IL-5Rα, and GM-CSFRα) (148,*149–154*), but that they share a common 120- to 130-kDa β chain, β_c (145,*155,156,*157). The α chains are the principal binding proteins for the cytokines, whereas the shared β_c subunit augments binding affinity but does not exhibit binding activity in the absence of the proper α chain. The α chains have relatively short cytoplasmic domains

▌ **TABLE 23.5 Features of Cytokines Whose Receptors Share β_c**

Cytokine	Major Source	Size	Cellular Targets	Chr. Loc. (h/m)	Exons
IL-3	T cells	h152/19aa m166/26 aa 22–34 kDa	Multiple lineages	5q31.1/11	5
IL-5	T cells	h139/22aa m133/21 45-kDa dimer	Eosinophils B cells (?)	5 q31.1/11	4
GM-CSF	T cells	h144/17aa m141/17aa 23 kDa	Granulocytes Macrophages	5q31.1/11	4

(approximately 55 amino acids long for IL-3Rα, IL-5Rα, and GM-CSFRα) and are not believed to play major roles in signaling function, whereas β_c, with its cytoplasmic domain of 432 amino acids, is the primary determinant of the signal. As a result, there is a relative compartmentalization of binding and signaling function for these cytokines, although the cytoplasmic domains of the GM-CSFRα and IL-5Rα chains (and, by analogy, perhaps the IL-3Rα chain), as well as β_c, appear to be capable of at least modulating the growth signals in transfected cells (145,*158–160*). In any case, the sharing of β_c helps to explain why the signals induced by IL-3, IL-5, and GM-CSF are similar on cells that can respond to more than one of these cytokines. The situation for the β_c family of cytokines is therefore quite different from the receptors for γ_c family cytokines, wherein the chains with the largest cytoplasmic domains (IL-2Rβ, IL-4Rα, IL-7Rα, IL-9Rα, and IL-21R) not only contribute most to signaling specificity, but also are the proteins principally involved in ligand binding (note that in the case of IL-2 and IL-15, IL-2Rα and IL-15Rα serve important roles as well). The shared chain, γ_c, serves a vital accessory function (hence the development of XSCID when the *IL2RG* gene is mutated), but it contributes less to cytokine binding and does not provide an obvious basis for signaling specificity (see following).

An interesting feature of the β_c family of hematopoietic cytokines is that there appears to be considerable redundancy of function, so that knockout mice that lack the ability to respond to all three cytokines (GM-CSF, IL-3, and IL-5) as a result of deletion of β_c as well as the murine IL-3–specific β_c-like protein (discussed in the following) nevertheless exhibit relatively normal hematopoiesis. These observations do not minimize the potency of these particular cytokines, but instead underscore a substantial redundancy for a particularly important set of functions (144,145,*161*). It is also noteworthy that β_c-deficient mice exhibit defective host responses to infectious challenge, suggesting that these hematopoietic cytokines play a vital role in promoting immune function.

Cytokines Receptors That Share gp130 (IL-6, IL-11, Oncostatin M [OSM], Ciliary Neurotropic Factor [CNTF], Leukemia-Inhibitory Factor [LIF], Cardiotrophin-1 [CT-1], NNT/BSF-3/CLC, and IL-27)

There are now eight cytokines that are known to utilize gp130 as a signal-transducing molecule (162,*163–171*,172,173). Some of the properties of these cytokines are summarized in Table 23.6. This family is often referred to as the IL-6 family of cytokines and includes IL-6, IL-11, oncostatin M (OSM), leukemia-inhibitory factor (LIF), ciliary neurotrophic factor (CNTF), cardiotrophin-1 (CT-1), NNT/BSF-3/CLC, and IL-27. This group of cytokines comprises molecules with a diverse range of actions, ranging beyond the hematopoietic and immune systems to the central nervous and

[a]Most of the data in this table are derived from *(166)*.
  Note that NNT-1 can support survival of chicken embryonic and sympathetic neurons, can induce amyloid A and analogous to IL-6 can induce B-cell hyperplasia.

cardiovascular systems, making them even more "multifunctional" than the γ_c and β_c families of cytokines, which appear to exert actions largely restricted to the lymphoid and hematopoietic systems.

IL-6 was originally identified and then cloned as a B-cell differentiation factor that stimulated terminal differentiation/maturation of B cells into antibody-producing plasma cells (174,175). However, IL-6 also can exert effects for T-cell growth and differentiation (and thus is a thymocyte "comitogen"), induce myeloid differentiation into macrophages, induce acute-phase protein synthesis of hepatocytes, and exert actions on keratinocytes, mesangial cells, hematopoietic stem cells, the development of osteoclasts, and neural differentiation of PC12 cells (168). IL-6 is also a mediator of amplified lymphocyte trafficking during febrile inflammatory responses, which is dependent on IL-6–mediated activation of L-selectin (176). IL-6 binds to an 80-kDa IL-6–binding protein, denoted IL-6Rα, which has a comparatively short 82-amino acid–long cytoplasmic domain (175,177) This IL-6-IL-6Rα complex then interacts with and recruits the 130-kDa signal transducing molecule, gp130, which together with IL-6Rα can form a functional IL-6 receptor (168). From a structural perspective, gp130 contains a total of six fibronectin type III modules, with the four conserved cysteine residues and the WSXWS motif being located in the second and third of these modules, starting from the N terminus. As such, these regions are topologically positioned a greater distance external to the cell membrane than is the case for the other type I cytokine receptors discussed previously.

The IL-6 system illustrates a novel twist related to the properties of their principal binding proteins: the cytoplasmic domain of IL-6Rα is superfluous for signaling; a soluble form of the IL-6Rα extracellular domain is in fact sufficient for ligand binding and coordination with gp130, a process termed IL-6 trans signaling (178). Thus, in the presence of soluble IL-6Rα and IL-6, many cell types that express gp130 but not IL-6Rα are capable of signaling in response to IL-6. It was observed that IL-6 signaling requires the dimerization of gp130 and that the overall complex contains two molecules each of IL-6, IL-6Rα, and gp130 (a dimer of a trimer or a hexamer) (179–181,183), providing a possible paradigm for the stoichiometry of subunits for other members of the IL-6 family of cytokines.

IL-11 was identified as a factor produced by a stromal cell line in response to stimulation with IL-1 (184,185). It was noted to exert a number of effects on hematopoiesis, particularly in combination with IL-3 and stem cell factor. Because IL-11 exhibited "IL-6–like activities," a cDNA was isolated based on the presence of IL-6–like activity in the presence of antibodies to IL-6 (186). Other actions of IL-11 include the ability to stimulate the proliferation of lymphoid and hematopoietic progenitor cells, stimulate megakaryocytic progenitors and megakaryocyte maturation, and stimulate erythroid progenitors (an action

not shared by IL-6) (184,185). Like IL-6, IL-11 can induce acute-phase proteins and augment antigen-specific B-cell responses, but it does not stimulate human myeloma cells (184–187). Subsequently, adipogenesis-inhibitory factor was cloned and found to be identical to IL-11 (188), revealing another action of IL-11. IL-11 is also produced in the lung eosinophils and various structural cells in the lung, and is expressed in patients with modest to severe asthma (189). IL-11 signals via a receptor complex containing both IL-11Rα (190) and gp130 (162). Interestingly, IL-11Rα mRNA can be alternatively spliced to yield a form lacking the cytoplasmic domain, and, like IL-6Rα, a soluble form of IL-11Rα can coordinate with IL-11 to trans-signal in cells expressing gp130 (191). Studies on the stoichiometry of the IL-11 receptor complex failed to reveal dimerization of gp130 to itself or LIFRβ. Thus, assuming that it forms a hexameric receptor complex, only five members are known—two molecules of IL-11 and IL-11Rα, and one of gp130—suggesting that another component may still be found (192).

Leukemia-inhibitory factor (LIF) is another multifunctional cytokine originally cloned based on the activity associated with its name (193). LIF can suppress the differentiation of pluripotent embryonic stem cells, inhibit adipogenesis (like IL-11), and induce monocyte differentiation of the M1 murine leukemia cell line, thus mimicking a number of the actions of IL-6 (194). In addition, it exerts a number of actions in the central nervous system, and LIF was shown to be identical to cholinergic neural differentiation factor (CDF) (195). CDF can induce acetylcholine synthesis while simultaneously suppressing catecholamine production, thereby inducing cholinergic function while suppressing noradrenergic function (195). LIF has been shown to be essential for embryo implantations (196). LIF binds to a receptor (LIFRβ) that is structurally related to gp130 (197), but the functional LIF receptor requires the heterodimerization of LIFRβ and gp130 as well (164).

Ciliary neurotrophic factor was discovered based on its ability to promote neuronal survival (198,199). CNTF signals through a receptor comprising LIFRβ and gp130, but additionally requires a specific binding protein (200,201), now denoted CNTFRα. Interestingly, CNTFRα lacks transmembrane and cytoplasmic domains and instead is a glycosyl-phosphatidylinositol (GPI)–linked receptor molecule. CNTFRα appears to provide a receptor–cytokine surface with which gp130 and LIFRβ can interact. Thus, CNTF is like IL-6 in that each requires initial binding to a receptor component (CNTFRα or IL-6Rα) that does not require its own cytoplasmic domain for signaling. Whereas IL-6 signaling involves homodimerization of gp130, CNTF signaling involves the heterodimerization of LIFRβ and gp130. In fact, the functional CNTF receptor appears to be a hexameric structure containing two molecules of CNTF, two of CNTFRα, and one each of gp130 and LIFRβ

(202). The receptor is expressed largely within the nervous system and in skeletal muscle, accounting for largely restricted actions of CNTF (200).

Oncostatin M (OSM) is a growth regulator that was originally identified based on its ability to inhibit the growth of A375 human melanoma cells *(203,204)*. OSM is a potent growth factor for Kaposi sarcoma in patients with acquired immunodeficiency syndrome (AIDS) *(205,206)*. OSM can bind directly to gp130 and signals through a receptor combination of gp130 and LIFRβ *(164)*, but it also has an alternative receptor comprising a specific OSM receptor subunit (OSMRβ) and gp130 (207). These are now known as the type I and type II OSM receptors, respectively. OSM is now known to enhance the development of both endothelial cells and hematopoietic cells, possibly by increasing hamangioblasts, a common precursor for endothelial and hematopoietic cells *(169)*.

Cardiotrophin-1 (CT-1) was initially isolated based on its actions on cardiac muscle cells *(208)*. However, it is now clear that it is a multifunctional cytokine with hematopoietic, neuronal, and developmental effects, in additional to its effects on cardiac development and hypertrophy (209,*210*). Like OSM and LIF, CT-1 can also signal through a heterodimer of LIFRβ and gp130 *(167)*. Interestingly, the CT-1 receptor on motor neurons may involve a third receptor component, possibly GPI-linked *(211,212)*.

Novel neurotrophin-1/B-cell stimulatory factor-3 (NNT-1/BSF-3), like CNTF, can also support the survival of chicken embryonic sympathetic and motor neurons *(171)*. Interestingly, in mice, NNT-1/BSF-3 can augment the effects of IL-1 and IL-6 and is a B-cell–stimulating factor (hence the term BSF-3). The NNT-1 receptor contains LIFRβ and gp130 *(171)*. NNT-1 is also known as cardiotrophinlike cytokine (CLC), and this forms a complex with a soluble receptor protein known as cytokinelike factor-1 (CLF-1). Together this complex is a second ligand for CNTFR *(213)*. It appears that CLC can also interact directly with soluble CNTFR to form a related cytokine (172).

IL-27 is an IL-6–related cytokine (214) that represents a dimer of the p28 protein and EB13 (Epstein–Barr virus–induced gene 3), which can induce proliferation of naïve CD4$^+$ T cells. p28 was also denoted as IL-30 but by itself has no known biologic action. Together with IL-12, IL-23, CLC/CLF-1, and CLC/soluble CNTFR, this is one of five cytokines that represent dimers comprising a type I cytokine and a soluble receptorlike protein. IL-27 signals via the WSX-1/TCCR receptor (214); discussed later in the section on diseases of cytokine receptors and related molecules) and gp130. IL-27 has pro- and anti-inflammatory effects. Although it was suggested to promote Th1 responses, it is clear that it can also antagonize such responses, and IL-27 can promote effector responses of both CD4$^+$ and CD8$^+$ T cells, of NK cells, and it additionally stimulates mast cells. The anti-inflammatory effects of IL-27 are indicated

TABLE 23.7 Composition of Receptors for the IL-6 Family of Cytokines

Cytokines whose receptors do not contain LIFR β	
IL-6	IL-6Rα + gp130
IL-11	IL-11Rα + gp130
OSM	OSMRβ + gp130
Cytokines whose receptors contain LIFR β	
LIF	LIFRβ + gp130
OSM	LIFRβ + gp130
CNTF	CNTFRα + LIFRβ + gp130
CT-1	LIFRβ + gp130 + ?CT1Rα
NNT-1/BSF-3/CLC + CLF-1	CNTFRα + LIFRβ + gp130
CLC + soluble CNTFRα	LIFRβ + gp130
Cytokines whose receptors contain OSMR β	
OSM	OSMRβ + gp130
IL-31	IL-31R + OSMRβ

Note that the sharing of CNTFRα by CNTF and the dimeric NNT-1/BSF-3/CLC–CLF-1 ligand helps to explain why the phenotype in CNTF$^{-/-}$ mice is less severe than that found in CNTFR$\alpha^{-/-}$ mice.

by the phenotype observed in the absence of WSX-1, which includes in increased mast cell and macrophage responses (215,216).

Thus, eight cytokines (IL-6, IL-11, LIF, CNTF, OSM, CT-1, NNT-1/BSF-3, and IL-27) all have receptors that are dependent on gp130 (reviewed in 217). These can be divided into two sets of cytokines: those known to not require LIFRβ, namely, IL-6, IL-11, and IL-27; and those that use both gp130 and LIFRβ (LIF, CT-1, OSM, CNTF, and NNT-1/BSF-3) (see Table 23.7), with OSM having two forms of receptors, each of which contains gp130 but only one of which contains LIFRβ. When cytokines share essentially the same receptor, one can hypothesize that two cytokines might exert identical actions on cells that can respond to both cytokines. It is clear that the presence of IL-6Rα, IL-11Rα, and CNTFRα (either on the cell surface or as a soluble receptor form, discussed in the following) determines whether a cell can respond to IL-6, IL-11, and CNTF. This raises the interesting question of whether functional homologs of these proteins also exist for LIF, OSM, CT-1, NNT-1/BSF-3, and IL-27. As noted previously, a third, possibly GPI-linked component of the CT-1 receptor indeed may exist.

Significance of the Sharing of Receptor Chains

Interestingly, γ_c, β_c, and gp130 all contribute to signaling, but none of these shared cytokine receptor proteins has primary binding activity for any known cytokine. Instead, they each increase binding affinity in the context of the primary binding protein for each cytokine. Consequently, the capacity of a cell to respond to a given cytokine is determined by the unique binding chain, but signaling pathways can be shared.

Other Receptors with Similarities to gp130 (G-CSFR, OB-R, IL-12Rβ1, IL-12Rβ2, and IL-31R)

As noted earlier, LIFRβ and OSMRβ bear some similarities to gp130 (207). In addition, the G-CSFR, the leptin receptor (also denoted OBR, for obesity receptor), IL-12/IL-23 receptor components, and IL-31R all resemble gp130. The amino acid identity among these different receptors, compared pairwise, ranges from 18% to 32%, with LIFRβ and OSMRβ being the most similar.

Leptin

Leptin is the product of the obesity (ob) gene, an adipose tissue–derived cytokine that plays a role in body-weight homeostasis (*218,219,*220). Additionally, leptin affects thymic homeostasisis, increasing thymocyte number and having antiapoptotic effects in the thymus and periphery. It is proinflammatory, promoting Th1 differentiation, and augmenting the production of TNF-α, IL-1, and IL-6 by monocytes/macrophages (220). The leptin receptor, OB-R, was cloned and found to be most closely related to the gp130 signal transducer, G-CSFR, and LIFRβ *(221)*. Interestingly, this receptor is encoded by the "diabetes gene," which is mutated in db/db mice (222).

IL-12 and IL-23

IL-12 is primarily produced by phagocytic cells in response to bacterial and intracellular parasites, such as *Toxoplasma gondii,* but it is also produced by other antigen-presenting cells, such as B cells *(223)*. IL-12 potently induces the production of IFN-γ by NK cells and T cells and is also a growth factor for preactivated but not resting NK and T cells. IL-12 was originally discovered as natural killer cell–stimulatory factor (NKSF) *(224)*. IL-12 also is a unique inducer of Th1 cell differentiation (see below). IL-12 can also induce the production of IL-2, IL-3, GM-CSF, IL-9, TNF-α, and M-CSF, although inducing IFN-γ is its most important known action (*223,*225). As is discussed later, in the section on immunodeficiency diseases, IL-12 is essential for the proper clearing of mycobacterial infections.

IL-12 can be thought of as having vital roles in both innate immunity and acquired immune responses. It is rapidly produced by NK cells and then T cells in response to antigens or foreign pathogens. This rapid response facilitates the activation of first-line defense against infections. In addition, however, IL-12 is also required for the subsequent differentiation of specialized T-cell populations, including the priming of Th1 cells for optimal production of IFN-γ and IL-2. IL-12 can act synergistically with hematopoietic growth factors, such as IL-3 and stem cell factor, to support the proliferation and survival of hematopoietic stem cells *(223)*. Structurally, IL-12 is a covalently linked dimer of 35- and 40-kDa peptides *(223)*; thus successful production of IL-12 requires that a cell transcribe both the p35 and p40 genes *(226)*. Interestingly, whereas p35 bears sequence similarity to IL-6 and G-CSF, p40 is homologous to the extracellular domains of IL-6Rα, CNTFRα, and G-CSFR and bears some of the features typical of type I receptors, including four conserved cysteines, a conserved tryptophan, and a WSEWAS motif, which has similarity to the typical WSXWS motif *(223)*. Moreover, as both IL-12 receptor (IL-12Rβ1 and IL-12Rβ2) chains bear some similarity to gp130 *(224,226,227)*, one can think of p40 as a functional homolog of the soluble p80 IL-6Rα chain. Thus, for this cytokine, part of the "receptor" has become part of the cytokine. Interestingly, all cells that produce IL-12 synthesize much more p40 than p35, suggesting that the careful control of signaling is at the level of the "primordial" p35 cytokine part of IL-12. p40 is on human chromosome 5q31-33, whereas p35 is on 3p12-13.2 *(223)*.

IL-23 is similar to IL-12 in that it also contains p40 *(228)*. However, rather than also containing p35, IL-23 is a dimer of a p40 and p19. IL-23 signals via a receptor that contains IL-12Rβ1 but not IL-12Rβ2 (229). Instead, another receptor chain, denoted IL-23R, is the second component of the IL-23 receptor *(230)*; both IL-12Rβ2 and IL-23R are located on chromosome 1 within 150 kilobases (kb) of each other *(230)*. Both IL-12 and IL-23 activate Jak2 and Tyk2. IL-12 and IL-23 can activate Stat1, Stat3, Stat4, and Stat5. Stat4 is the dominant STAT protein activated by IL-12 *(230)*. Interestingly, as compared to human IL-23R, murine IL-23R contains a 20-amino acid–duplicated region that spans the WQPWS motif. IL-23 appears to play a vital role in the maintenance, rather than in the initial differentiation, of Th17 cells (IL-17–producing cells), and IL-23 is essential for resistance to certain diseases, such as experimental autoimmune encephalomyelitis (EAE), that were originally believed to be Th1-mediated diseases. In the CD40-mediated model of inflammatory bowel disease, IL-12 p35 secretion controlled wasting disease and serum cytokine production but did not affect mucosal pathology, which instead was associated with IL-23/p19 (231). IL-27 is a related cytokine (discussed earlier), but it can act as an inhibitor of Th1 responses associated with intracellular infections such as *Toxoplasma gondii*. Whereas host defense to *T. gondii* is dependent on IL-12 and IFN-γ, IL-27–deficient mice control the parasite replication but develop a lethal inflammatory disease that is dependent on CD4[+] T cells. Additionally, IL-27 can inhibit Th2 actions (216).

IL-31

IL-31 is a four–α-helical–bundle cytokine that fits into the greater IL-6 extended family in that its receptor consists of IL-31RA and the OSMRβ *(232)*. IL-31R is a gp130-like type 1 receptor, with four splice variants. IL-31 is produced

primarily by activated T cells, and when overexpressed results in pruritis, alopecia, and skin lesions, indicating a potential role in dermatitis.

Other Examples of Shared Receptor Molecules

IL-7 and Thymic Stromal Lymphopoietin (TSLP) Share IL-7Rα

In addition to IL-7, a second stromal factor, TSLP (originally called thymic stromal–derived lymphopoietin and now thymic stromal lymphopoietin) has been identified that shares at least some actions with IL-7 (233,234), and whose receptor is a heterodimer of TSLPR and IL-7Rα (235,236). Interestingly, TSLPR is a remarkable 24% identical to γ_c, making it the cytokine receptor most like γ_c (235). Human and murine TSLP share only 43% amino acid identity, and human and murine TSLPR share only 39% identity *(237)*. This is extremely low for human and murine orthologous cytokine receptors; for example, human and murine γ_c are 70% identical *(238)*. In addition to their wide sequence divergence, murine and human TSLP were originally suggested to differ substantially in their actions. The major actions of murine TSLP were first reported to be as a B-cell differentiation factor that is important for the development of IgM$^+$-immature B cells from pre-B cells and as a weak thymic comitogen. In contrast, human TSLP appeared not to exert effects on these lineages but was found to be an epithelial-derived cytokine that potently activated dendritic cells related to Th2 allergic responses, an action not known to be shared by murine TSLP (239,*240*,241). However, the differences are in fact not so dramatic, as it is now clear that mouse TSLP can also activate dendritic cells, it plays a critical role in both atopic disease and asthma in mouse models, and these murine effects of TSLP are mediated via actions on both dendritic cells and CD4$^+$ T cells (242–245). Interestingly, human TSLP is expressed by Hassall corpuscles *(246)*, and it appears to promote selection of T_{reg} cells in human thymus, thus contributing to central tolerance (247). It is interesting, however, that mice that lack TSLPR have normal numbers of T_{reg} cells, indicating that TSLP is not absolutely essential for this function and that other molecules can at least substitute for TSLP.

Two Types of IL-4 Receptors, One of Which Also Responds to IL-13

As detailed previously, on T cells, IL-4 acts through a receptor comprising IL-4Rα and γ_c (the type I IL-4 receptor) (29,*30*). However, IL-4 can also signal through type II IL-4 receptors that do not express γ_c (248). IL-13 is another cytokine that shares some actions with IL-4 and was originally described as a T-cell–derived cytokine capable of inhibiting inflammation (249), although it is now clear that other cells such as NK cells and mast cells can also produce IL-13. IL-13 can induce identical signals to IL-4 on non-T cells that respond to IL-4, but lacks effects on mature T cells, as these cells do not bind IL-13 *(250,251)*. The shared actions of IL-4 and IL-13 include the ability to (a) decrease expression of inflammatory cytokines, (b) induce MHC class II expression, (c) induce CD23 expression and IgE production by B cells in humans, (d) inhibit IL-2–induced proliferation of chronic lymphocytic leukemia cells of B-cell origin, and (e) costimulate with anti-CD40 antibodies. This is explained by the observation that the type II IL-4 receptor consists of IL-4Rα plus IL-13Rα1 (252,*253*), with both IL-4 and IL-13 inducing indistinguishable signals on cells expressing this receptor. Interestingly, IL-4 binds primarily to IL-4Rα and IL-13 binds primarily to IL-13Rα1. This situation may be analogous to the situation for LIF, CT-1, and OSM, which can all act through receptors containing LIFRβ and gp130 but differ in their abilities to interact directly with each of these receptor proteins. An additional IL-13–binding protein, IL-13Rα2, has much higher binding affinity for IL-13 than does IL-13Rα1 (254). IL-13Rα2 is nonfunctional in terms of signaling and instead acts as a "decoy" receptor.

Although IL-13 was originally believed to be redundant with IL-4, it clearly has important distinctive actions as well. IL-13 may be vital in asthma, as blocking IL-13 can inhibit pathophysiologic changes of asthma (*255,256*). It also is clear that IL-13 regulates eosinophilic infiltration, airway hyperresponsiveness, and mucus secretion, and that it is a potent mediator of fibrosis (249). The phenotype of IL-13 knockout mice suggested a role for IL-13 in the ability to expel helminths *(257)* and it is clear that IL-13 can specifically modulate resistance to intracellular organisms, including *Leishmania major* and *Listeria monocytogenes* (249). IL-13 has also been identified as a factor that is secreted by and can stimulate the growth of Hodgkin and Reed–Sternberg cells (258).

An Example of Multiple Affinities of Binding for a Single Cytokine: Three Classes of IL-2 Receptors

Although cytokines typically signal via a single class of high-affinity cell surface receptor, more complex situations exist. The IL-2 system provides the very interesting illustration of a system with three classes of affinities of receptors (Table 23.8). In addition to the high-affinity receptor (IL-2Rα + IL-2Rβ + γ_c, $K_d \approx 10^{-11}$ M), there are both low-affinity (IL-2Rα alone, $K_d \approx 10^{-8}$ M) and intermediate-affinity (IL-2Rβ + γ_c, $K_d \approx 10^{-9}$ M) receptors (reviewed in (25,*40*). Low- and high-affinity receptors are expressed on activated lymphocytes, whereas intermediate-affinity receptors are found on resting lymphocytes, particularly on natural killer cells. Both intermediate- and high-affinity

▎ **TABLE 23.8** Classes of IL-2 Receptors

Affinity	K_d	Where Expressed	Composition	Functional
Low	10^{-8} M	Activated cells	IL-2Rα	No
Intermediate	10^{-9} M	Resting cells	IL-2Rβ and γ_c	Yes
High	10^{-11} M	Activated cells	IL-2Rα, IL-2Rβ, and γ_c	Yes

receptors can signal, thus suggesting that IL-2Rβ and γ_c are necessary and sufficient for signaling, in keeping with the theme of dimerization indicated earlier. Given that the intermediate-affinity form is functional, what, then, is the rationale for having a high-affinity IL-2 receptor that also contains IL-2Rα? This is a particularly relevant question in view of the fact that IL-2Rα has an extremely short cytoplasmic domain that does not appear to play a role in signaling. The importance of IL-2Rα is clearly demonstrated by the severely abnormal phenotype of IL-2Rα–deficient mice, which exhibit autoimmunity, inflammatory bowel disease, and premature death (140), and by the recognition that IL-2Rα mutations can cause an autoimmune syndrome in humans as well (259). A clue to the importance of IL-2Rα comes from the kinetics of association of IL-2 with each chain. Although the IL-2Rα appears to lack a direct signaling function, it has a very fast "on" rate for IL-2 binding (260). Thus, the combination of this rapid "on" rate with the slow "off" rate from IL-2Rβ/γ_c dimers results in high-affinity binding that is vital for responding to the very low concentrations of IL-2 that are physiologically present in vivo. Moreover, as activated T cells express approximately 10 times as many low-affinity as high-affinity receptors, IL-2Rα may serve as an efficient means of recruitment and concentration of IL-2 on the cell surface, allowing more efficient formation of IL-2/IL-2Rβ/γ_c signaling complexes.

As mentioned earlier, IL-2Rα is not a type I cytokine receptor. In the mid-1980s, it was noted to have homology to the recognition domain of complement factor B (261). Subsequently, however, the IL-15 receptor α chain was shown to also have a similar structure (104), with both IL-2Rα and IL-15Rα having what are called "sushi" domains, which contribute to ligand binding. The fact that IL-2 and IL-15 both have related α chains is consistent with the close relationship between IL-2 and IL-15 and the fact that the receptors for both IL-2 and IL-15 contain both IL-2Rβ and γ_c.

As IL-2Rα cannot transduce a signal by itself, the detection of IL-2Rα on the cell surface does not necessarily reflect IL-2 responsiveness. Because IL-2Rα was discovered before IL-2Rβ and γ_c, many early papers in the literature evaluated IL-2 receptor expression based on IL-2Rα expression alone, and, for example, the presence of this protein on a subpopulation of double-negative thymocytes is a useful phenotypic marker corresponding to a stage of development, but it does not by itself reflect IL-2 respon-

siveness. Each of the components of the IL-2 receptor is located on a different chromosome: Human IL-2Rα is located on chromosome 10p14-15 (262); IL-2Rβ is at 22q (263,264), and γ_c is at Xq13.1 (120), while the murine homologs are located at chromosomes 2, 15, and X.

Erythropoietin, Thrombopoietin, and Stem Cell Factor

Erythropoietin is vital for erythropoiesis and thrombopoietin for thrombopoiesis. These cytokines each bind to receptors that are homodimers (19,265). Interestingly, erythropoietin signaling may depend in part on the functional cooperation of the erythropoietin receptor and c-kit, the receptor for stem cell factor (266). This latter receptor has intrinsic tyrosine kinase activity and is not a type I cytokine receptor.

CYTOKINE AND CYTOKINE RECEPTOR PLEIOTROPY AND REDUNDANCY

It is well recognized that many cytokines exhibit the phenomena of cytokine "pleiotropy" and "redundancy" (217). Cytokine pleiotropy refers to the ability of a cytokine to exert many different types of responses, often on different cell types, whereas cytokine redundancy refers to the fact that many different cytokines can induce similar actions. One set of cytokines that exhibits cytokine pleiotropy is the γ_c family of cytokines. For example, IL-2 can induce T-cell growth, augment B-cell immunoglobulin synthesis, increase the cytolytic activity of lymphokine-activated killer and natural killer cells, and play an essential role in mediating activation-induced cell death; IL-4 can induce B-cell growth and immunoglobulin class switch; and IL-7 plays a major role in thymocyte development, but also can stimulate mature T cells, and at least in the mouse, can act as a pre–B-cell growth factor. The gp130 family cytokines also exhibit broad actions. For example, IL-6 exerts effects ranging from that of a comitogen for thymocyte activation to that of a mediator of the acute-phase response in liver. Regarding cytokine redundancy, it has already been highlighted that IL-2, IL-4, IL-7, IL-15, and IL-21 whose receptors contain γ_c, can act as T-cell growth factors, and that IL-3 has actions that overlap with IL-5 and GM-CSF.

The recognition that cytokines not only have overlapping actions but also share receptor components led to

the concepts of "cytokine receptor pleiotropy" and "cytokine receptor redundancy" (reviewed in 217). The first of these terms can be defined by the ability of a single cytokine receptor subunit to function in more than one receptor. Thus, examples include the sharing of γ_c, β_c, gp130, IL-4Rα, LIFRβ, and OSMRβ, as summarized earlier, as well as the sharing of IL-2Rβ by IL-2 and IL-15 receptors, the sharing of IL4Rα and IL-13Rα in type II IL-4 receptors and IL-13 receptors, and the sharing of IL-7Rα by the IL-7 and TSLP receptors. Another way of viewing receptor pleiotropy is that certain receptor chains are useful "modules" that function in more than one context.

The final term, cytokine receptor subunit redundancy, is the one with fewest examples. There is one well-documented example in mice, but not humans. IL-3 signals through IL-3Rα plus either β_c or an alternative unique IL-3Rβ that shares 91% amino acid identity with β_c and appears to be a completely functionally redundant protein for IL-3 signaling, but IL-3Rβ cannot substitute for β_c in the context of IL-5 or GM-CSF signaling (157). Other potential examples exist. For example, in type I and type II IL-4 receptors, IL-4Rα coordinates with either γ_c or IL-13Rα, respectively, and there are two types of OSM receptors, both of which contain gp130, but one of which contains a specific OSMR while the other contains LIFRβ. What remains unknown, however, is whether the signals mediated by these different types of receptors are truly identical so that there is redundancy, or whether there are distinctive features to the signals that IL-4 and OSM induce via the different receptors.

In addition to the preceding examples related to type I cytokines, the IL-10 subfamily of type II cytokines is interesting in that IL-10Rβ, IL-20Rα, IL-20Rβ, and IL-22Rα are each shared components, collectively affecting signaling in response to IL-10, IL-19, IL-20, IL-22, and IL-24 (reviewed in 217 and references below related to the IL-10 family of cytokines). Specifically, IL-10 signals via a receptor containing IL-10Rα and IL-10Rβ, IL-19 signals via a receptor containing IL-20Rα and IL-20Rβ, IL-20 signals via receptors containing IL-20Rβ and either IL-20Rα or IL-22Rα, IL-22 signals via receptors containing IL-10Rβ and IL-22Rα, and IL-24 signals through receptors containing IL-20Rβ plus either IL-20Rα or IL-22Rα. Two other IL-10 family members, IL-28 and IL-29, both signal via IL-28R + IL-10Rβ (267).

SOLUBLE RECEPTORS

Soluble forms of many cytokine receptors have been identified, including those for IL-1, IL-2, IL-4, IL-5, IL-6, IL-7, IL-13Rα2, GM-CSF, type I and type II IFNs, IL-22, and TNF *(268–270)*. As is clear from this list of cytokines, soluble receptors are not restricted to receptors that are type I

▶ TABLE 23.9 Soluble Cytokine Receptors

sIFNAR-2	

cytokine receptors, and in the case of IL-2, the principal soluble receptor protein is IL-2Rα, which is not a type I cytokine receptor. Soluble receptors can be created by alternative splicing that truncates the protein N-terminal to the transmembrane domain, resulting in a secreted protein rather than a membrane-anchored membrane in the case of IL-4Rα, IL-5Rα, IL-6Rα, IL-7Rα, IFNAR-2, and GM-CSFRα. Alternatively, they can be created by proteolytic cleavage of the membrane receptor, as is found for the receptors for IL-2Rα and TNFRI and TNFRII (reviewed in *269*) (Table 23.9). Although it is theoretically possible that a distinct gene might encode the soluble forms of a receptor, no such examples have been reported. In the cases in which proteolytic cleavage occurs, the identity of the proteases has not been identified. The major questions related to these soluble receptors are these: (a) Do they have physiologic or pathophysiologic functions? (b) How do their affinities compare to those of the corresponding cell surface receptor? (c) Do they have diagnostic, prognostic, and therapeutic applications?

Unfortunately, there is little information available on the in vivo role of soluble receptors. In general, in in vitro studies, soluble receptors can compete with their corresponding cell surface receptors, thereby serving negative regulatory roles. For example, this appears to be the case for the IL-22–soluble receptor. However, soluble IL-6Rα exerts an agonistic role because, as summarized earlier, IL-6 signaling occurs equally well via gp130 when the soluble rather than the transmembrane form of IL-6Rα interacts with IL-6. Nevertheless, a mutated form of IL-6Rα that cannot interact with gp130 but still binds IL-6 can effectively inhibit the actions of IL-6 *(271)*. In the case of IL-2Rα, there is no reported physiologic function for soluble IL-2Rα, as the affinity of the released receptor is, as expected, similar to that of the low-affinity receptor ($K_d \approx 10^{-8}$ M), making it unlikely to effectively compete with the high-affinity cell surface receptor ($K_d \approx 10^{-11}$ M). However, this and other soluble receptors could serve as cytokine carrier proteins and potentially could increase stability of a cytokine by protecting it from proteolysis *(269)*. Moreover, there are potential diagnostic and prognostic uses for measuring the level of shed receptors (Table 23.10).

▶ **TABLE 23.10** **Soluble IL-2 Receptors in Human Disease**

Malignancies
Hematologic
  Adult T-cell leukemia (ATL)
  Hairy-cell leukemia
  Acute lymphocytic leukemia
  Chronic lymphocytic leukemia (B-cell) (CLL)
  Acute myelogenous leukemia (AML)
  Chronic myelogenous leukemia (CML), especially in blast crisis
  Malignant lymphomas
    Hodgkin's disease
    Non-Hodgkin's lymphomas
Nonhematologic
  Adenocarcinoma of lung, breast, pancreas
  Small-cell bronchogenic carcinoma
  Ovarian, cervical, and endometrial cancers
  Nasopharyngeal carcinoma
  Melanoma

Infections
  HIV
  Tuberculosis
  Rubeola
  Infectious mononucleosis

Other Diseases
  End-stage renal disease
  Rheumatoid arthritis
  Systemic lupus erythematosis
  Scleroderma
  Sarcoidosis
After transplantation
After IL-2 administration

In adults, the mean sIL-2Rα levels are 280 $\pm$ 161 U/mL (levels tend to be higher in pediatric populations). The situations where the levels exceed 5,000 U/mL are ATL, hairy-cell leukemia, CML, and after IL-2 administration. The situations where levels are between 1,000 and 5,000 units/ml include AML, CLL, non-Hodgkin's lymphomas, AIDS associated with Kaposi sarcoma, tuberculosis, rubeola, and end-stage renal disease. Data are from *(268,269)*.

INTERFERONS (TYPE II CYTOKINES) AND THEIR RECEPTORS

Interferons (IFNs) represent an evolutionarily conserved family (Table 23.11) of cytokines that are related to the IL-10 family of type II cytokines. IFNs were discovered in 1957 on the basis of their antiviral activity and were the first cytokines that were discovered (272). IFNs are known as either type I or type II IFNs (*273–277,278–282*), where type I interferons include IFN-α (originally known as leukocyte IFN) and IFN-β (originally known as fibroblast IFN), and IFN-ε, IFN-κ, IFN-ω, IFN-δ, and IFN-τ. IFN-δ and IFN-τ are absent in humans. IFN-ω is closely related to the IFN-α and was formerly designated as an IFN-α. There are multiple (at least 12) IFN-α in mice and humans. In contrast, the other type I IFNs, IFN-β and IFN-ω, are each encoded by single human and murine genes near the IFN-α clus-

ter, and in addition there are multiple pseudogenes most closely related to IFN-α and IFN-ω. The type I IFNs are clustered on human chromosome 9 and murine chromosome 4. Type II interferon is IFN-γ, which is encoded by a single gene on human chromosome 12 and murine chromosome 10. IFN-α/β is produced after viral infection in many cell types, although plasmacytoid dendritic cells appear to be the largest producers of IFN-α/β. These type I IFNs inhibit viral replication and induce the apoptosis of virally infected cells. In addition, IFN-α/β mediate the activation of macrophages and NK cells, and they additionally affect the proliferation and survival of CD8$^+$ T cells.

The grouping of the IFN-α and IFN-β together as type I IFNs is logical not only because of the similar amino acid sequences and structures of these IFNs, but also based on the fact that they share the same receptor and induce essentially the same signals *(283,284)*; although DNA array analysis does show some differences in the genes induced by IFN-α and IFN-β, the basis for these differences is unclear *(285)*. These signals include antiproliferative and antiviral activities, but also the ability to stimulate cytolytic activity in lymphoyctes, natural killer cells, and macrophages. In contrast, IFN-γ has a distinct receptor. Type I and type II IFN receptors share a sufficient degree of similarity to each other so as to form a family *(286)*. The structure of the IFN-γ receptor (287) is shown in Figure 23.2. IFN receptors are referred to as type II cytokine receptors to reflect the substantial differences between these receptors and the type I cytokine receptors *(8)*. Because both type I and type II IFNs bind to type II cytokine receptors, IFNs are occasionally referred to as type II cytokines, but more generally are referred to as IFNs. Based on the similarity of the IL-10 receptor to the IFN-γ receptors *(8)*,

IL-10 was designated as a type II cytokine, and indeed, when its x-ray crystal was determined, IL-10 was found to be topologically related to IFN-γ *(14)*. As noted earlier, more recently a series of IL-10–related cytokines has been identified, including IL-19, IL-20, IL-22, IL-24, IL-26, IL-28, and IL-29, and these are also designated as type II cytokines. Among type II cytokines, IFN-γ has helices similar to those of the type I short-chain helical cytokines, but its short helices that occupy the AB and CD loops positions exhibit the long-chain cytokinelike AB-over-CD topology. IL-10 and IFN-α/β have long-chain structures *(8)*. Thus, the theme of short-chain and long-chain type I cytokines also extends to the interferons and the IL-10 family of type II cytokines.

Type I IFNs signal through a receptor known as the type I IFN receptor *(274,278,280,282,283)*, The receptor consists of at least two chains *(288–291)*. In contrast to the α- and β-chain nomenclature typical for type I cytokine receptors, IFN receptor chains are officially denoted as IFNAR-1 (previously also denoted IFN-αR1, IFNAR1, and IFN-Rα) and IFNAR-2 (previously also known as IFN-α/β receptor [IFN-α/βR], IFN-αR2, IFNAR2, and IFN-Rβ) *(292)*. IFNAR-2 has both short and long forms as well as a soluble form *(293)*. The long form has a much larger cytoplasmic domain and serves a more important role in signal transduction. Whereas IFNAR-1 cannot bind IFN-α, IFNAR-2 binds with low affinity, and the combination of both chains results in high-affinity binding *(293)* and function. As detailed later, IFNAR-1 binds the Janus family tyrosine kinase Tyk2, whereas IFNAR-2 binds Jak1. In addition to these cellular receptors, it is interesting that vaccinia virus and other orthopoxviruses encode a soluble form of type I IFN receptor that is related to the IL-1 receptors and that is capable of binding IFN-α, IFN-β, and IFN-ω *(294,295)*. This form of IFN receptor is therefore not a member of the type II cytokine family but instead is an immunoglobulin superfamily protein. The IFN-α are typically species-specific, although IFN-α8 is a human type I IFN that can bind to the mouse receptor. IFNAR-1 confers species specificity of binding.

IFN-γ was first recognized more than 40 years ago, in 1965, as immune IFN, named as IFN-γ in 1980, cloned in 1982, and then confirmed to be the same as primary macrophage-activating factor (MAF) *(274,283, 296,297,298)*. Although IFN-γ clearly possesses antiviral activity, it also has a range of actions on proinflammatory and anti-inflammatory host responses (279) For example, IFN-γ can prime macrophages to manifest antimicrobial and antitumor effects. Moreover, following IL-12–mediated differentiation of Th1 cells, IFN-γ is a major secreted product. This production is critical for host response to a range of infectious pathogens, including, for example, *Toxoplasma gondii*. IFN-γ inhibits the generation of Th2 cells as well as Th17 cells. IFN-γ is produced by a range of cells, including T$_{reg}$ cells, and in this context

appears to result in apoptosis of naïve cells and Th2 effector T cells. It is produced by NK cells and can mediate NK-dependent lysis of tumor cells, augment IgG2a isotype switching of B cells, and activate dendritic cells. Moreover, IFN-γ can either contribute to disease protection or can be protective, depending on the context (298). Finally, IFN-γ– or anti-IFN-γ– based therapies are being tried for a range of conditions.

IFN-γ is encoded by four exons on chromosome 12. IFN-γ forms a functional homodimer with an apparent molecular weight of 34 kDa, whereas little of the monomeric form can be detected and it is not biologically active. Each IFN-γ monomer has six α helices, four of which resemble the short-chain helical cytokines, and there is no β-sheet structure. The subunits interact in an antiparallel fashion. In contrast to the ability of many different cells to produce IFN-α, IFN-γ is more restricted, with it being produced primarily by NK cells, CD8$^+$ T cells, and the Th1 subclass of CD4$^+$ T cells (reviewed in *274*). Many signals, including antigen stimulation, IL-12, and IL-18, can induce the production of IFN-γ. IFN-γ exerts its effects through specific receptors that are expressed on all types of cells except erythrocytes. Interestingly, even platelets express IFN-γ receptors, raising the possibility that they can serve a function in transporting IFN-γ in the circulation *(274)*. The functional human receptor consists of two chains *(299)*: IFNGR-1, formerly also denoted IFNγR1 or IFNγRα *(292,300)*, a 90-kDa protein whose gene is located on human chromosome 6q16-22 and murine chromosome 10 *(297)*; and IFNGR-2, also denoted as IFNγRβ *(301,302)*, located on human chromosome 21q22.1 and murine chromosome 16 *(297)*. IFNGR-1 is required for ligand binding, whereas IFNGR-2 plays a role in signaling. Jak1 associates with the Leu–Pro–Lys–Ser sequence in the membrane-proximal region of the cytoplasmic domain of IFNGR-1 *(303)*, whereas Jak2 binds to IFNGR-2 *(304)*. The fact that IFN-γ is a homodimer explains how its binding induces the homodimerization of IFNGR-1, which then allows the recruitment of IFNGR-2. Thus, the functional IFN-γ receptor is believed to contain two molecules each of IFNGR-1 and IFNGR-2. Normal IFN-γ production is dependent on IL-12, and defective IFN-γ signaling is associated with failure to appropriately clear mycobacterial and other infections (discussed later).

Interleukin-10, a Type II Cytokine, and the Related Cytokines IL-19, IL-20, IL-22, IL-24, IL-26, IL-28, and IL-29

IL-10 is a type II cytokine that is produced by activated T cells, B cells, monocytes, NK cells, keratinocytes, and dendritic cells (305). The IL-10 gene contains five exons and is located on chromosome 1 in both mice and humans (305). IL-10 has an open reading frame of 178 amino acids,

including the signal peptide, and the mature protein is 18 kDa. Human IL-10 receptor maps to 11q23.3. IL-10 can inhibit the production of a number of cytokines, including IL-2, IL-3, IFN-γ, GM-CSF, and TNF-α, and falls in the category of a Th2 cytokine (305) (see later). IL-10 originally was identified as cytokine synthesis-inhibitory factor (CSIF) (267,*306*), produced by Th2 cells. However, it is also clear that B cells and dendritic cells also produce IL-10. IL-10 inhibits monocyte/macrophage/dendritic cell-dependent T-cell proliferation, in part by markedly decreasing synthesis of a variety of cytokines, expression of costimulatory molecules, and chemokines, to name just some of its inhibitory effects (267). Nevertheless, in addition to these indirect effects on T cells, IL-10 appears to exert direct stimulatory effects on thymocytes and T cells in vitro and to promote the development of B1 cells and activity of NK cells. IL-10–deficient mice develop a form of inflammatory bowel disease that is similar to Crohn's disease (305,*307*). Interestingly, the BCRF1 protein that is encoded by Epstein–Barr virus is very similar to IL-10 and shares many of its biologic properties as a macrophage "deactivating" factor, and as a costimulator of proliferation of B cells *(308)*. The EBV IL-10 homolog is a selective agonist, although its binding to the IL-10 receptor is somewhat impaired *(308)*. IL-10 is a major inhibitor of Th1 functions (305). Although it was suggested that IL-10 might also favor Th2 development, IL-4 is established as the major mediator of Th2 cell development. IL-10 instead plays a major role in limiting and terminating inflammatory responses (305).

The IL-10 receptor is most closely related to IFN receptors, making it a type II cytokine receptor *(309,310)*, thus corresponding to the close structural relationship of IL-10 to IFN-γ. The receptor for IL-10 consists of an IL-10Rα chain and IL-10Rβ (305); this latter protein is the same as CRF2-4, which was first identified as an "orphan" IFN receptor family member that is located on chromosome 21 within 35 kb of IFNGR-2 *(311,312)*.

A series of IL-10-related cytokines has been been identified, including IL-19, IL-20, IL-22, IL-24, IL-26, IL-28, and IL-29 (313,*314–317*). Data on biologic roles of some of these proteins is still limited. IL-19 was discovered as a gene that was induced in LPS-stimulated monocytes. Analogous to IL-20, IL-19 has been suggested to potentially be involved in the pathogenesis of chronic inflammatory diseases, such as psoriasis. IL-20 was found in epidermal cells, with overexpression resulting in aberrant epidermal differentiation; it was suggested to have a role in psoriasis. IL-22 was found as an IL-9–induced cytokine that can in turn induce acute-phase reactant production by hepatocytes and accordingly that it might be involved in inflammatory responses. It is produced mainly by activated Th1 cells, but its target cells are primarily in the digestive and respiratory systems, as well as keratinocytes, and it appears to promote innate immunity *(318)*. IL-22 is also

produced by Th17 cells (318a). IL-24 was originally discovered as melanoma differentiation-associated antigen 7 (Mda-7). IL-24 is induced in peripheral blood mononuclear cells (PBMC) with mitogens. Overexpression of IL-24 can induce apoptosis in a wide range of tumor cells, including, for example, melanoma and malignant gliomas, and infection with adenoviral-driven Mda7 can sensitize tumors to ionizing radiation (267). IL-26 was originally discovered as AK155. Very little is known regarding the function of IL-26. IL-28 (which exists in two isoforms, IL-28A and IL-28B, originally also called IFN-λ1 and IFN-λ2) and IL-29 (originally also called IFN-λ3) are induced in plasmacytoid dendritic cells by viral infection and exhibit antiviral activity, analogous to type I IFNs; nevertheless, they bind to a receptor consisting of IL-10Rβ and IL-28Rα *(319)*. Interestingly, the genes encoding IL-10, IL-19, IL-20, and IL-24 collocalize at human chromosome 1q32, whereas those encoding IL-22 and IL-26 are at 12q14-15 near the *IFNG* gene, and IL-28 and IL-29 are at 19q13 (267,*320*). Thus, these type II cytokines can be subdivided into three different groups based at least in part on chromosome localization.

SPECIES SPECIFICITY OF CYTOKINES

There are no general rules for the species specificity of human and murine cytokines and how the cytokines and their receptor chains have coevolved. To provide illustrative examples of each situation, human IL-2 can stimulate both human and murine cells, whereas murine IL-2 exhibits little action on human cells *(39)*. Conversely, human IL-12 does not work on murine cells, whereas murine IL-12 is biologically active on both murine and human cells *(223)*. This selective property of IL-12 is dependent on the species origin of p35. Finally, IL-4 exhibits rather strict specificity, so that human and murine IL-4 only induce responses on human and murine cells, respectively *(61,62)*. As noted previously, the IFN-α are generally specifies-specific, although IFN-α8 is not. In addition to these examples, varying degrees of relative species specificity have been demonstrated, depending on the cytokine; in other words, at times a cytokine from one species will work on another species, but with attenuated potency. Thus, virtually any combination of species specificities has been observed.

SIGNALING THROUGH INTERFERON AND CYTOKINE RECEPTORS

Our understanding of signaling through interferon and cytokine receptors has increased tremendously in the past few years. Multiple signaling pathways/molecules have been observed for various cytokines. Collectively, these include the Jak-STAT pathway, IRF family proteins, Ras-MAP kinase pathway, Src and Zap70 and related proteins, phosphatidyl inositol 3-kinase (PI 3-kinase), IRS-1 and IRS-2,

and phosphatases. Each of these pathways will be discussed in turn. The Jak-STAT pathways are very important for both type I and IFNs/type II cytokines, whereas the IRF proteins play central functions, more so for the IFNs than type I cytokines.

OVERVIEW OF JAKS AND STATS

The Jak-STAT pathway (26,*283*,321,322,*323*,324), serves as a rapid mechanism by which signals can be transduced from the membrane to the nucleus. Jak kinases are known as Janus family tyrosine kinases, and the acronym STAT denotes "signal transducer and activator of transcription." STAT proteins are substrates for Jak kinases. A tremendous amount of information is now available on Jaks and STATs that demonstrates their importance related to development, differentiation, proliferation, cellular transformation, and tumorigenesis.

Jaks

The Jak kinases are 116 to 140 kDa and comprise approximately 1 150 amino acids (*283*,322). The seven regions of conserved sequences in Jak kinases, denoted JH1 to JH7, are depicted in Figure 23.6. One of the hallmark features of these kinases is that, in addition to the presence of a catalytic tyrosine kinase domain (JH1), there is also a pseudokinase region (JH2). The name Janus kinase reflects the two faces of the mythological Roman god, with one face representing the true kinase and the other the pseudokinase. Although the JH nomenclature was used historically, it has obvious limitations in that, except for the JH1 catalytic domain and JH2 pseudokinase domain, it remains unclear whether the other JH regions correspond to discrete domains. Modeling has indicated five important regions, including an N-terminal domain, a FERM (4.1,

TABLE 23.12 Features of Janus Family Kinases				
Kinase	Inducible vs. Constitutive	Size	Chromo. Loc. (h/m)
Jak1	Constitutive	135 kDa	1p31.3/4
Jak2	Constitutive	130 kDa	9p23-24/19
Jak3	Inducible	116 kDa	19p13/8
Tyk2	Constitutive	140 kDa	19p13.2/9

ezrin, radixin, moesin) domain, SH2, kinaselike (which spans two of the JH domains), and kinase domains *(325)*.

There are four mammalian Jak kinases, Jak1 *(326)*, Jak2 *(327)*, Jak3 *(328,329)*, and Tyk2 *(330)*, each of which was identified as part of a study intended to identify new kinases (322). At least one Jak kinase is activated by every IFN and cytokine, and some cytokines activate two or three Jak kinases (*283*,321,322,*323*). Table 23.12 lists a number of features of each Jak kinase, whereas Table 23.13 summarizes the Jak kinases that are activated by a variety of cytokines.

Because Jak1, Jak2, and Tyk2 are expressed ubiquitously, each cell type expresses either three or in some cases all four Jak kinases (e.g, lymphoid cells that also express Jak3). The Jak kinases that are activated by a specific cytokine are those that can bind to its receptor's cytoplasmic domain. Jak kinases physically bind to the membrane proximal Box 1/Box 2 region of the cytoplasmic domains *(329–332,333,334)* and the N-terminal region of the Jaks is required for this function (*335,336,337*). In cytokine receptors, the Box 1 region is proline-rich *(22)*, suggesting that Jak kinases may have SH3-like domains in their N-terminal regions to mediate these interactions. As each cytokine or IFN receptor is a homodimer, heterodimer, or higher-order oligomer, it is reasonable to assume that at least two Jak molecules (either two molecules of one Jak or one molecule each of two different Jaks) typically will be activated, as one Jak will be associated with each
FIGURE 23.6 Schematic of Jak kinases. Shown are the locations of the seven JH domains. JH1 is the catalytic domain. JH2 is the pseudokinase domain, the presence of which prompted the naming of this family as Janus family tyrosine kinases. As noted in the text, the JH nomenclature has limitations and in fact masks the presence of an SH2 domain that spans parts of the JH4 and JH3 domains. Also shown is the conserved tyrosine (Y1007 in Jak2), whose phosphorylation is required for maximal catalytic activity.

▌**TABLE 23.13** **Cytokines and the Jaks They Activate**

Cytokine	Jak Kinase(s) Activated
IFNα/β	Jak1, Tyk2
IFNγ	Jak1, Jak2
Growth hormone	Jak2
Prolactin	Jak2
Erythopoietin	Jak2
Thrombopoietin	Jak2
IL-10	Jak1, Tyk2
IL-12, IL-23	Jak2, Tyk2
G-CSF	Jak1, Jak2
γ_c family	
IL-2, IL-4*, IL-7, IL-9, IL-15, IL-21	Jak1, Jak3
β_c family	
IL-3, IL-5, GM-CSF	Jak2, ?Jak1
gp130 family	
IL-6, IL-11, CNTF, LIF, OSM, CT-1	Jak1, Jak2, Tyk2
TSLP	Instead of Jaks, TSLP was suggested to activate a Tec family kinase *(575)*

Note that IL-4 activates Jak1 and Jak3 when it acts through the type I IL-4 receptor (IL-4Rα + γ_c, found for example on T cells). However, Jak3 is not activated when IL-4 signals through the type II IL-4 receptors (IL-4Rα + IL13Rα1, a form of receptor that is expressed on a number of non-T cells, including fibroblasts).

receptor chain. In accord with their ubiquitous expression, Jak1, Jak2, and Tyk2 are activated by a variety of different sets of cytokines (Tables 23.12 and 23.13). For example, Jak1 is activated not only by type I and type II IFNs, but also by the γ_c family of cytokines (e.g, IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21), whereas Jak2 is activated not only by IFN-γ but also by growth hormone, erythropoietin, prolactin, and the hematopoietic cytokines, IL-3, IL-5, and GM-CSF (321,322). Tyk2 is somewhat more restricted in that it is activated by IFN-α/β and IL-12/IL-23; the significance of its activation by gp130 family cytokines is less clear. Interestingly, Jak1, Jak2, and Tyk2 are recruited by each of the cytokine receptors that share gp130 as a signal-transducing molecule, raising the question of whether these cytokines require all three Jak kinases for optimal function or whether any one or two is/are sufficient. At least for IL-6, Jak1 is absolutely vital (338,339), whereas the importance of Jak2 and Tyk2 is less clear.

Jak3 is different from the other Jak kinases in that it is much more inducible. Moreover, Jak3 is activated only by the cytokines whose receptors contain γ_c (26,36). It is interesting that each cytokine whose receptor contains γ_c activates not only Jak3 but also Jak1. The basis for the activation of both Jak1 and Jak3 by IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21 is that Jak1 associates with each of the unique signaling chains (IL-2Rβ, IL-4Rα, IL-7Rα,

IL-9Rα, and IL-21R), whereas Jak3 associates with γ_c (26,36). Although this could be a coincidental result of coevolution of these cytokine systems, these observations raise the possibility that Jak1 is the Jak kinase that can most efficiently functionally cooperate with Jak3.

Given the wide range of cytokines that activate any particular Jak kinase and that in some cases multiple cytokines can activate the same set of Jaks, it is clear that the Jak kinases by themselves do not determine signaling specificity. For example, IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21 all activate Jak1 and Jak3, but induce a range of actions. Moreover, Jak2 is the only Jak kinase that is activated by growth hormone and erythropoietin, cytokines with different target cells and biologic functions. Interestingly, Jak2 is the Jak that interacts with all cytokine receptors that form homodimers. Given that homodimeric receptors are most likely the oldest cytokine receptors in evolution, this suggests that Jak2 might be the "primordial" Jak kinase from which others evolved.

Importance of Jak Kinases in Signaling

In addition to the activation of Jak kinases by multiples cytokines and interferons, a variety of other data indicate their importance for signaling. One of the vital series of experiments that led to the establishment of the critical role of Jak kinases in IFN signaling involved a group of mutant cell lines that were defective for interferon signaling, but wherein signaling could be rescued by genetic complementation (reviewed in 283). Defective signaling in response to IFN-α and IFN-β was found in a mutant fibroblast cell line (U1 cells) lacking Tyk2; defective signaling in response to IFN-α, IFN-β, and IFN-γ was found in a mutant cell line lacking Jak1 (U4 cells), and defective IFN-γ signaling was found in cells lacking Jak2 *(283)*. A variety of other data have indicated the importance of Jak kinases for other cytokine pathways. First, dominant negative Jak2 inhibits signaling by erythropoietin and growth hormone *(340,341)*, whereas a dominant negative Jak3 inhibits signaling in response to IL-2 *(342)*, and, as noted earlier, Jak1 is vital for IL-6 signaling. Second, humans (343,344) and mice (345,346,347) that are deficient in Jak3 exhibit developmental and signaling defects consistent with defective signaling. Third, humans with an activating mutation in Jak2 develop polycythemia vera *(348)*, and a Jak2 inhibitor inhibited the growth of acute lymphoblastic leukemia cells in vitro *(349)*. Fourth, a patient with mutation in Tyk2 developed a form of immunodeficiency (350). Fifth, in *Drosophila,* the *hopscotch* gene encodes a Jak kinase wherein loss-of-function alleles result in lethality and decreased proliferation, whereas a gain-of-function allele, *hopscotch*^*Tumorous-lethal* results in melanotic tumors and hypertrophy of the hematopoietic organs (351,352). Sixth, in zebrafish, Jak1 is vital for normal cell migration and anterior specification *(353)*.

Seventh, as discussed later, Jak kinases are constitutively activated in many cell lines infected with a number of viruses, including HTLV-I, v-Abl, spleen focus forming virus, and with v-src (354,*356*,357). These data together underscore the vital roles of Jaks in cytokine signaling. Depending on the function of the particular cytokine (e.g, development, differentiation, or proliferation), the particular Jak kinases potentially may be involved in a variety of processes, and when dysregulated, in at least certain settings, they appear to contribute to cellular transformation.

Jak3 Mutations Result in an Autosomal Recessive Form of Severe Combined Immunodeficiency (SCID) That is Indistinguishable from XSCID

A very large number of different mutations in γ_c have been observed in XSCID. As might be expected, in cases in which it has been examined, amino acid substitutions in the extracellular domain result in defective cytokine binding. In contrast, mutations or truncations in the γ_c cytoplasmic domain result in defective signaling. Analysis of a family in which a number of males exhibit a moderate form of X-linked combined immunodeficiency (XCID) revealed that this disease also resulted from a mutation in γ_c (32), (Leu 271 → Gln), that resulted in a decrease, but not total loss, of Jak3 association, in contrast to the loss of Jak3 interaction seen with mutations in the γ_c cytoplasmic domain that cause XSCID. Thus, the severity of the immunodeficiency correlated inversely with the degree of Jak3 activation (26,*36*). Moreover, it was predicted that Jak3 was required for T-cell and NK-cell development and that mutations in Jak3 might result in a clinical phenotype indistinguishable from that in XSCID (32). Indeed, this is the case in humans (343,344). As one would hypothesize, many mutations in Jak3 have been identified (322). Presumably, any mutation that interferes with its ability to interact with γ_c, with its catalytic activity, or with recruitment of substrates could result in clinical disease, ranging from moderate to severe immunodeficiency.

Analogous to the similarity of XSCID and Jak3-deficient SCID, mice deficient in either γ_c or Jak3 also have indistinguishable phenotypes (134,135,345,346,*347*). These in vivo data underscore the vital role of Jak3 in mediating γ_c-dependent functions and suggested that Jak3 is essential for most if not all γ_c functions. Some in vitro data indicate that γ_c may do more than recruit Jak3 *(342,358)*, and interestingly γ_c can interact with calpain *(359)*, but the recruitment of Jak3 is clearly essential and the defects in T-cell and NK-cell development associated with γ_c or Jak3 deficiency are indistinguishable. Because Jak3 deficiency is not clincially or phenotypically more severe than γ_c deficiency in humans and mice, it seems likely that γ_c is the major, if not only, protein with which Jak3 associates. Although Jak3 was suggested to associate with CD40 *(360)*, a functional role for Jak3 in CD40 signaling has been questioned *(361)*. The phenotypes of mice lacking each of the four Jak kinases are summarized in Table 23.14.

Jak2 Mutations and Translocations

The Jak2V617F mutations has now been identified in the vast majority of patients with polycythemia vera (*348*,362), some of whom had homozygous and some had heterozygous mutations. The homozygous patients had duplications of the mutated allele. This mutation results in a constitutively activated kinase and presumably confers factor-independent growth, something that has been demonstrated in transfected cell lines. Moreover, polycythemia patients exhibit erythropoietin-independent BFU-E. Furthermore, the *JAK2* locus is involved in a chromsomal translocation to create the TEL-JAK2 protein that is causally related to a human leukemia (363), further underscoring the relationship of Jak2 to the growth of hematopoietic cells.

Tyk2 Mutations and Human Immunodeficiency

A mutation in Tyk2 has now been identified in a patient with primary immunodeficiency (350). The patient had clinical defects more severe than anticipated from Tyk-deficient mice, with increased susceptibility to viral infections and atypical mycobacterial infections and defective signaling in response to IL-23, IL-6, and IL-10. Additionally, the patient had hyper IgE production, which perhaps corresponds to enhanced Th2 cell-mediated allergic inflammation in Tyk2$^{-/-}$ mice (364). Because this was a single patient, it remains to be determined if other individuals with Tyk2 deficiency will have this full range of clinical problems.

ACTIVATION OF JAKS AND THE JAK-STAT PARADIGM

The paradigm of Jak-STAT activation is shown in Figure 23.7, which also shows activation of other pathways, such as the Ras-MAP kinase and PI 3-kinase/Akt/p70 S6 kinase pathways. Following interferon or cytokine engagement, dimerization or higher-order oligomerization of receptor complexes is induced. This in turn allows the juxtapositioning of Jak kinases, facilitating transphosphorylation and activation. In receptors with only two chains, the direct transphosphorylation of one Jak by the other seems likely to occur. In more complex receptors, such as the IFN-γ system, because the receptor is a heterotetramer with two IFNGR-1 chains that each bind Jak1 and two IFNGR-2 chains that each bind Jak2, it is not clear if Jak1 and Jak2 transactivate each other or if one of the

▌**TABLE 23.14 Phenotypes of Mice Deficient in Type I and Type II Cytokines, Their Receptors, STATs, and Jaks**

Type I cytokines and their receptors

γ_c Family

IL-2 (*128,576*,577)	Normal thymic and peripheral T-cell development. Decreased polyclonal T-cell responses in vitro, but more normal in vivo responses to pathogenic challenges. Autoimmunity with marked changes in levels of serum immunoglobulin isotypes. Ulcerative colitis–like inflammatory bowel disease.
IL-4 *(131,132)*	Defective Th2 cytokine responses and class switch; defective IgG1 and IgE production.
IL-2/IL-4 *(133)*	Some features of both IL-2 and IL-4 knockout mice. No gross abnormalities of T-cell development.
IL-7 *(72)*	Greatly diminished thymic and peripheral T-cell development and B lymphopoiesis, resulting in profound lymphopenia.
IL-9 (88,*90*)	No T-cell defect. Defect in pulmonary goblet cell hyperplasia and mastocytosis following challenge with *Schistoma mansoni* eggs. No defect in eosinophilia or granuloma formation.
IL-15 *(100)*	Defective NK-cell development. Defect in CD8 memory T-cell homeostasis.
IL-2Rα (140)	Normal initial lymphoid development, but massive enlargement of peripheral lymphoid organs, polyclonal T- and B-cell expansions, and activated T cells, with impaired activation-induced cell death. Autoimmunity with increasing age, including hemolytic anemia and inflammatory bowel disease.
IL-2Rβ (141)	Severe autoimmunity including autoimmune hemolytic anemia. Die within approximately 3 mo. Deregulated T-cell activation. Dysregulated B-cell differentiation and altered immunoglobulin profile.
γc (134,135)	Greatly diminished thymic development but double negatives, double positives, and single positives all represented. Age-dependent accumulation of peripheral CD4$^+$ T cells with an activated memory phenotype. Greatly diminished numbers of conventional B cells, although B1 cells are present. No NK cells or $\gamma\delta$ cells. Absent gut-associated lymphoid tissue, including Peyer patches.
IL-4Rα *(578)*	Like IL-4$^{-/-}$ mice, they have defective Th2 cytokine responses and class switch; defective IgG1 and IgE production. In addition, they cannot expel *Nippostrongylus brasiliensis,* presumably because of defective IL-13 signaling.
IL-7Rα (71)	Greatly diminished thymic and peripheral T-cell development and B lymphopoiesis, resulting in profound lymphopenia.
IL-15Rα (99)	Defective NK-cell development. Defect in CD8 memory T cell homeostasis.
IL-21 (115a)	Normal development, defective Th17 development.
IL-21R (116,118,115c)	Normal development, diminished IgGI and elevated IgE, particularly after immunization. Defective Th17 development.
IL-4Rα/IL-21R (116)	Panhypogammaglobulinemia, with absent IgE production. Defective germinal center development with diminished or absent tingible body macrophages.
IL-13 *(257)*	Defective Th2-cell development and the ability to expel helminths.

β_c Family

IL-5 *(146)*	Decreased basal level of eosinophils and defective induction of eosinophils following infectious challenge. Developmental defect in CD5$^+$ B1 cells. Normal antibody and cytotoxic T-cell responses.
GM-CSF *(579,580)*	Normal basal hematopoiesis. Unexpected abnormalities of the lung; abnormal pulmonary homeostasis.
IL-3Rβ (581)	No defects (due to redundant function of β_c).
β_c (*161*,581)	Defective responses to IL-5 and GM-CSF, but normal responses to IL-3 (because of redundant function of IL-3Rβ). Diminished eosinophils—both basal levels and in responses to infectious challenge. Unexpected abnormalities of the lung characterized by pulmonary proteinosis and reduced phagocytosis by alveolar macrophages. In other words, the defects are a combination of those found in the IL-5– and GM-CSF–deficient mice.
IL-3Rβ + β_c double knockout (581)	Same phenotype as β_c-deficient mice, except that they cannot respond to IL-3.

gp130 Family

IL-6 *(582)*	Impaired acute-phase responses following infection or tissue damage. Decreased numbers of hematopoietic progenitor cells.
gp130 (583,584)	Embryonic lethal. Extreme hypoplastic development of the myocardium; although the ventricular wall was very thin, traveculation within the ventricle chamber was normal. Hematologic abnormalities characterized by greatly reduced CFU-S and somewhat reduced CFU-Gm and BFU-E. Markedly diminished size of thymus and numbers of thymocytes. Reduced primordial germ cells in embryonic gonads. Diminished size of placenta.
LIF *(585–587)*	Decreased hematopoietic progenitor cells. Normal sympathetic neurons but deficient neurotransmitter switch in vitro. Defective blastocyst implantation.
LIFRβ *(588,589)*	Postnatal lethality. Normal hematopoietic and germ-cell compartments, but multiple neurologic, skeletal, placental, and metabolic defects. The greater severity than found in LIF-deficient mice reflects that LIFRβ is shared by several cytokines, including CNTF, LIF, OSM, and CT1.
CNTF *(590)*	Progressive atrophy and loss of motor neurons.
CNTFRα *(591)*	Severe motor neuron–deficient, resulting in perinatal mortality. The more severe phenotype than in CNTF-deficient mice was unexpected and suggests that another cytokine may utilize CNTFRα.
IL-11Rα *(592)*	Blastocysts can implant but decidulaization cannot occur, associated with failure of pregnancy. Fetal lethal phenotype.
IL-12 p40 *(593)*	Impaired but not completely lacking in ability to produce IFNγ and to mount a Th1 response in vivo. Elevated secretion of IL-4, normal production of IL-2 and IL-10. Substantially decreased CTL responses. Resistant to infection with intracellular pathogens.
IL-12Rβ 1 *(594)*	Defective IL-12 signaling. IL-2 but not IL-12 could augment NK activity. Defective IFNγ production in response to ConA or anti-CD3. Severe defect in Th1 differentiation.

▎**TABLE 23.14 Phenotypes of Mice Deficient in Type I and Type II Cytokines, Their Receptors, STATs, and Jaks** (Continued)

IL-12 p35 (553,*595*)	Selective loss of IL-12 function without loss of IL-23. Less resistant to infection than p40 and IL-12Rβ 1 knockouts.
IL-12Rβ2 (*596*)	Selective loss of IL-12 function without loss of IL-23. Less resistant to infection than p40 and IL-12Rβ 1 knockouts.
IL-23 p19 (553,*597*)	Complete resistance to EAE, defective DTH response.
Epo, Tpo, G-CSF, and M-CSF	
Epo *(598)*	Embryonic lethal. Complete block of fetal liver erythropoiesis, resulting in severe anemia, yet normal development of BFI-E and CFU-E progenitor cells.
EpoR *(599)*	Same as Epo-deficient mice.
TpoR *(600)*	Decreased megakaryocytes and platelets, but other hematopoietic cells are present in normal numbers.
G-CSF *(601)*	Neutropenia and impaired neutrophil mobility. Diminished granulocytes, and macrophage precursors.
M-CSF *(602,603)*	Osteopetrosis, absence of teeth. Females are infertile, suggesting an unexpected role for M-CSF.
M-CSF + GM-CSF *(603)*	A combination of defects of both M-CSF and GM-CSF, with osteopetrosis and alveolar proteinosis. Die early of pneumonia.
Type II cytokines and their receptors	
IFNAR-1 *(604–606)*	Normal development. Defective immune defense against most viral infections tested, including lymphocytic choriomeningitis virus, Semliki Forest virus, Theiler virus, vesicular stomatitis virus. Normal resistance to *Listeria monocytogenes, Lesihmania major, Mycobacterium bovis* and *avium*.
IFNγ *(607–609)*	Normal lymphoid development. Impaired resistance to *Listeria monocytogenes, Lesihmania major, Mycobacterium bovis* and *avium*. Can mount curative responses to a number of viruses. CD4$^+$ effector cells default to the Th2 pathway after infection with *Leishmania*. Succumb to infection with *Toxoplasmosis gondii*.
IFNGR-1 *(605,606,610)*	Normal lymphoid development. Impaired resistance to *Listeria monocytogenes, Lesihmania major, Mycobacterium bovis* and *avium*. Can mount curative responses to a number of viruses.
IL-10 (305,*307*)	Normal lymphocyte development and antibody responses. Chronic entercolitis, anemia, and growth retardation. Augmented inflammatory responses.
STATs and Jaks	
Stat1 (*426*,427)	Defective responses to both type I and type II IFNs. Defective response to certain viruses and bacterial antigens.
Stat2 *(428)*	Defective signaling in response to type I IFNs; interestingly, the defect is not as severe in Stat2-deficient macrophages as it is in Stat2-deficient fibroblasts.
Stat3 *(429–433)*	Embryonic lethal. Embryos implant but cannot grow. The fact that this phenotype is even more severe than that seen with gp130 suggests a role for Stat3 via a gp130-independent cytokine. By Cre-lox methodology, Stat3 was also selectively targeted in T cells, which exhibit defective IL-2–induced proliferation that correlates with a defect in IL-2–induced IL-2Rα expression; as expected, T cells also exhibit defective signaling in response to IL-6. Stat3-deficient neutrophils and macrophages show defective IL-10 signaling. Stat3 is also essential for normal involution of the mammary epithelium, for wound healing, and for normal hair-cycle processes. Stat3-deficient DC exhibit defective Flt3L-dependent expansion of DC.
Stat4 (435,436)	Defective Th1 development. Essentially the same phenotype as in IL-12–deficient mice, including defective IL-12–mediated boosting of NK-cell cytolytic activity.
Stat5a (385,*440*)	Defective lobuloalveolar development in the mammary gland, a syndrome resulting from defective prolactin signaling. Defective IL-2–induced IL-2Rα expression and associated defects in IL-2–induced T-cell proliferation. Defective superantigen-induced expansion of Vβ 8 T cells. Defective antigen-induced recruitment of eosinophils into the lung as well as antigen-induced IgG1 production.
Stat5b (386,*441*)	Defective growth analogous to Laron dwarfism, a disease of defective growth-hormone signaling. Defective IL-2–induced IL-2Rα expression. More severe defects in IL-2–induced T-cell proliferation and NK-cell proliferation. Defective antigen-induced recruitment of eosinophils into the lung as well as antigen-induced IgG1 production. Defective NK cytolytic activity.
Partial Stat5a/Stat5b (*387,388*)	Defective signaling in response to prolactin and growth hormone. Absent NK-cell development. Major defect in T-cell proliferation and TCR signaling. Anemia.
Complete Stat5a/Stat5b (442)	Fetal lethality, absent T-cell development.
Stat6 (437,*438,439*)	Defective Th2 development, essentially the same phenotype as IL-4–deficient mice. Defective B-cell proliferation.
Jak1 (338)	Perinatal lethality, with defective signaling by gp130-dependent cytokines (IL-6, IL-11, CNTF, OSM LIF CT-1, and NNT-1/BSF-3). Defective signaling by γ_c-dependent cytokines (IL-2, IL-4, IL-7, IL-9, IL-15, IL-21; of these, IL-2 and IL-7 were formally evaluated).
Jak2 (611,*612*)	Fetal lethality with profound anemia due to defective signaling in response to erythropoietin.
Jak3 (345,346,*347*)	Very similar and possibly identical to γ_c-deficient mice. Defective signaling in response to γ_c-dependent cytokines (IL-2, IL-4, IL-7, IL-9, IL-15, IL-21). Greatly diminished T cells in thymus and spleen, but then age-dependent peripheral expansion of CD4$^+$ T cells. Unlike humans with JAK3 mutations, Jak3-deficient mice have greatly diminished B-cell numbers as well.
Tyk2 (613,*614*,615)	Mice lacking Tyk2 exhibit diminished signaling in response to IFNα/β and IL-12, but it is not abrogated. Primarily, Stat3 activation is diminished, even though Stat1/Stat2 and Stat4, respectively, are the STAT proteins that are primarily activated by IFNα/β and IL-12. Additionally, there are diminished responses to IFNγ and IL-18.
FIGURE 23.7 Schematic of cytokine signaling showing multiple signaling pathways activated by IL-2. Shown is the association of Jak1 and Jak3 with different chains of the receptor. Activation of Jak kinases results in tyrosine phosphorylation of IL-2Rβ. This allows the docking of Stat5 proteins via their SH2 domain. The STATs themselves are tyrosine-phosphorylated, dimerize, and translocate to the nucleus, where they modulate expression of target genes. The schematic also indicates that another phosphotyrosine mediates recruitment of Shc, which then can couple to the Ras/Raf/MEK/MAP kinase pathway. Also shown is the important PI 3-kinase pathway. These and other pathways are activated by many type I cytokines.

Jak kinases plays a dominant role. Indeed, one study suggests that Jak2 may phosphorylate both itself and Jak1, thereby increasing the catalytic activities of both kinases *(365)*. Jak1 in turn then phosphorylates IFNGR-1, allowing the recruitment of Stat1. In this model, it is additionally suggested that Jak2 phosphorylates Stat1 *(365)*. Interestingly, a kinase-dead mutant of Jak1 was able to mediate the induction of certain IFN-γ–induced genes, indicating a potential "structural" role for Jak1, but catalytically active Jak1 was essential for the establishment of the antiviral state *(365)*, emphasizing the essential role of both Jak1 and Jak2 for normal IFN-γ function.

The preceding discussion assumes that transphosphorylation of Jak kinases is a mechanism for the amplification of catalytic activity. Unless other kinases are involved, however, implicit to this idea is that the Jak kinases themselves must exhibit some basal activity that is amplified to a

higher level by auto- or transphosphorylation. It is reasonable to speculate that both models may be operative, depending on the system. Consistent with Jak kinases being activated by phosphorylation, mutagenesis of a critical tyrosine in Tyk2 *(366)* or Jak2 *(367)* (e.g, tyrosine 1007 in the case of Jak2) in the activation loop of the kinase domain inhibits activity. It is also conceivable that phosphorylation of other tyrosines on the Jaks may create appropriate motifs for the recruitment of additional signaling molecules.

The function of the pseudokinase domain remains unclear. No other metazoan protein tyrosine kinases contain such a domain. The JH2 lacks the third glycine in the critical Gly–X–Gly–X–X–Gly motif, is missing an aspartic acid that serves as the proton acceptor that is typically conserved in the catalytic loop of both tyrosine and serine kinases, and is missing the conserved phenylalanine in

the Asp–Phe–Glu motif that binds ATP (reviewed in 322). The absence of the critical amino acids summarized above presumably explains the lack of catalytic function of the JH2 domain *(327)*. Despite the lack of catalytic activity of the JH2 domain, there are increasing data in support of vital functions for this region. Although the kinase domain alone can act as an active kinase, it is interesting that a mutation in the Jak kinase JH2 domain can hyperactivate the *Drosophila* (*hop^Tum-l*/D-stat) Jak-STAT pathway and that the corresponding Glu 695-to-Lys mutation in murine Jak2 also resulted in increased autophosphorylation of Jak2 and phosphorylation of Stat5 in transfected cells *(368)*. Moreover, the JH2 domain may play an important role in mediating the interaction of Jaks with STAT proteins *(369)*.

Given that Jak kinases are associated with a wide range of IFN and cytokine receptors, it was to be predicted that Jaks would mediate signals involved in multiple processes. Indeed, these include important roles in development (as demonstrated by the lack of T-cell and NK-cell development associated with Jak3 deficiency, a defect at least partially due to defective signaling in response to IL-7 and IL-15), signaling in response to cytokines that are mitogenic growth factors (IL-2, IL-3, etc.), and in the antiviral response (IFNs). The analysis of the role of Jak1 in zebrafish not only revealed a role for Jak1 in early vertebrate development, it also demonstrated that during early development Jak1 kinase was exclusively of maternal origin *(353)*. These developmental roles for Jak1 in zebrafish are consistent with the importance of a Jak kinase in early *Drosophila* development as well *(370)*.

STAT PROTEINS ARE SUBSTRATES FOR JAKS THAT AT LEAST IN PART HELP DETERMINE SPECIFICITY

Given that there are only four Jak kinases and scores of cytokines, it is clear that Jaks by themselves cannot fully determine specificity. Indeed, different cytokines with different actions activate the same Jaks. One level of specificity comes from the same Jaks having different substrates, depending on the receptor. The best-characterized substrates for Jaks are the signal transducer and activator of transcription (STAT) proteins (321,322,*323*), and these appear to provide some but not all of the specificity, particularly given that there are only seven STAT proteins. Among the mutant cell lines with defects in IFN signaling, in addition to the ones with defects in Jaks that were noted previously, others were defective in STAT proteins, providing perhaps the earliest data proving a vital role for STAT proteins in signaling in response to IFNs.

STAT proteins are classically considered to be latent transcription factors that initially exist in the cytosol but

▎**TABLE 23.15 Cytokines and the STATs They Activate**

Cytokine	STATs Activated
IFN-α/β	Stat1, Stat2. Stat4
IFN-γ	Stat1
Growth hormone	Stat5a, Stat5b
Prolactin	Stat5a, Stat5b
Erythopoietin	Stat5a, Stat5b
Thrombopoietin	Stat5a, Stat5b
IL-10	Stat3
IL-12	Stat4, Stat3
G-CSF	Stat3
γ_c Family	
IL-2, IL-7, IL-9, IL-15, IL-21	Stat5a, Stat5b, Stat3, Stat1
IL-4	Stat6
IL-13	Stat6
TSLP	Stat5a, Stat5b
β_c Family	
IL-3, IL-5, GM-CSF	Stat5a, Stat5b
gp130 Family	
IL-6, IL-11, CNTF, LIF, OSM, CT-1	Stat3
Leptin	Stat3

Note that for IL-2, IL-7, IL-9, and IL-15, Stat5a and Stat5b appear to be the major STATs that are activated, although Stat3 in particular and Stat1 to a lesser degree can also be activated. For IL-21, Stat3 is the dominant STAT protein activated, followed by Stat1 and Stat5a/Stat5b *(35,454)*.

then must be activated by phosphorylation, with subsequent translocation to the nucleus. STATs were first discovered as factors that bound to the promoters of interferon-inducible genes. The seven mammalian STAT proteins are Stat1 (371), Stat2 *(372)*, Stat3 *(373,374)*, Stat4 *(375,376)*, Stat5a *(377,378,379–381)*, Stat5b *(379–382)*, and Stat6 *(383)*. Table 23.15 summarizes the cytokines that activate each of the STATs. Additionally, some STATs (e.g, Stat3) are known to have more than one isoform with distinct functions *(384)*. Although the STATs conserve a reasonable level of homology, Stat5a and Stat5b are unusually closely related, being 91% identical at the amino acid level *(379–382)*. It is interesting that murine and human Stat5a are more related than Stat5a and Stat5b within a single species. The same is true for murine and human Stat5b, suggesting that there has been evolutionary pressure to maintain the difference between Stat5a and Stat5b and that these two proteins might have certain distinctive functions. In this regard, Stat5a and Stat5b knockout mice exhibit both similarities as well as some differences in their phenotypes (385,386,*387,388*); however, given different levels of each Stat5 protein in certain tissues, it remains to be determined if the different phenotypes result from different intrinsic actions of Stat5a and Stat5b versus differences in the total level of Stat5.

Because active STAT proteins exist as dimers, the ability of at least some STATs to form heterodimers (e.g, Stat1
FIGURE 23.8 Architecture of a typical STAT protein. Shown are the locations of the following important regions: (a) the N-terminal region is shown to mediate the interaction of STAT dimers bound to adjacent GAS sites (known to be important for Stat1, but presumably true for all STATs); (b) the DNA-binding domain; (c) the SH2 domain that mediates STAT docking on receptors and STAT homodimerization/heterodimerization following tyrosine phosphorylation; and (d) the location of the conserved tyrosine whose phosphorylation allows the SH2-mediated dimerization. At least in Stat1 and Stat3, Serine 727, which is C-terminal to the conserved tyrosine, is an important site for phosphorylation. In the case of Stat1, p48 interacts downstream of the STAT dimerization domain. CBP/p300 interacts with two sites—at both the N terminus and the C terminus. Although it has been suggested that the region between the DNA-binding domains and the SH2 domain is an SH3 domain, this remains unproven and no interactions with proline-rich regions have been reported; as a result, I have omitted the labeling of this region as an SH3 domain. Note that this structure is typical of that for Stat1, Stat3, Stat4, Stat5a, and Stat5b. The main features are conserved in Stat2 and Stat6, but these are approximately 50 to 100 amino acids longer.

with Stat2 or Stat3 [reviewed in *323*]) increases the number of different complexes that can form. In addition, further complexity can be generated by the ability of at least some of the STATs to exist in alternatively spliced forms *(382,389)*. Some of these forms are inactive, and if alternative splicing of certain forms were regulated, it would allow for negative regulation.

A schematic of STAT proteins is shown in Figure 23.8. The STATs can be divided into two basic groups: those that are longer (Stat2 and Stat6, approximately 850 amino acids) and those that are shorter (Stat1, Stat3, Stat4, Stat5a, and Stat5b, between 750 and 800 amino acids). The STAT genes cluster in three locations. Murine Stat2 and Stat6 are both located on chromosome 10, Stat1 and Stat4 are located on chromosome 1, and Stat3, Stat5a, and Stat5b are located on chromosome 11 *(390)*. Correspondingly, human, Stat1 and Stat4 are on chromosome 2q32.2–2q32.3, Stat2 and Stat6 are on chromosome 12q13.2, and Stat 3, Stat5a, and Stat5b are closely positioned on chromosome 17q *(382)*.

The classic model is that in order for STATs to be "activated" and to be able to function as transcriptional activators, a number of cellular events must occur. They first bind to phosphorylated tyrosines on cytokine receptors, are tyrosine-phosphorylated, dissociate, dimerize, translocate from the cytosol to the nucleus, bind to target DNA sequences, and activate gene expression. A number of conserved structural features common to all STATs helps to explain these functions. These include an SH2 domain, a

conserved tyrosine residue, a DNA-binding domain, a C-terminal transactivation domain, and an N-terminal STAT tetramerization region. Other regions as well contribute important functions. These special features of STATs are discussed in the following. In addition, however, there is now evidence for the biologic function of nuclear STATs that are not phosphorylated, as discussed in the following.

Docking of STATs on Receptors or Other Molecules, Tyrosine Phosphorylation of STATs, and STAT Dimerization

Each STAT protein has an SH2 domain that plays two important roles: (a) for receptor docking, as has been shown, for example, for Stat1 docking on IFNGR-1 *(391)*, Stat2 docking on IFNAR-1 *(392)*, Stat3 docking on gp130 (393), Stat5a and Stat5b docking on IL-2Rβ and IL-7Rα (248,*394*), and Stat6 docking on IL-4Rα (395); and (b) for STAT dimerization wherein dimerization is mediated by the SH2 of one STAT interacting with the conserved phosphorylated tyrosine of another STAT protein. In the case of the IFN-α receptor, no Stat1 docking site on IFNAR-1 or IFNAR-2 has been identified, and it is believed that Stat1 may interact with Stat2 after Stat2 is itself tyrosine-phosphorylated (322). It is also possible that STATs can dock on Jaks, given the ability to coprecipitate Jaks and STATs directly (355,*369*). After docking has occurred, a conserved tyrosine (tyrosine 701 in Stat1, tyrosine 694 in Stat5a, etc.) can be phosphorylated. This

phosphorylation is required for SH2 domain–mediated STAT dimerization, and the phosphorylation likely occurs while the STAT is docked on the receptor in physical proximity to receptor-associated Jak kinases. Following STAT phosphorylation, the STAT protein dissociates from the receptor, and its dimerization with itself or another STAT is presumably then favored over its reassociation with the cytokine receptor chain, given that STAT dimerization involves two phosphotyrosine–SH2 interactions (a bivalent interaction), whereas docking on a receptor involves only one (monovalent interaction). Thus, efficient activation of STATs requires the presence in STATs of a conserved SH2 domain and a critical tyrosine.

Whereas some receptor proteins, such as IFNGR-1 (391) and IL-7Rα (248), have a single STAT docking site (for Stat1 and Stat5, respectively), a number of receptor molecules, including IL-2Rβ (248,394), IL-4Rα (395), gp130 (393), EPOR (396), and IL-10Rα (397), have more than one docking site for their respective STATs. The presence of more than one site provides functional redundancy, but also potentially could allow the simultaneous activation of two STAT molecules, providing a high local concentration of phosphorylated STATs, which called facilitate their dimerization.

STAT Nuclear Translocation and DNA Binding

Following dimerization, the STATs translocate into the nucleus, where they can bind to DNA as transcription factors. The mechanism for nuclear translocation was originally mysterious, given the absence of an obvious nuclear localization signal (398). However, it was shown that tyrosine-phosphorylated Stat1 dimers can interact directly with importin-α5, allowing internalization. This suggested that there indeed is a nuclear localization signal that is normally masked, and mutation of Leu 407 does not interfere with tyrosine phosphorylation, dimerization, or DNA binding, but prevents nuclear localization (398). Following its dephosphorylation, nuclear Stat1 is exported to the cytosol by a process that is dependent on the chromosome region maintenance 1 (CRM1) export reporter (399). Thus, both import and export of Stat1 appear to be regulated processes. These findings also generalize to Stat3, Stat5a, and Stat5b (399a).

Whereas the majority of STAT dimers bind DNA directly, in the case of IFN-α/β, Stat1-Stat2 heterodimers are formed, and these bind DNA in conjunction with a 48-kDa DNA binding protein known as interferon regulatory factor 9 (IRF9); the Stat1-Stat2-IRF9 complex is known as ISGF3 (reviewed in 323). In the case of other STAT dimers, accessory proteins are not required for DNA binding. The motif recognized by ISGF3 complexes is AGTTTNCNTTTCC (known as an ISRE, for interferon-stimulated response element), whereas the other STAT complexes bind more semi-
FIGURE 23.9 Three-dimensional structure of a Stat1 dimer bound to DNA. Reproduced from (400,401) with permission of Dr. Kuryian and Cell Press.

palindromic TTCN$_m$GAA motifs that are generally denoted as GAS motifs, for γ-interferon–activated sequences, reflecting their original discovery in the context of IFN-γ (283,321,322).

A series of chimeric STAT proteins were used to delineate a DNA-binding domain of approximately 180 amino acids, with two conserved subdomains. Although multiple STATs bind to the same motifs, their relative efficiencies vary, indicating fine specificities conferred by the different DNA-binding domains. For example, whereas Stat1 homodimers favor a TTCN$_3$GAA motif, Stat6 prefers a TTCN$_4$GAA motif (395). These differences partially explain why different STATs modulate the expression of nonidentical sets of target genes. The structures of Stat1 and Stat3β bound to DNA (400,401) (Figure 23.9) almost resemble that of a vertebral column, wherein the DNA represents the spinal cord. The N-terminal and coiled-coil domains are spatially the farthest from the DNA, whereas the DNA-binding domain, linker, and SH2 domain surround the DNA, with the stability apparently being provided by the SH2–phosphotyrosine interaction between the STAT monomers as well as each STAT monomer with interacting

DNA, presumably via a "half-GAS site" (402), as discussed under STAT tetramerization.

N-terminal regions mediate cooperative DNA binding of STAT proteins when multiple STAT binding sites occur in close proximity (*403*,404)—for example, in the IFN-γ gene *(403)*. In the IL-2Rα gene, IL-2 response elements have been described in both the 5′-regulatory region and the first intron, each of which has tandem GAS motifs that cooperate functionally to mediate IL-2–induced IL-2Rα transcription (*405–407*,408).

STAT proteins were the first transcription factors that were identified as targets for tyrosine phosphorylation. Previously, tyrosine phosphorylation was associated primarily with membrane-proximal events, but the tyrosine phosphorylation of STATs is associated with a membrane-proximal event, as the STATs dock on cell surface receptors. This phosphorylation then allows the rapid dimerization that facilitates nuclear localization and DNA binding. STATs can interact directly with Jak kinases (first shown for Stat5 and Jak3) (355), suggesting that STATs may at times dock on Jaks rather than on receptors.

Nonphosphorylated STATs Can Be Nuclear

In addition to the classical tyrosine-phosphorylation–mediated dimerization and nuclear translocation, it is now clear that STAT proteins can exist in the nucleus even without being tyrosine-phosphorylated, and in that context can modulate gene expression (*409,410*,411). Moreover, nonphosphorylaed STATs (e.g, Stat4) can form N-domain–mediated dimers (412).

Optimal Binding Sites for STATs

The optimal binding motifs for several STAT proteins have been determined. For Stat1, Stat3, and Stat4, a TTCC-SGGAA motif was defined *(323,403)*, whereas Stat5a and Stat5b optimally bind a TTCYNRGAA motif (402) and Stat6 binds a TTCNTNGGAA motif (where Y is C or T and R is G or A) (395,402). Unexpectedly, purified Stat5a expressed in a baculoviral expression system binds efficiently as either a dimer or a tetramer, whereas similarly prepared Stat5b binds primarily as a dimer, suggesting a greater efficiency for homotetramerization of Stat5a than for Stat5b (402). Whereas dimeric STAT protein binding strongly preferred canonical motifs, the range of sequences recognized by Stat5a tetramers is broad, often occurring to two imperfect motifs or with one canonical motif with an associated "TTC" or "GAA" half-GAS motif. The optimal inter-GAS motif spacing is 5 to 7, although some naturally occurring sites, such as that in the PRRIII element of the IL-2Rα gene, has a spacing of 11 (402). The presence of suboptimal GAS motifs spaced at appropriate distances to allow tetrameric binding may allow greater specificity via cooperative binding of STAT oligomers. Interestingly,

a number of STAT-regulated genes, such as Bcl-x and Pim-1, have "half-GAS motifs" located near full GAS motifs, suggesting that tetrameric binding is involved in the regulation of these genes (402).

Transcriptional Activation by STATs

In addition to tyrosine phosphorylation, some STATs can be phosphorylated on serine, and Stat1 and Stat3 phosphorylation at Ser 727 in the C-terminal transactivation domain is required for full activity *(413–415)*. The Ser 727 region resembles a MAP kinase recognition site, and MAP kinase activity was reported to be required for IFN-α/β–induced gene expression *(416)*. Ser 727 mediates the interaction of Stat1 with MCM5, a member of the minichromosome maintenance family of proteins; this interaction presumably is important for maximal transcriptional activation (417). In contrast, Stat2 is not serine-phosphorylated *(323)*, and although Stat5a and Stat5b are serine-phosphorylated, the biologic role, if any, of this phosphorylation is unclear.

In addition to this regulated modification of the STAT proteins, STATs can also interact with other factors. For example, as noted earlier, Stat1-Stat2 heterodimers bind DNA only after interacting with IRF9 to form ISGF3 *(323)*. Stat1 interacts with and synergizes with Sp1 for transcriptional activation in the ICAM-1 gene *(418)* and with TRADD to influence IFN-γ signaling *(419)*. An alternatively spliced shorter form of Stat3, denoted Stat3β, associates with c-Jun to enhance transcriptional activity (420). Moreover, certain STATs can interact with the potent transcriptional coactivators CBP/p300 *(421–423)*. In the case of Stat1, this is mediated by interactions involving both the N-terminal and C-terminal regions of Stat1 and the CREB- and E1A-binding regions of CBP, respectively *(422)*. Stat5a has been shown to associate with the glucocorticoid receptor *(424)*. Additionally, the IL-2-response element in the IL-2Rα gene requires not only Stat5 binding but also the binding of Elf-1, an Ets family transcription factor, to a nearby site *(405)*. Thus, active STAT complexes appear to involve the coordination of STAT proteins with other factors. The corepressor SMRT (silencing mediator for retinoic acid receptor and thyroid hormone receptor) was identified as a potential Stat5-binding partner that binds to both Stat5a and Stat5b, and potentially plays a negative regulatory role *(425)*.

Specificity of STATs

Analogous to the Jaks, the same STATs are activated by multiple cytokines. The phenotypes of mice that lack expression of each of the seven STAT proteins are known, and these knockout models have helped to clarify which cytokines depend critically on a given STAT protein. Stat1 knockout mice exhibit defects that are very selective for

the actions of type I and type II IFNs (426,427), suggesting that Stat1 is vital only for the actions of IFNs, even though a variety of other cytokines have been reported to activate Stat1. Although it is possible that Stat1 plays an important but redundant role for at least some of these other cytokines, the phenotype of Stat1-deficient mice indicates a need for caution in the interpretation of in vitro experiments that use high concentrations of cytokines or cell lines. Stat2-deficient mice exhibit defects consistent with selective inactivation of IFN-α/β signaling *(428)*. Stat3-deficient mice exhibit fetal lethality; the embryos implant, but they exhibit defective development and growth *(429)*. Deletion of Stat3 within specific lineages has revealed that mice that lack Stat3 in T cells *(430)* have normal lymphoid development but exhibit a defect in IL-2–induced IL-2Rα expression, somewhat analogous to what is seen in Stat5a- and Stat5b-deficient mice (see below). Neutrophils and macrophages that lack Stat3 exhibit defective signaling to IL-10, and it is known that Stat3 is important for the normal involution of the mammary epithelium, for wound healing, and for the normal hair cycle *(431,432)*. Dendritic cells that lack Stat3 exhibit a defect in Flt3L-dependent differentiation *(433)*, and APCs that are deficient in Stat3 exhibit disruption of priming of antigen-specific CD4$^+$ T cells *(434)*. Stat4-deficient mice exhibit a phenotype similar to that of IL-12–deficient mice (i.e, defective Th1 development), consistent with the observation that Stat4 is activated by IL-12 (435,436). Analogously, Stat6-deficient mice exhibit a phenotype similar to that of IL-4-deficient mice (i.e, defective Th2 development) *(437,438,439)*, in keeping with the observation that Stat6 is activated only by IL-4 and the closely related cytokine, IL-13. Interestingly, mice that lack Stat5a exhibit a defect in prolactin-mediated effects, including defective lobuloalveloar proliferation *(440)*, whereas mice that lack Stat5b have defective growth similar to that found in Larons dwarfism *(441)*. Thus, although Stat5a and Stat5b appear to always be induced coordinately, each of these STATs is important in vivo. In addition to these defects, both Stat5a-deficient and Stat5b-deficient mice have defects in T-cell development and signaling (385,386). Stat5a-deficient mice have diminished numbers of splenocytes and exhibit a defect in IL-2–induced IL-2Rα expression (385). Stat5b-deficient mice have similar defects, but also have diminished thymocytes (386). Most dramatically, these mice have a major defect in the proliferation of freshly isolated splenocytes (386), and defective NK-cell development (386). Mice that lack both Stat5a and Stat5b in lymphoid cells exhibit a dramatic defect in T-cell development (442), and even hypomorphic expression of both Stat5a and Stat5b is sufficient to result in a lack of NK-cell development *(387)*. Presumably, the lack of T-cell development relates to defective IL-7 signaling, whereas the lack of NK-cell development relates to defective IL-15–dependent Stat5 activation. Stat5a/Stat5b double-knockout mice exhibit lethality associated with severe anemia that develops in these mice (443).

STATs Are Evolutionarily Old

Just as *Drosophila* has a Jak kinase, there is a *Drosophila* STAT, denoted as either DSTAT or STAT92E (444,*445)*. The existence of Jak kinases and STAT proteins in lower organisms suggests that the system is evolutionarily old. A STAT has been identified in *Dictyostelium* that recognizes the sequence TTGA *(446)*, has highest sequence similarity to Stat5b, and can bind mammalian ISREs *(446)*. Interestingly, *Saccharomyces cerevisiae* do not appear to have STATs, as no SH2 domains have been identified in the entire *S. cerevisiae* genome.

What Types of Functions Are Mediated by STATs?

First and foremost, STAT proteins can translocate to the nucleus and bind to regulatory regions of target genes and influence transcription. Although STATs are generally activators of transcription, at least in the case of the *c-myc* gene, Stat1 can function as a transcriptional repressor *(447)*.

STAT proteins were discovered based on the study of IFN-inducible genes as part of studies intended to understand the cellular differentiation events that lead to development of the antiviral state. In addition to roles in differentiation, STAT proteins can contribute, directly or indirectly, to survival and/or mitogenic/proliferative responses that typify hematopoietic and immunologic cytokines, such as IL-3, IL-5, GM-CSF, IL-2, and IL-4 (322): First, a number of in vitro systems have demonstrated that viruses or viral oncogenes are associated with activated Jak-STAT pathways, suggesting a role for STATs in cellular transformation. Indeed, Stat3 and Stat5 have been implicated as oncogenes, with compelling data for transformation capability of Stat3 in cell lines, persistently tyrosine-phosphorylated STATs in several types of leukemia and lymphoma, and the development of T-lymphoblastic lymphomas in Stat5 transgenic mice (448). The role of Stat3 in the tumor microenvironment makes it an attractive target for cancer immunotherapy *(449)*. Second, there is diminished proliferation in a number of the STAT knockout mice that have been analyzed. For example, Stat4-deficient cells exhibit diminished cellular proliferation to IL-12 (435,436), whereas Stat6-deficient mice exhibit diminished proliferation to IL-4 (437,*438)*, and Stat5-deficient mice have diminished T-cell proliferation to IL-2 (385,386). Some of these effects are indirect, based on modulation of receptor expression. For example, Stat6-deficient mice exhibit decreased IL-4Rα expression. Similarly, the absence of Stat5 results in decreased IL-2–induced IL-2Rα expression as well as decreased proliferation (385,386). Thus, in

at least some cases, decreased proliferation results at least in part from decreased expression of receptor components. Stat5a and Stat5b appear to regulate Bcl-XL induction, indicating their ability to affect cell survival (443). Finally, it is interesting that Stat1 has been linked to cell growth arrest and induction of the cdk inhibitor p21$^{WAF1/CIP1}$ *(450)*, and that activation of Stat1 occurs in thanatrophoric dysplasia type II dwarfism as the result of a mutant fibroblast growth factor receptor (FGFR3) *(451)*. In this chondrodysplasia, the mutant FGFR3 induces nuclear translocation of Stat1, expression of p21$^{WAF1/CIP1}$, and growth arrest, suggesting a possible relationship to the disease. Thus, different STATs may potentially mediate either growth expansion or growth arrest. Moreover, STATs may potentially play other types of roles, as well. For example, Stat3 has been reported to serve as an adapter to couple PI 3-kinase to the IFNAR-1 component of type I IFN receptors *(452)*.

A more complete understanding of the actions of the different STAT proteins may be facilitated with a compilation of the genes that are regulated by each STAT. Progress in this area has been made for a number of cytokines, but particularly for the IFNs *(285)*. It is also important to recognize that not all cytokine signals are dependent on STATs, as illustrated, for example, by Stat1-independent IFN signals *(453)*, Stat5-independent IL-2 signals *(394)*, and Stat1/Stat3-independent IL-21 signals *(454)*.

Do Other Proteins Bind to GAS Motifs?

At least one non-STAT protein can bind to GAS motifs. The *BCL6* gene is often mutated or has undergone translocations in diffuse large-cell B-cell lymphomas. Interestingly, Bcl-6 binds to GAS motifs capable of binding Stat6 and specifically can inhibit IL-4 action (455). Mice that lack Bcl-6 expression exhibit defective germinal-center formation, suggesting that formation of germinal centers may be at least partially dependent on Bcl-6–regulated (presumably negative) control of certain STAT-responsive genes (455).

OTHER LATENT TRANSCRIPTION FACTORS AS EXAMPLES OF CYTOPLASMIC-TO-NUCLEAR SIGNALING (NF-κB, NF-AT, AND SMADs)

An exciting feature of STAT proteins is that they exist in an inactive form in the cytosol and then are rapidly translocated to the nucleus. The rapid activation within minutes of signals from cell membrane to nuclear DNA binding makes the STAT acronym very apt, analogous to the urgency associated with "STAT" emergency physician orders in clinical medicine. The rapid activation of STAT proteins is somewhat analogous to several other transcription factors *(456)*. NF-κB also undergoes rapid nuclear transloca-

tion, but by a completely different mechanism from STATs. In contrast to STAT proteins, for which the tyrosine phosphorylation of the STATs is an initiator of nuclear translocation, for NF-κB it is the serine phosphorylation and/or uquitination of IκB that results in its dissociation and/or destruction, allowing the release and translocation of NF-κB. There is the classical NF-κB pathway used by many cytokines, which involves the IKKα/IKKβ/IKKγ-dependent phosphorylation of IκB, resulting in the activation of NFκB1 (p50)/Rel-A (p65) heterodimers as well as the alternative pathway in which a homodimer of IKKα mediates the activation of NFκB2 (p52)/Rel-B heterodimers *(457–459,*460). A third example of cytosolic to nuclear translocation occurs with NF-AT (nuclear factor of activated T-cell) family proteins *(461,*462), which are vital for regulating transcription of a number of cytokines, including, for example IL-2, IL-4, and GM-CSF. NF-AT is translocated to the nucleus, where it associates with AP-1 family proteins to form a functional complex. It is the activation of calcineurin and dephosphorylation of NF-AT that allows its nuclear translocation. A fourth example of cytosolic to nuclear translocation occurs with the SMAD proteins that mediate TGF-β signaling, which contributes to Th17 differentiation (discussed later). For SMADs, the phosphorylation is on serine and the kinase is intrinsic to the receptor, but like STATs, activation of these latent transcription factors is rapid and initiated by the binding of a growth factor. Thus, several mechanisms, each involving phosphorylation or dephosphorylation, have evolved to allow cytoplasmic to nuclear translocation of latent transcription factors.

OTHER SUBSTRATES FOR JAKS

Because Jaks are potent cytosolic tyrosine kinases, it is evident that the Jaks may do more than just phosphorylate tyrosine residues on receptors where STAT proteins dock as well as phosphorylating the STATs. In vitro data indicate that Jak kinases also can phosphorylate receptor tyrosines other than the docking sites for STATs. For example, in the case of IL-2Rβ, Jak1 can phosphorylate not only tyrosines 392 and 510, which are STAT docking sites, but also tyrosine 338, which is a docking site for Shc *(394)*, all of which are required for maximal proliferation. Jak kinases are known to autophosphorylate themselves or transphosphorylate other Jaks. Other molecules are potentially phosphorylated by Jak kinases, including the STAM adapter molecule *(463)* and the p85 subunit of PI 3-kinase *(464)*.

IRF Family Proteins

Interferon-regulatory factors form a family of nine proteins that are regulated by type 1 IFNs (281). They each have a well-conserved N-terminal DNA-binding

domain that forms a helix–loop–helix structure as well as a C-terminal interaction domain. IRFs are critical for a number of actions, including type I IFN-dependent gene transcription (281). Select IRFs play critical roles in TLR-mediated IFN induction. IFRs can have negative as well as positive effects. For example, IFN-γ–mediated repression of IL-4 is mediated by IRF protein(s) *(465)*.

OTHER SIGNALING MOLECULES IMPORTANT FOR CYTOKINES

Other Tyrosine Kinases besides JAKS

In addition to their activation of Jak kinases, a number of cytokines can activate Src family kinases. For example, IL-2 can activate p56^{lck} *(466,467)* in T cells and p59^{lyn} and p53/p56^{lyn} in B-cell lines *(468,469)*. The activation of some of these kinases has been reported to be mediated by associating with the "A" region of IL-2Rβ. Another tyrosine kinase, Syk, has been reported to associate with the S region of IL-2Rβ *(470)*. However, the significance of these interactions is less clear than that for Jak kinases. First, cells that lack Lck can proliferate vigorously in response to IL-2 *(471,472)*. Second, when the A region is deleted, proliferation still occurs, albeit at a lower level than seen with wild-type IL-2Rβ *(473)*. However, Y338, which is required for the recruitment of Shc, is in the A region and is required for normal proliferation *(394)*. Thus, it is possible that the decrease in proliferation associated with deletion of the A region relates more to the loss of Y338 than it does to the loss of association of Lck. Moreover, in *Il2rb*$^{-/-}$ mice reconstituted with an IL-2Rβ A–region mutant, proliferation is increased rather than decreased *(474)*. Additional investigation is required to clarify the role of activation of Src family kinases by IL-2 and other cytokines. The significance of the Syk interaction also remains unclear. As Syk and Jak1 both associate with the S region of IL-2Rβ, mutations that delete the S region simultaneous prevent both associations, making it hard to determine the specific role of Syk. Syk-deficient mice exhibit normal IL-2 proliferation *(475)*, further suggesting that Syk may not play an important role in IL-2–induced proliferation. The G-CSF receptor also can form a complex with Lyn and Syk *(476)*, but again, Syk-deficient mice do not exhibit a defect in G-CSF signaling *(475)*. β_c has also been reported to interact with Src family kinases *(477)*; gp130 has been reported to associate with a number of other kinases, including Btk, Tec, and Fes *(478–480)*; and IL-4Rα has been shown to interact with Fes *(481)*. However, relatively little is known about the significance of tyrosine kinases other than Jaks in cytokine signaling. Additionally, PI 3-kinase, p38, ERK, and JNK can each become activated, leading to activation of many downstream transcription factors, including NF-κB, AP1, PU.1, IRF1, IRF4, and IRF8, to mediate a program of gene expression.

IRS Proteins

IRS-1 was discovered as a tyrosine-phosphorylated substrate of the insulin receptor *(482)*. IRS proteins have a large number of phosphotyrosine docking sites, particularly for the p85 subunit of PI 3-kinase, and they presumably serve to recruit important accessory molecules. Interestingly, both insulin and IL-4 could induce tyrosine phosphorylation of an IRS-1–like molecule in hematopoietic cells, and 32D myeloid progenitor cells lack IRS-1 and could only signal in response to insulin or IL-4 when they were transfected with IRS-1 *(483)*. Both the insulin receptor and IL-4Rα proteins contain NPXY sequences that are important for IRS-1 or IRS-2 binding; in IL-4Rα, this is contained within a sequence denoted as the I4R motif *(484)*.

Other cytokines have subsequently been shown to activate IRS-1 and/or IRS-2. For example, growth hormone can induce phosphorylation of IRS-1 *(485)* and IRS-2 *(486)*, IFN-γ and LIF induce phosphorylation of IRS-2 *(486)*, and the γ_c-dependent cytokines, IL-2, IL-7, and IL-15, can induce tyrosine phosphorylation of IRS-1 and IRS-2 in T cells *(487)*. The significance of these findings remains unclear, as 32D cells reconstituted with a complete IL-2 receptor can proliferative vigorously in response to IL-2 *(471)*, whereas, as noted, in these same cells IL-4 responsiveness requires coexpression of both IL-4Rα and IRS-1, indicating different roles for IRS proteins for different cytokines.

Phosphatidylinositol 3-Kinase

PI 3-kinase is a lipid kinase that consists of an 85-kDa regulatory subunit and a 110-kDa catalytic subunit *(488)*. PI 3-K phosphorylation and activation can be induced by a number of cytokines *(489–492)*, and the use of inhibitors, such a wortmannin or LY294002, has demonstrated its importance in signaling for at least certain cytokines. IRS-1 has multiple docking sites for PI 3-kinase (YXXM motifs) and thus for some cytokines, such as IL-4, the association of IRS-1 might be the mechanism by which PI 3-K can be recruited.

The Ras/MAP Kinase Pathway

Another major signaling pathway for a number of cytokines is the Ras/MAP kinase pathway (493). This pathway presumably is used by cytokines whose receptors recruit the Shc adaptor molecule, which in turn mediates the recruitment of Grb2 and Sos, leading eventually to the activation of Ras. In turn, Ras couples to the MAP kinase pathway through a well-defined signaling cascade. Certain cytokines, such as IL-2 and IL-3, appear to use this pathway, whereas others, such as IL-4, do not, indicating that this pathway is differentially important depending on the cytokine that is being used.

DOWNMODULATION OF CYTOKINE SIGNALS

Much of the preceding discussion has centered on the mechanisms by which cytokines induce signals. However, the mechanisms by which cytokine signals can be terminated are also extremely important. There are multiple levels at which negative regulation can occur. These include (a) regulating a balance between the production (transcriptional and translational control) of the cytokine, its receptor, and/or downstream signaling molecules and the degradation of these same molecules; and (b) regulation of the activation state of the receptor and downstream signaling molecules. For example, these can be mediated by transcriptional repressors or molecules that either inhibit cytokine signaling (e.g, SOCS proteins) or reverse-activated states (e.g, phosphatases).

Transcriptional control of cytokine production is a widely used mechanism. Many T-cell–derived cytokines, such as IL-2, IL-3, and IL-4, are produced only by activated T cells, and their production is lost with the loss of activation. IL-15 provides an example in which translation of the protein is carefully regulated, in part, by the existence of multiple upstream ATGs (96). Most cytokine receptor chains are constitutively expressed, but some, such as IL-21R and IL-2Rβ, are regulated in part by signals that act through the T-cell receptor. The most regulated receptor chain may be IL-2Rα, whose expression is absent on resting lymphocytes but strongly induced following stimulation with antigens, mitogens, and certain cytokines; however, the transcriptional/translational control of most cytokine receptors is poorly studied.

Because phosphorylation events are vital for the creation of phosphotyrosine docking sites, dephosphorylation is an obvious mechanism of control. Indeed, two tyrosine phosphatases, Shp-1 (formerly also known as SHP, HCP, SH-PTP1, and PTP1C) and Shp-2 (formerly also known as Syp and PTP1D) have been shown to play roles related to cytokine signaling (494,495). Shp-1 mutations cause the motheaten (*me*) and viable motheaten (*me*^{v}) phenotypes in mice (496,497). The viable motheaten mouse has a less severe phenotype that is associated with increased numbers of erythroid progenitor cells and hyperresponsiveness to Epo (498), suggesting that Shp-1 might normally diminish responsiveness to Epo. Indeed, it was demonstrated that Shp-1 binds directly to the EpoR when Y429 is phosphorylated (499). This tyrosine is located in a "negative" regulatory region of the EpoR, and when mutated, Epo-responsive cells can grow in lower concentrations of Epo. Following Shp-1 binding to Y429, dephosphorylation and inactivation of Jak2 is facilitated (499). Thus, the negative regulation of Epo signaling appears to be at the level of a receptor-dependent inactivation of a Jak kinase. Shp-1 has also been shown to interact with β_c and to mediate diminished IL-3–induced signaling (500), and

to be able to associate with both Tyk-2 (501) and Jak2 (502).

Shp-2 has generally been considered primarily an "activating" phosphatase; it is therefore interesting that it can also interact with Jak1, Jak2, and Tyk2 (503). In addition to the presumed dephosphorylation of Jak kinases by phosphatases, STAT proteins also appear to be regulated at the level of tyrosine dephosphorylation (504), and interestingly, it has been shown that dephosphorylation of phosphotyrosine on Stat1 dimers requires extensive spatial reorientation of the two monomers within the dimer, something that is facilitated by the N-terminal domain that is involved in tetramerization (505). Finally, another type of phosphatase, namely, the lipid phosphatases, known as SHIP and SHIP2, can act as negative regulators of cytokine signals (506).

In addition to Shp1 and Shp2, CD45, PTP1B, and T-cell PTP (TCPTP) have been reported to regulate Jak kinases. CD45 appears to play roles related to erythropoietin and IFN signaling. PTP1B has been reported to dephosphorylate Jak2 and TYk2, and TCPTP has been reported to dephosphorylate Jak1 and Jak3 (324). In the cytosol, Shp2 and PTP1B have also been reported to dephosphorylate cytosolic Stat5 and nuclear Stat1 and Stat3, whereas TCPTP has been reported to dephosphorylate Stat1 and Stat3 in both cytosol and nucleus, but additional work is needed to determine whether these events are occurring physiologically in vivo (324).

In addition to tyrosine phosphatases, dual specificity phosphatases with specificity for both tyrosine and serine/threonine exist and multiple members can negatively regulate MAP kinases (508a). Some of these are relatively lineage-restricted and can regulate signaling by type I cytokines (508b).

In addition to dephosphorylation, another mode of negative regulation is by degradation. In addition to the degradation of receptor molecules, Stat1 itself is a target of the ubiquitin-proteasome pathway (507). Finally, it is possible that regulation also can occur at the level of alternative splicing. In this regard, alternatively spliced versions of some of the STATs (323,382,389) have been reported.

THE CIS/SOCS/JAB/SSI FAMILY OF INHIBITORY ADAPTER PROTEINS

In 1995, the prototype molecule for an interesting class of proteins was discovered. The prototype molecule was named CIS, for cytokine-inducible, SH2-containing protein, and it was shown to negatively regulate the actions of a set of cytokines (508,509). CIS is rapidly induced by a variety of cytokines, including IL-2, IL-3, GM-CSF, and erythropoietin, to associate physically with both the β_c and erythropoietin receptors (508,509). Subsequently, a

related protein, variably denoted SOCS-1 (suppressor of cytokine signaling-1), JAB (Jak-binding protein), and SSI-1 (STAT-induced STAT inhibitor-1), was identified that could negatively regulate the activity of other cytokines, including IL-6 (*510*,511,*512*) and IL-2, among others. Interestingly, this protein could associate with Jak family kinases, whereas this function has not been reported for CIS. A total of eight CIS/SOCS/JAB/SSI family members have been identified that collectively regulate signals in response to multiple cytokines (*513*,*514*,,515,*516*). These proteins are now generally known as SOCS proteins and share a central SH2 domain and a C-terminal region known as a SOCS box. Additional SOCS box–containing proteins lack SH2 domains and include proteins known as ASBs (ankyrin repeat-containing proteins with a SOCS box), SSBs (SPRY domain-containing proteins with a SOCS box), and WSBs (WD40 repeat-containing proteins with a SOCS box). SOCS proteins tend to be expressed at very low levels in nonactivated cells and to be induced by cytokines and pathogens. Following their induction, they negatively influence cytokine signaling, serving as negative feedback regulators. Their actions can extend beyond type I cytokines; for example, SOCS-1 can negatively regulate LPS responses *(517)*.

Knockout mice for a number of the SOCS proteins have been prepared, alone and in combination. CIS KO mice are relatively normal, but CIS transgenic mice exhibit low body weight, failure of lactation, and diminished numbers of NK and NKT cells as well as altered TCR-mediated responses, presumably related to its ability to inhibit Stat5-dependent responses including those related to growth hormone, prolactin, IL-15, and IL-2, as well as others. SOCS1 knockouts exhibit multiorgan inflammation and neonatal lethality as the result of augmented responsiveness to IFN-γ, and this lethality can be prevented if the mice are crossed to IFN-γ-deficient mice. Interestingly, Socs1$^{-/-}$ mice also indicate an essential role for SOCS1 in thymocyte differentiation, and there are diminished numbers of maturing B cells. Deletion of SOCS1 within thymocytes/T cells/NK T cells results in multiple lymphoid abnormalites with increased CD8$^+$ T cells as a result of increased sensitivity to γ_c-dependent cytokines including IL-7 *(518)*. SOCS2 knockout mice exhibit gigantism, ostensibly due to dysregulated growth hormone signaling. SOCS3 knockout mice exhibit embryonic lethality as a result of placental insufficiency and dysregulated responses to LIF and IL-6, as well as hematopoietic defects. Conditional SOCS3 knockout mice have revealed a physiologic role for SOCS3 in regulating G-CSF signaling in myeloid cells and for "emergency" granulopoiesis (519) as well as for IL-6/gp130 signaling (520,*521*). SOCS6 knockous have mild growth retardation (324,515,*522*). Additional SOCS knockout mice and various combinations continue to be generated, adding additional information to this important area of negative regulation of STAT-dependent signaling.

PIAS PROTEINS

Protein inhibitors of activated STAT (PIAS) proteins are other negative regulators of cytokine actions (324,*523*–*527*), with PIAS-1 being an inhibitor of Stat1-binding activity and PIAS-3 being a similar inhibitor of Stat3-binding activity. These PIAS proteins block the DNA-binding activity of STAT dimers. Two other members, PIASx (which has both α and β splice variants) and PIASy, have also been described, with PIASx inhibiting Stat4 and PIASY inhibiting Stat1. They appear to act at least in part as transcriptional corepressors by recruiting other proteins such as histone deacetylase. In addition, PIASx and PIASy have added actions, not restricted to the context of STAT inhibition. For example, PIASy is a nuclear matrix–associated SUMO E3 ligase (a ubiquitin-related protein) that can repress the activity of the Wnt-responsive transcription factor, LEF1 *(526)*. PIASy coexpression results in the covalent modification of LEF1 by SUMO. Thus, as a class, PIAS proteins have more than one type of action (324).

THE T-HELPER PARADIGM: Th1, Th2, AND Th17

T-helper 1 (Th1) and Th2 cells were originally described based on the patterns of cytokine production by murine T cells (528), but the paradigm was extended to human cells as well (*529*,*530*,531–533). Th1 cells secrete IL-2, TNF, IFN-γ, and lymphotoxin, whereas Th2 cells produce IL-4, IL-5, IL-6, IL-9, IL-10, and IL-13. The cytokines produced by Th1 and Th2 cells are sometimes referred to as type 1 and type 2 cytokines (for Th1 and Th2 cytokines); unfortunately, this results in potential confusion as IL-4 is a type I (four–α-helical–bundle) cytokine that is functionally a type 2 cytokine (in that it is produced by Th2 cells).

In humans, the Th1 and Th2 patterns of cytokine production are similar, but not all the cytokines are as tightly restricted (*529*,*530*,531–533). IFN-γ is the cytokine most reliably produced by Th1 cells, whereas IL-4, IL-5, and IL-9 are produced by Th2 cells. In both species, certain cytokines, including IL-3 and GM-CSF, are produced by both Th1 and Th2 cells. The Th1/Th2 division of T-helper cells has proved useful in correlating the function of Th1 cells with cell-mediated immunity (inflammatory responses, delayed-type hypersensitivity, and cytotoxicity) and Th2 cells with humoral immunity. Of the Th2 cytokines, IL-4 is particularly important in driving IgE responses. As the division of Th1 and Th2 cells is not always perfect, when cells produce both Th1 and Th2 cytokines, they are called Th0 cells, whereas Th3 cells refer to cells that produce high levels of TGFβ.

A number of murine and human physiologic and disease states correspond to Th1 or Th2 responses/patterns (reviewed in 529–533). In general, among infectious diseases, resistance to intracellular bacteria, fungi, and

protozoa is linked to mounting a successful Th1 response. Th1 responses can also be linked to pathology, such as arthritis, colitis, and other inflammatory states. Effective protection against extracellular pathogens, such as helminths, requires a Th2 response, and the enhanced humoral immunity may result in successful neutralization of pathogens by the production of specific antibodies. In humans, Th1 and Th2 cytokines are each dominant in the different types of lesions found in leprosy, with Th1 cytokines dominating in tuberculoid lesions and Th2 cytokines dominating in lepromatous lesions. In HIV infection, a simple Th1/Th2 pattern does not exist. The situation has been complicated by the fact that IL-4 expression is relatively transient, whereas IL-10 expression is more sustained. This has led to the current thought that IL-10 and IL-12 may be the most important cytokines controlling disease progression in AIDS *(529)*. Interestingly, Th0 and Th2 cells seem to be more susceptible to HIV than Th1 cells, potentially explaining why the virus can persist even in the absence of Th1 cells. Overall, human diseases that are characterized primarily by Th1 responses include Hashimoto thyroiditis, Graves ophthalmopathy, multiple sclerosis, type 1 diabetes mellitus, Crohn disease, rheumatoid arthritis, lyme arthritis, reactive arthritis, acute allograft rejection, unexplained recurrent abortions, *Helicobacter pylori*-induced peptide ulcer, and sarcoidosis (533). In contrast, diseases characterized primarily by Th2 responses include Omenn syndrome, vernal conjunctivitis, atopic disorders, progressive systemic sclerosis, cryptogenic fibrosing alveolitis, chronic periodontitis, progression to AIDS in HIV infection, and tumor progression (533).

It is believed that Th1 and Th2 cells are derived from a common precursor (Thp cells). IL-12 is the major driving force to induce Th1 differentiation, whereas IL-4 induces Th2 differentiation, although IL-2 and Stat5 are required for optimal Th2 differentiation (*534,*535). Corresponding to these findings, as discussed earlier in this chapter, Stat4-deficient mice are defective in IL-12 signaling and exhibit a defect in Th1 development. Lineage commitment to Th1 and Th2 is now better understood in terms of transcription factors, where T-bet, Stat4, HLX, and EOMES are transcription factors influencing Th1 commitment and Stat6, c-Maf, JunB, NFATc1, and GATA-3 are more specific for Th2 cells (536,*537,*538). The process by which the differentiated Th cells produce cytokines is one in which the genetic loci need to become competent for efficient transcription. One can think of this process as involving an initiation phase dependent on STAT proteins, a commitment phase mediated by factors such as T-bet and GATA3, and a final stabilization phase in which transcription is maintained without further stimulation *(539)*. Part of this process involves chromatin remodeling, a process that involves histone-modifying enzymes as well as specific transcription factors (540), to allow transcription, for example, of the IL-4/IL-13 locus *(539)*, with Th2 lineage commitment involving demethylation of the IL-4 gene (*541,*542),

and Th1 commitment involving demethylation of the IFN-γ gene (298,543).

In addition to the major differences between Th1 and Th2 cells in the production of IFN-γ, it was observed that Th subsets differed markedly in their abilities to respond to IFN-γ, where the proliferation of Th2 clones was inhibited and that of Th1 clones was not *(544)*. Interestingly, the unresponsiveness of Th1 clones resulted from the absence of IFNGR-2, whereas Th2 cells express IFNGR-2 *(545,546)*. Thus, Th1 cells produce IFN-γ and can thereby inhibit the proliferation of Th2 cells. As noted earlier, IL-12 is the major inducer of Th1 cells. It is therefore interesting that Th2 cells do not respond to IL-12, and it is now clear that this extinction of IL-12 signaling results from their loss of expression of the IL-12Rβ2 subunit of the IL-12 receptor *(547)*. Apparently, IL-4 inhibits IL-12Rβ2 expression, whereas IFN-γ overcomes this inhibition *(547)*. The abilities of mice to survive infections is critically linked to the Th patterns of cytokines. For example, the ability to survive toxoplasmosis depends strictly on IFN-γ/IL-12 production (a Th1 pattern) (532).

In the past couple of years, another lineage of Th cells has been identified, known as Th17 cells *(548)*, which produce IL-17 in a manner dependent on IL-23 (549,*550*) and ROR-γ *(551)*. Interestingly, polarization of Th17 cells is dependent on TCR stimulation, TGFβ, and IL-6, but is independent of IL-23, which instead may be required for maintaining/expanding these cells (552,553,*554,555*). TGFβ may be less important for Th17 differentiation in the human (555a,555b). In a number of mouse autoimmune diseases that were believed to be caused by Th1 cells, the elimination of such cells paradoxically augmented the severity of disease, and it has become clear that Th17 cells are responsible, rather than Th1 cells. For example, EAE is exacerbated when IL-12/IFN-γ are eliminated. In contrast, the elimination of IL-23 (by eliminating either the p40 subunit shared by IL-12 and IL-23 or by eliminating p19) confers resistance to EAE (553,556). Whereas IL-23 promotes Th17 cell numbers, IL-27 can negatively regulate their development (556). It is now clear that IL-21/IL-21R play a critical role in Th17 differentiation (115a,115b,115c). Some specialized effector CD4$^+$ T cells have suppressor activity and are known as regulatory T cells (Treg cells) (discussed in Chapter 30).

DISEASES OF CYTOKINE RECEPTORS AND RELATED MOLECULES

A Range of Cytokine-Related Causes of SCID

As detailed earlier, mutations in the γ_c cause XSCID, and mutations in Jak3 cause a similar T$^-$B$^+$NK$^-$ SCID. Given that γ_c-dependent cytokines activate primarily Stat5a and Stat5b as signaling molecules downstream of the Jaks,

it remains an open question as to whether mutations in these STAT proteins also cause human disease. Although one might hypothesize that mutations in either Stat5a or Stat5b alone might not cause a phenotype, because of potential redundancy, mice that lack Stat5a or Stat5b exhibit defects in T- and NK-cell numbers as well as T-cell proliferation and NK cytolytic activity (385,386), and mice that lack both Stat5a and Stat5b have an even more profound defect, with absent T-cell (442) and NK-cell development (387). Given that Stat5a and Stat5b are tandem genes, perhaps a deletion of the Stat5a/Stat5b region of chromosome 17 would result in a new form of SCID, although it is likely that such a deletion could result in fetal lethality resulting from defective erythropoiesis, given the importance of Stat5a and Stat5b for Epo signaling.

It can be predicted that human immunodeficiencies might also result from mutations in some of the cytokines whose receptors contain γ_c, or from mutations in other components of the receptors for these cytokines. Indeed, as noted earlier, patients with IL-2 deficiency exhibit a SCID-like syndrome, due to inadequate function of their T cells, and recently an unusual immunodeficiency has been found to result from a mutation in IL-2Rα (259). One patient with defective IL-2Rβ expression also had an immunodeficient syndrome characterized by autoimmunity (557), somewhat analogous to IL-2Rβ–deficient mice. Given that mutations in IL-7Rα in humans cause T$^-$B$^+$NK$^+$ SCID (129), mutations in IL-7 might be predicted to cause a similar syndrome. The one major difference might be that IL-7–deficient humans might not be capable of receiving a successful bone marrow transplant if stromal IL-7 is required for the graft. Such patients have not yet been identified. Given the defective NK-cell development and CD8$^+$ memory T-cell development in IL-15– and IL-15Rα–deficient mice, it is likely that these types of defects would also occur in humans lacking either of these proteins. However, again, such patients have not yet been identified. Although IL-9 transgenic mice develop lymphomas (558), IL-9–deficient mice exhibit defects related to mast cells and mucous production rather than lymphoid defects. Thus, defects related to the IL-9 system seem unlikely as causes of SCID. At present, defective expression of IL-2, IL-2Rα, IL-2Rβ, IL-7Rα, γ_c, and Jak3 are the only cytokine-related mutations that have been found to cause SCID, with Tyk2 being implicated in another form of immunodeficiency. More time will be required to determine whether mutations in other cytokines, cytokine receptors, Jaks, or STATs can also cause SCID.

Defects in the Ability to Clear Mycobacterial Infections

A number of immunodeficiencies have been characterized in which affected individuals cannot properly clear mycobacterial infections. These have also turned out to be diseases of defective cytokine signaling. Mutations have been found in the components of either IL-12 itself or in the IFN or IL-12/IL-23 receptors, with mutations having been found in either the gene encoding the p40 subunit of IL-12 (which, as noted earlier, is also a component of IL-23) (559), in IL-12Rβ1 (a component of both the IL-12 and IL-23 receptors) (560), or in either the IFNGR-1 or IFNGR-2 components of IFN-γ receptors (561,562). The critical role of IL-12 for Th1 cell-mediated differentiation and production of IFN-γ provides the explanation for finding similar clinical syndromes in humans lacking the p40, IL-12Rβ1, IFNGR1, or IFNGR-2. Moreover, one patient with a mutation in the STAT1 gene was also identified with a similar clinical syndrome (563), indicating that, as anticipated, Stat1 is a critical mediator of the IFN-γ signal. Interestingly, this patient had a mutation on only one STAT1 allele, but the mutation was a dominant negative mutation that selectively inhibited the formation of Stat1 dimers (hence abrogating IFN-γ signaling) but yet had at most only a modest effect on the ability to form ISGF3, hence leaving signaling in response to IFN-α/β relatively intact.

Mutations in the WSX-1/TCCR Type I Receptor

Interestingly, there is a type I cytokine receptor denoted as TCCR or WSX-1 that is related to IL-12β2, and its mutation results in defective Th1-related responses and diminished IFN-γ production, resulting in susceptibility to Leishmania major and *Listeria* monocytogenes (172,564,565). TCCR/WSX-1 is an essential component of the receptor for IL-27 (214) and also has been found to be required for resistance to *Trypanosoma cruzi* (566,567).

Other Diseases Associated with Cytokine Receptors

A number of other diseases have been reported that are related to cytokine receptors. First, mutations in the growth hormone receptor have been found in a form of dwarfism (Laron dwarfism) (568) in which target cells cannot respond to growth hormone. Interestingly, some aspects of Stat5b deficiency are related to this syndrome. Second, a single patient with a form of congenital neutropenia (Kostmann syndrome) has been found to have a mutation in one of his G-CSF receptor alleles (569). Third, a kindred of patients with familial erythrocytosis has truncation in the erythropoietin receptor, resulting in hypersensitivity to erythropoietin (570). Finally, an altered virally encoded form (v-mpl) of the thrombopoietin receptor (c-mpl) was originally identified as the oncogene of the myeloproliferative leukemia virus (MPLV) (571).

Modulation of Cytokines and the Clinic

Certain diseases are associated with increased levels of cytokines or other situations in which treatment with an anti-cytokine receptor antibody is a rationale therapy. One

example is Castleman disease, which is associated with overproduction of IL-6 by lymph node cells, leading to the successful treatment of this disease with IL-6 receptor blockade (175,572). Anti-IL-6R–based therapy also has utility for rheumatoid arthritis and possibly for Crohn's disease (175,573). Blocking the IL-2 receptor has been used in the treatment of patients with adult T-cell leukemia and other neoplasias, and the use of humanized and conjugated antibodies has produced responses in a number of individuals. Humanized anti-Tac monoclonal antibody, marketed under the name Daclizumab, has shown very strong efficacy in the treatment of allograft rejection as well as in T-cell–mediated autoimmune disorders including multiple sclerosis, uveitis, and tropical spastic paraparesis. Conjugated antibodies to both IL-2Rα and IL-2Rβ are also being tested for use in a variety of malignant disorders wherein the malignant cells express these proteins. Thus, there is the possibility of therapy, either based on blocking the cytokine or based on eliminating the responding cells (574).

CONCLUSION

Type I cytokines and IFNs are involved in the regulation of an enormous number of immunologic and nonimmunologic processes. There has been a progressive transition from viewing these as discrete molecules with special actions to sets of molecules that can be grouped according to shared receptor components and common signaling pathways. Signaling is one area in which our understanding has greatly expanded; the pathways that are activated are similar for many cytokines, even when the biologic functions they induce are dramatically different. Although some of the differences can be explained by "compartmentalization," according to which cells produce the cytokine and which cells express receptors that allow them to respond to the cytokine, a tremendous amount still needs to be learned about how distinctive signals are triggered, as well as more regarding the sets of genes that are induced by each cytokine. These will provide vital information important to the quest to completely understand the mechanisms by which type I cytokines and IFNs can effect their actions. At the same time, the generation of knockout mice for most cytokines and their receptors, as well as many signaling molecules, has provided in vivo clues as to vital functions served by these cytokines. Caution is clearly needed, however, in generalizing from these findings to human biology, given some apparently major differences in roles served, such as the essential role played by IL-7 in both humans and mice for T-cell development, whereas IL-7 is also essential for B-cell development in mice but not in humans. The identification of so many human disorders associated with cytokines and cytokine receptors has tremendously helped to teach us more about human biology as well.

Interleukin-1 Family of Ligands and Receptors

Charles A. Dinarello

HISTORICAL BACKGROUND

The history of interleukin-1 (IL-1) begins in the period 1943 to 1948 with studies by Menkin and Beeson on the pathogenesis of fever and the properties of the fever-producing protein called endogenous or leukocytic pyrogen. Many investigators primarily interested in the links connecting fever, infection, and inflammation studied leukocytic pyrogen. In 1972, Waksman and Gery reported that soluble factors from macrophages augmented lymphocyte proliferation in response to mitogenic stimuli. Kampschmidt contributed to the discovery phase of IL-1 by characterizing soluble factors that induced the synthesis of acute-phase proteins. In the field of rheumatoid arthritis, Krane and Dayer demonstrated that IL-1 induced prostaglandins and collagenases in synovial fibroblasts, and Saklatvala described IL-1 in the context of its ability to destroy cartilage. Others provided data that IL-1 was a colony-stimulating factor and induced neutrophilia. The term "interleukin" was established to streamline the description of the growing number of biological properties attributed to soluble factors from macrophages and lymphocytes. IL-1 was the name given to the macrophage product, and IL-2 was used for the lymphocyte product. At the time of the "interleukin" assignments, the amino acid sequences of IL-1 and IL-2 were unknown. Despite studies on highly purified preparations, the large number of diverse biological activities attributed to IL-1 as a single molecule engendered considerable skepticism. With the cloning of IL-1 in 1984 (1,2), however, study of the recombinant molecule established that IL-1 was indeed a pleiotropic cytokine that induced inflammation as well as augmented immunologic responses. In fact, humans injected with recombinant IL-1 manifested each of the biological properties that had been previously reported in animals using IL-1 purified from human blood monocytes. With the use of agents that specifically block IL-1 activity, it has been possible to define the role of this first interleukin in human disease, which has resulted in reduction of severity in some diseases.

OVERVIEW OF THE IL-1 FAMILY IN INFLAMMATION

Of the 11 members of the IL-1 family (IL-1F) of ligands, four gene products (IL-1α, IL-1β, IL-1 receptor antagonist, and IL-18) have been thoroughly studied *in vitro* and in animal models of disease. In the case of humans, the blocking of IL-1 activity has entered clinical medicine. The IL-1 receptor antagonist (IL-1Ra) is approved in several countries for treating the signs and symptoms, including joint destruction, of rheumatoid arthritis. It is estimated that more than 100,000 patients with rheumatoid arthritis and related diseases have been treated with IL-1Ra, some for more than 10 years. IL-1Ra has also been used in patients with type 2 diabetes, arresting the loss of the insulin-producing pancreatic beta cells in the islets of Langerhans (3). In addition to IL-1α, IL-1β, IL-1Ra, and IL-18, other members of the IL-1 family are found in various human tissues. The most recent addition to the IL-1 family is IL-1F11 (IL-33), the ligand for the former orphan receptor ST2. IL-33 plays a role in mast cell functions and the Th2 response.

The IL-1 Family as Proinflammatory Cytokines

Unlike IL-2 and other cytokines that affect lymphocyte function, differentiation, and expansion, most members of the IL-1 family of ligands primarily affect inflammation. Within the IL-1 family, several possess proinflammatory properties, whereas others possess antiinflammatory activities. The family of IL-1 receptors also transduce proinflammatory as well as antiinflammatory signals. What is meant by "proinflammatory"? The proinflammatory members of the IL-1 family stimulate the expression of genes associated with acute inflammation as well as chronic inflammation. The best example of an IL-1 family member in the context of inflammation is IL-1β. The ability of IL-1β to induce gene expression and synthesis of cyclooxygenase type 2 (COX-2), type 2 phospholipase A, and inducible nitric oxide synthase (iNOS) accounts for prostaglandin

E_2 (PGE$_2$), platelet-activating factor, and nitric oxide (NO) production. The results are fever, lowered pain threshold, vasodilation, and hypotension.

Another important proinflammatory property of IL-1β is its ability to increase the expression of adhesion molecules such as intercellular adhesion molecule-1 on mesenchymal cells and vascular-cell adhesion molecule–1 on endothelial cells. Together with the induction of chemokines, these properties of IL-1β promote the infiltration of inflammatory and immunocompetent cells from the circulation into the extravascular space and then into tissues, where tissue remodeling is the end result of chronic IL-1–induced inflammation. IL-1β is also an angiogenic factor and plays a role in tumor metastasis and blood vessel formation. In mice deficient in IL-1β, vascular endothelial cell growth factor (VEGF) cannot stimulate formation of blood vessels, and malignant melanoma cells do not spread. IL-1β also acts on bone marrow stem cells for differentiation of the myeloid series of progenitor cells. In humans injected intravenously with low doses of IL-1β, 1 to 10 ng/kg, fever is observed, as well as increased levels of adrenocorticotropic hormone, blood neutrophils, nitric oxide, acute-phase proteins, and several cytokines and chemokines. Humans are particularly sensitive to IL-1β, and a dose of 50 ng/kg results is frank hemodynamic shock.

Blocking IL-1 Activity

Specific blockade of IL-1 activity in humans has defined the role for this cytokine in several diseases. IL-1Ra is the specific receptor antagonist for IL-1α and IL-1β but not for any other member of the IL-1 family. When IL-1Ra occupies the IL-1 receptor type I (IL-1RI), bona fide IL-1 cannot bind to the receptor and there is no biological response to IL-1. The existence of this highly specific, naturally occurring receptor antagonist in cytokine biology appears to be unique to the IL-1 family. In addition to IL-1Ra, the administration of neutralizing monoclonal antibodies to IL-1β or the IL-1 Trap (4) has been used to treat patients with rheumatoid arthritis. Although each of the IL-1–blocking therapies reduces the severity of rheumatoid arthritis, other treatments are also used to treat this disease. For example, anti–tumor necrosis factor-α (TNFα), anti-CD20 monoclonal antibody, and CTLA4-Ig are also effective therapies for rheumatoid arthritis. There are, however, other inflammatory diseases that rapidly remit with IL-1–blocking therapies but are not responsive to blocking TNFα. Those diseases in which IL-1 blockade is highly effective are termed "autoinflammatory" diseases to distinguish them from "autoimmune" diseases.

IL-1 and the Autoinflammatory Diseases

One important criterion for characterizing a disease as "autoinflammatory" is that on the blocking of IL-1 activity, patients experience a rapid and sustained cessation of symptoms, as well as reductions in biochemical and hematologic markers of the disease. The clinical manifestations of the autoinflammatory syndromes are recurrent fevers, neutrophilic leukocytosis, rashes, painful and deforming arthritis, and high serum levels of acute-phase reactants. Progressive deafness, leptomeningitis, and amyloidosis may also be present in some patients. The adult and juvenile forms of Still's disease fall into the "autoinflammatory" group. Since the use of the IL-1 Trap and the use of monoclonal anti–IL-1β antibodies are equally effective in treating autoinflammatory diseases, the culprit in these diseases is IL-1β and not IL-1α. Another criterion for classification of an autoinflammatory disease is a reduction in disease severity with the use of caspase-1 inhibition, which, as discussed later, targets the processing and secretion of IL-1β.

The biological basis for "autoinflammatory" diseases appears to be an increase in the spontaneous as well as inducible secretion of active IL-1β from blood monocytes. Increased release of IL-1β from primary blood monocytes has been documented in many of these patients compared to healthy controls. Most autoinflammatory diseases are syndromes. They include neonatal-onset multi-inflammatory disease, the Muckle-Wells syndrome, familial cold-induced autoinflammatory syndrome, hyper–immunoglobulin D (IgD) syndrome, familial Mediterranean fever, and urate crystal arthritis (gout). Although these syndromes are rare, the clinical manifestations are common to many inflammatory and infectious diseases.

The Inflammasome

The "inflammasome" plays an important role in processing inactive IL-1β, IL-18, and IL-33 precursors into active cytokines. The inflammasome is an assembly of intracellular proteins that activates caspase-1. Caspase-1 is an intracellular cysteine protease that cuts the N-terminal amino acids at the aspartic acid residue in the P1 position. In the case of IL-1β, caspase-1 cleaves the N-terminal 116 amino acids from the IL-1β precursor, thereby converting the precursor into an active cytokine. As shown in Figure 24.1, there are several steps in the processing and secretion of mature IL-1β. Cryopyrin is one of the essential proteins that comprise the inflammasome. Some patients with an autoinflammatory disease have mutations in cryopyrin, resulting in a loss in the control of IL-1β processing by caspase-1. There are also patients who have the clinical and hematologic characteristics of autoinflammatory syndromes but not mutations in cryopyrin. Nevertheless, spontaneous and inducible secretion of IL-1β from blood monocytes is elevated in these patients. The increase is modest (three- to fourfold compared to monocytes from healthy subjects), but these patients are debilitated from the chronic inflammatory process of their disease.
FIGURE 24.1 Steps in the activation of the caspase-1 inflammasome, processing of the interleukin-1β (IL-1β) precursor, and secretion of IL-1β. Primary blood monocytes from healthy human subjects are first activated by Toll-like receptor (TLR) ligands, for example, endotoxin binding to TLR-4 (1). The transcription (2) and translation into the IL-1β precursor (3) take place in the cytosol, not the endoplasmic reticulum (34). On activation of the P2X7 receptor by ATP (4), there is a rapid efflux of potassium from the cell (5a), resulting in fall in intracellular levels of potassium (5b). The fall in intracellular potassium levels triggers the assembly of the components of the caspase-1 inflammasome (6) with cryopyrin, ASC, and Cardinal. The assembled components of the inflammasome initiate the processing of pro-caspase-1, resulting in the formation of the active caspase-1 (7). Active casapse-1 cleaves the IL-1β precursor in the cytosol (8a) or in the secretory lysosome (8b), resulting in the carboxy-terminal mature IL-1β. An influx of calcium into the cell (9) with an increase in intracellular calcium levels (153,154) provides a mechanism by which mature IL-1β is released from the cell (10). The rise in intracellular calcium activates phosphatidylcholine-specific phospholipase C and calcium-dependent phospholipase A (2), which facilitate the secretion of IL-1β with exocytosis of the lysosomal contents (154). TIR, Toll-IL-1-receptor.

Table 24.1 lists examples of syndromes that fall into the "autoinflammatory" class and are treated by reducing the activity of IL-1β.

OVERVIEW OF THE IL-1 FAMILY IN IMMUNE RESPONSES

IL-1 as a Costimulator of T Cells

IL-1 (IL-1α or IL-1β) functions as a costimulator of T cell functions, primarily together with an antigen or a mitogen. For example, IL-1 is a costimulator for T cell proliferation, in that the combination of IL-1 plus a mitogen such as phytohemagglutinin (PHA) or concanavalin A (ConA) results in a greater production of IL-2 than either PHA or ConA alone. Alone, IL-1 does not induce IL-2. In fact, in the absence of a coactivator, IL-1 has no effect on T cells. The widely used bioassay for the immunologic activity of IL-1 for T cell proliferation is costimulation with a mitogen on murine thymocytes. Human thymic epithelium produces constitutive levels of IL-1α, which can function as a growth factor. However, it is unlikely that IL-1 plays a significant role in thymic growth and function because mice deficient in IL-1α or IL-1β or the IL-1RI have normal thymic development. Similar to IL-1α, IL-18 is strongly expressed

[c]IL-1 blockade with IL-1Ra protected the insulin-producing beta cells of the islets but did not affect peripheral insulin resistance. Hyperglycemia stimulates IL-1β secretion from the beta cell and accounts for the loss of the beta cell mass in type 2 diabetes (67).

in thymic epithelial cells. IL-18 induced CD11b-positive dendritic cells from thymocytes, and these IL-18–inducible dendritic cells were highly efficient at presenting antigen to CD4- and CD8-positive T cells.

IL-1 and Th2 Immune Responses

For the most part, IL-1 as a Th2 cytokine is derived from models of murine asthma. After airway sensitization to various antigens or haptens, the mice are challenged by inhalation of the antigen. The responses to antigen challenge are increased airway responsiveness to bronchoconstricting agents, infiltration of the lungs by eosinophils, and increased expression of IL-4. However, in mice deficient in IL-1RI or treated with neutralizing anti–IL-1β antibodies, the response to inhaled antigen is markedly reduced (5). By the use of airway sensitization with ovalbumin, eosinophil and neutrophil infiltration after inhalation antigen challenge was prevented in mice expressing IL-1Ra adenovirus (6). Suppression of IL-5 was also observed.

IL-1 and B Cell Functions

In 1983, a neutralizing antibody to human IL-1β was shown to inhibit pokeweed mitogen–stimulated human B cell proliferation and the generation of Ig-secreting cells (7). Since then, a role for IL-1β in antibody production has been repeatedly reported. For example, mice deficient in IL-1β do not produce anti–sheep red blood cell antibodies,

a T-dependent response (8). However, antibody production by T-independent antigens was normal in mice deficient in both IL-1α and IL-1, as was the proliferative response to anti-CD3. The evidence that IL-1β is a growth factor for B cell proliferation may be due to IL-1–mediated induction of IL-6. In fact, *in vitro* and *in vivo*, IL-6 is often under the control of IL-1. Therefore the effect of IL-1 on B cell functions may reflect the ability of IL-1 to induce IL-6.

IL-1 and Th17

The differentiation of naive CD4 T cells into IL-17–producing T cells plays a greater pathogenic role in models of autoimmune disease than do Th1 T cells producing IFNγ. IL-17 production is sustained by IL-23, and several autoimmune and inflammatory diseases do not develop in mice deficient in IL-23. The place of IL-1 in the generation of Th17 responses appears essential because T cells from mice deficient in IL-1RI fail to induce IL-17 on antigen challenge (9). IL-23 does not sustain IL-17 in IL-1RI–deficient T cells, and the combination of IL-23 plus either IL-1α or IL-1β is synergistic in the induction of IL-17. Even TNFα enhancement of IL-23–induced IL-17 is IL-1 dependent. Although the combination of IL-6 plus TGFβ induces IL-17, IL-6 production is often under the control of IL-1, particularly IL-1β. Therefore, one interpretation of one role of IL-1 in one generation of Th17 responses is the dependency of IL-6 production on IL-1 activity.

These studies are consistent with results on mice deficient in IL-1Ra. These mice develop a spontaneous rheumatoid arthritis–like disease. However, the disease does not develop in mice deficient in IL-17 (10). Furthermore, IL-1 activation of the cosignaling receptor OX40 induces IL-17. Taken together, these findings indicate that IL-1 appears to be upstream of IL-6 and OX40 activation and thus IL-17 production. The findings are also consistent with the observation that mice deficient in both IL-1α and IL-1β do not develop experimental autoimmune encephalomyelitis (EAE) (11). Several studies show that IL-1 and IL-17 act synergistically on the induction of nitric oxide, PGE, and cartilage breakdown, which is not unexpected, because IL-1 induces IL-17, and IL-17 in turn stimulates the production and release of IL-1β from primary human blood monocytes. In general, proinflammatory cytokines induce each other.

IL-18 Induces Th1 and Th2 Cytokines

Because IL-18 participates with IL-12 and IL-15 in the production of IFNγ, IL-18 is considered a classic Th1-inducing cytokine; however, there is a well-described role for IL-18 in the Th2 response (12). For example, IL-18 induces IL-4 and the number of IL-4–positive cells from activated natural killer (NK) T cells in the absence of IL-12. In general, the presence of IL-12 shifts the activity of IL-18 toward IFNγ and the Th1 response, whereas IL-18

in the absence of IL-12 drives the Th2 response. Combined overexpression of IL-18 and caspase-1 results in the development of spontaneous atopic dermatitis with increased expression of Th2 cytokines and IgE (13). In transgenic mice overexpressing IL-18, serum levels of IgE, IgG1, IL-4, and IFNγ were significantly increased (14). Therefore, high IL-18 production can polarize toward both Th1 and Th2 responses.

CASPASE-1 AND THE PROCESSING OF IL-1 FAMILY MEMBER PRECURSORS

With the exception of IL-1Ra, each member of the IL-1 family is initially synthesized as an inactive precursor molecule without a signal peptide. After processing by the removal of N-terminal amino acids by the specific intracellular cysteine protease called caspase-1, the resulting molecules are called "mature" forms. Caspase-1 is the first member of a large family of intracellular cysteine proteases with important roles in programmed cell death. However, there is little evidence that caspase-1 participates in programmed cell death. Instead, caspase-1 seems to be primarily used by the cell to cleave the IL-1β and IL-18 precursors. IL-33 also uses caspase-1 for cleavage (15). As shown in Figure 24.1, caspase-1 cleaves IL-1β, but the same steps are likely involved for the cleavage of IL-18 and IL-33. In the word "caspase" the "asp" refers to the aspartic acid in the P1 position. The aspartic acid in the P1 position is the recognition amino acid for all caspases. After cleavage, the mature form of IL-1β is generated as a 17.5-kDa molecule. Figure 24.2 depicts the caspase-1 cleavage sites of IL-1β, IL-18, and IL-33. Although caspase-1 is primarily responsible for cleavage of the precursor intra-

cellularly, other proteases such as proteinase-3 can process the IL-1β precursor extracellularly into an active cytokine (16). Proteinase-3 may also contribute to the processing of IL-18 (17).

DEFICIENCY IN IL-1 FAMILY MEMBERS

Mice deficient in IL-1RI, IL-1 receptor accessory protein (IL-1RAcP), IL-1α, or IL-1β or doubly deficient in IL-1α and IL-1β exhibit a phenotype no different from that of wild-type mice of the same strain. Thus, mice without IL-1 activity live in routine animal facilities. From these observations, one can conclude that IL-1α and IL-1β, which play important roles in disease, are not essential for normal embryonic development, postnatal growth, homeostasis, reproduction, or resistance to routine microbial flora. These mice also do not exhibit evidence of spontaneous carcinogenesis, and their life span appears to be normal. Lymphoid organ architecture is also normal. Each of these observations has been made regardless of background mouse strain. Nevertheless, in the context of an inducible disease, infection, or inflammatory challenge, a deficiency in IL-1 has a demonstrable effect on outcomes. In contrast, mice deficient in IL-1Ra do not exhibit normal reproduction, have stunted growth, and in selected strains develop spontaneous diseases such as rheumatoid arthritis–like polyarthropathy and a fatal arteritis (18,19).

In general, young mice deficient in IL-18 exhibit reduced responses in several models of disease. For example, IL-18–deficient mice are resistant to endotoxin lethality, collagen-induced arthritis, Fas ligand–mediated hepatitis, graft versus host disease, ConA-induced hepatitis, and allograft rejection. In contrast, a deficiency in the IL-18 receptor α chain results in a hyperresponsive phenotype to inflammatory challenges and greater production of TNFα, IFNγ, and chemokines (20). In a model of EAE, mice deficient in IL-18 exhibited the opposite in terms of disease severity to mice deficient in the IL-18 receptor (21). These findings challenge the underlying assumption that the IL-18 receptor is unique to IL-18. The conclusion from these findings is that an unknown ligand binds to the IL-18 receptor and delivers a negative signal, suppressing cytokine production and inflammation. As discussed later, the IL-1 family member IL-1F7 binds to the IL-18 receptor and may deliver an inhibitory signal.

PRODUCTION OF IL-1 FAMILY MEMBERS

Transcriptional Regulation of IL-1β

The primary sources of IL-1β are blood monocytes, tissue macrophages, and dendritic cells. B lymphocytes and NK cells also produce IL-1β. Fibroblasts and epithelial cells,

however, generally do not produce the cytokine. In health, circulating human blood monocytes or bone marrow aspirate do not constitutively express IL-1β. Constitutive expression of IL-1β in the human hypothalamus has been described (22). Several malignant tumors express IL-1β as part of their neoplastic nature, particularly acute myelogenous leukemia, multiple myeloma, and juvenile myelogenous leukemia, each of which exhibits constitutive expression of IL-1β. In general, production of IL-1β in tumors contributes to their ability to spread and to induce neovascularization (23–25).

Nearly all microbial products induce IL-1β via the various ligands of the Toll-like receptors (TLRs). TLR–4 is used by lipopolysaccharide (LPS) to induce several cytokines, and the induction of IL-1β is particularly sensitive to low (1 to 10 pg/mL) concentrations of LPS. A LPS–IL-1 response element has been described in which a complex of STAT-1, tyrosine phosphorylated interferon response factor 8, and Spi/PU.1 is required (26). IL-1β mRNA levels rise rapidly within 15 minutes but begin to decline after 4 hours. This decrease is likely due to the synthesis of a transcriptional repressor and/or a decrease in mRNA half–life or the action of micro RNA. However, when IL-1 is used as a stimulant of its own gene expression, IL-1β mRNA levels are sustained for more than 24 hours compared to microbial stimulants. Raising intracellular cAMP levels with histamine enhances IL-1α–induced IL-1β gene expression and protein synthesis (27). Inhibition of translation by cycloheximide results in enhanced splicing of exons, excision of introns, and increased levels of mature mRNA (superinduction) by two orders of magnitude. Thus, synthesis of mature IL-1β mRNA requires an activation step to overcome an apparently intrinsic inhibition to process precursor mRNA.

Unlike the promoter of IL-1α, the promoter region for IL-1β contains a TATA box. Unlike most cytokine promoters, IL-1β regulatory regions are distributed over several thousand base pairs upstream and a few base pairs downstream from the transcriptional start site. The topic of IL-1β gene regulation has been reviewed in detail (26). In addition to a cAMP response element, there is an NFκB-like site. Activating protein-1 (AP-1) sites also participate in LPS-induced IL-1β gene expression.

There is no constitutive gene expression for IL-1β in freshly obtained human peripheral blood mononuclear cells (PBMCs) from healthy donors using more than 40 polymerase chain reaction cycles (28,29); however, the same PBMCs express constitutive mRNA for IL-18 (29). In Western blot analysis from the same PBMCs, the precursor for IL-18 was present but not the IL-1β precursor. Constitutive IL-18 gene expression and the precursor IL-18 protein were also observed in freshly obtained murine splenocytes (29). In these splenocytes, there was no constitutive expression of the IL-1β gene or protein. Other than to distinguish differences between IL-1β and IL-18 in the

same cells, the clinical significance of constitutive gene and protein expression for IL-18 in health places IL-18 and the caspase-1 inflammasome in a unique situation.

Dissociation Between Transcription and Translation

Non-TLR ligands such as the complement component C5a, hypoxia, adherence to surfaces, or clotting of blood induce the synthesis of large amounts of IL-1β mRNA in monocytic cells without significant translation into the IL-1β protein (30). This dissociation between transcription and translation is characteristic of IL-1β but not most cytokines. It appears that these endogenous stimuli are sufficient to provide vigorous signal for transcription but not for translation. The IL-1β mRNA assembles into large polyribosomes without significant elongation of the peptide (31). Without translation, most of the IL-1β mRNA is degraded. However, adding TLR ligands or IL-1 itself to monocytes with high levels of IL-1β mRNA results in augmented translation in somewhat the same manner as the removal of cycloheximide after superinduction. One explanation is that stabilization of the AU-rich 3′ untranslated region takes place in cells stimulated with LPS. The stabilization of mRNA by microbial products may explain why low concentrations of LPS or a few bacteria or *Borrelia* organisms per cell induce the translation of large amounts of IL-1β (32). It is also possible that IL-1β mRNA is degraded by micro RNAs.

FUNCTIONS OF THE IL-1 FAMILY

Table 24.2 lists the members of the IL-1 family and their primary function. This chapter keeps the terms IL-1α, IL-1β, and IL-18, as well as IL-1Ra. The most recent addition to the IL-1 family, IL-1F11, is also termed IL-33, which is used in this chapter. Most members of the IL-1 family are

▶ **TABLE 24.2 Interleukin-1 Family Members**

New Name	*Other Name*	*Property*
IL-1F1	IL-1α	Agonist
IL-1F2	IL-1β	Agonist

IFNγ, interferon-γ; IL, interleukin.

located on the long arm of chromosome 2. All IL-1 family members are closely related to the primary amino acid sequences of IL-1β,L–1Ra, and IL-18. From the intron-exon organization, some members represent gene duplications. In the case of IL-1F5 and IL-1F10, the duplication of the IL-1Ra gene has taken place (33). IL-1F9 is also related to IL-1Ra; it does not function as a receptor antagonist, however, but rather as an agonist. IL-33 (IL-1F11) is closely related to IL-18. However, as described later, the activity of IL-1 family members is not determined by its structure but instead by its ability to transmit a signal or act as a receptor antagonist.

IL-1F1 (IL-1α)

The intron-exon organization of the IL-1 genes suggests duplications of a common gene 350 million years ago. Before this common IL-1 gene, there may have been another ancestral gene from which fibroblast growth factors (FGFs) also evolved because IL-1 and FGFs share significant amino acid homologies. Like FGFs, IL-1α is synthesized as a precursor molecule without a signal peptide; unlike IL-1β, the IL-1α precursor is biologically active. Most proteins are translated by the endoplasmic reticulum, but the 31-kDa IL-1α precursor is synthesized in association with cytoskeletal structures (microtubules and microfilaments). Immunohistochemical studies of IL-1α in LPS-stimulated human blood monocytes revealed a diffuse staining pattern. By comparison, in the same cell, IL-1Ra, which has a signal peptide, is localized to the Golgi complex (34). Even under conditions of cell stimulation, human blood monocytes do not process or readily secrete mature IL-1α. In contrast to IL-1β, IL-1α is not commonly found in the circulation or in body fluids except during severe disease, in which case the cytokine may be released from dying cells (36). Calpain, a calcium-activated cysteine protease associated with the plasma membrane, is responsible for cleavage of the IL-1α precursor into a mature molecule. It is unclear whether calpain cleavage of the IL-1α precursor is functional under physiologic conditions. The propiece of the IL-1α precursor is active intracellularly as a nuclear factor (35).

IL-1α as an Autocrine Growth Factor

The concept that IL-1α acts as an autocrine growth factor assumes that the intracellular IL-1α precursor regulates normal cellular differentiation, particularly in epithelial and ectodermal cells. In support of the concept, an antisense oligonucleotide to IL-1α reduces senescence in endothelial cells (37,38). In a murine Th2 cell line, IL-1α functions as an essential autocrine and paracrine growth factor, based on studies using an antisense IL-1α oligonucleotide or anti–IL-1α antibodies. Thymic epithelium also

produces IL-1α constitutively, and a requirement for IL-1α has been demonstrated to regulate the expression of CD25 (IL-2 receptor α chain) and maturation of thymocytes. However, the concept that IL-1α acts as an autocrine growth factor for skin or thymic epithelial cells must be interpreted carefully because mice deficient in IL-1α show no demonstrable defects in growth and development, including skin, fur, epithelium, and gastrointestinal function (39).

Is there is a role for intracellular precursor IL-1α in normal cell function? The effect, if any, would arise from the presence of large amounts of the intracellular form of the IL-1Ra (icIL-1Ra) (40). This form of the IL-1Ra also binds to the IL-1RI and prevents signal transduction. In fact, icIL-1Ra is produced in the same cells that express the IL-1α precursor and are believed to compete with the intracellular pool of precursor IL-1α for nuclear binding sites. However, normal epithelial functions in the IL-1α–deficient mouse as well as the IL-1Ra–deficient mouse do not support the concept that there is a natural role for IL-1α in epithelial growth and differentiation.

Membrane IL-1α

Precursor IL-1α can be found on the surface of several cells, particularly on monocytes and B lymphocytes, in which case it is referred to as membrane IL-1α (41). Membrane IL-1α is biologically active; its biological activities are neutralized by antibodies to IL-1α but not to IL-1β. Membrane IL-1α is likely anchored to the cell membrane via a lectin interaction involving mannose residues. A mannose-like receptor appears to bind membrane IL-1α (42). Membrane IL-1α plays an important role in inflammation because mice deficient in IL-1α exhibit reduced inflammation in models in which cell death and the release of intracellular IL-1α does not take place (43).

Autoantibodies to IL-1α

Neutralizing autoantibodies directed against IL-1α may function as natural buffers for IL-1α. Autoantibodies to IL-1α have been detected in healthy subjects as well as in patients with various autoimmune diseases. Autoantibodies to IL-1α are neutralizing IgG antibodies that bind the IL-1α precursor as well as mature IL-1α (44). An inverse correlation has been observed between the levels of anti–IL-1α antibodies and clinical disease activity.

Biological Functions of Constitutive IL-1α

Primary cells contain constitutive levels of the IL-1α precursor and not IL-1β (45). Most cell lines, including tumor cell lines, contain constitutive levels of IL-1α (35,46,47). It is not surprising that, because the IL-1α precursor is

biologically active and found in normal epithelial cells, including thymic epithelium, contents from necrotic cells contain biologically active IL-1α (36). It is well known that contents of necrotic cells are inflammatory, and hence their activity is due to IL-1α present in either the cytosol or the membrane fraction (35). Even if a cell contains the IL-1β precursor, any biological activities of its contents would be due to IL-1α because the IL-1β precursor is inactive (45). Furthermore, epithelial cells do not contain caspase-1, and therefore processing of the IL-1β or IL-18 precursor cannot yield the biologically active form of either cytokine. Therefore, using necrotic cells as a source of inflammation will favor IL-1α activity, not IL-1β or IL-18, because the IL-18 precursor is also inactive. Constitutively expressed IL-1α is critical for several IFNγ activities. In a study with the WISH epithelial cell line, what were considered to be intrinsic IFNγ activities depended largely on constitutively expressed IL-1α. IFNγ activities were inhibited by antibodies to IL-1α but not to IL-1β (47). It was also reported that antibodies to IL-1α and not to IL-1β prevent the biological activities of necrotic cells (36).

Studies in IL-1α–Deficient Mice

Mice deficient in IL-1α are born healthy and develop normally. After subcutaneous injection of turpentine, which induces a local inflammatory response, wild-type and IL-1α–deficient mice develop fever and acute-phase proteins, whereas IL-1β–deficient mice do not (39). In addition, although the induction of glucocorticoids after turpentine injection was suppressed in IL-1β–deficient mice, this suppression was not observed in IL-1α–deficient mice. However, expression of IL-1β mRNA in the brain decreased 1.5-fold in IL-1α–deficient mice, whereas expression of IL-1α mRNA decreased more than 30-fold in IL-1β–deficient mice. These data suggest that IL-1β exerts greater control over production of IL-1α than does IL-1α over the production of IL-1β. In caspase-1–deficient mice, IL-1α production is also reduced (48), suggesting that production of IL-1α is under the control of IL-1β.

The effects of IL-1 on atherogenesis caused by a high-cholesterol diet was evaluated in mice deficient in either IL-1α or IL-1β (43). Serum amyloid A protein, a marker of inflammation in atherogenesis, was markedly lower in IL-1α–deficient mice than in wild-type or IL-1β–deficient mice. IL-1α–deficient mice had significantly higher levels of non–high-density-lipoprotein cholesterol. The beneficial effect of IL-1α deficiency was due to bone marrow cells. Transplantation of bone marrow cells from IL-1α–deficient mice resulted in a reduction in aortic lesion size twice that observed in mice transplanted with IL-1β–deficient bone marrow cells. Therefore, IL-1α appears to play a greater role in the pathogenesis of lipid-mediated atherogenesis than IL-1β, and this may be due to an effect

of membrane IL-1α. However, without IL-1α, the nuclear factor function of the IL-1α propiece is also absent.

IL-1F2 (IL-1β)

Processing and Secretion of IL-1β via the Caspase-1 Inflammasome

Inactive pro–caspase-1 is constitutively expressed in macrophagic cells as a primary transcript of 45 kDa requiring two internal cleavages before becoming an enzymatically active heterodimer comprised of a 10- and a 20-kDa chain. The active-site cysteine is located on the 20-kDa chain. Due to alternate RNA splicing, there are five isoforms of human caspase-1 (α, β, γ, δ, and ε); caspase-1α cleaves the caspase-1 precursor as well as the IL-1β precursor. It is presumed that caspase-1β and γ also process precursor caspase-1. In the presence of specific inhibitors of caspase-1, the generation and secretion of mature IL-1β is reduced, and precursor IL-1β accumulates mostly inside the cell. The precursor is also found outside the cell, supporting the concept that precursor IL-1β can be released from a cell independent of processing by caspase-1.

The rate-limiting step in the processing and secretion of active IL-1β takes place in the caspase-1 inflammasome. As shown in Figure 24.1, several intracellular proteins form a complex with cryopyrin, a large protein with a domain of leucine-rich repeats similar to those of TLR, to form the inflammasome. Cryopyrin was initially discovered in patients with familial cold autoinflammatory syndrome, a genetic disease characterized by hives, fevers, and elevated acute-phase proteins after exposure to cold (49). Assembly of the inflammasome components with inactive pro–caspase-1 takes place after a fall in intracellular potassium. ATP activation of the P2X7 receptor opens the potassium channel, and simultaneously, as potassium levels fall, caspase-1 is activated by the inflammasome. As shown in Figure 24.1, the cleavage of the IL-1β precursor by active caspase-1 can take place in the specialized secretory lysosomes or in the cytoplasm. An increase in intracellular calcium is also required for the mature IL-1β to exit the cell.

The function of caspase-1 inflammasome is primarily to convert inactive pro–caspase-1 into the active enzyme. This activation is triggered by the efflux of potassium and is rapidly followed by the appearance of mature IL-1β in the supernatant together with the processed caspase-1. However, a single amino acid mutation in cryopyrin results in activation of caspase-1 without a requirement for a sudden fall in the level of intracellular potassium to activate the inflammasome. Mutated cryopyrin allows for the assembly of the complex of interacting proteins in the presence of normal intracellular levels of potassium. Cells from patients with Muckle-Wells syndrome or neonatal-onset multiinflammatory disease secrete more IL-1β than do cells from healthy controls. Although studied using an

exogenous stimulant such as endotoxin, monocyte secretion of IL-1β from these patients is stimulated by endogenous inflammation *in vivo*; in fact, the most likely endogenous stimulant is IL-1β itself.

Any disease process that includes an increase in the steady-state levels of caspase-1, components of the inflammasome, or the IL-1β precursor carries the potential to be an "autoinflammatory" disease. Blocking IL-1β in patients with mutations in cryopyrin is associated with an *in vitro* reduction in the secretion of IL-1β from monocytes when compared to secretion before treatment (50). IL-1β stimulates both its own gene expression and translation of the mRNA into the precursor (51,52).

Effects in Mice Deficient in IL-1β

The IL-1β–deficient mouse has shown no abnormal findings after 10 years of continuous breeding. However, on challenge, IL-1β–deficient mice exhibit specific differences from their wild-type controls. The most dramatic difference is in the response to local inflammation followed by a subcutaneous injection of turpentine. Within the first 24 hours, IL-1β–deficient mice injected with turpentine do not manifest an acute-phase response, do not de-

velop anorexia, have no circulating IL-6, and have no fever (53,54). These findings are consistent with those reported in the same model using anti–IL-1R type I antibodies in wild-type mice (53). IL-1β–deficient mice also have reduced inflammation after zymosan-induced peritonitis (55). Additional studies have also found that IL-1β–deficient mice have elevated febrile responses to LPS, IL-1β, and IL-1α. In contrast, IL-1β–deficient mice have nearly the same responses to LPS as do wild-type mice (56), with some notable exceptions. IL-1β–deficient mice injected with LPS have little or no expression of leptin mRNA or protein (57).

As shown in Table 24.3, in the mouse, IL-1β is critical for local and systemic inflammation. Another characterization of IL-1β deficiency can be seen in relation to body temperature, activity, and feeding during live influenza virus infection. Body temperature and activity were lower in IL-1β–deficient mice (58). The anorexic effect of influenza infection was similar in both groups of mice. The mice deficient in IL-1β exhibited a higher mortality to influenza infection than the wild-type mice. In addition, mice deficient in IL-1α have a brisk inflammatory response to turpentine-induced inflammation, whereas IL-1β deficient mice have nearly no response.

▌ **TABLE 24.3 Effects in Interleukin-1β–Deficient Mice**

Disease Model	Effects
LPS-induced fever	Fever similar to wild type or ↑ fever
LPS-induced leptin	↓ Circulating leptin
LPS-induced hypoglycemia	Normoglycemia
LPS-induced shock lung	No effect on neutrophil infiltration
LPS-induced coagulopathy	Plasminogen activator inhibitor unchanged
Disseminated *Canada albicans*	↓ Peritoneal neutrophils, ↓ superoxide production
Zymosan peritonitis	↓ Inflammation, ↓ mortality, and ↓ IL-6 and chemokines
Turpentine-induced inflammation	↓ Fever, ↓ IL-6; ↓ SAA ↓ cortisone, ↓ COX-2
C protein–induced myositis	↓ Disease severity
IL-1α–induced fever	↑ Fever, ↑ cytokines
B16 melanoma	↓ Hepatic metastasis, ↓ VCAM-1
Brain ischemia–reperfusion	↓ Neuronal death
Model of myasthenia gravis	↓ Disease development
Systemic lupus erythematosus	↓ Anti-dsDNA, ↓ disease severity
Collagen-induced arthritis	↓ Disease severity, ↓CD40 ligand, ↓OX40
Fas-expressing tumors	↓ Neutrophil infiltration
Turpentine-induced coagulopathy	↓ Plasminogen activator inhibitor
Contact hypersensitivity	↓ Langerhans cell activation
Steady-state levels p65 (NFκB)	↓ Levels and nuclear translocation
Delayed type hypersensitivity	↓ Sensitized CD4$^+$ T cells, ↓ proliferation to antigen
Airway hypersensitivity to antigen	↓ Bronchoconstriction, ↓ IgG1 and IgE
Carcinogen-induced tumors	↓ Tumors, ↓ neutrophil infiltration
Injury-induced astrogliosis	↓ Glial fibrillary acid protein
Meniscus model of osteoarthritis	↓ Damage to cartilage
VEGF-mediated neovascularization	↓ Hypoxia-inducible factor-1α, ↓ VEGF, ↓ VEGFR-2

COX-2, cyclooxygenase type 2; dsDNA, double-stranded DNA; Ig, immunoglobulin; IL, interleukin; LPS, lipopolysaccharide; SAA, serum amyloid A; VCAM-1, vascular cell adhesion molecule-1; VEGF, vascular endothelial cell growth factor; VEGFR-2, vascular endothelial cell growth factor receptor-2.

Differences in Carcinogenesis Between IL-1α– and IL-1β–Deficient Mice

Mice deficient in IL-1β were compared to mice deficient in IL-1α in the microenvironment after chemical carcinogenesis (25). In IL-1β–deficient mice, tumors developed more slowly or did not develop in some mice. A deficiency in IL-1α, on the other hand, did not impair tumor development compared to wild-type mice injected with the same carcinogen. In IL-1Ra–deficient mice, tumor development was the most rapid. A leukocyte infiltrate was found at the site of carcinogen injection. The neutrophilic infiltrate was almost absent in IL-1β–deficient mice, whereas in IL-1Ra–deficient mice, a dense neutrophilic infiltrate was observed. In wild-type mice, the leukocytic infiltrate was sparse, and the infiltrate that was observed in IL-1α–deficient mice was similar to that of control mice. These findings may reflect the fact that IL-1β is secreted into the microenvironment, resulting in the emigration of monocytes and neutrophils, whereas IL-1α, which remains cell associated, is less likely to affect the microenvironment. The relationship of neutrophil-derived oxygen radicals and carcinogenesis is known.

IL-1F3 (IL-1Ra)

The IL-1 receptor antagonist (IL-1Ra) was first termed the "IL-1 inhibitor." The "inhibitor" had been reported by several groups (59), but it was Phillipe Seckinger, working in the laboratory of Jean-Michel Dayer, who demonstrated that the inhibitor of IL-1 prevented IL-1 binding to cells. The IL-1 inhibitor was purified to homogeneity, and the amino acid sequence was used to clone the molecule from a monocyte cDNA library (60). The IL-1 inhibitor was renamed the IL-1 receptor antagonist (IL-1Ra), and the generic name anakinra is used for the recombinant form of IL-1Ra. The amino acid sequence of IL-1Ra is more homologous to that of IL-1β than to that of IL-1α. There is only one IL-1Ra gene, but several isoforms exist. Unlike IL-1β, IL-1Ra has a classic leader peptide and is readily secreted. Other forms of IL-1Ra, namely intracellular forms lacking a leader peptide but derived from the same gene, have been reported. When expressed as a mature recombinant molecule, intracellular IL-1Ra blocks IL-1 binding as well as does the secreted form.

The Structural Analysis of the IL-1RI/IL-1Ra Complex

X-ray crystallography reveals that IL-1β has two sites of binding to IL-1RI. IL-1Ra also has two binding sites, which are similar to those of IL-1β. However, one of the binding sites of IL-1Ra binds to IL-1RI with a high affinity such that the second binding site is not available to recruit the IL-1RAcP. After binding of IL-1Ra to IL-1RI–bearing cells, there was no phosphorylation of the epidermal growth factor receptor, a well-established and sensitive assessment of IL-1 signal transduction. Overwhelming evidence that IL-1Ra is a pure receptor antagonist comes from studies of intravenous injection of IL-1Ra into healthy humans. At doses 1 million–fold greater than that of IL-1α or IL-1β, IL-1Ra had no agonist activity in humans (61).

Studies Using IL-1Ra in Animals

Because IL-1Ra exhibits no species specificity, a large body of data exists revealing a role for IL-1 in animal models of disease. As shown in Figure 24.3, when IL-1Ra binds to IL-1RI, there is no formation of the heterodimer with the IL-1RAcP chain, and in the presence of IL-1β, there is no activity. IL-1β can also bind to the IL-1R type II (IL-1RII) either on the cell surface or in the extracellular space. Table 24.4 lists the effect of IL-1Ra in various animal models of disease.

IL-1Ra (Anakinra) Treatment in Humans with Rheumatoid Arthritis

The recombinant form of IL-1Ra is called by the generic name anakinra. There have been several randomized, placebo-controlled, double-blind trials with anakinra in
FIGURE 24.3 Events following the binding of IL-1Ra to IL-1RI. The IL-1RI binds IL-1Ra (1). The high-affinity binding of IL-1Ra to IL-1RI prevents the binding of IL-1β to the receptor (2). The complex of IL-1Ra with IL-1RI does not recruit the IL-1RAcP (3), and as a result there is failure for the receptor chains to dimerize (4). Without dimerization, there is no signal to the nucleus (5). In the extracellular compartment, IL-1β can bind to sIL-1RII (6) or cell surface IL-RII (7) and prevent active IL-1β from transmitting a signal.

▶ **TABLE 24.4 Effects of IL-1 Receptor Antagonist *in vivo***

Models of live infection
  Improved survival, reductions in shock, nitric oxide production, intestinal inflammation and hypoglycemia. Decreased levels of circulating
    cytokines, insulin-like growth factor–1, thrombin, tissue plasminogen activator, plasminogen activator inhibitor, and elastase.
Models of local and systemic inflammation
  Decreased accumulation of neutrophils. Reductions in loss of cartilage proteoglycan.
  Decreased pancreatic and hepatic inflammation. Reduced myeloperoxidase levels and cytokines/chemokines.
Models of acute or chronic lung injury
  Decreased neutrophil infiltration, eosinophil accumulation, capillary leak, and airway hyperactivity. Prevention of pulmonary fibrosis,
    hypoxia-induced pulmonary hypertension.
Models of central nervous system injury
  Decreased lethality, stress-induced hypothalamic-pituitary axis, astrocytosis, edema, and infarct brain monoamine levels and number of necrotic
    neurons.
Models of metabolic dysfunction
  Reduction in hepatocellular damage, muscle protein breakdown, hyperglycemia, weight loss, and bone loss.
Models of autoimmune diseases
  Decreased in severity of experimental allergic encephalomyelitis, systemic lupus, graft versus host disease in mice, islet allograft rejection,
    contact hypersensitivity, adjuvant arthritis, and streptozotocin-induced diabetes.
Models of malignant disease
  Increased survival. Reduction in subcutaneous and metastatic melanoma. Decreased tumor-mediated weight loss. Reduction in colony
    formation and cytokine production of human acute myelogenous leukemia cells *in vitro*. Reduced spontaneous interleukin-6 and prostaglandin
    E_2 production in multiple myeloma cells.
Models of angiogenesis
  Decreased new blood vessel growth in tumors, reduced neovascularization by vascular endothelial cell growth factor.
Impairment of host responses

rheumatoid arthritis. A dose of 100 mg of anakinra administered subcutaneously daily has been approved in several countries. Due to a short serum half-life—less than 6 hours—daily dosing is effective when assessed by the number of swollen joints, activity, pain score, and C-reactive protein (CRP) levels. A total of 472 patients with severe rheumatoid arthritis were studied in a European multicenter trial (62). The rate of radiologic progression of joint destruction in the patients receiving anakinra was significantly less than in the placebo group at 24 weeks (63). An additional evaluation of these patients revealed a decrease in the rate of progression in erosion and joint space narrowing compared to placebo. These clinical findings are consistent with anakinra blocking the osteoclast-activating factor. Osteoclast activating factor, in fact, is IL-1β (64). In patients who received anakinra, synovial biopsies before and after 24 weeks of daily treatment revealed evidence of decreased cellular infiltration and expression of the adhesion molecules E-selectin and vascular cell adhesion molecule-1 using immunohistochemical techniques (65).

IL-1Ra (Anakinra) Treatment in Type 2 Diabetes

IL-1β was shown to be highly injurious to the insulin-producing pancreatic beta cell (66). High glucose concentrations induce IL-1β production from human beta cells,

resulting in impaired insulin secretion, decreased cell proliferation, and beta cell death (67). In a placebo-controlled trial in patients with type 2 diabetes, anakinra treatment for 13 weeks resulted in a significantly lower levels of glycated hemoglobin level compared to the placebo group (3). The blockade of IL-1 was also associated with lower levels of CRP and IL-6.

IL-1Ra (Anakinra) Treatment of Autoinflammatory Diseases

Table 24.1 lists several autoinflammatory diseases that have been treated with anakinra. In most cases, the responses have been rapid and sustained with daily injections. However, because of the short half-life of anakinra, cessation of treatment results in a rapid return of disease activity (50,68). Nevertheless, on restarting treatment, disease activity is again controlled. As stated in the introductory remarks, autoinflammatory diseases are associated with increased secretion of IL-1β from blood monocytes (69–72).

Mice Deficient in IL-1Ra

Mice deficient in IL-1Ra have low litter numbers and exhibit growth retardation in adult life (73). These animals also have elevated basal concentrations of plasma IL-6 and exhibit higher levels of hepatic acute-phase proteins than wild-type control mice. Injection of LPS in

IL-1Ra–deficient mice results in increased lethality. The most dramatic phenotype has been observed in IL-1Ra–deficient mice crossed into a BALB/c background (18). In these mice, a chronic inflammatory polyarthropathy develops spontaneously. The joints show prominent synovial and periarticular infiltration of inflammatory cells, osteoclast activation, and bone erosion. The histologic pattern is similar to that of humans with rheumatoid arthritis. There are elevated levels of rheumatoid factor and anti–double-stranded DNA antibodies. Steady-state levels of COX-2, IL-1RI, IL-1β, IL-6, and TNFα mRNA in the affected joints are also increased. IL-17 is required for IL-1Ra–deficient mice to develop the arthritis (10). The onset of this autoimmune process also requires a genetic background favoring the Th2 response, which produces antibodies rather than cytotoxic T cells in response to antigens. The immunologic stimulus likely occurs when either an endogenous antigen or an antigen from the intestinal flora triggers a Th2 response, which, in the absence of endogenous IL-1Ra, results unopposed IL-1 activities.

IL-1Ra–deficient mice also develop a lethal arterial inflammation involving primary and secondary branch points of the aorta (19). These are stress points in the vessel wall due to blood flow and are also the same locations at which atherosclerotic plaques are commonly found. The lesions are characterized by transmural infiltration of neutrophils, macrophages, and CD4$^+$ T cells. Death is due to vessel wall collapse, stenosis, and organ infarction. Heterozygotes, which have reduced but detectable levels of endogenous IL-1Ra compared to wild-type controls, do not die from this severe arteritis but do develop small arterial lesions.

IL-1F4 (IL-18)

IL-18 is unquestionably a proinflammatory cytokine in the IL-1 family. The tertiary structure of the mature form of IL-18 closely resembles that of IL-1β (74). However, the biology of IL-18 is hardly the recapitulation of IL-1β. There are several unique and specific properties in the biology of IL-18. For example, in healthy human subjects and also in normal mice, gene expression for IL-1β in blood mononuclear cells and hematopoietic tissue is absent, and there is no evidence to suggest that the IL-1β precursor is constitutively present in cells (29). In contrast, in the same blood samples large amounts of the IL-18 precursor are present. Peritoneal macrophages and mouse spleen also contain the precursor in the absence of disease (29).

Together with IL-12, IL-18 participates the T helper-1 (Th1) paradigm. This property of IL-18 is due to its ability to induce IFNγ either with IL-12 or IL-15. Without IL-12 or IL-15, IL-18 does not induce IFNγ. IL-12 or IL-15 upregulates the IL-18 receptor β chain (IL-18Rβ), which

is essential for IL-18 signal transduction. Without IL-12 or IL-15, IL-18 plays a role in Th2 diseases (12). The role of IL-18 in the Th17 responses is unclear, but, being an inducer of IFNγ, IL-18 likely contributes to the actions of Th17 cells. Several IL-18–linked diseases are associated with elevated levels of IFNγ. Indeed, the original description of IL-18 was "IFNγ inducing factor." Diseases such as systemic lupus erythematosus, macrophage activation syndrome, rheumatoid arthritis, type 1 diabetes, Crohn's disease, psoriasis, and graft versus host disease are believed to be mediated, in part, by IL-18.

Like IL-1β, IL-18 is initially synthesized as an inactive precursor (molecular weight 24,000) and requires caspase 1 cleavage for processing into a mature molecule of molecular weight 18,000 (Figure 24.2). After an injection of endotoxin, caspase 1–deficient mice do not have circulating IFNγ (75). IL-12–induced IFNγ is also caspase 1 dependent (76), again suggesting that microbial toxins (via TLR) require IL-18 for IFNγ production. In general, processing of the IL-18 precursor is caspase-1 dependent, but exceptions exist. For example, Fas ligand stimulation results in the release of biologically active IL-18 in caspase 1–deficient murine macrophages (77). Similar to IL-1β processing, proteinase–3 appears to activate processing to mature IL-18 (17).

IL-18–Binding Protein

The discovery of the IL-18–binding protein (IL-18BP) took place during the search for the soluble receptors for IL-18 in human urine (78). IL-18BP is a constitutively secreted protein with exceptional affinity to IL-18 (400 pM) (Figure 24.6). There is limited amino acid sequence homology between IL-18BP and cell-surface IL-18 receptors; IL-18BP lacks a transmembrane domain and contains only one Ig-like domain (79). Present in the serum of healthy humans at a 20-fold molar excess compared to IL-18 (80), IL-18BP may contribute to a default mechanism by which a Th1 response to foreign organisms is blunted to reduce triggering an autoimmune responses to a routine infection. IL-18BP is a naturally occurring, specific inhibitor of IL-18, neutralizing IL-18 activities. A clinical preparation of human IL-18BP has been shown to be safe in patients (81). Other options for reducing IL-18 activities include inhibitors of capsase-1, human monoclonal antibodies to IL-18, soluble IL-18 receptors, and anti–IL-18 receptor monoclonal antibodies.

Natural neutralization of human IL-18 by IL-18BP takes place during a common viral infection. In *Molluscum contagiosum*, characterized by raised but bland eruptions, there are large numbers of viral particles in the epithelial cells of the skin, but histologically there are few inflammatory or immunologically active cells in or near the lesions. Clearly, the virus fails to elicit an inflammatory or immunologic response. Amino acid similarity exists

between human IL-18BP and a gene found in various members of the poxviruses, the greatest of which is found to be expressed in *Molluscum contagiosum* (82). The ability of viral IL-18BP to reduce the activity of mammalian IL-18 likely explains the lack of inflammatory and immune cells in the infected individual and provides further evidence for the natural ability of IL-18BP to interfere with IL-18 activity.

IL-18, Hyperphagia, and the Metabolic Syndrome

Starting at age 16 weeks, IL-18–deficient mice overeat, become obese, and exhibit lipid abnormalities, increased atherosclerosis, insulin resistance, and diabetes mellitus reminiscent of the metabolic syndrome (83). The higher body weight is attributed to enhanced food intake, which starts to diverge from those of wild-type animals at a relatively early age and reaches values of 30% to 40% higher than that of wild-type mice. A striking finding was an increase of more than 100% in the percentage of adipose tissue in the IL-18–deficient animals, which was accompanied by fat deposition in the arterial walls. The insulin resistance was corrected by exogenous recombinant IL-18. Mice deficient in IL-18 respond normally to a challenge with exogenous leptin, suggesting that a unique mechanism is responsible for the higher food intake in the IL-18–deficient animals.

IL-1F5

IL-1F5 shares 47% amino acid identity with IL-1Ra and is expressed in human monocytes activated by LPS. From the gene sequence, the predicted amino acid sequence of IL-1F5 does not have a leader peptide for secretion, which is in sharp contrast to the IL-1Ra (IL-1F3). IL-1F5 failed to exhibit agonist activity using induction of IL-6 from fibroblasts, a well-described biological property of IL-1α and IL-1β (84). Furthermore, IL-1F5 did not block the IL-1α– or IL-1β–induced IL-6– or IL-18–induced production of IFNγ (84). Therefore, IL-1F5 possesses neither IL-1– or IL-18–like agonist activities nor the property to act as a receptor antagonist for IL-1, despite it close amino acid identity to IL-1Ra.

It appears, however, that IL-1F5 functions as an antiinflammatory member of the IL-1 family. IL-1F5 induces IL-4, which can reduce IL-1 activity. The antiinflammatory effects of IL-1F5 include downregulating the responses to IL-1β as well as LPS; in mice deficient in IL-4, IL-1F5 is less effective as an antiinflammatory cytokine (85). The ability of IL-1F5 to dampen inflammation is via its interaction with the single immunoglobulin IL-1–related receptor (SIGIRR), also known as Toll-IL-1-receptor-8 (TIR8). SIGIRR is an orphan member of the

IL-1 family of receptors, and in mice deficient in SIGIRR, there is more inflammation than in wild-type control mice (85).

IL-1F6

IL-1F6 is a proinflammatory member of the IL-1 family. The cytokine binds to the IL-1R–related protein (IL-1Rrp2) as its ligand-binding chain and recruits the IL-1 receptor accessory protein (IL-1RAcP) to form the heterodimer. High levels of IL-1F6 are found in mouse embryonic tissues rich in epithelial cells (86). In humans, IL-1F6 is observed in keratinocytes but not fibroblasts, but it is believed to contribute to the inflammation of psoriasis. On forming the heterodimer with IL-1Rrp2 and IL-1RAcP, IL-1F6 activates NFκB, similar to IL-1β (87). In addition to NFκB activation, IL-1F6 also activates mitogen-activated protein kinase, c-Jun N-terminal kinase, and extracellular signal-related kinase (ERK) 1/2 (87).

IL-1F7

Although IL-1F7 (formerly IL-1H4) is structurally related to IL-1Ra (36%), this IL-1 family member binds to the IL-18 receptor α chain and therefore has attracted attention as being related to IL-18 (88). IL-1F7 has no leader peptide, and the recombinant form has been expressed with a N-terminus from a predicted caspase–1 site (89). There are two forms of IL-1F7: a full-length peptide and a splice variant with an internal 40–amino acid deletion (88). The binding of IL-1F7 to the soluble IL-18R α chain has also been observed. However, in contrast to IL-18, recombinant IL-1F7 does not induce IFNγ in whole human blood cultures, in PBMCs, or in various cell lines. Therefore, it is unlikely that IL-1F7 is a true agonist for the IL-18 receptor. In other studies, IL-1F7 bound to a recombinant form of the extracellular domains (soluble) of the IL-18 receptor α chain linked to the Fc of IgG but not to the extracellular domains (soluble) of the IL-1 type I receptor or ST2 (see later discussion) (90). Although IL-1F7 binds to the IL-18 receptor α chain, IL-1F7 is not a receptor antagonist for IL-18. When injected directly into murine tumors, adenovirus expressing IL-1F7 there was a significant reduction in tumor growth (91). The antitumor effects of IL-1F7 was diminished in mice deficient in IL-12, IFNγ, or Fas ligand (91).

IL-1F7 also binds to the IL-18–binding protein (IL-18BP) (92). This may be due to the similarities of IL-18BP to the third domain of the IL-18 receptor α chain. On formation of a complex with IL-18BP, there is decrease in IL-18 activity. In fact, there is increased inflammation in mice deficient in the IL-18 receptor α chain, whereas there is less inflammation in mice deficient in IL-18 itself (20). It is possible that IL-1F7 delivers a negative signal via the

IL-18 receptor α chain. In mice with experimental allergic encephalomyelitis, a deficiency in the IL-18 receptor α chain results in the opposite outcome to that in mice deficient in IL-18 (21). In the two studies, the investigators came to the conclusion that IL-18 receptor α chain binds another ligand in addition to IL-18 and that this ligand may be IL-1F7.

IL-1F8

The receptor for IL-1F8 is IL-1Rrp-2 (IL-1R6) and is expressed on human synovial fibroblasts and human articular chondrocytes. In response to stimulation by recombinant IL-1F8, there is increased production of proinflammatory mediators (93). Although IL-1F8 steady-state mRNA is constitutive in chondrocytes, the cytokine is inducible by IL-1β in synovial fibroblasts. Circulating levels of IL-1F8 patients with rheumatoid arthritis, osteoarthritis, or septic shock were similar to those in healthy subjects. It unclear what role extent IL-1F8 plays in joint disease, although constitutive expression in primary chondrocytes may indicate a role for the cytokine in osteoarthritis.

IL-1F9

IL-1F9 is constitutively expressed primarily in the placenta and the squamous epithelium of the esophagus. The three-dimensional folding of IL-1F9 is similar to that of IL-1Ra; nevertheless, IL-1F9 is a proinflammatory cytokine binding to IL-1Rrp2 and recruiting the IL-1RAcP. IL-1F9 triggers the same kinase cascade and NFκB as IL-1F6 (see previous discussion).

IL-1F10

IL-1F10 shares 37% amino acid identity with the IL-1Ra and a similar three-dimensional structure (94). This cytokine is secreted from cells and is expressed in human skin, spleen, and tonsil. Recombinant IL-1F10 has been shown to bind to the isolated extracellular domains IL-1 receptor type I, but it is unclear whether IL-1F10 binds to complete cell surface–bound IL-1 receptors. Although these data suggest that IL-1F10 is likely to be a receptor antagonist (95), compared to IL-1Ra, its role in health and disease is unclear.

IL-1F11

IL-1F11 is also known as IL-33. This new member of the IL-1 family requires caspase-1 processing and signals through the T1/ST2 receptor (15). ST2 is also termed the

IL-33 receptor α chain (IL-33Rα). Activation of ST2, formerly an orphan member of the IL-1 receptor family for 16 years, drives T helper type 2 (Th2) responses. The new cytokine, IL-33, is the specific ligand for ST2. In 1994, the receptor termed ST2 was first reported as regulated by the estrogen-inducible transcription factor Fos (96). This receptor was very similar to the IL-1 receptor type I and the IL-18 receptor α chain in that ST2 also has three extracellular Ig domains and an intracellular Toll domain (Figure 24.3). Despite a search for its cognate ligand, there was never a convincingly specific candidate; it was always assumed, however, that the ligand for ST2 would be a member of the IL-1 family. IL-33 recapitulates much of the existing data that ST2 promotes Th2-type responses. IL-33 is identical to a nuclear factor primarily expressed in high endothelial venules (NF-HEV) (97), suggesting that, similar to IL-1α (35), IL-33 acts as a proinflammatory cytokine by binding to ST2 as well as a nuclear factor and regulates transcription (97).

There is no dearth of studies on ST2 tissue-specific localization, regulation of its expression, and its effects in transgenic mice overexpressing ST2, as well as on deletion, neutralization, and antibody cross-linking of ST2. Elevated levels of the soluble form of ST2 were present in the circulation of patients with various inflammatory diseases, and exogenous administration of pharmacologic doses of soluble ST2 neutralized the putative ligand and reduced inflammation (98). Furthermore, several studies suggested that whatever the ligand is for this orphan receptor, it plays a role in allergic-type diseases because activation of ST2 uniquely drives Th2 responses. Structurally, IL-33 is closest to IL-18 rather than IL-1β. The dominant property of IL-33 is the induction of IL-4, IL-5, and IL-13 in addition to properties anticipated for a Th2-type cytokine. Diseases believed to be due to increased immunoglobulin production may also be related to IL-33. IL-33 induces the production of IL-6, IL-1β, and PGE from mast cells.

Mice injected with human IL-33 exhibit impressive pathologic changes in the arterial walls, lungs, and intestinal tissues (15). Of particular relevance to the concept that IL-33 drives a Th2 response is that esosinophilic infiltration was a prominent finding in the lung. Although the interpretation of *in vivo* effects after the administration of an exogenous cytokine should be conservative, the findings are clearly consistent with IL-33 being a proinflammatory ligand of the IL-1 receptor family. Even before researchers had the ability to test IL-33–mediated activation, others had reported that neutralization of the putative ST2 ligand using soluble ST2 markedly reduced joint inflammation, synovial hyperplasia, and joint erosion when given in the therapeutic phase of collagen-induced arthritis in mice (98). Moreover, it appears that organs with high numbers of mast cells appear to undergo dramatic changes on injection of IL-33 into mice. Consistent with a role in allergic diseases, IL-33 induces the cytokines IL-5 and IL-13

in vivo, known contributors of allergic diseases. Mice deficient in ST2 do not develop a Th2 response to *Schistosoma* egg antigen.

It remains unclear how IL-33 favors the Th2 response. Similar to IL-1β, IL-33 induces IL-6, which is an adjuvant for antibody production. IL-33 signal transduction requires a coreceptor for biological activities, and similar to IL-1, IL-33 uses the IL-1 receptor accessory protein. IL-33 induction of IL-6 is prevented by a blocking antibody to IL-1RAcP (99). IL-33 initiates signal transduction via activation of NFκB, which is typical of IL-1α, IL-1β, and IL-18 (15), but other studies have shown that antibody cross-linking of ST2 does not result in activation of NFκB but instead that of AP-1. There are also studies that IL-33 has antiinflammatory properties by inhibiting angiotensin II–induced phosphorylation of IκB in cardiac fibroblasts (100). ST2 can sequester TLR adaptor molecules such as MyD88 and Mal (101).

The idea of IL-33 as a member of the IL-1 ligand family gains considerable legitimacy because processing of the IL-33 precursor is accomplished by caspase-1 (15), similar to IL-1β and IL-IL-18. It is possible that lack of processing IL-33 into an active cytokine may contribute to the protection afforded caspase-1–deficient mice. From the first report of the existence of ST2 (96), a high level of expression of this receptor on mast cells has been a prominent finding. The Th2 response favors antibody production, including IgE and IgG.

IL-1 RECEPTOR FAMILY

The IL-1 receptor family encodes 10 members, some of which are orphan receptors. As shown in Figure 24.3, most belong to the group containing three IgG-like segments for the extracellular domain of the receptor. In general, the extracellular domains of these receptors can be cleaved from the cell surface by proteases; they are then termed "soluble" receptors. Soluble receptors can serve two functions: By binding to the ligand, they can neutralize the activity of the ligand, but they can also act as ligand carriers. Although most soluble receptors are generated by proteolytic cleavage from the cell surface receptors, this is apparently not the mechanism for high levels of soluble IL-1RAcP (sIL-1RAcP) (102). sIL-1RAcP forms a complex with IL-1β and sIL-1RII and is an effective mechanism for neutralization of IL-1β activity (103). Constitutive secretion of sIL-1RAcP accounts for its high serum levels. Supporting this concept is the existence of a splice variant of the IL-1RAcP that lacks a transmembrane anchor. Once synthesized, sIL-1RAcP is released by the liver as an acute-phase protein, as is IL-1Ra (104). As shown in Figure 24.4, sIL-1RAcP forms a complex of IL-1β with sIL-1RII in the extracellular space. Thus, a large molar excess of sIL-1RAcP provides at least three mechanisms by which to neutralize secreted IL-1β.

Table 24.5 summarizes the IL-1 receptor family and their functions (105). IL-1R1, IL-1R2, and IL-1R3 are the bona fide receptors for IL-1α and IL-1β. IL-1R4, also known as ST2, is no longer an orphan receptor because IL-33 binds to this receptor (15). Before the identification of IL-33 as the ligand for ST2, a number of studies had examined the function, distribution, and gene regulation of this receptor, particularly on mast cells (106). IL-1R5 was formerly an orphan receptor termed IL-1R–related protein–1 (107), but it was subsequently discovered to be the ligand-binding (α) chain of the IL-18 receptor (108), now termed IL-18Rα.

The IL-1R–related protein–2 (IL-1R6) is the receptor for the agonists IL-1F6, IL-1F8, and IL-1F9, but is also the receptor for IL-1F5, which is the antagonist for IL-1F9 (86,105). IL-1R7, formerly the non–ligand-binding chain of the IL-18 receptor termed IL-1RAcPL (109), is now named IL-18Rβ chain. Similar to the IL-1R–AcP, the IL-18Rβ is essential for IL-18 signal transduction (109,110).

Two members of the IL-1 receptor family are particularly singular in that they are found on the X chromosome. These are IL-1R8 and IL-1R9, both homologous to IL-1RAcP and IL-18Rβ. IL-1R9 is highly homologous to IL-1R8. Both forms have no known ligands, and the receptors are found in the fetal brain. Nonoverlapping deletions and a nonsense mutation in the IL-1R8 gene were found in patients with cognitive impairment (111), in which expression in the adult hippocampal area may play a role in memory or learning. The cytoplasmic domains of IL-1R8 and IL-1R9 are longer than the other accessory chains. The IL-1R9 may function as a negative receptor. This was shown in cells overexpressing this receptor in addition to IL-1RI and IL-1RAcP, in which IL-1β signaling was blocked with a specific antibody to IL-1RAcP. In the presence of the antibody, IL-1β–induced luciferase was suppressed, suggesting that a possible complex of the type I receptor with IL-1β plus IL-1R9 results in a negative signal (112).

Single Ig IL-1 Related Receptor

Single Ig IL-1 related receptor (SIGIRR) is a negative regulator of both IL-1α and IL-1β activities and also of TLR agonists. Although there is only a single IgG domain for the extracellular segment, the cytoplasmic domain contains a Toll domain and has the longest cytoplasmic domain of all the members of the IL-1 receptor family (Figure 24.5). Initially, SIGIRR was thought to be expressed primarily in kidney, lung, and gastrointestinal tract, primarily in resting epithelial cells. However, SIGIRR is also expressed in human monocytes and mouse macrophages in response to the stresses associated with infection and transient hypoxia. Dendritic cells also express SIGIRR (113). In a study of patients resuscitated from cardiac arrest, the peripheral monocytes displayed increased steady-state levels of SIGIRR, which were associated with increased gene
FIGURE 24.4 IL-1 signal transduction and decoy receptors. IL-1β binding to the IL-1RI (1) recruits the IL-1RAcP (2) to form a heterodimeric receptor (1 + 2). The cytoplasmic Toll domains on each receptor chain approximate (3). MyD88 and Tollip are recruited (4). MyD88 binding to the cytoplasmic domains triggers the phosphorylations of the IL-1–receptor associated kinases IRAK-4, IRAK-2, and IRAK-1 (5). TRAF-6 is recruited (6). Phosphorylated IRAK-1 and TRAF-6 migrate to the membrane and associate with TAK-1, TAB1, and TBA2 (7). The complex of TAK-1, TAB1, TAB 2, and TRAF-6 migrates to the cytosol, where TAK-1 is phosphorylated following the ubiquination of TRAF-6 (8). Phosphorylated TAK-1 activates IKKβ (9), and phosphorylated IKKβ phosphorylates IκB (10). Phosphorylated IκB degrades, releasing NFκB, which enters the nucleus (11). In addition to the phosphorylation of IKKβ, TAK-1 also activates MAPK p38 and JNK (12). On the surface of the cell, IL-1RII, a decoy receptor, may also bind IL-1β (13), but this complex does not recruit IL-1RAcP, and there is no signal. In the extracellular space, the extracellular domains (soluble or sIL-1RII) of the IL-1RII bind IL-1β and neutralize its activity (14). sIL-1RII can also bind IL-1β and form a complex with soluble IL-1RAcP (15) or cell-bound IL-1RAcP (16). In the latter two complexes, IL-1β is not available to bind to IL-1RI and therefore cannot transmit a signal.

expression for the antiinflammatory cytokine IL-10 and a decrease expression for TNFα. In microglia of mice infected with murine leukemia virus, a gene array of 14,000 genes revealed that only 3 genes were differentially ex- pressed between the virulent and nonvirulent strains of the viruses, and one of these genes was SIGIRR (114).

With overexpression of SIGIRR in the form of a chimeric molecule with IL-1RAcP, suppression of

FIGURE 24.5 IL-1 family of receptors.

IL-1–driven NFκB was observed. SIGIRR inhibition of IL-1–driven NFκB does not require the presence of the extracellular domain of SIGIRR. The complex of IL-1 with IL-1RAcP activates NFkB, but in the presence of SIGIRR there is suppression of the response. In another study, inhibition of IL-1 activity required the extracellular single Ig domain of SIGIRR (115). The mechanism for suppression of the IL-1 responses in cells overexpressing SIGIRR is one of competitive inhibition of MyD88, such that there is no activation of IRAK or TRAF-6 (115). The inhibition of MyD88, IRAK, and TRAF-6 by SIGIRR is not due to the formation of complex with IL-1RAcP or IL-1RI. Overexpression of SIGIRR results in inhibition of LPS and IL-1 activities, whereas mice deficient in SIGIRR exhibit heightened inflammation. Mice deficient in SIGIRR develop a more severe disease in response to LPS or chronic colitis (113,116). Overexpression of SIGRR in 293 cells inhibits both IL-1– and IL-18–induced NFκB reporter activity but not IFNγ activity (116). Splenocytes from mice deficient in SIGRR produce severalfold greater levels of the mouse chemokines KC and MIP–2 and IFN-inducible protein 10 after LPS. In a model of live *Pseudomonas* keratitis, a blocking antibody to SIGIRR resulted in increased bacterial counts and increased steady-state mRNA levels of IL-1β, IL-18, and IL-18 (117). Overexpression of SIGIRR in macrophages resulted in decreased mRNA levels for IL-1RI, IFNγ, IL-12, and IL-IL-18. Thus SIGIRR downregulates the responses to IL-1 and TLR4.

IL-1 Receptor Type I

There is considerable amino acid homology between IL-1RI and IL-1RAcP in extracellular domains. IL-1RAcP does not bind IL-1 itself, but instead it "wraps around" the complex of IL-1:IL-1RI. As shown by X-ray crystallization studies, IL-1RI exhibits a conformational change when binding IL-1β, and apparently this shape change allows the IL-1RAcP to form the heterodimer (Figure 24.4). The cytoplasmic domain of IL-1RI is unique in that it contains homology to the *Drosophila* Toll protein. The area of homology is termed Toll-IL-1-receptor (TIR) domain. TIR domain is also found in the cytoplasmic domains of each TLR. The TIR domain of IL-1RI is necessary for signal transduction. The TIR domain of the coreceptor IL-1RAcP is also essential for IL-1 activity. Although most cells express IL-1RI constitutively, expression of IL-1RAcP is not constitutive in some cells.

In general, IL-1-responsiveness is more a reflection of receptor expression than ligand binding (118). The failure to show specific and saturable IL-1 binding to cells is often due to the low numbers of surface IL-1RI on primary cells. In cell lines, the number of IL-1RIs can reach 5,000 per cell, but primary cells usually express less than 200 receptors per cell. In some primary cells there are less than 50 per cell, and IL-1 signal transduction has been observed in cells expressing less than 10 type I receptors per cell.

Human IL-1α binds to cell surface and sIL-1RI with approximately the same affinity (100 to 300 pM) as does IL-1Ra. If one examines the binding of IL-1Ra, the affinity is even higher than that of IL-1α. IL-1Ra avidly binds to the surface type I receptor (50 to 100 pM). Of the three members of the IL-1 family (IL-1α, IL-1β, and IL-1Ra), IL-1β has the lowest affinity for the cell-bound form of IL-1RI (500 pM to 1 nM). The greatest binding affinity of the three IL-1 ligands for IL-1RI is IL-1Ra. In fact, the off-rate is slow, and binding of IL-1Ra to cell-bound IL-1RI is nearly irreversible. Compared to IL-1Ra, IL-1α binds to IL-1RI with affinities ranging from 100 to 300 pM. By

comparison, IL-1β binds more avidly to the non–signaling type II receptor (100 pM).

Gene and Surface Regulation of IL-1RI

The entire gene is distributed over 29 kb; the genomic organization of the human type I receptor reveals three distinct transcription initiation sites contained in three separate segments of the first exon. The most proximal (5$'$) promoter region lacks a TATA or CAAT box, with striking similarity to the promoters of housekeeping genes rather than highly regulated genes. The transcription initiation start site contains nearly the same motif as that for the TdT gene (119). Phorbol esters, PGE$_2$, dexamethasone, epidermal growth factor, IL-2, and IL-4 increase surface expression of IL-1RI. In cells that synthesize PGE$_2$, IL-1 upregulates its own receptor via PGE$_2$; however, when PGE$_2$ synthesis is inhibited, IL-1 downregulates IL-1RI in the same cells. Part of the immunosuppressive properties of TGFβ may be due to downregulation of the IL-1RI on T cells. Despite the housekeeping nature of its promoters, IL-1RI is regulated in the context of inflammation and immune responses.

Studies in IL-1RI–Deficient Mice

Mice deficient in IL-1RI develop normally and exhibit no particular phenotype, similar to that observed in IL-1α– or IL-1β–deficient mice. When given a turpentine abscess, IL-1RI–deficient mice exhibited an attenuated inflammatory response compared with wild-type mice. Delayed-type hypersensitivity responses are reduced in IL-1RI–deficient mice. IL-1RI–deficient mice are susceptible to infection with *Listeria monocytogenes*. Lymphocytes from IL-1RI–deficient mice with major cutaneous leishmanial infection produced more IL-4 and IL-10 but less IFNγ than did those from wild-type mice. Although IL-1α is constitutively expressed in the skin, the barrier function of skin remains intact in mice deficient in IL-1RI (120). Cells deficient in IL-1RAcP have normal binding of IL-1α and IL-1Ra (binding to the IL-1RI being intact in these mice) but a 70% reduction in binding of IL-1β (121). In these cells, there is no biological response to IL-1α, despite binding of IL-1α to the type I receptor. The results suggest that IL-1RAcP and not IL-1RI is required for IL-1β binding and biological response to IL-1.

Mice injected with LPS have been studied. IL-1RI–deficient mice exhibit the same decrease in hepatic lipase as wild-type mice. Mice deficient in IL-1RI did not develop trabecular bone loss after ovariectomy compared to wild-type controls (122). Mice deficient in IL-1RI failed to develop inflammatory lesions of in the central nervous system or evidence of clinical EAE. Although cells from IL-1RAcP–deficient mice bound IL-1α, there was no activation of genes dependent on NFκB or activator protein-1 (121). In general, mice deficient in IL-1RI exhibit reduced

disease severity, as do wild-type mice injected with pharmacologic doses of IL-1Ra.

IL-1R Type II

As reported by Colotta et al., IL-1RII is a decoy receptor (123). As shown in Figures 24.3 and 24.4, the extracellular segment of the IL-1RII has three typical Ig-like domains; there is a transmembrane segment but a short cytoplasmic domain. The short cytoplasmic domain is unable to initiate signal transduction because there is no TIR domain. Therefore, IL-1RII captures IL-1 without signaling. Vaccinia and cowpox virus genes encode for a protein with a high amino acid homology to the extracellular or soluble domains of sIL-1RII. The viral form of the sIL-1RII serves to reduce the inflammatory and immune response of the host to the virus. In humans, sIL-1RII is released from the cell surface by a protease; sIL-1RII has a particularly high affinity for mature IL-1β and therefore functions as a naturally occurring neutralization mechanism for IL-1β.

IL-1β binding to the sIL-1RII is nearly irreversible. The precursor form of IL-1β also preferentially binds to sIL-1RII. A more efficient function of the type II receptor is to form a trimeric complex of the IL-1β with sIL-1RII and the IL-1RAcP chain (124). This mechanism serves to deprive the cell of both IL-1β and a functional receptor accessory chain. As shown in Figure 24.4, the type II receptor participates in four different complexes to deprive the cell of a response to IL-1β.

Modulation of IL-1 Activity by IL-1RII

The type II receptor is selectively expressed on macrophages, B lymphocytes, and chondrocytes. For example, B lymphocytes express 20-fold more type II receptors than type I receptors, but in T lymphocytes, this ratio is only 5-fold. Relevant to IL-1–mediated cartilage breakdown and inhibition of proteoglycan synthesis, chondrocytes express an excess of type II receptors. As shown in Figure 24.4, sIL-1RAcP forms complexes on the cell surface of IL-1β bound to type II receptors and accounts for the ability of sIL-1RAcP to reduce B lymphocyte activation (125). sIL-1RAcP inhibits IL-1–induced NFκB activity in B cells but not T cells, whereas IL-1Ra inhibited IL-1 on both cell types (126). sIL-1RAcP inhibits IL-1 signaling on cells expressing either low levels of membrane IL-1RAcP or high levels of IL-1RII.

sIL-1RI

The administration of the extracellular domain of the type I receptor (sIL-1RI) has been used in models of inflammatory and autoimmune disease. Administration of murine sIL-1RI to mice increased the survival of heterotopic heart allografts, reduced the hyperplasic lymph node response

to allogeneic cells, and inhibited responses to LPS, acute lung injury, and delayed-type hypersensitivity. In the accelerated model of autoimmune diabetes induced by cyclophosphamide in the nonobese diabetic mouse, repeated injections with sIL-1RI protected the mice from insulin-dependent diabetes mellitus in a dose- dependent fashion. sIL-1RI may act as ligand carrier. In mice, intravenous injection of sIL-1RI alone induced a rapid increase in circulating IL-1α but not of TNFα or IL-1β (127). This observation is consistent with the view that sIL-1RI acts as a carrier for IL-1α.

Effect of IL-1sRI in Humans

Recombinant human sIL-1RI has been administered intravenously to healthy humans without side effects or changes in physiologic, hematologic, or endocrinologic parameters. Thus, similar to infusions of IL-1Ra, administration of sIL-1RI reinforces the conclusion that IL-1 does not have a role in homeostasis in humans. sIL-1RI has also been injected into humans in an attempt to reduce the systemic responses to experimental endotoxin. There were no effects on fever or systemic symptoms (128). In contrast to sIL-1RI, pretreatment of subjects with IL-1Ra prior to intravenous endotoxin resulted in a statistically significant decrease (40%) in circulating neutrophils (129). High doses of sIL-1RI were associated with higher levels of circulating TNFα and IL-8 as well as cell-associated IL-1β (128). Although there was a decrease in the level of circulating IL-1β compared to placebo-treated subjects, there was also a 43-fold decrease in the level of circulating IL-1Ra ($p <$ 0.001) due to complexing of sIL-1RI with endogenous IL-1Ra. These results support the *in vitro* binding data showing that sIL-1RI binds IL-1Ra and reduces the biological effectiveness of this natural IL-1 receptor antagonist in inhibiting IL-1.

sIL-1RI was administered subcutaneously to patients with active rheumatoid arthritis in a randomized, double-blind study (130). Similar to the placebo-treated patients, lower doses of the soluble receptor did not result in improvement. Despite the lack of clinical improvement, cell surface monocyte IL-1α expression in patients receiving sIL-1RI was significantly reduced. Other parameters of altered immune function in common in patients with rheumatoid arthritis also showed reduction. One possible explanation for the lack of clinical response despite efficacy in suppressing immune responses could be the inhibition of endogenous IL-1Ra. A trial of sIL-1RI was conducted in patients with relapsed and refractory acute myeloid leukemia (131). Serum levels of IL-1β, IL-6, and TNFα did not change. The goal of any anti–IL-1 strategy is to prevent IL-1 binding to surface receptors. The disadvantage of sIL-sRI therapy is the possibility that these receptors will either prolong the clearance of IL-1 or bind the natural IL-1Ra.

The soluble form of IL-1RI and IL-1RII circulate in healthy humans at molar concentrations that are 10- to 50-fold greater than those of IL-1β measured in septic patients and 100–fold greater than the concentration of IL-1β after intravenous administration (132). Why do humans have a systemic response to an infusion of IL-1α (133) or IL-1β? One concludes that binding of IL-1 to the soluble forms of IL-1R types I and II exhibits a slow "on" rate compared to cell-bound IL-1RI.

IL-1 SIGNAL TRANSDUCTION

Binding of IL-1 to IL-1RI

This section examines signaling pathways following the binding of either IL-1α or IL-1β to IL-1RI; most of the structural analysis between IL-1 and IL-1RI is based on the binding of IL-1β. Once IL-1β binds to IL-1 RI, the distal first domain folds over IL-1β, and this exposes sites in the ligand that bind IL-1RAcP. Only after the formation of IL-1RI/IL-1β does IL-1RAcP join the complex and is high-affinity binding observed (Figure 24.4). Therefore, IL-1 binds to the IL-1RI with a low affinity, causing a structural change in the ligand followed by recognition by the IL-1RAcP. Antibodies to either IL-1RI or IL-1RAcP block IL-1 activity, supporting the concept that both chains, IL-1RI and IL-1RAcP, are needed for activity. Whereas most cells express surface IL-1RI, in IL-1-responsive cells, one assumes that there is also expression of IL-1RAcP.

Of special consideration to the study of IL-1 signal transduction is the unusual discrepancy between the low number of receptors (fewer than10 in some cells) and the low concentrations of IL-1 (10 pM) that induce a biological response. In primary cells, the number of IL-1RIs is low (fewer than 100 per cell), and a biological response occurs when only as few as 2% to 3% of IL-1RI receptors are occupied. An extensive "amplification" step(s) takes place following the initial post–receptor-binding event. The most likely mechanism for signal amplification is multiple and sequential phosphorylations (or dephosphorylations) of kinases.

Characteristics of the Cytoplasmic Domains of the IL-1RI and IL-1RacP

The cytoplasmic domains of the IL-1RI or IL-1RAcP do not contain a consensus sequence for intrinsic tyrosine phosphorylation, but deletion mutants of the receptor reveal specific functions of some domains. For example, there are four nuclear localization sequences, which share homology with the glucocorticoid receptor. Three amino acids (Arg-431, Lys-515, and Arg-518), also found in the Toll protein, are essential for IL–1-induced IL-2 production in mammalian cells (134). However, the significance of the nuclear localization sequences in IL-1RI is unknown.

Early Events in IL-1 Signaling

The earliest event after the formation of the IL-1 receptor heterodimer is the approximation of the cytoplasmic domains of each receptor chain (Figure 24.4). Within 1 minute, there is recruitment of the myeloid differentiation protein 88 (MyD88, a cytoplasmic adapter molecule), the Toll-interacting protein (Tollip), and the IL-1 receptor activating kinase (IRAK). There are four IRAKs. Deletion of specific amino acids in the IL-1RAcP TIR domain results in loss of IRAK association (135). It is the close proximity of the TIR domains of each chain that recruits MyD88. Limited sequence homology of the cytoplasmic domain of gp130 (the IL-6 family signaling receptors) with that of IL-1RI and IL-1RAcP suggests that complex formation of IL-1R/IL-1/IL-1RAcP transduces a signal similar to that observed with the dimerization of gp130. In fact, deletion of the gp130 shared sequences from the IL-1RI cytoplasmic domain results in a reduced response to IL-1. IL-1 shares several prominent biological properties with gp130 ligands; for example, fever, hematopoietic stem cell activation, and the stimulation of the hypothalamic-pituitary-adrenal axis are common to both IL-1 and IL-6.

Recruitment of MyD88 and IL-1 Receptor Activating Kinases

The small cytosolic protein MyD88 has many of the characteristics of cytoplasmic domains of receptors, but MyD88 lacks any known extracellular or transmembrane structure. Mice deficient in MyD88 do not respond to IL-1, IL-18, or most of the TLR ligands. It is unclear exactly how this protein functions because it does not have any known kinase activity. However, it may assist in the binding of the IRAKs to the complex and hence function as an adapter molecule. Of the four IRAKs (136), IRAK-2 associates with MyD88 and undergoes autophosphorylation (137). In mice with a deletion in IRAK-4, there is reduced LPS as well as IL-1 signaling (136). The binding of IRAK-1 and IRAK-2 to the IL-1R complex is an essential step in the activation of NFκB (138). In addition to MyD88, TNF receptor–associated factor-6 (TRAF-6) docks to the complex. TRAF-6 phosphorylates NFκB, inducing kinase (139), but some studies suggest that this kinase is not necessary for IL-1 signaling. However, in mice deficient in TRAF-6, there is no IL-1 signaling in thymocytes, and the phenotype exhibits severe osteopetrosis and defective formation of osteoclasts (140).

The IL-1 Signaling Cascade

Using immunoprecipitation and tandem mass spectrometry, a thorough analysis has been made of proteins that are rapidly phosphorylated after IL-1 binding. Within 15 seconds, the IL-1 signaling complex contains IL-1RI, IL-1RAcP, IL-1, and MyD88 (141). The complex appears to be stable with prolonged activation. In the stable complex, a 60-kD phosphorylated protein was identified as IRAK-4 (141). As in previous studies, only serine/threonine residues are phosphorylated in IL-1 signaling and not tyrosine. Although MyD88 is not phosphorylated, IRAK-1, 2, and 4 in the complex are phosphorylated. TRAF-6 also associates with IRAK–1. IRAK-1 is the only component of the IL-1 receptor complex that dissociates from the complex, and together with TRAF-6 it migrates to the membrane.

The Role of TGFβ-Activated Kinase-1 in IL-1 Signaling

TGFβ-activated kinase-1 (TAK-1), TAB1, and TAB2 form a membrane-associated complex to which IRAK-1–TRAF-6 binds (142). Polyubiquitination of TRAF-6 results in the phosphorylation of TAK-1, which then migrates to the cytoplasm (Figure 24.4). In the cytoplasm, phosphorylated TAK-1 activates several kinases. These are IκB kinases (IKK) (143), MAPK p38 (144), and JNK. Activated IKK degrades IκB, and NFκB is released to translocate to the nucleus and trigger gene expression.

Activation of MAP Kinases

Most consistently, IL-1 activates p38 MAP kinase, which phosphorylates serine and threonine residues on epidermal growth factor receptor, heat-shock protein p27, myelin basic protein, and serine 56 and 156 of casein. The p42/44 MAP kinase family is associated with signal transduction by growth factors including *ras-raf-1* signal pathways. In rat mesangial cells, IL-1 activates the p42/44 MAP kinase within 10 minutes and also increases *de novo* synthesis of p42 (145).

p38 MAP Kinase Activation

The p38 MAPK plays an important role in IL-1 activity. MAP kinases are highly conserved proteins homologous to the *HOG-1* stress gene in yeasts. In fact, when *HOG-1* is deleted, yeasts fail to grow in hyperosmotic conditions; however, the mammalian gene coding for the IL-1–inducible p38 MAP kinase (146) can reconstitute the ability of the yeast to grow in hyperosmotic conditions. In primary human monocytes stimulated with hyperosmolar NaCl, LPS, IL-1, or TNF, indistinguishable phosphorylation of the p38 MAP kinase takes place and results in IL-8, IL-1β, IL-1α, and TNFα gene expression, and synthesis takes place (28). Thus, the MAP p38 kinase pathways involved in IL-1, TNF, and LPS signal transductions share certain elements that are related to the primitive stress-induced pathway. The dependency of Rho members of the GTPase family (see later discussion) for IL-1–induced activation of p38 MAP kinases has been demonstrated (147).

This latter observation links the intrinsic GTPase domains of IL-1RI and IL-1R-AcP with activation of the p38 MAP kinase.

As discussed previously, signal transduction of IL-1 requires phosphorylation of TAK-1 for phosphorylation of MAPK. For the phosphorylation of TAK-1, polyubiquitination of TRAF-6 is required. Ubiquitination of TRAF-6 is dependent on E2 ubiquitin conjugating enzyme Ubc13. In cells conditionally deficient in Ubc13, IL-1–induced degradation of IκB was unaffected in mouse embryonic fibroblasts. However, IL-1–induced phosphorylation of p38 MAPK, JNK, and ERK was markedly reduced, whereas TNF-induced phosphorylation of MAPK was unaffected (148).

GTPases

Both a sequence and a structural comparison of the cytosolic segment of IL-1RI with the *ras* family of GTPases has been made. The known amino acid residues for GTP binding and hydrolysis by the GTPase family align with residues in the cytoplasmic domain of the IL-1RI. These finding are consistent with a model in which, with dimerization of the two IL-1 receptor chains, activation of the putative GTP-binding sites on the IL-1 receptor cytosolic domains takes place, followed by binding of small G proteins, hydrolysis of GTP, and activation of a phospholipase. In chondrocytes, IL-1 triggers an increase in intracellular calcium followed by the organization of filamentous actin in the cytoskeleton (149). IL-1 stimulation initiates a rise in the cellular level of calcium from intracellular stores, which is mediated by phospholipase C (150). The influx of calcium into the cell also takes place via activation of G protein–coupled receptors.

Some of the biochemical changes associated with signal transduction are likely cell specific. Within 2 minutes, hydrolysis of GTP, phosphatidylcholine, phosphatidylserine, or phosphatidylethanolamine and release of ceramide by neutral, not acidic, sphingomyelinase, have been reported. In general, multiple protein phosphorylations and activation of phosphatases can be observed with 5 minutes, and some are thought to be initiated by the release of lipid mediators. Phosphorylation of phospholipase A2–activating protein also occurs in the first few minutes, which leads to a rapid release of arachidonic acid.

IL-18 Signals Similarly to IL-1

MyD88-deficient mice do not respond to IL-18. Thus, MyD88 is an essential component in the signaling cascade that follows IL-1, TLR ligand, and IL-18 binding. The cascade of sequential recruitment of MyD88, IRAK-1, 2, 3, and 4 and TRAF-6 followed by the degradation of IκB and release of NFκB are nearly identical for IL-1 and for IL-18 (Figure 24.6). In IL-18–stimulated U1 macrophages, which
FIGURE 24.6 IL-18 signal transduction. The affinity of mature IL-18 for the IL-18Rα is low ($K_d = 50$ nM) but increases 100-fold with a complex of IL-18Rβ. Signal transduction in IL-18 involves MyD88 and IRAKs. TRAF-6 is also a part of IL-18 signaling. TRAF-6 is required for the phosphorylation of p38 MAP.

already expresses the gene for IL-18Rα, there is translocation of NFκB and stimulation of human immunodeficiency virus type 1 production (151).

TNF-Related Cytokines in Immunity

Carl F. Ware

INTRODUCTION

Lymphocytes are highly mobile, transiting the vascular and lymphatic circulatory systems with limited stopovers in organized lymphoid tissues (lymph nodes, spleen, and Peyer's patches), in which they commune to initiate immune responses. Cytokines, both secreted and membrane-anchored proteins, serve as the communication media of the immune system. Cytokines in the tumor necrosis factor (TNF) superfamily help to orchestrate the development, homeostasis, and effector actions of cells in the immune system. The diversification of the TNF superfamily is evidenced by its roles in regulating cells of neuronal, skeletal, and ectodermal origin. This chapter focuses on members in the TNF superfamily that are primarily involved in regulating immunity.

The ligands belonging to the TNF superfamily initiate intercellular communication by binding specific receptors on the surface of the receiving cell. The TNF receptors (TNFRs) form a corresponding superfamily of cognate membrane proteins that initiate intracellular signaling pathways that influence growth, differentiation, and survival. The TNF-related ligands are membrane bound and require cell–cell contact to initiate signaling,

although some ligands may be secreted in soluble form, influencing cellular responses at locations distant from the source of production. Each ligand–receptor pair forms a "system"; there are more than 40 distinct ligand–receptor systems. Many of the ligands and receptors engage more than one cognate, thereby forming "circuits" of signaling systems, which often function together as coordinated or integrated networks with other cytokines to regulate a specific cellular process. The signals delivered to the cytosol activate transcription factors such as NF-κB and AP1, which in turn initiate the expression of hundreds of genes that alter cellular differentiation. In addition, some TNFRs activate cell death pathways, both apoptotic and necrotic, terminating cellular life. Genetic mutations have revealed the importance of individual TNF superfamily members in human immune responses and development. Moreover, the beneficial effects of TNF antagonists in patients with certain autoimmune diseases have brought the need to understand the complexities of the TNF superfamily into sharp focus.

The nomenclature of the TNF superfamily is a bit of a morass for students new to the field, although introduction of a numerical system standardizing gene names (http://www.gene.ucl.ac.uk/nomenclature/) helps in accessing genomic databases. However, the use of more common, often colorful, acronyms continues. The name, rank, and genomic identification of each ligand (Table 25.1) and receptor (Table 25.2) are tabulated along with additional pertinent information for human and mouse genes.

TNF LIGAND FAMILY

The TNF-related cytokines are type II transmembrane proteins (intracellular N-terminus) with a short cytoplasmic tail (15 to 25 residues in length) and a larger extracellular region (approximately 150 amino acids) containing the signature TNF homology domain where the receptor-binding sites are located (Figure 25.1). The TNF homology domain assembles into trimers, the functional unit of the ligand. Atomic analysis of several members of the family (*1–5*) revealed that the ligands have a highly conserved tertiary structure folding into a β-sheet sandwich, and yet amino acid sequence conservation is limited to less than 35% among the family members. The conserved residues defining this superfamily are primarily located within the internal β strands that form the molecular scaffold, which promote assembly into trimers. Although most of the TNF ligands self-assemble into homotrimers, heterotrimers can also form between lymphotoxin-α (LTα) and LTβ (6), and between APRIL and BAFF (7). The stoichiometry of the LT heterotrimer is 1:2 (LT$\alpha\beta$2), which imparts its distinct receptor specificity from the LTα homotrimer. Of interest, complement component C1q and several related proteins are structurally related to the TNF family, containing a TNF homology domain, a rather surprising finding, given the apparent functional divergence between the complement and TNF systems (8). Alternate splicing can also generate distinct ligands, such as the splice form joining TWEAK and APRIL (TWE-PRIL) (9), the alternate ligands

for ectodysplasin receptor (10), and a cytosolic form of LIGHT (11).

The genetic organization of TNF ligands is highly conserved, typically encoded in three or four exons, with the fourth exon encoding most of the extracellular TNF homology domain. The genes encoding TNF, LTβ, and LTα reside adjacent to each other in a compact locus in the class III region of the major histocompatibility gene complex (MHC) (in humans at chromosome 6p21) sandwiched between the antigenic-peptide-presenting MHC proteins encoded by MHC class I and II genes (6,*12*). Three other genetic clusters of TNF-related cytokines are found within the corresponding MHC paralogous regions, located on chromosomes 1, 9, and 19, with a remarkably conserved gene structure and transcriptional orientation and a function linked to regulating cellular immune responses (11). The evolutionary pressures retaining this genetic configuration of the MHC in general are encompassed in the paralogy theory of genome evolution (13). Conservation of gene structure of the TNF ligands outside of these MHC paralogs is limited. An evolutionarily conserved pathway in *Drosophila melanogaster*—the Eiger-Wengen system—is structurally and functionally related to the TNF superfamily (TNFSF)–related signaling pathway, although this system is predominantly expressed in the nervous system in invertebrates (*14*,15,*16*).

TNF RECEPTOR FAMILY

Members of the TNF receptor superfamily (TNFRSF) include proteins of vertebrate and viral origin. Most of the signaling receptors in the TNFRSF are type I transmembrane glycoproteins (N-terminus exterior to the cell). However, several TNFRSF members lack a membrane-anchor domain, are proteolytically cleaved from the surface, or are anchored via glycolipid linkage (e.g., TRAILR3). These soluble receptors, termed "decoy receptors," retain their
FIGURE 25.1 Structure of tumor necrosis factor (TNF) and TNF receptor (TNFR). **Top:** TNF. The β-sandwich of TNF monomer (1A8M.pdf) (shown as a ribbon diagram) contains two stacked β-pleated sheets each formed by five antiparallel β strands (wide ribbons given letter designations, A to G) that fold into a Greek key or "jelly-roll" topology (193). The inner β sheet (strands A, A′, H, C, and F) is involved in contacts between adjacent subunits, which promotes assembly into a trimer. The trimer is formed such that one edge of each subunit is packed against the inner sheet of its neighbor. The outer β sheet (strands B, B′, D, E, and G) is surface exposed. The trimeric structure is characteristic of all TNF-related ligands. The type II configuration of TNF (N-terminus inside the cell) anchors TNF to the membrane. The TNF trimer is approximately 60 Å in height with a relatively flat base residing close to the membrane, resembling a bell shape (shown as a surface representation with different shades of gray used for each subunit of the trimer). The surface-exposed loops between A-A′ and D-E strands are involved in receptor binding. TNF is cleaved by TNFα-converting enzyme (TACE), a member of the ADAM family of metalloproteinases (ADAM17) involved in processing of many cell surface proteins. TACE is a type I transmembrane protein that cleaves TNF between residues Val75 and Ala76; when all three sites are cleaved, TNF is released into a soluble form. **Bottom:** TNF receptor and ligand complex. The ectodomain of TNFR1 forms an elongated molecule with CRD1 proximal to the N-terminus (depicted as a ribbon diagram). The face of TNFR1 on the left engages LTα. In the ligand–receptor complex the elongated receptor (dark) lies along the cleft formed between adjacent subunits. Shown (space-filling) is a single TNFR1 in complex with two subunits of LTα (lighter shading); the receptor N-terminus points upward, closest to the base of the ligand (*trans* orientation). In the exploded view, TNFR1 is removed from in front of the ligand, revealing the contact residues in the ligand, which are primarily located in the D-E and the A′-A″ β strands (dark shading). TNFR1 is rotated 180 degrees, exposing the contact residues in the receptor (light shading). Structures from 1TRN.pdf (17) as visualized with MacPyMOL (http://www.pymol.org).

ligand-binding properties and compete with cellular receptors for the specific ligands, thus earning the title of decoy receptor. The structural motifs in the cytoplasmic domains further categorize the TNFR into two groups based on their signaling properties: those that contain a death domain and those that engage TNFR-associated factors (TRAFs).

The cysteine-rich domain (CRD) in the extracellular, ligand-binding region defines membership in the TNFRSF (Figure 25.1). Each CRD typically contains six cysteine residues forming three disulfide bonds. The CRD is pseudorepeated in different members, ranging from one to six. Based on the crystal structures solved for several TNFRSF members, the CRD confers an elongated shape and sidedness to the ectodomain (17,*18*). The crystal structure of the complex between TNFR1 and one of its ligands, the LTα homotrimer, revealed that residues in CRD2 and 3 of TNFR1 contact the ligand. Variation in binding interactions has been identified; for example, the receptors for BAFF have one functional CRD (*2*,19).

RECEPTOR–LIGAND COMPLEX

The binding specificity of the various members of the TNF ligand and receptor superfamilies show monotypic interaction, yet several members interact with multiple partners (20) (Figures 25.2 and 25.3). The binding interactions between TNF-related ligands and TNFR are typically of high affinity, with equilibrium binding constants measured in the high-picomolar to low-nanomolar range. The membrane position of the ligands further enhances the binding interaction with their receptors. In the membrane-anchored position the ligands and receptors must be in *trans* to form a complex. In the LTα-TNFR1 complex, the surface loops between A-A″ and D-E β strands contain many of the amino acid residues that make contact with the receptor, with the receptor-binding site formed as a composite by adjoining subunits in the trimeric ligand (17) (Figure 25.1).

The trimeric architecture of the TNF ligands, containing three equivalent receptor-binding sites, provides the basis for initiating signaling through aggregation or clustering of receptors, which is supported by the finding that receptor-specific bivalent antibodies can act as agonists and mimic the signaling activity of the natural ligand *(21)*. Indeed, antibodies or peptides mimetic to TNFR can function as antagonists blocking the ability of the natural ligand to bind the receptor while simultaneously activating the receptor as an agonist (22). Some ligands, such as FasL, TRAIL, and BAFF, form higher-ordered oligomers of the basic trimer. These higher-ordered oligomers promote supraaggregation of receptors, enhancing or sustaining signaling pathways in the receptor-bearing cell (23,*24*). Overexpression of TNFR in cells can also lead to ligand-independent signaling, a feature bestowed in part by the propensity of the cytosolic tails to self-associate *(25)*. In the physiologic setting, the expression level and compartmentalization of these receptors are tightly controlled. A subregion in the first CRD of TNFR1, known as the pre-ligand assembly domain (PLAD), may restrict the orientation of the unligated receptor to prevent spontaneous activation *(26)*. It is not known whether this mechanism applies to all members of the TNFRSF. Of interest, some patients with periodic fever syndrome have mutant TNFR1 that form abnormal disulfide-linked oligomers that are retained intracellullary and provoke the misfolded protein response (27).
FIGURE 25.2 The tumor necrosis factor (TNF) superfamily major histocompatibility complex (MHC) paralogs. Members of the TNF ligand superfamily (above) and their corresponding receptors (below) are identified by connecting arrows. The ligands are grouped according to their chromosomal (Chr) locations in the MHC paralogous regions. The number of cysteine-rich domains is depicted for each TNF receptor (TFNR), and TNFRs containing a death domain are identified by cylinder in the cytoplasmic tail. (Modified from Ware CF. TNF superfamily. *Cytokine Growth Factors Rev*. 2003;14:181, with permission.)

The TNF Superfamily

Alternate Ligands

There is significant divergence in the ligands and the mechanisms of ligand binding by the TNFR family. A major branch point is exemplified by the ligands for p75 neurotrophin receptor (nerve growth factor and the other neurotrophins), which are structurally unrelated to the TNF ligand family. Molecular contacts between NGF and p75NTR occur through two spatially separated binding regions located at the first and second CRD and the junction between the CRD3 and CRD4 (28). The p75NTR functions in complex with two other proteins, Nogo66 and LINGO, and this complex engages myelin-associated inhibitory factors. TROY/Taj can supplant p75NTR in this complex (29). Like p75 NTR, DR6, RELT, and TROY/Taj do not bind any of the known TNF ligands. The pathways activated by p75NTR and TROY/Taj systems show both positive and inhibitory regulation of axonal regeneration (29,30).
