In Loving Memory

Nature's first green is gold,
Her hardest hue to hold.
Her early leaf's a flower;
But only so an hour.
Then leaf subsides to leaf.
So Eden sank to grief,
So dawn goes down to day.
Nothing gold can stay.

Robert Frost, 1923

PREFACE

Immunology is the quintessential medical science. Indeed, no branch of the medical sciences has improved the health of people more than the application of immunologic principles to prevention of disease. Smallpox has been eliminated from the planet as a natural infection, as has poliomyelitis from the Western Hemisphere. Hepatitis B vaccine has prevented more cancers than any intervention other than smoking cessation. The newly introduced human papilloma virus vaccine promises to cut strikingly the toll of cervical cancer.

The continued need for progress in immunology is clear. The HIV epidemic roars on. Disappointing results from vaccine trials require a redoubled effort to understand how to build the new generations of vaccines that can attack the really hard problems, including HIV, tuberculosis, and malaria, among infectious diseases. Highly effective therapeutic vaccines for cancers still elude us, but progress in understanding the innate immune system and regulatory T cells places new tools in our hands to continue the attack on this major problem.

Understanding the basis of inflammation and the cytokine world has given us effective drugs to treat rheumatoid arthritis and other autoinflammatory/autoimmune diseases. The value of the interventions based on this knowledge, such as the use of tumor necrosis factor (TNF), interleukin-6 (IL-6), and IL-1 blockers, is now established. The application of anti-CD20 in the treatment of autoimmune disorders shows great promise.

Fundamental Immunology has the goal of aiding in the education of a new generation of immunologists who can both probe more deeply into the organizing principles of the immune system and can translate this new information into effective treatments and preventatives that can extend and enlarge on the record of immunologic science in bettering the lot of humankind.

Were I beginning the task of preparing a comprehensive text of immunology today, I might have titled it *Immunology, Endless Fascination*. Certainly that describes my own view of this science over the more than 25 years that I have been working on the six editions of *Fundamental Immunology*. I had believed that scientific progress was marked by periods of intense creativity, during which new concepts were established, followed by longer periods of consolidation, when work that made important but anticipated advances would dominate. Perhaps that will prove to be true of modern immunology as well when it is looked at by a disinterested observer, but for one in the midst, the pace of discovery seems to speed up with each passing year. *Endless fascination* certainly describes my experience of immunology.

During the interval since the previous edition, there have been major advances in every field of immunology. Indeed, in one of the most striking pieces of work, an entirely new adaptive immune system has been discovered. Pancer, Cooper, and their colleagues have shown that jawless vertebrates, rather than using an adaptive immune system based on the immunoglobulin superfamily T-cell and B-cell receptors, evolved an entirely distinct adaptive system based on the use of leucine-rich repeat molecules as the recognition elements. The understanding of innate immunity continues to grow with the deepening understanding of the range of microbial sensors and of how they link to the adaptive immune system. The 2007 Lasker Prize for Basic Medical Sciences went to Ralph Steinman for his discovery of dendritic cells, which interpret the messages of the innate system to the adaptive system. The importance of regulatory T cells continues to grow, as does our insight into the mechanisms of their action. The cytokine biology field expands and broadens in its importance. The number of interleukins is now into the mid-30s, and some of the more recently discovered molecules have the most important functions. The application of imaging technologies that allow the visualization of the in vivo behavior of the cells and tissues of the immune system has provided spectacular insights into the structure and dynamics of the system and promises still more amazing results in the future. The field of systems immunology, still in its infancy, has given notice that it will be a major approach to our science in the next decades.

I hope that this sixth edition will convey this dynamism and provide the reader with both a solid grounding in our field and with much of the very latest that has been achieved. As with each of the previous editions, most of the chapters are entirely new and not simple reworkings of the chapter in the previous edition. In order to contain the sixth edition within one volume, a decision was made to limit the number of references that will be printed in the text. For those chapters in which there are substantially in excess of 200 references cited in the text, the authors have selected 200 to be included in the print version of the book. All are included in the electronic version. The electronic version can be accessed at www.fundamentalimmunology.com.

As before, this edition begins with an introductory chapter, "The Immune System," aimed at giving an overview of modern immunology and providing those new to the field with the basis to go on to the subsequent chapters. This is followed by an "expanded introduction" provided by the sections, "Organization and Evolution of the Immune System," "Immunoglobulins and B Lymphocytes," and "T lymphocytes." I have introduced a new and extended section, "The Intersection of Innate and Adaptive Immunity," which is followed by the section, "Regulation and Effector Functions of the Immune Response." The book concludes with sections devoted to the immune system's role in protection against pathogenic microorganisms, "Immu-

nity to Infectious Agents," and on how the immune system is involved in a variety of human disorders, "Immunologic Mechanisms in Disease."

I repeat a word of caution that has been in the Preface to each edition. Immunology is moving very fast. Each of the chapters is written by an expert in the field, but in some areas there may be differences of opinion expressed by equally accomplished authors. I ask the reader to take note of the differences and to follow developments in the field.

William E. Paul

Fundamental Immunology

Introduction

The Immune System

William E. Paul

The immune system is a remarkable defense mechanism. It makes rapid, specific, and protective responses against the myriad potentially pathogenic microorganisms that inhabit the world in which we live. The tragic examples of acquired immunodeficiency syndrome (AIDS) and the inherited severe combined immunodeficiencies (SCID) graphically illustrate the consequences of a nonfunctional adaptive immune system. AIDS patients and children with SCID often fall victim to infections that are of little or no consequence to those with normally functioning immune systems. The immune system also has a role in the rejection of tumors and, when dysregulated, may give rise to a series of autoimmune diseases, including insulin-dependent diabetes mellitus, multiple sclerosis, rheumatoid arthritis, systemic lupus erythematosus, and inflammatory bowel diseases, among others.

Fundamental Immunology has as its goal the authoritative presentation of the basic elements of the immune system, of the means through which the mechanisms of immunity act in a wide range of clinical conditions, including recovery from infectious diseases, rejection of tumors, transplantation of tissue and organs, autoimmunity and other immunopathologic conditions, and allergy, and how the mechanisms of immunity can be marshaled by vaccination to provide protection against microbial pathogens.

The purpose of this opening chapter is to provide readers with a general introduction to our current understanding of the immune system. It should be of particular importance for those with a limited background in immunology, providing them with the preparation needed for subsequent chapters of the book. Rather than providing extensive references in this chapter, each of the subject headings will indicate the chapters that deal in detail with the topic under discussion. Those chapters will not only provide an extended treatment of the topic, but will also furnish the reader with a comprehensive reference list.

KEY CHARACTERISTICS OF THE IMMUNE SYSTEM

Innate Immunity (Chapters 14, 15, and 18)

Powerful nonspecific defenses prevent or limit infections by most potentially pathogenic microorganisms. The epithelium provides both a physical barrier to the entry of microbes and produces a variety of antimicrobial factors. Agents that penetrate the epithelium are met with macrophages and related cells possessing "microbial sensors" that recognize key molecules characteristic of many microbial agents. These "pattern recognition receptors" include several families of molecules, of which the most intensively studied are the Toll-like receptors (TLRs). Each TLR recognizes a distinct substance (or set of substances) associated with microbial agents: TLR4 recognizes lipopolysaccharides; TLR3, double-stranded RNA; and TLR9, unmethylated CpG-containing DNA. Since the recognized substances are generally indispensable to the infectious agent, microbial sensors provide a highly efficient means to recognize potential pathogens.

The interaction of a TLR with its ligand induces a series of intracellular signaling events of which activation of the NF-κB system is particularly important. Macrophage activation with enhancement of the cell's phagocytic activity and the induction of antimicrobial systems aid in the destruction of the pathogen. The induction of an inflammatory response as a result of the activation of the innate immune system recruits other cell types, including neutrophils, to the site.

The innate immune system also acts to recruit antigen-specific immune responses, not only by attracting cells of the immune system to the site of the infection, but also through the uptake of antigen by dendritic cells (DC) and its transport by these cells to lymphoid tissues where primary immune responses are initiated. Activated DCs express cell surface costimulatory molecules and produce cytokines that can regulate the quality of the immune response so that it is most appropriate to combating the infectious agent.

Primary Responses (Chapters 9 and 13)

Primary immune responses are initiated when a foreign antigenic substance interacts with antigen-specific lymphocytes under appropriate circumstances. The response generally consists of the production of antibody molecules specific for the antigenic determinants of the immunogen and of the expansion and differentiation of antigen-specific helper and effector T lymphocytes. The latter include cytokine-producing cells and killer T cells, capable of lysing infected cells. Generally, the combination of the

innate immune response and the primary adaptive response are sufficient to eradicate or to control the microbe. Indeed, the most effective function of the immune system is to mount a response that eliminates the infectious agent from the body—so-called *sterilizing immunity*.

Secondary Responses and Immunologic Memory (Chapters 9, 13, and 28)

As a consequence of initial encounter with antigen, the immunized individual develops a state of immunologic *memory*. If the same (or a closely related) microorganism is encountered again, a secondary response is made. This generally consists of an antibody response that is more rapid, greater in magnitude, and composed of antibodies that bind to the antigen with greater affinity and are more effective in clearing the microbe from the body. A more rapid and more effective T cell response also ensues. Thus, an initial infection with a microorganism often initiates a state of immunity in which the individual is protected against a second infection. In the majority of situations, protection is provided by high-affinity antibody molecules that rapidly clear the reintroduced microbe. This is the basis of most licensed vaccines; the great power of vaccines is illustrated by the elimination of smallpox from the world and by the complete control of polio in the western hemisphere.

The Immune Response Is Highly Specific and the Antigenic Universe Is Vast

The immune response is highly specific. Primary immunization with a given microorganism evokes antibodies and T cells that are specific for the antigenic determinants found on that microorganism but that generally fail to recognize (or recognize only poorly) antigenic determinants expressed by unrelated microbes. Indeed, the range of antigenic specificities that can be discriminated by the immune system is enormous.

The Immune System Is Tolerant of Self-antigens (Chapters 29 and 30)

One of the most important features of the immune system is its ability to discriminate between antigenic determinants expressed on foreign substances, such as pathogenic microbes, and potential antigenic determinants expressed by the tissues of the host. The failure of the system to make full-blown immune responses to self-antigens is referred to as *immunologic tolerance*. Tolerance is a complex process that actually involves several distinct mechanisms. One element, perhaps the most important, is an active process involving the elimination or inactivation of cells that can recognize self-antigens. In addition, there are mech-

anisms through which cells that encounter antigens (e.g., self-antigens) in the absence of cues from the innate immune system may fail to make a response, may make a minimal response or may be inactivated through a process referred to as *anergy*. Finally, a specialized set of T cells exist, designated regulatory cells that actively *suppress* responses against self-antigens. Indeed, individuals who have mutations in the key transcription factor Foxp3 expressed by the regulatory cells develop severe multiorgan autoimmunity (polyendocrinopathy, enteropathy X-linked [IPEX] syndrome). The critical necessity to control self-reactivity is clearly shown by this multilayered system that involves elimination, inactivation, and suppression.

Immune Responses Against Self-antigens Can Result in Autoimmune Diseases (Chapters 41 and 42)

Failure in establishing immunologic tolerance or unusual presentations of self-antigens can give rise to tissue-damaging immune responses directed against antigenic determinants on host molecules. These can result in autoimmune diseases. As has already been mentioned, a group of extremely important diseases are caused by autoimmune responses or have major autoimmune components, including systemic lupus erythematosus, rheumatoid arthritis, insulin-dependent diabetes mellitus, multiple sclerosis, myasthenia gravis, and regional enteritis. Efforts to treat these diseases by modulating the autoimmune response are a major theme of contemporary medicine.

AIDS Is an Example of a Disease Caused by a Virus That the Immune System Generally Fails to Eliminate (Chapter 39)

Immune responses against infectious agents do not always lead to elimination of the pathogen. In some instances, a chronic infection ensues in which the immune system adopts a variety of strategies to limit damage caused by the organism or by the immune response. Indeed, herpes viruses, such as human cytomegalovirus (CMV), frequently are not eliminated by immune responses and establish chronicity in which the virus is controlled by immune responses. One of the most notable infectious diseases in which the immune response generally fails to eliminate the organism is AIDS, caused by the human immunodeficiency virus (HIV). In this instance, the principal infected cells are those of the immune system itself, leading to an eventual state in which the individual can no longer mount protective immune responses against other microbial pathogens. Indeed, under the assault of HIV, control of viruses such as CMV is lost and they may cause major tissue damage.

Major Principles of Immunity

The major principles of the immune response are:

Elimination of many microbial agents through the non-specific protective mechanisms of the innate immune system.

Cues from the innate immune system inform the cells of the adaptive immune system as to whether it is appropriate to make a response and what type of response to make.

Cells of the adaptive immune system display exquisitely specific recognition of foreign antigens and mobilize potent mechanisms for elimination of microbes bearing such antigens.

The immune system displays memory of its previous responses.

Tolerance of self-antigens.

The remainder of this introductory chapter will describe briefly the molecular and cellular basis of the system and how these central characteristics of the immune response may be explained.

CELLS OF THE IMMUNE SYSTEM AND THEIR SPECIFIC RECEPTORS AND PRODUCTS

The immune system consists of several distinct cell types, each with important roles. The lymphocytes occupy central stage because they are the cells that determine the specificity of immunity. It is their response that orchestrates the effector limbs of the immune system. Cells that interact with lymphocytes play critical parts both in the presentation of antigen and in the mediation of immunologic functions. These cells include DCs and the closely related Langerhans cells, monocyte/macrophages, natural killer (NK) cells, neutrophils, mast cells, basophils, and eosinophils. In addition, a series of specialized epithelial and stromal cells provide the anatomic environment in which immunity occurs, often by secreting critical factors that regulate migration, growth and homeostasis, and gene activation in cells of the immune system. Such cells also play direct roles in the induction and effector phases of the response.

The cells of the immune system are found in peripheral organized tissues, such as the spleen, lymph nodes, Peyer's patches of the intestine, and tonsils, where primary immune responses generally occur (see Chapter 2). Many of the lymphocytes comprise a recirculating pool of cells found in the blood and lymph, as well as in the lymph nodes and spleen, providing the means to deliver immunocompetent cells to sites where they are needed and to allow immunity that is initiated locally to become generalized. Activated lymphocytes acquire the capacity to enter nonlymphoid tissues, where they can express effector functions and eradicate local infections. Some memory lymphocytes are "on patrol" in the tissues, scanning for reintroduction of their specific antigens. Lymphocytes are also found in the central lymphoid organs, the thymus, and bone marrow, where they undergo the developmental steps that equip them to mediate the responses of the mature immune system.

Individual lymphocytes are specialized in that they are committed to respond to a limited set of structurally related antigens. This commitment exists before the first contact of the immune system with a given antigen. It is expressed by the presence on the lymphocyte's surface of receptors specific for determinants (epitopes) of the antigen. Each lymphocyte possesses a population of receptors, all of which have identical combining sites (this is a slight oversimplification, as occasionally T cells and less frequently B cells may express two populations of receptors). One set, or clone, of lymphocytes differs from another clone in the structure of the combining region of its receptors and thus in the epitopes that it can recognize. The ability of an organism to respond to virtually any non–self-antigen is achieved by the existence of a very large number of different lymphocytes, each bearing receptors specific for a distinct epitope. As a consequence, lymphocytes are an enormously heterogeneous group of cells. Based on reasonable assumptions as to the range of diversity that can be created in the genes encoding antigen-specific receptors, it seems virtually certain that the number of distinct combining sites on lymphocyte receptors of an adult human can be measured in the millions.

Lymphocytes differ from each other not only in the specificity of their receptors but also in their functions. There are two broad classes of lymphocytes: the B lymphocytes, which are precursors of antibody-secreting cells, and the T (thymus-derived) lymphocytes. T lymphocytes express important helper functions, such as the ability to aid in the development of specific types of immune responses, including the production of antibody by B cells and the increase in the microbicidal activity of macrophages. Other T lymphocytes are involved in direct effector functions, such as the lysis of virus-infected cells or certain neoplastic cells. Regulatory T lymphocytes have the capacity to suppress immune responses.

B LYMPHOCYTES AND ANTIBODY

B Lymphocyte Development (Chapter 7)

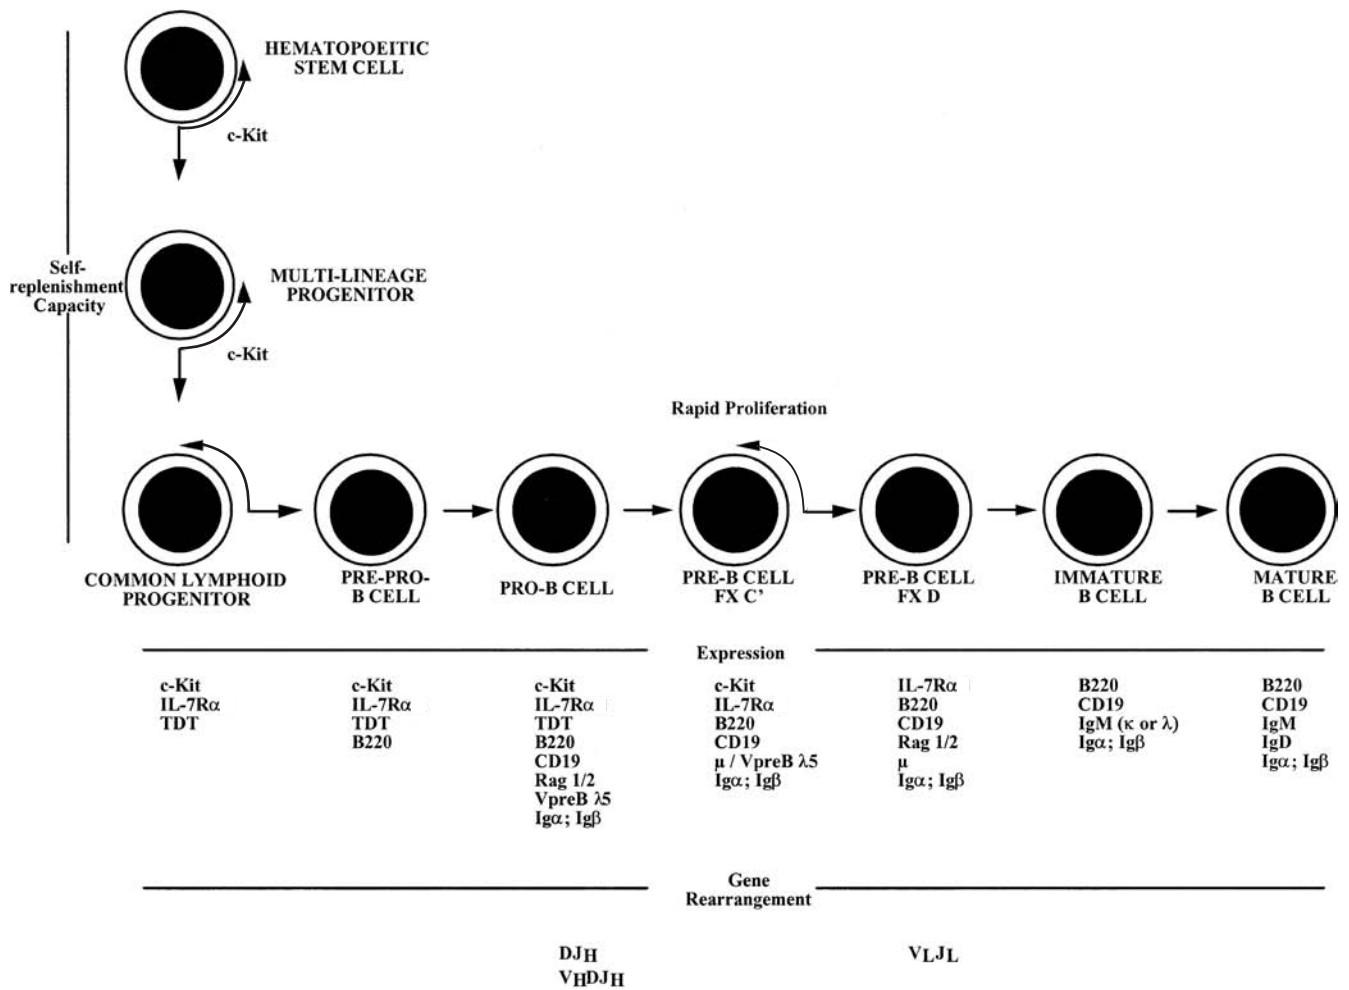
B lymphocytes derive from lymphoid progenitor cells, which in turn are derived from hematopoietic stem cells (Figure 1.1). A detailed picture has been obtained of the molecular mechanisms through which committed early members of the B lineage develop into mature B


FIGURE 1.1 The patterns of gene expression, timing of gene rearrangement events, and capacity for self-replenishment and for rapid proliferation of developing B lymphocytes are indicated. (Adapted from Richard R. Hardy and Kyoko Hayakawa, B cell development pathways, *Annual Review of Immunology*. 2001;19:595–621.)

lymphocytes. These events occur in the fetal liver and, in adult life, in the bone marrow. Interaction with specialized stromal cells and their products, including cytokines such as interleukin (IL)-7 and B cell activating factor of the TNF family (BAFF) are critical to the normal regulation of this process.

The key events in B cell development involve commitment to the B lineage and repression of the capacity to differentiate to cells of other lineages. In pro-B cells and pre-B cells, the genetic elements that encode the antigen-specific receptors are assembled. These receptors are immunoglobulin (Ig) molecules specialized for expression on the cell surface. Igs are heterodimeric molecules consisting of heavy (H) and light (L) chains, both of which have variable (V) regions, which contribute to the binding of antigen and that differ in sequence from one Ig molecule to another (see Chapters 4 and 6), (Figure 1.2), and constant (C) regions.

The genetic elements encoding the variable portions of Ig H and L chains are not contiguous in germline DNA or in the DNA of nonlymphoid cells (see Chapter 6) and (Figure 1.3). In pro- and pre-B cells, these genetic elements are translocated to construct an expressible V region gene. This process involves a choice among a large set of potentially usable variable (V), diversity (D), and joining (J) elements in a combinatorial manner and depends upon the RAG proteins, RAG1 and RAG2, that are essential for the recombination process. Such combinatorial translocation, together with the addition of diversity in the course of the joining process, results in the generation of a very large number of distinct H and L chains. The pairing of H and L chains in a quasi-random manner further expands the number of distinct Ig molecules that can be formed.

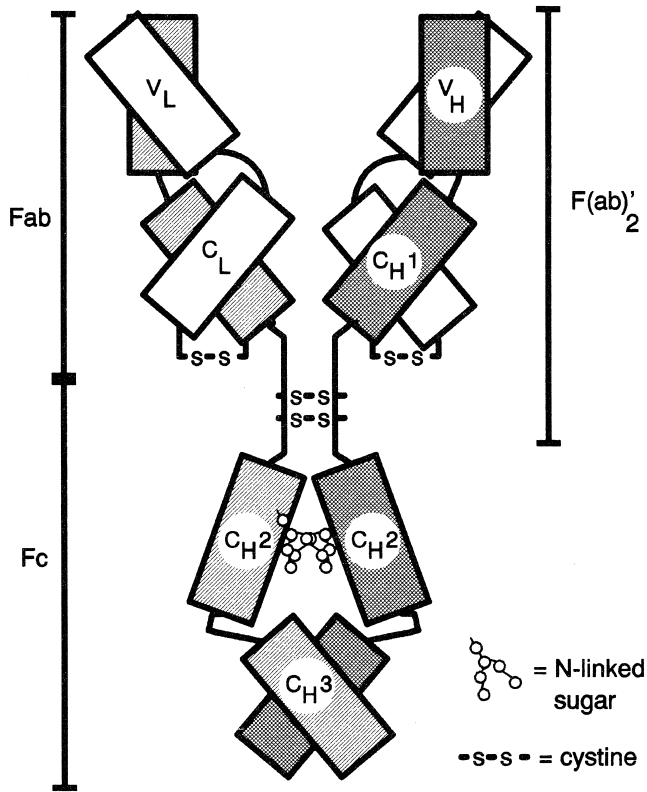
The H chain variable region is initially expressed in association with the product of the μ constant (C) region


FIGURE 1.2 A schematic representation of an Ig molecule indicating the means through the V regions and the CH1 and CL regions of H and L chains pair with one another and how the CH2 and CH3 regions of the H chains pair.

gene. Together these elements encode the μ IgH chain, which is used in Igs of the IgM class.

The successful completion of the process of Ig gene rearrangement and the expression of the resultant IgM on the cell surface marks the transition between the pre-B and B cell states (Figure 1.1). The newly differentiated B cell initially expresses surface Ig solely of the IgM class. The cell completes its maturation process by expressing on its surface a second class of Ig composed of the same L chain and the same H chain variable (VDJ) region but of a different H chain C region; this second IgH chain is designated δ, and the Ig to which it contributes is designated IgD, so that the mature naïve B cells expresses both IgM and IgD surface molecules that share the same V region.

The differentiation process is controlled at several steps by a system of checks that determines whether prior steps have been successfully completed. These checks depend on the expression on the surface of the cell of appropriately constructed Ig or Ig-like molecules. For example, in the period after a μ chain has been successfully assembled but before an L chain has been assembled, the μ chain is expressed on the cell surface in association with a surrogate light chain, consisting of VpreB and λ5. Pre-B cells that fail to express this μ–VpreB λ5 complex do not move forward to future differentiation states or do so very inefficiently.

B Lymphocyte Activation (Chapter 8)

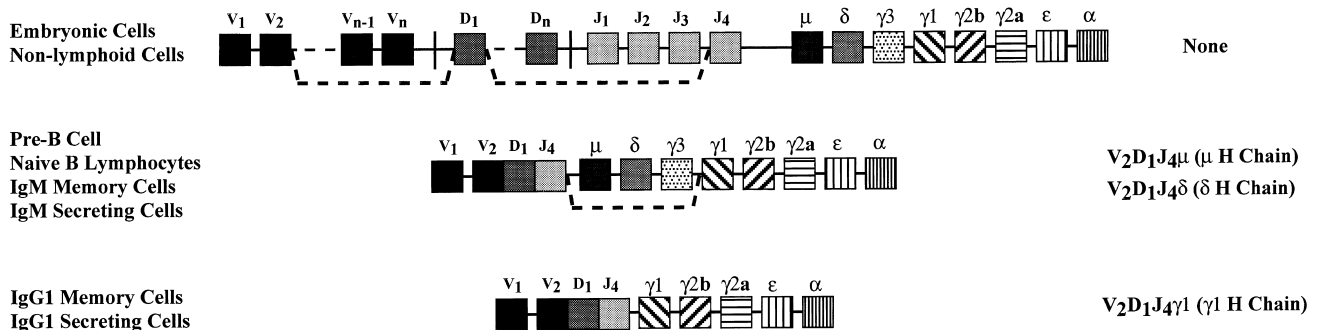
A mature B cell can be activated by an encounter with antigen expressing epitopes that are recognized by its cell surface Ig (Figure 1.4). The activation process may be a


FIGURE 1.3 Organization and translocation of mouse IgH genes. IgH chains are encoded by four distinct genetic elements: Igh-V (V), Igh-D (D), Igh-J (J), and Igh-C. The V, D, and J genetic elements together specify the variable region of the H chain. The Igh-C element specifies the C region. The same V region can be expressed in association with each of the C regions (μ, δ, γ3, γ1, γ2b, γ2a, ε and α). In the germline, the V, D, and J genes are far apart, and there are multiple forms of each of these genes. In the course of lymphocyte development, a VDJ gene complex is formed by translocation of individual V and D genes so that they lie next to one of the J genes, with excision of the intervening genes. This VDJ complex is initially expressed with μ and δ C genes but may be subsequently translocated so that it lies near one of the other C genes (e.g., γ1) and in that case leads to the expression of a VDJ γ1 chain.

Cognate T Cell- B Cell Help

A

Cross-linkage-dependent B Cell Activation

B
FIGURE 1.4 Two forms of B cell activation. **A:** Cognate T cell/B cell help. Resting B cells can bind antigens that bear epitopes complementary to their cell surface Ig. Even if the antigen cannot cross-link the receptor, it will be endocytosed and enter late endosomes and lysosomes where it will be degraded to peptides. Some of these peptides will be loaded into class II MHC molecules and brought to the cell surface, where they can be recognized by CD4$^+$ T cells that bear receptors specific for that peptide–class II complex. This interaction allows an activation ligand on the T cells (CD40 ligand) to bind to its receptor on B cells (CD40) and to signal B cell activation. In addition, the T cells secrete several cytokines that regulate the growth and differentiation of the stimulated B cell. **B:** Cross-linkage-dependent B cell activation. When B cells encounter antigens that bear multiple copies of an epitope that can bind to their surface Ig, the resultant cross-linkage stimulates biochemical signals within the cell leading to B cell activation, growth, and differentiation. In many instances, B cell activation events may result from both pathways of stimulation.
direct one, dependent on cross-linkage of membrane Ig molecules by the antigen (*cross linkage–dependent B cell activation*), or an indirect one, occurring most efficiently in the context of an intimate interaction with a helper T cell, in a process often referred to as *cognate help*.

Because each B cell bears membrane Ig molecules with identical variable regions, cross-linkage of the cell surface receptors requires that the antigen express more than one copy of an epitope complementary to the binding site of the receptor. This requirement is fulfilled by antigens with repetitive epitopes. Among these antigens are the capsular polysaccharides of many medically important microorganisms such as pneumococci, streptococci, and meningococci. Similar expression of multiple identical epitopes on a single immunogenic particle is a property of many viruses because they express multiple copies of envelope proteins on their surface. Cross linkage–dependent B cell activation is a major protective immune response mounted against these microbes. The binding of complement components (see Chapter 33) to antigen or

antigen–antibody complexes can increase the magnitude of the cross linkage–dependent B cell activation due to the action of a receptor for complement, which, together with other molecules, increases the magnitude of a B-cell response to limiting amounts of antigen.

Cognate help allows B cells to mount responses against antigens that cannot cross-link receptors and, at the same time, provides costimulatory signals that rescue B cells from inactivation when they are stimulated by weak cross-linkage events. Cognate help is dependent on the binding of antigen by the B cell's membrane Ig, the endocytosis of the antigen, and its fragmentation into peptides within the endosomal/lysosomal compartment of the cell. Some of the resultant peptides are loaded into a groove in a specialized set of cell surface proteins, the class II major histocompatibility complex (MHC) molecules (Figure 1.5). The resultant class II–peptide complexes are expressed on the cell surface. As will be discussed, these complexes are the ligands for the antigen-specific receptors of a set of T cells designated CD4 T cells. CD4 T cells that have
FIGURE 1.5 Illustration of the structure of the peptide binding domain (α1 and β1) of a class II MHC molecule (HLA-DR; protein data bank designation 1DLH) bound to an antigenic peptide from influenza hemagglutinin. (Adapted by D. H. Margulies from Stern, L. J., et al. Crystal structure of the human class II MHC protein HLA-DR1 complexed with an influenza virus peptide. *Nature,* 1994;368(6468):215–221.)

receptors specific for the class II–peptide complex expressed on the B cell surface recognize and interact with that B cell. That interaction results in the activation of the B cell through the agency of cell surface molecules expressed by the T cells (e.g., the CD40 ligand [CD154]) and cytokines produced by the T cell (Figure 1.4). The role of the B cell receptor for antigen is to create the T cell ligand on the surface of antigen-specific B cells; activation of the B cell derives largely from the action of the T cell. However, in many physiologic situations, receptor cross-linkage stimuli and cognate help synergize to yield more vigorous B cell responses. Recently, it has been shown that the association of ligands for TLRs with antigen will strikingly enhance B cell responses.

B Lymphocyte Differentiation (Chapters 7 and 9)

Activation of B cells prepares them to divide and to differentiate either into antibody-secreting cells or into memory cells, so that there are more cells specific for the antigen used for immunization. Those cells that differentiate into antibody-secreting cells account for primary antibody responses. Some of these antibody-secreting cells migrate to the bone marrow where they may continue to produce antibody for an extended period of time and may have lifetimes in excess of one year.

Memory B cells give rise to antibody-secreting cells upon re-challenge of the individual. The hallmark of the antibody response to rechallenge (a secondary response) is that it is of greater magnitude, occurs more promptly, is composed of antibodies with higher affinity for the anti-

gen, and is dominated by Igs expressing γ, α, or ε C regions (IgG, IgA, or IgE) rather than by IgM, which is the dominant Ig of the primary response.

Division and differentiation of cells into antibody-secreting cells is largely controlled by the interaction of the activated B cells with T cells expressing CD154 and by their stimulation by T cell–derived cytokines.

The differentiation of activated B cells into memory cells occurs in a specialized microenvironmental structure in the spleen and lymph nodes, the germinal center (GC). The increase in antibody affinity occurs also takes place within the GC. This process, designated *affinity maturation,* is dependent on somatic hypermutation. The survival of B cells within the GC depends on their capacity to bind antigen so that as the amount of antigen diminishes, B cells that have higher affinity receptors, either naturally or as a result of the hypermutation process, have a selective survival and growth advantage. Thus, such cells come to dominate the population.

The process through which a single H chain V region can become expressed with genes encoding C regions other than μ or δ is referred to as *Ig class switching*. It is dependent on a gene translocation event through which the C region genes between the genetic elements encoding the V region and the newly expressed C gene are excised, resulting in the switched C gene being located in the position that the Cμ gene formerly occupied (Figure 1.3). This process also occurs mainly in GCs. Both somatic hypermutation and Ig class switching depend upon the action of activation-induced cytidine deamidase (AID) that plays an important role in the breakage and repair of DNA, which is essential for recombination events.

B1 and Marginal Zone B Lymphocytes (Chapters 7 and 9)

B lymphocytes consist of at least three distinct populations: conventional B cells, B1 B cells, and marginal zone (MZ) B cells. B1 B cells were initially recognized because some express a cell-surface protein, CD5, not generally found on other B cells. In the adult mouse, B1 B cells are found in relatively high frequency in the peritoneal cavity but are present at low frequency in the spleen and lymph nodes. B1 B cells are quite numerous in fetal and perinatal life. B1 B cells appear to be self-renewing, in contrast to conventional B cells, in which division and memory are antigen driven.

MZ B cells are localized in a distinct anatomical region of the spleen (the marginal zone) that represents the major antigen-filtering and scavenging area. Like B1 B cells, MZ B cells express a repertoire biased toward bacterial cell wall constituents and senescent self-components. MZ and B1 B cells respond very rapidly to antigenic challenge, likely independently of T cells. Uniquely, among all populations of B cells, MZ B cells are dependent on Notch-2 signaling for their development.

B1 B cells and MZ B cells are responsible for the secretion of the serum IgM that exists in nonimmunized mice, often referred to as *natural IgM*. Among the antibodies found in such natural IgM are molecules that can combine with phosphatidyl choline (a component of pneumococcal cell walls) and with lipopolysaccharide and influenza virus. B1 B cells also produce autoantibodies, although they are generally of low affinity and in most cases not pathogenic. There is evidence that B1 B cells are important in resistance to several pathogens and may have a significant role in mucosal immunity.

B Lymphocyte Tolerance (Chapter 29)

One of the central problems facing the immune system is that of being able to mount highly effective immune responses to the antigens of foreign, potentially pathogenic, agents while ignoring antigens associated with the host's own tissues. The mechanisms ensuring this failure to respond to self-antigens are complex and involve a series of strategies. Chief among them is elimination of cells capable of self-reactivity or the inactivation of such cells. The encounter of immature, naïve B cells with antigens with repetitive epitopes capable of cross-linking membrane Ig can lead to elimination of the B cells, particularly if no T cell help is provided at the time of the encounter. This elimination of potentially self-reactive cells is often referred to as *clonal elimination*. Many self-reactive cells, rather than dying upon encounter with self-antigens, undergo a further round of Ig gene rearrangement. This *receptor editing* process allows a self-reactive cell to substitute a new receptor and therefore to avoid elimination.

There are many self-antigens that are not encountered by the developing B cell population or that do not have the capacity to cross-link B cell receptors (BCR) to a sufficient degree to elicit the receptor editing/clonal elimination process. Such cells, even when mature, may nonetheless be inactivated through a process that involves cross-linkage of receptors without the receipt of critical costimulatory signals. These inactivated cells may be retained in the body but are unresponsive to antigen and are referred to as *anergic*. When removed from the presence of the anergy-inducing stimulus, anergic cells may regain responsiveness.

Immunoglobulins

Structure (Chapter 4)

Igs are the antigen-specific membrane receptors and secreted products of B cells. They are members of a large family of proteins designated *the Ig supergene family*. Members of the Ig supergene family have sequence homology, a common gene organization, and similarities in three-dimensional structure. The latter is characterized by a structural element referred to as the *Ig fold,* generally consisting of a set of seven β-pleated sheets organized into two apposing layers (Figure 1.6). Many of the cell surface proteins that participate in immunologic recognition processes, including the T cell receptor (TCR), the CD3 complex, and signaling molecules associated with the BCR (Ig-α and Ig-β), are members of the Ig supergene family.

The Igs themselves are constructed of a unit that consists of two H chains and two L chains (Figure 1.2). The H and L chains are composed of a series of domains, each consisting of approximately 110 amino acids.

The L chains, of which there are two types (κ and λ), consist of two domains. The carboxy-terminal domain is essentially identical among L chains of a given type and is referred to as the *constant (C) region*. As already discussed, the amino-terminal domain varies from L chain to L chain and contributes to the binding site of antibody. Because of its variability, it is referred to as the *variable (V) region*. The variability of this region is largely concentrated in three segments, designated the *hypervariable* or *complementarity-determining regions* (CDR). The CDRs contain the amino acids that are the L chain's contribution to the lining of the antibody's combining site. The three CDRs are interspersed among four regions of much lower degree of variability, designated framework regions (FR).

The H chains of Ig molecules are of several classes determined by their constant regions (μ, δ, γ [of which there are several subclasses], α and ε). An assembled Ig molecule, consisting of one or more units of two identical H and L chains, derives its name from the C region of the H chain that it possesses. Thus, there are IgM, IgD, IgG, IgA, and IgE antibodies. The H chains each consist of a single amino-terminal V region and three or four C regions.
FIGURE 1.6 Schematic drawing of the V and C domains of an Ig L chain illustrating the "Ig fold." The β strands participating in the antiparallel β-pleated sheets of each domain are represented as arrows. The β strands of the three-stranded sheets are shaded, whereas those in the four-stranded sheets are white. The intra-domain disulfide bonds are represented as black bars. Selected amino acids are numbered with position 1 as the N terminus. (Reprinted with permission from Edmundson AB, Ely KR, Abola EE, et al. Rotational allomerism and divergent evolution of domains in immunoglobulin light chains. *Biochemistry* 1975;14:3953–3961.)

In many H chains, a hinge region separates the first and second C regions and conveys flexibility to the molecule, allowing the two combining sites of a single unit to move in relation to one another so as to promote the binding of a single antibody molecule to an antigen that has more than one copy of the same epitope. Such divalent binding to a single antigenic structure results in a great gain in energy of interaction (see Chapter 5). The H chain V region, like that of the L chain, contains three CDRs lining the combining site of the antibody and four FRs.

The C region of each H-chain class conveys unique functional attributes to the antibodies that possess it. Among the distinct biologic functions of each class of antibody are the following:

IgM antibodies are potent activators of the complement system (Chapter 33).

IgA antibodies are secreted into a variety of bodily fluids and are principally responsible for immunity at mucosal surfaces (Chapter 31).

IgE antibodies are bound by specific receptors (FcεRI) on basophils and mast cells. When cross-linked by antigen, these IgE–FcεRI complexes cause the cells to release a set of mediators responsible for allergic inflammatory responses (Chapter 43).

IgD antibodies act virtually exclusively as membrane receptors for antigen.

IgG antibodies, made up of four subclasses in both humans and mice, mediate a wide range of functions including transplacental passage and opsonization of antigens through binding of antigen–antibody complexes to specialized Fc receptors on macrophages and other cell types (Chapters 18 and 22).

IgD, IgG, and IgE antibodies consist of a single unit of two H and L chains. IgM antibodies are constructed of five or six such units, although they consist of a single unit

when they act as membrane receptors. IgA antibodies may consist of one or more units. The antibodies that are made up of more than a single unit generally contain an additional polypeptide chain, the J chain, that appears to play a role in the polymerization process. In addition, secreted IgA expresses a chain, secretory piece, that is derived from the receptor for polymeric IgA, which plays a role in the transport of IgA across the cells lining the lumen of the gut.

Each of the distinct Igs can exist as secreted antibodies and as membrane molecules. Antibodies and cell surface receptors of the same class made by a specific cell have identical structures except for differences in their carboxy-terminal regions. Membrane Igs possess a hydrophobic region, spanning the membrane, and a short intracytoplasmic tail, both of which are lacking in the secretory form.

Immunoglobulin Genetics (Chapter 6)

The components of the Ig H chain gene have already been alluded to. To reiterate, the IgH chain gene of a mature lymphocyte is derived from a set of genetic elements that are separated from one another in the germline. The V region is composed of three types of genetic elements: V_H, D, and J_H. More than 100 V_H elements exist; there are more than 10 D elements and a small number of J_H elements (four in the mouse). An H chain $V_H D J_H$ gene is created by the translocation of one of the D elements on a given chromosome to one of the J_H elements on that chromosome, generally with the excision of the intervening DNA. This is followed by a second translocation event in which one of the V_H elements is brought into apposition with the assembled $D J_H$ element to create the $V_H D J_H$ (V region) gene (Figure 1.3). Although it is likely that the choice of the V_H, D, and J_H elements that are assembled is not entirely random, the combinatorial process allows the creation of a very large number of distinct H chain V region genes.

Additional diversity is created by the imprecision of the joining events and by the deletion of nucleotides and addition of new, untemplated nucleotides between D and J_H and between V_H and D, forming N regions in these areas. This further increases the diversity of distinct IgH chains that can be generated from the relatively modest amount of genetic information present in the germline.

The assembly of L chain genes follows generally similar rules. However, L chains are assembled from V_L and J_L elements only. Although there is junctional diversity, no N regions exist for L chains. Addition diversity is provided by the existence of two classes of L chains, κ, and λ.

An Ig molecule is assembled by the pairing of an IgH chain polypeptide with an IgL chain polypeptide. Although this process is almost certainly not completely random, it allows the formation of an exceedingly large number of distinct Ig molecules, the majority of which will have individual specificities.

The rearrangement events that result in the assembly of expressible IgH and IgL chains occur in the course of B cell development in pro-B cells and pre-B cells, respectively (Figure 1.1). This process is regulated by the Ig products of the rearrangement events. The formation of a μ chain signals the termination of rearrangement of H chain gene elements and the onset of rearrangement of L chain gene elements, with κ rearrangements generally preceding λ rearrangements. One important consequence of this is that only a single expressible μ chain will be produced in a given cell, since the first expressible μ chain shuts off the possibility of producing an expressible μ chain on the alternative chromosome. Comparable mechanisms exist to ensure that only one L chain gene is produced, leading to the phenomenon known as *allelic exclusion.* Thus, the product of only one of the two alternative allelic regions at both the H and L chain loci are expressed. The closely related phenomenon of L chain isotype exclusion ensures the production of either κ or λ chains in an individual cell, but not both. An obvious but critical consequence of allelic exclusion is that in most cases an individual B cell makes antibodies, all of which have identical H and L chain V regions, a central prediction of the clonal selection theory of the immune response. During the process of receptor editing, secondary rearrangements may occur, and, in some instances, the receptor editing process is associated with the expression of both κ and λ L chain genes by an individual B cells

Class Switching (Chapter 6)

An individual B cell continues to express the same IgH chain V region as it matures but it can switch the IgH chain C region it uses (Figure 1.3). Thus, a cell that expresses receptors of the IgM and IgD classes may differentiate into a cell that expresses IgG, IgA, or IgE receptors and then into a cell-secreting antibody of the same class as it expressed

on the cell surface. This process allows the production of antibodies capable of mediating distinct biologic functions but that retain the same antigen-combining specificity. When linked with the process of affinity maturation of antibodies, Ig class switching provides antibodies of extremely high efficacy in preventing reinfection with microbial pathogens or in rapidly eliminating such pathogens. The associated phenomena of class switching and affinity maturation account for the high degree of effectiveness of antibodies produced in secondary immune responses.

The process of class switching is known to involve a recombination event between specialized switch (S) regions, containing repetitive sequences, that are located upstream of each C region (with the exception of the δ C region). Thus, the S region upstream of the μ C_H region gene (Sμ) recombines with an S region upstream of a more 3' isotype, such as Sγ1, to create a chimeric Sμ/Sγ1 region and in the deletion of the intervening DNA (Figure 1.7). The genes encoding the C regions of the various γ chains (in the human γ1, γ2, γ3, and γ4; in the mouse γ1, γ2a, γ2b, and γ3), of the α chain, and of the ε chain are located 3' of the Cμ and Cδ genes.

The induction of the switching process is dependent on the action of a specialized set of B cell stimulants. Of these, the most widely studied are CD154, expressed on the surface of activated T cells, and the TLR ligands such as bacterial lipopolysaccharide (LPS). The targeting of the C region that will be expressed as a result of switching is largely determined by cytokines. Thus, IL-4 determines that switch events in the human and mouse will be to the ε C region and to the γ4 (human) or γ1 (mouse) C regions. In the
FIGURE 1.7 Ig class switching. The process through which a given VDJ gene in a stimulated B cell may switch the C region gene with which it is associated from μ to another, such as γ1, is illustrated. A recombination event occurs in which DNA between a cleavage point in Sμ and one in Sγ1 forms a circular episome. This results in Cγ1 being located immediately downstream of the chimeric Sμ/γ1 region, in a position such that transcription initiating upstream of VDJ results in the formation of VDJCγ1 mRNA and γ1 H-chain protein.

mouse, interferon-gamma (IFN-γ) determines switching to γ2a and transforming growth factor-beta (TGF-β) determines switching to α. A major goal is to understand the physiologic determination of the specificity of the switching process. Because cytokines are often the key controllers of which Ig classes will represent the switched isotype, this logically translates into asking what regulates the relative amounts of particular cytokines that are produced by different modes of immunization.

As already noted, both the switching process and somatic hypermutation depend upon the AID. Mice and humans that lack AID fail to undergo both Ig class switching and somatic hypermutation.

Affinity Maturation and Somatic Hypermutation (Chapters 6 and 9)

The process of generation of diversity embodied in the construction of the H and L chain V region genes and of the pairing of H and L chains creates a large number of distinct antibody molecules, each expressed in an individual B cell. This primary repertoire is sufficiently large so that most epitopes on foreign antigens will encounter B cells with complementary receptors. Thus, if adequate T cell help can be generated, antibody responses can be made to a wide array of foreign substances. Nonetheless, the antibody that is initially produced usually has a relatively low affinity for the antigen. This is partially compensated for by the fact that IgM, the antibody initially made, is a pentamer. Through multivalent binding, high avidities can be achieved even if individual combining sites have only modest affinity (see Chapter 5). In the course of T cell–dependent B cell stimulation, particularly within the GC, a process of somatic hypermutation is initiated that leads to a large number of mutational events, largely confined to the H chain and L chain V region genes and their immediately surrounding introns.

During the process of somatic hypermutation, mutational rates of 1 per 1,000 base pairs per generation may be achieved. This implies that, with each cell division, close to one mutation will occur in either the H or L chain V region of an individual cell. This creates an enormous increase in antibody diversity. Although most of these mutations will either not affect the affinity with which the antibody binds its ligand or will lower that affinity, some will increase it. Thus, some B cells emerge that can bind antigen more avidly than the initial population of responding cells. Because there is an active process of apoptosis in the GC from which B cells can be rescued by the binding of antigen to their membrane receptors, cells with the most avid receptors should have an advantage over other antigen-specific B cells and should come to dominate the population of responding cells. Thus, upon rechallenge, the affinity of antibody produced will be greater than that in the initial response. As time after immunization elapses,

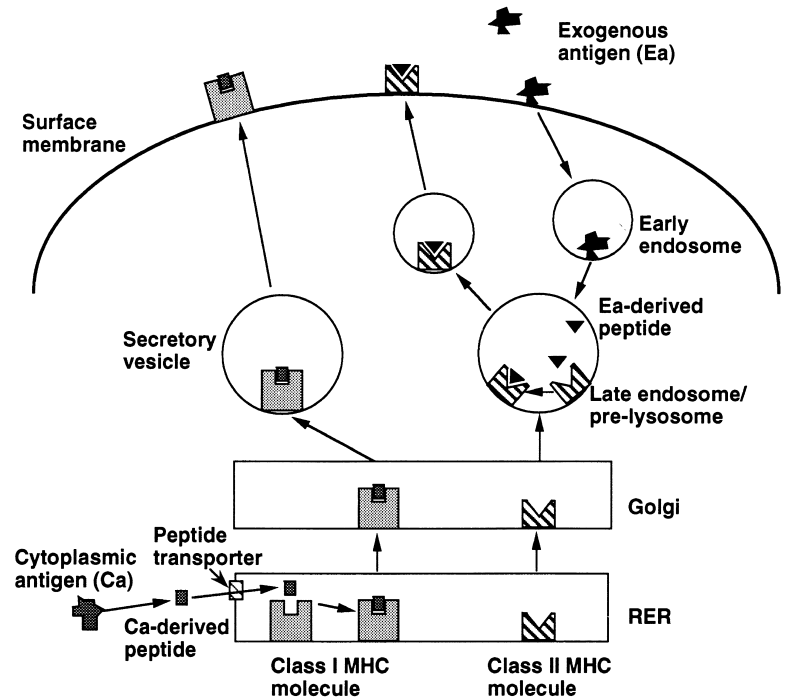
the affinity of antibody produced will increase. This process leads to the presence in immunized individuals of high-affinity antibodies that are much more effective, on a weight basis, in protecting against microbial agents and other antigen-bearing pathogens than was the antibody initially produced. Together with antibody class switching, affinity maturation results in the increased effectiveness of antibody in preventing reinfection with agents with which the individual has had a prior encounter.

T LYMPHOCYTES

T lymphocytes constitute the second major class of lymphocytes. They derive from precursors in hematopoietic tissue, undergo differentiation in the thymus (hence the name *thymus-derived [T] lymphocytes*) and are then seeded to the peripheral lymphoid tissue and to the recirculating pool of lymphocytes (see Chapter 12). T cells are subdivided into two distinct classes based on the cell surface receptors they express. The majority of T cells express antigen-binding receptors (TCRs) consisting of α and β chains. A second group of T cells express receptors made up of γ and δ chains. Among the α/β T cells are two important sublineages: those that express the coreceptor molecule CD4 (CD4 T cells) and those that express CD8 (CD8 T cells). These cells differ in how they recognize antigen and mediate different types of regulatory and effector functions.

CD4 T cells are the major *helper* cells of the immune system. Their helper function depends both on cell surface molecules such as CD154, induced upon these cells when they are activated, and on the wide array of cytokines they secrete when activated. CD4 T cells tend to differentiate, as a consequence of priming, into cells that principally secrete the cytokines IL-4, IL-13, IL-5, IL-6, and IL-10 (T_{H2} cells), into cells that mainly produce IFN-γ and lymphotoxin (T_{H1} cells) or into cells that produce IL-17 and related cytokines (T_{H17} cells). T_{H2} cells are very effective in helping B cells develop into antibody-producing cells, T_{H1} cells are effective inducers of cellular immune responses, involving enhancement in the microbicidal activity of monocytes and macrophages and consequent increased efficiency in lysing microorganisms in intracellular vesicular compartments, while T_{H17} cells are efficient recruiters of granulocytes and other cells of the inflammatory system and play a major role in responses to extracellular bacterial pathogens. Naïve CD4 T cells can also be stimulated to differentiate into induced regulatory T cells (iT_{regs}). However, most T_{regs} develop as a independent lineage of CD4 T cells. T_{regs} express the forkhead transcription factor Foxp3 and many express large amounts of the α chain of the IL-2 receptor (CD25).

T cells mediate important effector functions. Some of these are determined by the patterns of cytokines they

FIGURE 1.8 Pathways of antigen processing. Exogenous antigen (Ea) enters the cell via endocytosis and is transported from early endosomes into late endosome or prelysosomes, where it is fragmented and where resulting peptides (Ea derived peptides) may be loaded into class II MHC molecules. The latter have been transported from the RER through the Golgi apparatus to the peptide-containing vesicles. Class II MHC molecules–Ea-derived peptide complexes are then transported to the cell surface, where they may be recognized by TCR expressed on CD4+ T cells. Cytoplasmic antigens (Ca) are degraded in the cytoplasm and then enter the RER through a peptide transporter. In the RER, Ca-derived peptides are loaded into class I MHC molecules that move through the Golgi apparatus into secretory vesicles and are then expressed on the cell surface where they may be recognized by CD8+ T cells (Reprinted with permission from Paul WE, in Gallin JI, Goldstein, I, Snyderman, R, eds. *Inflammation.* New York: Raven, 1992:776.)


secrete. These powerful molecules can be directly toxic to target cells and can mobilize potent inflammatory mechanisms. In addition, T cells, particularly CD8 T cells, can develop into cytotoxic T lymphocytes (CTLs) capable of efficiently lysing target cells that express antigens recognized by the CTLs.

T Lymphocyte Antigen Recognition (Chapters 10, 20, and 21)

T cells differ from B cells in their mechanism of antigen recognition. Ig, the BCR's receptor, binds to individual antigenic epitopes on soluble molecules or on particulate surfaces. BCRs recognize epitopes expressed on the surface of native molecules. Antibody and BCRs evolved to bind to and to protect against microorganisms in extracellular fluids.

By contrast, T cells invariably recognize cell-associated molecules and mediate their functions by interacting with and altering the behavior of such *antigen-presenting cells* (APCs). Indeed, the TCR does not recognize antigenic determinants on intact, undenatured molecules. Rather, it recognizes a complex consisting of a peptide, derived by proteolysis of the antigen, bound into a specialized groove of a class II or class I MHC protein. Indeed, what differentiates a CD4 T cell from a CD8 T cell is that the CD4 T cells recognize peptide–class II complexes, whereas the CD8 T cells recognize peptide–class I complexes.

The TCR's ligand (i.e., the peptide–MHC protein complex) is created within the APC. In general, class II MHC molecules bind peptides derived from proteins that have been taken up by the APC through an endocytic process (Figure 1.8). These endocytosed proteins are fragmented by proteolytic enzymes within the endosomal/lysosomal compartment, and the resulting peptides are loaded into class II MHC that traffic through this compartment. Peptide-loaded class II molecules are then expressed on the surface of the APC where they are available to be bound by CD4 T cells that have TCRs capable of recognizing the expressed cell surface peptide–MHC protein complex. Thus, CD4 T cells are specialized to largely react with antigens derived from extracellular sources.

In contrast, class I MHC molecules are mainly loaded with peptides derived from internally synthesized proteins, such as viral gene products. These peptides are produced from cytosolic proteins by proteolysis within the proteasome and are translocated into the rough endoplasmic reticulum. Such peptides, generally nine amino acids in length, are bound by class I MHC molecules. The complex is brought to the cell surface, where it can be recognized by CD8 T cells expressing appropriate receptors. This property gives the T cell system, particularly CD8 T cells, the ability to detect cells expressing proteins that are different from, or produced in much larger amounts than, those of cells of the remainder of the organism (e.g., viral antigens [whether internal, envelope, or cell surface] or mutant antigens [e.g., active oncogene products]), even if these proteins, in their intact form, are neither expressed on the cell surface nor secreted.

Although this division of class I–binding peptides being derived from internally synthesized proteins and class II–binding peptides from imported proteins is generally
FIGURE 1.9 The T cell antigen receptor. Illustrated schematically is the antigen binding subunit comprised of an $\alpha\beta$ heterodimer, and the associated invariant CD3 and ζ chains. Acidic (–) and basic (+) residues located within the plasma membrane are indicated. The open rectangular boxes indicate motifs within the cytoplasmic domains that interact with protein tyrosine kinases.

correct, there are important exceptions to this rule that are central for the function of the immune system. The most effective priming of naïve CD8 T cells occurs in response to peptide–MHC-I complexes expressed by DCs, and yet many viruses do not infect these cells but rather target other cell types. It is now recognized that viral antigens produced by infected cells can be taken up by DCs and loaded into class I molecules in a process referred to as cross-presentation.

T Lymphocyte Receptors (Chapter 10)

The TCR is a disulfide-linked heterodimer (Figure 1.9). Its constituent chains (α and β, or γ and δ) are Ig supergene family members. The TCR is associated with a set of transmembrane proteins, collectively designated the CD3 complex, that play a critical role in signal transduction. The CD3 complex consists of γ, δ (note that the CD3 γ and δ chains and the TCR γ and δ chains are distinct polypeptides that, unfortunately, have similar designations), and ε chains and is associated with a homodimer of two ζ chains or a heterodimer of ζ and η chains. CD3 γ, δ, and ε consist of extracellular domains that are Ig supergene family members. The cytosolic domains of CD3 γ, δ, and ε and of ζ and η contain one or more copies of the immunoreceptor tyrosine-based activation motif (ITAM) (D/ExxYxxLxxxxxxxYxxL/I) that is found in a variety of chains associated with immune recognition receptors. This motif appears to be very important in the signal transduction process and provides a site through which

protein tyrosine kinases can interact with these chains to propagate signaling events.

The TCR chains are organized much like Ig chains. Their N-terminal portions are variable and their C-terminal portions are constant. Furthermore, similar recombination mechanisms are used to assemble the V-region genes of the TCR chains. Thus, the V region of the TCR β chain is encoded by a gene constructed from three distinct genetic elements ($V\beta$, D, and $J\beta$) that are separated in the germline. Although the relative numbers of $V\beta$, D, and $J\beta$ genes differ from that for the comparable IgH variable region elements, the strategies for creation of a very large number of distinct genes by combinatorial assembly are the same. Both junctional diversity and N region addition further diversify the genes, and their encoded products. TCR β has fewer V genes than IgH but much more diversity centered on the D/J region, which encodes the equivalent of the third CDR of Igs. The α chain follows similar principles, except that it does not use a D gene.

The genes for TCR γ and δ chains are assembled in a similar manner except that they have many fewer V genes from which to choose. Indeed, γ/δ T cells in certain environments, such as the skin and specific mucosal surfaces, are exceptionally homogeneous. It has been suggested that the TCRs encoded by these essentially invariant γ and δ chains may be specific for some antigen that signals microbial invasion and that activation of γ/δ T cells through this mechanism constitutes an initial response that aids the development of the more sophisticated response of α/β T cells.

T Lymphocyte Activation (Chapter 11)

T cell activation is dependent on the interaction of the TCR–CD3 complex with its cognate ligand, a peptide bound in the groove of a class I or class II MHC molecule, on the surface of a competent APC. Through the use of chimeric cell surface molecules that possess cytosolic domains largely limited to the ITAM signaling motif alluded to earlier, it is clear that cross-linkage of molecules containing such domains can generate some of the signals that result from TCR engagement. Nonetheless, the molecular events set in motion by receptor engagement are complex ones. Among the earliest steps are the activation of tyrosine kinases leading to the tyrosine phosphorylation of a set of substrates that control several signaling pathways. Current evidence indicates that early events in this process involve the src family tyrosine kinases p56^{lck}, associated with the cytosolic domains of the CD4 and CD8 coreceptors, and p59^{fyn}, and ZAP-70, a Syk family tyrosine kinase that binds to the phosphorylated ITAMs of the ζ chain. The protein tyrosine phosphatase CD45, found on the surface of all T cells, also plays a critical role in T cell activation.

A series of important substrates are tyrosine phosphorylated as a result of the action of the kinases associated with the TCR complex. These include a (i) set of adapter proteins that link the TCR to the ras pathway; (ii) phospholipase Cγ1, the tyrosine phosphorylation of which increases its catalytic activity and engages the inositol phospholipid metabolic pathway, leading to elevation of intracellular free calcium concentration and activation of protein kinase C; and (iii) a series of other important enzymes that control cellular growth and differentiation. Particularly important is the phosphorylation of LAT, a molecule that acts as an organizing scaffold to which a series of signaling intermediates bind and upon which they become activated and control downstream signaling.

The recognition and early activation events result in the reorganization of cell surface and cytosolic molecules on the T cell, and correspondingly, on the APC to produce a structure, the *immunological synapse*. The apposition of key interacting molecules involving a small segment of the membranes of the two cells concentrates these interacting molecules in a manner that both strengthens the interaction between the cells and intensifies the signaling events. It also creates a limited space into which cytokines may be secreted to influence the behavior of the interacting cells. The formation of the immunological synapse is one mechanism through which the recognition of relatively small numbers of ligands by TCRs on a specific T cell can be converted into a vigorous stimulatory process.

In general, normal T cells and cloned T cell lines that are stimulated only by TCR cross-linkage fail to give complete responses. TCR engagement by itself may often lead to a response in which the key T cell–derived growth factor, IL-2, is not produced and in which the cells enter a state of anergy such that they are unresponsive or poorly responsive to a subsequent competent stimulus (see Chapter 29). Full responsiveness of a T cell requires, in addition to receptor engagement, an accessory cell–delivered costimulatory activity. The engagement of CD28 on the T cell by CD80 or CD86 on the APC (or the engagement of comparable ligand/receptor pairs on the two cells) provides a potent costimulatory activity. Inhibitors of this interaction markedly diminish antigen-specific T cell activation *in vivo* and *in vitro,* indicating that the CD80/86–CD28 interaction is physiologically very important in T cell activation (see Chapters 13 and 15).

The interaction of CD80/86 with CD28 increases cytokine production by the responding T cells. For the production of IL-2, this increase appears to be mediated both by enhancing the transcription of the IL-2 gene and by stabilizing IL-2 mRNA. These dual consequences of the CD80/86–CD28 interaction cause a striking increase in the production of IL-2 by antigen-stimulated T cells.

CD80/86 has a second receptor on the T cell, CTLA-4, that is expressed later in the course of T cell activation. The bulk of evidence indicates that the engagement of CTLA-4 by CD80/86 leads to a set of biochemical signals that terminate the T cell response. Mice that are deficient in CTLA-4 expression develop fulminant autoimmune responses.

T Lymphocyte Development (Chapter 12)

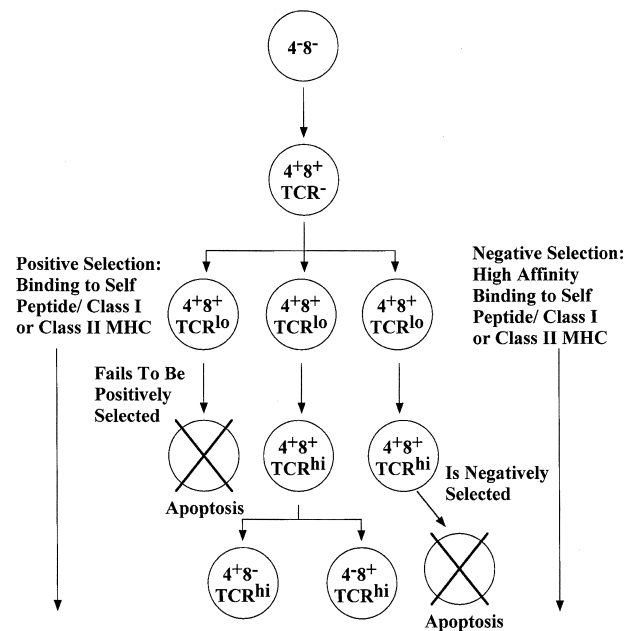
Upon entry into the thymus, T cell precursors do not express TCR chains, the CD3 complex, or the CD4 or CD8 molecules (Figure 1.10). Because these cells lack both CD4 and CD8, they are often referred to as *double-negative* (*DN*) *cells*. Thymocytes develop from this DN pool into cells that are both CD4$^+$ and CD8$^+$ (double-positive cells) and express low levels of TCR and CD3 on their surface. In turn, double-positive cells further differentiate into relatively mature thymocytes that express either CD4 or CD8 (single-positive cells) and high levels of the TCR–CD3 complex.


FIGURE 1.10 Development of α/β T cells in the thymus. Double-negative T cells (4^-8^-) acquire CD4 and CD8 (4^+8^+) and then express α/β TCRs, initially at low levels. Thereafter, the degree of expression of TCRs increases and the cells differentiate into CD4 or CD8 cells and are then exported to the periphery. Once the T cells have expressed receptors, their survival depends upon the recognition of peptide/MHC class I or class II molecules with an affinity above some given threshold. Cells that fail to do so undergo apoptosis. These cells have failed to be *positively selected*. Positive selection is associated with the differentiation of 4^+8^+ cells into CD4 or CD8 cells. Positive selection involving peptide/class I MHC molecules leads to the development of CD8 cells whereas positive selection involving peptide/class II MHC molecules leads to the development of CD4 cells. If a T cell recognizes a peptide/MHC complex with high affinity, it is also eliminated via apoptosis (it is *negatively selected*).

The expression of the TCR depends on complex rearrangement processes that generate TCR α and β (or γ and δ) chains. Once TCR chains are expressed, these cells undergo two important selection processes within the thymus. One, termed *negative selection,* is the deletion of cells that express receptors that bind with high affinity to complexes of self-peptides with self-MHC molecules. This is a major mechanism through which the T cell compartment develops immunologic unresponsiveness to self-antigens (see Chapters 12 and 29). In addition, a second major selection process is *positive selection,* in which T cells with receptors with "intermediate affinity" for self-peptides bound to self-MHC molecules are selected, thus forming the basis of the T cell repertoire for foreign peptides associated with self-MHC molecules. It appears that T cells that are not positively selected are eliminated in the thymic cortex by apoptosis. Similarly, T cells that are negatively selected as a result of high-affinity binding to self-peptide–self-MHC complexes are also deleted through apoptotic death. These two selection processes result in the development of a population of T cells that are biased toward the recognition of peptides in association with self-MHC molecules from which those cells that are potentially autoreactive (capable of high-affinity binding of self-peptide–self-MHC complexes) have been purged.

One important event in the development of T cells is their differentiation from double-positive cells into CD4$^+$ or CD8$^+$ single-positive cells. This process involves the interaction of double-positive thymocytes with peptide bound to class II or class I MHC molecules on accessory cells. Indeed, CD4 binds to monomorphic sites on class II molecules, whereas CD8 binds to comparable sites on class I molecules. The capacity of the TCR and CD4 (or of the TCR and CD8) to bind to a class II MHC (or a class I MHC) molecule on an accessory cell leads either to the differentiation of double-positive thymocytes into CD4$^+$ (or CD8$^+$) single-positive T cells or to the selection of cells that have "stochastically" differentiated down the CD4 (or CD8) pathway.

Less is understood about the differentiation of thymocytes that express TCRs composed of γ/δ chains. These cells fail to express either CD4 or CD8. However, γ/δ cells are relatively numerous early in fetal life; this, together with their limited degree of heterogeneity, suggests that they may comprise a relatively primitive T cell compartment.

T Lymphocyte Functions (Chapter 13)

T cells mediate a wide range of immunologic functions. These include the capacity to help B cells develop into antibody-producing cells, the capacity to increase the microbicidal action of monocyte/macrophages, the inhibition of certain types of immune responses, direct killing of target cells, and mobilization of the inflammatory response. In general, these effects depend on their expression of specific cell-surface molecules and the secretion of cytokines.

T Cells That Help Antibody Responses (Chapter 13)

Helper T cells can stimulate B cells to make antibody responses to proteins and other T cell–dependent antigens. T cell–dependent antigens are immunogens in which individual epitopes appear only once or only a limited number of times so that they are unable to cross-link the membrane Ig of B cells or do so inefficiently. B cells bind the antigen through their membrane Ig, and the complex undergoes endocytosis. Within the endosomal and lysosomal compartments, the antigen is fragmented into peptides by proteolytic enzymes and one or more of the generated peptides are loaded into class II MHC molecules, which traffic through this vesicular compartment. The resulting complex of class II MHC molecule and bound peptide is exported to the B cell surface membrane. T cells with receptors specific for the peptide/class II molecular complex recognize that complex on the B cell.

B cell activation depends not only on the binding of peptide–class II MHC complexes on the B cell surface by the TCR but also on the interaction of T cell CD154 with CD40 on the B cell. T cells do not constitutively express CD154; rather, it is induced as a result of an interaction with an activated APC that expresses a cognate antigen recognized by the TCR of the T cell. Further, CD80/86 are generally expressed by activated but not resting B cells so that interactions involving resting B cells and naïve T cells generally do not lead to efficient antibody production. By contrast, a T cell already activated and expressing CD154 can interact with a resting B cell, leading to its upregulation of CD80/86 and to a more productive T cell/B cell interaction with the delivery of cognate help and the development of the B cell into an antibody-producing cell. Similarly, activated B cells expressing large amounts of class II molecules and CD80/86 can act as effective APC and can participate with T cells in efficient cognate help interactions. Cross-linkage of membrane Ig on the B cell, even if inefficient, may synergize with the CD154/CD40 interaction to yield vigorous B cell activation.

The subsequent events in the B cell response program, including proliferation, Ig secretion, and class switching either depend on or are enhanced by the actions of T cell–derived cytokines. Thus, B cell proliferation and Ig secretion are enhanced by the actions of several type I cytokines, including IL-2 and IL-4. Ig class switching is dependent both on the initiation of competence for switching, which can be induced by the CD154/CD40 interaction, and on the targeting of particular C regions for switching, which is determined, in many instances, by cytokines. The best studied example of this is the role of IL-4 in determining

switching to IgG1 and IgE in the mouse and to IgG4 and IgE in the human. Indeed, the central role of IL-4 in the production of IgE is demonstrated by the fact that mice that lack the IL-4 gene or the gene for the IL-4 receptor α chain, as a result of homologous recombination-mediated gene knockouts, have a marked defect in IgE production.

Although $CD4^+$ T cells with the phenotype of T_{H2} cells (i.e., IL-4, IL-13, IL-5, IL-6, and IL-10 producers) are efficient helper cells, T_{H1} and T_{H17} cells also have the capacity to act as helpers. Because T_{H1} cells produce IFN-γ, which acts as a switch factor for IgG2a in the mouse, T_{H1}-mediated help often is dominated by the production of IgG2a antibodies.

Induction of Cellular Immunity (Chapters 13 and 18)

T cells also may act to enhance the capacity of monocytes and macrophages to destroy intracellular microorganisms. In particular, IFN-γ enhances several mechanisms through which mononuclear phagocytes destroy intracellular bacteria and parasites, including the generation of nitric oxide and induction of tumor necrosis factor (TNF). T_{H1} cells are particularly effective in enhancing microbicidal action because they produce IFN-γ. By contrast, three of the major cytokines produced by T_{H2} cells, IL-4, IL-13 and IL-10, block these activities; IL-4 and IL-13 induce an alternative gene activation program in macrophages resulting in *alternatively activated macrophages*, characterized (in the mouse) by the expression of arginase 1 and chitinase. Thus, T_{H2} cells often oppose the action of T_{H1} cells in inducing cellular immunity and in certain infections with microorganisms that are intracellular pathogens of macrophages, a T_{H2}-dominated response may be associated with failure to control the infection.

Regulatory T Cells (Chapter 30)

There has been a longstanding interest in the capacity of T cells to diminish as well as to help immune responses. Cells that mediate such effects are referred to as T_{regs}. T_{regs} may be identified by their expression of Foxp3 and of CD25, the IL-2 receptor alpha chain. These cells inhibit the capacity of both CD4 and CD8 T cells to respond to their cognate antigens. The mechanisms through which their suppressor function is mediated are still somewhat controversial. In some instances, it appears that cell–cell contact is essential for suppression, whereas in other circumstances, production of cytokines by T_{regs} has been implicated in their ability to inhibit responses. Evidence has been presented for both IL-10 and TGFβ as mediators of inhibition.

T_{regs} have been particularly studied in the context of various autoimmune conditions. In the absence of T_{regs}, conventional T cells cause several types of autoimmune responses, including autoimmune gastritis and inflammatory bowel disease. T_{regs} express cell surface receptors, allowing them to recognize autoantigens and their responses to such recognition results in the suppression of responses by conventional T cells. Whether the receptor repertoire of T_{regs} and the conventional T cells are the same has not been fully determined, although there is increasing evidence that T_{regs} derive from a thymic CD4 T cell population with relativley high affinity for self-antigen. As noted earlier, iT_{regs} can be derived in the periphery from naïve CD4 T cell populations. This is seen when naive cells are stimulated by their cognate ligands in the presence of TGFβ.

Cytotoxic T Cells (Chapter 34)

One of the most striking actions of T cells is the lysis of cells expressing specific antigens. Most cells with such cytotoxic activity are CD8 T cells that recognize peptides derived from proteins produced within the target cell, bound to class I MHC molecules expressed on the surface of the target cell. However, CD4 T cells can express CTL activity, although in such cases the antigen recognized is a peptide associated with a class II MHC molecule; often such peptides derive from exogenous antigens.

There are two major mechanisms of cytotoxicity. One involves the production by the CTL of perforin, a molecule that can insert into the membrane of target cells and promote the lysis of that cell. Perforin-mediated lysis is enhanced by a series of enzymes produced by activated CTLs, referred to as *granzymes*. Many active CTLs also express large amounts of fas ligand on their surface. The interaction of fas ligand on the surface of the CTL with fas on the surface of the target cell initiates apoptosis in the target cell.

CTL-mediated lysis is a major mechanism for the destruction of virus-infected cells. If activated during the period in which the virus is in its eclipse phase, CTLs may be capable of eliminating virus and curing the host with relatively limited cell destruction. However, vigorous CTL activity after a virus has been widely disseminated may lead to substantial tissue injury because of the large number of cells that are killed by the action of the CTLs. Thus, in many infections, the disease is caused by the destruction of tissue by CTLs rather than by the virus itself. One example is hepatitis B, in which much of the liver damage represents the attack of HBV-specific CTLs on infected liver cells.

It is usually observed that CTLs that have been induced as a result of a viral infection or intentional immunization must be reactivated *in vitro* through the recognition of antigen on the target cell. This is particularly true if some interval has elapsed between the time of infection or immunization and the time of test. This has led to some question being raised as to the importance of CTL immunity in protection against reinfection and how important

CTL generation is in the long-term immunity induced by protective vaccines. However, in active infections, such as seen in HIV$^+$ individuals, CTL that can kill their targets cells immediately are often seen. There is much evidence to suggest that these cells play an active role in controlling the number of HIV$^+$ T cells.

CYTOKINES (Chapters 23, 24, 25, and 26)

Many of the functions of cells of the immune system are mediated through the production of a set of small proteins referred to as cytokines. These proteins can now be divided into several families. They include the type I cytokines or hematopoeitins that encompass many of the interleukins (i.e., IL-2, IL-3, IL-4, IL-5, IL-6, IL-7, IL-9, IL-11, IL-12, IL-13, IL-15, IL-21, IL-23, and IL-27), as well as several hematopoietic growth factors; the type II cytokines, including the interferons and IL-10; the TNF-related molecules, including TNF, lymphotoxin, and Fas ligand; Ig superfamily members, including IL-1, IL-18, and IL-33; and the chemokines, a growing family of molecules playing critical roles in a wide variety of immune and inflammatory functions. IL-17 and its congeners, including IL-25, constitute a structurally unique set of cytokines.

Many of the cytokines are T cell products; their production represents one of the means through which the wide variety of functions of T cells are mediated. Most cytokines are not constitutive products of the T cell. Rather, they are produced in response to T cell activation, usually resulting from presentation of antigen to T cells by APCs in concert with the action of a costimulatory molecule, such as the interaction of CD80/86 with CD28. Although cytokines are produced in small quantities, they are very potent, binding to their receptors with equilibrium constants of $\sim 10^{10}$ M^{-1}. In some instances, cytokines are directionally secreted into the immunological synapse formed between a T cell and an APC. In such cases, the cytokine acts in a paracrine manner. Indeed, many cytokines have limited action at a distance from the cell that produced them. This appears to be particularly true of many of the type I cytokines. However, other cytokines act by diffusion through extracellular fluids and blood to target cells that are distant from the producers. Among these are cytokines that have proinflammatory effects, such as IL-1, IL-6, and TNF, and the chemokines, that play important roles in regulating the migration of lymphocytes and other cell types.

Chemokines (Chapter 26)

A large family of small proteins that are *chemotactic cytokines* (chemokines) have been described. While members of this family have a variety of functions, perhaps the most dramatic is their capacity to regulate leukocyte migration and thus to act as critical dynamic organizers of cell distribution in the immune and inflammatory responses. The receptors for chemokines are seven transmembrane-spanning, G protein–coupled receptors.

The chemokines are subdivided based on the number and positioning of their highly conserved cysteines. Among chemokines with four conserved cysteines, the cysteines are adjacent in one large group (the CC chemokines) while in a second large group they are separated by one amino acid (CXC chemokines). There are also rare chemokines in which the cysteines are separated by three amino acids (CX3C) or in which there are only two conserved cysteines (C chemokines).

Individual chemokines may signal through more than one chemokine receptor and individual receptors may interact with more than one chemokine, producing a very complex set of chemokine/chemokine receptor pairs and providing opportunities for exceedingly fine regulation of cellular functions.

THE MAJOR HISTOCOMPATIBILITY COMPLEX AND ANTIGEN PRESENTATION (see Chapters 19 and 20)

The MHC has already been introduced in this chapter in the discussion of T cell recognition of antigen-derived peptides bound to specialized grooves in class I and class II MHC proteins. Indeed, the class I and class II MHC molecules are essential to the process of T cell recognition and response. Nonetheless, they were first recognized not for this reason but because of the dominant role that MHC class I and class II proteins play in transplantation immunity (see Chapter 44).

When the genetic basis of transplantation rejection between mice of distinct inbred strains was sought, it was recognized that although multiple genetic regions contributed to the rejection process, one region played a dominant role. Differences at this region alone would cause prompt graft rejection, whereas any other individual difference usually resulted in a slow rejection of foreign tissue. For this reason, the genetic region responsible for prompt graft rejection was termed the *major histocompatibility complex*.

In all higher vertebrates that have been thoroughly studied, a comparable MHC exists. The defining features of the MHC are the transplantation antigens that it encodes. These are the class I and class II MHC molecules. The genes encoding these molecules show an unprecedented degree of polymorphism. This, together with their critical role in antigen presentation, explains their central role as the target of the immune responses leading to the rejection of organ and tissue allografts.

The MHC also includes other genes, particularly genes for certain complement components. In addition, genes for the cytokines TNF-α and lymphotoxin (also designated TNF-β) are found in the MHC.

Class I MHC Molecules (Chapter 19)

Class I MHC molecules are membrane glycoproteins expressed on most cells. They consist of an α chain of approximately 45,000 daltons noncovalently associated with β2-microglobulin, a 12,000-dalton molecule (Figure 1.11). The gene for the α chain is encoded in the MHC, whereas that for β2-microglobulin is not. Both the α chain and β2-microglobulin are Ig supergene family members. The α chain is highly polymorphic, with the polymorphisms found mainly in the regions that constitute the binding sites for antigen-derived peptides and that are contact sites for the TCR.

The class I α chain consists of three extracellular regions or domains, each of similar length, designated α1, α2, and α3. In addition, α chains have a membrane-spanning domain and a short carboxy-terminal cytoplasmic tail. The crystal structure of class I molecules indicates that the α1 and α2 domains form a site for the binding of peptides derived from antigens. This site is defined by a floor consisting of β sheets and bounded by α-helical walls. The polymorphisms of the class I molecule are mainly in these areas.
FIGURE 1.11 Model of the class I HLA-A2 molecule. A schematic representation of the structure of the HLA-A2 class I MHC molecule. The polymorphic α1 and α2 domains are at the top. They form a groove into which antigen-derived peptides fit to form the peptide–MHC class I complex that is recognized by TCRs of CD8$^+$ T cells. (Reprinted from Bjorkman PJ, et al. *Nature*. 1987;329:506–512).

In the human, three loci encoding classical class I molecules have been defined; these are designated HLA-A, HLA-B, and HLA-C. All display high degrees of polymorphism. A similar situation exists in the mouse. In addition, there are a series of genes that encode class I–like molecules (class Ib molecules). Some of these have been shown to have antigen-presenting activity for formulated peptides, suggesting that they may be specialized to present certain prokaryotic antigens. The class Ib molecule CD1 has been shown to have antigen-presenting function for mycobacterial lipids, providing a mechanism through which T cells specific for such molecules can be generated. CD1d, presenting certain endogenous or exogenous phospholipids, is recognized by a novel class of T cells (NK T cells) that produce large amounts of cytokines upon immediate stimulation.

Class II MHC Molecules (see Chapter 19)

Class II MHC molecules are heterodimeric membrane glycoproteins. Their constituent chains are designated α and β; both chains are Ig supergene family members, and both are encoded within the MHC. Each chain consists of two extracellular domains (α1 and α2; β1 and β2, respectively), a hydrophobic domain, and a short cytoplasmic segment. The overall conformation of class II MHC molecules appears to be quite similar to that of class I molecules. The peptide-binding site of the class II molecules is contributed to by the α1 and β1 domains (Figure 1.5); it is within these domains that the majority of the polymorphic residues of class II molecules are found.

A comparison of the three-dimensional structures of class I and class II molecules indicates certain distinctive features that explain differences in the length of peptides that the two types of MHC molecules can bind. Class I molecules generally bind peptides with a mean length of nine amino acids, whereas class II molecules can bind substantially larger peptides.

In the mouse, class II MHC molecules are encoded by genes within the I region of the MHC. These molecules are often referred to as I region–associated (Ia) antigens. Two sets of class II molecules exist, designated I-A and I-E, respectively. The α and β chains of the I-A molecules (Aα and Aβ) pair with one another, as do the α and β chains of I-E (Eα and Eβ). In heterozygous mice, α and β chains encoded on alternative chromosomes (i.e., Aα^b and Aβ^k) may cross-pair so that heterozygous mice can express both parental and hybrid class II molecules. However, the degree of cross-pairing is allele specific; not all hybrid pairs are formed with equal efficiency.

In the human, there are three major sets of class II molecules, encoded in the DR, DQ, and DP regions of the HLA complex.

Class II molecules have a more restricted tissue distribution than do class I molecules. Class II molecules

are found on B cells, DCs, epidermal Langerhans cells, macrophages, thymic epithelial cells, and, in the human, activated T cells. Levels of class II molecule expression are regulated in many cell types by interferons and in B cells by IL-4. Indeed, interferons can cause expression of class II molecules on many cell types that normally lack these cell surface molecules. Interferons also can cause striking upregulation in the expression of class I MHC molecules. Thus, immunologically mediated inflammation may result in aberrant expression of class II MHC molecules and heightened expression of class I molecules. Such altered expression of MHC molecules can allow cells that do not normally function as APCs for $CD4^+$ T cells to do so and enhances the sensitivity of such cells to CD8 T cells. This has important consequences for immunopathologic responses and for autoimmunity.

Antigen Presentation (Chapter 20)

As already discussed, the function of class I and class II MHC molecules is to bind and present antigen-derived peptides to T cells whose receptors can recognize the peptide–MHC complex that is generated. There are two major types of antigen-processing pathways, specialized to deal with distinct classes of pathogens that the T cell system must confront (Figure 1.8).

Extracellular bacteria and extracellular proteins may enter APCs by endocytosis or phagocytosis. Their antigens and the antigens of bacteria that live within endosomes or lysosomes are fragmented in these organelles and peptides derived from the antigen are loaded into class II MHC molecules as these proteins traverse the vesicular compartments in which the peptides are found. The loading of peptide is important in stabilizing the structure of the class II MHC molecule. The acidic pH of the compartments in which loading occurs facilitates the loading process. However, once the peptide-loaded class II molecules reach neutral pH, such as at the cell surface, the peptide–MHC complex is very stable. Peptide dissociation from such class II molecules is very slow, with a half-time measured in hours. The peptide–class II complex is recognized by T cells of the CD4 class with complementary receptors. As already pointed out, the specialization of CD4 T cells to recognize peptide–class II complexes is partly due to the affinity of the CD4 molecule for monomorphic determinants on class II molecules. Obviously, this form of antigen processing can only apply to cells that express class II MHC molecules. Indeed, APCs for CD4 T cells principally include cells that normally express class II MHC molecules, including DCs, B cells, and macrophages.

T cells also can recognize proteins that are produced within the cell that presents the antigen. The major pathogens recognized by this means are viruses and other obligate intracellular (non–endosomal/lysosomal)

microbes that have infected cells. In addition, proteins that are unique to tumors, such as mutant oncogenes, or are overexpressed in tumors also can be recognized by T cells. Endogenously produced proteins are fragmented in the cytosol by the proteases in the proteasome. The resultant peptides are transported into the rough endoplasmic reticulum through the action of a specialized transport system. These peptides are then available for loading into class I molecules. In contrast to the loading of class II molecules, which is facilitated by the acid pH of the loading environment, the loading of class I molecules is controlled by interaction of the class I α chain with β2-microglobulin. Thus, the bond between peptide and class I molecule is generally weak in the absence of β2-microglobulin, and the binding of β2-microglobulin strikingly stabilizes the complex. (Similarly, the binding of β2-microglobulin to the α chain is markedly enhanced by the presence of peptide in the α chain groove.) The peptide-loaded class I molecule is then brought to the cell surface. In contrast to peptide-loaded class II molecules that are recognized by CD4 T cells, peptide-loaded class I molecules are recognized by CD8 T cells. This form of antigen processing and presentation can be performed by virtually all cells because, with a few exceptions, class I MHC molecules are universally expressed.

Although the specialization of class I molecules to bind and present endogenously produced peptides and of class II molecules to bind and present peptides derived from exogenous antigens is generally correct, there are exceptions, many of which have physiologic importance. Particularly important is the representation by class II$^+$ cells of antigens derived from class II$^-$ cells.

T Lymphocyte Recognition of Peptide–MHC Complexes Results in MHC-Restricted Recognition (Chapter 10)

Befor the biochemical nature of the interaction between antigen-derived peptides and MHC molecules was recognized, it was observed that T cell responses displayed *MHC-restricted antigen recognition*. Thus, if individual animals were primed to a given antigen, their T cells would be able to recognize and respond to that antigen only if the APCs that presented the antigen shared MHC molecules with the animal that had been immunized. The antigen would not be recognized when presented by APCs of an allogeneic MHC type. This can now be explained by the fact that the TCR recognizes peptide bound to an MHC molecule. MHC molecules display high degrees of polymorphism, and this polymorphism is concentrated in the regions of the class I and class II molecules that interact with the peptide and that can bind to the TCR. Differences in structure of the MHC molecules derived from different individuals (or different inbred strains of mice) profoundly affect the

recognition process. Two obvious explanations exist to account for this. First, the structure of the grooves in different class I or class II MHC molecules may determine that a different range of peptides are bound or, even if the same peptide is bound, may change the conformation of the surface of the peptide presented to the TCR. Second, polymorphic sites on the walls of the α-helices that are exposed to the TCR can either enhance or diminish binding of the whole complex, depending on their structure. Thus, priming an individual with a given antigen on APCs that are syngeneic to the individual will elicit a response by T cells whose TCRs are specific for a complex consisting of a peptide derived from the antigen and the exposed polymorphic residues of the MHC molecule. When the same antigen is used with APCs of different MHC type, it is unlikely that the same peptide/MHC surface can be formed, and thus the primed T cells are not likely to bind and respond to such stimulation.

Indeed, this process also occurs within the thymus in the generation of the T cell repertoire, as already discussed. T cells developing within the thymus undergo a positive selection event in which those T cells capable of recognizing MHC molecules displayed within the thymus are selected (and the remainder undergo programmed cell death). This leads to the skewing of the population of T cells that emerges from the thymus so that the cells are specialized to respond to peptides on self-MHC molecules. One of the unsolved enigmas of positive selection within the thymus is how the vast array of T cells with receptors capable of reacting with a very large set of foreign peptides associated with self-MHC molecules are chosen by self-MHC molecules that can only display self peptides. It is believed that a high degree of cross-reactivity may exist so that T cells selected to bind a given class I (or class II) molecule plus a particular self-peptide can also bind a set of other (foreign) peptides bound to the same MHC molecule. Further, the affinity of an interaction required for positive selection in the thymus appears to be considerably lower than that required for full activation of peripheral T cells. Thus, thymocytes selected by a given self-peptide–self-MHC complex will generally not mount a full response when they encounter the same peptide–MHC complex in the periphery, although they will respond to a set of foreign peptide–MHC complexes to which they bind with higher affinity. Recognition of the self-peptide–self-MHC complex in the periphery may nonetheless have important consequences such as sustaining the viability of resting lymphocytes.

Our modern understanding of T cell recognition also aids in explaining the phenomenon of immune response (Ir) gene control of specific responses. In many situations, the capacity to recognize simple antigens can be found in only some members of a species. In most such cases, the genes that determine the capacity to make these responses have been mapped to the MHC. We would now explain Ir gene control of immune responses based on the capacity of different class II MHC molecules (or class I MHC molecules) to bind different sets of peptides. Thus, for simple molecules, it is likely that peptides can be generated that are only capable of binding to some of the polymorphic MHC molecules of the species. Only individuals who possess those allelic forms of the MHC will be able to respond to those antigens. Based on this, some individuals are nonresponders because of the failure to generate a peptide–MHC molecule complex that can be recognized by the T cell system.

This mechanism also may explain the linkage of MHC type with susceptibility to various diseases. Many diseases show a greater incidence in individuals of a given MHC type. These include reactive arthritides, gluten-sensitive enteropathy, insulin-dependent diabetes mellitus, and rheumatoid arthritis (see Chapters 41 and 42). One explanation is that the MHC type that is associated with increased incidence may convey altered responsiveness to antigens of agents that cause or exacerbate the disease. Indeed, it appears that many of these diseases are due to enhanced or inappropriate immune responses.

Antigen-presenting Cells (Chapter 15)

T cells recognize peptide–MHC complexes on the surface of other cells. Such cells are often referred to as *antigen-presenting cells*, or *APC*. Although effector cells can mediate their functions by recognizing such complexes on virtually any cell type, naïve cells are most efficiently activated by a set of specialized APC, the DCs. DCs are a multimember family including the plasmacytoid DCs which are the principal source of type I interferons in viral infections.

In general, in their immature form, DCs are resident in the tissues where they are efficient at capturing and endocytosing antigen. Their antigen capture activity is dependent upon expression of several surface receptors including Fc receptors, receptors for heat shock proteins, and C-type lectins. If they receive signals, such as various inflammatory stimuli, often mediated by TLRs, they down-regulate the expression of these molecules but increase their expression of surface MHC molecules and various costimulatory molecules such as CD80/86. In addition, such stimulation induces expression of chemokine receptors, such as CCR2 and CCR7. The latter allow stimulated DCs to follow signals from the chemokines CCL19 and CCL21 and to migrate into the T cell zone of lymph nodes. As part of the maturation process, they may also acquire the capacity to produce cytokines and express surface molecules that can aid in determining the polarization of T cell priming. This includes the production of IL-12 , IL-23, IL-6 and the expression of inducible costimulator (ICOS) ligand and of Notch ligands. Interaction of naïve

T cells with immature DCs may induce a state of peripheral tolerance.

One important function of DCs is the ability to acquire antigen from virally infected cells and to *cross present* it through the class I pathway. This allows DCs to aid in the priming of precursors of cytotoxic T cells specific for viruses that do not infect the DCs themselves.

EFFECTOR MECHANISMS OF IMMUNITY

The ultimate purpose of the immune system is to mount responses that protect the individual against infections with pathogenic microorganisms by eliminating these microbes or, where it is not possible to eliminate infection, to control its spread and virulence. In addition, the immune system may play an important role in the control of the development and spread of some malignant tumors. The responses that actually cause the destruction of the agents that initiate these pathogenic states (e.g., bacteria, viruses, parasites, tumor cells) are collectively the effector mechanisms of the immune system. Several have already been alluded to. Among them are the cytotoxic action of CTLs, which leads to the destruction of cells harboring viruses and, in some circumstances, expressing tumor antigens. In some cases, antibody can be directly protective by neutralizing determinants essential to a critical step through which the pathogen establishes or spreads an infectious process. However, in most cases, the immune system mobilizes powerful nonspecific mechanisms to mediate its effector function.

Effector Cells of the Immune Response

Among the cells that mediate important functions in the immune system are cells of the monocyte/macrophage lineage, NK cells, mast cells, basophils, eosinophils, and neutrophils. It is beyond the scope of this introductory chapter to present an extended discussion of each of these important cell types. However, a brief mention of some of their actions will help in understanding their critical functions in the immune response.

Monocytes and Macrophages (Chapter 18)

Cells of the monocyte/macrophage lineage play a central role in immunity. One of the key goals of cellular immunity is to aid the macrophages in eliminating organisms that have established intracellular infections. In general, nonactivated macrophages are inefficient in destroying intracellular microbes. However, the production of IFN-γ and other mediators by T cells can enhance the capacity of macrophages to eliminate such microorganisms. Several

mechanisms exist for this purpose, including the development of reactive forms of oxygen, the development of nitric oxide, and the induction of a series of proteolytic enzymes, as well as the induction of cytokine production. Macrophages can act as APCs and thus can enlist the "help" of activated, cytokine-producing CD4$^+$ T cells in regulating their function.

Although macrophages function as APCs for attracting activated T cells, they do not appear to be particularly effective in the activation of naïve CD4 T cells. In instances in which they are the site of infection or have phagocytosed infectious agents or their proteins, antigens from these agents may be transferred to DCs. In such cases the DCs would be the principal APCs that activate naïve or possibly resting memory CD4 T cells. This process is often described as cross-presentation. Such activated T cells would then be available to help infected macrophages.

Natural Killer Cells (Chapter 16)

Natural killer, or *NK*, cells play an important role in the immune system. Indeed, in mice that lack mature T and B cells due to the *scid* mutation, the NK system appears to be highly active and to provide these animals a substantial measure of protection against infection. NK cells are closely related to T cells. They lack conventional TCR (or Ig) but express two classes of receptors. They have a set of activating receptors that allow them to recognize features associated with virally infected cells or tumor cells. They also express receptors for MHC molecules that shut off their lytic activity. Thus, virally infected cells or tumor cells that escape the surveillance of cytotoxic T cells by down-regulating or shutting off expression of MHC molecules then become targets for efficient killing by NK cells because the cytotoxic activity of the latter cells is no longer shut off by the recognition of particular alleles of MHC class I molecules.

In addition, NK express a receptor for the Fc portion of IgG (FcγRIII). Antibody-coated cells can be recognized by NK cells, and such cells can then be lysed. This process is referred to as antibody-dependent cellular cytotoxicity (ADCC).

NK cells are efficient producers of IFN-γ. A variety of stimuli, including recognition of virally infected cells and tumor cells, cross-linkage of FcγRIII and stimulation by the cytokines IL-12 and IL-18, cause striking induction of IFN-γ production by NK cells.

Mast Cells and Basophils (Chapter 43)

Mast cells and basophils play important roles in the induction of allergic inflammatory responses. They express cell

surface receptors for the Fc portions of IgE (FcεRI) and for certain classes of IgG (FcγR). This enables them to bind antibody to their surfaces, and when antigens capable of reacting with that antibody are introduced, the resultant cross-linkage of FcεRI or FcγR results in the prompt release of a series of potent mediators such as histamine, serotonin, and a variety of enzymes that play critical roles in initiating allergic and anaphylactic-type responses. In addition, such stimulation also causes these cells to produce a set of cytokines, including IL-3, IL-4, IL-13, IL-5, IL-6, granulocyte-macrophage colony-stimulating factor (GM-CSF), and TNFα, that have important late consequences in allergic inflammatory responses.

Granulocytes

Granulocytes have critical roles to play in a wide range of inflammatory situations. Rather than attempting an extended discussion of these potent cells, it may be sufficient to say that in their absence it is exceedingly difficult to clear infections with extracellular bacteria and that the immune response plays an important role in orchestrating the growth, differentiation, and mobilization of these crucial cells. Recent work indicates that T_{H17} cells are particularly important because of their role in recruiting granulocytes to sites of immune responses.

Eosinophils (Chapter 43)

Eosinophils are bone marrow–derived myeloid cells that complete their late differentiation under the influence of IL-5. They migrate to tissue sites in response to the chemokine eotaxin and as a result of their adhesion receptors. Since T_{H2} cells can produce IL-5 and stimulate the production of eotaxin, eosinophil accumulation is often associated with T_{H2}-mediated inflammation. Eosinophils store a series of proteins in their secondary granules including major basic protein, eosinophil cationic protein and eosinophil peroxidase. When released, these proteins are responsible for much of the damage that eosinophils mediate both to helminthic parasites and to the epithelium. Eosinophils have been implicated as important in protective responses to helminths and in the tissue damage seen in allergic inflammation in conditions such as asthma.

The Complement System (Chapter 33)

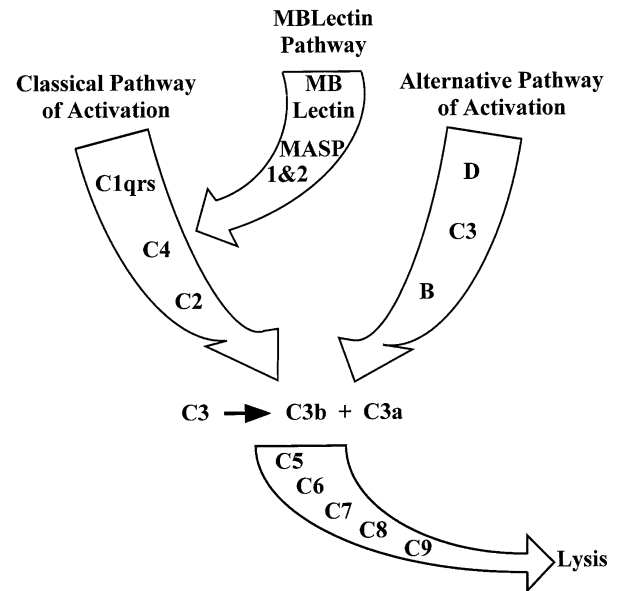
The complement system is a complex system of proteolytic enzymes, regulatory and inflammatory proteins and peptides, cell surface receptors, and proteins capable of causing the lysis of cells. The system can be thought of as consisting of three arrays of proteins. Two of these sets of


FIGURE 1.12 The complement system. The classical pathway of complement activation, usually initiated by the aggregation of C1 by binding to antigen–antibody complexes, resulting in the formation of an enzyme, a C3 convertase, that cleaves C3 into two fragments, C3b and C3a. The classical pathway can also be initiated by the aggregation of MBL as a result of binding sugars expressed in the capsules of many pathogenic microbes. The components of the MBL pathway appear to mimic the function of C1qrs. The alternative pathway of complement activation provides a potent means of activating complement without requiring antibody recognition of antigen. It results in the formation of a distinct C3 convertase. The fragments formed by cleaving C3 have important biologic activities. In addition, C3b, together with elements of the classical pathway (C4b, C2a) or the alternative pathway (Bb, properdin), form enzymes (C5 convertases) that cleave C5, the initial member of the terminal family of proteins. Cleavage of C5 leads to the formation of the membrane attack complex that can result in the osmotic lysis of cells.

proteins, when engaged, lead to the activation of the third component of complement (C3) (Figure 1.12). The activation of C3 releases proteins that are critical for opsonization (preparation for phagocytosis) of bacteria and other particles and engages the third set of proteins that insert into biologic membranes and produce cell death through osmotic lysis. In addition, fragments generated from some of the complement components (e.g., C3a and C5a) have potent inflammatory activities.

The Classical Pathway of Complement Activation

The two activation systems for C3 are referred to as the *classical pathway* and the *alternative pathway*. The classical pathway is initiated by the formation of complexes of antigen with IgM or IgG antibody. This leads to the binding

of the first component of complement, C1, and its activation, creating the C1 esterase that can cleave the next two components of the complement system, C4 and C2.

C4 is a trimeric molecule, consisting of α, β, and γ chains. C1 esterase cleaves the α chain, releasing C4b, which binds to surfaces in the immediate vicinity of the antigen–antibody–C1 esterase complex. A single C1 esterase molecule will cause the deposition of multiple C4b molecules.

C2 is a single polypeptide chain that binds to C4b and is then proteolytically cleaved by C1 esterase, releasing C2b. The resulting complex of the residual portion of C2 (C2a) with C4b (C4b2a) is a serine protease whose substrate is C3. Cleavage of C3 by C4b2a (also referred to as *the classical pathway C3 convertase*) results in the release of C3a and C3b. A single antigen–antibody complex and its associated C1 esterase can lead to the production of a large number of C3 convertases (i.e., C4b2a complexes) and thus to cleavage of a large number of C3 molecules.

The components of the classical pathway can be activated by a distinct, non–antibody-dependent mechanism. The mannose-binding lectin (MBL) is activated by binding to (and being cross-linked by) repetitive sugar residues such as N-acetylglucosamine or mannose. The activation of MBL recruits the MBL-associated serine proteases MASP-1 and MASP-2, which cleave C4 and C2 and lead to the formation of the classical pathway C3 convertase. Because the capsules of several pathogenic microbes can be bound by MBL, this mechanism provides an antibody-independent pathway through which the complement system can be activated by foreign microorganisms.

The Alternative Pathway of Complement Activation

Although discovered more recently, the alternative pathway is the evolutionarily more ancient system of complement activation. Indeed, it, and the MBL activation of the classical pathway, can be regarded as important components of the innate immune system. The alternative pathway can be activated by a variety of agents such as insoluble yeast cell wall preparations and bacterial lipopolysaccharide. Antigen–antibody complexes also can activate the alternative pathway. The C3 convertase of the alternative pathway consists of a complex of C3b (itself a product of cleavage of C3) bound to the b fragment of the molecule factor B. C3bBb is produced by the action of the hydrolytic enzyme, factor D, that cleaves factor B; this cleavage only occurs when factor B has been bound by C3b.

Apart from the importance of the alternative pathway in activating the complement system in response to nonspecific stimulants, it also can act to amplify the activity of the classical pathway, because the C3 convertase of the classical system (C4b2a) provides a source of C3b that can

strikingly enhance formation of the alternative pathway convertase (C3bBb) in the presence of factor D.

The Terminal Components of the Complement System

C3b, formed from C3 by the action of the C3 convertases, possesses an internal thioester bond that can be cleaved to form a free sulfhydryl group. The latter can form a covalent bond with a variety of surface structures. C3b is recognized by receptors on various types of cells, including macrophages and B cells. The binding of C3b to antibody-coated bacteria is often an essential step for the phagocytosis of these microbes by macrophages.

C3b is also essential to the engagement of the terminal components of the complement system (C5 through C9) to form the membrane attack complex that causes cellular lysis. This process is initiated by the cleavage of C5, a 200,000-dalton two-chain molecule. The C5 convertases that catalyze this reaction are C4b2a3b (the classical pathway C5 convertase) or a complex of C3bBb with a protein designated properdin (the alternative pathway C5 convertase). Cleaved C5, C5b, forms a complex with C6 and then with C7, C8, and C9. This C5b/C9 complex behaves as an integral membrane protein that is responsible for the formation of complement-induced lesions in cell membranes. Such lesions have a donutlike appearance, with C9 molecules forming the ring of the donut.

In addition to the role of the complement system in opsonization and in cell lysis, several of the fragments of complement components formed during activation are potent mediators of inflammation. C3a, the 9,000-dalton fragment released by the action of the C3 convertases, binds to receptors on mast cells and basophils, resulting in the release of histamine and other mediators of anaphylaxis. C3a is thus termed an *anaphylotoxin,* as is C5a, the 11,000-dalton fragment released as a result of the action of the C5 convertases. C5a is also a chemoattractant for neutrophils and monocytes.

Finally, it is important to note that the process of activation of the complement cascade is highly regulated. Several regulatory proteins (e.g., C1 esterase inhibitor, decay accelerator factor, membrane cofactor protein) exist that function to prevent uncontrolled complement activation. Abnormalities in these regulatory proteins are often associated with clinical disorders such as hereditary angioedema and paroxysmal nocturnal hemoglobinuria.

CONCLUSION

This introductory chapter should provide the reader with an appreciation of the overall organization of the immune system and of the properties of its key cellular and molecular components. It should be obvious that the immune

system is highly complex, that it is capable of a wide range of effector functions, and that its activities are subject to potent, but only partially understood, regulatory processes. As the most versatile and powerful defense of higher organisms, the immune system may provide the key to the development of effective means to treat and prevent a broad range of diseases. Indeed, the last two sections of this book deal with immunity to infectious agents and immunologic mechanisms in disease. The introductory material provided here should be of aid the uninitiated reader in understanding the immunologic mechanisms brought into play in a wide range of clinical conditions in which immune processes play a major role either in pathogenesis or in recovery.

Organization and Evolution of the Immune System

Lymphoid Tissues and Organs

Eitan M. Akirav, Shan Liao, and Nancy H. Ruddle

INTRODUCTION

The mammalian immune system has evolved to provide defense against invading pathogens, taking advantage of the innate and adaptive systems. Although cells that can respond to pathogens are scattered in tissues throughout the body, the optimal structures for the response to antigens are organized, compartmentalized cellular aggregates that allow antigen concentration and presentation to a limited number of antigen-specific lymphocytes. The primary lymphoid organs are the sites where diverse populations of naïve, functionally mature lymphocytes are generated to

disperse throughout the body and await foreign invaders. This remarkable differentiation process occurs in a foreign antigen-independent fashion. The secondary lymphoid organs and mucosal-associated lymphoid tissues are discrete sites in which naïve, antigen-specific T and B lymphocytes encounter invaders to generate an adaptive response. The lymph nodes and spleen, located in anatomically distinct sites, have traditionally been described as somewhat static structures. In fact, they are responsive to environmental influences and undergo remarkable changes in the course of antigenic challenge. The spleen, lymph nodes, Peyers patches, tonsils and adenoids, and the (mouse and rat) nose-associated lymphoid tissue (NALT) are controlled by precise developmental programs. Somewhat less anatomically restricted tissues that are even more sensitive to the environment include accumulations of lymphoid cells that are organized but less discretely defined: the bronchus associated lymphoid tissues (BALT) and isolated lymphoid follicles (ILF). Tertiary lymphoid organs, or more accurately, tertiary lymphoid tissues, are accumulations of lymphoid cells that arise ectopically in sites that are not anatomically restricted and are not regulated by developmental programs. Such chronic lymphoid-cell infiltrates into organs, such as the pancreas and joints, are not usually delimited by a capsule, as are the thymus and the majority of secondary lymphoid organs. They respond to environmental stimuli and arise during chronic inflammation subsequent to microbial infection, graft rejection, or autoimmunity by the process of lymphoid neogenesis (1,2). They are classified as tertiary lymphoid tissues because they resemble secondary lymphoid organs with regard to cellular composition and compartmentalization, chemokines, and vascular addressins. In this chapter, the structure, function, trafficking patterns, and developmental signals that regulate the hierarchy of lymphoid organs will be described.

PRIMARY LYMPHOID ORGANS

The primary lymphoid organs are the sites where pre-B and pre-T lymphocytes mature into naïve T and B cells in the absence of foreign antigen. Each T or B cell expresses a unique receptor that can recognize and respond to foreign antigens, and in most cases, discriminate between self and foreign antigens. Naïve cells leave the primary lymphoid organs having received and responded to developmental cues that result in the rearrangement of their genetic material to generate a repertoire capable of recognizing and responding to a wide variety of foreign antigens. In the course of maturation in the primary lymphoid organs, the naïve lymphocytes express various chemokine receptors and adhesion molecules that direct them to secondary lymphoid organs.

▌ **TABLE 2.1 Chemokines Implicated in Lymphoid Organ Development and Maintenance**

Standard Name	Common Names	Receptor
CXCL12	SDF-1	CXCR4
CXCL13	BCA-1, BLC	CXCR5
CCL17	TARC	CCR4
CCL19	ELC, MIP-3β	CCR7
CCL20	MIP-3α	CCR6
CCL21	SLC, 6Ckine	CCR7
CCL25	TEC, TECK	CCR9
CCL28	MEC	CCR10

Fetal Liver

The earliest lymphoid cell precursors derive from self-renewing hematopoietic precursors called hematopoietic stem cells (HSCs). During ontogeny, these cells occupy several niches. In the fetal mouse, the first wave of hematopoiesis occurs in the yolk sac and aorta-gonad-mesonephros region at E10.5 (3). The placenta also contains HSC activity (4,5). Cells leave these tissues and migrate to the spleen and then the bone marrow under the influence of chemokines and adhesion molecules. The cells in the fetal liver CXCL12 (stromal cell derived factor, or SDF-1) (Table 2.1), in contrast to those in the bone marrow, also respond to the cytokine known as Steel factor (6). The fetal liver is the source of CD4$^+$CD3$^-$ lymphoid tissue inducer cells that express LTα and LTβ. The crucial importance of these cells in the development of secondary lymphoid organs is described later. Differentiation of HSC cells to B cells occurs in the fetal liver but does not require IL-7. Of the several different subsets of B cells, those generated by the fetal liver HSCs are somewhat limited and are of the B-1 subset (7). They do not give rise to CD5 B cells, predominately B1-B cells, and do not express terminal deoxynucleotidyl transferase and myosinlike light chain (7,8). It is not known whether these differences are intrinsic to the cells or are due to differences in the cytokine environment of fetal liver and bone marrow. P-selectin, E-selectin, and VCAM-1 are required for the cells to leave the fetal liver and move to the bone marrow (9,10).

Adult Bone Marrow

Functions

The bone marrow is the source of self-renewing populations of stem cells. These cells include precursors for HSCs and endothelial progenitor cells (ESC), which may derive from a single precursor (11). Bone marrow contains adult stem cells that can differentiate into adipocytes, chondrocytes, osteocyes, and myoblasts (12). The possibility that the bone marrow serves as a source of stem cells to, for

example, repopulate the liver or that the stem cells residing in the bone marrow exhibit plasticity that allows them to develop into cells of other differentiated types has generated great interest in this organ (13). This chapter concentrates on the role of the bone marrow as an immunological organ, giving rise to B cells and T-cell precursors and serving as a repository for plasma cells. Prethymocytes leave the bone marrow and seed the thymus, where they undergo differentiation to naïve T cells. Bone marrow stromal cells secrete growth factors crucial for the development of HSCs. Additional factors enable the differentiation of immature B cells from HSC. The several stages of B cell differentiation that include Fraction A (pre-pro B cell), Fraction B/C (pro-B cell), and Fraction D (pre-B cell) are described in detail in Chapter 7 of this volume.

In addition to serving as a primary lymphoid organ where B cell differentiation and development occur, the bone marrow is also a home for antibody-secreting cells (14). After B cells have interacted with antigens in the secondary lymphoid organs, they enter the blood stream and travel to the marrow. Thus, this organ not only serves as a primary lymphoid organ, but also as a reservoir for fully differentiated plasma cells.

Architecture: Cellular and Functional Niches

The microenvironment of the bone marrow, contained in the central cavity of bone, is a complex three-dimensional structure with cellular niches that influence B cells during their development and later, as plasma cells, as they return to the bone marrow. The bone marrow has a rich blood supply with a nutrient artery that branches into ascending and descending arteries, which further divide into cortical capillaries, periosteal capillaries, and endosteal capillaries and finally merge into a sinus (15). Previously, the prevailing understanding of B cell differentiation in the bone marrow was that primitive HSCs were located in close contact with the endosteum near osteoblasts (the "endosteal niche"). During the course of differentiation into mature B cells, they moved into the central region of the bone marrow cavity (the "vascular niche") (16). The former niche was identified as the location of HSC; the latter, as the site of B cell differentiation (17). Recently, this anatomic concept has been challenged, because it has been reported that HSCs are found throughout the bone marrow. It has become clear that growth factors and cytokines produced by different stromal cells influence cells at certain stages in their differentiation. Thus, it is more appropriate to consider functional or cellular, rather than anatomical, niches (15,18). Once the HSCs differentiate into immature B cells expressing cell surface IgM, they undergo processes of negative selection and receptor editing, leave the bone marrow, and travel through the blood stream to the secondary lymphoid organs where they complete their differentiation.

Several cytokines and chemokines influence B cell differentiation in the bone marrow. Flt-3 ligand (also called Flk-2L) signals B cell differentiation and growth and synergizes with several other hematopoietic growth factors (19). Its receptor, Flt-3 (also known as Flk-2), expressed by primitive HSCs, is a member of the class II tyrosine kinase family. In contrast to fetal liver, HSCs from adult bone marrow do not respond to Steel factor. Chemokines contribute to B cell differentiation in the bone marrow and define the functional niches. Many of these factors affect other lymphoid cells, such as dendritic and T cells. For an excellent review of this topic, see Nagasawa (15). Several of these factors, whose functions have been identified in gene deletion studies in mice, in morphologic analysis, and in cell culture studies, play roles in multiple aspects of lymphoid organ development; their activities, though important in the bone marrow, are not limited to that organ. CXCL12, also known as SDF1, or stromal cell-derived factor-1, is a chemokine that is crucial for recruitment of HSCs to the bone marrow. It is widely expressed by osteoblasts, reticular cells (18) and endothelial cells (20). In fact, the interaction of HSCs expressing CXCR4, the receptor for CXCL12, with that chemokine on the endothelial surface is the first step in its exit from the circulation into the marrow (21). CXCL12 is also essential for the earliest stage of B cell development (pre-pro B cells). Its receptor, CXCR4, is expressed on early B cells and is down-regulated in pre-B cells. It remains at low levels in immature B cells and mature B cells in secondary lymphoid organs but is up-regulated after B cells interact with antigen and differentiate into plasma cells (14). This explains the propensity of antibody secreting cells to return to the bone marrow. Once a pre-pro B cell has interacted with CXCL12, it moves on to a different cell expressing IL-7. In B cell development, IL-7 acts later than CXCL12 in a narrow window between pro-B cells and immature B cells in the scheme proposed by Nagasawa (15).

Traffic In and Out: Chemokines and Adhesion Molecules

The extensive vascularization of the bone marrow allows the entrance of hematopoietic precursors and plasma cells and the egress of mature cells. Hematopoietic progenitor recruitment to the bone marrow in the mouse has been shown to be dependent on the interaction of a variety of chemokines, integrins, and selectins and their receptors, counter-receptors, and ligand vascular cell adhesion molecules. These include $\alpha 4$ integrin (VLA4 or $\alpha 4\beta 1$) and VCAM-1 (22), P-selectin glycoprotein ligand-1 (PSGL-1) and E-selectin (23), and $\alpha 4\beta 7$ and mucosal addressin cell adhesion molecule (MAdCAM-1) (24). It has not been determined whether pre-B cells and precursor T cells in the bone marrow down-regulate one set of addressins and up-regulate another to enter into the secondary lymphoid

organs and thymus. A small subpopulation of newly formed B cells in the bone marrow that expresses L-selectin has been described (25), suggesting a mechanism for entrance into lymph nodes.

In addition to the acquisition of immunoglobulin expression that occurs in the bone marrow under the control of stromal cells (see Chapter 7), B cells express various chemokine receptors and adhesion molecules in the process of differentiation. In a study of human bone marrow B cells, it was determined that pro-B and pre-B cells migrate toward CXCL12 but not toward a wide range of other chemokines, including CCL19 and CCL21, though they do express low levels of CCR7, the receptor for CCL19 and CCL21. However, mature bone marrow B cells do respond to CCL 19 and CCL 21 (26), CXCL13 (indicating a functional CXCR5), and CCL20 (MIP 3α). But CCR6 expression and responsiveness to CCL20 was only seen in mouse B cells after they had migrated into the periphery during the process of maturation in the circulating B cell pool (27).

Thymus

Function

The thymus is defined as a primary lymphoid organ due to its inimitable role in T cell development. Indeed, a mutant known as the "nude" (*nu/nu*) mouse, which lacks a normal thymus, is completely devoid of mature T cells (28). Recently, an additional, previously unappreciated thymus-like organ has been described in the mouse (29). This so-called "cervical thymus" is organized similarly to the main thymus and is capable of supporting T cell development. Although some studies suggest that T cells can develop extrathymically in organs such as the gut epithelium (30), the thymus remains the main site for T cell maturation, education, and selection. T cell precursors represent more than 95% of total cells in the thymus and give rise to mature T cells. These cells are crucial components of the adaptive immune system in that they are highly specific in their ability to recognize a nearly infinite number of antigens owing to their diverse repertoire (28,31).

The T cell repertoire is shaped during development in the thymus by the processes of positive and negative selection. Negative selection insures that T cells, which are capable of recognizing the organism's self-antigens presented on major histocompatibility complex (MHC) class I or II with high affinity, are eliminated prior to their export to the periphery. This process results in the deletion of approximately 95% of T cell precursors in the thymus (32). In contrast, positive selection allows for T cells recognizing self-antigen with low to medium affinity to leave the thymus and protect the organism against invading pathogens.

Although negative selection is highly efficient in eliminating the majority of self-reactive T cells, some cells do escape the thymus and exit to the periphery. These so-called "autoreactive cells" impose a serious threat to various organs, as their activation may result in the development of autoimmune diseases. The immune system has evolved several ways to prevent the activation of autoreactive T cells in the periphery. One mechanism that protects against autoimmunity is the generation of a T cell population capable of suppressing activation of self-reactive T cells. These thymus-derived protective T cells, known as regulatory or suppressive T cells, recognize self-antigens with relatively high affinity.

Thymic Architecture

The thymus in the mouse consists of two symmetric lobes located above the heart, while in humans the thymus is multilobed. Each lobe can be divided into three distinct regions: capsule, cortex, and medulla. The latter two regions harbor thymocytes at various maturation stages. Although maturing T cells constitute the majority of cells in the thymus, other cell types such as macrophages, dendritic cells, B cells, and epithelial cells are also present (33). Histological analysis of the thymus reveals a clear distinction between the thymic cortex and medulla, which are separated by a cortico-medullary border. The thymic cortex appears darker and more densely populated with T cell precursors, whereas the medulla appears considerably lighter and contains smaller numbers of T cells relative to other cell types (Figure 2.1, top panel). Blood vessels and small blood capillaries are found throughout the thymus. The fact that T cell progenitors are found in the more highly vascularized cortico-medullary border suggests that blood vessels in this region facilitate the entry of T cell progenitors into the thymic parenchyma (34). In the thymic medulla, the close association between medullary thymic epithelial cells and thymic blood vessels (35) suggests that these vessels may act as organizers of the medullary thymic compartment. Lymphatic vessel distribution coincides with that of blood vessels and capillaries (36). The majority of lymphatic vessels are located in the thymic medulla, though some can also be found in the cortex. The role of lymphatic vessels in thymic function remain unclear, although it has been proposed that these vessels may deliver extrathymic antigens into the thymus or export mature T cells from the thymus into the circulation.

Cellular Composition and Functions

T cell precursors at various stages of differentiation represent the majority of cells in the thymus. The education and selection of T cells in the thymus is mediated by antigen-presenting cells (APCs) of either hematopoietic or stromal origin. The different stages in T cell selection and maturation that take place in distinct regions of the thymus (Figure 2.1, bottom panel) are discussed at length
FIGURE 2.1 **Top panel:** Thymic structure. Low-power magnification of a Haematoxylin-stained frozen section of a mouse thymus. The cortex is well populated with lymphocytes; the medulla is less tightly packed and thus stains less intensely. **Bottom panel:** Thymic cellular populations. Diagram of a mouse thymus. Precursor T cells enter through blood vessels at the cortico-medullary junction. They progress to the medulla, where they undergo differentiation from double negative (DN) to double positive (DP) cells expressing T cell receptors. Thymic stromal cells provide growth factors. DP cells undergo positive selection, under the influence of cortical thymic epithelial cells (cTEC). Single positive (SP) CD4 or CD8 cells migrate into the medulla where they undergo negative selection, mainly through AIRE expressing mTECs and DCs. SP cells, having undergone differentiation, exit through blood vessels (not shown) to the periphery.

in Chapter 12. Briefly, lymphoid progenitors enter the thymus at the cortico-medullary border (34). Following their entry, these cells, identified as double negative (DN) T cells due to a lack of expression of the cell surface molecules CD4 and CD8, undergo four maturation steps termed DN1–DN4, which are distinguished by the expression of

two additional cell surface molecules: CD25 and CD44 (37,38). DN3 cells migrate to the subcapsular zone while rearranging their T cell receptor (TCR) β chain and expressing it in combination with a surrogate α chain. Those cells that have successfully rearranged the genes for α and β chains of the TCR become double positive (DP) cells and express both CD4 and CD8 surface markers. In the cortex, DP cells undergo negative and positive selection (39,40). Positively selected DP cells further differentiate into single positive (SP) cells expressing either CD4 or CD8. Following their differentiation, SP cells relocate to the medulla, where they mature and undergo further rounds of deletion. SP cells that do survive are then exported out of the thymus (41). DN precursors can give rise to an additional T cell population expressing the $\gamma\delta$TCR. These T cells are distinct from TCR$\alpha\beta$ T cells in their tissue distribution and recognition of antigens. TCR$\alpha\beta$ DP cells control the development of TCR$\gamma\delta$ cells via the production of the cytokine, lymphotoxin β (LTβ) (42).

The thymic parenchyma consists of a complex three-dimensional structure supported by thymic epithelial cells (TECs). TECs in the thymic cortex and thymic medulla are phenotypically and functionally distinct and support different stages of T cell maturation. Several cell surface markers are used to distinguish medullary TECs (mTECs) from cortical TECs (cTECs) in the mouse. Among these markers are the cytokeratins K5 and K8, the adhesion molecule Ep-CAM, and the glycoprotein Ly-51. K8 and Ly-51 are expressed by cTECs, while K5 and Ep-CAM are expressed by mTECs (43,44). TECs are unique in that they express MHC II constitutively similarly to professional APCs. The role of TECs in T cell selection was recently elucidated by their expression of the transcription factor, autoimmune regulator (AIRE). This transcription factor plays an important role in T cell selection and prevention of autoimmunity as illustrated by the fact that humans with a mutated form of the AIRE gene exhibit polyendocrine autoimmunity due to inadequate T cell selection (45). It has become clear that AIRE controls the expression of certain tissue-specific antigens in the thymus, such as insulin, a protein that is unique to the β cells of the islets of Langerhans in the pancreas (44,46). The expression of tissue-specific antigens in the thymus facilitates the negative selection of maturing T cells, which would otherwise be allowed to leave the thymus. The thymic medulla includes distinct structures also known as Hassall's corpuscles. Originally described by Arthur Hill Hassall in 1849, this structure consists of concentric stratified keratinizing epithelium. Hassall's corpuscles are implicated in several processes of the thymus (47), including the expression of tissue-specific antigens, such as insulin (48), and serve as a prominent site for T cell apoptosis (49).

Dendritic cells (DCs) are professional antigen-presenting cells that are found in the thymus. Thymic DCs can be divided into two distinct populations. The first

originates from a thymocyte precursor (50,51), whereas the second is derived from partially mature peripheral DCs that continuously enter the thymus from the circulation (52). DCs do not appear to be involved in positive selection but do contribute to negative selection (53–56). They have been recently implicated in the selection of regulatory T cells in humans (57). Activation of thymic DC can be mediated in part by the IL-7-like cytokine, known as thymic stromal lymphopoietin (TSLP). In the human thymus, TSLP is preferentially produced by Hassall's corpuscles, and TSLP-activated DCs can alter the fate of self-reactive T cell from deletion to positive selection of regulatory T cells (58). These findings highlight the heterogeneity of DCs and emphasize their ability to fulfill different roles during T cell development in the thymus.

Macrophages and B cells are additional hematopoietic-derived professional APCs in the thymus. In contrast to DCs, thymic macrophages are located throughout the thymus and do not play a significant role in T cell selection (59). B cells are detected in human and mouse thymus at relatively low numbers (60,61) and are characterized by the expression of the cell surface molecule CD5. They are capable of producing antibodies of several different isotypes (62). It has been suggested that thymic B cells induce negative selection in developing thymocytes (60), as B cell–deficient mice show a limited T cell repertoire when compared with normal mice (63).

Traffic In and Out: Adhesion Molecules and Chemokines

The extravasation of leukocytes from blood and lymphatic vessels into the thymus is mediated by adhesion molecules. These molecules also play an important role in facilitating lymphocyte homing into various regions of the thymus. Indeed, thymic blood vessels express the adhesion molecules ICAM-1, VCAM-1, CD34, peripheral node addressin (PNAd), and vascular adhesion protein-1 (VAP-1) (64). The expression of high levels of ICAM-1, VCAM-1, and VAP-1 on venules near the cortico-medullary border suggests that these molecules may play a role in the recruitment of thymocyte progenitors. More specifically, VAP-1, which is restricted to the venules surrounding the sites of progenitor homing, can mediate the extravasation of leukocytes. The regional distribution of these adhesion molecules further illustrates the importance of a distinct anatomical separation between cortex and medulla and represents their individual functions.

Chemokine-mediated T cell migration and traffic to and within the thymus is crucial for normal T cell selection. The compartmentalization of the thymus is orchestrated by a milieu of chemokines. The thymic cortex is involved in the maturation of DN cells to DP cells and in positive and negative selection of DP T cells, while the medulla acts as the site of negative selection and possibly positive selec-

tion of SP T cells and regulatory T cells, respectively. Various chemokines that are produced by the thymic cortex and medulla allow T cells expressing different chemokine receptors to home to specific regions of the thymus. This differential expression of chemokines is complemented by the fact that T cells at different maturation states express certain chemokine receptors. During development, the entry of the lymphoid progenitor into the thymus is highly dependent on CCL21 and CCL25, which bind the chemokine receptors CCR7 and CCR9, respectively. Mice lacking CCR7 or CCL21 (65,66) show a transient delay in thymus colonization by lymphocytes (day 14.5), and this delay is further extended (day 17.5) in mice lacking CCR9 (67). Lymphoid progenitors enter the thymus at the cortico-medullary border and commence their migration outward toward the subcapsular region of the cortex as DN3 cells. The expression of the chemokine receptors CXCR4 and CCR7 by DN cells is important in directing cell migration (68,69). In the subcapsular region, DN thymocytes that have successfully rearranged their TCR$\alpha\beta$ chains progress to the DP cell stage. Positively selected DP cells move inward toward the thymic medulla for further differentiation into SP cells. The ligands for CCR7 are crucial in mediating the migration of positively selected DP cells into the medulla, as illustrated by the fact that a deficiency in CCR7 or its ligands, CCL19 or CCL21, prevents DP cell relocation from the cortex to the medulla and results in abnormal central tolerance (70,71). The export of positively selected SP T cells out of the thymus is also dependent on chemokines. Chemokines involved in T cell emigration are CXCL12 and its receptor CXCR4, which repels SP cells out of the thymus (72), and CCL19, which promotes T cell emigration from the thymus of newborn mice (73). The chemoattractant, sphingosine 1-phosphate (S1P), is a additional mediator of T cell emigration. SP T cell express the S1P receptor (S1P$_1$) and are attracted to the high levels of S1P present in the serum promoting their egress (74,75).

While the role of different thymic compartments and chemokines in the maturation of naïve SP T cell has been extensively studied, the thymic regions and chemokines that control the selection of regulatory T cells remain largely unknown. Some studies suggest that cTECs are sufficient for mediating regulatory T cell development (76), while others implicate DCs as key APCs in regulatory T cell selection in the thymic medulla (57,77). It may be that chemokines produced by both cTECs and thymic DCs play a role in regulatory T cell selection, albeit during different stages of maturation.

Development

The initial development of the thymus at midgestation in the mouse is independent of vascularization or bone marrow–derived cells. In the mouse, the thymus rudiment is first evident on day 11 of gestation as it evolves from

the endoderm of the third pharyngeal pouch (78). This gives rise to the thymic lobes as well as to the parathyroid gland. On day 12.5 of gestation, a separation of the primordium is observed, and by day 13.5 a distinct thymus is apparent. Evidence has suggested that not only the pharyngeal pouch endoderm, but also the ectoderm may also be involved in thymic development (79,80). More specifically, it was suggested that the pharyngeal pouch ectoderm contributes to the development cTECs, whereas the endoderm contributes solely to the development mTECs. This "dual origin" model was mainly supported by histological data, as well as data collected from thymi of *nu/nu* mice (81–83). Recently, it was shown that both thymic cortex and medulla are derived solely from the pharyngeal pouch endoderm (84) and that, although the endoderm and ectoderm are found in close proximity between gestational day 10.5 and 11, only the endoderm actively contributes to thymic development (85). These findings support the so-called "single origin" model of thymus development.

The contribution of lymphocytes to the normal development of thymic cortex and medulla is well recognized. In models of T cell deficiency, cTEC and mTEC development is halted at different stages depending on the stage of T cell arrest. If T cell development is arrested at the DN stage, as in the recombinase-activating gene (RAG)–deficient mouse, the thymic medulla is greatly reduced while the thymic cortex remains unaffected (86,87). A more severe phenotype is observed in transgenic mice that overexpress the human CD3-signaling molecule. In these mice, T cell arrest occurs earlier than in RAG-knockout mice, leading to a loss of both cortex and medulla and to a shift from a three- to a two-dimensional structure of the thymic epithelia (87).

Recently, two cytokines, LT α (also called tumor necrosis factor β) and LT β, have been identified as master regulators of mTEC development and expression of tissue-specific antigens. LT α and β are members of the tumor necrosis factor (TNF) superfamily and mediate the processes of secondary lymphoid organ development and inflammation (1,88). In the absence of LT, tissue-specific antigen and AIRE expression are reduced and certain mTEC subpopulations fail to develop (89,90). T cells appear to be the main source for LT production in the thymus (42), further highlighting the importance of lymphocytes in its development.

The development of the thymus in humans closely follows the model of thymic development in the mouse and bird. Similar to the mouse, thymic colonization by hematopoietic stem cells occurs relatively early, at week 8.2 of gestation. During this stage, the thymic medulla and cortex are organized, suggesting that thymocytes are required for normal thymic development. Between gestation week 9.5 and 10, the first signs of thymocyte negative selection are evident and by gestation week 10 to 12.75 the gradual onset of positive selection is detected (91).

SECONDARY LYMPHOID ORGANS AND TISSUES

Naïve cells express their receptors for specific antigens, leave primary lymphoid organs, circulate through the blood stream, migrate into the tissues, and lodge in secondary lymphoid organs. The frequency of naïve cells specific for an individual antigen is quite low (estimates range from 1 in 10^5 to 1 in 10^7). Thus, the chance that an individual T or B cell will encounter its specific antigen in the circulation is rather low. Secondary lymphoid organs are strategically located in anatomically distinct sites where foreign antigen and antigen-presenting cells efficiently concentrate and activate rare antigen-specific lymphocytes, thus leading to the initiation of adaptive immune responses and generation of long-lived protective immunity. These organs include highly organized, encapsulated, and compartmentalized tissues, such as lymph nodes, spleen, appendix, tonsils, murine NALT, and Peyers patches. Naïve cells are also primed in less discrete tissues throughout the body, including the BALT, cryptopatches, and ILF.

Lymph Nodes

Lymph nodes are yellowish, bean-shaped structures dispersed along lymphatic vessels. The lymphatic vessel system plays important roles in tissue-fluid balance, fat transport in the intestine, and the immune response. In contradistinction to blood vessels, which form a closed recirculating system, lymphatic vessels comprise a blind-end, unidirectional transportation system. The absorbing lymphatic vessels, or lymphatic capillaries, remove interstitial fluid and macromolecules from extracellular spaces and transport the collected lymph through the primary collector. The collected lymph and its cellular contents are transported into the thoracic duct and returned back to the blood circulation. In humans, lymph collected from the entire lower body region, the left head, and arm region accumulates in the thoracic duct and returns to blood circulation via the left subclavian vein; lymph collected from right head and arm region returns to blood via the right subclavian vein.

Lymph nodes, usually embedded in fat, are located at vascular junctions and are served by lymphatic vessels. Although most lymph nodes are classified as peripheral lymph nodes, a few (cervical, mesenteric, and sacral), termed mucosal nodes, express a slightly different complement of endothelial adhesion molecules, cooperate with the mucosal system, and are regulated somewhat differently in development (discussed later). Although all lymph nodes are vascularized and thus can receive antigens from the blood stream, they are also served by a rich lymphatic vessel system and are thus particularly effective in mounting responses to antigens that are present in tissues. These

antigens may be derived from foreign invaders that are transported by antigen-presenting cells or can be derived from self-antigens. Thus, lymph nodes extend the role of the primary lymphoid organs and discriminate between dangerous foreign antigens and benign self-antigens. This capacity relies on the antigen-presenting cells and their state of activation in the lymph node and the recognition capacity of the naïve T and B cells.

Lymph nodes can also function as niches for generating peripheral tolerance, an additional mechanism to minimize the effects of those self-reactive T-cells that escape central tolerance in the thymus (92). DCs constitutively sample self-antigens and migrate to draining lymph nodes even in the steady state (93–95). Because most self-antigen–bearing DCs in lymph nodes are immature (96) and have low levels of costimulatory molecules, they are not effective at activating naïve cells. They regulate self-reactive T cells by inducing anergy, clonal deletion, and expanding regulatory T cells (95–99).

Structure and Organization

The highly compartmentalized lymph node is surrounded by a capsule derived from lymphatic vessels (Figure 2.2, top and bottom panels). The cortical region includes discrete clusters called primary follicles consisting of densely packed naïve B cells and follicular dendritic cells (FDCs). After B cells encounter their cognate antigen, they are activated and proliferate, and secondary follicles and germinal centers develop. T cells and DCs distribute in the paracortex. Macrophages reside in the subcortical zone and in the medullary area. Plasma cells are also concentrated in the medulla as they prepare to leave the lymph node and circulate to the bone marrow. FDCs, a population of mesenchymal origin, support B cell follicles or germinal centers under stimulation (1). In addition, a network composed of reticular fibers, fibrous extracellular matrix bundles, and fibroblastic reticular cells, support the entire lymph node (100). Compartmentalization of cells in the lymph node is orchestrated by lymphoid chemokines CCL19, CCL21, and CXCL13. CCL19 is made by stromal cells in the paracortical region and the protein is transported to the surface of high endothelial venules (HEVs) (101). CCL21 is encoded by several genes (102); CCL21-leu is expressed by lymphatic vessels outside the lymph node (103); CCL21-ser is made by stromal cells and HEVs in the lymph node. CCL19 and CCL21 recruit CCR7 expressing cells across the HEVs and direct T cells and dendritic cells to the paracortical region. CXCL13, produced by stromal cells in the B cell follicles, attracts CXCR5-expressing B cells (104). After naïve T and B cells encounter antigens, they undergo extensive changes in expression of chemokine receptors and adhesion molecules that result in their movement to different areas of the lymph node or leaving it all together (105,106). Sphingosine-1-phosphate receptor 1 ($S1P_1$) fa-

cilitates lymphocyte egress from lymph nodes as they move towards the ligand, S1P in the lymph (107,108).

Lymph Node Vasculature

Recirculating lymphocytes leave the bloodstream via HEVs, specialized vessels with a high cuboidal endothelium, and migrate into the lymph node parenchyma. After surveying antigens in the lymph nodes, lymphocytes leave those organs via efferent lymphatic vessels and finally return to blood circulation. Afferent lymphatic vessels allow entrance of soluble antigen and antigen-presenting cells into lymph nodes, and efferent lymphatic vessels return lymphocytes back to the blood (109–111). In this manner, HEVs and lymphatic vessels maintain lymph node lymphocyte homeostasis during the steady state.

Blood Vessels

Blood endothelial cells play a crucial role in lymphocyte trafficking in the lymph node. One or two arteries enter the lymph node at the hilus. These arteries branch and pass through the medulla area, enter the cortex, and sometimes continue in the subcapsular area. Beneath the subcapsular sinus, the branching capillaries form loops and some of them become arteriovenous communications (AVCs). AVCs become HEVs in the cortex area and occasionally extend from the subcapsular sinus to the medulla. HEVs constitute a specialized postcapillary network in the lymph node, playing a critical role in lymphocyte recirculation. Each main HEV trunk receives three to five branches lined with high endothelial cells and two or three branches lined with flat endothelial cells. The luminal diameters of HEVs progressively increase from cortex to medulla. Finally, HEVs merge into segmental veins in the medulla area and join larger veins in the hilus (109) (Figure 2.2, top panel). Intravital microscopy has revealed that the entire venular tree consists of five branching orders, with the higher orders in the paracortex and the lower orders in the medulla and hilus areas. Only the higher-order venules, located in the T cell area, are specialized into HEV and are recognized by the monoclonal antibody MECA-79 (110,111). Approximately one in four lymphocytes enters the lymph node via HEVs (112), whereas other capillaries and arterioles are normally nonadhesive. Peripheral node addressin (PNAd), defined by the MECA-79 antigen, is also known as an L-selectin ligand and is a characteristic HEV adhesion molecule. PNAd is composed of a variety of core glycoproteins, including GlyCAM-1, CD34, Sgp200, and podocalyxin; these proteins must be sialylated, sulfated, and fucosylated to become the functional L-selectin ligand (i.e., PNAd). These posttranslational modification events involve several enzymes, including FucT-IV, FucT-VII, and HEC-6ST. HEC-6ST (also called LSST, GST-3, HEC-GlcNAc6ST, GlcNAC6ST-2, gene name
FIGURE 2.2 **Top panel:** Lymph node structure and functional regions. The lymph node is divided into an outer cortex and inner medulla surrounded by a capsule and lymphatic sinus. The cortex includes B cells and follicular dendritic cells. The paracortical region includes T cells and dendritic cells. Macrophages are found in the subcapsular sinus and medullary cord. Lymphocytes enter into the lymph node through an artery at the hilus region, and into the parenchyma through high endothelial venules (HEV) expressing PNAd and CCL19 and CCL21. These chemokines are also made by stromal cells. T cells and DCs are directed to the paracortical region by CCL19 and CCL21. B cells are directed to the cortex by CXCL13. After interaction with antigen and T cells, germinal centers develop. Antigen and DCs drain into the lymph node from the tissues through afferent lymphatic vessels. Antigen continues to percolate through the node via a conduit system. Activated cells leave through efferent lymphatic vessels. Diagram of the blood network of a rat lymph node (right) is adapted from Anderson et al. (109). Note the arteriovenous communications (AVC), the venous sphincters (VS), and cells leaving the HEVs into the parenchyma. **Bottom panel:** Lymph node compartmentalization. Immunofluorescent staining of B cells (anti-B220, green) in follicles in the cortex and T cells (anti-CD3, red) in the paracortical area. The medulla is unstained.

Chst4) (113–117), which is uniquely expressed in high endothelial cells, sulfates glycoproteins in the Golgi apparatus (118) to generate the MECA-79 epitope. PNAd, expressed on the endothelial surface, slows down (tethers) naïve L-selectin[hi] lymphocytes in their progress through the blood vessels. After this initial interaction, CCL19 and CCL21 on the HEVs are instrumental in activating the lymphocyte integrin LFA-1. This results in tight binding of LFA-1 to ICAM-1 on the HEV, facilitating diapedesis of lymphocytes for transendothelial migration toward the chemokines located in the paracortical region (T cells, DCs) or cortex (B cells). Interestingly, the HEV-lymphocyte interaction is not random in different lymphoid tissues in the mouse (119,120). T lymphocytes adhere preferentially to peripheral lymph node HEVs, B cells prefer to adhere to HEVs in Peyers patches, and T and B cells exhibit an intermediate pattern of adhesion to mesenteric lymph node HEVs (32,119,121). The selective adhesion of naïve lymphocytes to HEVs is at least partially controlled by the differentially expressed adhesion molecules in different lymphoid organs. MAdCAM-1, the ligand for the integrin $\alpha_4\beta_7$, is expressed on HEVs of mesenteric lymph nodes and Peyers patches in adult mice; it is only apparent in early development on HEVs of peripheral lymph nodes and is thus a marker of immature HEVs in those nodes. MAdCAM-1 is rapidly replaced after birth by PNAd in mouse peripheral lymph nodes (122).

Lymphatic Vessels

Lymphatic vessels also play critical roles in the immune response. The collected lymph and cell contents enter the lymph node via several afferent lymphatic vessels and filter through the node. In this manner, soluble antigen and antigen-bearing antigen-presenting cells from peripheral tissues are efficiently concentrated in the draining lymph node and initiate an adaptive immune response. Lymphatic vessels are observed in the draining lymph node and concentrate in the subcapsular sinus and medullary area (109). Factors from afferent lymph can be either transported deep into the lymph node cortex or move via the subcapsular sinus and leave the lymph node through efferent lymphatic vessels (100). Several markers of human and murine lymphatic vessels including lymphatic vessel endothelial hyaluronan receptor (LYVE-1), Prox-1, podoplanin, the vascular endothelial growth factor receptor-3 (VEGFR-3), and CCL21 have recently been described (123).

Conduit System

A conduit system in the lymph nodes physically connects the lymphatic sinus with the walls of blood vessels and enables the incoming factor(s) from lymph to move rapidly deep into the paracortical area (100,109). The conduit system consists of four layers: (a) a core of type I and type III collagen bundles; (b) a microfibrillar zone composed largely of fibrillins; (c) a basement membrane abundant with laminins 8 and 10, perlecan, and type IV collagen that provides a supportive structure; and (d) fibroblastic reticular cells that embrace the entire conduit system (124,125). This conduit system enables incoming lymph to penetrate deep into the T cell area. In fact, soon after immunization, resident DCs quickly pinocytose and process soluble antigens draining into the regional lymph node (126). A special subset of immature DCs, called conduit associated DCs, can take up and process antigens moving along the conduit (125). In this manner, the conduit system probably provides a physical support for rapid initiation of adaptive immune responses after immunization.

The Intimate Relationship Between Lymph and HEVs

Incoming lymph is necessary for the maintenance of HEV phenotype and function. After afferent lymphatic vessels are severed, dramatic changes occur in HEVs. These include flattening of the endothelium, a decrease in the uptake of ^{35}S-sulphate (a functional marker of HEC-6ST) (127,128), a reduction of lymphocyte adherence to the vessels (129–131), and decreased expression of PNAd and HEV genes, *GlyCAM-1* and *Fuc-TVII* (130–132). However, an increase in MAdCAM-1 expression (130) suggests that these events are not simply due to a general down regulation of blood vessel gene expression, and indicates that continual accumulation of afferent lymph factor(s) in lymph nodes is necessary for HEV maintenance. The nature of such lymph factor(s) is unknown.

Topographic relations between HEVs and the lymphatic sinus have been described in the rat mesenteric lymph nodes. Some HEVs are located in the medulla area and positioned closely with the lymphatic sinus (109). Occasionally, HEVs are separated from an adjacent lymphatic sinus by only a thin layer of collagen bundles. The closely apposed HEV and lymphatic sinus in medulla provide the physical support for the intimate relationship between lymph and HEV. However, most HEVs are located in the paracortex area and are separated from lymphatic sinus by lymphocytes. The conduit system physically connects the subcapsular sinus and HEVs and allows incoming lymph factor(s) to migrate rapidly to the wall of HEVs (109,133,134). Low molecular weight fluorescent tracers (below 70kD) move rapidly via the conduit system and lead directly to the wall of HEVs. In this manner, low molecular weight tracers can migrate with lymph within minutes to HEVs and enter the HEV lumen (100). Lymph-borne chemokines likely adopt this route to regulate HEV function. IL-8 administration via afferent lymph increases lymphocyte HEV transmigration within minutes (109,135). In addition, lymph-borne chemokine MIP-1α also enters the

conduit system and moves rapidly to HEVs (100). These data suggest that lymph factor(s) can quickly access and regulate HEVs.

Development

Despite their distinctions in the adult with regard to morphology and expressed genes, a close association of blood vessels and lymphatic vessels is seen during embryogenesis. The generation of embryonic lymphatic vessels from preexisting veins in pig embryos was first described in the early 1900s and has recently been molecularly defined (136–138). As early as mouse E9.5-10, upon the formation of vascular system, LYVE-1 is expressed in venous endothelial cells. In response to an unknown lymphatic vessel induction signal, these endothelial cells then polarize to become lymphatic-biased endothelial cells. At nearly the same time, PROX-1, expressed in a restricted subpopulation of endothelial cells in the cardinal vein, generates a feedback signal for the further maintenance of budding and migration of endothelial cells. At E11.5-12.0, CCL21 is expressed in these lymphatic-biased endothelial cells, as is VEGFR-3, which is reduced in blood endothelial cells. The endothelial cells expressing LYVE-1, PROX-1, VEGFR-3, and CCL21 become irreversibly committed towards a lymphatic pathway (139,140). The further separation of lymphatic endothelial cells from venous endothelium requires a Syk/SLP-76 signal (141). Thus, for a long period during early lymphangiogenesis, some endothelial cells express both blood vessel and lymphatic vessel markers, indicating the close association of these two vascular systems. Mesenchymal lymphangioblasts may also contribute to early lymphangiogenesis (142). Whether embryonic lymphatic vessels originate by budding from preexisting veins or from mesenchymal lymphangioblasts, a close association of lymphatic and venous endothelial cells is seen in the lymphatic and venous junction formation during early embryogenesis. The lymphatic venous junction remains in adults and plays an essential role in connecting the function of the two vascular systems.

Histologic studies in the rat reveal that popliteal and inguinal lymph node anlagen originally appear in a limited mesenchymal area along the vein wall at E17. The next day, lymphatic vessels form a sac running parallel to the vein. The lymph node anlage develops into a bulb-shaped structure with lymphatic vessels and the subcapsular sinus originating from the remaining lymphatic vessel. At the next stage, the lymph node divides into a primitive cortex, the basic network of reticular cells and medulla, and lymphocytes scatter in the lymph node anlage. Blood vessels branch into the lymph node and later develop into HEVs (143). The primary follicles appear at day 18 after birth, indicating that B cell migration into lymph nodes is a later event during lymphoid organogenesis. Later studies show that first lymphocytes invading the lymph node during lymphoid organogenesis are T cells; B cells become detectable only in the later stages (144–146).

Cytokines, Chemokines, and Transcription Factors in Lymphoid Organogenesis

The important roles of tumor necrosis factor/lymphotoxin-receptor (TNF/LT) family members in lymphoid organ development are well established. $LT\alpha3$, signaling through TNFRI and TNFRII, and membrane-bound $LT\alpha_1\beta_2$, signaling through $LT\beta$ receptor ($LT\beta R$), have been implicated. Mice deficient in $LT\alpha$ lack all lymph nodes and Peyers patches and exhibit a disorganized spleen and severely disorganized NALT (discussed later) (147–149). Mice deficient in $LT\beta$ lack peripheral lymph nodes but retain mesenteric, sacral, and cervical lymph nodes (150–152). $Lt\beta r^{-/-}$ mice have a phenotype similar to that of $lt\alpha^{-/-}$ mice (153). $LT\beta R$ is also recognized by $LT\beta$-related ligand, LIGHT, which also binds to the herpes virus entry mediator (HVEM). LIGHT-$LT\beta R$ signaling does not appear to play an essential role during lymphoid organogenesis, because no significant defect is observed in $LIGHT^{-/-}$ mice (154); however, mice doubly deficient in LIGHT and $LT\beta$ have fewer mesenteric lymph nodes than mice deficient in $LT\beta$ alone, indicating a cooperative effect of the two $LT\beta R$ ligands. Treatment of pregnant females with an inhibitory soluble protein of $LT\beta R$ ($LT\beta R$ and human IgG Fc fusion protein, $LT\beta R$-Ig) inhibits most lymph nodes in the developing embryos, depending on the time of administration. Mesenteric lymph nodes are not inhibited by this treatment. These studies indicate that individual lymph nodes differ in the nature and time of cytokine signaling during development (155). Several additional cytokine and chemokine-receptor pairs are crucial for lymphoid organogenesis. Mice deficient in IL-7 or IL-7R (156,157), TRANCE or TRANCER, also called RANKL and RANK (158,159), exhibit defects in lymph node development. CXCR5- or CXCL13-deficient mice (160,161) lack some lymph nodes and almost all Peyers patches (88).

The NF-κB signaling pathways, downstream of the TNF family, play important roles in lymphoid organ development (162). The alternative pathway, characterized by NF-κB-inducing kinase (NIK) and IKKα is particularly important. *aly/aly* mice, which have a point mutation in *nik*, lack all lymph nodes and Peyers patches (163,164). In these mice, $LT\beta R$, but not TNFR, mediated signaling between NIK and members the TRAF family appears to be disrupted (164–166). $LT\beta R$ signaling induces gene expression via both the classical and alternative NF-κB pathways in mouse embryo fibroblasts. The classical pathway mediated by p50:p65 heterodimers induces expression of proinflammatory genes (*VCAM-1, MIP1b, MIP2*). Intraperitoneal injection of an agonistic $LT\beta R$ antibody induces splenic chemokines (CCL19, CCL21, and CXCL13) and requires

NIK activity and subsequent p100 processing (167). IKKα is a critical component in alternative NF-κB pathway. Mice with a mutated form of the *ikkα* gene have reduced HEV expression of HEC-6ST and GlyCAM-1, further confirming that the LTβR signal regulates HEVs through the alternative NFκB pathway (168). Several other signaling pathways that contribute to lymphoid organogenesis include helix-loop-helix transcription factor inhibitor (Id2) and retinoic acid-related orphan receptors (RORs) RORγ and RORγt (169–171).

Studies of lymph node anlage formation reveal the mechanisms by which cytokines trigger and coordinate lymphoid organogenesis. The circulating CD4[+]CD3[−]CD45[+] hematopoietic progenitor cells called lymphoid tissue-inducer cells, which are derived from fetal liver progenitors (88,170,172–174), provide crucial signals for inducing lymph node organogenesis. These lymphoid tissue-inducer cells, which express the integrin $\alpha_4\beta_7$ and interact with VCAM-1 positive stromal organizer cells, accumulate in the developing lymph node, forming clusters with resident stromal organizer cells, to initiate a cascade of intracellular and intercellular events that lead to the maturation of the primordial lymph node (1,88). During this early step, a positive feedback loop involves several signaling pathways, including LT$\alpha\beta$/LTβR, IL-7R/IL-7, CXCR5/CXCL13, and TRANCER/TRANCE expressed on the lymphoid tissue-inducer cells and the stromal organizer cells. The prolonged interaction between lymphoid tissue-inducer cells and stromal organizer cells promotes the development of HEVs, which support the entry of naïve lymphocytes (175). It is unclear how HEVs differentiate from the flat blood vessels during early lymphoid organogenesis. At birth, HEVs of all lymph nodes express MAdCAM-1, which is replaced in the first few days in peripheral lymph nodes by PNAd (176). Both MAdCAM-1 and PNAd are expressed in mucosal lymph nodes. LTα alone can induce MAdCAM-1, but PNAd requires LT$\alpha\beta$ (2,177,178). In the remaining mesenteric lymph nodes of $lt\beta^{-/-}$ mice, PNAd expression is impaired (178), indicating that optimal lymph node HEV PNAd expression requires LT$\alpha_1\beta_2$ signaling through the LTβR and the alternative NFκB pathway (168). Since the maturation of HEVs is coincident with further development of the lymph node (122,143), the homing of LT-expressing lymphocytes most likely contributes to HEV maturation.

Changes in Lymph Nodes after Immunization

Studies in rabbit, sheep, and rodents have revealed that lymph nodes undergo dramatic changes and remodeling after immunization. Early after a variety of immunogenic exposures, such as skin painting with oxazolone, injection of ovalbumin or sheep red blood cells in adjuvant, or bacterial or viral infection, remodeling occurs. This remodeling is apparent as a complex kinetics of changes in lymph flow, lymph cell content, blood flow, HEV gene expression, and lymphatic vessels (Figure 2.3). Afferent lymph flow and lymph cell content increase soon after initial inflammation and eventually return to a normal level (179–183). Lymph node lymphangiogenesis occurs, which eventually resolves (184,185). Blood flow and lymphocyte migration into lymph nodes peak at 72–96 hours (152,182,186,187), accompanied by an increase in HEV number and dilation (188,189), accounting for the significant lymph node enlargement apparent at 72–96 hours (186). After skin grafting, the permeability of rat lymph node HEVs is increased at 24–48 hours, and more branches form on HEVs at day 4. However, only 38% of the new HEV branches are lined by high endothelial cells, and the percentage is increased to 96% on day 10, indicating that the HEV matures progressively in the draining LN after antigen exposure (109). Efferent lymph flow also increases soon after immunization, but lymph cell content in the efferent lymph drops during the first several hours, indicating the first wave of accumulation of lymphocytes in the draining lymph node. The cell content of the efferent lymph later increases and peaks at 72–96 hours (190). These events, taken together, contribute to the significant enlargement of the draining LN at day 4 after immunization. During the early times after immunization, despite the increase in the number of HEVs, the expression of genes that contribute to L-selectin ligand, including FucT-VII, GlyCAM-1 and Sgp200, and HEC-6ST is initially down-regulated followed by a recovery (132,185,191). However, despite the down-regulation of chemokines CCL21 and CXCL12, some genes such as those encoding CXCL9, CCL3, and E-selectin are up-regulated (192), as is MAdCAM-1 (185), suggesting a reversion to an immature phenotype before the eventual recovery of the mature phenotype.

In rodents, HEV maturation is coincident with the continuing development of the lymph node and population of lymphocytes after birth, indicating that the mature HEV phenotype relies on the lymph node microenvironment (122,143). Plasticity of the mature lymph node is also seen after injection of LTβR-Ig. LTβR-Ig treatment reduces lymph node cellularity, reverts the HEV phenotype to the immature state, inhibits FDC function, and disrupts immune responses to foreign antigens (185,193,194). Thus, in addition to its critical role in lymphoid organogenesis, LTβR is essential in maintaining mature lymph node phenotype and function.

Spleen

Function

The spleen is a large reddish organ located beneath the diaphragm, close to the stomach and the pancreas. It is a crucial site for antigen clearance and presentation to T and B cells and is particularly important in responding to
FIGURE 2.3 Plasticity of lymph nodes after immunization. Initially the lymph node enlarges due to increased blood flow and lymphocyte proliferation. Blood vessels proliferate and HEVs express markers typical of an immature phenotype. During the recovery period, HEVs recover to a mature phenotype. Lymphangiogenesis is induced during the remodeling period.

bloodborne antigens. In addition to its role as a secondary lymphoid organ, the spleen filters blood and removes damaged platelets, aged erythrocytes, and apoptotic cells. An additional function, consequent to its destruction of effete erythrocytes, is its role in iron recycling. In some species, such as the horse, the spleen stores blood that is released after stress. The spleen is particularly important in defense against bloodborne pathogens and contributes most significantly to defense against bacterial infections (195).

Architecture and Cellular Composition

The structure of the spleen is maintained by a fibrous capsule and trabeculae of fibrous connective tissue (Figure 2.4). The general principles of splenic organization are similar across species, though specifics may differ (196–200). Upon gross observation after slicing, the spleen can be divided into two areas: red pulp and white pulp. These compartments are anatomically and functionally distinct. The red pulp, in its activities as a hematogenous organ, removes damaged cells and acts as a site for iron storage and turnover. The white pulp is an organized lymphoid structure. The spleen is highly vascularized. The splenic artery, located immediately below the capsule is the source

of cells and antigens. The artery branches into arterioles and cords in the red pulp where macrophages engulf antigen and remove it from the circulation. Blood then collects in venous sinuses that empty into the efferent splenic vein. Some blood reaches the marginal sinus and marginal zone (MZ), which demarcates the red and white pulp. Blood containing residual antigen then percolates through the MZ into the white pulp. The white pulp is surrounded by the MZ, a structure that differs somewhat between humans and rodents. The human MZ, which consists of inner and outer marginal zones, is surrounded by a perifollicular zone; the rodent MZ is a single structure and has no perifollicular zone. The MZ is an important transition between the innate and acquired immune systems, because it is the first region after the red pulp encountered by bloodborne antigens and is richly supplied with specialized phagocytic cells: the MZ macrophages and MZ metallophilic macrophages. The MZ macrophages express Toll-like receptors (TLRs) crucial for pattern recognition of bacteria and viruses and several other receptors that facilitate binding of pathogens. These include SIGNR1 and MARCO. SIGNR1, a C-type lectin in the mouse that is a homologue of human DC-SIGN (201), is also found in medullary and subcapsular macrophages in the lymph node. On splenic

FIGURE 2.4 Organization of the spleen white pulp. **Top panel:** Immunofluorescent staining of a white pulp unit in the mouse spleen. T cells (anti-CD4$^+$anti-CD8$^+$, red) are localized around the central arteriole. B cells (anti-IgM, green) are localized in follicles around the T cell area, surrounded by a layer of metalophillic macrophages (labeled with monoclonal antibody-MOMA-1) and a more peripheral layer of marginal zone macrophages (labeled with monoclonal antibody ERTR9, orange). The marginal zone (MZ) is located between the metalophillic macrophage and the MZ macrophage layers (not shown) (307). **Bottom panel:** Structure of the marginal sinus in a thick (100 micrometer) frozen section of mouse spleen with targeted insertion of the *LacZ* gene into the ephrin B2 locus. Eprhrin B2 is expressed at high levels in the central arteriole, in radial branches of the central arteriole, and in the marginal sinus. LacZ is visualized by staining with FITC-labeled anti-LacZ antibody. Note the transition from discrete arteriolar vessels to a network of flattened vessels at the transition to the marginal sinus plexus (C. Zindl, University of Alabama at Birmingham, Birmingham, AL). MZ macrophages, it appears to be crucial for the capture of a wide variety of pathogens, including yeast, bacteria, and viruses (202, 203). MARCO (macrophage-associated receptor with collaganeous structure), expressed constitutively on MZ macrophages (204), is a class-A scavenger pattern recognition receptor, which is a trimeric Type II protein. The TLR, SIGNR1, and MARCO receptors, which are all expressed on MZ macrophages, act synergistically to recognize, endocytose, and eliminate microorganisms (205). MZ metallophilic macrophages are located at the border of the MZ and differ from the MZ macrophages in that

they express the sialic acid-binding Ig-like lectin sialoadhesin (Siglec-1), which binds to oligosaccharide ligands present on many cells. The ability of siglecs to interact with lipopolysaccharide on meningococcal bacteria (206) suggests that the metallophilic macrophages may also serve as an early line of defense. Lymphocytes express CD43, a counter receptor for Siglec-1 (207), suggesting that the metallophilic macrophages may use this pair of molecules to facilitate movement of lymphocytes into the white pulp. The MZ also contains a specialized subset of B cells that differ phenotypically and functionally from follicular B

cells; they can be considered as a bridge between the innate and adaptive immune systems. They express higher levels of IgM and a somewhat limited B cell receptor repertoire compared to follicular B cells, and they express TLR9 and respond to CpG DNA (208). The organization of the remainder of the white pulp of the spleen is similar to that of the lymph node, compartmentalized into T and B cell areas. The white pulp consists of a central arteriole that is surrounded by T cells, also known as the periarteriolar lymphoid sheath (PALS), that are surrounded by B cells. As in the lymph node, T cells interact with DCs and B cells. B cells migrate to the follicles, where they interact with follicular DCs. At the T–B cell border, T cells interact with B cells. Germinal centers are the site of somatic hypermutation and Ig class switching. Plasma cells are found mainly in the red pulp.

Although the spleen does not have an afferent lymphatic system and initial antigen transport must occur through the blood vasculature, a conduit system has been described that allows antigens and chemokines to be transported through the white pulp in a manner similar to that described for the lymph node (209). This conduit differs with regard to the identity of the transported molecules by the fact that it contacts the blood, rather than the lymphatic system.

Traffic In and Out: Chemokines and Adhesion Molecules

Cell trafficking in the spleen is similar to that which occurs in the lymph node in some respects and differs from it in others. The lymphoid chemokines, CXCL13, CCL19, and CCL21 position cells in the splenic white pulp as they do in the lymph node. However, lymphoid chemokine production is limited to stromal cells, since the spleen has no HEVs. CXCL12 is expressed in the splenic red pulp (210). As B cells differentiate into plasma cells, they down-regulate CXCR5 and CCR7 and up-regulate CXCR4. As plasma cells, they migrate toward that chemokine, out of germinal centers and into the red pulp or return to the bone marrow.

The role of adhesion molecules with regard to lymphocyte traffic in the spleen is still unclear. Since the spleen lacks HEVs, the well-understood process by which lymphocytes leave the circulation and enter into the parenchyma of lymph nodes is not relevant, and there is no evidence for expression of PNAd (211). However, CD62L (L-selectin) is up-regulated in late transitional cells in the spleen, hinting at the possibility of an additional L-selectin ligand (212). Lymphocytes enter into the white pulp through the marginal sinus and MAdCAM-1 and ICAM-1 are expressed by cells lining that structure (213, 214). However, treatment with anti-MAdCAM-1 or anti-$\alpha 4\beta 7$ antibodies does not inhibit homing to the spleen, suggesting that this ligand-receptor pair is not required for lymphocyte entrance into the white pulp (213). Nolte et al.

reported that several molecules associated with homing to lymph nodes, including L-selectin, CD44, PSGL-1, and $\alpha 4$ integrins, are not required for entry into the white pulp (214). Early studies indicating that treatment with an antibody that blocks the α_L-integrin chain of LFA-1 inhibits homing by only 20%, and that lymphocytes deficient in LFA-1 enter the white pulp (214), suggested that LFA-1 is not absolutely essential for entry of all cells into the white pulp. However, both $\alpha 4\beta 1$ and LFA-1 integrins are necessary for B cell retention in the MZ (215), indicating a role for VCAM-1 and ICAM-1. This effect is most pronounced with regard to MZ B cells; follicular B cells express lower levels of the integrins, and their entry into the spleen is not affected by treatment with antibodies that inhibit $\alpha 4$ or α_L. However, an important role for integrins in lymphocyte entry into the white pulp was revealed by combined treatment with antibodies to VCAM-1 and LFA-1, suggesting that entry into the white pulp is, in fact, integrin dependent (216). Once lymphocytes have encountered antigen, they most likely undergo changes in chemokine receptors and adhesion molecules similar to those noted in the lymph nodes, leave the white pulp, and enter the red pulp (plasma cells) or the circulation. $S1P_1$ plays a role in the spleen, but it appears to contrast with that in the lymph node. S1P receptors 1 and 3 are expressed by MZ B cells and $S1P_1$ is required for B cell localization in the MZ (217); MZ B cells from $S1P_1$-deficient mice are not found in the MZ but are found in the follicles. Further, MZ B cells down-regulate $S1P_1$ after activation, allowing their entrance into the white pulp. In contrast to the well-defined route of egress of activated lymphocytes from the lymph node through the efferent lymphatic vessels, the exit route from the spleen is not understood. The observation of channels that bridge into the marginal zone (218) suggests one route of egress.

Development

Because the spleen has characteristics of both a hematopoietic organ and a secondary lymphoid organ, the genes that regulate its development include, in addition to LT, other genes concerned with patterning and hematopoiesis. Several genes that contribute to the development of the spleen are also crucial for normal development of other nonlymphoid organs. The first sign of splenic development in the mouse occurs at E10.5-11, as progenitor cells begin to condense within the dorsal mesogastrium, adjacent to the stomach and dorsal pancreas. The spleen and pancreas are so intimately associated that it is difficult to distinguish between them at these early stages. In fact, many genes that affect splenic development also contribute to pancreatic development. Several of these are homeobox genes and transcription factors that are expressed in the spleno-pancreatic mesenchyme at E10.5 (summarized in 195). The effects of just one of these genes, *Hox11* (now called *Tlx1*; 195), are on the spleen.

The others affect multiple organs. *Tlx1* was originally described as an oncogene in T cell childhood acute leukemias (10,14) involving the translocation breakpoint (219). *Tlx1*-deficient mice are asplenic (220), and the product of this gene is a cell survival factor (221). Several additional genes that are important for development of lymph nodes, NALT, and Peyers patches also contribute to splenic development. Mice deficient in members of the LT/TNF ligand receptor family and their downstream signaling molecules in the classical and alternative pathways exhibit defects in splenic development. However, none of these molecules is necessary for the early splenic anlagen, as mice deficient in any of the chemokines or cytokines retain a spleen. The defects are mainly observed as an absence of particular cell populations or disorganized white pulp. The changes in organization are due in part to a reduction or near absence of lymphoid chemokines (CXCL13, CCL19, CCL21) (222). Lymphoid chemokine mRNA expression is reduced in the spleens of mice deficient in TNFR1, TNF, LTα, or LTβ, though CXCL12 mRNA levels are normal. However, treatment with an agonistic LTβR antibody induces expression of the lymphoid chemokines and CXCL12, suggesting that signaling through both the classical and alternative NFκB pathways are responsible for organization of splenic white pulp. Several cell populations are absent in mice deficient in genes signaled by the LT/TNF pathways (200). Mice deficient in LTα exhibit a disorganized white pulp with loss of T and B cell compartmentalization, loss of MZ macrophages, metallophilic macrophages, MZ B cells, MAdCAM-1 sinus lining cells, and germinal centers. $Lt\beta^{-/-}$ mice exhibit similar characteristics except that the disorganization is somewhat less pronounced. $Tnf^{-/-}$ and $Tnfr1^{-/-}$ mice show defects in all the above, with the exception of MZ B cells. The cytokines necessary for maintenance of splenic architecture are produced by T cells, B cells, and CD4$^+$CD3$^-$ cells (223,224).

Plasticity after Virus Infection

Though much is known regarding changes in the lymph node after immunization, the spleen has not been studied as extensively in this regard. However, after infection with cytomegalovirus, white pulp T–B compartmentalization is disrupted (225). The spleens of *lta*-deficient mice exhibit a marked reduction in expression of CCL21-ser. This is even further reduced in cytomegalovirus infection, indicating that, in the adult, LT-independent pathways can contribute to maintenance of expression of lymphoid chemokines.

MUCOSAL-ASSOCIATED LYMPHOID TISSUES

Mucosal-associated lymphoid tissues (MALT), though in some cases less structurally defined than the other sec-ondary lymphoid tissues, quantitatively include the vast majority of lymphoid cells in the body. Because of their initial contact with the environment, they can be considered to be the body's gatekeepers. They are major producers of secreted IgA, allowing protection of epithelial surfaces. Further, the mucosal tissues play an important role in mounting defense against pathogens by generating cells that migrate to other sites. They are also responsible for inducing and maintaining tolerance to food antigens and commensal bacteria (226). The structure and organization of these tissues provide insight into their biological roles. Although the structure and location of some mucosal lymphoid tissues are predetermined, all are somewhat plastic and prone to induction and remodeling, because they are in intimate association with the external environment and under constant exposure to environmental antigens. The tonsils and adenoids in humans and the NALT in rodents have a capsule, a clear organization, and are in fixed locations. The Peyers patches are structurally defined and located in the intestine, but their number and location vary by species and antigen exposure. The BALT and ILF are located in fixed organs, the lung and the small intestine, but are even more plastic and subject to environmental influences.

Tonsils and Adenoids

The first defense against pathogens entering through the alimentary and respiratory portals is a group of lymphoid accumulations around the wall of the throat called Waldeyer's ring (227). Humans have one adenoid and several tonsils: two tubal, two palatine, and one lingual. These tissues have an extensive epithelial surface, which penetrates into the organ with a series of crypts. These provide additional surface area for the capture of pathogens. A specialized cell, called a mutifenestrated, microfold, or membranous (M) cell, is located in the epithelial surface of the tonsil, and, because of its high transcytotic capacity, transports antigens to the underlying lymphoid tissue. This tissue is compartmentalized and organized in a fashion similar to lymph nodes, with B cell follicles, FDCs, germinal centers, and interfollicular T cells and DCs (228). The tonsils contain a large complement of B cells, many of which are positive for IgA (227) and the polymeric IgA receptor, or secretory component (229), crucial for transport of that immunoglobulin across the epithelium. This secreted IgA provides an early form of defense against pathogens entering through the oral route. The cells in the tonsil are directed to their respective locations in that organ by chemokines similar to those in the lymph node, which include CCL19 and its receptor CCR7 (230). CCL25 and CCL28 and their receptors CCR9 and CCR10 are also detected in the tonsils (231). Tonsil HEVs express ICAM-1 (227) and, importantly, CD34, which, upon modification, is bound by the PNAd-defining MECA-79 antibody (211,

232). This allows entrance of L-selectin^hi naïve cells into the organ to interact with antigen. MAdCAM-1 is expressed weakly or not at all (233). Because the tonsils are frequently inflamed, they also express additional chemokines, cytokines, and adhesion molecules more typical of inflammatory sites, such as CCL19 (230), VCAM-1, and E- and P-selectin (151).

Nose-associated Lymphoid Tissue

The NALT, a pair of lymphoid organs above the soft palate in mice and rats, is considered analogous to human tonsils and adenoids due to its common embryonic origin from Waldeyer's ring (234). Its biologic importance lies not only in its immediate physical proximity to the external environment, but more important, its demonstrated crucial role with regard to generation of responses in the genitourinary track (235). After nasal immunization, IgA is detected in vaginal washes (149,236,237) and cytotoxic T cells are found in vaginal draining lymph nodes (238). The NALT drains into the cervical lymph node, and that node has been demonstrated to play a role in NALT activity and can even act as an inductive site in its absence (239). However, the NALT itself is clearly an inductive site for both humoral and cellular immune responses (240) and supports class switching to IgA (241). The NALT includes M cells and a large complement of B cells, surrounded by T cells. Lymphoid chemokines CCL19, CCL21, and CXCL13 define T and B cell areas in a manner similar to the lymph node. Both CCL19 and CXCL13 are made by stromal cells, whereas, in contrast to lymph nodes, CCL21 mRNA is detectable only in HEVs (149). NALT HEVs express high levels of luminal and abluminal PNAd and HEC-6ST (149). The major homing receptor-ligand pair to this organ involves L-selectin-PNAd interaction, rather than MAdCAM-1 (242).

Development

The NALT in the mouse and rat is hypocellular at birth and undergoes dramatic changes at the age of weaning. These changes include expression of LTα and LTβ and lymphoid chemokines, T and B cell compartmentalization, and HEV maturation (149). In fact, the fully developed NALT is not apparent until 6 weeks after birth. Although Id2 is required for initiation of the NALT (243), in contrast to lymph nodes, RORγT, LTα, and LTβ are not required for its initiation (148). However, the organ is hypocellular in mice deficient in the LTα, LTβ, IL7R, and NIK signaling pathways (149,168,244). CXCL13, CCL19, and CCL21 are also not required for initiation of the NALT structure; even in the absence of these chemokines, at 10 days of age, a small number of CD4$^+$CD3$^-$ cells are apparent. Nevertheless, chemokines and LT are required for NALT organization and function (148,149,245), and the alternative NFκB pathway is required for T and B cell compartmentalization, expression of chemokines, and the HEV genes *glycam-1* and *hec-6st* (168). The data concerning the continued maturation of NALT up to 6 weeks after birth strongly suggests that environmental influences are important for its maintenance and development.

Bronchus-associated Lymphoid Tissue

BALT is less organized but more environmentally regulated than Peyers patches or NALT. Some debate exists regarding whether BALT is a normal structure or whether it is entirely dependent on antigenic stimulation. If the former, it would be considered to be a secondary lymphoid organ; if the latter, a tertiary lymphoid organ (see discussion following). This varies by species in that it is common in rabbits and rats, less frequent in guinea pigs and pigs, and absent in cats and normal human lungs (246). It is not a prominent structure in the laboratory mouse, but its presence varies by strain and age (247). The BALT is highly dependent on immunological stimulation in that the number of lung lymphoid aggregates varies, at least in the pig, by the extent of exposure to microbes (248). The lung is capable of generating an immune response in splenectomized $lt\alpha^{-/-}$ mice that lack lymph nodes and Peyers patches (249), suggesting that an organized tissue is present or can be induced in the lung. An inducible form of the BALT (iBALT) develops in $lt\alpha^{-/-}$ mice upon infection with influenza virus (250). The iBALT has many characteristics of secondary lymphoid organs, including CXCL13 and CCL21 expression, T and B compartmentalization, FDCs, and PNAd$^+$ HEVs. Data obtained from mice that lack all other lymphoid organs indicate that memory can be generated in the iBALT (251). Similar structures have been described in humans with pulmonary complications of rheumatoid arthritis (245), though they were not apparent in the lungs of patients with several other forms of lung inflammation. Many of the infiltrates in the rheumatoid arthritis patients exhibit the characteristics of secondary lymphoid organs, including LTα, LTβ, lymphoid chemokines, T and B cell compartmentalization, germinal centers, DCs, PNAd, and a lymphatic vessel marker, M2A.

Peyers Patches

Peyers patches are lymphoid aggregates in the submucosa of the small intestine (Figure 2.5, top panel). They are present in most species, though their number and location vary. They have a single layer of epithelial cells, called the follicle-associated epithelium (FAE); interspersed in these follicles are M cells that lack surface microvilli and surface mucus, similar to those in the tonsil and NALT. Because the Peyers patches lack afferent lymphatic vessels, the M cells are critical transporters of antigen. As noted above, M cells are transcytotic. Further, they express receptors
FIGURE 2.5 Organization of the Peyers patch. **Top panel:** Photomicrograph of Peyers patch. The Peyers patch is located in the intestine near intestinal villi. The follicle-associated epithelium (FAE) is in contact with the gut lumen. M cells (not shown) in the FAE transport antigen into the subepithelial dome, populated by DCs and T cells. The interfollicular T cell–rich region surrounds the B cell follicle and germinal center. Courtesy of A. Iwasaki (Yale University School of Medicine, New Haven, CT). **Bottom panel:** *In situ* hybridization of chemokine mRNAs. On the left, CCL21 mRNA defines the T cell zone and HEVs; on the right, CXCL13 defines the B cell zone.

for some pathogens, including HIV (252) and Salmonella (253), facilitating their uptake. Below the FAE is a diffuse area, the subepithelial dome, which includes DCs and lymphocytes. The Peyers patch organization is similar to that of the lymph node with compartmentalized B cell follicles, T cells, and antigen-presenting cells. T cells are found in the subepithelial dome, in the interfollicular region, and in germinal centers (Figure 2.5, bottom panel) (254).

Although M cells transport antigen across the epithelial barrier, they are not believed to have a crucial role in processing or presenting antigen. Peyers patches are populated by several subsets of DCs (255,256) that produce various chemokines, important in generating either immunity or tolerance.

Traffic In and Out: Chemokines and Vasculature Adhesion Molecules

Cells enter the Peyers patches through HEVs, whose appearance is similar to those in lymph nodes. However, in contrast to peripheral lymph nodes, the HEVs of Peyers patches express MAdCAM-1 (257), and homing depends on $\alpha4\beta7$ interaction on lymphocytes. Luminal PNAd is rarely found in Peyers patch HEVs; only occasional abluminal expression is detected. This pattern is identical to that seen in lymph node HEVs in $hec\text{-}6st^{-/-}$ mice (113), suggesting that this modifying enzyme is not expressed in Peyers patch HEVs. However, lymphocytes from mice that lack in both L-selectin ligand and $\alpha4\beta7$ home less efficiently to Peyers patches than do lymphocytes from mice that lack only one or the other of the ligands (258,259), suggesting that an L-selectin ligand does contribute to homing to Peyers patches. Although P-selectin is expressed only weakly on Peyers patch HEVs, cells from mice deficient in that molecule show reduced rolling and adhesion in vivo, implicating P-selectin as well as MAdCAM-1 in homing to Peyers patches (258).

Lymphoid chemokines CCL19, CCL21, and CXCL13 are found in the T and B cell areas (260) (Figure 2.5, bottom panel). CXCL12 mRNA is made by stromal cells, but the protein is also found on HEVs (260), presumably transported in a manner similar to CCL19 (101). CXCL16 is constitutively produced by the FAE (254), even under germ-free conditions. CD4$^+$ and CD8$^+$ cells that express CXCR6 are found in the Peyers patches and require CXCL16 to home to the subepithelial dome, indicating a role for this chemokine receptor pair that has not been noted in lymph nodes. CCL20 and its receptor CCR6 are particularly important in Peyers patches. CCL20 is made by the intestinal epithelium, and it plays a crucial role in dendritic cell trafficking to Peyers patches (261). Peyers patch HEVs express CCL25, the ligand for CCR9, which has been defined as a mucosal homing chemokine receptor (67). Efferent lymphatic vessels from Peyers patches drain primed lymphocytes to the mesenteric lymph nodes.

Development

Models for Peyers patch organogenesis and maintenance have come from analysis of knock-out mice and from carefully phenotyping the cells in the anlagen during mouse embryonic development. Several cytokines and chemokines have been shown to be crucial for PP

development. $lt\alpha^{-/-}$ and $lt\beta^{-/-}$ mice completely lack Peyers patches (147,262) as do mice that lack CXCR5, the receptor for CXCL13 (161). Since mice deficient in the LTβR also lack Peyers patches (263), these effects are mediated in large part through LT$\alpha_1\beta_2$. However, some $tnfr1^{-/-}$ mice lack organized Peyers patches, suggesting that either LTα3 or TNFα also influences generation or later stages in maintenance of Peyers patches (264). Similar to lymph nodes, mice deficient in IL-7 also lack PP (156). Mice deficient in CXCR5 or CXCL13 exhibit small or no Peyers patches (160,161,260), as do mice deficient in RORγt, Id2, NIK, and factors in the classical and alternative NFκB pathways (162,263). Peyers patch development differs from that of lymph nodes in the absence of a requirement for RANKL (158). A model for the embryonic development of Peyers patches, first proposed by Nishigawa and colleagues (265,266), has been experimentally substantiated (267). This model proposes stages that are similar to those described earlier for lymph node development and, in fact, provided the framework for studies in that organ. The first sign of Peyers patch development at E15.5 in the mouse is the appearance of regions on the small intestine that stain positively with antibodies to ICAM-1, VCAM-1, and LTβR. The cells in these aggregates are called the organizer cells. CXCL13, CCL19, and CCL21 are also apparent, as is IL-7. At E17.5, clusters of IL-7R$^+$CD4$^+$CD3$^+$ inducer cells are found. These express LTα and LTβ, CXCR5 and CCR7, Id2, and RORγ. They also express $\alpha4\beta1$ integrin activated by CXCR5 (268) that allows interaction with the VCAM-1$^+$ organizer cells. At E18.5, mature T and B cells enter through HEVs, CCL20 is produced by the FAE, and DCs expressing CCR7 and CCR6 are found. By day 4, the typical microarchitecture is apparent, with M cells and T and B cell compartmentalization (269).

Peyers patches are quite plastic in that they are affected by environmental influences, including bacterial flora. Their number and cellularity increase after immunization, and their lymphoid cell content decreases with aging (1,270). Lymphocytes also influence the maintenance of Peyers patches. Mice that lack mature T and B cells have either undetectable or small Peyers patches that lack follicles and germinal centers (271,272). B cell–deficient mice retain some M cells, suggesting that T cells may regulate M cell maintenance. When B cell–deficient mice are reconstituted by a membrane IgM transgene, FAE and M cells are found at levels comparable to those of normal mice (271), indicating that cells in addition to CD4$^+$CD3$^-$ inducer cells are crucial for the maintenance of mature, functioning Peyers patches.

Cryptopatches and Isolated Lymphoid Follicles

Even more environmentally regulated lymphoid tissues have been described in the adult gut. The cryptopatches in the lamina propria containing lymphoid tissue-inducer cells and DCs can give rise to ILF. The cryptopatches are composed of lin$^-$c-kit$^+$ cells, DCs, and VCAM-1$^+$ stromal cells with few or no mature T and B cells. The cryptopatch cells express RORγt, IL-7R, and CCR6 (273), and their development is dependent on IL-7, CCR6, and its receptor CCL20. Cryptopatches are quite plastic, and although the LT family is necessary for their development, they can be restored by administration of wild-type bone marrow to adult $lta^{-/-}$ mice.

After mice are exposed to microbes or during some forms of autoimmunity, cryptopatches give rise to ILFs (274,275), which resemble primitive lymph nodes. ILFs are found in the colon and small intestine in the mouse and serve as sites of mucosal immunity. ILFs include B cells and T cells, and, in fact, require B cells, but not T cells, expressing LT for their formation (270). In contrast to lymph nodes, they also require the TNFR1 (276). ILFs are quite plastic; they resolve completely after mice are treated with antibiotics or cytokine inhibitors (105,170,270,274,276).

TERTIARY LYMPHOID TISSUES

Similarities to Secondary Lymphoid Organs

Tertiary lymphoid tissues, also termed tertiary lymphoid organs, are ectopic accumulations of lymphoid cells that arise in nonlymphoid organs during chronic inflammation through a process termed lymphoid neogenesis (also lymphoid neoorganogenesis) (2). The iBALT could be considered as either a secondary or tertiary lymphoid tissue. This semantic issue epitomizes the plasticity of all lymphoid organs and the fact that lymphoid organ regulation represents a continuum from ontogeny through chronic inflammation. A notable difference between secondary lymphoid organs and tertiary lymphoid tissues is the fact that the latter can arise in almost any organ in the adult. Nonetheless, tertiary lymphoid tissues exhibit remarkable morphologic, cellular, chemokine, and vasculature similarities to secondary lymphoid organs. They exhibit T and B cell compartmentalization, naïve T and B cells, DCs, FDCs, plasma cells and lymphoid chemokines CCL19, CCL21, and CXCL13. Vessels with the morphological characteristics of HEVs have been detected in tertiary lymphoid tissues. In some cases, they express MADCAM-1. In others, they express PNAd and the enzymes and scaffold proteins necessary to generate that functional L-selectin ligand (118,178,277). Lymphatic vessels have been noted in tertiary lymphoid tissues (278,279), though it is not clear whether they function as afferent or efferent vessels.

Lymphoid neogenesis has been noted in humans in autoimmunity, microbial infection, and chronic allograft rejection (Table 2.2) (1). These accumulations occur in atherosclerotic plaques with expression of FDCs, organized B cell follicles, HEVs (HECA-452), and CCL19 and

▶ **TABLE 2.2** **Lymphoid Neogenesis in Human Autoimmunity, Infectious Diseases, and Graft Rejection**

Disease	Affected Tissue	Characteristics
Autoimmunity		
	Synovial membrane	T and B cells, plasma cells, GCs, FDCs, CXCL13, CCL21, HEVs (PNAd, HEC-6ST)
Sjögren's syndrome	Salivary glands	T and B cells, plasma cells, GCs, FDCs, CCL21, CXCL12, CXCL13 HEVs (PNAd)
Myasthenia gravis	Thymus	T and B cells, GCs, FDCs
Hashimoto's thyroiditis	Thyroid	T and B cells, GCs, FDCs CCL21, CXCL13, CXCL12, plasma cells, HEVs (PNAd)
Grave's disease	Thymus	T and B cells, GCs, FDCs, CCL21, CXCL13, CXCL12, HEVs (PNAd)
Multiple sclerosis	Brain	Lymphatic capillaries, B cell follicles and centroblasts, GCs, CCL19, CCL21, CXCL12, CXCL13
Ulcerative colitis	Colon	CXCL13
Inflammatory bowel disease (Crohn's disease)	Bowel	T cell-B compartments, LVs, HECA-452$^+$ HEV
Psoriatic arthritis	Joint	T cells and B cells, CXCL13, CCL19, CCL21, HEVs (PNAd)
Infectious diseases		
Borrelia burgdorferi/ Lyme Disease	Joints	T and B cells, FDCs, HEVs
Borrelia burgdorferi/ Neuroborreliosis	Central nervous system/ cerebrospinal fluid	CXCL13
Hepatitis C virus	Liver	T cell-B compartments, MAdCAM-1
Bartonella henselae/cat scratch disease	Granuloma	CXCL13
Graft rejection		
Organ		
Heart		Germinal centers
Kidney		Germinal centers, lymphatic vessels

CCL21 in addition to those chemokines more often associated with acute inflammation (280). Ectopic lymphoid tissues are also apparent in several animal models of autoimmune disease. The pancreatic infiltrates in early stages of diabetes in the nonobese diabetic (NOD) mouse express lymphoid chemokines (281) and HEVs expressing MAdCAM-1 (282,283), PNAd, and HEC-6ST (118). The brain in experimental autoimmune encephalomyelitis, a model of multiple sclerosis, has HEVs, CCL19, CCL21, CXCL13, and FDCs (284–286). The thyroid in the BB rat has T and B cell compartmentalization and DCs (287), and the gut in autoimmune gastritis in the mouse has HEVs and CXCL13 (288). Atherosclerotic plaques of apoprotein-E–deficient mice exhibit a marked increase in T and B cells and expression of CCL19 and CCL21 (289,290). Interestingly, although recruitment of T and B cells to the vessel wall depends in part on L-selectin, MECA-79–stained HEVs are not seen (289), suggesting the existence of an additional L-selectin ligand. Lymphoid neogenesis also occurs in chronic mouse heart allograft rejection (291).

Tertiary lymphoid tissues have been induced in several transgenic mouse models with the use of tissue-specific promoters driving the expression of inflammatory cytokines or lymphoid chemokines (1). These murine models, in addition to serving as examples of autoimmunity, have provided invaluable insight into the regulation of secondary lymphoid organ development.

From Chronic Inflammation to Organized Lymphoid Microenvironments

Data generated from analyzing the cellular and molecular requirements for secondary lymphoid organ development have provided a paradigm for understanding the development of tertiary lymphoid tissues in chronic inflammation. This paradigm proposes that the processes and molecules governing secondary lymphoid organs are also the basis of tertiary lymphoid tissue development (2) and informs understanding of both secondary and tertiary lymphoid tissues. The physiologic event(s) that precipitate

lymphoid neogenesis remain unclear. Data obtained from experiments in knockout and transgenic mice and clinical observations indicate that cooperative activities of TNF/LT family members and the lymphoid chemokines play central roles in this process.

Inflammation is a localized response to tissue injury, irritation, or infection often marked by tissue damage. Acute inflammation is an early innate immune response that is generally short-lived and self-limiting. However, in some situations, acute inflammation transitions to a chronic inflammatory response that is long-lived and self-perpetuating. Tertiary lymphoid tissues arise under conditions of constitutive cytokine or chemokine expression, but the precise signal(s) that initiates their development is unknown. By integrating studies of lymphoid neogenesis in human pathologies and in animal models, it is becoming clear that at least three critical events promote tertiary lymphoid tissue formation: inflammatory (e.g., TNF/LT) cytokine expression, lymphoid chemokine production by stromal cells, and HEV development. It is not known if lymphoid tissue inducer cells are necessary for lymphoid neogenesis, although such cells have been noted in the mouse models of lymphoid neogenesis (292).

Functions of Tertiary Lymphoid Tissues

Ectopic accumulation of lymphoid cells has been considered the hallmark of destructive inflammation. Indeed, some tertiary lymphoid tissues are accompanied by tissue damage. However, it is likely that tertiary lymphoid tissues in chronic inflammation have roles in addition to tissue destruction. In the case of microbial infection, it is likely that lymphoid neogenesis occurs as a way to sequester pathogens and prevent their access to the other parts of the body. This may represent a primitive form of immunity. Although local antigen presentation within the tertiary lymphoid tissue itself likely functions to prevent bacteremia or viremia, the propensity for tertiary lymphoid tissues to develop into lymphomas, and the ability of tertiary lymphoid tissues to serve as sites of prion accumulation, are obvious manifestations of possible detrimental functions (293). Further, the development of tertiary lymphoid tissues in autoimmunity may perpetuate disease.

Data from both human and murine studies provide compelling evidence that tertiary lymphoid tissues are permissive microenvironments for the induction of antigen-specific immune responses. Extensive immunohistochemical analyses of tertiary lymphoid tissues in autoimmunity and other chronic inflammatory states have established the presence of GCs and FDC networks in these tissues; several groups have demonstrated that tertiary lymphoid tissue GCs can support B cell differentiation. Microdissection of discrete lymphocytic foci and subsequent DNA sequence analysis of germinal center B cells from the inflamed synovial tissue of patients with rheumatoid arthritis revealed a restricted number of Vκ gene rearrangements, a result consistent with oligoclonal B cell expansion in the synovial tissue (294). Somatic hypermutation is apparent in synovial germinal center B cells (295). Further, synovial B cells exhibit a limited number of heavy and light chain gene rearrangements consistent with local clonal expansion of these cells. The molecular analysis of tertiary lymphoid tissue GCs from the salivary glands of patients with primary Sjögren's syndrome or the thymus of myasthenia gravis patients demonstrates oligoclonal B cell proliferation in these tissues in addition to somatic hypermutation of Ig variable genes (296–298). Together, these studies indicate that tertiary lymphoid tissue GCs in several autoimmune pathologies can support antigen-driven clonal expansion and extensive diversification.

Another important hallmark of antigen-driven B cell responses is the terminal differentiation of activated B cells into Ig-secreting plasma cells. Plasma cells have been detected in tertiary lymphoid tissues associated with GCs in rheumatoid arthritis (299) and in Sjögren's syndrome. Mice expressing LTα under the control of the insulin promoter (RIPLTα) exhibit tertiary lymphoid tissue at the sites of transgene expression (i.e., pancrease, kidney, and skin). After immunization with sheep red blood cells, evidence of isotype switching is apparent in these cellular infiltrates (2). Although the presence of plasma cells in tertiary lymphoid tissues is consistent with local antigen presentation, it is occasionally unclear whether these cells develop in the tertiary lymphoid tissues themselves or have migrated from canonical secondary lymphoid tissues. Nonetheless, when taken together, these studies indicate that tertiary lymphoid tissues in several human pathologies and animal models support antigen-driven B cell differentiation marked by somatic hypermutation of immunoglobulin variable genes, affinity maturation, isotype switching, and terminal differentiation into antibody-secreting plasma cells.

T cell priming occurs in tertiary lymphoid tissues, as suggested by the presence of isotype-switched plasma cells in the RIPLTα tertiary lymphoid tissues (2) and T cell epitope spreading in the central nervous system during experimental allergic encephalomyelitis (300). The restricted TCR repertoire in a melanoma-associated tertiary lymphoid tissue (301) further supports the concept that tertiary lymphoid tissues can act as priming sites. The demonstration of naïve T cell proliferation in the islets of NOD mice after surgical removal of pancreatic lymph nodes (302) suggests, together with evidence noted above, that tertiary lymphoid tissues present antigen to naïve cells at the local site and generate an immune response. Determinant or epitope spreading, a phenomenon that arises in several autoimmune diseases, occurs when epitopes other

than the inducing antigen become major targets of an ongoing immune response. It is considered to occur subsequent to the tissue damage induced by the initiating autoreactive T cells and therefore is the result of the presentation of new antigens (303). Data generated in murine models of central nervous system inflammation support the possibility that intermolecular and intramolecular epitope spreading occurs in tertiary lymphoid tissues in the central nervous system (300).

Plasticity and Adaptability of Tertiary Lymphoid Tissues

Tertiary lymphoid tissues are the most plastic and adaptable of the lymphoid tissues. First, lymphoid neogenesis can be induced by a variety of stimuli. Their nimbleness in this regard suggests that they might represent the most primitive tissues in the immune system. Tertiary lymphoid tissues can be "turned off" (i.e., resolved) upon removal of the initial stimulus or after therapeutic intervention. The destruction of the islets of Langerhans β cells in Type I diabetes mellitus is an example of a situation in which removal of the antigen stimulus is accompanied by tertiary lymphoid tissue resolution. Antibiotic treatment results in the resolution of tertiary lymphoid tissues and even MALT lymphomas (304). Treatment has been shown to resolve some established tertiary lymphoid tissues, reversing insulitis and protecting against diabetes in NOD mice (305). Such treatment can also "turn off" established tertiary lymphoid tissues in a mouse model of collagen-induced arthritis (306). These studies are similar to those described earlier regarding the plasticity of lymph nodes after mice are immunized or treated with LTβR-Ig (185,193), again emphasizing the commonality of these tissues.

CONCLUSION

The immune system depends on a remarkable organization of tissues and cells. The organs have defined functions that include generation of an immune repertoire (primary lymphoid organs) and responding to antigens (secondary lymphoid organs and tertiary lymphoid tissues). Development of primary and secondary lymphoid organs depends on precisely regulated expression of cytokines, chemokines, and adhesion molecules. Similar signals regulate the transition from inflammation to tertiary lymphoid tissues. Chemokines and adhesion molecules regulate trafficking in and out of lymphoid organs. Secondary lymphoid organs are remarkably plastic in their response to antigenic assault and adapt with changes in expression of chemokines and adhesion molecules to maximize encounter of antigens with antigen-specific cells. Tertiary lymphoid tissues, characteristic of many pathologic states, may actually represent the most primitive form of lymphoid tissues in their even greater plasticity and ability to develop directly at the site of antigen exposure.

Evolution of the Immune System

Martin F. Flajnik and Louis Du Pasquier

INTRODUCTION

Defense mechanisms are found in all living things, some surprisingly elaborate even in so-called "primitive" organisms. Although in recent years new adaptive or adaptive-like (somatically generated) immune systems have been discovered in invertebrates and the jawless fish, adaptive immunity-based on immunoglobulin (Ig), T cell receptors (TCR), and the major histocompatibility complex (MHC) is only present in jawed vertebrates (gnathostomes); because of clonal selection, positive and negative selection in the thymus, MHC-regulated initiation of all adaptive responses, etc., the major elements of the adaptive immune system are locked in a coevolving unit. In addition, a large cast of supporting players, including a considerable array of cytokines and chemokines, adhesion molecules, costimulatory molecules, and well-defined primary and secondary lymphoid tissues, evolved in the jawed vertebrates as well. This system was superimposed onto an innate system inherited from invertebrates, from which some innate molecules were coopted for the initial phase of the adaptive response and others for effector mechanisms at the completion of adaptive responses. In jawed vertebrates, fine-tuning or adaptations (or degeneration) in each taxon is observed and not a steady progression from fish to mammals as is seen—for example, in evolution of the telencephalon (forebrain) in the nervous system or in heart specialization. Given that all the basic adaptive immune system features are present in cartilaginous fish and none were lost (that we know of), variation on the theme (differential utilization) rather than progressive installation of new elements is the rule (1). In this chapter, there are only a few cases of increasing complexity in the adaptive system superimposed upon the vertebrate phylogenetic tree, but many examples of contractions/expansions of existing gene families; thus, on average "more (or less) of the same" rather than "more and more new features" is the rule. We observe a bush growing from a short stem rather than a tall tree with well-defined branches, and thus deducing primitive traits is not always easy.

Figure 3.1 displays the extant animal phyla ranging from the single-celled protozoa to the protostome and deuterostome lineages. It is often suggested or assumed that molecules or mechanisms found in living protostomes, like the well-studied *Drosophila,* are ancestral to similar molecules/mechanisms in mouse and human. While this is true in some cases, one should instead recognize that *Drosophila* and mouse/human have taken just as long (over 900 million years ago (MYA)) to evolve from a common ancestral triploblastic coelomate (an animal with three germ layers and a mesoderm-lined body cavity, features shared by protostomes and deuterostomes), and clearly *Drosophila* is not our ancestor (i.e., the manner by which flies and mouse/human utilize certain families of defense molecules may be quite different and both may be

nothing like the common ancestor). Thus, understanding how model invertebrates and vertebrates perform certain immune tasks is always an important first step, but we only understand what is primordial or derived when we have examined similar immune mechanisms/molecules in species from a wide range of animal phyla. We will touch on all of the defense molecule families listed in Figures 3.1 and 3.2 and Table 3.1 and will emphasize those that have been conserved evolutionarily and those that have evolved rapidly.

GENERAL PRINCIPLES OF IMMUNE SYSTEM EVOLUTION

Rapid Evolution of Defense Mechanisms

Immune systems are often compared to the Red Queen in *Alice's Adventures in Wonderland,* (Red Queen's Hypothesis [2]), who must keep moving just to avoid falling behind: "Now, here, you see, it takes all the running you can do, to keep in the same place. If you want to get somewhere else, you must run at least twice as fast as that!" Because of the perpetual conflict with pathogens, the immune system is in constant flux. This is exemplified by great differences in the immune systems of animals that are even within the same phylogenetic group (e.g., mosquito and fruitfly, both arthropods). In fact, defense mechanisms are extremely diverse throughout the invertebrate phla, as Keppler et al. put it recently: "not homogeneous, not simple, not well understood" (3). In the vertebrate frame of reference, the most rapidly evolving system is natural killer (NK) cell recognition, governed by different classes (superfamilies) of receptors in mice and humans, but recently shown to be extremely plastic even within the same family (4). Rapid evolution of immune system molecules and mechanisms is a general rule, but we shall see that molecules functioning at different levels of immune defense (recognition, signaling, or effector) evolve at widely varying rates (5).

Convergent Evolution

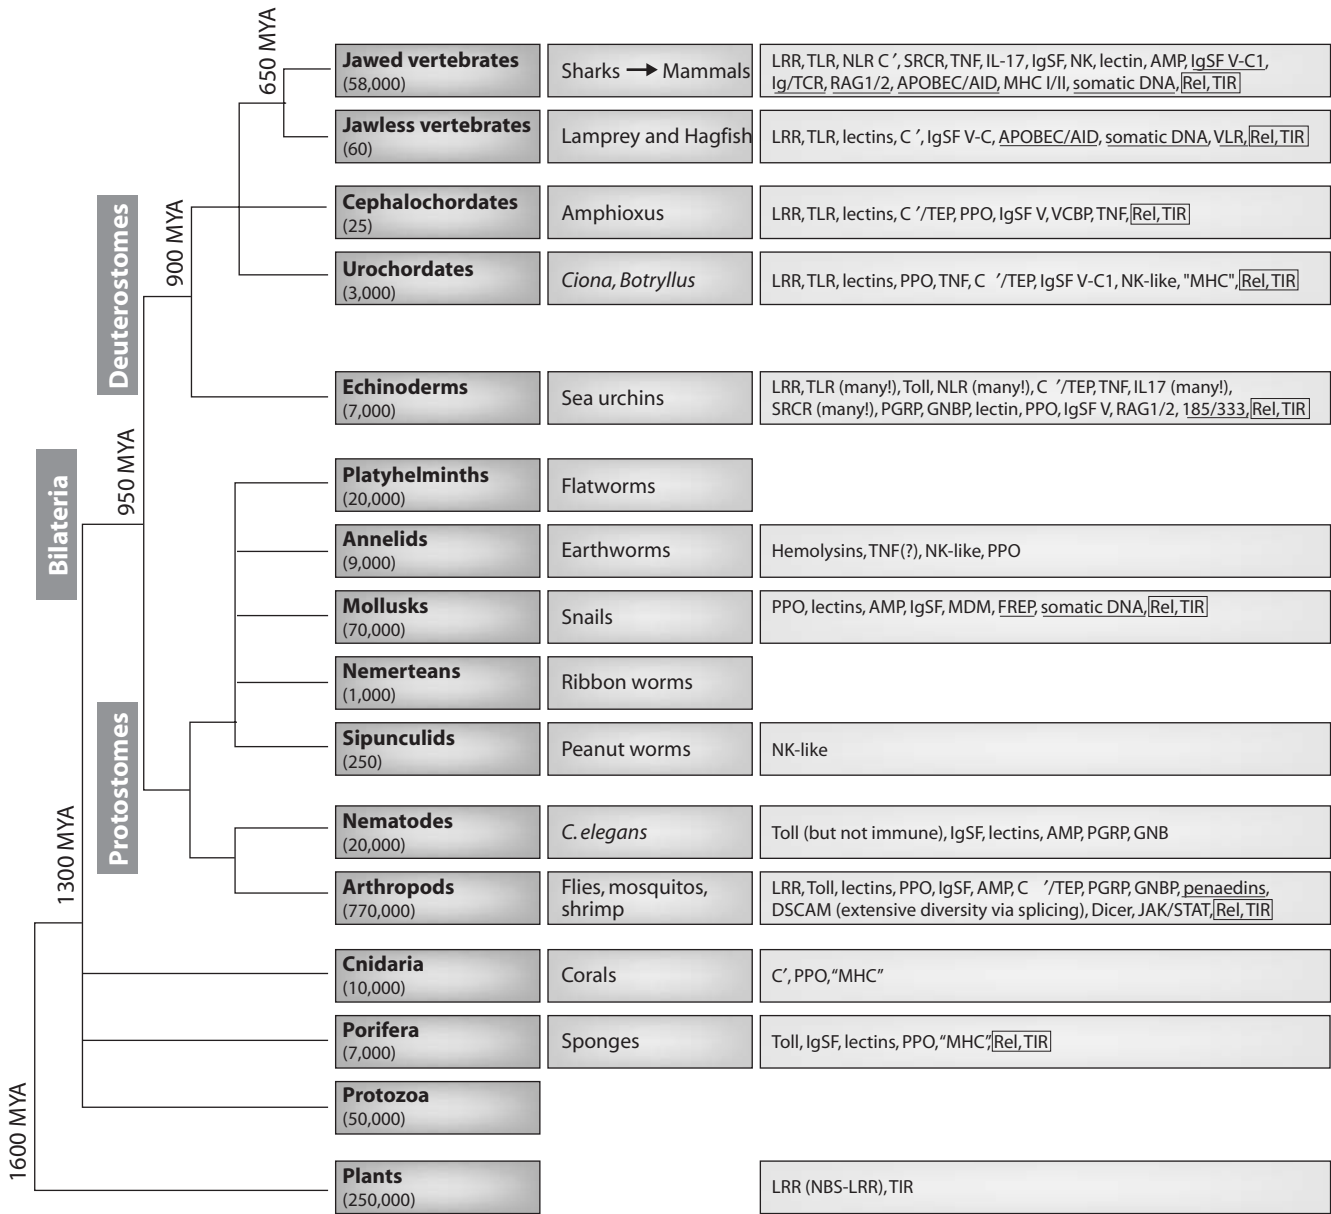
As mentioned earlier, when our informational database was small, it was assumed that the same features appearing in different taxa proved that they were present in the common ancestor as well (i.e., divergent evolution). While this dictum still holds true and establishes one of the dogmas of comparative immunology, later we discovered, because of the aforementioned rapid evolution of immune systems, often convergence of similar function has occurred in evolution (i.e., the same function or molecular conformation has arisen in different organisms), sometimes in species that are relatively closely related. Although we will discuss several cases of convergent evolution throughout the


FIGURE 3.1 Major animal groups and immune mechanisms/molecules described to date in each group. The first box in each row describes the animal taxon and the approximate number of species in that group. The next box shows specific examples of species or subgroups. The third box lists molecules/mechanisms found in each group: Underlined terms indicate somatic changes to antigen receptors or secreted molecules. Figure modified from (20) and (32). See Table 3.1 for definition of the acronyms.

chapter, for frame of reference, the NK cells, which use different receptor families in primates and rodents to achieve precisely the same ends, are a striking example of convergence (4).

Multigene Families

Immune genes are often found in clusters, with extensive contraction and expansion via "birth and death" processes (6). It is well known that such clusters can change rapidly over evolutionary time due to unequal recombination and gene conversion (and not only in the immune system, but in any cis-duplicating gene family). Often, families of related immune genes—especially those involved in recognition events—are found near the telomeres of chromosomes, presumably to further promote gene-shuffling events. Nonclassical MHC class I loci and NK receptors are two conspicuous examples of this phenomenon, again believed to be a consequence of the race against pathogens. We will discuss many examples of how such multigene

FIGURE 3.2 Major molecular families described in the text, and representatives of each family: Leucine-rich repeats (LRR), immunoglobulin superfamily (IgSF), peptidoglycan-recognition protein (PGRP), Gram negative–binding protein (GNBP), and C-type lectins. Representative structures are shown above for LRR (VLR, [104]), PGRP [306], and C-type lectin [307]). Other acronyms are defined in Table 3.1. For the NLR model, the echinoderms have N-terminal death domains (DD) while all other animals have CARDs. Figure modified from (32) with permission.

▶ **TABLE 3.1** Molecules and Abbreviations Found Throughout the Text

Acroynym/Defense Molecule	Full Name	Function
AID	Activation-induced cytidine deaminase	SHM/gene conversion/CSR
APOBEC	Apolipoprotein B mRNA editing enzyme catalytic polypeptide	Innate immunity (antiviral)
AGM	Aorta/Gonad/Mesonephros	Embryonic origin of hematopoietic cells
AMP	Antimicrobial peptide	Innate immunity
APAR	Agnathan paired antigen receptor	Similarities to Ig/TCR and NK receptors
Bf	Factor B	Enzyme of C′ cascade
C′	Complement	Innate/adaptive immunity
CARD	Caspase-recruitment domain	Domain in intracellular defense molecules
CATERPILLER or CLR	CARD, transcription enhancer, R(purine)-binding, pyrin, lots of leucine repeats	Apoptosis/immunity/inflammation
CSR	Class-switch recombination	Adaptive humoral immunity
DSCAM	Down's syndrome cell-adhesion molecule	Insect immune (adaptive?) defense and neuron specification
ECM	Extracellular matrix	
FBA	F box associated domain	Intracellular domain
FcRN	Fc receptor neonatal	MHC-like FcR
FREP	Fibrinogen-related protein	Mollusk (adaptive?) defense
GALT	Gut-associated lymphoid tissue	
GNBP	Gram-negative binding protein	Response to gram-negative bacteria
GPI	Glycophosphatidylinositol	Lipid linkage to cell membrane (e.g., VLR)
Hemolysin		Cell lysis
ICE	Interleukin-converting enzyme	IL-1β processing
Ig	Immunoglobulin	Adaptive immunity
IgSF	Immunoglobulin superfamily	Innate/adaptive immunity
IFN	Interferon	Innate (type I)/adaptive (type II) immunity
IMD	Immune deficiency	Insect innate defense
IRF	Interferon regulatory factor	Innate (transcription factor)
ITAM	Immunoreceptor tyrosine-based activation motif	Signaling motif for NK and antigen receptors
ITIM	Immunoreceptor tyrosine-based inhibitory motif	Signaling motif for NK and antigen receptors
GC	Germinal center	
KIR	Killer IgSF receptor	NK cell receptor
Lectins	e.g., Galectin, C-type, S-type	Many (e.g., NK receptors, selectins)

▶ **TABLE 3.1 Molecules and Abbreviations Found Throughout the Text** (Continued)

Acroymym/Defense Molecule	Full Name	Function
LMP	Low-molecular-weight protein	Proteasome subunit
LRR	Leucine-rich repeat	Innate/adaptive immunity module
MAC	Membrane-attack complex	C′, pore-forming
MACPF	MAC-perforin domain	Potential pore former
MASP	MBP-associated serine protease	Lectin C′ pathway
MBP (or MBL)	Mannose-binding protein (lectin)	Lectin C′ pathway
MDM	Mollusk defense molecule	IgSF defense molecule
MHC	Major histocompatibility complex	T cell recognition; innate immunity
MIF	Macrophage inhibitory factor	Innate immunity; inflammation
MyD88 (also dMyD88)	Myeloid differentiation primary response gene 88	TLR adaptor
NK cell	Natural killer cell	Vertebrate innate cellular immunity
NALP	NACHT leucine-rich repeat and PYD-containing protein	Intracellular PRR
NBD-LRR	Nucleotide-binding domain LRR	Motif of intracellular defense molecules
NFκB	Nuclear factor-κ B (Rel homology domain)	Evolutionarily conserved transcription factor
NLR	NACHT leucine-rich repeat protein	Intracellular PRR
NOD	Nucleotide oligomerization domain protein	Intracellular PRR
NOS	Nitric oxide synthase	Intracellular killing innate defense molecule
PAMP	Pathogen-associated molecular pattern	Conserved target epitopes on Pathogens
PCD	Programmed cell death	Many pathways
Penaeidin		Defense molecule in shrimp
PGRP	Peptidoglycan-recognition protein	Gram-positive bacteria defense family; receptor and effector
PPO	Propolyphenol oxidase	Plant/invertebrate defense (melanization)
PRR	Pattern-recognition receptor	Recognize PAMP, innate/adaptive immunity
Polμ	DNA polymerase μ	Error-prone polymerase (related to TdT)
PYD	Pyrin domain	Domain in intracellular defense molecules
PPO	Prophenoloxidase	invertebrate defense molecule
RAG	Recombination-activating gene	Ig/TCR rearrangement
RFP-Y	Restriction Fragment Polymorphism-Y	Chicken nonclassical MHC gene cluster
RIG	Retinoic acid-inducible gene	Intracellular double-stranded RNA recognition
SHM	Somatic hypermutation	Adaptive humoral immunity
SPE	Spaetzle-processing enzyme	Insect defense molecule in Toll cascade
SRCR	Scavenger receptor cysteine-rich	Innate immunity recognition molecule
TAP (and TAP-L)	Transporter associated with antigen processing	Transports peptides from cytosol to ER lumen
TCR	T cell receptor	Adaptive defense
TdT	Terminal deoxynucleotidyl transferase	Involved in Ig/TCR rearrangement
TEP	Thioester-containing protein	Opsonization (like C3)
TGF	Transforming growth factor	Immunosuppressive cytokine
UPD	Unpaired	Protostome cytokine induced by viral infection
TNF	Tumor necrosis factor	Proinflammatory cytokine (and family)
V-, C1-, C2-, I-	Variable, constant 1 and 2, intermediate IgSF domain	IgSF domain types
VCBP	Variable domain chitin binding	Amphioxus defense molecule
VLR	Variable lymphocyte receptor	Agnathan adaptive defense molecule
XNC	*Xenopus* nonclassical	*Xenopus* class Ib cluster
185/333	Sea urchin defense molecule	(adaptive?) Defense

families have been exploited in different species throughout the chapter.

Gene duplication, either in the clusters mentioned above or as a consequence of *en bloc* duplications, certainly have been major features of immune system diversity and plasticity. The evidence is becoming clearer that two genomewide duplications (the so-called *2R hypothesis*) occurred early in vertebrate history, tracking very well with the emergence of the Ig/TCR/MHC-based adaptive immune system (7,8). This theory forms the basis for much that will be discussed concerning the development of the vertebrate adaptive immune response.

Polymorphism

Polymorphism (and polylocism) increases the diversity of recognition capacity in a population. It can be generated any time during the history of a gene family of either receptor or effector molecules: MHC, Toll-like receptors (TLR), Ig, TCR, NK receptors and related molecules, and AMPs are just a few examples. Polymorphism provides populations with flexibility in the face of the changing pathogenic environment. This subject, central to the studies on MHC, leukocyte receptor complex (LRC), and natural killer cell complex (NKC), is becoming well documented for immunity-related genes in insects as well. In *Drosophila*, polymorphism in signal transduction and pathogen recognition genes is significantly associated with variability in immunocompetence. Polymorphism in regulatory networks is indeed expected since parasites often target its elements (5).

Somatic Generation of Diversity

Somatic modifications can take place at multiple levels to generate immune system diversity. Long believed to be the sole domain of jawed vertebrates, modifications at the DNA level via somatic hypermutation (SHM), gene conversion, or rearrangement (primary and secondary [e.g., receptor editing]) irreversibly modify genes within an individual. The well-known V(D)J joining, class switch recombination (CSR), and SHM are examples of this processes in the Ig superfamily (IgSF) receptors of jawed vertebrates, but recent work has shown quite convincingly that modifications to genomic DNA can also occur in the jawless fish and some invertebrates (9). The list of organisms undergoing such diversity of germline immune genes will only grow as more organisms are examined and more genome and EST sequencing projects are undertaken (Figure 3.1).

Alternative splicing can be a source of tremendous diversity in some gene families encoding receptors involved in immunity in insects and crustaceans. The DSCAM (Down syndrome cell adhesion molecule) gene in several invertebrates (described in detail; see page 70) was shown to generate enormous diversity via RNA processing (10). In the vertebrate lineage, this mechanism is important in determining the function of different molecules, best known for the Igs (transmembrane [TM] versus secreted forms, as well as inflammatory versus neutralizing forms in non-mammalian vertebrates).

Further diversity can be obtained by the assembly of multichain receptors in which different components are combined. The classical example in the jawed vertebrate adaptive immune system is that of Ig light (L) and heavy (H) chains of antibodies, but similar combination can occur with insect peptidoglycan-recognizing proteins (PGRP), vertebrate TLR, and many other receptors in which all the components have not been discovered.

MAJOR GENE FAMILIES INVOLVED IN IMMUNITY

The involvement of relatively few gene families in the immune system probably reflects the fact that there were few evolutionary scenarios leading to recognition binding with reasonable affinities, and once invented those features were exploited in every niche where they were selectable (11,12). Some of the most common families (Figure 3.2) are IgSF, leucine rich repeat (LRR), C-type lectins, and the tumor necrosis family (TNF), and certain other domains in immune recognition (e.g., scavenger receptor cysteine-rich, SRCR; see Table 3.1). As a means of introduction, we describe in some detail two of these families, which are displayed prominently in this chapter.

Leucine-rich Repeats

The LRR family of receptors has a long evolutionary history (Figure 3.2) (13). LRR consist of 2 to 45 motifs of 20 to 30 amino acids in length XLXXLXLXXNX-HXXHXXXXFXXLX that fold into an arc shape, the concave part of which is well suited for protein-protein or protein-carbohydrate interactions. Molecular modeling suggests that the conserved pattern LxxLxL, which is shorter than the previously proposed LxxLxLxxN/CxL is sufficient to impart the characteristic horseshoe curvature to proteins with 20- to 30-residue repeats. LRR are often flanked by cysteine-rich domains. LRRs occur in proteins ranging from viruses to eukaryotes and include tyrosine kinase receptors, cell-adhesion molecules, resistance (R) factors in plants, and ECM-binding glycoproteins (e.g., peroxidasin) and are involved in a variety of protein-protein interactions: signal transduction, cell adhesion, DNA repair, recombination, transcription, RNA processing, disease resistance, apoptosis, and the immune response.

LRR-containing proteins can be associated with a variety of other domains, whether they are extracellular (LRR associated with IgSF or fibronectin type III [FN3]) or intracellular (caterpiller family LRR associated with a variety of effector domains, discussed later). In these chimeric molecules, the LRR moiety is involved in recognition, most likely due to its extraordinarily plastic structure. There are at least six families of LRR proteins, characterized by different lengths and consensus sequences of the repeats (14). Repeats from different subfamilies never occur simultaneously and have most probably evolved independently in different organisms.

LRR proteins are involved in immunity from plants to all metazoa. The functions they can exert in the immune systems range from control of motility of hemocytes and lymphocytes (15) to specific recognition of antigens via a novel system of gene rearrangement (the variable lymphocyte receptors, or VLR, described later). LRR can occur in soluble forms, the ECM, in the cytosol, or as TM forms,

either integral membrane proteins or glycophoshatidyl-inositol (GPI)-anchored. The apparent lack of unity in evolution of some gene families, the change in commitment from one function to another is also well illustrated by the evolutionary fate of Toll and TLR. In triploblastic metazoans the structurally closely related members of this family range from not being involved in immunity (in several invertebrates) to becoming the equivalent of a cytokine receptor or a pathogen recognition receptor (PRR), like the vertebrate TLR (16).

Immunoglobulin Superfamily

IgSF domains are encountered in a very large number of molecules in the animal kingdom and constitute the most prevalent domain in defense molecules (17). They are found intracellularly (e.g., connectin), as cell adhesion molecules, many of which are in the nervous system (e.g., neural cell adhesion molecule (NCAM)), coreceptors and costimulatory molecules of the immune system (e.g., CD79, CD80), molecules involved in antigen presentation to lymphocytes (e.g., class I molecules), certain classes cytokine receptors (e.g., IL1R), and of course Ig and TCR, where they were first characterized and were bestowed with their name (Ig). They can be associated with other domains, such as fibronectin (FN; e.g., titin) and LRR, or they can be the sole constitutive elements of the polypeptide chain often linked to a TM segment and a cytoplas-

mic tail (or GPI-linked). The β barrel IgSF structure was adopted independently in other families such as cadherins, calycins, lipocalin, etc., and the superfamily has hundreds of members and has been selected for several different functions. These functions are somehow related, almost all involved with protein-ligand interactions. The vertebrate lymphocyte surface can express more than 30 different IgSF members (17).

IgSF domains are commonly classified according to different domain constitution in their β strands and loops (Figure 3.3). All conform to the stable shape of a β barrel consisting of two interfacing β sheets, usually linked by a disulfide bridge. There are three types of domains: variable (V) and two type of constant (C1 and C2); the so-called *I set domain* is intermediate between the C1 and C2. The V domain is most complex with more strands (C' and C''), which make up complementarity determining region (CDR) 2 in conventional Igs and TCRs. C1 domains lack these strands entirely and C2/I domains have varying sizes in the C'/C'' region. V domains, either alone (e.g., the new antigen receptor, NAR) or in association with another V domain (e.g., Ig H/L), recognize the antigenic epitope, and are therefore the most important elements for recognition. Domains with the typical V fold, whether belonging to the true V set or the I set, have been found from sponges to insects (e.g., amalgam, lachesin and fascicilin), and even in bacteria. The mollusk FREPS (fibrinogen-related proteins, described; see page 70) have one or two V-like

FIGURE 3.3 Major types of immunoglobulin superfamily (IgSF) domains (V, variable; I, intermediate; C1, constant domain-1; C2, constant domain-2). The domains are made up entirely of β strands that make up two sheets: A, B, D, E in one sheet and C, (C', C''), F, and G in the other sheet. An intrachain disulfide bond is usually found that connects the two sheets (cys in the B and F strands). In Ig and TCR, the V exon encodes the A–F strands and the J segment encodes the G strand (a Gly-X-Gly tripeptide is encoded in the J segment of antigen receptors and in some non-rearranging domains of the "VJ-type"). Information taken from (11,17).

domains at their distal end, associated with a fibrinogen-like domain.

The binding capacities of a V domain can reside in different areas of the molecule (interstrand loops, A-A′ strand, F strand). In diversified molecules such as Ig/TCR, these regions are the targets for variation in shape and charge. The binding capacities can be modulated whether one domain acts as a single receptor unit (e.g., IgNAR), or whether it is associated with a contiguous domain (e.g., KIR, VCBP) or with another polypeptide chain (e.g., TCR, Ig). In the case of a dimer, the binding capacity can again be modulated by the presence or the absence in the G strand of a diglycine bulge, which can modify the space between the faces of the Ig domain. In several cases, the sites responsible for binding are known (KIR, Ig, TCR); in many other cases they are not known but inferred from crystal structures and/or variability plots (LITR, CHIR, FcRH, TREMs DSCAM, hemolin (11]).

IMMUNITY IN PLANTS AND INVERTEBRATES

Immune responses are often subdivided into recognition, signaling, and effector phases, which are subjected to different pressures defined by whether orthology is maintained and the relative divergence rates of the genes responsible for the various phases (5). Recognition molecules are from well-conserved families, but as described earlier, their genes are subjected to rapid duplication/deletion so that orthology is rarely maintained. By contrast, signaling pathways are well conserved (see Figure 3.6), despite the fact that the genes are often divergent in sequence. Effector molecules can either be extremely conserved (e.g., reactive oxygen intermediates) or extremely divergent to the point of being species-specific (e.g., antimicrobial peptides, AMP). Here, we break down the immune response into these three phases, beginning with the cells involved in recognition.

Recognition

Initiation of an immune reaction can theoretically involve either the recognition of non-self, altered self, or the absence of self. Non-self recognition can take place with receptors (PRR, pattern recognition receptors) for the so-called *pathogen-associated molecular patterns* (PAMP), which are defined as evolutionarily conserved epitopes expressed by molecules of pathogens but not host cells (18). The second mode, altered self, is typified by molecules that are induced in self-cells during infections and recognized by conserved defense molecules, similar to the SOS systems mentioned later in the MHC section, or by peptide presentation on MHC molecules. A third mechanism, "Am I still myself," depends on recognition of self-tags and their changes in expression (19)—for example, NK recognition

of self-MHC molecules through KIR and C-type lectins. These latter two mechanisms have not been described in the invertebrates for immune defense against pathogens, but it would not be surprising if they were revealed in the future, considering the new features of invertebrate immune systems that have been discovered recently.

Whether the invader is related to an animal host (cells from individuals of the same species or cells from a parasitoid) or are very distant from the host (fungi and bacteria), there are different principles of recognition. Yet PAMP determinants have been identified on very different organisms—sugars such as $\beta 1,3$ glucan of fungi, lipopolysaccharide (LPS) and peptidoglycans of bacteria, and phosphoglycan of some parasites—and they can trigger the same cascade of events. The foreign ligand can be bound by a molecule in solution that initiates an effector proteolytic cascade (e.g., clotting or the complement cascade). However, a proteolytic cascade can be initiated and result in the production of a self-ligand that interacts with a cell surface receptor. In this way there need not be a great diversity of cell surface receptors, an advantage in the absence of clonal selection.

Of the more than 1 million described species of animals (Figure 3.1) ∼95% are invertebrates representing 33 phyla, some with one species (Placozoa, Cycliophora) and others with more than 1 million (Arthropoda). Since they have major differences in body plans, development, size, habitat, etc., wildly different types of immune systems in diverse species should be expected. Early studies of invertebrate immunology reached no consensus of how immunity should be examined, but because vertebrate immunity was often defined through transplantation reactions, attempts to reveal specific memory by allograft rejection as detailed in the following discussions was often used. After (mostly failed) attempts to demonstrate memory of such responses in the invertebrates (see following discussion) and after extensive molecular studies, a consensus was reached that an invertebrate adaptive immune system involving somatic generation of antigen receptors and their clonal expression was highly unlikely (however, now with caveats noted in following dicussion). Phagocytosis has long been cited as one example of such conservation, together with several proteins of the acute phase response and complement cascades. During innate responses in which memory to a particular antigen does not exist, selection is at the level of the species polymorphism and diversity. However, the term "innate" can be too rigid and masks the possibility of other somatic alterations of invertebrate immune system molecules, as will be discussed (20).

Invertebrate Cells

Examples of conservation of fundamental mechanisms of genetic control of developmental pathway between protostomes and deuterostomes, even in the absence of

Vertebrates

FIGURE 3.4 Comparison of blood cell differentiation in insects (*Drosophila*) and vertebrates. Homologous transcription factors are noted with superscripts: 1, Srp and GATA; 2, Lz and AML-1; 3, Ush and FOG-1. This figure was modified from (23,25); details in the text.

homology of the cells or organ considered, are accumulating: Wings are not homologous between *Drosophila* and birds, yet they follow a similar logic of development that includes a common network of genes. This applies also to the organization and expression of the homeotic gene clusters and eye formation through the function of a complex of proteins including Pax-6 (21,22). The cell types involved, besides direct interaction with the external layer of cells on the skin, or external teguments, are specialized cells of mesodermal origin devoted to defense. This

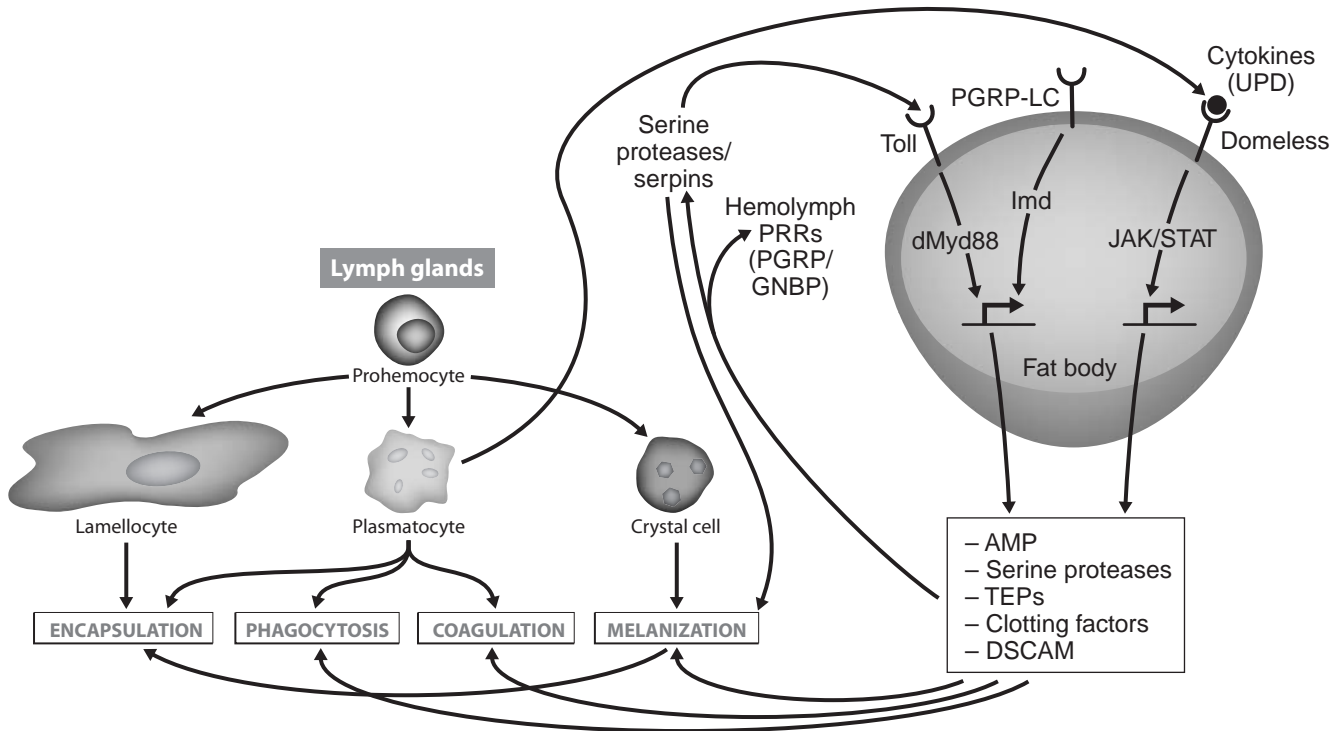
is true for all coelomates where effector cells have been identified (Figure 3.4). The cells can be circulating or sessile, and often are found associated with the gut. Several morphologically distinct hemocyte types in insects cooperate in immune responses: They attach to invading organisms and isolate them, trapping larger organisms in nodules or forming large multicellular capsules around them. Indirect evidence for the role of hemocytes in immune responses can be derived by contrasting properties of such cells in healthy and parasitized


FIGURE 3.5 Types of immune responses in the insects, with *Drosophila* as the prototype. Secreted defense molecules are made by fat body cells in response to pathogens, which either act as direct effector molecules, or feed back on hemocytes to stimulate their defense functions. Unpaired (UPD) is produced after virus infection, stimulating defense molecule upregulation via the JAK/STAT pathway. Not shown is the RNAi pathway, also induced on virus infection. This figure was modified from (31,90) with permission. Details on stimulation of the Toll and Imd pathways.

animals (i.e., modifications in adherence and opsonic activity).

All eumetazoa show heterogeneity of the free circulating cells, generically called *hemocytes* (arthropods), *coelomocytes, amebocytes* (annelids, mollusks, and echinoderms), or *leukocytes* (Sipunculids). However, the repertoire of insect "blood cells" is clearly less heterogeneous than that of vertebrates. Basically three or four types of cell lineages can be identified in *Drosophila*: plasmacyte, crystal cells, and lamellocytes (Figures 3.4, 3.5) and an equivalent number in Lepidoptera (butterflies). They ultimately play important roles in development and in immunity. The functional roles they play consist of immune defense, disposing of apoptotic and other debris, contributing to the extracellular matrix (ECM), and modeling of the nervous system. The immunity role encompasses phagocytosis, encapsulation, and at time production of effector molecules (Figure 3.5). Both roles require recognition of PAMPS or self-derived defense molecules (i.e., opsonization) at the cell surface (23–25).

Only in a few organisms has the characterization of hemocyte lineages gone beyond morphological or basic physiological functions. Among these free circulating cells are always one or more types that can undergo phagocyto-sis. Different cells participate in encapsulation, pinocyto-sis, and nodule formation and can on stimulation produce a great variety (within an individual and among species) of soluble effector molecules that may eliminate the pathogen (Figure 3.5). In an attempt to integrate all of the data available in invertebrates, Hartenstein (23) has proposed a unified nomenclature of four basic types: prohemocytes, hyaline hemocytes (plasmatocytes or monocytes), granular hemocytes (granulocytes), and eleocytes (chloragocytes). These designations will be found in the following description of the blood cell types.

Although vertebrate blood cells are derived from mesoderm, free-moving cells with analogous and sometime homologous functions, and genes can be found in all metazoa including those that have no typical mesoderm (and obviously no coelom). Porifera (sponges) remain perhaps the only metazoan completely without mesoderm and they have many motile amoebocytes (26). They apparently function for digestion, phagocytosis, and renewal of stem cells. Some archeocytes seem to be the phagocytic effectors. In triploblastic acoelomates like flatworms, motile cells can be observed in the parenchyma, perhaps corresponding to pluripotent cells—they can differentiate into many cell types of unknown immune function.

Earthworm (annelid) coelom-tropic coelomocytes are called *eleocytes*. They contain glycogen and lipid and are considered of the same lineage as the chloragocytes involved in the production of immune effector molecules such as fetidin or lysenin. The phagocytic cells of annelids are apparently granular "leukocytes" derived from the somatopleura and involved in wound healing, whereas the ones derived from the splanchnopleura participate in immunity. Heterogeneity of annelid coelomocytes is not encountered in primitive oligochaetes or in hirudinae (leeches). Phagocytic coelomocytes show an acid phosphatase activity and a beta glucoronidase activity (27). The large coelomocytes and free chloragocytes (eleocytes) in the typhlosole of *Eisenia foetida* appear to produce the bacteriolytic and cytolytic factor lysenin (28). Chloragocytes were also identified with plaque assays and produce fetidin (another name for lysenin). From electron microscopy (EM) studies, macrophagelike cells seem to be involved in graft rejection. In the closely related Sipunculid phylum, two main cell types can be identified in the blood, erythrocytes (a rare occurrence in invertebrates) and granular leukocytes. The latter are capable of cytotoxicity and even have dense granules reminiscent of vertebrate "NK cells" (29).

Two developmental series have been described in mollusks—the hyaline and granular cells—but cephalopods seem to have only one lineage. They participate in encapsulation, with hemocytes adhering around the foreign body like *Drosophila* lamellocytes. Phagocytosis is carried out by the wandering hemocytes (27). In oysters, EM revealed different types of circulating hemocytes, including granular hemocytes resembling the granulocytes of Sipunculus mentioned earlier (30). In crustaceans, the situation is similar to that in mollusks, with three main populations identified based again on the presence of granules in the cytoplasm. The hyaline cells are involved in the clotting process and the granular cells in phagocytosis, encapsulation, and the pro-phenoloxidase (PPO) pathway (Figure 3.5). The hematopoietic organ is located on the dorsal and dorsolateral regions of the stomach (24).

In insects, the so-called *prohemocytes* are believed to be the stem cells (Figures 3.4, 3.5). They are only found in the embryonic head mesoderm and the larval lymph glands but not in the hemolymph. However, prohemocytes are frequent in both the hemolymph and hematopoietic organs of the lepidopteran *Bombyx* (silkmoth). Plasmatocytes of *Drosophila* have a phagocytic function. This type of hemocyte is equivalent to the granulocytes of *Bombyx*, which play a key role in phagocytosis in normal larvae. Lamellocytes seem to be unique to *Drosophila*, but they are probably the equivalent of the Lepidopteran plasmacytoid cells. Their precursors reside in the larval lymph gland, where they differentiate in response to macroscopic pathogens, following a brief phase of mitosis linked to the presence of the pathogens and under hormonal control via ecdysone. The transcription factors (GATA, Friend-of-GATA, and Runx family proteins) and signal transduction pathways (Toll/NF-kappaB, Serrate/Notch, and Janus Kinase/Signal transduction activators of transcription (JAK/STAT)) that are required for specification and proliferation of blood cells during normal hematopoiesis, as well as during hematopoietic proliferation that accompanies immune challenge, have been conserved throughout evolution (Figure 3.4). The specific differentiation of lamellocytes requires the transcription factor Collier. The mammalian early B cell factor (EBF), an orthologue of Collier, is involved in B cell differentiation in mice. The *Drosophila* crystal cells are responsible for melanization through the PPO system (see later discussion). In silkworm oenocytoids, crystallike inclusions are also found, but they disappear later after bleeding (23,25,31).

Echinoderm coelomocytes express a diversity of effector functions, but no studies of lineages have been performed. In echinoderms, the number of different coelomocytes may vary according to the family. The sea urchin is endowed with at least four cell types, only one of which only is phagocytic and corresponds to the bladder or filiform forms. Another type is described as the round vibrating cell involved in clotting. Pigment cells (red spherule cells) have been detected ingesting bacteria; the morphology of phagocytic cells can vary enormously precluding any easy classification (32).

In tunicates, amoeboid cells circulate in the blood and are involved in a large number of processes, such as clotting, excretion, nutrition budding, and immunity. Large numbers of blood cells are present (avg. 10^7 per mL) in the blood of ascidians such as *Ciona*. Hemoblasts are considered to be undifferentiated cells, perhaps the equivalent of the prohemocytes of arthropods or the neoblasts of annelids. Blood cells in ascidians proliferate in the connective tissue next to the atrium. The pharyngeal hematopoietic nodule of this animal contains a large number of hyaline and granular cells called *leukocytes* with supposed intermediary forms of differentiation between blast and granular mature types. The granular form is likely to be involved in postphagocytic activity, like in the earthworms (33). Adoptive transfer of alloimmunity in the solitary tunicate *Styela* can be achieved via lymphocytelike cells (34).

In amphioxus, cells with phagocytic capacity have been identified in the coelom with a morphology resembling more the phagocytic echinoderm cells than urochordate blood cells, a fact that is consistent with the new systematic positions of amphioxus and echinoderms (35). Both free cells and the lining of the perivisceral coelom are able to phagocytose bacteria. Recently, cells with the morphological appearance of lymphocytes and expression of lymphocyte-specific genes were detected in this species; this is the earliest identification of such cells in phylogeny (36,37).

Hematopoietic Cell Origins: Hematopoiesis in Invertebrates

The history of the hemocytes cannot be dissociated from that of the mesoderm among the metazoa. The Bilaterian ancestor was most likely a small acoelomate or pseudo-coelomate worm similar to extant platyhelminths (flatworms) or nemathelminths (Figure 3.1). A specialized vascular system or respiratory system was probably absent, although cells specialized for transport and excretions were likely present because they exist in most extant Bilaterian phyla. One can further assume that groups of mesoderm cells in the Bilaterian ancestor could have formed epithelial structures lining internal tubules or cavities (splanchopleura). In coelomates, the mesoderm transforms into an epithelial sac, the walls of which attach to the ectoderm (somatopleura) and the inner organs (splanchnopleura). Blood vessels are formed by tubular clefts bounded by the splanchnopleura. Excretory nephrocytes are integrated into those vascular walls, which also gives rise to blood cells circulating within the blood vessels (the pronephros of anurans and head kidney of teleost fish are important heneatopoietic organs in vertebrates, see Figure 3.14). Thus, further evolutionary changes separated the three systems, but there was a close original connection between them.

The origin of hemocytes has been investigated mainly in arthropods, particularly in *Drosophila* (Figure 3.4). When examining principles that govern hematopoietic pathways, similarities have been observed with vertebrates, raising interesting evolutionary issues (23,25). In jawed vertebrates, the yolk sac or its equivalent gives rise to blood precursors that are primarily erythroid in nature. In succession, definitive hematopoiesis occurs in the aorta/gonad/mesonephros (AGM) region of the embryo, encompassing all of the different cell types and multipotent progenitors (although this is controversial). Like in the vertebrates, hematopoiesis in insects is biphasic. One phase occurs in the embryo and the other during larval development. Additionally, these waves occur in distinct locations of the embryonic head mesoderm and the larval lymph gland. In the early embryo, expression of the GATA factor serpent (*Srp*) can be detected in the head mesoderm. This GATA family of zinc (Zn)-finger transcription factors is conserved from yeast to vertebrates where they are involved in various aspects of hematopoiesis. Blood cell formation in the head follows *Srp* expression, whereas in the lymph gland there is a long delay between *Srp* expression and the appearance of the lymph gland–derived hemocytes (38). Hematopoiesis in the head mesoderm and yolk sac may be related evolutionarily. A further similarity occurs at the AGM/lymph gland level in *Drosophila*. The lymph gland develops from a part of lateral mesoderm that also gives rise to vascular and excretory cells, much like the vertebrate AGM. The conserved relationship between blood precursors and vascular and excretory systems is intriguing.

Responses of Hemocytes

Proliferation of hemocytes on stimulation is an unresolved issue in the invertebrates; clearly, clonal selection resulting in extensive proliferation is not the rule. The turnover of cell populations has been the object of numerous, often unconvincing experiments. Still new data have emerged, and it is clear that in several invertebrate phyla, proliferation occurs in certain cell types following encounters with pathogens. Very little cell proliferation occurs in the circulation of crayfish, but cells in the hematopoietic tissue divide after an injection of the PAMP β1,3-glucan. New cells in the circulation developed into functional SGCs and GCs expressing the pro–phenol oxidase (PO) transcript. RUNT protein expression was upregulated prior to release of hemocytes. In contrast, pro-PO was expressed in these cells only after their release into the circulation (39).

By contrast to the study of transcription factors that regulate hematopoiesis, relatively little is known about cytokines that drive hematopoiesis among invertebrates. It was reported that differentiation and growth of hematopoietic stem cells *in vitro* from crayfish required the factor astakine, which contains a prokineticin domain (40); prokineticins are involved in vertebrate hematopoiesis, another case of conservation during the evolution of growth factors and blood cell development.

Parasitization of *Drosophila* by the wasp *Leptopilina boulardi* leads to an increase in the number of both lamellocytes and crystal cells in the *Drosophila* larval lymph gland. This is partially due a limited burst of mitosis, suggesting that both cell division and differentiation of lymph gland hemocytes are required for encapsulation. In genetic backgrounds where ecdysone levels are low (*ecdysoneless*) the encapsulation response is compromised, and mitotic amplification is absent. This ecdysone-dependent regulation of hematopoiesis is similar to the role of mammalian steroid hormones such as glucocorticoids that regulate transcription and influence proliferation and differentiation of hematopoietic cells (41).

Phagocytosis

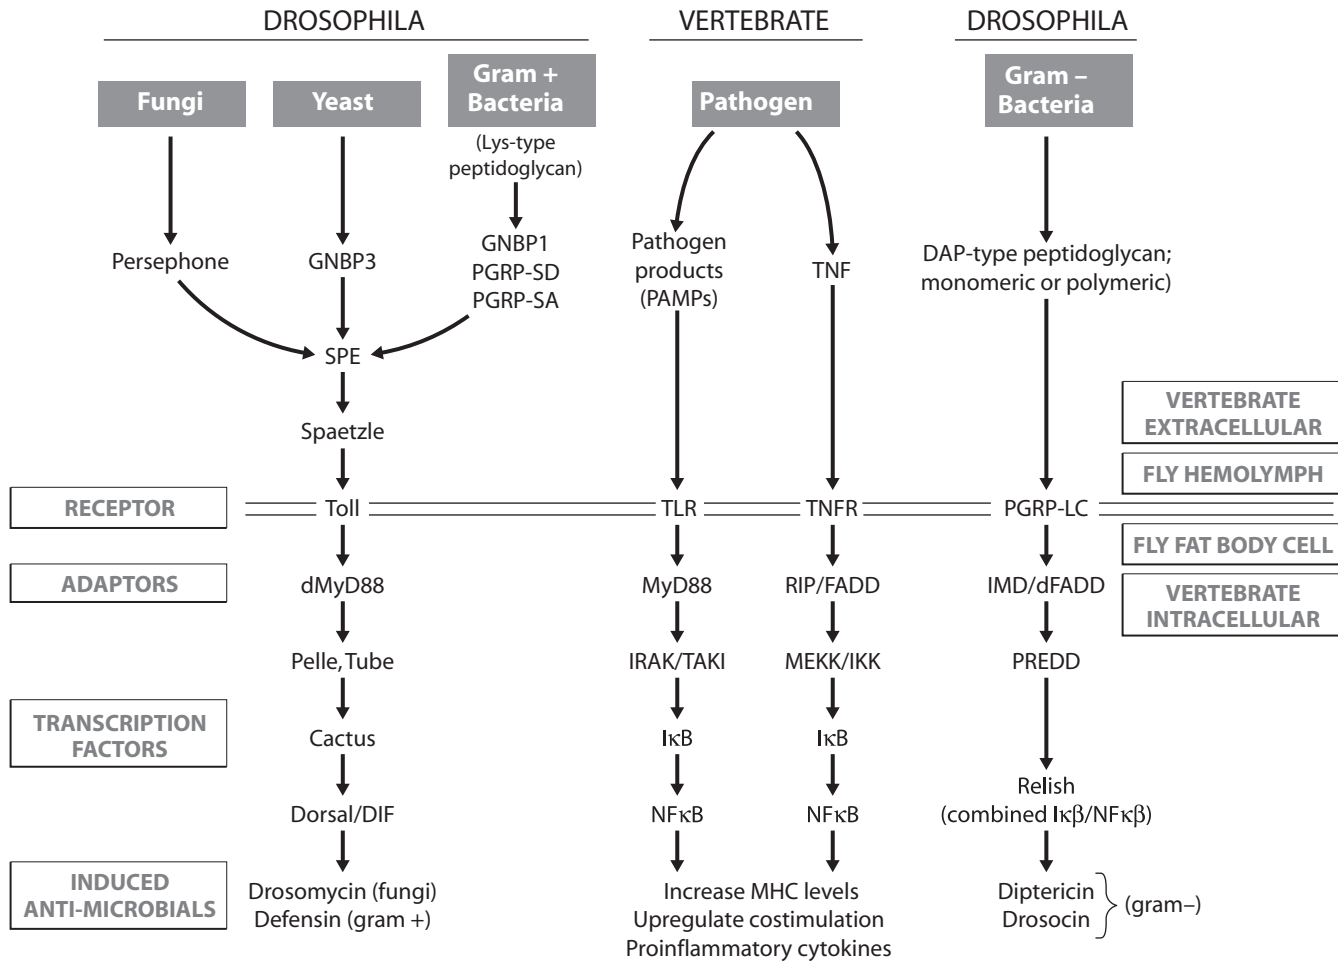
To obtain phagocytosis at the site of microorganism invasion implies recruitment of cells via chemoattraction. In vertebrates, this can be done by several categories of molecules, such as chemokines like IL-8 or the complement fragments C3a and C5a (as mentioned later, C3a fragments as we know from mammals may be found in tunicates but not other nonvertebrates; yet, C3 may be cleaved in different ways in the invertebrates.) C3b, MBL, and many other lectins can function as opsonins, and recent studies of TEPs, DSCAMs, and eater have added to this


FIGURE 3.6 Comparison of immune response induction, intracellular pathways, and immune outcome in *Drosophila* and vertebrates. Note that the initiation of the response and the outcome(s) are quite different, but the intracellular signaling pathways are well conserved evolutionarily (details in the text). This figure was modified with permission from (31).

repertoire (Figure 3.5) (31). Ingestion follows phagocytosis, and then killing occurs by an oxidative mechanism with the production of reactive oxygen radicals and nitric oxide. These mechanisms are conserved in phylogeny, as described earlier. Unique to mammals and presumably all jawed vertebrates, the activation of phagocytes also leads to upregulation of the antigen processing machinery, costimulatory molecules, and proinflammatory cytokines that can enhance adaptive immunity (Figure 3.6) (42).

Melanization

A major defense system in invertebrates is the melanization of pathogens and damaged tissues (Figure 3.5) (43). The process is controlled by the circulating enzymes PPO and PO. The system is activated by GNBP, PGRP, LPS-binding proteins, and other proteins that can bind to various PAMPs (Figure 3.5). The complexes launch a cascade of serine protease activities resulting in cleavage

of the pro-form of a prophenoloxidase-activating enzyme into the active form that in turn activates the PPO into PO. This leads to the production of quinones and finally melanin. Melanization can completely inhibit parasite growth, whereas concomitant with PPO activation, many other immune reactions are initiated, such as the generation of factors with antimicrobial, cytotoxic, opsonic, or encapsulation-promoting activities. The presence of specific proteinase inhibitors (of the serpin family) prevents unnecessary activation of the cascade and overproduction of toxic products. Phenoloxidase is the key enzyme responsible for the catalysis of melanization. It is a marker of the prophenoloxidase-activating system, and it can be an immune effector by itself as demonstrated in ascidians. It is therefore interesting to assess its conservation within all metazoa. A survey of the different organisms revealed the presence of phenoloxidase in many deuterostome and protostome phyla, and related molecules are also present in sponges. In arthropods, several PPO genes are present in

the genome (nine in *Drosophila* and *Aedes*). Some may have different "immune" functions, such as injury repair. Several components that would maintain the role of melanization in immunity may be lacking in different phyla even if many elements are conserved, and so far the best examples of melanization associated with immunity are still found almost exclusively among arthropods and to a lesser extent in annelids. Despite the presence of molecules involved the pathway, the PPO cascade *per se* does not exist in vertebrates.

DEFENSE FAMILIES, BOTH RECOGNITION AND EFFECTOR

NOD and Intracellular Sensors

As mentioned earlier, proteins with the LRR motif are commonly found in defense molecules (Figure 3.2). One major family of intracellular sensors in animals is the NOD/NLR/CATERPILLER (CLR) group: (<u>CARD</u> (caspase-recruitment domain), <u>T</u>ranscription <u>E</u>nhancer, <u>R</u> (purine)-binding, <u>Pyrin</u>, <u>L</u>ots of <u>LE</u>ucine <u>R</u>epeats), which have an N-terminal CARD domain (a death domain [DD] in echinoderms), a central NBD (nucleotide-binding domain) or NACHT domain that regulates oligomerization, and C-terminal LRRs that provide the specificity for PAMPS (44) (Table 3.1, Figure 3.2). The composition of each member can vary drastically in structure and function. Several prominent members of the human CLR family include CIITA, CIAS1, and NOD2 and are linked to immunologic disorders that are hereditary, such as Crohn's disease. This indicates that these molecules not only are directly involved in defense but also regulate immune pathways (45), perhaps similar to new paradigms for how they function in plant defense. Thus far, the NLR have only been found in deuterostomes, which is somewhat surprising considering that plants have intracellular defense proteins with a similar structure.

The plant resistance (R) immune defense genes encode a NBD/LRR motif combined to other protein domains.

It has been proposed that the large number of NBD/LRR proteins in plants is due to gene-for-gene relationship for recognizing pathogen-specific products (46). The specificity of plant R proteins also depends principally on the LRR, and these are targets for diversifying selection, as described earlier for multigene families. Homo- and hetero-associations might generate further diversity to mediate appropriate responses. Recent evidence suggests that on recognition of pathogen effector molecules, the plant intracellular sensors derepress genes involved in basal defense by inactivating suppressor factors (47).

NLR are expressed by echinoderm coelomocytes, representing a highly diversified family (>200 members, similar to the TLR and SRCR, see later discussion) (Figures 3.1, 3.2). As mentioned, it is surprising that these genes do not seem to be represented in protostomes. On the contrary, in the vertebrates a search of the *Danio rerio* database did yield a large number of NBD/LRR sequences (32). NOD binds its ligand intracellularly, and the CARD domain associates with a kinase (RIP2) that activates the NFκB/MAP kinase cascade. In humans, most NLR genes are encoded in clusters on chromosomes 11p15, 16p12, and 19q13, where six sequences are found in a single region.

The retinoic acid-inducible gene-1 (RIG-1) is a newly described intracellular defense molecule that is unrelated to the NOD proteins, with N-terminal CARD and C-terminal helicase domains (48). With the helicase domain, RIG-1 binds to double-stranded RNA found in viruses or even to degraded cellular RNAs as a sign of distress (49). RIG genes are found in all vertebrates tested, and the family also has been expanded in the sea urchin.

PGRP and β1-3 Glucan Receptors

Numerous ligand-binding receptors have been recognized at the surface of invertebrate hemocytes (Figures 3.2, 3.5) or in solution. Insects have up to 19 PGRPs classified into short (S) and long (L) forms. S forms are soluble and found in the hemolymph, cuticle, and fat-body cells (31). L forms are mainly expressed in hemocytes as integral membrane proteins where their final structure depends on combinatorial association of different isoforms, modulated by alternative splicing. The expression of insect PGRPs is often upregulated by exposure to bacteria. They can activate the Toll or immune deficiency (Imd) signal transduction pathways or induce proteolytic cascades that generate antimicrobial products, melanization, or induce phagocytosis, and hydrolyze peptidoglycan (Figure 3.6). Homologues of PGRP are encountered in vertebrates, but they are only in soluble forms that display direct microbicidial activity (50). Both soluble and TM forms are present in sea urchins, some with potential catalytic function. Human PGRP genes are found on chromosomal paralogues 1q21 and 19q13/p13. In mice, a PGRP homologue (TagL) may be secreted as an inducible protein or retained on intracellular membranes. All detected splice-variant isoforms of TagL bind to bacteria and peptidoglycan. This binding was associated with the C-terminal portion of the polypeptides. Thus, this variety of isoforms of a single gene may play a role in circulating bacteria recognition in mammals.

Gram-negative binding proteins (GNBP, or beta 1-3 glucan receptors) are related to bacterial beta1-3 glucanases. They are found in insects and other arthropods (Figures 3.2, 3.5) where they bind gram-negative bacteria, fungal β-1, 3-glucans, LPS, or bacterial lipoteichoic acid (without necessarily showing glucanase activity.). An orthologue is present in the sea urchins, but not in vertebrates. Drosophila GNBP1, together with PGRP-SA, is required to activate the Toll pathway in response to infection (31). GNBPs have also been examined in both termites and

Daphnia. The *Daphnia* GNBP, like the *Drosophila* proteins, are under purifying selection. However, in termites, two *GNBP* genes showed some evidence of positive selection. It is possible that living in colonies exposes termites to higher pathogen pressures and more host-specific pathogens, resulting in stronger selection acting on their immunity genes (51).

Down Syndrome Cell Adhesion Molecule

DSCAM in *Drosophila* and other insects was described originally by neurobiologists as an axon-guidance protein, dependent on a large number of isoforms (>30,000) generated by alternative splicing of the Igsf domains and the TM segment. Recently, DSCAM was shown to be involved in insect immunity as well, expressed in cells of the hematopoietic lineage; like in the nervous system, a large number of splice variants are involved, clearly different from the ones expressed in neurons (10). DSCAM consists of nine Igsf domains and FN domains, present as either a membrane or soluble form (presumably generated by proteolysis of the membrane form). The membrane forms apparently signal through a known transduction pathway (DOC PAK) that has not yet been examined in detail. Each cell expresses only a fraction of the isoform repertoire.

Suppressing DSCAM (RNAi) and anti-DSCAM treatment significantly inhibit phagocytosis. Soluble DSCAM constructs with different exon combinations were found to have differential pathogen-binding properties. In addition, suppression of DSCAM in mosquitoes results in an impaired immunity to *Plasmodium*; exposure of hemocytes to different pathogens in culture gives rise to specific modifications and selection of alternative splicing patterns (52). The diversification of DSCAM seems to be specific for arthropods since neither flatworm nor sea urchin (nor vertebrate) DSCAM is diversified. The vertebrate DSCAM has only two forms, using two alternate TM exons. Human DSCAM is duplicated on chromosomes 21 and 11 but does not appear to be involved in immunity (53).

FREPs

Mollusk (genus *Biomphalaria*) FREPs are proteins found in the hemolymph with an IgSF moiety (one or two V-like domains) and a fibrinogen domain. FREP gene expression is upregulated following exposure to mollscan parasites such as schistosomes (54); a strain resistant to schistosomes shows an upregulation of the FREP 2 and 4 genes of up to 50-fold. The original discovery of FREPs followed the recovery of snail proteins that bound to worm antigens and thus this is one case in which the correlation between an invertebrate receptor and its ligand is clear. However, it is not known whether the IgSF or fibrinogen domain (or both) bind to the antigen or what effector functions are induced after FREP binding.

FREP diversity is remarkable in that many polymorphic genes as well as alternate mRNA splicing are used to generate the diversity. In addition, there appears to be a diversification mechanism that modifies the FREP genes, either via mutation or gene conversion in the region that encodes the IgSF domains (55). There are ~11 germline genes as suggested by Southern blotting with two to three members/gene subfamily. Therefore, finding 25 sequences within one individual for one member of a subfamily was strongly suggestive of somatic mutation.

185/333

There are a number of additional expanded gene families in the sea urchin genome that encode proteins with immune-related functions (Figure 3.1). The *185/333* genes were first noted because they are highly upregulated in coelomocytes after exposure to whole bacteria and LPS (56). Transcripts of the *185/333* genes constitute up to 6.5% of mRNA in activated coelomocytes. The *185/333* genes represent another family of linked and diverse genes that may be upregulated during immune responses. The encoded proteins have no detectable similarity to any other gene family, but they are highly diversified and are produced by a subset of coelomocytes. The mechanism by which diversity is generated is not known.

Variable Domain Chitin-binding Proteins

First discovered in amphioxus but present in *Ciona* as well, VCBP consist of two Ig domains of the V type but with a different folding motif when compared to Ig or TCR V domains followed by a chitin-binding domain (CBP). The CBP resembles chitinases found throughout the animal kingdom, and, like dedicated chitinases, VCBP are usually expressed in the gut. Apparently, there are no cell-surface expressed forms and thus all VCBP are likely to be effector molecules. Their diversity is enormous, apparently entirely because of polymorphism and polylocism. Each individual can carry up to five genes per haplotype, and in limited studies (11 individuals) an identical haplotype has not been encountered. While the general structure of the V domain is like that of the vertebrate rearranging antigen receptors (but with some unusual properties, including packing in a "head-to-tail" dimeric fashion, totally unlike Ig and TCR)(57). VCBP diversity does not reside in the Ig/TCR CDR resides but rather in the A, A′, and B strands, like in DSCAM.

Penaeidins

Another example of diverse defense molecules is the penaedins, present in crustaceans (shrimp). Penaeidins are AMPs consisting of a conserved leader peptide followed by an N-terminal proline-rich domain and a C-terminal

cysteine-rich domain. Three classes of penaeidins, PEN2, PEN3, and PEN4, are expressed by shrimp hemocytes. A great diversity of isoforms is generated, with substitutions and deletions within the proline- and cysteine-rich domains, suggesting that this is a highly diverse gene family (58). Each penaeidin class is encoded by a unique gene and isoform diversity is generated by polymorphism.

Scavenger Receptors

The SRCR (SRCR) superfamily is an ancient and highly conserved group of cell surface and secreted proteins, some of which are involved in the development of the immune system as well as the regulation of both innate and adaptive immune responses. Group B SRCR domains usually contain eight regularly spaced cysteines that allow the formation of a well-defined intradomain disulfide-bond pattern. Scavenger receptors are best known for their housekeeping function of taking up lipids modified by oxidation or acetylation, but they have many other functions as well, such as uptake of apoptotic bodies (CD36 [59]).

SRCR have been studied mainly in the coleomocytes of echinoderms. Within six hours after bacterial injection, sea urchin coelomocytes upregulate a variety of genes, including an extremely diverse family of SRCR (60). A very large number of SRCR domains are present (~1,200), but each individual may express different groups of SRCR genes at different levels (and even with differential splicing). To assume that they are all involved in defense is premature, because SRCR genes can be both up- and downregulated after infection with bacteria. As mentioned, this high level of gene duplication is a general rule in the echinoderms. Recently, a new TM receptor in the SRCR family was discovered in *Drosophila* called *eater,* which, along with TEPS and DSCAM, is a major player in phagocytosis (61).

In mammals, the SRCR family as a whole is also poorly defined but is involved in endocytosis, phagocytosis, and adhesion, and some members act as PRR that bind to LPS or other bacterial components. One mammalian SRCR (gp340) is secreted into the saliva where it binds streptococci and helicobacter. SRCR are widespread in the human genome and participate as domains in the structure of numerous receptors (e.g., S4D-SRCRB, CD6, CD5-L, CD163), but without showing the high level of duplication seen in the echinoderm families.

C-type Lectins

Lectins were originally defined by their ability to bind carbohydrates, and some have been described previously (and throughout the chapter). They are found in many phyla in either membrane or secreted forms (62). C-type lectins, including CD94 and the Ly49 and NKG2 families, are encoded in the NKC and are central to NK cell function. A molecule resembling CD94 has been detected on a sub-

set of hemocytes in *Botryllus* and *Ciona,* the functions of which are unknown (63). Effector cells of immunity probably also carry the receptors for the histocompatibility locus described recently (see below).

Another large gene family that is implicated in the response of the sea urchin to immune challenge includes 100 small C-type lectins, suggesting the existence of a complex immune system in the sea urchin (32). Diversity of immune receptors due to polymorphism within a population can be enormous. In some cases, polymorphism might be such that hardly two identical individuals are found within a population.

Peroxidasin

Among molecules containing LRR motifs and acting extracellularly, peroxidasin occupies a special place because of its involvement in hemocyte biology in insects and because of its homology to the LRR motifs in the agnathan VLR. *Drosophila* peroxidasin is an assembly of a cysteine-rich motif, six LRR, and four IgSF domains (64). The molecule is conserved in vertebrates although a role in immunity has not been reported. Another molecule called *peroxinectin,* with similarity at the level of the peroxidase region, has been described in crustaceans and shown to be associated with immunity via the PPO cascade (65). Its involvement in immunity is unlike any other effector so far described but illustrates the utility of LRR in many different types of molecules and processes. Pathogens bound by AMP can be phagocytosed or walled off by a barrier of flattened hemocytes and ECM. The ECM forms a basement membrane that becomes stabilized partly through peroxidases that generate tyrosine-tyrosine bonds. The combination of LRR and Ig structures suggests that peroxidasin may precisely mediate adhesion of cells to the ECM.

Defensins

Each metazoan phylum produces a variety of molecules with intrinsic antimicrobial activity (66). Some families are evolutionarily conserved, but generally they diverge rapidly and orthologous relationships are not apparent. There are numerous reviews at the following site: www.bbcm.univ.trieste.it/~tossi/pag4.htm#uno. The best-studied group of AMPs is the defensins, which are amphipathic cationic proteins; their positively charged surface allows them to associate with negatively charged membranes (more common in pathogens), and a hydrophobic surface that allows them to disrupt the membranes (either by disordering lipids or actually forming pores). Most of the molecules are proteins, but an antimicrobial lipid called squalamine, which also is modeled to have hydrophobic and positively charged surfaces, is found at very high levels in dogfish body fluids (67). Defensins can either be constitutively expressed (e.g., in respiratory epithelia in mammals), or inducible (e.g., see the following discussion

for *Drosophila,* Figures 3.5, 3.6). Certain responses that seem systemic, like the production of *Drosophila* defensins, can also take place locally in the damaged tissues themselves; otherwise, a systemic response is initiated in organs distant from the site of infection, such as the fat body in *Drosophila* where induction of bactericidal peptide expression occurs. Defensins are the focus of great attention in commercially bred species such as oysters, mussels, and crustaceans, and it is hoped that they will be applied to medicine, whether they are derived from invertebrates or from vertebrates.

Toll and Toll-like Receptors (TLR)

Toll receptors were originally described in *Drosophila* as genes involved in early development. Later, they were also shown to be essential sensors of infection, initiating antimicrobial responses (68). This family was then revealed to be a major player in innate immunity in the vertebrates as well. As mentioned earlier, across the metazoa, structurally closely related members of the Toll family range from not being involved in immunity (in *C. elegans* and apparently in the horseshoe crab), to being the equivalent of a cytokine receptor (in *Drosophila*), to being pathogen recognition molecules in the vertebrates. Six spaetzlelike and eight Toll-like molecules have been identified in *Drosophila,* but only one or two of them are used in immunity. In jawed vertebrates, they belong to a multigene family of PRR specific for diverse PAMPs and exhibiting different tissue distributions and subcellular locations (69,70). In humans, many are on chromosome 4p and q (TLR 2, 1, 6, 10), but the others are distributed on chromosomes 9, 1, 3, and X.

Ectodomains of TLRs comprise 19 to 25 tandem repeats of LRR motifs made of 20 to 29 aa capped by characteristic N- and C-terminal sequences (Figure 3.2). All of the Toll receptors are homologous and appear similar in domain constitution among insects, echinoderms, and mammals. They also share the TIR domain, which is the intracellular segment shared with the IL1/18/33 receptors of vertebrates, as well as other molecules in plants. TIR domains associate with Myd88 to initiate signaling cascades culminating in the activation of NFκB/Rel (see further discussion later). The specificity of vertebrate TLR binding is concentrated in residues in the concave face of the receptor, which can be modified by various insertions after position 10 of the repeat (Figure 3.2). This feature is not present in the Tolls of invertebrates, which, as mentioned, are activated indirectly by pathogens. Thus, recognition within the Toll/TLR family is different in vertebrates and invertebrates, whereas the signaling cascades activated by Toll/TLR are remarkably conserved (31) (see below, Figure 3.6).

In *Drosophila,* Toll is triggered by an interaction with the unique ligand spaetzle, which is the product of a series of proteolytic cascades, with the most critical enzyme being recently identified (Spaetzle-processing enzyme or SPE [71]). Activation of the cascades triggers the production of AMPs (Figure 3.6). The specificity of recognition is not achieved at this receptor level but rather in solution via other intermediates (see below). In the horseshoe crab, Toll activation by coagulin could perhaps trigger the expression of wound healing proteins involved in restoration of tissues. *C. elegans* has only one Toll receptor, and rather than being antimicrobial, it promotes avoidance of a flatworm pathogen (72).

The arsenal of TLR in vertebrates is endowed with more specific and diverse capacities. Each vertebrate TLR has its range of specificities and, in addition, combinations of different TLR can create different binding specificities (e.g., the association of TLR2 with TLR6 or TLR1 and 2 [73]) This divergence in recognition function is well illustrated by the phylogenetic analysis of the Toll and Toll-related receptors in the different phyla, such as arthropods and vertebrates. Toll and related proteins from insects and mammals cluster separately in the analysis, indicating independent generation of the major families in protostomes and vertebrates (74). Consistent with the expansion of SRCR and NLR genes in sea urchins, hundreds of TLRs also were found in this species (32). TLR of the protostome-type are in small number (three members) while the vertebrate-type has been enormously amplified, all within a single family (222 members) and most without introns. Vertebrate TLRs do not diverge rapidly and evolve at about the same rate, and while there have been some duplications in amphibians and fish, they are not greatly expanded like in the echinoderms (no more than ~20 genes in any species).

PROTEOLYTIC AND SIGNALING CASCADES

Proteolytic cascades are initiated immediately following interaction of foreign material bound by preformed proteins in solution, and this principle is conserved throughout evolution. Indeed, the proteolytic cascade upstream of production of the Toll ligand spaetzle resembles the complement or clotting cascades. The PPO cascade of arthropods leading to melanization and the genesis of antibacterial products described above is another example in which peptidoglycans on microbial surfaces initiate a cascade resulting in the degranulation of hemocytes.

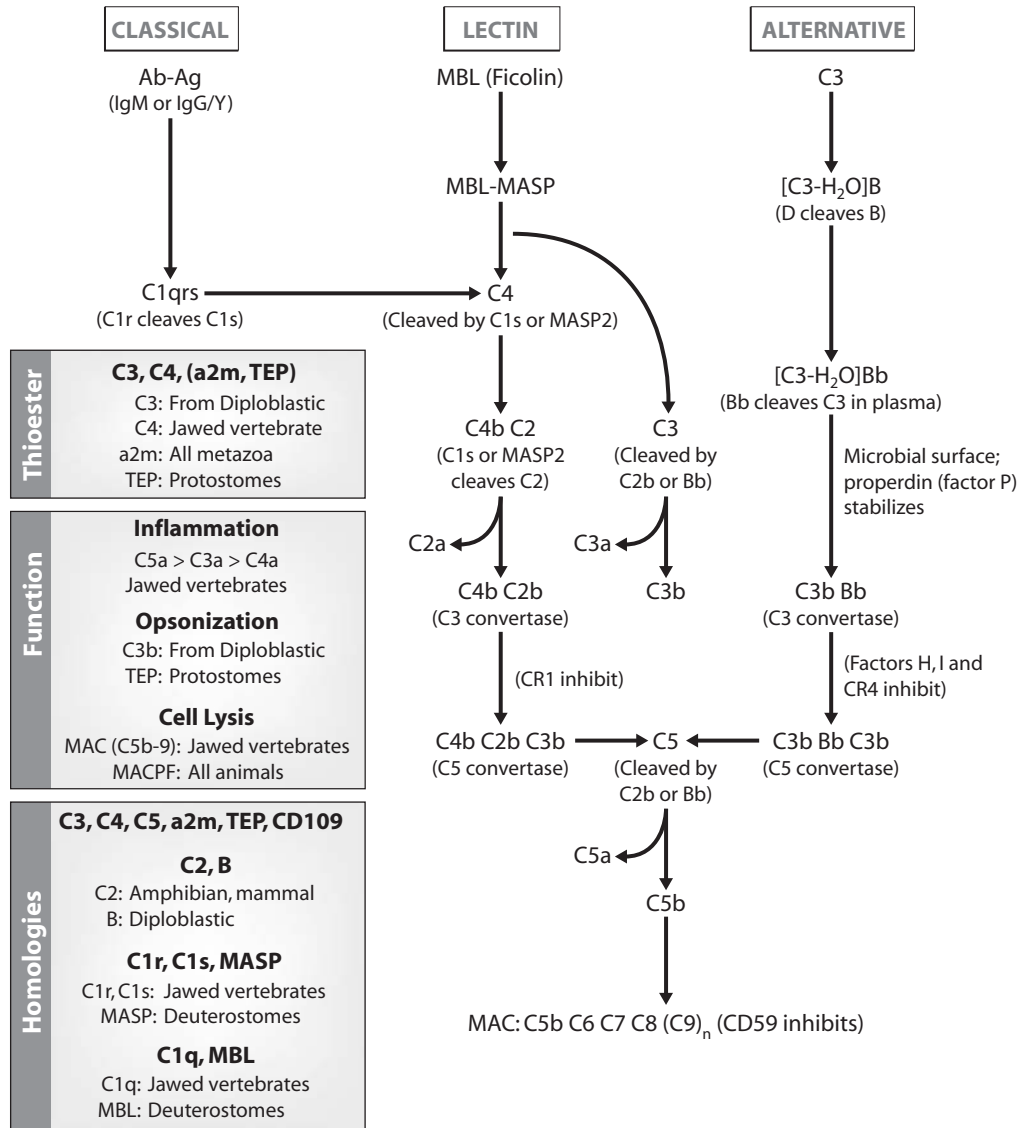
The best-studied immune proteolytic cascade that is (perhaps) surprisingly well conserved in the animal kingdom is complement (5,75). In contrast to the other defense molecules that we have discussed, orthologous complement genes can be detected in all of the deuterostomes without a great deal of expansion/contractions of the gene family (5). The three major functions of complement in jawed vertebrates are: (a) coating of pathogens to promote uptake by phagocytes (opsonization); (b) initiation of inflammatory responses by stimulating smooth muscle contraction, vasodilation, and chemoattraction of leukocytes;


FIGURE 3.7 Evolution of the complement system. The general pathways and appearance of the various components in the phylogenetic tree are emphasized (75).

and (c) lysis of pathogens via membrane disruption (Figure 3.7). The focal point of complement is C3, which lies at the intersection of the alternative, classical, and lectin pathways of complement activation. It is the only known immune recognition molecule (besides its homologue C4) that makes a covalent bond with biologic surfaces. C3 has a nonspecific recognition function, and it interacts with many other proteins, including proteases, opsonic receptors, complement activators, and inhibitors. In the alternative pathway, C3 apparently exposes its thioester bond in solution, and in the presence of host cell surfaces lacking regulatory proteins that stop C3 in its tracks (by cleaving it into iC3b), it associates with the protease factor B (B or Bf). After binding to C3, B becomes susceptible to cleavage by the spontaneously active factor D, resulting in formation of the active protease Bb that in combination with the covalently attached C3 cleaves many molecules of C3 in an amplification step. Another nonadaptive recognition system, the lectin pathway, starts with the MBL (or the lectin ficolin), which is a PRR of the collectin family that binds mannose residues on the surface of pathogens and can act as an opsonin. MBL is analogous to C1q, with its high-avidity binding to surfaces by multiple interaction sites through globular C-terminal domains, but apparently it is not homologous to C1q. Like C1q, which associates with the serine proteases C1r and C1s, the MASP proteases (MBL-associated serine proteases) physically interact with MBL and not only activate the classical pathway of complement by splitting of C4 and C2 (the same function as C1s; MASP-2 appears to be the active protease), but also can activate the alternative pathway in ways that are not understood and thus completely bypass the classical

pathway. Indeed MASP-1 and -2 are homologs of C1r and C1s. Both C1q and MBL can be involved in promoting the uptake of apoptotic bodies by phagocytes, via receptors that remain elusive. Recently, it has been shown that another lectin, ficolin, is also capable of initiating the MASP pathway (76), and it would not be surprising if other activators were discovered in the future. Finally, the classical pathway, which is dependent on antibody molecules bound to a surface, results in the same potential effector outcomes described earlier for the alternative pathway. Novel molecules initiating this pathway are C1q, C1r, C1s, C4, C2, as well as specific negative regulatory proteins.

C3 and MBL (and ficolin) are vital players in the immediate innate immune response in vertebrates, and both have been described in non vertebrate deuterostomes. Thus far, the best-studied invertebrate systems for investigation of C3 evolution are the sea urchin and the ascidians *Halocynthia* and *Ciona,* in which C3 and B molecules and genes have been analyzed in some detail (32,75). In contrast to the very high levels of C3 found in the plasma of jawed vertebrates, sea urchin C3 is not expressed at high levels but is induced in response to infection in coelomocytes. The C3 opsonic function clearly has been identified, but so far initiation of inflammatory or lytic responses (if they exist) has not been obvious. Receptors involved in the opsonization in echinoderms have not been identified, but in the ascidian gene fragments related to the C3 integrin receptor CR3 were identified, and antisera raised to one of the receptors inhibited C3-dependent opsonization.

Hagfish and lamprey C3-like genes were thought to be ancestral C3/C4 genes because the sequence predicts two processing sites (leading to a three-chain molecule), like C4, but a C3-like properdin-binding site is clearly present. However, like C3 in other animals the hagfish protein is composed of only two chains of 115 and 72 kDa, and sea urchin and ascidian C3 sequences predict only two chains (one proteolytic processing site). The lamprey, but not sea urchin C3, has a recognizable C3a fragment known from mammals to be involved in inflammation, so complement's role in inflammation may be a vertebrate invention (but see below).

Thioester-containing proteins (TEPs) have been isolated from *Drosophila* and the mosquito *Anopheles* (77). While the insect molecules function in a C3-like fashion (opsonization), phylogenetic analysis does not show them to be more related to C3 or α2-macroglobulin. TEPs in both these species function as opsonins, binding to parasites and promoting their phagocytosis or encapsulation. The evolution of multimember TEP families in these two insects followed independent evolutionary paths, perhaps as a result of specific adaptation to distinct ecological environments. The *Drosophila* genome encodes six TEPs (whereas there are 15 genes in *Anopheles*), three of which are upregulated after an immune challenge. Two of the *Drosophila* genes evolve rapidly (under positive selection),

perhaps in response to certain parasites' capacity to block TEP activation.

Recently, C3-like genes were identified in the coral (78) and in the horseshoe crab *Limulus* (79). Good phylogenetic support was obtained for their relationship to C3, as compared to other members of the thioester-containing family like the TEPs. This suggests that the emergence of C3 as a defense molecule predates the split between protosomes and deuterostomes. A gene resembling the proteolytic enzyme Bf was discovered in these protostomes as well (and in sea anenomes), suggesting that the entire system was in place a billion years ago (Figure 3.1). The lack of C3 in many other protostomes suggests that the ancestral gene was lost and replaced by the TEPs in the majority of protostomes species (75).

In jawed vertebrates and some lower deuterostomes, certain species express more than one C3 gene, suggesting that the innate system might compensate in animals that do not optimally make use of their adaptive immune system. Changes in the amino acid composition of the C3-binding site are found that may somehow regulate the types of surfaces bound by the different isotypes. Likewise, in lower chordates such as *Ciona*, C3 and other complement components can be duplicated. Diversification of the carbohydrate recognition domains has been observed also in the *Ciona* MBL family (nine members).

Like Ig/TCR/MHC, the classical complement pathway and the terminal pathway membrane-attack complex (MAC) appear first in cartilaginous fish. However, because MBL can activate the classical pathway in mammals, it is possible that some portion of this pathway exists in pre-jawed vertebrates. Nevertheless, C4 and C2 genes have not been detected to date in jawless fish or invertebrates. A *bona fide* C2 homologue has only been identified to the level of amphibians, although duplicate B genes were isolated from cartilaginous fish and teleost fish that may function both in the classical and alternative pathways (75). The lytic or MAC pathway, which is initiated by the cleavage of C5 into C5a and C5b, also has not been described in taxa older than cartilaginous fish. Thus, opsonization and perhaps the induction of inflammatory responses were the primordial functions of the lectin/complement pathways. However, a cDNA clone for CD59, a molecule that inhibits MAC formation in self-cells, was identified from a hagfish library, and some of the terminal components of the pathway have been detected in lower deuterostomes with no described functions. Interestingly, proteins with the MAC/perforin (MACPF) domain have been detected throughout the animal kingdom, and some are even involved in cytotoxic reactions; however, it seems that only vertebrates have *bona fide* terminal C components that are highly evolved for targeted destruction of cell membranes (32,75).

C3, C4, C5, and α2m are members of the same small family. A new cell surface–expressed (GPI-linked) member

of this family with unknown function, CD109, has been discovered (80). The protease inhibitor α2m, clearly present in invertebrates (protostomes and deuterostomes) and vertebrates, is thought to be the oldest, but obviously this must be viewed with caution considering the new data in coelenterates. Along with its ability to bind to and inactivate proteases of all known specificities through a "bait region," it has been shown to be opsonic as well in some situations. α2m, C3, and C4 have internal thioester sites, so this feature is primordial; C5 subsequently lost the site. The first divergence probably occurred between α2m and C3, with C5 and then C4 emerging later in the jawed vertebrates. Consistent with Ohno's vertebrate polyploidization scheme is the fact that C3, C4, and C5 genes are located on three of the four previously described paralogous clusters in mammals (see Figure 3.14), and this also fits with the absence of classical (no antibody) and lytic (no MAC) pathways in phyla older than cartilaginous fish. α2m is encoded at the border of the NK complex in mice and humans, and there are some tempting similarities between these regions and the other MHC paralogues. The C3a and C5a receptors that promote the inflammatory responses on complement activation have been identified in several vertebrates and (perhaps) some lower dueterostomes (81); they are G protein–coupled receptors whose genes may also be found on the Ohnologues (C3aR, chr 12p13; C5aR, chr 19q13). If indeed such receptors are found in the prejawed vertebrates, as suggested by recent pioneering experiments in *Ciona* (82) and *Styela* (83), it will be interesting to determine whether they are involved in some type of inflammation, thought to be the domain of the vertebrates (84).

Signaling Through Innate Surface Recognition Molecules

Four pathways of innate immunity triggering have conserved elements (if not the complete pathways) in eukaryotes: the Toll/TLR-like receptors, the TNFα/IMD receptors, the intracellular Nod, and the JAK/STAT (Figures 3.2, 3.5, 3.6). Although Toll receptors have been found in almost all triploblastic coelomates, most of the work and the elucidation of pathways has been accomplished in *Drosophila* because of the well known advantages of the model. The diversity of peptides that can be produced via the Toll/Imd pathways is substantial and classified in several categories depending on the type of pathogen that is recognized (e.g., gram [+], drosocin, gram (−), [−], diptericin; fungal, drosomycin) with different effector functions. *Drosophila* antimicrobial molecules were originally discovered by Hans Boman and colleagues in 1981, a seminal finding that heralded the molecular analyses of innate immunity in the invertebrates (85).

Toll and Imd Pathways

As described, invertebrate toll receptors are homologous to the vertebrate TLR in the sense that they are integral membrane proteins with an LRR binding regions. *Drosophila* Toll is activated after it binds spaetzle, the product of a proteolytic cascade activated in solution after the interaction of molecules produced by fungi or gram-positive bacteria with soluble PRR; as mentioned, the enzyme that mediates this cleavage has recently been identified (71). The Toll-interleukin 1 receptor (TIR) cytoplasmic domain of the Toll receptor then interacts with MyD88 (itself having a TIR domain) followed by Tube and Pelle, leading to activation of the homologous NFκB system (Cactus or Diff) that then induces transcription of various defense peptides (31,86,87). This is remarkably similar to the cascade of events following activation of mammalian TLRs where after their interaction with PAMPs at the cell surface, a cascade is induced through TLRs, including MyD88, IRAK, TRAF, TAK1, to NFκB via the IKK signalosome (Figure 3.6). Thus, infection-induced Toll activation in *Drosophila* and TLR-dependent activation in mammals reveal a common ancestry in primitive coelomates (or previous), in which defense genes under the control of a common signaling pathway lead to activation of Rel family transactivators.

The Imd pathway is employed for *Drosophila* responses to gram-negative bacteria (31,88). After interaction with a newly characterized cell surface receptor (the PRR PGRP-LC described earlier), in a cascade similar to the mammalian TNFαR signaling pathway, *Drosophila* tak1, an IKK signalosome, and a Relish-mediated (instead of Diff) NFκB step, results in transcription of antibacterial peptides like diptericin (Figure 3.6). The *Drosophila* intracellular pathway is like the mammalian TNFα receptor cascade, which also progresses via a death domain Mekk3, the signalosome, and NFκB resulting in cytokine production. In both cases, a link to pathways leading to programmed cell death is possible; overexpression of *Drosophila* Imd leads to apoptosis. When the activation of either the fly Toll or Imd pathway is considered, they are analogous to a mammalian cytokine/cytokine receptor system (e.g., TNFα) in which a soluble self-molecule activates cells via a surface receptor. Fitting with the recent paradigm put forward on recognition, signaling, and effector phases of the immune response, the diversity of external recognition systems is not matched by an equivalent diversity of intracellular signaling pathways (5). There are conserved signaling cascades coupled to the receptors, giving the impression of conservation of the innate immunity pathways; yet these pathways are also used in development, so which is primordial is an open question.

Responses to Viruses in the Invertebrates

Compared to responses to extracellular pathogens in the invertebrates, the study of responses to intracellular pathogens like viruses is in its infancy. First discovered in plants and in *C. elegans*, the RNAi pathway of defense

against viruses is also operative in *Drosophila* and *Anopheles* (89). Double-stranded RNAs (dsRNA, viral or otherwise) are recognized by the enzyme Dicer 2, generating siRNAs that can associate with complementary RNAs and induce their degradation.

Viruses also induce an "interferonlike response" through a cytokine receptor (domeless) that is homologous to the IL6 receptor and signals through the JAK/STAT pathway. After viral infection, unknown signals (ds RNA?) induce the production of cytokines of the unpaired (Up) family that bind to domeless on neighboring cells and upregulate a large number of genes involved in defense (Figure 3.5). Nothing is known about the effector pathways of these responses, but mutants of one of the induced genes results in increased viral load.

In summary, arthropods (and presumably other invertebrates) use an RNAi pathway as well as a signaling pathway to combat viruses (90,91). As opposed to the systemic plant RNAi response, the same pathway in protostomes is rather cell autonomous. This response was lost in the vertebrates, presumably because: 1) Viruses have been able to effectively counter this response and render it ineffective, and 2) there have been remarkable evolutionary innovations in the vertebrate innate and adaptive immune systems to combat viruses. The discovery of a viral immune response quite like a type I interferon (IFN) response in vertebrates demonstrates that the three major signaling pathways of defense in Drosophila, Toll, Imd, and JAK/STAT, are similar to the vertebrate TLR/IL-1R, TNF, and IL6/IFN pathways, respectively (90).

Natural Killing Activity Across Metazoa

The word *cytotoxicity* encompasses vastly different protocols of cell killing by different cell types. It can be an effector function of cells of the adaptive (CTL or NKT cells) or of the innate arm (*bona fide* NK, see following discussion) of the jawed vertebrate immune system. Similarly the term *NK cells* covers different cell types and functions. NK cells of vertebrates can "recognize" missing self-MHC class I, but also ligands induced on stressed cells following virus infection, transformation, or stress. They can also have an immunoregulatory role by interactions with APCs. Many of these features obviously profit from a comparative approach.

In natural killing, the common denominator is the spontaneous reaction—that is, it does not require any (known) antigenic priming, but does require cell contact. Some form of natural killing can be observed from the earliest metazoans onward. Some marine sponge and corals avoid fusion with one another by the utilization of cytotoxic cells or induce apoptosis at the level of the teguments (92). Phenomena more similar to vertebrate NK killing are observed in sipunculid worms, where allorecognition among populations was shown to result in killing of allogeneic erythrocytes by lymphocytelike cells (93). Similar cases can be also encountered in annelids and molluscs (94). The role of IgSF and lectin receptors known to be involved as NK cell receptors in vertebrates has not been examined in these invertebrates, even though some candidate homologues have been identified.

When comparative morphology or function is not informative, searching for conservation of transcription factors or cell surface markers may be useful. Surveys of IgSF genes across databases have not yielded any promising candidates to date. Despite the presence of polymorphic IgSF members of the receptor tyrosine kinase (RTK) family in sponges, their role in allorecognititon or killing has not been demonstrated (95). As mentioned, similarities were found among the lectin families, especially in prochordates where cytotoxicity has been reported and associated with a discrete population of hemocytes, the granular amoebocytes. The urochordate genome (*Botryllus*, *Halocynthia*, *Ciona*) encodes many lectins with or without typical carbohydrate recognition signatures. Among them, a putative CD94 homologue has been cloned and its expression followed in *Botryllus*; this gene is differentially regulated during allorecognition, and a subpopulation of blood cells carries the corresponding receptor on its cell surface. An orthologue exists in *Ciona*. The function of urochordate CD94 is difficult to envisage, because these animals do not have the known ligand for the CD94 and NKG2 complex (i.e., MHC class I molecules). In addition, polymorphic receptors and ligands for the *Botryllus* histocompatibility reactions have been uncovered (see below), and CD94 does not seem to have any role in this process. However, CD94 is not an independent receptor, and finding it without its partner (NKG2 family members) that can be either activating or inhibiting does not reveal much. It can even be recruited in other cell types such as those in the nervous system, at least in *Ciona* (96).

Other C-type lectin homologs of CD209 and CD69 are linked to the CD94/L gene on *Ciona* chromosome 1 (LDP, personal observation). Could they be part of a "pre-NK complex"? Interestingly, all the human homologs of those lectin genes are present either in the NK complex on 12 p13 (CD94, CD69) or on an MHC paralogue 19p13 (CD209). Taken together with studies of the chicken MHC, which encodes some C-type lectins (see below), the data suggest that a conserved MHC-linked region containing several lectin genes was present before the emergence of MHC class I and II genes.

In addition, a number of genes encoding membrane proteins with extracellular C-type lectin and immunoreceptor tyrosine-based inhibitory motifs (ITIMs) or immunoreceptor tyrosine-based activation motifs (ITAMs), plus their associated signal transduction molecules, were identified in *Ciona*, which suggests that activating and inhibitory receptors have an MHC class I and II–independent function and an early evolutionary origin.

The ligands of these *Ciona* molecules are of great interest to uncover. ITIM- and ITAM-containing molecules have not been encountered in the protostomes (97).

VERTEBRATE ADAPTIVE IMMUNITY

Until recently, it was believed that only the jawed vertebrates had an adaptive immune system. From the discussion of invertebrate immune responses earlier, clearly there are mechanisms to generate high levels of diversity (apparently, even somatically), one of the hallmarks of an adaptive response (9). As described in the Introduction, we feel that the boundary between innate and adaptive immunity is artificial, and at times it is not a useful dichotomy when studying immune responses in diverse organisms (20). Despite this reluctance to exclusively categorize systems as innate or adaptive, some features clearly fall into the latter category, such as clonal expression of highly diverse receptors and specific memory. This condition is not fulfilled for the DSCAM, FREP, penaedin, or 185/333 invertebrate systems described earlier (to our knowledge), but of course we must be open to new mechanisms outside to the jawed vertebrate style of adaptive immunity.

Agnathan VLR

Long ago, the jawless vertebrates (hagfish and lampreys) were reported to mount humoral responses to sheep red blood cells (SRBC), keyhole limpet hemocyanin (KLH), bacteriophage, *Brucella*, and human RBC. For anti–group A streptococcal antigens, hagfish "antibodies" recognize predominantly rhamnose, while mammals recognize N acetylglucosamine. These "antibodies," or at least a proportion of them, were actually the complement component C3 (98). The alternative complement pathway was known in cyclostomes from earlier studies (see earlier discussion), and now most investigators believe that hagfish/lamprey have no rearranging Ig/TCR genes. Lamprey and hagfish do, however, possess cells resembling lymphocytes and plasma cells, with expression of lymphocyte- or at least leukocyte-specific genes, but the quest for RAG or *bona fide* Ig or TCR genes has been a miserable failure. Reports of specific memory in allograft rejection was difficult to reconcile with absence of the rearranging machinery and the possibility to generate specific lymphocyte clones (99).

Our view of the jawless fish immune system has been radically transformed over the past three years. Pancer et al. (100) prepared cDNA libraries of naïve lymphocyte RNA subtracted from lymphocyte RNA derived from lamprey larvae (ammocoetes) that had been immunized to a bacterial/PAMP mixture and found a highly diverse set of LRR sequences enriched in the immunized animals. The clones were not only diverse in sequence, but also in the number of LRR "cassettes" found between invariant 5′ (LRR NT) and 3′ (LRR CT) cassettes (Figure 3.8). Unlike what has been discussed earlier for immune genes in many species (especially the sea urchins), there were not a great number of the germline NT and CT cassettes, suggesting that a somatic recombination process, convergent with Ig/TCR rearrangement, occurred in the developing lamprey lymphocytes. The 5′ and 3′ LRR cassettes are separated by an intron in the genes encoding the germline VLR. Upstream and downstream of the invariant exons are a large number

FIGURE 3.8 Genetics, generation of diversity, and speculative cell biology of the hagfish variable lymphocyte receptor (VLR) system (308). The top line shows an incomplete VLR gene (NT and CT, N-terminal and C-terminal cassettes, respectively). During lymphocyte ontogeny, upstream and downstream LRR cassettes are inserted between the NT and CT gene segments, resulting in an intronless, mature VLR gene (2nd line). VLR proteins are attached to the lymphocyte surface via a GPI linkage and may be released into the blood on antigenic stimulation. Boxed is a hagfish VLR protein, the structure of which was recently elucidated by Kasahara and colleagues (104).

of LRR, which become inserted between the 5′ and 3′ cassettes, presumably during differentiation of the lymphocyte (Figure 3.8). Individual lymphocytes apparently express a uniquely rearranged VLR gene in monoallelic fashion. The potential VLR repertoire may be as great as 10^{14}, vastly outnumbering the lymphocytes within an individual.

Fragments of homology between the LRR cassettes allow for joining and then priming of the synthesis of a copy of the particular transferred cassette. Because these small regions of homology are found throughout the cassettes, "hybrid" LRR can also be formed, further enhancing the diversity over a simple insertion of cassettes. This type of genomic change resembles the initial stage of gene conversion, but because there is not a complete transfer of genetic material between two homologous gene segments, but actually an addition of sequence, the assembly of the mature VLR is more similar to a recombinational mechanism described in yeast called "copy choice" (101). The enzymology of "copy choice" has not been examined; since a gene conversionlike process occurs, perhaps an APOBEC family member is involved. Indeed, APOBEC family members have been detected from the lamprey genome project and seem to be expressed in a lymphocyte-specific fashion (102). Because APOBEC family members are involved in repertoire building in jawless and jawed vertebrates, mutation/gene conversion may have predated RAG-mediated repertoire building of the repertoire.

VLR expressed on naïve lymphocytes are predicted to be associated via a GPI linkage, which has been proven in transfection experiments of mammalian cells. These receptors can also function as effectors in a soluble form: Lampreys immunized to anthrax spores responded with the production of soluble antigen-specific VLRs (103). Presumably, on stimulation, the lamprey lymphocyte either cleaves the GPI linkage, or there is a biosynthetic process that allows "plasma cells" to secrete the molecules. Such a type of recognition, activation, and "secretion" is obviously quite similar to the B cell system of the jawed vertebrates.

VLR homologs were found in two additional lamprey species (*Lampetra appendix* and *Ichthyomyzon fossor*), whereas two types of VLR genes A and B are expressed in hagfish, the only other order of contemporary jawless vertebrates. As in the sea lamprey, the incomplete hagfish germline VLR-A and -B generate somatically highly diverse repertoires. The presence of VLRs in both orders of extant agnathans lends additional molecular evidence favoring a monophyletic origin of cyclostomes. Across phyla, the comparison of the short LRR motifs can be misleading. VLR homologs have been identified in *Ciona* with 32% identity 47% similarity conservation, although without any demonstration of diversity or involvement in immunity. Interestingly the amphioxus genome harbors a large number of intronless VLR-like sequences. They might represent an alternative germline VLR diversity akin to the echinoderm

gene families (TLR, SRCR) described earlier; one could even speculate that they are related to the ancestral VLR before invasion of its analogous "RAG transposon" (discussed later).

The crystal structures of three VLR have been determined (one VLR-A and two VLR-B). As expected for members of this family (see earlier discussion), the framework, or backbone, of the LRR is very similar between the cassettes. Diversity between cassettes is concentrated in the concave surface, presumably the region coming in contact with antigen. The first glance at these diverse receptors in consistent with the idea that VLR-based immunity is an anticipatory immune system, convergent with the Ig/TCR system of jawed vertebrates (104).

In sum, the VLR cell-surface receptors and the soluble molecules appear to be analogous to the jawed vertebrate membrane and secreted BCR, though much needs to be done to understand how VLR-bearing lymphocytes become stimulated. If there is only one type of lymphocyte in the lamprey, one would expect activation to be similar to T-independent pathways in jawed vertebrates (i.e., either direct stimulation through the surface VLR or surface VLR stimulation in combination with a PRR/PAMP interaction). Are VLR responsible for the graft rejections seen in the old experiments? It does not seem likely since MHC molecules have not been detected in the jawless fish. Grafting experiments should be repeated to study potential VLR involvement.

The independent development of two different strategies for receptor somatic diversification at the dawn of vertebrate evolution approximately 500 million years ago reveals the magnitude of the selective pressure applied on to the immune system and the emergence of individualized adaptive responses (99). Apparently, the elaborate innate and "semi-adaptive" immune responses that have evolved in several invertebrates were not sufficient for survival at particular times in evolution.

T Cell Receptors

Ig, TCR, and MHC class I and class II are all composed of IgSF domains (Figure 3.3). The membrane-proximal domains of each Ig/TCR/MHC chain are IgSF C1-set domains, while the N-terminal domains of Ig and TCR proteins are V-set domains encoded by genes generated via rearrangement of two or three gene segments during ontogeny (the membrane-distal domains of MHC are a special case; see later discussion). In all vertebrates studied to date, TCR are membrane-bound and never secreted, while almost all Ig proteins have TM and secreted forms (105).

α/β *Constant Domains*

Genes encoding the two types of TCR, α/β (which accounts for all known MHC-restricted regulatory and effector functions) and γ/δ (which to the best of our knowledge

recognize antigens in an Ig-like manner and may play immunoregulatory or homeostatic roles during certain infections) existed in the earliest jawed vertebrates. cDNA sequences from species in the oldest vertebrate class (cartilaginous fish) revealed genes homologous to all four mammalian TCR chains. As mentioned, although many IgSF members exist in the invertebrates, thus far no *bona fide* Ig/TCR sequences (i.e., IgSF genes generated by somatic rearrangements) have been isolated from jawless vertebrates or invertebrates, a theme repeated throughout the chapter. Several genes from jawless fish and lower deuterostomes resemble antigen receptors, and they will be described in another section.

While TCR genes have been cloned from representatives of most vertebrate classes, few biochemical data are available, except in birds where α/β and γ/δ TCR have been identified with monoclonal antibodies (mAbs) (106). In amphibians, the *Xenopus* α/β TCR was coimmunoprecipitated with cross-reactive antibodies raised against human CD3ε chains (107). α chains from diverse vertebrates are poorly conserved, and the structure of the Cα IgSF domain itself is unusual: Only strands A, B, C, E, and F can be identified; strands E and F are shorter than those of mammals, and strand D is absent. The lack of conservation in this extracellular domain, as well as deletions found in bird and teleost fish TCR (especially in the connecting peptide), suggest that the coreceptor may be structurally distinct from mammalian CD3 complex components. Even within a class, the sequence divergence is great—for example, catfish Cα has only 44% and 29% amino acid identity to trout and pufferfish Cα, respectively.

Pre-Tα, which associates with TCR β chains during thymocyte development, has been identified only in mammals (108). The pre-Tα protein has no V domain, suggesting that the Vβ with which it associates acts as a single-chain binder. Unlike all of the other TCR chains, pre-Tα has a long cytoplasmic tail, which seems to be important for T cell differentiation. Interestingly, the pre-Tα gene is linked to the MHC in mammals, and phylogenetic studies should be performed to determine whether this linkage group is ancient (see later discussion).

The TM region and cytoplasmic tail of Cα are the most conserved parts of the molecule. Cα and Cβ TM segments in all species have the so-called *CART motif,* in which conserved amino acids form an interacting surface with the CD3 complex (109). Besides CART, the opposite TM face with conserved residues Ile-Lys-Leu interacts with other CD3 components. The cytoplasmic region is remarkably conserved among all vertebrates. TCR β genes have been sequenced from several species of cartilaginous and bony fish and two species of amphibians (axolotl and *Xenopus*). In addition to the typical IgSF domain features, there are several conserved regions among vertebrate TCRβ chains, especially at positions 81–86, probably involved in TCR dimerization. There are also remarkable differences: The

solvent-exposed segment 98–120 in mammals is absent in all nonmammalian vertebrates. This loop has been shown in mouse TCR to be important for negative selection events in the thymus; perhaps the absence of this region in nonmammalian vertebrates results in subtle differences in tolerance induction as compared to mouse/human (110). The number of Cβ genes varies in different species: The horned shark has more TCR Cβ genes than the skate, but its genome size is largest of any elasmobranch so far studied. Unlike all other vertebrates, the axolotl has four Cβ genes as well as 4 DJCβ clusters that rearrange to the same collection of Vβs.

Like Cα, Cβ sequences are not well conserved in evolution (e.g., the *X. laevis* Cβ gene does not cross-hybridize with *X. tropicalis* genomic DNA, and catfish Cβ has only 41%–42% identity with other teleost Cβ and 26% identity with horned shark Cβ). Two different catfish Cβ cDNA sequences were identified, suggesting the existence of either two loci or allotypes, as is found in mammals. Indeed, the damselfish Cβ was shown to be encoded by two polymorphic genes, and this feature seems to extend to other teleosts. As the polymorphic sites are believed to interact with the associated CD3-signalling molecules, the authors suggested that signals might be transduced to T cells in different ways depending on the particular expressed Cβ allele. Also the damselfish Cα gene seems to be encoded by polymorphic alleles as well (111).

α/β *Variable Domains*

Because T cell recognition is MHC-restricted, TCR V regions have been evolutionarily selected for different properties as compared to Ig; indeed TCR V regions are much less similar to each other than are Ig V regions (105). Further, TCR Vs, unlike IgV$_H$, have conserved CDR3 lengths, suggesting that there is a restricted size for recognition of MHC-peptide complexes (112).Four Vα families were identified among only six skate cDNA clones, and six Vα families were identified in trout, and three in channel catfish. In the axolotl, five Vα and at least 14 Jα segments were identified, and 32 different trout Jαs have been sequenced. Thus, the α loci in all vertebrates examined have many J segments, and consistent with the mammalian paradigm, the absence of D and the large numbers of J segments favors the potential for receptor editing during thymic positive selection. A large number of Vβ gene families are another evolutionarily conserved feature. At least seven TCR Vβ families were isolated from horned sharks, and four to six in skate. at least four in trout (one with limited amino acid sequence similarity to the human Vβ 20 family), and 19 in *Xenopus*. In axolotls, Vβs are classified into nine categories, each with 75% or more nucleotide identity; since only 35 genes were cloned, there are probably more families, and several are related to mammalian Vβ genes (human Vβ13 and Vβ20). The D segment is encountered in all vertebrate classes, alone or in conjunction with other

Dβ. These segments usually encode glycines, suggesting a selection for flexibility in TCR CDR3 (112).

The *Fugu* α/δ locus suggests an organization similar to mouse/human, but with more rearrangement by inversion (interestingly, similar to the Ig L chain loci in teleosts; see discussion later in the chapter). The complete elucidation of the salmon α/δ TCR locus demonstrated extraordinary diversity of all gene segments, including the large number of Jα segments, and the flounder TCR loci are also highly diverse (105,113). Pulsed field gel analysis suggested that the horned shark α and δ TCR loci are closely linked (114).

The γ/δ TCR

cDNA sequences from the skate have significant identity with prototypic mammalian γ and δ TCR genes with extensive V region diversity, putative D segments in δ, and varying degrees of junctional diversity (114). Some of the six Vαs can associate with Cδ, and no specific Vδ has been detected, strongly suggesting that like mammals, the axolotl δ locus lies within the α locus. Vδ diversity was diminished in thymectomized animals, and TCR δ chains are expressed by cells in lymphoid organs, skin, and intestine. Chicken γ/δ T cells were identified long ago (106). Expression is found in thymus, spleen, and a γ/δ T cell line, but not in B cells or α/β T cell lines. Three V subfamilies, three J gene segments, and one C gene were identified at the TCR γ locus. All Vγ subfamilies participate in rearrangement during the first wave of thymocyte development, and the γ repertoire diversifies from embryonic day 10 onward, with random V-J recombination, nuclease activity, and P and N nucleotide addition. A new type of γ/δ TCR has been described in sharks and marsupials, which will be described in the IgNAR section that follows.

In ruminants and chickens (so-called *GALT species*—see discussion later in this chapter), the γ/δ repertoires are quite diverse, and there seems to be ligand-mediated selection of γ/δ cells during ontogeny. In sheep, where γ/δ TCR diversity is thymus dependent and follows a developmentally regulated progression, no invariant γ/δ TCRs are found. The degree of γ/δ expression is correlated with the evolution of the TCR V families in warm-blooded vertebrates. Indeed, mammals can be classified into "γ/δ low" (humans and mice, in which γ/δ T cells constitute limited portion of the T cell population) and "γ/δ high" (sheep, cattle, and rabbits, in which such γ/δ cells compose up to 60% of T cells). TCR V genes form subgroups in phylogenetic analyses, and humans and mice have representative loci in most subgroups whereas the other species appear to have lost some (115). Thus, γ/δ-low species have a high degree of TCR-V gene diversity, while γ/δ-high species have limited diversity. Interestingly this pattern is similar to that found for IgV$_H$ genes (see discussion later in this chapter).

Generally speaking, the γ/δ TCR can either be used for innate recognition (e.g., the cells in the skin of mice or the blood of humans) or adaptively with an enormous reper-toire in ways we do not understand well—this will be discussed in more detail in the IgNAR and Conclusions sections.

Immunoglobulins

A typical Ig molecule is composed of four polypeptide chains (two heavy [H] and two light [L]) joined into a macromolecular complex via several disulfide bonds (Figure 3.9; note that an entire review issue has recently been devoted to the topic of comparative aspects of Igs, *Dev. Comp. Immunol.* 2006, Vol 30, issues 1 and 2). Each chain is composed of a linear combination of IgSF domains, much like the TCR, and almost all molecules studied to date can be expressed in secreted or TM forms.

Ig Heavy Chain Isotypes

Like all other building blocks of the adaptive immune system, Ig is present in all jawed vertebrates (Figures 3.1 and 3.9). Consistent with studies of most molecules of the immune system, the sequences of IgH chain C region genes are not well conserved in evolution, and insertions and deletions in loop segments occur more often in C than in V domains. As a consequence, relationships among non-μ isotypes (and even μ isotypes among divergent taxa) are difficult to establish. Despite these obstacles, recent work has allowed us to infer a working evolutionary tree among all of the isotypes.

IgM

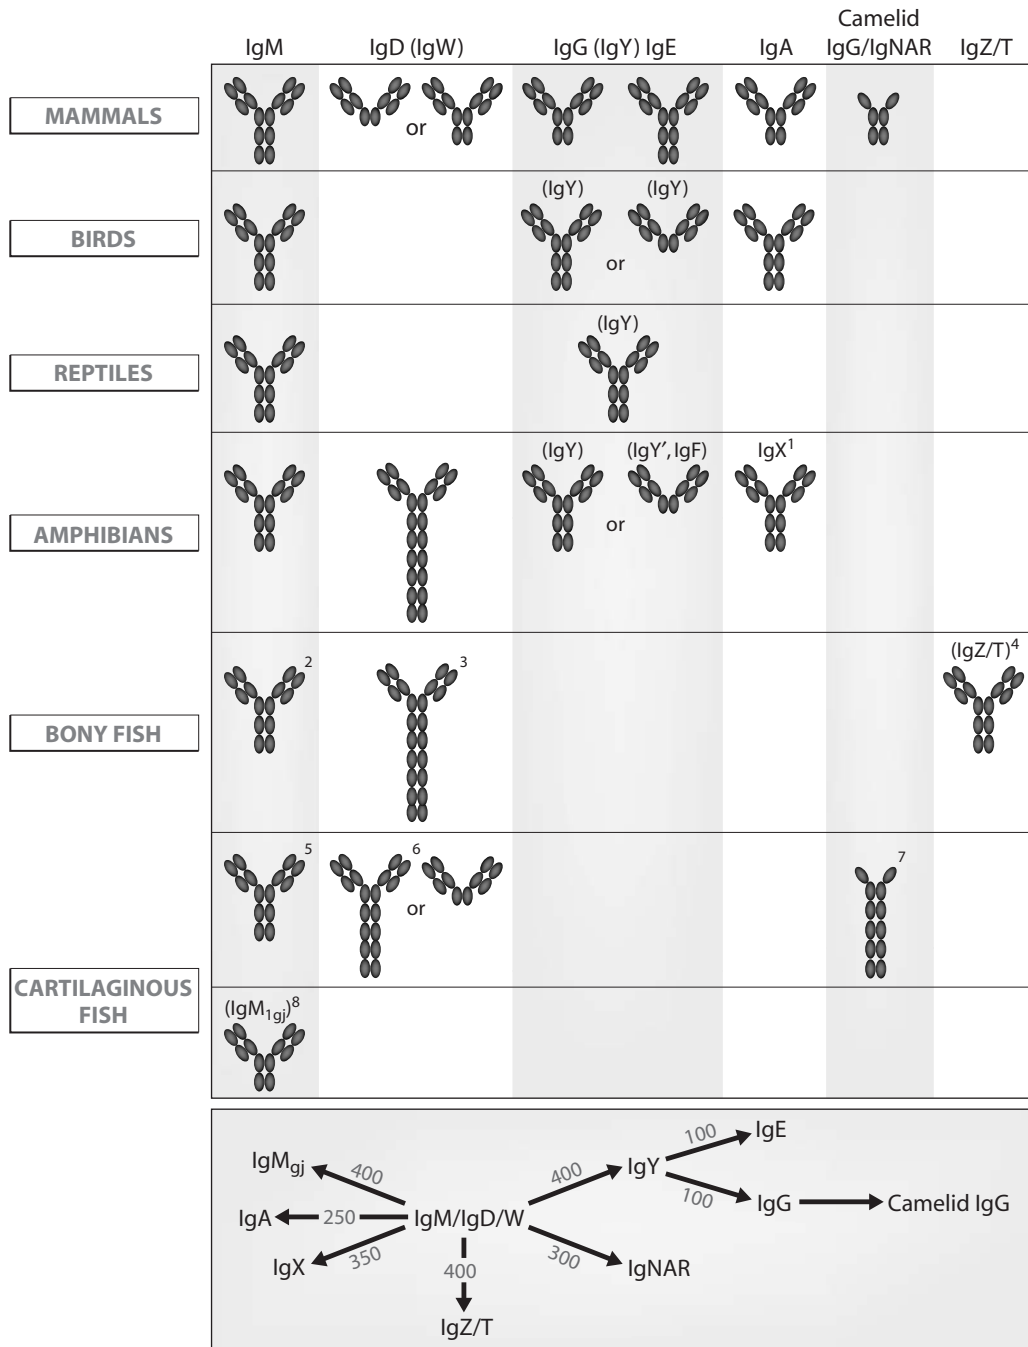
IgM is present in all jawed vertebrates and has been assumed to be the primordial Ig isotype. It is also the isotype expressed earliest in development in all tetrapods; until recently it was believed to be the case in fish as well, but this view has changed recently (see discussion later in this chapter).The secretory μ H chain is found in all vertebrates and usually consists of one V and four C1 domains and is heavily glycosylated. H chains associate with each other and with L chains through disulfide bridges in most species, and IgM subunits form pentamers or hexamers in all vertebrate classes except teleost fish which form tetramers (116). The μ C$_H$4 domain is most evolutionarily conserved, especially in its C-terminal region. There are several μ-specific residues in each of the four C$_H$ domains among vertebrates, suggesting a continuous line of evolution, which is supported by phylogenetic analyses. Like TCR TM regions described earlier, μ TM regions are also well conserved among sharks, mammals, and amphibians, but the process by which the Ig TM mRNA is assembled varies in different species (117). In all vertebrate classes except teleosts, the μ TM region is encoded by separate exons that are spliced to a site on μ mRNA located ~30 bp from the end of the C$_H$4-encoding exon. In contrast, splicing of teleost fish μ mRNA takes place at the end of C$_H$3 exon. In holostean fish (gar and sturgeon), cryptic splice


FIGURE 3.9 Ig isotypes in the jawed vertebrates. The bottom panel displays the approximate divergence times of all isotypes. IgM/D/W was found at the inception of adaptive immunity (160). **1:** IgX is in the IgA column because it is preferentially expressed in the intestine, but it is actually most similar in sequence to IgM; **2:** secreted IgM in teleost fish is a tetramer—the TM form only has three C domains; **3:** the teleost fish IgD H chains incorporate the μC1 domain via alternative splicing; **4:** the new bony fish isotype, IgZ/T, may not be found in all fish species; **5:** the secreted form of shark/skate IgM is present as a pentamer and monomer at ~equal levels; **6:** the TM form of IgW has 4 C domains; **7:** a major TM form of IgNAR has three C domains, and IgNAR is related to camelid IgG by convergent evolution; **8:** no TM form has been found (to date) for IgM$_{1gj}$.

donor sites are found in the C_H4 sequence that could lead to conventional splicing, but in the bowfin there is another cryptic splice donor site in C_H3. Some modifications apparently related to the particular environment were noticed in the Antarctic fish *Trematomus bernacchii*. There are two remarkable insertions, one at the V_H-C_H1 boundary and another at the C_H2-C_H3 boundary; the latter insertion results in a very long C_H2-C_H3 hinge region. Rates of nonsynonymous substitutions were high in the modified regions, suggesting strong selection for these modifications. These unusual features (also unique glycosylation sites) may permit flexibility of this IgM at very low temperatures (118).

It has been known for a long time that in all elasmobranchs, IgM is present at very high amounts in the plasma of cartilaginous fish and that it is found in two forms: multimeric (19S) and monomeric (7S) (119). It is unlikely that the two forms are encoded by different gene clusters since: 1) Peptide maps are identical; 2) early work by Clem found the sequences of the cysteine-containing tail of 19S and 7S H chains to be identical; and 3) all identified germline VH families are represented for the 19S form (116). Although most studies (but not all) reported that 19S and 7S are not differentially regulated during an immune response, in a recent study, the 19S response wanes over time and a stable 7S titer is maintained for periods of up to two years after immunization (120). In addition, antigen-specific 7S antibodies observed late in the response have a higher binding strength than those found early, suggesting a maturation of the response, also generally at odds with the previous literature. Finally, when specific antibody titers were allowed to drop, a memory response was observed that was exclusively of the 7S class. This work has shown that a "switch" indeed occurs in the course of an immune response; whether the "switch" is due to an induction of the 19S-producing cells to become 7S producers, or whether there are lineages of 19S- and 7S-producing B cells is an open question. One working hypothesis is that J chain expression is important for regulating whether a B cell makes 19S or 7S Ig, but of course that could be at the lineage level or the switch level.

IgM$_{1gj}$. Nurse shark *Ginglymostoma cirratum* expresses an IgM subclass in neonates (121). The V_H gene of this subclass underwent V-D-J rearrangement in germ cells ("germline-joined" or "gj"; see discussion later in this chapter). Expression of H_{1gj} is detected in primary and secondary lymphoid tissues early in life, but in adults only in the primary lymphoid tissue, the epigonal organ (see later discussion). H_{1gj} associates covalently with L chains and is most similar in sequence to IgM H chains, but like mammalian IgG, it has three rather than the typical four IgM constant domains; deletion of the ancestral IgM second domain thus defines both IgG and IgM$_{1gj}$. Because sharks are in the oldest vertebrate class known to possess anti-bodies, unique or specialized antibodies expressed early in ontogeny in sharks and other vertebrates were likely present at the inception of the adaptive immune system. It is suggested that this isotype interacts either with a common determinant on pathogens or a self-waste product.

IgNAR (Ig NAR) and NAR-TCR. A dimer found in the serum of nurse sharks and so far restricted to cartilaginous fish, IgNAR is composed of two H chains each containing a V domain generated by rearrangement and five constant C1 domains (122). IgNAR was originally found in sera, but TM forms exist as cDNA and cell-surface staining is detected with specific mAbs. The single V resembles a fraction of camel/llama (camelid) IgG that binds to antigen in a monovalent fashion with a single V region (116). In phylogenetic trees, NAR V domains cluster with TCR and L chain V domains rather with that V_H. A molecule with similar characteristics has also been reported in ratfish, although it was independently derived from IgM like the camelid molecule emerged from *bona fide* IgG. IgNAR V region genes accumulate a high frequency of somatic mutations (see later discussion).

The crystal structure of a Type I IgNAR V regions showed that, in contrast to typical V regions, they lacked CDR2 and had a connection between the two IgSF sheets much like an IgSF C domain (Figure 3.3, [123,124]). The domain wraps around its antigen (hen egg lysoszyme), with the CDR3 penetrating into the active site of the enzyme. The structure of a type II V region was revealed as well, showing a disulfide bond between CDR1 and CDR3 that forces the most diverse regions of the molecule to form a raised cap, similar to what has been described for camelid V domains (116,124). In total, the differential placement of disulfide bonds forces major changes in the orientations of CDR1 and CDR3 and provides two major conformations for antigen binding.

While analyzing the TCRVδ repertoire in nurse sharks, an entirely new form of this chain, which encodes three domains, V-V-C, was detected (125). The C is encoded by the single-copy Cδ gene, and the membrane-proximal V is encoded by a Vδ gene that rearranges to the DJδ elements. The membrane distal V domain is encoded by a gene in the NAR family, found in a rearranging VDJ cluster typical of all cartilaginous fish Ig clusters. The NAR-TCR V genes, unlike IgNAR V genes that have three D segments, only have a single D region in each cluster. The particular Vδ loci linked to each NAR-TCR gene—called *NAR-TCR-supporting Vδ*—encode a cysteine in CDR1 that likely makes a disulfide bridge with the NAR-TCR V domain. The J segment of the rearranged NAR-TCR V gene splices at the RNA level directly to the supporting Vδ segment, which has lost its leader exon. This organization likely arose from an IgNAR V cluster that translocated to the TCRδ locus upstream of a Vδ gene segment. After modifications of the supporting Vδ genes, this entire V-V gene set duplicated and diverged

several times in different species of sharks. About 25% of the expressed nurse shark TCR δ repertoire is composed of this new type of TCR (encoded by 15-20 V-V genes in this species) and have proposed that the typical γ/δ TCR acts as a scaffold on which sits the single chain NAR V.

Our interpretation is that, true to the proposal that γ/δ TCRs interact with free antigen, the NAR V is providing a binding site that can interact with antigen in a different way than conventional heterodimeric Vs. Thus, this is the first case in which a particular V region family has been shown to be associated with a BCR and TCR; in the case of the BCR, the function likely resides within the Fc portion of IgNAR and for the TCR the function (cytokine secretion, killing) lies within the T cell itself. Interestingly, a second TCRδ chain locus has also been described in marsupials with properties similar to NAR-TCR (126). In this case, there are also two V domains, but one (proximal to the membrane) is germline-joined and only the membrane-distal domain undergoes rearrangement. This new TCRδ locus is preferentially expressed early in development. Discovery of two such antigen receptor loci in sharks and marsupials suggests that this type of receptor will be found in other vertebrates as well.

IgR/IgNARC/IgW/IgX/IgD

All elasmobranchs studied to date have another isotype called *IgW* (116). It was probably discovered long ago in skates as a non–IgM-secreted isotype called *IgR,* but no protein sequence of this molecule has been obtained for confirmation. Subsequently, an Ig gene was discovered in skates encoding a three-domain molecule with an unusual secretory tail that was named IgX (not to be confused with another isotype with that name in amphibians, Figure 3.9). A high molecular weight (MW) species detected by northern blotting with an IgW probe suggested that there might be a longer form of this isotype, subsequently shown to be true in the sandbar shark (IgW), nurse shark (IgNARC—it was so-named because the C domains had highest similarity to IgNAR C domains) and skate). It was originally believed that sharks only expressed the long (seven-domain) IgW form, but they were later shown to have both secretory forms); the reason for the discrepancy was shark-to-shark variation in expression of the short form, for unknown reasons (127). The major IgW TM form, like IgM, is composed of five domains, but variants with three domains—like the secretory forms—were also detected. Very little is known about the function of this isotype, as IgW-specific mAbs have not been generated as they have for IgM and IgNAR.

IgW was thought to be a dead-end isotype in the cartilaginous fish, but a homologue was found in the lungfish (128). It also is present in two secreted forms, one with eight domains and the other, like in the elasmobranchs, with three domains (unfortunately the secretory tail was not sequenced, and the TM form was not studied). Re-

cently, an Ig isotype was found in *X. tropicalis* most related to the lungfish IgW (129,130). Computer searches of databases for the *X. tropicalis* genome project uncovered a new isotype flanked by the IgM and IgX genes at the IgH locus (Figure 3.10). The deduced amino acid sequence obtained from the exons on the genomic scaffold suggests a nine-domain molecule. The N-terminal C domains and the TM regions are most similar to mouse and human IgD regions, and its genomic location also suggests that it is an IgD equivalent. Thus, these new data reveal that like IgM, IgW/D is an isotype that was present at the emergence of all extant vertebrate taxa.

An interesting feature of this IgD/W locus is that it is highly plastic in evolution, both in terms of the number of domains in different fish species and the plethora of splice variants found, at least in cartilaginous fish (127). In sharks, two of the C domains were derived ∼250 million years ago by a tandem duplication event, and there was a *Xenopus*-specific, two-domain tandem duplication event as well. Within teleost fish, the number of C exons for this isotype is different in various species, and the secreted and TM forms seem to be encoded by different loci in the catfish (Figure 3.10). In addition to the splice variants described earlier in the cartilaginous fish and lungfish, in teleosts, the IgM C1 domain exon is spliced into the IgD transcript (131). Even in mammals, there are different numbers of C domains in different species, and even exons that have emerged quite recently in evolution. It is our impression that this is the Ig locus that evolution "plays with," perhaps using it for different functions in vertebrate taxa. We are obviously at the beginning of our analysis of this system, but perhaps an evolutionary perspective of IgD/W will eventually lead to an understanding of the function of this ancient isotype.

IgZ/T

A third, novel bony fish isotype was uncovered in screens of the EST and genomic databases called *IgZ* in zebrafish and *IgT* in trout (132,133). Its genomic organization parallels the TCR α/δ locus in that the IgZ/T D, J, and C elements are found between the VH and Cζ/Cμ exons (Figure 3.10). IgZ/T is a five-domain H chain predicted to associate with L chains. The authors propose that lymphocytes bearing IgZ may be B1 cell equivalents, but a preliminary VH repertoire analysis does not suggest that unique sets of V regions are expressed on IgZ compared to IgM. IgT is not preferentially expressed over IgM early in trout development, and there is high expression in the spleen throughout ontogeny into adulthood. The effector function of IgZ/T is not known, but there may be species-specific differences in expression during ontogeny and in adult life among bony fishes.

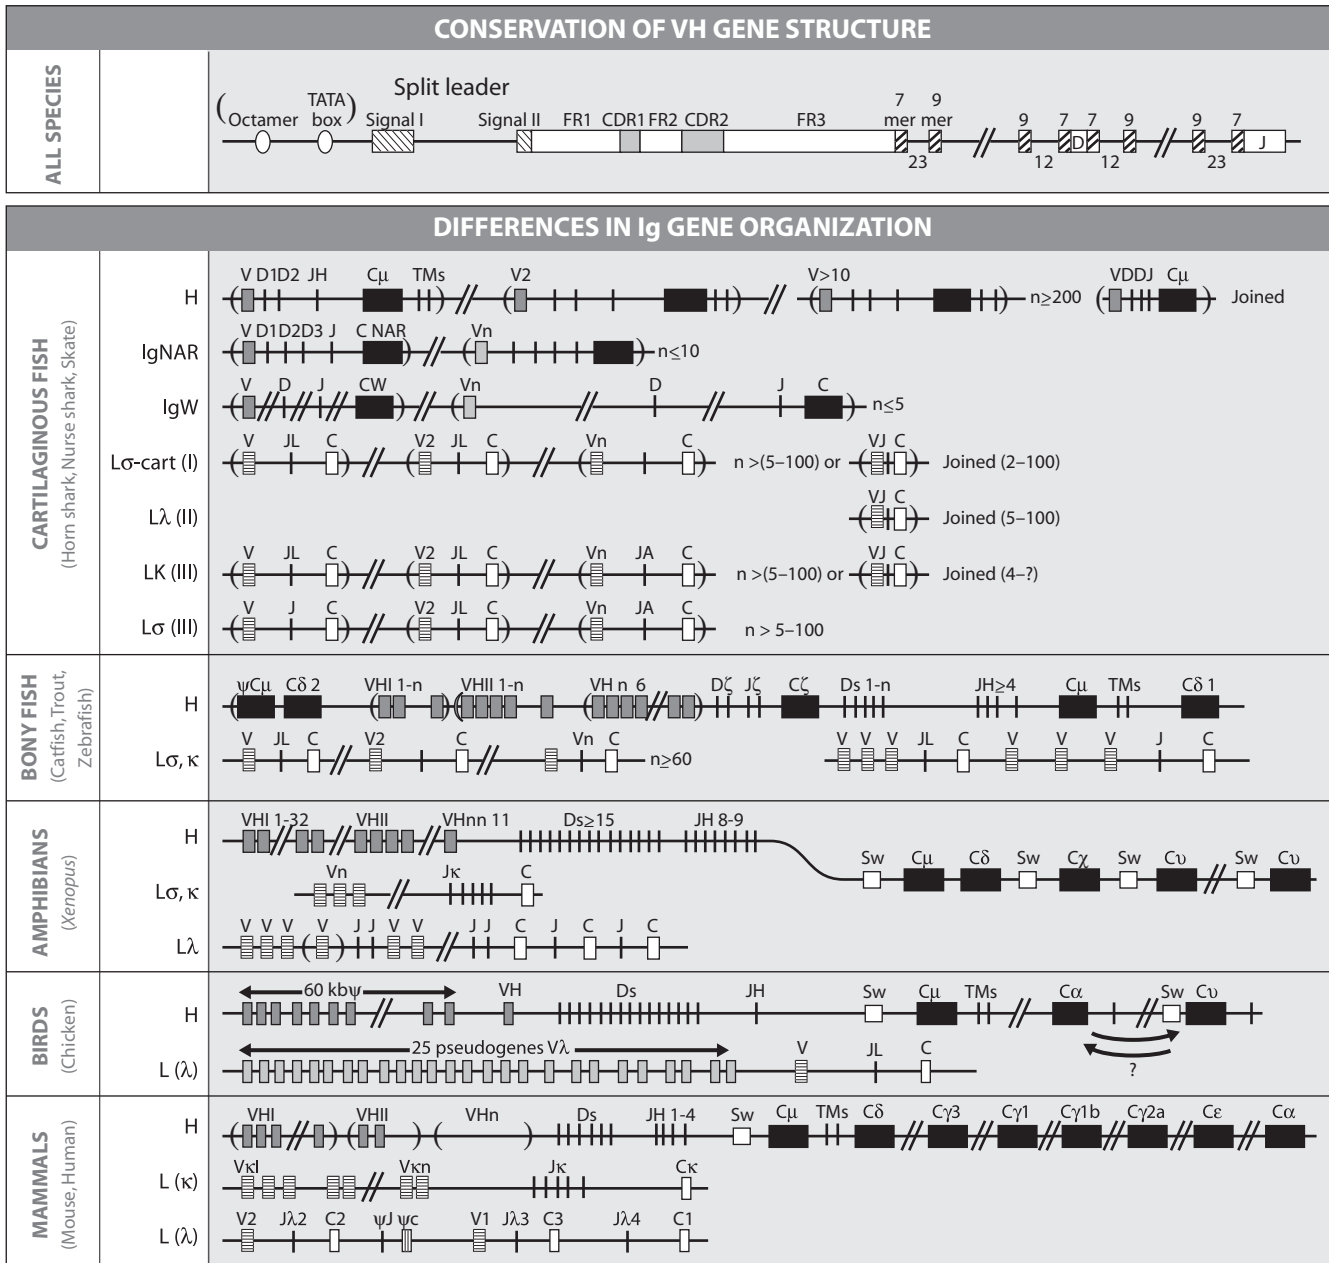
Other Isotypes Related to IgG, IgE, IgA and the Switch. Other isotypes consist of four C domains in nonmammalian vertebrates, including *Xenopus* IgY and IgX, non-μ


FIGURE 3.10 Organization of H and L chain genes in all jawed vertebrates. All cold-blooded gnathostomes except bony fish have three L chain isotypes, κ, λ, and σ; mammals have κ and λ; and birds have only λ. V_H genes, gray; C_H genes, black; V_L genes, horizontal lines; V_C genes, white. The top line shows a germline V, D, J gene with canonical RSS and promoter elements. Isotypes for each class are found in Figure 3.9. See text for details.

isotypes of *Rana*, IgY of axolotl, and IgA and IgY of birds (116,134). In *Xenopus*, IgY is thymus dependent; IgM and IgX are not, although thymectomy impacts specific IgM antibody production (i.e., antigen-specific IgM can be produced, but there is neither an increase in affinity after immunization nor elicitation of plaque-forming cells). IgM and IgX plasma cells are abundant in the gut, while IgY is expressed primarily in spleen. Axolotl IgM is present in the serum early during development and represents the bulk of specific antibody synthesis after antigenic challenge. In contrast to *Xenopus* IgY, the axolotl orthologue appears late in development and is relatively insensitive to immunization. From one to 7 months post-hatching, axolotl IgY is present in the gut epithelium, associated with a

secretory component. IgY progressively disappears from the gut and is undetectable in the serum of 9-month-old animals. Thus, axolotl IgY, like *Xenopus* IgX, may be analogous to mammalian IgA. *Xenopus* IgX and IgY are not homologous (similar to sequence) to any mammalian non-μ Ig isotype and are most similar to IgM. The TM and cytoplasmic domains of *Xenopus* TM IgY, however, share residues with avian IgY and mammalian IgG and IgE, suggesting that mammalian/avian isotypes share a common ancestry with amphibian IgY (135). This homology is especially interesting, because a study in mice suggested that the IgG cytoplasmic tail is the central molecular element promoting rapid memory responses. Finally, another *Xenopus* isotype was discovered from the databases, called *IgF* (130) or *IgY'* (because it is closely related to IgY, probably duplicating within the *Xenopus* lineage). Like other isotypes described in this section, it only has two C domains, but rather than alternative splicing, the gene is organized in such a manner. There has been no biochemical identification of IgF to date.

Although cartilaginous and teleost fish have multiple Ig isotypes, CSR appears first in evolution in amphibians (134,136). CSR results from fusing switch regions upstream of the μ gene and another 3′ isotype gene, accompanied by the deletion of the intervening sequences. Among vertebrates, mammalian and bird class switch regions are GC-rich and contain tandem repeats in which certain motifs such as TGGGG, GGGGT, AGCT, GGCT are abundant. Because of the GC richness of these regions, transcription generates stable R loops that provide single-stranded substrates for AID activity. The first comparative studies on switch were done in the amphibian *Xenopus,* where the switch μ and χ region is not GC rich but AT-rich and cannot form R loops (137). Replacement in mouse of the switch region with the *Xenopus* switch μ showed that it mediated efficient CSR and that the junctions were associated with the short palindromic AGCT motifs, already recognized as the main component of the *Xenopus* switch μ region. As predicted from the absence of R loops, *Xenopus* switch μ supported recombination in both orientations. The breakpoints were located in the AGCT palindrome-rich region of the switch box. Other motifs have been identified in the other switch regions, such as in IgX and chicken isotypes; all of these correspond to the DGYW hotspot consensus. AID-mediated deamidation in the context of these motifs may be the conserved major event in the initiation of CSR.

As mentioned, a single gene can encode different Ig forms, such as for duck IgY, cartilaginous fish IgW, and camel IgG loci (116). It has been suggested that the two avian IgY short and long forms could be the functional equivalents of both IgE and IgG, respectively; the same may be true of the cartilaginous fish IgW short and long forms with two and six domains, respectively. As mentioned, IgF or IgY' also falls into this category but not through alternative splicing (130).

V_H *Evolution*

Diversity of the immune repertoire depends on the variety of V segments inherited in the germline and on the further diversification by rearrangement (CDR3 only) and SHM (all CDR). Early in life the repertoire depends chiefly on the inheritable genes as one finds little N-region diversity and somatic mutation (with exceptions; see discussion later in this chapter). A central question is how antibody germline V genes diversify CDR during evolution while they are subject to homogenizing forces operating in most multigene families. Perhaps environmental antigens have played a major role in shaping the germline repertoire and have selected some V_H/V_L germline sequences used by neonates. V_H families arose in a bony fish lineage and have been conserved for hundreds of millions of years (138). Conserved regions defining families are found on solvent-exposed faces of the V_H, at some distance from the antibody-combining site. Phylogenetic analyses show clustering of V_H into groups A, B, C, D, and E. All cartilaginous fish V_H belong to the monophyletic group E; bony fish V_H genes cluster into all groups (one group [D] unique only to them). By contrast, group C includes bony fish sequences as well as V_H from all other classes except cartilaginous fish. Another phylogenetic analysis classifies mammalian V_H genes in three "clans" (I, II, and III), which have coexisted in the genome for >400 million years. Only in cartilaginous fish does it appear that V_H gene families have been subjected to concerted evolution that homogenized member genes (except for the IgM_{1gj} V region described earlier). It has been debated whether Ig V genes could be under direct positive selection, because these genes hypermutate somatically. However several features (e.g., codon bias) and discovery of high-replacement/silent ratios in germline gene CDR codons indeed argue for positive selection during evolution (139,140).

In summary, much of the V_H germline repertoire has been conserved over extremely long periods of vertebrate evolution. The birds and some mammalian species that rely on gut-associated lymphoid tissue (GALT) to generate Ig diversity (see the discussion later in this chapter) are exceptions with a reduced germline repertoire (at least expressed repertoire), but as will be seen later in this discussion, gene conversion and SHM compensate for this situation in formation of the primary repertoire. Even in the cartilaginous fish where there is a single V_H family, there is nevertheless heterogeneity in CDR1 and CDR2 sequences (as well as hypermutation) that must boost diversity in the expressed repertoire.

Ig Light Chains

L chains can be classified phylogenetically not only by their sequence similarity, but also by the orientation of their V and J RSS, which differ for mammalian λ and κ. There has been much debate regarding the affiliations of

L chains in various vertebrates, but as sequences have accumulated, a picture starts to emerge (141). Contrary to what was believed, the κ and λ L chains emerged early in vertebrate evolution, probably in the cartilaginous fish or placoderms (Figure 3.10). In addition, a third L chain, σ, originally described in *Xenopus* as a dead-end isotype, appears to be the ancestral clade and is present in all cold-blooded vertebrates.

Elasmobranchs have four L chain isotypes (types I, II, III, and IV), and the combined data suggest that they are present in all elasmobranchs. Type IV seems to be the ancestral group and is the orthologue of the unusual *Xenopus* σ L chain, and type I is a dead-end variant of this isotype called σ-*cart* (for cartilaginous fish). Type II L chains are the λ of birds, *Xenopus,* and mammals and have been cloned from sharks and skates; all genes of this isotype are "germline-joined." The type III is clearly κ-like, at least in the V region (and RSS orientation). These relationships are more noticeable in the V sequences, which have some defining characteristics such as CDR length; while the C sequences also fall into the same clusters, they do so with much less phylogenetic support (141). Different elasmobranch species express the L chain isotypes preferentially—for example, κ in nurse sharks, σ in horned sharks, and λ in sandbar sharks. This pattern of expression may be due to expansions/contractions of the different isotype genes in various elasmobranch lineages (142).

Almost all of the L chains in bony fish can be categorized as either κ or σ, despite the large number of gene expansions and contractions. Genes in different species can be found either in the cluster type organization, translocon, or some intermediate type ([143]; discussed later in this chapter). In some species, mAbs were produced that distinguish L chain classes, such as the F and G L chains of the catfish, which are both of the κ type but are quite divergent in sequence.

MAb studies suggested the existence of three *Xenopus* L chain isotypes of 25, 27, and 29 kD with heterogeneous 2D gel patterns and preferential association of some L chain isotypes with IgY H chains (142). Indeed, three *Xenopus* L chains genes have been isolated: ρ (now κ), σ, and λ. Only one C gene is present in the ρ locus, and it encodes the most abundant L chain. The V and J RSS are of the κ-type, and the five identified J segments are nearly identical (Figure 3.10). The locus is deleted, like mammalian κ, when the other isotype genes are rearranged. Southern hybridizations with genomic DNA from different animals showed V_L sequences to be both diverse and polymorphic. The third *X. laevis* L chain isotype predicted from the biochemical studies is related to mammalian λ genes and consists of six distinct V_L families. In the σ locus, the J segment has an unusual replacement of the diglycine bulge by two serines. The *Rana* major L chain type has an unusual intrachain disulfide bridge that is seemingly precludes covalent association of its H and L chains (142).

Two L chain types were identified in reptiles. Chickens and turkeys only express one L chain (λ) with a single functional V and J gene, and the manner by which diversity is generated is likely responsible for this unusual evolutionarily derived arrangement (discussed later). Nonproductive rearrangements are not detected on the unexpressed L chain allele, and thus there is a strong pressure to generate functional joints (discussed later). Such a system probably rendered a second (or third) L chain locus superfluous. Within mammals (marsupial *Monodelphis domestica*), the Vλ repertoire is composed of at least three diverse families related to distinct placental families, suggesting the divergence of these genes before the separation of metatherians and eutherians more than 100 million years ago. Opossum λJC sequences are phylogenetically clustered, as if these gene duplications were recent and the complexity of the λ locus seems greater than that found at the H chain locus (144).

In summary, all vertebrate groups except the birds have two to four L chain isotypes, all of which can be categorized as κ, λ, or σ (and in cartilaginous fish, σ-cart) (141). However, we are still at a loss to understand the significance of possessing multiple isotypes, because there is scant evidence that L chains have any effector functions. It has been suggested that different isotypes may provide distinct CDR conformations in association with H chains, or there may be L chain/H chain preferences that provide some advantage that is not obvious (145). At least the differential CDR sizes for σ as compared to κ/λ suggest that the former rationale is plausible.

The J Chain

The joining (J) chain is a small polypeptide, expressed by mucosal and glandular plasma cells, that regulates polymer formation of IgA and IgM. J chain incorporation into dimeric IgA and pentameric IgM endows these antibodies with the ability to be transported across epithelial cell barriers. J chain facilitates creation of the binding site for poly-Ig receptor (spIgR, secretory component in the Ig polymers), not only by regulating the polymeric structure, but apparently also by interacting directly with the receptor. Therefore, both the J chain and the pIgR/SC are key proteins in secretory immunity (146). Mouse IgM is synthesized as hexamers in the absence of J chain and as pentamers in its presence. Since some *Xenopus* EM studies suggested the existence of Ig hexamers, it was of interest to examine J chain conservation over evolutionary time. J chain cDNAs have been reported in all jawed vertebrates. The existence of *Xenopus* J chain suggests that, unlike mouse IgM, *Xenopus* IgM forms hexamers with J chain; alternatively the previous EM studies identified IgX as the hexameric isotype (the χ chain has a stop codon before the Cys of C_{H4} domain and thus cannot make a covalent attachment to J chain) (134). The highest level of J chain expression was detected in frog and bird intestine,

correlating well with a role for J chain in mucosal immunity (although obviously not for IgX secretion). Elasmobranch J chain shows high similarity to the N-terminal half of J chains from other vertebrates but is divergent or even missing in the other regions (146). This result suggests that the function of J chain may be solely for IgM polymerization in elasmobranchs, and the transporting function arose later in evolution; consistent with this idea, *Xenopus,* but not shark, J chain is capable if interacting with human IgA and poly-Ig receptor. There was a claim for J chain's presence in many protostomic invertebrates since a homologue was cloned in earthworms (147), but no J chain sequences have appeared in any of the protostomes or deuterostome invertebrate databases (e.g., *C. elegans, Drosophila*).

Antigen Receptor Gene Organization

V_H Regions

A rearranged V_H gene consists of a leader (encoded by a split exon) followed by four framework regions and three CDRs (Figure 3.10). Canonical V_H CDR1 nucleotide sequences are conserved in all jawed vertebrates, likely as targets for SHM (148). A major germline difference is the lack of conserved octamers and TATA box in the 5′ region of shark Vs. In all species, functional V genes are assembled by rearrangement and joining of germline V, D, and J elements. Cartilaginous fish H chains are encoded by large numbers of clusters (>100 in horned shark; ~15 in the nurse shark) (116,149). For IgNAR, there are only four V regions/haploid genome, and only a few IgW V genes are detected in nurse sharks (but a large number in skates). In teleosts, seven V_H families have been characterized in the catfish, each containing up to 7 to 10 genes (most with open reading frames), and in the trout, 11 V_H families were identified. *Xenopus* has at least 11 V families, three of which (V_{H1-3}) contain 20 to 30 members and ~10% to 30% pseudogenes; the other families are smaller (one to eight genes), so the total number of functional V_H elements is ~90 to 100. Reptiles have very large pools of V_H segments: The turtle *Pseudemys scripta* has four families, with ~700 V_H/haploid genome (10% to 20% pseudogenes), and at least 125 genes homologous to the mouse V_H S107 gene were detected in another turtle species, *Chelydra serpentine*. Importantly, the V_H complexity does not seem to limit diversity of the antibody repertoire in any ectothermic vertebrate studied to date. There are actually fewer functional human V_H (44 functional, 79 pseudogenes that fall into seven families) than in many ectotherms. Dynamic reorganization of the H chain V regions seems to have occurred at least eight times between 133 million and 10 million years ago (138). Perhaps species that utilize somatic mutation/selection "optimally" rely less on germline diversity, and therefore fewer functional genes are required. Only ~10% of *Xenopus* V_H are pseudogenes in the three

families (V_{H1-3}) that have been exhaustively studied; thus, *Xenopus,* with fewer lymphocytes, has a greater number of functional V_H genes than humans.

Chondrichthyan Germline-joined Genes

In all vertebrate species, functional Ig genes are assembled by rearranging DNA segments scattered on the chromosome. However, in cartilaginous fish, some V genes are the products of V(D)J rearrangement in eggs/sperm (9,116,150). Type I L chain (σ) genes are all germline-joined in skates but split in horned sharks, and the piecemeal germline joins (e.g., VD, VDD, VDDJ) found in many horned shark H chain gene clusters and in nurse shark L chain type I (σ) clusters strongly suggest that the germline-joining is a derived feature (Figure 3.10). Definitive proof came from a study of a germline-joined nurse shark type III (κ) L chain gene, shown by phylogenetic analysis to have been joined within the past 10 million years (150). When there is a *mixture* of joined and conventional genes, the split genes are expressed in adults, while the joined genes are expressed at significant levels only early in ontogeny. When *all* of the genes in a particular family are joined (e.g., skate type I L chain genes and type II (λ) L chains in all elasmobranchs), they continue to be expressed into adult life at high levels. In mammals, what may appear like germline-rearranged V genes are in most cases processed pseudogenes (e.g., pseudo Vκ on chromosome 22 in human or in mouse). However, it is possible that the surrogate L chain gene VpreB is the product of a germline-joining event in the line leading to mammals.

Organization of Rearranging Genes

As mentioned, shark IgH chain genes are structured into perhaps hundreds of clusters, each consisting of V, D, J, and C elements (116); all evidence from studies in horned shark, nurse shark, skate, and sandbar shark (and holocephalan ratfish) suggest that V, D, and J genes rearrange only within one cluster (Figure 3.10). While there is extensive N-region diversity and sometimes usage of two D segments (three Ds in IgNAR), and there are V_H subfamilies having substantial CDR1/2 heterogeneity, diversity of the primary repertoire is lower than in other vertebrates since there is no (or infrequent) rearrangement between clusters. The special constitution of the shark H and L chain loci suggests an exclusion mechanism similar to that of mouse TCR γ loci, also in clusters. It appears that only one V_H transcript is expressed in each lymphocyte, consistent with isotypic exclusion, despite the many clusters (151). Bony fish (teleosts and chondrosteans, such as the sturgeon), frogs, reptiles, and mammals have very similar architectures of their H chain locus—the so-called *translocon configuration* (Figure 3.10). As described earlier, multiple families of V_H genes, each consisting of many apparently functional elements (1 to 30 per family), are separated from a smaller number of genomic D and

J elements. The possibility of combinatorial rearrangement enables more diversification than is possible with the cartilaginous fish clusters for a given number of segments. In birds, the organization is similar but all V genes except those most 3′ to the D elements are pseudogenes (discussed later in this chapter).

L chain gene organization is more variable. In elasmobranchs, the organization is the same (i.e., in clusters) as the H chain locus without the D segments. The prototypic horned shark type I (σ) L chain has a cluster organization in which V, J, and C segments are closely linked. As mentioned earlier, bony fish L chain genes have the shark cluster-type organization, but some species have multiple V genes in some clusters, demonstrating that there is rapid evolution of not only sequence, but also gene organization in this taxon (143). In *Xenopus*, there are multiple Vκ(ρ) presumably derived from one family, 5J and a single C gene segment (152). In cartilaginous fish and birds, there has been coevolution of Ig gene architecture for H and L loci, but the teleosts have shown that this is not a rule.

D Segments

D segments are always present in one of the two loci encoding an Ig/TCR heterodimer (IgH and TCR β,δ), and the pressure that maintains this asymmetry is unknown. Cartilaginous fish have one or two D genes/H chain clusters, and there are only minor variations among the clusters. In teleosts, amphibians, and reptiles, where the organization of the H chain locus is similar to humans, the number of Ds deduced from cDNAs ranges from 10 to 16. Two germline D segments have been identified in *Xenopus,* and their RSS follow the rules defined in mammals. In birds, there are 15 very similar D$_H$.

There are several reasons why D segments may have been preserved throughout evolution. Incorporation of D segments augments CDR3 diversity and size, obviously directly influencing the combining site (116,134). Three different Ds contribute to IgNAR CDR3, and besides generating great diversity, CDR3 length and amino acid composition fulfills special tertiary structure requirements: D-encoded cysteine residues bond with cysteine(s) in the body of the V domain, thereby stabilizing a loop involved in the antigen-binding of this unusual monomeric receptor (123). A similar situation has been reached by convergence in the monomeric variant of camel IgG. Finally, rearrangement of one locus "locks it in" and allows the second locus to undergo receptor editing, as is the case for negative selection of the B cell repertoire and positive selection of the T cell repertoire.

Major Histocompatibility Complex

T cells distinguish self from nonself through the presentation of small peptides bound to MHC class I and class II molecules (i.e., MHC restriction). The genetic restriction of T cell–APC collaboration, processing of antigen by professional APCs, and T cell education in the thymus described in mice hold true (or is assumed) for most vertebrate classes (153). No MHC-regulated T cell responses have been documented in cartilaginous fish, but the identification of polymorphic class I and II and rearranging TCRα/β genes (discussed earlier) strongly suggest that functional analyses will reveal MHC restriction of adaptive responses. Similarly, urodele amphibians are notorious for their poor immune responses (discussed later in this chapter), and biochemical and molecular evidence suggests that class II polymorphism is low in the axolotl. In addition, like the cod, axolotls have very high numbers of expressed class I loci, which might play into their poor adaptive immunity.

Class I/II Structure Through Evolution

The three-dimensional organizations of class I and class II are remarkably similar: The two membrane-distal domains of both molecules form a peptide-binding region (PBR) composed of two antiparallel α helices resting on a floor of eight β strands, and the two membrane-proximal domains are IgSF C1. Although sequence identity among class I and class II genes in vertebrates is low (like most other immune genes), the four extracellular domain organization and other conserved features are likely to be found in the ancestral class I/II gene (154). An intrachain disulfide bridge exists within the class I PBR α2 and class IIβ1 domains, but not the class I/II PBR α1 domains, and phylogenetic trees show that these respective domains are most similar (Figure 3.11). Bony fish class II α1 domains, like class II DMα molecules that are as old as the *bona fide* class II genes, do have a disulfide bridge. The exon/intron structure of class I and class II extracellular domains is also well conserved, but some teleosts have acquired an intron in the exon encoding the IgSF β2 domain. Other conserved features of class I genes include a glycosylation site on the loop between the α1 and α2 domains (shared with class II β chains), a Tyr, and one to three Ser in the cytoplasmic regions that can be phosphorylated in mammals, as well as several stabilizing ionic bonds. Class II, with its two TM regions, differs from class I with only one; conserved residues in the class II α and β TM/cytoplasmic regions facilitate dimerization. In summary, because sequence similarity is very low among MHC genes in different taxa, these conserved features are important for function and maintenance of structure (154).

β2m was the second IgSF molecule (C1-type) ever to be identified, originally found at high levels in the urine of patients with kidney disease. It associates with most class I molecules (discussed later in this chapter). Besides mammals, β2m genes have been cloned from representatives of all vertebrate classes except cartilaginous fish. The β2m gene is outside the MHC in all species tested and is a single-copy gene in all species except cod and trout, in which it

FIGURE 3.11 Amino acid residues conserved in classical class I and class II molecules in all jawed vertebrates. Displayed are sequences of HLA-A2 and DR1, for which crystal structures are available (309,310). Bold residues are found in the majority of classical class I/II sequences (or all but one class). Residues above the alignment for class I PBR a-1 and a-2 (Y-7, Y-59, Y/R-84, T-123, K-146, W-147, Y-171; note that Y-84 is invariant in mammals but R in all other vertebrates), and below the alignments for class II PBR a-1 and a-2 (Fa-53, Sa-55, Na-62, Na-69, Wb-61, Hb-78, Nb-82) are invariant residues that bind to mainchain atoms of acquired peptides. For the IgSF C1 domains, residues above the alignment are conserved in C1 set domains (17). Double-underlined residues are conserved glycosylation sites. Cysteines in the class I a-2 and class II b-1 that form conserved PBR disulfide bonds are indicated. Strands (S) and helices (H) for the PBR and strands for the IgSF domains are displayed. Figure modified from Kaufman et al (154).

has undergone multiple duplications. Based on the levels of similarity between the various domains of class I and class II, it is expected that β2m was originally encoded in the MHC and may still be present in some extant vertebrates (154).

Classical and Nonclassical Class I and Class II

Class Ia (classical) and class Ib (nonclassical) genes are found in all of the major groups of jawed vertebrates. Class Ia genes are defined by their ubiquitous expression, their presence in the MHC proper, and by high polymorphism. In addition, class Ia proteins almost always have eight conserved residues at both ends of the PBR that interact with "mainchain" atoms of bound peptides and constrain their size to eight or nine residues; this feature often distinguishes class Ia from class Ib (discussed later in this chapter). Thus, tight binding of peptides, a likely source of conformational changes in class I allowing transport through the ER and cell surface expression, is an evolutionarily conserved trait (155). In nonmammalian vertebrates, one of these residues at the C-terminus is lysine rather than tyrosine, the functional significance of which is unclear (154).

The class Ia/Ib distinction holds in most taxa: One to three polymorphic class Ia genes are expressed ubiquitously in most species, while other minimally polymorphic or monomorphic class Ib genes can be expressed in a tissue-specific fashion. The class Ib genes can be split into two major groups: one set that is most related to the class Ia genes within a taxon and thus recently derived, and one group that is ancient and emerged near the origin of the adaptive immune system. In mouse and human, the set most closely related to class Ia genes are closely linked within the MHC. In nonmammalian vertebrates, however, this first set are found in gene clusters on the same chromosome as the MHC proper but far enough away to segregate independently from MHC—for example, chicken (*Rfpy*) and *Xenopus* (*XNC*) (153). One *Xenopus* class Ib gene is expressed specifically in the lung and thus likely has a specialized function, and chicken Rfpy is associated with resistance to pathogens. Class Ib genes related but unlinked to the classical class I have also been found in bony

and cartilaginous fish, and quite recently a lineage of class II–linked class I genes was discovered in bony fish (discussion later in this chapter for significance; (156). Thus, class Ib genes that arise in each taxon seem to have true class I–like functions, but perhaps have become specialized (sometimes the distinction between class Ia and class Ib is blurry; see the discussion later in the chapter) (157). The second set of older class Ib genes that predates divergence of taxa can have very different functions. For example, the neonatal Fc receptor (FCRN) is involved in binding and transport of IgG molecules across epithelia as well as protecting them from degradation (the Brambell receptor). Further, molecules only described so far in mouse/human are composed only of a PBR without IgSF domains; these unusual class I molecules do not bind peptides but rather are important for the regulation of NK and T cell function during infection. The paradigm for these SOS responses is the MIC class Ib molecule, which does have an IgSF domain but clearly does not bind peptides. Some teleost class Ib genes that fall outside the major cluster of fish class I genes may fit into this category (158,159). Finally, molecules like CD1 bind nonpeptidic antigens for presentation to innatelike NK-T cells. The phylogenetic analysis predicts that CD1 and FcRN are old class I genes, which may be present today in all vertebrates (however, discussion later in this chapter about CD1); the age revealed by the phylogenetic tree also correlates well with the hypothesis that ancient duplication events predating the emergence of jawed vertebrates resulted in the appearance of CD1, FcRN, and MHC-linked class I genes (see discussion later in this chapter). Was the original function of class I linked to antigen presentation (peptidic or otherwise), induction of an SOS response, or to housekeeping functions? We do not currently have the answer, because class Ia and class Ib molecules are just as ancient. The discovery of class I–like genes in animals derived from ancestors predating adaptive immunity (if such genes exist) will help resolve this question, but to date no recognizable MHC molecules or their kin have been detected in pre-jawed vertebrates (32).

Class II molecules also have nearly invariant residues that bind to main chain atoms of peptides, but these are in the center of the groove (Figure 3.11). Thus, tight binding to main chain peptide atoms occurs in the center of the class II PBR, and peptides are free to protrude from both ends (154). The only nonclassical class II molecules so far identified are the previously mentioned DM molecules that lack these residues. Thus far, DM molecules have been cloned only from tetrapods and have not been detected in any fish species, despite the large genomic and EST databases for the bony fish (160). Thus, they either had not emerged at the time fish arose or were lost in the bony fish lineage; phylogenetic trees suggest the latter and would be consistent with the rapid rate of genome evolution in the teleosts (161,162).

Polymorphism of MHC Class I and Class II Genes

High levels of polymorphism and genetic diversity are characteristic of most classical MHC genes, in fact the highest of any gene family studied to date. MHC variation among taxa has been derived via mutation, gene conversion, and recombination, and alleles are formed over evolutionary time. However, it is the retention of ancient allelic lineages through selection that accounts for the high levels of diversity observed within species (163). The repertoire of antigens recognized by MHC alleles is determined by the amino acids in the PBR, such that different MHC alleles recognize different sets of peptide derivatives. Although even minor alterations of the anchor residues in the PBR can drastically change the peptide binding capacity of an MHC molecule, in general, MHC alleles that differ by only a few amino acids can overlap considerably in their peptide binding repertoires, while highly divergent alleles bind unique sets of peptides. The differential binding capacities of MHC alleles form the basis of two models of balancing selection proposed to account for the extreme diversity observed at MHC. Overdominance, or heterozygote advantage, assumes that heterozygous individuals are capable of binding a wider array of pathogenic peptides than homozygous individuals; hence, they should be selectively favored (164). Alternately, negative frequency-dependent selection is based on the premise that a coevolutionary arms race between host MHC and pathogens exists, resulting in the development of escape mechanisms by pathogens to common MHC alleles and according an advantage to rare alleles (165). Although numerous individual studies exist providing support for one or the other of these selective mechanisms, from a population genetics standpoint, they give very similar theoretical results and are difficult to distinguish.

MHC Gene Organization

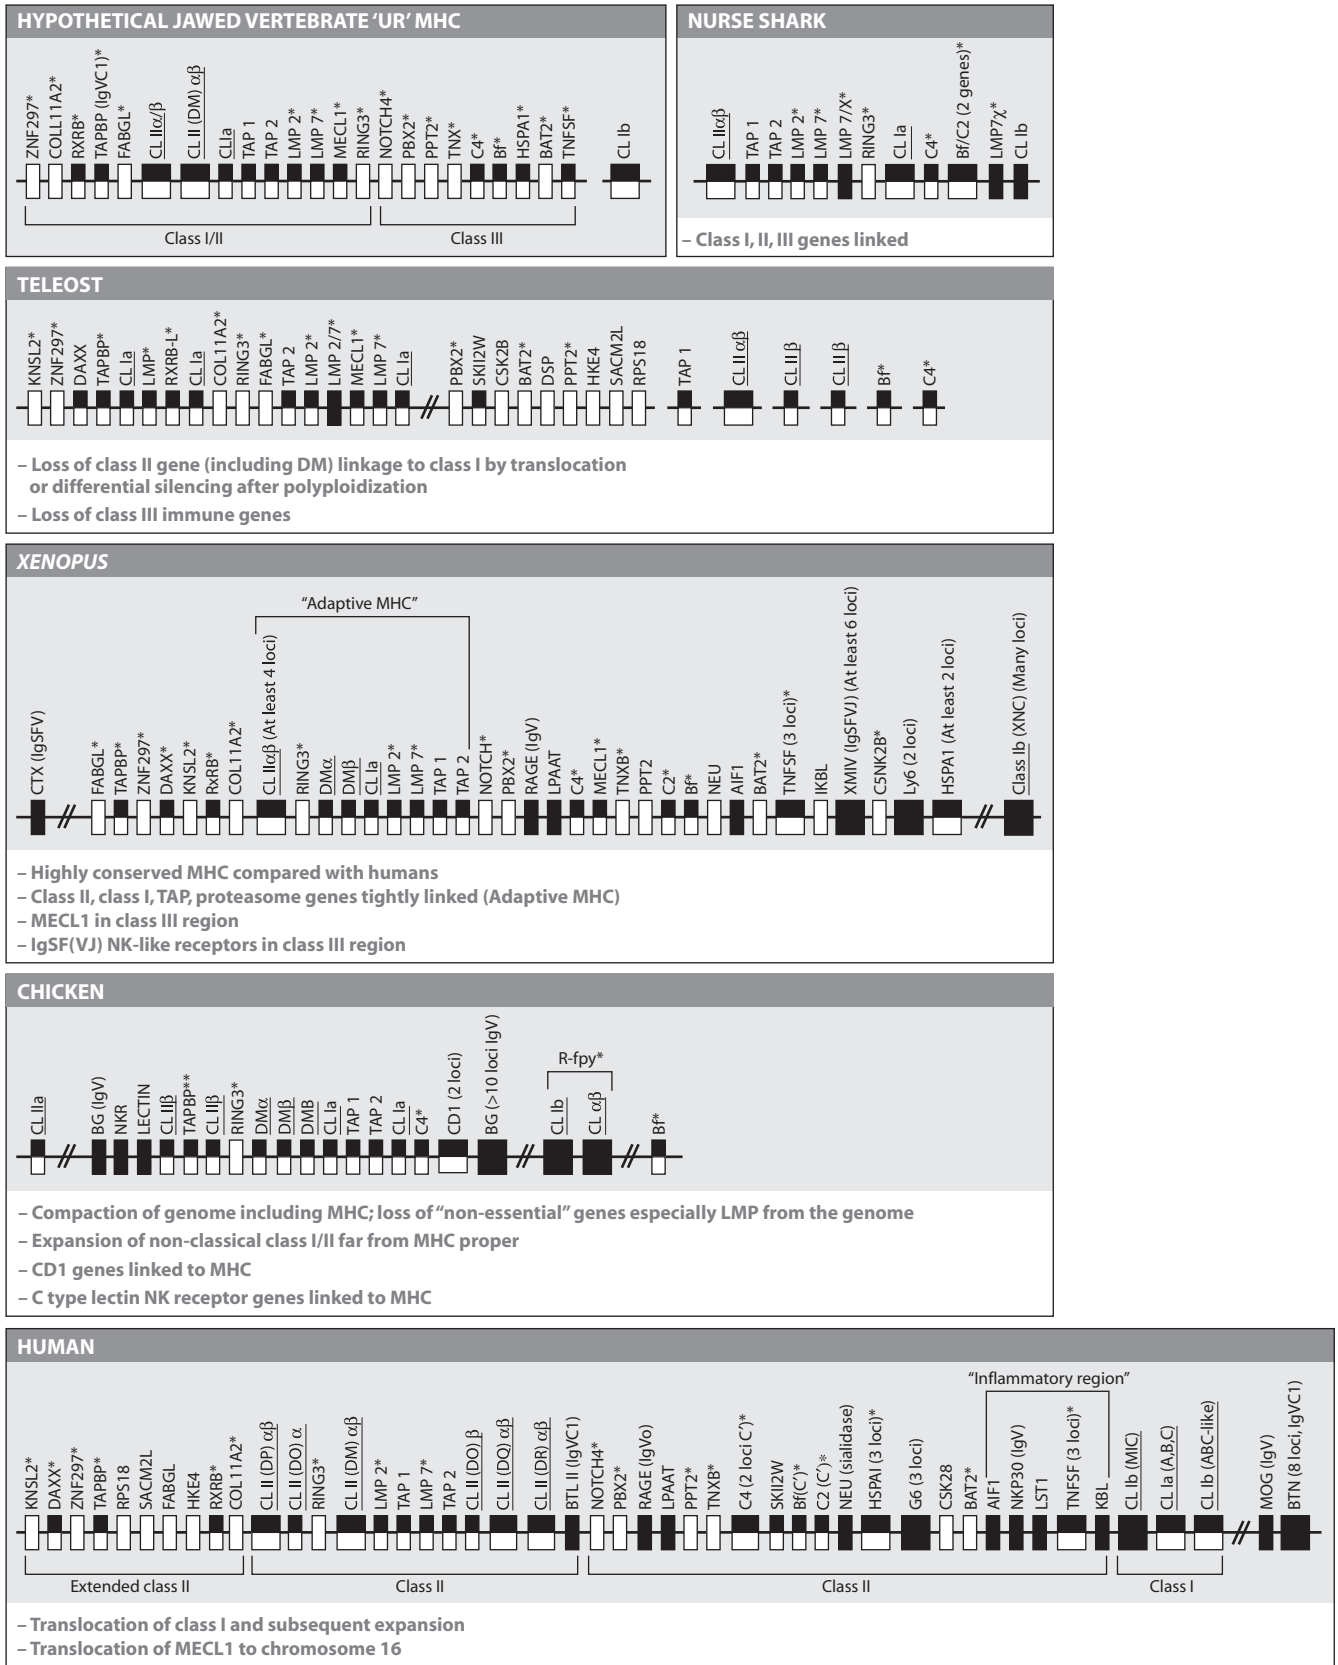
As mentioned earlier, because class I and class II proteins are structurally similar, it is no surprise that their genes are linked, a primordial trait subsequently lost only in bony fish. But why are structurally unrelated class I processing genes, including the immune proteasome components *lmp2* and *lmp7* and the *TAP* genes, also found in the MHC? There are two possible scenarios: primordial linkage of ancestral processing and presenting genes in the MHC or later recruitment of either the processing/presenting genes into a primordial MHC. Based on the presence of similar clusters of MHC genes on paralogous chromosomal regions in humans and mice, Kasahara et al. (7,166) proposed that ancestors of class I, class II, proteasome, transporter, and class III genes were already linked before the emergence of the adaptive immune system (Figures 3.12, 3.13). Genomewide duplications around the time of the origin of vertebrates (the 2R hypothesis), as proposed by Ohno (167), may have provided the raw material from which the immune system genes was assembled


FIGURE 3.12 MHC evolution. White indicates that the gene is found in at least one other species besides human; black designates a gene with known or inferred immune function; asterisk indicates an ancestral gene found on at least two paralogous MHC regions in mammals; large box indicates at least two genes in the particular region; double slash indicates linkage far away on the same chromosome; space between lines indicates that the genes are on different linkage groups. The teleost MHC is a composite of the zebrafish, trout, *Fugu,* and medakafish maps. Extensively modified from (153,311).

FIGURE 3.13 Genomewide duplication (2R) model of MHC evolution. Displayed are the MHC paralogous regions and their human chromosomal designations, first identified by Kasahara (7,166). Note that such paralogous regions have also been studied for chemokine receptors (259), TNF and TNF receptors (312), and IgSF molecules involved in cell-cell interactions and costimulation (11). Asterisks indicate that NK cell receptors (NKR) of the IgSF and C-type lectin categories from the NKC and LRC, respectively, are likely to have been in the Ur MHC based on linkages seen today in various taxa. VJ and C1 genes noted in the Ur MHC were likely related to the antigen receptor ancestor.

(discussed later in this chapter). As for all other adaptive immune genes described so far, neither class I/II nor immunoproteasome/TAP have been isolated from hagfish nor lampreys, and all of these genes as well as other genes involved in immunity could have emerged as a consequence of the duplications. Because class I genes are found on two or three of the clusters, class I–like molecules may have predated class II in evolution. Indeed, NK-like recognition of a class I or class I–like molecule encoded in an ancestral linkage group may have been at the origin of the adaptive immune system (discussed later in this chapter).

TAP is an interesting case in that the MHC-linked genes were clearly not part of the Ur MHC, but rather they were "recruited" to the MHC early in evolution. TAPs are members of the very large ABC transporter family and are most closely related to bacterial ABC transporters; this suggests that TAP1/2 were derived from a bacterial, or more likely a mitochondrial, gene, via horizontal transfer (168). Further, a close homologue of TAP1/2, TAP-L (TAP-like), unlike all of the other Ig/TCR/MHC genes we have discussed, is found in jawless fish (169). TAP-L's function is not known, but it may be involved in cross presentation (170). In summary, the TAP genes are not following any of the "rules" that seem to hold true for the other genes involved in adaptive immunity. This story will be exciting to monitor.

In all nonmammalian vertebrates, and even in marsupials (171), the imunoproteasome and TAP genes are closely linked to class I genes, not to class II, in a true "class I region." This result is most striking in bony fish (*Fugu*, zebrafish, medaka, trout), because class I/lmp/TAP/TAPBP and class II are found on different chromosomes (153,162; Figure 3.12). The class III region, historically defined by

the innate immune genes such as Bf/C2, and C4 are also present in the *Xenopus* and elasmobranch MHC, showing that association of class I/II with such genes is ancient (160). If Kasahara's interpretation is correct—that is, that MHC syntenic groups found on different mammalian chromosomes resulted from ancient block duplications—it is expected that the physical association of ancestral class I, II, and III genes predated the emergence of jawed vertebrates, and such syntenies in ectothermic vertebrates are not surprising (Figures 3.12, 3.13). Indeed, linkage studies in nonvertebrates amphioxus and *Ciona* do support an ancient linkage of class I, II, and III genes (172). Taken together, the data reveal that lack of synteny of class I, class II, and class III genes in teleosts is a derived character (161). Independent assortment of class I and class II may allow these genes to evolve at different rates: In some telesots, class Ia alleles form ancient, slowly evolving lineages, whereas class II genes evolve at similar rates as mammalian MHC alleles (173,174).

The chicken MHC, the B complex, is on a microchromosome, and intron sizes and intergenic distances are both quite small so that the entire complex is only a few hundred kb as compared to more than 4,000 kb in humans and *Xenopus*. Class Ia (BF), class IIβ (BL and DM), and TAP genes are in the MHC, but there is no evidence for immunoproteasome genes, and almost all class III genes have been deleted except for C4 (175). The quail MHC is similar, although is somewhat expanded, especially in genes related to the C-type lectin NK receptors (176). Although most class III genes are found on other chromosomes, *lmp2*/7 and *MECL1* genes are actually absent from the genome; indeed, peptides bound to chicken class I

molecules sometimes have C-terminal glutamic acid or aspartic acid, which are rare after proteolysis by mammalian proteasomes containing lmp2 and lmp7. To explain the correlation of diseases with particular haplotypes, Kaufman proposed that the chicken has a minimal essential MHC composed of only those genes absolutely required to remain in the complex. This concept has been reenforced recently by an analysis of resistance to viral infection (Rous sarcoma virus) governed by classical class I molecules (177).

Surprisingly, CD1 genes are closely linked to the chicken MHC (178,179). As mentioned earlier, CD1 genes in mammals seem to be on one of the MHC paralogous regions, and it was suggested that it arose as a consequence of the *en bloc* duplication (see Figure 3.13). While this is still possible (i.e., there was differential silencing of CD1 and other class I genes on the two paralogous chromosomes), the more likely scenario is that CD1 arose by gene duplication within the MHC itself in an ancestor of warm-blooded vertebrates; no *bona fide* CD1 genes have been detected to date in any fish or amphibians.

In summary, in all animals except placental mammals, classical class I genes map closely to the *TAP* and *lmp* genes, suggesting that the processing, transport, and presenting genes were in an original "class I region" (153,180). The tight linkage of the functionally, but not structurally, related genes strongly suggests that such genes coevolve within particular MHC haplotypes. Indeed, in *Xenopus* there are biallelic lineages of class Ia, LMP7, and TAP that are always found as a set in wild-caught animals. Although teleosts underwent an explosive adaptive radiation 100 million years ago and primordial syntenies have been lost in many cases (162), there are deep lineages of class Ia genes in many species, also found for *Xenopus* and cartilaginous fish class Ia genes. A recent study in medaka suggests that divergent noncoding regions between the class I processing and presenting genes do not permit recombination between lineages, hence preserving the linkage disequilibrium (181). In (most) eutherian mammals, the class I region is not closely linked to lmp/TAP and is very unstable, with rapid duplications/deletions expected in a multigene complex; the same class I instability extends to the non-MHC linked class Ib genes in *Xenopus* species.

Class I/II Expression

In *Xenopus* species, immunocompetent larvae express high levels of class II on APCs such as B cells, but express only very low levels of class Ia molecules on hematopoietic cells until metamorphosis. Expression of the immunoproteasome element *lmp*7 and all identified class Ib isotypes is also very low. Larval skin and gut, organs with epithelia in contact with the environment, appear to coexpress class I (transcripts) and class II (182). Such expression may provide immune protection during larval life; perhaps expression of class Ia is limited to organs that undergo massive destruction and remodeling at metamorphosis. Class II molecules also change their distribution after metamorphosis and are highly expressed by unstimulated T cells. Axolotl class II molecules are also regulated differentially during ontogeny, expressed in young animals on B cells and then expanding to all hematopoietic cells, including erythrocytes, later in life. Changes in MHC expression are not correlated with cryptic metamorphosis in axolotls, but class II expression by erythrocytes is correlated to the switch from larval to adult globins. Unlike *Xenopus*, class I transcripts isolated so far are expressed early in ontogeny, from hatching onward.

Carp class I and class II transcripts are detected in embryos 1 day after fertilization and reach a plateau at day 14. However, the suspected class Ia protein does not appear until week 13, whereas β2m can be detected several weeks earlier (183). It was suggested that another class I molecule is expressed during early development of the carp hematopoietic system, perhaps one of the unusual nonclassical molecules that groups outside the teleost cluster. Interestingly, recent work has shown that class I is expressed in the brain of young, but not adult fish, suggesting that class I molecules may play a role in neurogenesis (184).

Lymphoid Tissues and Cells of Jawed Vertebrates

Hematopoisis and Transcription Factors

As mentioned earlier, transcription factors of the family PAX 2/5/8, GATA 1,2,3, ets/erg, and runt domain-containing factors have been cloned in several invertebrates (Figure 3.4). One plausible model to explain the genesis of true lymphocytes in vertebrates is that closely related members of transcription factor families are the result of a relatively late divergence in lineage pathways followed by specialization of duplicated genes (185). These duplications could be those that apparently occurred during the history of chordates (see MHC and "origins" section). Within deuterostomes, the generation of true GATA 2 and 3 probably occurred after echinoderms diverged from the chordate branch and the GATA, ets, EBF, Pax5 dependent pathways of T/B cell differentiation are thus specific to vertebrates. It is already known that lampreys express a member of the purine box 1 (PU.1)/spleen focus-forming virus integration-B (Spi-B) gene family that is critically and specifically involved in jawed vertebrate lymphocyte differentiation. Expression has been detected in the gut, which may be related to the fundamental nature of "GALT" as a lymphoid cell-producing organ (see Figure 3.14).

In vertebrates, the generation of T, B and NK lymphocyte lineages from pluripotent hematopoietic stem cells depends on the early and tissue-specific expression of *Ikaros* (and related loci), which by means of alternative splicing produces a variety of zinc finger DNA-binding
FIGURE 3.14 Evolution of lymphoid tissues in the vertebrates. All jawed vertebrates have a thymus and a spleen with demarcated T and B cell zones. Fish have different bone marrow equivalents (Epigonal, Leydig, head kidney), and amphibians are the oldest group with lymphopoietic bone marrow (also the fist to have a typical IgH chain class switch). Germinal centers are found only in warm-blooded vertebrates, see (134,189).

transcription factors. The orthologues of *Ikaros*, *Aiolos*, *Helios*, and *Eos* have been identified in the skate *Raja eglanteria,* where two of the four *Ikaros* family members are expressed in their specialized hematopoietic tissues (epigonal and Leydig organs; discussed later), like in mammals (186). An *Ikaros*-related gene has been identified in the lamprey *P. marinus*, in which neither Ig nor TCRs have been identified. In lower deuterostomes, single genes that seem to be related to the ancestor of the Ikaros and Ets family of transcription factors exist, further suggesting that the division of labor between the family members in the jawed vertebrates was a result of en bloc duplications (187,188). The conservation of *Ikaro*s structure and expression reinforces its role as a master switch of hematopoiesis.

Lymphoid Tissues

In addition to the molecules and functions characteristic of adaptive immunity, primary (lymphocyte-generating) and secondary (immune response-generating) lymphoid tissues also define the specific immune system (134,189). The thymus is present in all jawed vertebrates, but not in the jawless fish, further solidifying the lack of (at least) conventional T cells outside the gnathostomes. *All* animals have hematopoietic cell-generating tissues (Figures 4.4, 4.14), and outside of the so-called *GALT species,* B cells develop in such bone marrow equivalents in all jawed vertebrates. With the advent of clonal selection, the accumulation and segregation of T and B cells in specialized organs for antigen presentation became necessary, and indeed the spleen is found in all jawed vertebrates, but not in agnathans or invertebrates. As mentioned earlier, if there is only one type of lymphocyte in agnathans that expresses VLR genes, then regulation by other cell types may not be required to initiate immune responses (i.e., the agnathans

may be an example of a B cell–only system regulated cell autonomously through the antigen-specific receptor and costimulatory receptors).

All vertebrate species rearrange their antigen receptor genes (except the case mentioned earlier for some cartilaginous fish germline-joined genes [9,190]). Besides rearrangement, with combinatorial joining of gene segments and imprecision of the joins, there are two other sources of diversity to generate the repertoires: the TdT enzyme that modifies boundaries of rearranging gene segments, and somatic mutations, found exclusively in B cells usually introduced during immune responses (9,134). However, progression of rearrangement during B and T cell development and diversification follow different rules in different vertebrates. It is conceivable that species hatching early with just a few lymphocytes are under pressures to develop a rapid response and may not use the same mechanisms as species protected by the mother's uterine environment. It is also possible that immune systems of species with few offspring are under stronger pressures than species that have many offspring, and this could be reflected in the manner diversity is generated. Studies of B and T cell differentiation have been performed in many vertebrates. RAG and TdT genes have been cloned in representatives of many classes, probes that allow the monitoring of lymphocyte development (discussed later in the chapter). Reagents have become available, permitting an accurate monitoring of T cell appearance in the lymphoid organs of ectotherms (crossreactive anti-CD3 sera or TCR probes), as well as mAbs and gene probes specific for Ig H/L chains that allow examination of B cells. As a rule, the thymus is the first organ to become lymphoid during development. Another emerging rule is that development of the thymus-dependent MHC-restricted T cell repertoire is

similar in all species, and this is reflected in the evolution of TCR gene organization described earlier; in contrast, B cell repertoire generation differs dramatically among different species, at times even within the same class of vertebrates (9,134).

Cartilaginous Fish

Like all other major adaptive immune system components, cartilaginous fish are the first in evolution to possess a thymus originating from pharyngeal pouches (191). As in mammals, it has a distinct cortex/medulla structure, and terminal deoxyribonucleotidyl transferase (TdT) expression was detected in thymocytes with crossreactive antisera and more recently by northern blotting. Interestingly, unlike all other vertebrates, age is not an indicator as to the size of the cartilaginous fish thymus; it can be small or large at any stage of development. GALT is also important in elasmobranchs, but lymphoid tissue in the spiral valve (intestine) does not have typical secondary lymphoid tissue structure; the spleen is the only tissue with compartmentalization of cells into discrete T cell and B cell zones (192). The Leydig and epigonal organs (associated with the gonads) are lymphopoietic and erythropoietic, producing mainly granulocytes and lymphocytes and there is high RAG expression in these tissues (discussed later). Lymphocytes form nodules in the epigonal organ, probably indicative of differentiative events.

During dogfish development, the liver is the first tissue to contain Ig+ cells at 2 months, followed by the interstitial kidney at 3 months (193). The thymus, spleen, and Leydig organ appear at 4 months, and the epigonal organ and the GALT are the last tissues to differentiate. The hematopoietic/lymphoid nature of the kidney and thymus disappears after hatching, whereas the other lymphomyeloid tissues persist through adult life. At hatching, when embryos are exposed to waterborne antigens, structural development of the lymphomyeloid tissues is well advanced. In the nurse shark, neonatal spleen white pulp consists entirely of class II-negative B cells; by 5 months after birth, T cell zones containing class II dendritic–like cells appear adjacent to the B cell zones. Both the B cell and T cell zones are vascularized, and no detectable marginal zone separates red pulp from white pulp (192).

In the skate *Raja eglanteria,* Ig and TCR expression is sharply upregulated relatively late in development (8 weeks). At this age TCR and TdT expression is limited to the thymus; later, TCR gene expression appears in peripheral sites in hatchlings and adults (194). IgM expression is first detected in the spleen of young skates but IgW is expressed first in gonad, liver, Leydig organ, and thymus. In adults, Leydig organ and spleen are sites of the highest IgM and IgW expression. In nurse sharks, 19S IgM appears in the serum before 7S IgM and IgNAR, and this profile is reflected in the lack of IgNAR+ cells in the spleen until 2 months after birth. RAG and TdT expression in the thy-

mus and epigonal organ of the nurse shark suggests that lymphopoiesis is ongoing in adult life. In contrast to most other vertebrates, N-region diversity is detected in skate and nurse shark IgM and IgNAR CDR3 from the earliest stages analyzed, suggesting that a full-blown diverse repertoire is important for young elasmobranchs (192). As mentioned earlier, a subset of Ig genes is pre-rearranged in the germline of chondrichthyans, and many of those germline-joined genes are transcribed in the embryo and hatchling, but not in the adult. This pattern fits with the expression of the nurse shark IgM_{1gj} with its germline-joined V region and suggests that some germline-joined genes "take advantage" of their early transcriptional edge, and thus some clusters can be selected for specialized tasks in early development. With many gene clusters, it is not known how "clusteric exclusion" is achieved at the molecular level (and why the germline-joined gene expression is extinguished in adult life), but as mentioned earlier, preliminary experiments suggest that only one H chain cluster is expressed in each lymphocyte (151).

The architecture of cartilaginous fish Ig loci allows greatest diversity only in CDR3, because the CDR2 and CDR1 are always encoded in the germline and V segments do not combine with (D)J segments from other clusters. Yet the number of possible CDR3 is essentially limitless, and the number of germline clusters is also high (at least 15 genes in each species; and usually 3 rearrangement events take place since 2 D segments are in each cluster). Thus, the potential diversity is greater than the number of lymphocytes, a general rule for generation of diversity in the vertebrates.

Bony Fish

The teleost thymus gland originates from the pharyngeal pouches and can be uni-, bi-, or trilobed, depending on the species (195). It is the first organ to become lymphoid, and its structure may differ from species to species. The cortex/medulla architecture is not as precise in other vertebrate species, but the duality of the compartment is apparent. The spleen contains the basic elements seen in other vertebrates—blood vessels, red pulp, and white pulp—but the distinction between red and white pulp is less obvious (the white pulp being poorly developed). In the spleen, the ellipsoids, which are actually terminal capillaries, have a thin endothelial layer surrounded by fibrous reticulum and an accumulation of cells, mainly macrophages. Lymphocyte accumulations are often seen in their vicinity, especially during immune responses, which have been suggested to be primitive germinal centers, but they are not homologous. Red pulp is rich in melanomacrophage centers, groups of pigment-containing cells at bifurcations of large blood vessels, which may regulate immune responses. The other main lymphoid organ is head kidney, believed to function as mammalian bone marrow. The

transparent zebrafish is being developed as a new model to study T cell differentiation (196).

In the sea bass *Dicentrarchus labrax,* a mAb detects differentiating T cells (perhaps pre-T cells) as well as mature T cells, as evidenced by the presence of TCR mRNA in the sorted populations. Cells seem to migrate from surrounding mesenchyme and subsequently mature in the thymus like in all vertebrates studied so far. T cells appear earlier in ontogeny (between 5 and 12 days after hatching) than cytoplasmic Ig$^+$ pre-B cells, which are detected only at 52 days post-hatching. Adult levels of T and B cells are reached between 137 and 145 days after hatching, quite a long time compared to young amphibians. In all teleosts examined, the thymus is the primary organ for T lymphocyte generation and head kidney the primary organ for B cell development (197).

RAG1 of the trout *Oncorhynchus mykiss* differs from mammalian RAG1 genes by the presence of an intron of 666 bp (an intron is also found in the sea urchin RAG1 gene in a similar position, [32]). Compared with other RAG1 sequences, trout RAG1 has a minimum of 78% similarity for the complete sequence and 89% similarity in the conserved region (aa 417-1042). RAG1 transcripts are detected chiefly in thymus, pronephros, mesonephros, spleen, and intestine starting at day 20 after fertilization. Trout TdT is highly expressed within the thymus and to a lesser extent in the pronephros beginning at 20 days post-fertilization, which correlates with the appearance of these two tissues. Because the H chain cluster is in the translocon configuration and there are many V_H families, it is assumed that diversity is generated in the mouse/human mode.

The best studies of mature B cell activation and homing have been done in trout (198,199). Immunization of animals results in the production of short-term Ig-secreting cells in the blood and spleen and long-lived plasma cells in the head kidney. Further analysis with B cell–specific transcription factors like PAX5 and BLIMP1 reinforced the previously noted functional studies and showed that the blood contains primarily "resting" B cells and the head kidney both plasma cells and B cell precursors. These last findings appear to be true of the cartilaginous fish as well, with the epigonal organ as the head kidney primary lymphoid tissue equivalent (Flajnik, unpublished). Interestingly, recent studies have shown trout (and other ectothermic) B cells to be quite efficient at phagocytosis, raising questions about myeloid/lymphoid lineage commitment in the vertebrates (200).

Amphibians

In anurans, the thymus develops from the dorsal epithelium of the visceral pouches (the number of pouches varies with species) and is the first tissue to become lymphopoietic (201). It is colonized from days 6/7 onward by precursors derived from lateral plate and ventral mesoderm through the head mesenchyme. Precursors proliferate *in situ* as the epithelium begins to express MHC class II molecules but not classical class I molecules. By day 8, thymic cortex/medulla architecture resembles that of other vertebrates. Amphibians possess a spleen with red and white pulp, GALT with no organized secondary lymphoid tissue, and many nodules (but no lymph nodes), with lymphopoietic activity in the kidney, liver, mesentery, and gills. The general morphology of lymphoid organs varies greatly according to species and changes with the season. In *Xenopus,* splenic white pulp is delineated by a boundary layer, and the central arteriole of the white pulp follicle terminates in the red pulp perifollicular area, a T-dependent zone. Anurans, like all ectothermic vertebrates lack germinal centers (Figure 3.14). In *Bufo calamita,* colloidal carbon particles injected via the lymph sac are trapped by red-pulp macrophages, which then move through the marginal zone to the white pulp. Giant, ramified, non-phagocytic cells found in both white and red pulp have been proposed to be dendritic cells. *Xenopus* bone marrow does not appear to be a major lymphoid organ from histologic observation, but high RAG expression in this tissue suggests lymphopoietic activity (202). The maintenance of RAG expression throughout adult life suggests that lymphocytes are continually produced.

Thymectomy decreases or abolishes allograft rejection capacity, mixed lymphocyte reaction (MLR) and phytobemagglutinin (PHA) responsiveness, IgY antibody synthesis, and all antibody responses that increase in affinity to classic thymus-dependent antigens. MLR reactivity matures before the ability to mount IgY responses in primary responses. Thymectomy at 7 days of age delays allograft rejection and abrogates specific IgY responses, whereas later in life it only abrogates antibody responses (201). Thymectomy performed later greatly affects the pool of peripheral T cells, as monitored with mAbs specific for molecules such as CD8. Early thymectomy results in the complete absence of T cells, but lymphocytes with T cell markers, perhaps corresponding to NK T cells, can still be detected. In *Xenopus,* thymocytes induce weak GVH reactions, whereas splenic T cells are good helpers and strong GVH inducers. The thymus contains some IgM-producing B cells and memory cells poised to switch to IgY synthesis, and *in vitro* responses are down-regulated by naïve thymus cells. Nitrosomethylurea (NMU) eliminates T cells and thereby abrogates alloreactivity, but rejection of xenografts is not abolished and thus may be controlled by thymus-independent mechanisms. *Xenopus* B cells respond *in vitro* to low doses of LPS not by proliferation, but rather by Ig synthesis and also respond to tumor-promoting agent (TPA). Old reports of B cell proliferation can be attributed to contaminants in LPS preparations (201).

Urodele embryos initially produce five pairs of thymic buds, the first two of which disappear (203). This results in a three-lobe thymus in *Ambystoma,* but in *Pleurodeles* and *Triturus* it forms one lobe. No cortex-medulla boundary is present, and the thymus generally resembles a canonical

cortex. There are at least three types of stromal epithelial cells. There is no lymphopoietic activity in axolotl bone marrow, and hematopoeisis takes place in the spleen and in the peripheral layer of the liver. The spleen is not clearly divided into white and red pulp.

Axolotl lymphocytes proliferate in response to diverse mitogenic agents (204). In larval or adult axolotls, a population of B cells stimulated by LPS and can synthesize and secrete both IgM and IgY. T cell responses to mitogens or allogeneic determinants are allegedly poor, but adult (older than 10 months) splenocytes and thymocytes respond well to PHA when the medium is supplemented with 0.25% bovine serum albumin (BSA), rather than 1% fetal bovine serum. T cells are activated in these experiments, as shown by cell depletion with mAbs *in vitro,* and *in vivo* by thymectomy. Axolotl lymphocytes, like mammalian lymphocytes, proliferate *in vitro* when stimulated by staphylococcal enterotoxins A and B (SEA and SEB superantigens).

About 40% of TCRβ VDJ junctions in 2.5-month-old *Ambystoma* larvae have N additions, compared to about 73% in 10–25-month old animals. These VDJ junctions had ∼30% defective rearrangements at all stages of development, which could be due to the slow rate of cell division in the axolotl lymphoid organs, and the large genome in this urodele. As mentioned earlier, many axolotl CDRβ3 sequences, deduced from in frame VDJ rearrangements, are the same in animals of different origins (105). In contrast, in *Xenopus,* rearrangement starts on day 5 after fertilization for the V_H locus, and within 9 days all V_H families are used. V_H1 rearranges first followed by V_H3, and by day 9–10 V_H 2, 6, 9, and 10 begin being rearranged, and then V_H 5, 7, 8, 11, on day 13. For VL, the κ locus is the first to rearrange on day 7 (two days after V_H), a situation similar to that found in mammals. During this early phase, B cells are present in the liver, where their number increases to ∼500 cells (205). Later in larval life, rearrangement resumes at metamorphosis, as suggested by the low incidence of pre-B cells and by the reexpression of RAG during the second histogenesis of the lymphoid system. T cells show a similar type of RAG expression/cell renewal during ontogeny as the B cells, and the larval and adult Vβ T cell repertoires differ significantly. Even early in development, tadpoles express a highly variable TCR β repertoire despite the small number of lymphocytes (8,000–10,000 splenic T cells); little redundancy in TCR cDNA recovered from young larvae implies that clone sizes must be extremely small, unlike the axolotl situation.

In *Xenopus,* no lymphoid organ apart from the thymus is detectable until day 12 when the spleen appears and with it the ability to respond to antigen. For B cells, until this time, no selection occurs as suggested by the random ratio of productive/nonproductive VDJ rearrangements (2:1). After day 12, this ratio becomes 1:1 (i.e., the rearrangements have been selected). cDNA sequences on day 10–12 (when the number of B cells increases from 80 to 500) are not redundant as if each sequence was represented by one

cell. RAG expression together with the detection of DNA rearrangement circles in the bone marrow suggests that rearrangement is ongoing throughout life and is not restricted to an early period like in birds. Tadpole rearrangements are characterized by a lack of N-region diversity, like in mammals but not axolotls or shark/skate (see earlier discussion), and thus very short CDR3. During ontogeny TdT appears in significant amounts in thymus of tadpoles at metamorphic climax, but little expression is detected at earlier stages, which correlates well with the paucity of N-region addition in larval IgH chain sequences. Studies of the ontogeny of the *Xenopus* immune system have revealed a less efficient tadpole immune response (skin graft rejection and Ig heterogeneity and affinity); the absence of TdT expression during tadpole life fits well with the findings of lower larval Ig (and TCR) diversity ([201], see discussion later in this chapter).

Reptiles. In all reptiles studied, the thymic cortex and medulla are clearly separated. The spleen has well-defined white and red pulp regions, but T and B cell zones have not been delineated with precision. In *C. scripta,* white pulp is composed of two lymphoid compartments: Lymphoid tissue surrounds both central arterioles and thick layers of reticular tissue called *ellipsoids* (206). Even after paratyphoid vaccine injection, splenic germinal centers are not formed, as in fish and amphibians. Splenic red pulp is composed of a system of venous sinuses and cords. In *Python reticulatus,* dendritic cells involved in immune complex trapping have been identified and may be related to mammalian follicular dendritic cells. GALT develops later than spleen during development, and it appears to be a secondary lymphoid organ (but does not seem to contain the equivalent of the bursa of Fabricius). Lymph node–like structures, especially in snakes (*Elaphe*) and lizards (*Gehyra*) have been reported.

Reptiles, the evolutionary precursors of both birds and mammals, are a pivotal group, but unfortunately the functional heterogeneity of reptile lymphocytes is poorly documented. There seems to be T/B cell heterogeneity because an antithymocyte antiserum altered some T cell–dependent functions in the viviparous lizard *Chalcides ocellatus*. Embryonic thymocytes responded in MLR at all stages, but Concanavalin A (ConA) responsiveness increased gradually during successive stages and declined at birth. In the alligator (*Alligator mississippiensis*), like in mammals after glass-wool filtration, nonadherent PBL responded to PHA and not to LPS, whereas adherent cells were stimulated by LPS.

Birds. The thymus, which develops in chickens from the third and fourth pharyngeal pouches, consists of two sets of seven lobes, each with definitive cortex/medulla. The thymus becomes lymphoid around day 11 of incubation. Splenic architecture is less differentiated than in mammals. It is not lymphopoietic during embryogenesis, as RAG-positive cells are found mainly in yolk sac and

blood. Birds are the first vertebrate group where follicular germinal centers and T-dependent areas comprising the periarteriolar lymphatic sheath (PALS) are encountered. Plasma cells are located in the red pulp. γ/δ TCR$^+$ T lymphocytes are chiefly concentrated in sinusoids, whereas α/β T cells fill the PALS (106). Lymph nodes seem to be present in water and shore birds but not in chickens and related fowl.

The bursa of Fabricius is a primary lymphoid organ unique to birds in which B cells are produced (207). It arises at day 5 of development and involutes 4 weeks later (see B cell differentiation). T–B heterogeneity is obviously well defined in birds (indeed, the "B" in B cell stands for *bursa*.) The effects of thymectomy—T and B cell collaboration and generation of MHC-restricted helper and killer cells—are very similar to mammals, the other class of warm-blooded vertebrates.

During the embryonic period, chicken stem cells found in yolk sac and blood rearrange their IgH and L V genes simultaneously over a very restricted period of time, and very few cells colonize each bursal follicle (about 10^4 follicles). Three weeks after hatching, these cells have differentiated in the bursa and then seed the secondary lymphoid tissues, after which time B cells are no longer generated from multipotent stem cells; thus, only $\sim 2 \times 10^4$ productive Ig rearrangements occur in the life of the chicken (208). When an antiserum to chicken IgM is administered *in ovo* to block this early bursal immigration, there are no stem cells arising later in development that can colonize the bursa, and these chickens lack B cells for their entire lives (209). Although the general Ig locus architecture is similar to that of frogs and mammals, only one rearrangement is possible, as there is only one functional V_L or V_H on each allele. Diversity is created during bursal ontogeny by a hyperconversion mechanism in which a pool of pseudogenes (25 ψL and approximately 80 ψH) act as donors, and the unique rearranged gene acts as an acceptor during a proliferative phase in bursal follicles (Figure 3.10 [208,210]). For H chains, the situation is more complex, as there are multiple D elements. During ontogeny, selection of productive rearrangements parallels the selection of a single D reading frame, suggesting that the many D segments favor D–D joins to provide junctions that are diversified by gene conversion; the hyperconversion mechanism can also modify Ds because most donor pseudogenes are fused VD segments. The gene conversion process requires AID, which is also required for SHM and class switch (211).

Since diversification by gene conversion occurs after Ig rearrangement and cellular entry into bursal follicles, and there is only a single germline V_H and V_L expressed on all developing B cells, it was tempting to implicate a bursal ligand binding to cell surface IgM to initiate and sustain cellular proliferation and gene conversion. However, surface expression of IgM devoid of V regions permitted the typical B cell developmental progression, demon-strating that such receptor/ligand interactions are not required (212). Thus, currently we know little about how cells enter the bursa, which signals induce them to proliferate/convert, and how cells arrest their development and seed the periphery.

Mammals and Evolution of the Thymus

The discovery of a second (cervical) functional thymus in mice has raised some ontogenetic and immunological questions (213). Is this second thymus the result of an atavism, or does it correspond to what is seen in humans when a cervical thymus can form under certain pathogenic conditions during the migration of the thymus to its final mediastinal location? There are examples of cervical thymi in primitive mammals such as marsupials as well as in some prosimians. An "extra" thymus also is reminiscent of the multiple thymi encountered quite frequently in cold-blooded vertebrates.

As described, the thymus is promiscuous with regard to its precise developmental origin (206). The thymus arises from pouches 2–6 in cartilaginous fish, from the second pouch in frogs, the second and third in reptiles, and from the third or fourth in bony fish, birds, and mammals. The final number of thymi can also be variable. It ranges from five pairs of organs in sharks, to four in caecilian amphibians, to three in urodeles, and finally to one in many teleost fish species, anurans, and many mammals. The thymus of reptiles varies in terms of location and number of lobes reflecting variation in embryonic origin. The thymus may be found anywhere from the base of the heart to the neck. For example, in lizards and snakes there are two lobes on each side of the neck with no subdivision in lobules. The crocodilian thymus is an elongated chainlike structure, not unlike that of birds. In turtles, the thymus is a pair of lobes divided in lobules at the bifurcation of the common carotid associated with the parathyroids. The multilobed thymus in birds is not the equivalent of the multiple thymi found in sharks because the subdivision is secondary to primary organogenesis. Regardless of the underlying ontogenetic mechanism leading to the development the cervical thymus in mice, the result is suggestive of the secondary "thymus spreading" in birds, but it differs with regard to an uneven final size distribution. All marsupials, except koalas and some species of wombats that only have a cervical thymus, have a thoracic thymus similar to that of placentals. Some marsupials (kangaroos and possums) also have a cervical thymus; their thoracic thymus derives from the third and fourth pharyngeal pouches, whereas the cervical thymus arises mainly from the ectoderm of the cervical sinus with some participation from the second and third pouch (like in reptiles).

The second mouse thymus seems to show primitive characteristics such as the existence of a single lobe, a superficial location and a position compatible with an origin involving another pharyngeal pouch (presumably the

second) that would be a marsupial and therefore perhaps a reptilian character (189). Embryology helps in determining the possible scenarios: During mouse ontogeny, the canonical thymus anlage can be recognized, beginning on day 11.5 in development, as a group of Foxn1-expressing cells located ventrally in the third pharyngeal pouch. If the cervical thymus were derived from an independent anlage, one would rather expect to detect Foxn1+ cells in the endoderm outside the third pouch. This argues for a common origin of thoracic and cervical thymi and against a second thymus anlage outside the third pouch, and, hence, against the above hypothesis that the cervical thymus represents an atavistic organ.

Generation of Diversity in Warm-blooded Vertebrates

Perhaps surprisingly, mechanisms leading to the generation of repertoire diversity vary among mammalian species. As data accumulate, categories can be made depending on the mode of B cell development: Rabbits, cattle, swine, and chickens (the so-called *GALT group*), unlike fish, amphibians, reptiles, and primates/rodents, use a single V_H family, of which only a few members (sometimes only one) are functional (134,214). This GALT group uses gene conversion or hypermutation in hindgut follicles early in life (rather than bone-marrow throughout life) to diversify their antibody repertoire. At the rabbit H locus, as in the chicken, a single V_H is expressed in most peripheral B cells. During development, B cells that have rearranged this particular V in the bone marrow (and other sites) migrate to the appendix where this rearranged gene is diversified by gene conversion using upstream donor V segments. This development of B cells in rabbits is dependent on the intestinal microflora (215), and efforts are being made to define the potential bacterial superantigens involved, as well as binding sites on IgM necessary for the differentiation. In ruminants, the ileal Peyer's patches (IPP) are the bursalike primary B cell–generating tissues. Although bursa, appendix, and sheep IPPs show morphological similarities, the mechanisms generating diversity are different: conversion in the chicken and hypermutation in sheep, and both in the rabbit (134). As described earlier, most of the GALT group also appears to lack IgD; thus IgD might serve some purpose in repertoire development in some groups of mammals and not others (216).

In summary, the organization of the lymphoid tissues is perhaps the only element of the immune system that shows increasing complexity that can be superimposed on the vertebrate phylogenetic tree (Figure 3.14). The absence of primary and secondary lymphoid tissues (thymus and spleen) is correlated with the absence of a rearranging or hypermutating receptor family in other animals, with the exception of the agnathan VLR in which the relevant lymphoid tissues (if they exist) are not yet defined. While all jawed vertebrates have a true secondary lymphoid tissue (spleen), ectotherms lack lymph nodes and organized GALT. In addition, while ectotherms clearly have B cell zones resembling follicles, and despite the clear ability for ectothermic B cells to undergo SMH and at least some degree of affinity maturation, germinal centers with follicular dendritic cells are not formed after immunization; clearly this was a major advance in the evolution of the vertebrate immune system (discussed later in this chapter).

The potential repertoire of Ig and TCR combining sites is enormous in all jawed vertebrates. The potential antigen receptor repertoire in all species for both T and B cells is far greater than could ever be expressed in an animal because of cell number limitations. Not all species or all gene families use combinatorial joining for repertoire building, but all species assemble V, (D), and J gene segments to generate their functional Ig genes during B cell ontogeny, and the imprecision of this assembly creates great somatic diversity. Thus, from this survey in various species, one could not predict that there would be major differences in immune responses in representatives of different vertebrate classes, and yet in the next section we shall see that mouse/human antibody responses are superior to those in many taxa.

Adaptive Immune Responses

The quality of T cell and B cell responses depends on the heterogeneity and diversity of the antigen receptor repertoires, the ability to select cells in secondary lymphoid tissues, and other undefined factors. As described, because of the indefinite and huge number of potential Ig/TCR V region sequences in most taxa, potential diversity exceeds the number of available lymphocytes. Yet, while potential repertoires are diverse in all vertebrate classes, and polymorphic MHC class I and II and TCR genes have been isolated from all classes, antibody diversity in non-mammalian vertebrates is relatively low (217,218). The expressed repertoire has been studied by indirect methods based on structural studies, affinity measurements during the maturation of the immune response, enumeration of antigen-binding Igs by isoelectrofocusing (IEF), and idiotypic analysis. Sequences of Ig and TCR genes expressed over the course of a response help to estimate diversity at another level, allowing studies of V genes diversified by gene conversion or somatic mutation during a response in a precise way. In the following survey, we describe studies of specific antibody synthesis, T cell responsiveness (T–B collaboration, MHC restriction). NK and NK-T cells will be considered in this section as well. Because of space limitation we focus on ectothermic vertebrates and birds.

Cartilaginous Fish

Natural antibodies binding many antigens have been detected at surprisingly high levels in chondrichthyans and in some teleosts. After immunization (for instance with 2-furyloxazolone-*Brucella,* or p-azobenzenearsonate), the horned shark mounts a low-affinity 19S IgM antibody

response, which varies little among individuals and does not increase in affinity after prolonged immunization. Variation of L chains isolated from individuals is limited, with the major bands having identical isoelectric points. Nurse sharks immunized to heat-killed streptococcal A variant vaccine produced antibodies that among outbred individuals had very different L chain gel electrophoresis patterns (219).

The relative homogeneity and large number of V genes hindered somatic mutation studies until a single unique reference horned shark IgM V_H gene was found. Mutations in this gene were slightly more frequent than those in *Xenopus* (discussed later). Mutation rates could not be calculated, and no correlation with an immune response was attempted. The mutations were predominantly found at GC bases, and the frequency was rather low. Nevertheless, this work proved that somatic mutation preceded diversity obtained by combinatorial association of gene segments in evolution (220). In contrast to mutations in the horned shark IgM V_H genes, unusual patterns of somatic mutation were detected in nurse shark type II germline-joined L chains. Half of the mutations (338/631) occur in tandem without the G–C bias seen in *Xenopus* or shark H chain V genes. Tandem mutations and point mutations take place simultaneously and are unlikely to be generated by gene conversion, since there are no repeated patterns or potential donor genes (221). The germline-joined L chain genes can only diversify through SHM, perhaps like the hypothetical prototype V region gene prior to RAG-mediated rearrangement (i.e., SHM may have preceded gene rearrangement as the primordial somatic diversification mechanism; discussed later in the chapter). Lastly, a reappraisal of mutation at H chain loci in the nurse shark showed that the mutations were not so different from the L chains (222); the differences from the previous work were the different shark species and the analysis of all H chain loci in the species rather than only one unusual locus.

The small number of IgNAR genes also made it possible to analyze somatic mutation, and in the first experiments, random cDNAs were examined. The mutation frequency is about 10 times that of *Xenopus* and horned shark IgM, and even higher than in most studies in mammals. It is difficult to establish a pattern for the mutations due to their high frequency and because they are often contiguous, like in the L chain gene study described earlier; however, mutations are not targeted to GC bases, and analysis of synonymous sites suggested that the mechanism is similar to human/mouse (219). Mutations even in the randomly isolated clones appeared to be under positive selection in IgNAR secretory but not TM clones, strongly suggesting that mutations do not generate the primary repertoire like in sheep but arise only after antigenic stimulation.

Recent studies suggested that there is affinity (223) maturation and memory generation in nurse sharks. Soon af-

ter immunization with hen egg lysozyme (HEL) and IgM response can be detected, primarily of the pentameric class. Over time, 7S IgM and IgNAR responses develop, and the 7S antibodies have a higher binding strength than those of the 19S class (120). When titers are permitted to drop to baseline, a memory response can be induced by immunization of antigen without adjuvant. However, unlike responses in higher vertebrates, the titers do not increase over those in the primary response, suggesting a peculiar type of regulation of antigen-specific IgM and IgNAR. Nevertheless, these data strongly suggest that the hallmarks of an adaptive response occur in sharks. In another study, a family of HEL-specific IgNAR clones was followed over time after immuniczation, and a 10-fold increase in the affinity of an already high-affinity germline clone (10^{-9} M) was observed. These results suggest that affinity maturation, memory, and "switch" to the monomeric IgM isotype occurs, but it takes much longer to attain these adaptive hallmarks compared to mammals, perhaps a paradigm for ectotherms (218).

The role of T cells in shark immune responses has not been studied in detail. No thymectomy experiments have been performed, and T cells have not been monitored during an immune response. Shark MLR and graft rejection have been attempted—MLR with little success (probably for technical reasons), and grafts with the demonstration of a chronic type of rejection for which the genetics has not been analyzed. However, from the MHC and TCR studies, it is clear that all of the molecular components are available for proper antigen presentation in sharks and skates, and recent studies of splenic architecture suggestive of T cell zones containing class II$^+$ dendritic cells argue for a prominent T cell regulatory role in adaptive immunity (114,192). Further, an increase in binding strength and memory response also strongly suggest a T cell involvement in humoral immunity.

Bony Fish

There are high levels of low-affinity natural antibody (up to 11% of total Ig) to nitrophenylacetate (NP) in some bony fish. Natural antibodies in catfish have been correlated with resistance to virus infection or furonculosis. As a rule, and like in cartilaginous fish, little affinity maturation has been detected in fish, although some changes in fine specificities were noticed in the trout with a sensitive ELISA-based test. B cell and Ig heterogeneity was demonstrated in carp using mAbs, and DNP-specific antibody-secreting cells were identified with the ELISPOT assay in pronephros and spleen cell suspensions after immunization. The number of IEF antigen-specific bands per individual is small (up to 23), and there is little variation from one outbred individual to another. In sea bass, extremely low variability was reported in CDR1, and no variability in CDR2 or CDR3 in DNP-specific L chains, suggesting expression of dominant monospecific antibodies (217).

The mild increase in trout antibody affinity (similar to that found in *Xenopus*) is attributed to selection of either minor preexisting B cell populations or somatic mutants. In partially inbred self-fertilized or gynogenetic trout, variability of specific responses is even more restricted. Affinity measured by equilibrium dialysis was of the order of 2.0×10^{-6} M for TNP-specific antibodies. The percentage of L chains of the catfish "F" and "G" types can vary greatly in the course of a response (2 weeks versus 3 months). A large literature deals with vaccination attempts in teleost fish, due to their economic importance. The availability of catfish B cell, macrophage, and T cell lines have been instrumental in analyses of antibody production. There are puzzling differences in responses from different teleost groups, much like differences between urodeles and anurans (amphibians). Cod, for example, do not respond well to specific antigen and have very high levels of "natural antibodies."

Like the sharks, isolation of TCR genes and the existence of a polymorphic class I and class II molecules suggest that antigen presentation is operative in teleosts, but, unlike sharks, functional experiments examining mammalianlike T-APC interactions have been performed. TCR mRNAs are selectively expressed, and specific TCR rearrangements have been detected in catfish clonal cell lines, which produce factor(s) with leukocyte growth promoting activity. Modifications of the trout T cell repertoire during an acute viral infection have also been followed. In nonintentionally immunized trout, adaptation of the spectratyping technique for TCRβ CDR3 length revealed a polyclonal naïve T cell repertoire. After an acute infection with viral hemorrhagic septicemia virus (VHSV), CDR3 size profiles were skewed for several Vβ/Jβ combinations, corresponding to T cell clonal expansions. Both "public" and "private" T cell expansions were detected in the infected genetically identical individuals. The "public" response resulted in expansion of Vβ4/Jβ1-positive T cells that appeared first in the primary response and were boosted during the secondary response (224). Further work examined the fine specificity of the T cell response to the virus, which is a model for studies in cold-blooded animals (225).

We have seen that species living in extreme cold develop adaptive structural differences in their Igs. At the level of global immune response, temperature exerts a great influence in ectothermic vertebrates in general, low temperature generally being immunosuppressive. Lowering the water temperature from 23°C to 11°C over a 24-hour period suppresses both B and T cell functions of catfish for 3–5 weeks as assessed by *in vitro* responses. Virgin T cells are most sensitive to this cold-induced suppression, a property shared with mammals when tested appropriately. Fish have developed ways to adapt to the lack of fluidity of their B cell membranes by altering the composition of fatty acid by using more oleic acid at low temperatures. After appropriate *in vivo* acclimation, catfish T cells are better able to cap cell surface molecules at low assay temperatures than are B cells, suggesting that capping is not the low temperature–sensitive step involved in T cell immunosuppression in catfish (226).

Evidence that fish possess cytotoxic cells was derived from allograft rejections and graft versus host (GVH) reaction studies. *In vitro* studies have now shown that leukocytes from immunized fish specifically kill a variety of target cells (allogeneic erythrocytes and lymphocytes, hapten-coupled autologous cells); fish CTL of the $\alpha\beta$ (and perhaps $\gamma\delta$) lineages as well as NK cells were found. Naïve catfish leukocytes spontaneously kill allogeneic cells and virally infected autologous cells without sensitization, and allogeneic cytotoxic responses were greatly enhanced by *in vitro* alloantigen stimulation (227). Cloned cytotoxic cells contain granules and likely induce apoptosis in sensitive targets via a putative perforin/granzyme or by Fas/FasL-like interactions. An Fc receptor for IgM (FcμR) was detected on some catfish NK-like cells that appears to "arm" these cells with surface IgM (228). All catfish cytotoxic cell lines express a signal-transduction molecule with homology to the Fcγ chain of mammals. This chain with an ITAM motif is an accessory molecule for the activating receptor NKP46 on mammalian NK cells. Importantly, these cytotoxic cells do not express a marker for catfish nonspecific cytotoxic cells (NCC). NCC have been found in other fish species, including trout, carp, damselfish, and tilapia, and they spontaneously kill a variety of xenogeneic targets, including certain fish parasites and traditional mammalian NK cell targets. Unlike mammalian NK cells, NCCs are small agranular lymphocytes found in lymphoid tissues (pronephros and spleen), but rarely in blood. Recently, the gene for catfish NCCRP-1 was sequenced and found to be a novel type III membrane protein with no sequence homology to any known mammalian leukocyte receptor (229).

Amphibians

Differences in immune system features between urodele (axolotl) and anuran (*Xenopus*) amphibians, already discussed for MHC and Ig complexity, are also seen in immune responses. Rarely is such divergence seen within one vertebrate class (although the two groups diverged over 250 million years ago). Urodeles express a very restricted antibody repertoire in response to specific antigen that peaks at 40 days postimmunization and is entirely of the IgM class, even though the serum also contains IgY (230). They do not respond well to thymus-dependent antigens, which may be due to lack of T cell help, yet their expressed TCR diversity looks normal. A population of axolotl B cells proliferates specifically in response to LPS and also secretes both IgM and IgY. Moreover, a distinct lymphocyte subpopulation proliferates significantly in response to the T cell mitogens ConA. T cells from young axolotls (before 10 months) do not have this functional ability. As mentioned earlier, axolotl T cells also can be stimulated with

to SEA/SEB known from mammalian studies to be superantigens.

Anuran larvae can respond specifically (with only 10^6 lymphocytes) to many antigens, with a modest affinity maturation of the IgM anti-DNP response. In adults, the number of different anti-DNP antibodies does not exceed 40, versus 500 in mammals. In secondary responses, the peak of the response is about 10-fold higher and is reached in 2 weeks; there are no major changes in affinity over this initial rise. Anti-DNP Abs, or even nonimmune Ig pools, yield easily interpretable sequences for the first 16 N-terminal residues of both H and L chain V regions. However, this simple view was challenged when a great heterogeneity of cDNA sequences could be detected in animals after immunization. Isogenic *Xenopus* produce homogenous antibodies to DNP, xenogenic RBC, or phosphorylcholine with identical or similar IEF spectrotypes and idiotypes, while outbred individuals differ (231). Both IEF spectrotypes and idiotypes are inheritable, suggesting that diversity is a reflection of the germline repertoire without a major contribution from somatic mutations. Thus, somatic mutations were followed during the course of an antigenspecific immune response at the peak of the modest affinity maturation in larvae and adults (232). The V_H genes, like their mammalian homologues, contain the sequence motifs described previously that target hypermutation. Of the 32 members of the V_H1 family involved in the anti-DNP response, expression of only five was detected, indicating that immunization was being monitored. Few mutations were detected (average: 1.6 mutations per gene, range: 1–5), and there was not a strong preference for mutations in CDR1 and 2 and virtually none in CDR3. Like in the shark IgM study noted earlier (but not IgNAR or type II L chains), the mutations were targeted to GC bases, and such a pattern has been suggested to be the first phase of SHM in mouse/human; perhaps *Xenopus* has lost the second phase of the process that results in an evening of mutation frequency for all bases (233). While the mutation frequency was lower than in mammalian B cells, the rates were only four- to seven-fold less in *Xenopus*. Thus, there is no shortage of variants, and the reasons for the low heterogeneity and poor affinity maturation may be due to less than optimal selection of the mutants. Indeed, because of a relatively low ratio of replacement to silent mutations in the CDRs, it was argued that there is no effective mechanism for selecting mutants, which in turn might be related to the absence of GC in *Xenopus*. In summary, the data from hypermutation, cDNA heterogeneity, and spectrotype dominance suggests that in the absence of refined modes of selection in late-developing clones, B cells producing somatic mutants may be out-competed by antibodies generated earlier in the response.

Essential T cell functions in anurans were shown with *in vitro* assays for T–B collaboration and MHC restriction, demonstrating the similarity of the role of MHC in *Xenopus* and mammals. Regulatory T cells have been shown indirectly in hematopoeitic/thymic chimaeras for control of CTL generation and in antibody responses. Ig synthesis can be enhanced following thymectomy in axolotl or *Xenopus*, again implying a role for thymic-dependent regulatory cells. As described previously, the class switch first occurs in amphibians, and thymectomy early in life totally prevents IgY, but not IgX synthesis; thus, T cells are absolutely required for the switch and also for high affinity IgM responses. Switching can also be induced in tadpoles, although one must hyperimmunize animals for this response, due to a paucity of T cells in larvae. The switch is also temperature-dependent, and as described earlier for channel catfish, ectotherm T cells are quite temperature-sensitive (201).

Similar to studies in mammals, the chaperone gp96 has been shown to shuttle peptides into target cells to make such cells targets for MHC-restricted CTL lysis. Immunization of frogs with gp96 from a thymic tumor results in the elicitation of CTL that display antitumor activity. Elegant experiments with gp96 vaccination have also shown that CTL activity against minor histocompatibility antigens is MHC-restricted. As mentioned earlier, NK cells have been characterized in *Xenopus* with mAbs that recognize non-B/T cells. Those cells kill MHC class I–negative target tumor cells but not class I$^+$ lymphocytes, and after thymectomy these cells are enriched in the spleen. More recently, CD8$^+$ cells expressing TCR were isolated with the same mAb suggesting the existence of amphibian NK-T cells. Expression of the mAb epitope on cells is induced by PMA/ionomycin and is also detected in CTL when MHC-dependent cytotoxicity is reduced.

Reptiles

Lack of an increase in affinity and homogeneity of IEF spectrotypes suggest low antibody heterogeneity in reptiles. In the turtle *Pseudemys scripta*, a number of genomic VH sequences, representing possibly four families, were isolated, as was a genomic $C\mu$, all shown to be encoded at a single locus. In Northern hybridizations, the $C\mu4$ probe detected two transcripts; of the four VH groups, only one was expressed, and multiple bands indicated the presence of at least two non-μ transcripts. Among 32 unique VDJ rearrangements from one animal, there were 22 sequence variants in FR4, suggesting either a large number of J segments or somatic modification (234). The latter interpretation is supported by point mutations found in FR3 and CDR3. For T cells, there are no data on T effector function, but there are studies on the behavior of T cell population changes due to seasonal and hormonal variations. Thymocytes from the turtle *Mauremys caspica* proliferate in response to PHA and ConA and can kill tumor target cells by both ADCC-mediated and NK-mediated cytotoxicity. Proliferative responses to PHA and ConA were higher for both sexes in spring and for females in winter than in the other seasons.

Birds and Mammals

Sequence data and L chains patterns on 2-D gel electrophoresis showed less antibody heterogeneity in chicken than in mouse. The poor increase in affinity of chicken anti-DNP and antifluorescein antibodies again indicates lower heterogeneity. Few changes occur after immunization, even if one waits one year after several injections. Perhaps similar to the trout study described earlier, a restricted population of high-affinity antibodies was found only after immunization in Freund's complete adjuvant (235). Hyperconversion and somatic mutation in Ig genes have been found in splenic germinal center B cells after immunization. The relatively poor affinity maturation of the chicken response may be due to a balance between gene conversion and somatic mutation. Indeed, modification of V genes with segments of DNA is not an optimal strategy for fine-tuning antibody responses. In the rabbit there is also conversion/mutation by B cells in germinal centers after immunization. Within mammals, large variations are found from marsupials with no obvious secondary response, to mice with 1,000-fold increases in affinity, but the basis for the relatively poor responses has not been established.

In conclusion, although all vertebrates have a very large potential for generating diverse antibodies after immunization, only some mammals studied to date make the most of this potential. Perhaps pressures on the immune system of cold-blooded vertebrates have been less intense due to a stronger innate immunity, and the architecture of their lymphoid system is not optimal for selecting somatic mutants, or the great rises in affinity detected in antihapten responses are not physiologically relevant. An immune system using somatic diversification at its "best" is well adapted to species where the value of single individuals is important (i.e., species with small progenies). Has that been the condition for the creation and selection of somatic rearrangement and of the optimal usage of somatic mutations? If this explanation provides a rationale for the utilization of somatic mechanisms in generating a repertoire and improving it, it does not tell us why it works so well in certain species and not in others. Perhaps the key is the organization of secondary lymphoid organs. Likely, a combination of factors (e.g., endothermy, secondary lymphoid tissues, mutation versus conversion, the hypermutation mechanism itself, rates of proliferation [pathogen and lymphocyte], etc.) are at work in the regulation of antibody responses (218).

NK AND NK-LIKE CELLS

NK cells express both activating and inhibitory cell surface receptors; in fact, the paradigm for positive and negative signaling via such receptors began with these cells; however, activating and inhibitory receptors (often paired) are conserved throughout vertebrates and invertebrate deuterostomes and are expressed in hematopoietic cell types of all types. In NK cells, stimulation of the activating receptors, which associate with proteins having an ITAM (DAP12 or DAP10 conserved at least to the level of bony fish [236]), results in killing of target cells. Inhibitory signaling receptors all possess cytoplasmic ITIMs, which recruit phosphatases and generally are dominant over the activating receptors. These receptors fall in two categories, IgSF and C-type lectin group V(II). In general, NK receptors recognize MHC class I molecules of either the classical or nonclassical type, the latter sometimes encoded by viruses.

Evolution of NK Receptor Families

As mentioned, NK cells in mammals can use different types of receptors, even encoded by different gene families. Some are conserved and others are highly variable even if one can group them into defined multigene families. Some families show conservation of domains throughout the jawed vertebrates. When dealing with the origin of these genes in invertebrates, one has to imagine under what pressures they evolved; pathogens come immediately to the mind rather than MHC class I molecules that appeared "simultaneously" with the RAG-mediated adaptive system. The most interesting phylogenetic information could come from future studies in deuterostomes such as echinoderms, protochordates, and agnathans. The question is whether NK cells, or NK-like cells, preceded the emergence of T and B lymphocytes.

As described in the Introduction, NK receptors are the most rapidly evolving molecular component of the gnathostome immune system (4). All known ligands for these diverse NK receptors are MHC class I molecules, or molecules of host or pathogen origin related to MHC class I. The KIR families are divergent, as very few genes are conserved even between chimpanzees and humans, and there are different numbers of genes in KIR haplotypes within a species. By contrast, CD94/NKG2 receptors are conserved throughout mammals. So whereas receptors for polymorphic class I molecules are divergent, those for nonpolymorphic class I molecules are conserved (despite the fact that their ligands Qa1 and HLA-E are not orthologous). Altogether, rapid evolution of NK cell receptor gene families distinguishes members of a species and causes substantial species-specific differences in NK cell receptor systems. NK cells play other important roles in other innate immune responses, for example in antiviral immunity. NK cell recognition of virus-infected cells engages the activating KIR and Ly49 receptors and NKG2D in this process. Thus, viruses are hypothesized to supply the evolutionary pressure on diversification of NK cell receptors. In fact, it has been shown in mice that inhibitory receptors can rapidly mutate into activating receptors when viral "decoy" class I molecules evolve to engage inhibitory receptors (237).

Comparative Studies of NK Function

NK cells were detected in *Xenopus* by *in vitro* ^{51}Cr assays. Splenocyte effectors from early thymectomized frogs spontaneously lyse allogeneic thymus tumor cell lines that lack MHC antigen expression. This activity is increased after the injection of tumor cells or after treating the splenocytes *in vitro* with mitogens, suggesting lymphokine activation of the killers. Splenocytes isolated with an anti-NK mAb revealed large lymphoid cells with distinct pseudopodia. Immunohistology indicated that each anti-NK mAb routinely labeled cells within the gut epithelium, but NK cells were difficult to visualize in spleen sections.

In amphibians. NK cell studies are especially interesting because of natural experiments done by nature (i.e., the absence or low levels of MHC classical class I during larval life of some species like *Xenopus* [238]). They are *bona fide* NK cells, distinct from T cells, since they fail to express TCR Vβ transcripts. NK cells emerge in late larval life, 7-weeks post-fertilization, about 2 weeks after the time when cell-surface class I can be detected. The proportion of splenic NK cells remains very low until 3–4 months of age, but by 1 year there is a sizeable population. Therefore, NK cells fail to develop prior to MHC class I protein normal expression (at least NK cells of the type that can be measured with these assays and with NK cell-specific mAbs) and do not contribute to the larval immune system, whereas they do provide an important backup for T cells in the adult frog by contributing to antitumor immunity. The molecules that govern killing in *Xenopus* have not been identified.

NK cells have also been described in a number of teleost fish with the most in-depth studies in catfish, in which there are clonal lines of cytotoxic cells (see earlier discussion).

Perforin and granzyme homologs are indeed found in birds, amphibians, and teleost fish (Ensembl). As mentioned earlier in the complement section, homologs with the MAC/perforin domains even exist in *C. elegans* and insects, with no functional evidence.

Phylogeny of NK Lectins

The phylogenetic appearance of NK lectins in the vertebrates has not been examined in detail. However, BLAST searches reveal possible homologues at least to the level of teleost fish, whereas no hits have been reported from cartilaginous fish or agnathans, but at least for the cartilaginous fish this may be due to a lack of sequence data. As mentioned previously, a CD94 homologue has been detected in lower deuterostomes, but its true orthology is dubious. A CD94/NKG2-like gene has been described in cichlid fish even though the orthology is not clear and no functional work has been done. Group II C-type lectin receptors, which are structurally similar to group V

(NK) receptors, have been characterized in bony fish (239). A zebrafish multigene family of group II immune-related, lectinlike receptors (illrs) was identified from the databases with possible inhibiting or activating signaling motifs. These genes are differentially expressed in the myeloid and lymphoid cell lineages.

Given the apparent lack of MHC class I and class II in agnathans and their convergently acquired adaptive immune system (see earlier discussion), it is difficult to envisage how NK cells with receptors of any type might function in these animals. It should be mentioned, however, that sequence similarity might be difficult to detect for an MHC PBR, given the rapid rate of evolution of this gene family. Further, it would not be shocking if there were NK cells with ligands encoded by other gene families—in mammals, ligands for some activating NK receptors like NKp44 and NKp30 have not been identified. It would be of interest to study the non–VLR-expressing lymphocytes in agnathans (if such cells exist) for their killing potential or gene expression.

Interestingly, recent studies in mammals have shown that some of these NKC-encoded lectinlike receptors in the Nkrp-l family can recognize other lectinlike molecules, termed Clr, also encoded in the NKC (240). Having linked loci encoding receptor-ligand pairs suggests a genetic strategy to preserve this interaction; perhaps the CD94 homologues of invertebrates are genetically linked to genes encoding their ligands. In addition, as described later in this chapter, the close genetic linkage of receptor and ligand genes is a common theme in "histocompatibility reactions" throughout the animal and plant kingdoms.

Phylogeny of IgSF NK Receptors

IgSF activating receptors have been recognized as such from teleost fish onward with a relatively convincing NKP44 homologue in carp, but with no functional data. These sequences of the fish V domain NKP44 resemble the chicken CD300-L family as well as some skate molecules that could perhaps permit the extension of the lineage to the cartilaginous fish. NKp30 homologues have been detected in *Xenopus*; in addition, as described in the MHC section, there are V(J) genes within the frog MHC that are ancient homologues of NKp30 and may be NK receptors of both activating and inhibitory types (160). NITRs, seemingly specific of teleost fish, have one or two Ig domains with a charged residue in the TM and could therefore be associated (by analogy) to an ITAM DAP12 equivalent (discussed later [241]).

IgSF inhibitory receptors usually form larger families of molecules in comparison to activating receptors. This function can be devoted to two distinct families of receptors, giving another example of the extremely rapid evolution of these molecules. There are many ITIM-carrying IgSF integral membrane receptors across the

classes of vertebrates, and they seem to have had independent histories since it is difficult to convincingly detect orthologous genes between species. This is especially true of multigene families in fish, with members equipped with possible ITIMs, including the teleost NITR and LITR, and bird CHIR and CD300L. Several members of these families can be expressed on NK cells, but expression studies are in their infancy in fish. It is sometimes difficult to distinguish FcRh families from NK KIR-like domains, and both FcR and KIR seem to stem from a same lineage. Given the role of the FcR binding to *bona fide* antibodies and conferring specificities to cells of the innate arms of the immune system, it is likely that these molecules will be restricted to jawed vertebrates. The KIR activity that can incorporate pathogen and virus recognition may be more primitive, but the ancestry of KIR is not well understood, and the *bona fide* KIR family seems to be restricted to primates.

Genes encoding the classical FcRs on the long arm of human chromosome 1 (1q21–23) are linked to other FcR-like genes. A large multigene family, which includes genes encoding the FcγR and the NK cell Ig-like receptors, is located in the LRC (human chromosome 19q13). This region could in fact be paralogous to 1q23 and may even have been originally associated with the MHC (discussed later). These families belong to a larger class of activating or inhibitory receptors. Their phylogenetic conservation in birds, amphibians, and bony fish suggests a biological importance even though the size of the families, their expression pattern, and the specific nature of the receptors vary greatly among species (242). In several cases, a commitment to a task in the immune system may not be conserved among homologous members and the evolutionary fate of the family will be probably affected. Comparison of key residues in the domains may suggest a possible common involvement in MHC recognition for the two families recently discovered in birds (CHIR [243]) and the teleosts (IpLITR [244]). Other families were generated within a single class or even within a single order of vertebrates (e.g., the KIR described earlier). The relationships of KIR with many other multigene families such as IpLITR or NITR remain to be explored. What was the scenario that led to the present mammalian situation? If the fish observation on potential MHC binding holds true, the KIR-type of receptor seems to be the most primitive NK cell receptor.

Other IgSF Families to Explore Further

Thymocytes express members of the IgSF TIM (T cell Ig and mucin domain-containing molecule) (245) corresponding to another independent amplification of non-rearranging V domains on chromosome 5, with 3 members, whereas the homologous locus on chromosome 11 in mice has 8. Nothing is known about relatives outside mammals.

In more primitive vertebrates, the physical or genetic linkage of relatively large IgSF families is well documented in the teleost NITR but not yet elucidated in the case of other interesting families in protochordates like the VCBP. In the sea urchin genome, many IgSF await a complete analysis and will certainly contribute to a better understanding of the evolution and origin of Ig/TCR. Among those, the discovery of leukocyte-expressed receptors APAR (agnathan paired receptors) in hagfish of what might have been a precursor of Ig or TCR (246). APARs resemble Ag receptors and are expressed in leukocytes and predicted to encode a group of membrane glycoproteins with organizations characteristic of paired Ig-like receptors. APAR-A molecules are likely to associate with an adaptor molecule with an ITAM and function as activating receptors. In contrast, APAR-B molecules with an ITIM motif are likely to function as inhibitory receptors Thus, the APAR gene family has features characteristic of paired Ig-like receptors. APAR V domains have a J region and are more closely related to those of TCR/BCR than any other V-type domain identified to date outside of jawed vertebrates. Thus, the extracellular domain of APAR may be descended from a V-type domain postulated to have acquired RSS in a jawed vertebrate lineage.

In jawed vertebrates, three such receptor families with VJ-type domains have been identified: a small family of mammalian proteins known as SIRP, a large family of the previously described teleost NITR, and MHC-linked XMIV in *Xenopus*. NITR were originally believed to be part of the LRC, but this is unlikely on further analyses. NITR encode a variable (V) region, a unique V-like C2 (V/C2) domain, a TM region (with or without a positively charged residue), and a cytoplasmic tail containing ITIM. They seem to form a teleost-specific family with no good homologue outside this class although they appear somewhat related to NKp30. NITRs can be expressed by cells of the hematopoietic lineage, presumably lymphocytes as judged from MLR. Eleven related genes encoding distinct structural forms have been identified in the channel catfish. In zebrafish, NITR genes group into 12 distinct families, including inhibitory and activating receptors. An extreme level of allelic polymorphism is apparent, along with haplotype variation, and family-specific isoform complexity (9).

CYTOKINES AND CHEMOKINES

Many cytokines/chemokines and their receptors, like most molecules of the immune system, evolve rapidly. However, consistent with the "Big Bang" theory, it is an emerging picture that the majority of cytokines and chemokines found in mouse and human are also found in the genome and EST projects of nonmammalian vertebrates, best studied in chickens (247) and certain bony fish (248). This suggests

that whatever the initiating "force" in the evolution of the Ig/TCR adaptive immune system, the network of cytokines and chemokines emerged (practically) full blown early in evolution. While the overall picture is clear, the details are only starting to be understood, especially at the functional level. What is becoming apparent, however, is that some of the cyto/chemokine families in fish (and perhaps other groups) have been expanded or contracted in a species- or class-specific manner. This will clearly be a topic of interest in the future.

The Proinflammatory Cytokines, IL-1, IL-18, IL-6, IL-8, and TNFα

IL-1, IL-6, TNFα, and IL-8 are the prototypic cytokines associated with inflammatory responses, which are defined by induction of vasodilation and vascular permeability, and upregulation of innate immune system–specific molecules that have direct functions or that costimulate/attract T and B cells. Classically, many of these activities can be assayed in supernatants from LPS-stimulated phagocytes by determining whether thymocytes are stimulated to proliferate when one also adds suboptimal concentrations of T cell mitogens. It was reasonable to hypothesize that such cytokines, which act both at a distance as well as in a cognate fashion, might be found in the invertebrates. Indeed, IL-1-like *activities* have been described for echinoderm coelomocytes (either IL-1-like production by such cells, or the ability of the cells to respond to mammalian IL-1), but unfortunately no molecular data revealing the structures of the active invertebrate cytokine/cytokine receptor have been reported. In fact, no orthologue has been detected in the genome projects from protostomian invertebrates, and only IL-17 and TNF homologues have been detected in nonvertebrate deuterostomes (32,97), and IL-8 in agnathans (249); thus, we may consider these as primordial cytokines related to the vertebrate versions. A molecule from earthworms capable of activating the prophenoloxidase defense pathway cross-reacted with a mAb directed to mammalian TNFα (250). However, this molecule had no homology to TNFα on sequencing, but its activity is nonetheless quite interesting.

IL-1 activity as measured by costimulation assays or as a consequence of LPS (or other PAMPs) stimulation has been detected in all nonmammalian vertebrates. IL-1β upregulation has been detected after treatment of macrophages with LPS, consistent with its inflammatory function in mammals. In addition, injection of gram-negative bacteria into trout induced IL-1β expression in many tissues. Identity with the mammalian IL-1β gene in all other species ranges from 28% to 40% (identity between mammalian IL-1α and IL-1β is about 25%). In nonmammalian species, IL-1β lacks a so-called *ICE cleavage site,* important for function in mouse/human (251). IL-18 is an

IL-1-related cytokine, and in contrast to IL-1 seems more focused in its function of potentiating TH1 responses. IL-18 has been detected in birds and fish, but the tissue distribution in fish seems to be expanded as compared to mammals. Additionally, IL-18 in nonmammalian vertebrates contain the ICE cleavage site, unlike its cousin IL-1β.

Both chicken IL-1β and the IL-1R were identified and have been expressed as recombinant proteins. The IL-1R homology to mammalian orthologues is quite high (61% identity), but the highest similarity is found in the cytoplasmic domains. In addition, there are four blocks of high similarity to the cytoplasmic tail of Toll/TLR proteins, and IL-1R and TLR use similar signal transduction cascades (see previous discussion). As mentioned, IL-8 has been identified in the jawless lamprey and in various gnathostomes such as trout, flounder, and perhaps chicken; a chicken CXC chemokine called *K*60 clusters with IL-8 in phylogenetic trees and is upregulated in macrophages stimulated with LPS, IL-1β, and IFN (247). Interestingly, Marek's disease virus expresses an IL-8 homologue (v-IL-8), which may be involved in inducing immune deviation.

The TNF family in mammals includes the canonical TNFα, lymphotoxin (LT)α, and LTβ, all encoded at the distal end of the MHC class III region, as well as a large number of other members with diverse immune functions (153). TNFα is the best studied of these cytokines, and it is one of the key regulators of innate and adaptive immunity. The other two cytokines have a more limited tissue distribution and function, especially in their roles in lymphoid tissue development. TNF homologues have been detected in sea urchin, *Ciona,* and amphioxus, consistent with the idea that such a multifunctional cytokine would predate the jawed vertebrate adaptive immune system. Homologues have also been cloned from several teleost species and TNFα expression in leukocytes is upregulated within 4 hours after treatment with LPS, IL-1β, and PMA. While there is good phylogenetic support for orthology of fish TNFα to that of mammals, the other TNF genes seem to be teleost-specific duplicates rather than the LT genes (252). Conversely, in *Xenopus,* the three TNF family members described above in mammals are closely linked in the class III region of the MHC (160). This is a bit of a surprising result, as all of these family members seem to be lacking in chickens, consistent (according to the authors) with a lack of lymph nodes in these animals (247); however, the unusual nature of the MHC in birds (e.g., the immunoproteasome genes are missing) rather is consistent with a loss of TNF genes in these animals, which is indeed surprising, especially for TNFα.

Interleukin-2/15

Costimulation assays of thymocytes, as described earlier for IL-1, and perpetuation of T cell lines with stimulated T cell supernatants are performed to detect IL-2 or "T cell

growth factor" activities. Unlike IL-1, IL-2–like factors generally stimulate cells only from the same species, and it is a "cognate" cytokine, meant for release only between closely opposed cells, or as an autocrine factor. From teleost fish to mammals, stimulated T cell supernatants costimulate thymocyte proliferation or can maintain the growth of T cell blasts, and the orthologue has been detected in bony fish and birds. The chicken IL-2 protein is only 24% identical to human IL-2 and only 70% identical to a near cousin, the turkey. IL-2's relative IL15 has also been cloned in the chicken (253). A candidate IL-2R in chicken was identified by a mAb recognizing a 50-kDa molecule only on stimulated T cells (thus an IL-2Rα homologue). This mAb blocks costimulation by IL-2–like molecules in chicken T cell supernatants and also reduces the capacity of T cell blasts to absorb IL-2–like activity from supernatants. IL-2 has been studied in the bony fish *Fugu*. In both chicken and the deduced *Fugu* IL-2 protein, there is a second set of cysteine residues, which are found in IL-15 and thus is a primordial feature (254). Syntenic to the IL-2 gene in *Fugu* is the IL-2 relative IL-21.

The common γ chain (γC) is the signaling subunit of the IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21 receptors; absence of this chain in mammals leads to major defects in lymphocyte development ("boy in the bubble"). A γC homologue was cloned in rainbow trout with unusually high identity (44%–46%) to mouse/human genes. IL-1β, but not LPS, upregulated the trout gene in macrophage cultures and a fibroblast cell line. Identification of this protein subunit should allow the biochemical isolation of several fish cytokine receptors.

In summary, similar phenomena described in mammals for IL-2 and IL-2R expression seem to exist in all jawed vertebrates. Future studies will lead not only to an understanding of IL-2 evolution at the structural level, but also insight into the seasonal changes in T cell stimulation in reptiles, the differential capacity of larval and adult amphibian T cells to produce or respond to T cell growth factors, and hyperstimulation of T cells in the mutant obese chicken strain.

Interferons

Type I IFN is expressed in leukocytes (IFN-α) and virus-infected fibroblasts (IFN-β) and induces inhibition of viral replication in neighboring cells, as well as molecules of the innate immune system such as iNOS and IRF-1. In contrast, type II IFN (IFN-γ or immune IFN) is synthesized by activated T cells, activates macrophages, and upregulates class I, class II, immune proteasome subunits, and TAP, and a large number of other genes. IFN has not been detected in the invertebrates, and in general cellular immunity in the invertebrates has lagged behind the explosion of data on humoral immunity. However, as described

earlier, viral immunity does include a JAK/STAT response analogous to the IFN response of the deuterostomes (90).

Antiviral activity is detected in supernatants from virally infected fish fibroblasts, epithelial cell lines, and leukocytes. All of the biochemical properties of mammalian type I IFN (e.g., acid-stable, temperature-resistant) are present in these fish supernatants, and the putative IFN reduces viral cytopathic effects in homologous cell lines infected with virus. *In vivo,* passive transfer of serum from virally infected fish protects naïve fish from acute viral pathogenesis. There appears to be two lineages of type I IFNs in fish that are specific to this group. In chickens, there are up to 10 closely related, intronless type I IFN genes. Sequence identity to human type I IFN ranges from 25% to 80% with the apparent functional gene having highest similarity (255).

Type II IFN has been cloned in chickens and several teleosts. The chicken gene is 35% identical to human type II IFN and only 15% identical to chicken type I IFN. Recombinant chicken IFN stimulates nitric oxide production and class II expression by macrophages. The gene has been cloned in trout, *Fugu*, and zebrafish, and has been studied mostly in the trout where it has been shown to upregulate γIP10 and activate protein kinase C (PKC). Thus, at least in chickens and teleost fish, type II IFN seems to have the same function as in mammals, suggesting that the TH1-type responses emerged early in vertebrate evolution.

TH1 Cytokines Besides Type II IFNs

IL-12 is generally considered to be a proinflammatory cytokine produced by APC that promotes a TH1 response after exposure to intracellular pathogens. Consistent with the ancient derivation of TH1 responses, the two subunits of IL-12 p70 (p35 and p40) have been found in chickens and several teleost species. However, studies of *Fugu* suggest that the regulation of the two subunits is not the same as in mammals, which must be supplemented with functional studies and extension to other species (248).

The p40 subunit of IL-12 can also associate with p19 to form the cytokine IL-23, which is involved in the induction of TH17 cells. This subunit has yet to be found in any nonmammalian vertebrate. Similarly, whether the IL-12-related cytokine IL-27 is found in nonmammalian vertebrates is not known.

TH2 Cytokines: IL-4, IL-5, IL-9, and IL-13

Responses to extracellular pathogens are largely regulated by TH2 cytokines in mammals. IL-4 is the most pleiotropic cytokine in this regard, provoking the production of neutralizing cytokines, stimulation of eosinophils, and an antagonism of TH1 responses. IL-4, IL-5, and IL-13 are encoded in the so-called TH2 cytokine complex in mammals, and all of the genes are coordinately upregulated after

stimulation of a nearby locus-control region. This same "TH2 complex" is found in chickens (256), but in *Xenopus* only the IL-4 gene has been identified to date, and it is controversial whether *any* of the genes are found in the teleost fish, although a candidate gene was detected in pufferfish that has a tissue distribution inconsistent with being genuine IL-4 (257).

Thus, at this stage of study, it may be that lower vertebrates do not have "full-blown" TH2 responses, consistent with the lack of canonical allergic responses in ectothermic vertebrates. On the other hand, we must be careful, because cytokine genes evolve rapidly and relying on synteny is not always dependable, especially in the teleost fish. It will be of interest to see whether IL-4 in nonmammalian vertebrates will promote switching to isotypes that are incapable of promoting inflammatory responses. In addition, further studies of this family and its receptors in teleost and cartilaginous fish will reveal whether this facet of the adaptive immune response is indeed a relative newcomer.

Transforming Growth Factor (TGF)β and IL-10

TGF forms a large family with pleiotropic effects in many developmental systems. For the immune system, TGF-β isoforms are best known for their capacity to suppress adaptive immune responses (even across species barriers), although they can also stimulate lymphocytes under certain conditions. TGF-β inhibits macrophage activation in trout and growth of T cell lines in *Xenopus* species. Trout TGF-β, most similar to mammalian TGF-β1 and -β5 (62%–66% identity), is expressed in lymphoid tissues and brain, but not in the liver. Two forms of TGF-β were isolated in *Xenopus* species, both of which act on embryonic ectoderm to induce mesoderm. Recombinant *Xenopus* TGF-β, like the mammalian form, also can inhibit IL-2-like dependent growth of splenic lymphoblasts. Four TGF-β isoforms were isolated from chickens, as opposed to three major forms in mammals. The three major forms of the cytokine have been isolated in several teleost species (248).

IL-10 is often considered along with TGF-β because it is mostly an immunosuppressive cytokine with multiple effects; both cytokines are expressed in subsets of "Treg" cells in mammals. This cytokine was originally discovered by its ability to suppress TH1 responses, but now is known to have a much-expanded role. IL-10 has been found in chickens and a large number of teleosts. As usual, functional experiments have lagged behind the molecular work, but recombinant chicken IL-10 can block IFNγ production by splenocytes. Of the cytokines related to IL-10, including IL-19, IL-20, and IL-24, only IL-20 was found to date in the *Fugu* genome.

Note that there have been no "Treg" experiments reported *per se* in the comparative literature, but many older

experiments that suggest that such cells exist. More than 25 years ago, experiments in *Xenopus* showed that graft rejection could be delayed when lymphocytes from metamorphosing animals were adoptively transferred into adult frogs (258). This result suggested that a "wave" of suppressor cells emerged near the time of metamorphosis that evolved to protect animals from autoimmunity when adult-specific molecules were expressed. It is time to reexamine such experiments with modern tools.

IL-17

Recently, besides TH1 and TH2 cells, two new classes of CD4 cells, TH17 and the aforementioned Treg, have become popular among immunologists. TH17 is proposed to be a cell type important for inflammatory responses to extracellular bacteria via stimulation of neutrophils. Despite its late appearance on the scene in the general literature, this cytokine appears to be one of the oldest, with homologues in lower deuterostomes like amphioxus and extensively amplified in sea urchins (32). Even the different isoforms seem to be conserved among the jawed vertebrates, which should initiate many new avenues of study over the next few years.

The isolation of nonmammalian cytokines and cytokine receptor genes has followed molecular characterization of antigen receptors and MHC. However, with the advent of the genome and EST projects, we are rapidly acquiring a comparative view of this field, at least at the genetic and molecular level. Teleost fish and chickens have paved the way in this field, but amphibian and cartilaginous fish databases will soon be complete and provide the big picture. Already, it seems that cytokines like TNF and IL-17 are most primordial, with homologues in *Ciona*, amphioxus, and sea urchins. Conversely, *none* of the other so-called *adaptive cytokines* seem to be present in the lower deuterostomes, consistent with the Big Bang theory of adaptive immunity. If it is true that the jawless fish lack these genes as well, despite their convergent adaptive immune system, one can point to the evolution of lymphoid organs and the segregation of lymphocyte subsets into discrete areas to help to explain the explosion and recruitment of these genes.

Despite our "big picture" knowledge of the emergence of cytokines, obviously functional experiments have lagged behind. Further, is it true that TH2 responses are evolutionary latecomers, or are our early attempts at finding the genes in ectotherms because of some "missing pieces" in the databases (or our ability to find some of the genes)? Some genes may have been lost, as described earlier for the chicken—again, further studies of amphibians and cartilaginous fish should help in our understanding. In mammals, the LT TNF family members are important in the development of lymph nodes, and yet the three genes are present in lymph node–less *Xenopus*—what are their

functions? If we can uncover these other roles in non-mammalian vertebrates, it could be quite informative to reinvestigate such functions in mammals. Finally, chickens and fish have evolved their own paralogues of some of the well-known cytokine genes; their study should reveal selection pressures on particular species that could also be quite informative in our understanding of the gestalt of the cytokine network.

General Evolution of Chemokines and Their Receptors

Chemokines and chemokine receptors are essential for many aspects of the immune system, including the differentiation of lymphoid tissues, trafficking of hematopoietic cells during ontogeny and immune responses, and even stimulation of cells under various conditions. With the advent of the genome and EST projects, a recent paper showed that, consistent with the Bing Bang theory of adaptive immune system evolution, all of the major classes of chemokines and their receptors emerged in the bony fish lineage (259) and probably will be found in cartilaginous fish as well when the genome is complete. In fact, bony fish have more chemokines/receptors than any other vertebrate, including amphibians and mammals.

Interestingly, no CC or CXC chemokines/receptors were detected in lower dueterstomes like *Ciona* and sea urchin. The chemokine receptors are members of the G protein-coupled receptor (GPCR) family, and of course such molecules are found in all animals. However, no members of the specialized family (GPCRγ) to which chemokine receptors belong were found in lower deuterostomes. The chemokine receptor genes are found on four chromosomes in mammals, each of which contain the HOX genes, one of the gene families that provided evidence for the 2R hypothesis early in the reawakening of this theory (7). The distribution of chemokine receptor genes on these chromosomes correlates very well with 2R and helps to account for the large-scale gene expansion of this family in the jawed vertebrates. Thus far, very few chemokines/receptors (e.g., IL-8 and CXCR4) have been detected in agnathans, but they are clearly present and likely required for movement of VLR-expressing cells throughout the body.

EVOLUTION OF ALLORECOGNITION

Histocompatibility Reactions in Plants and Invertebrates

Before the true role of MHC was discovered, histocompatibility reactions were the major means used to investigate evolutionary aspects of the immune system in comparative immunology. Scrutinizing specific memory in graft rejection assays across the animal kingdom demonstrated that allorecognition was almost universal among metazoa

and led to speculations on the origins of vertebrate MHC (260). However, the mechanisms and molecular underpinnings of such alloreactions remained unsolved. With the new genome projects and functional analyses, a true picture starts to emerge when one examines these old experiments.

The prevention of self-fertilization has evolved several times in the plant kingdom (261). In one case, the molecular mechanism for the phenomenon has been elucidated in study of the highly polymorphic self-recognition (*S*) locus of crucifers. Genes encoding TM-receptor Ser/Thr kinases called SRK (*S*-locus receptor protein kinase) are expressed in the stigma and closely linked to genes for soluble SCR (*S*-locus cysteine-rich) proteins expressed by pollen. Both genes are highly polymorphic, and if a self-SCR is recognized by an SRK, pollen tube growth and hence self-fertilization is inhibited. SRKs are members of a plant gene family that have been recruited for this purpose, and the SCRs have structural similarities to the amphipathic defensins described earlier; thus, perhaps molecules involved in microbial pattern recognition were coopted for this new purpose. Here, the two very different linked genes must coevolve, in ways not understood, within each haplotype to ensure mutual binding of the self-gene products. Thus, while similar mechanisms at the genetic and population levels described earlier (e.g., balancing selection, ancient allelic lineages, coevolution of linked genes, etc.) are operational for *S* locus, MHC, and other recognition systems, clearly pressures can coopt quite different types of gene families for involvement in the recognition events. Close linkage of polymorphic receptor and ligand genes involved in all of the histocompatibility reactions outside of the jawed vertebrates is an inviolable rule.

The life histories of several aquatic invertebrates in the taxa Porifera, Cnidaria, Bryozoa, and Tunicata (Figure 3.1) are characterized by the sexual production of motile larvae that settle, metamorphose, and initiate asexual reproduction by budding. This results in the growth of a colony (polyps in Cnidaria or zooids in Tunicata). Colonies often compete for space and may develop histocompatibility reactions in the zone of contact. In addition, cell-lineage parasitism, in which the somatic or germ cell lineage of one partner replaces that of the other, may ensue if colonies fuse into a chimera (262). Thus, allorecognition also protects the genetic integrity of the individual. In some species, fusion is apparently restricted to tissues of the same individual (complete matching), in other species such as bryozoans, fusion also occurs between genetically distinct individuals if they share kinship (partial matching) (263). Two divergent invertebrate phyla have been studied in detail: Cnidaria and Tunicata (Figure 3.1). To preface this section, in no case does the genetic region responsible for the histocompatibility reactions resemble the vertebrate MHC, except by high polymorphism of all systems, and at times, analogous outcomes.

Porifera

Sponges (Porifera) are the phylogenetically oldest extant metazoan phylum. A surprising characteristic of sponges, considering their phylogenetic position, is that they possess a sophisticated histocompatibility system. Recently, elements of the sponge immune system have been analyzed at the molecular level. By differential display, two genes were identified in *S. domuncula*, the products of which are involved in a still undetermined manner in aggregation. Sponge cells associate in a species-specific process through multivalent calcium-dependent interactions of carbohydrate structures on a 200 kd extracellular membrane-bound proteoglycan called "aggregation factor." The glycan moiety is involved in cell adhesion and exhibits differences in size and epitope content among individuals, suggesting the existence of allelic variants. Therefore, strong carbohydrate-based cell adhesion evolved at the very start of metazoan history. Other genes involved in these reactions include one that is similar to the vertebrate MHC-linked allograft inflammatory factor (AIF-1, Figure 3.12) and another to the T cell factor transcription factor (TCF). AIF-1 and TCF genes are upregulated *in vivo* after tissue transplantation, and *in vitro* in mixed sponge cell reaction (MSCR). Polymorphic IgSF molecules are found on the surface of sponge cells, but their relationship to allorecognition events (if one exists) is not clear (264).

Allogeneic recognition *in vitro* led to apoptotic cell death in one partner and survival in the other. The process is controlled by a differential expression of the pro-apoptotic and pro-survival proteins that are characteristic for the initiation of apoptosis (caspase, MA3, ALG-2 protein) and the prevention of programmed cell death (2 Bcl-2 homology proteins, FAIM-related polypeptide and DAD-1-related protein). In an apoptotic mixed cell combination, characteristic apoptotic genes were expressed, while in the nonapoptotic aggregates the cell-survival genes are upregulated (265). In another species, *Microciona,* allogeneic interactions also induce cellular reactions involving gray cells (sponge immunocytes) and finally apoptosis. Analogous (but probably not homologous) to T cell responses, the response is inhibited by cyclosporin A (266).

Sponge genetics is in its infancy, but from observation of 50 pairs of larval grafts within one F1 progeny of the marine sponge *Crambe,* 75% could fuse, a proportion suggesting that the genetic control depends on one locus and sharing of one haplotype results in fusion; a 100% fusion between mother and offspring is consistent with this interpretation. Unfortunately, individuals from a given mother may not have the same father, complicating the issue. Still the few data available are consistent with a single or at least major histocompatibility locus (or region), the "rule" in other invertebrate phyla described in the following.

Cnidaria

The existence of highly polymorphic histocompatibility loci was demonstrated long ago in various corals or sea anemone, but the diploblastic colonial cnidarian *Hydractinia* was the only species to provide a model to analyze genetic control of such reactions. In 1950, Hauenschild noticed that allorecognition seemed to be under the control of a single genetic region with multiple alleles (267), and this system has been studied in great detail by Buss and his colleagues. Colonies of *Hydractinia* encrust the shells of hermit crabs, where they grow by elongation and branching of stolons. Embryos and larvae fuse indiscriminately. However, when two or more larvae are recruited to the same substratum, colonial forms may come into contact through their stolons. If the two colonies are histocompatible, stolon tips adhere and fuse, establishing gastrovascular connections and a permanent genetic chimera. If tips are incompatible, colonies fail to adhere. They swell (hyperplastic stolons) with the migration of nematocysts, which discharge and damage the tissues. In addition, transitory fusions can also occur in a few cases. Similar to the genetics of the sponge alloreactions discussed earlier (and in other invertebrates and plants), colonies fuse if they share one or two haplotypes, reject if they share no haplotypes, and display transitory fusion if they share only one allele at one haplotype and no alleles at the other. Examination of the polymorphic locus governing this reaction (*alr*) revealed that two closely linked polymorphic loci (likely encoding receptor and ligand) are involved (268). The *alr*-encoded receptors, as well as the effectors of the reaction (other than the nematocysts), are unkown.

Urochordates

Compared to Cnidaria, tunicates shared a recent common ancestor with the vertebrates and thus might be expected to have a histocompatibility system more related to MHC. Allorecognition has been studied in both colonial forms and solitary ascidians. The model originally developed by Oka and Watanabe in the tunicate *Botryllus* (269), a colonial ascidian, has been studied over the past 25 years by several groups (270). What attracted extra attention to this system was the discovery that the locus controlling histocompatibility was linked to, or was the same locus, as that controlling fertilization by preventing self-fertilization; in this case, the sperm must be genetically disparate from the egg.

Metamorphosis in *Botryllus* is followed by budding that eventually gives rise to a large colony of asexually derived genetically identical individuals (zooids), united through a vascular network. At the periphery of the colony, the vasculature ends in small protrusions called *ampullae,* which are the sites of interaction when two colonies meet during their expansion. The interaction results in either fusion of the two ampullae to form a single chimeric colony

sharing a common blood supply, or a rejection reaction during which the interacting ampullae are destroyed, thus preventing vascular fusion. Hemocytes (morula cells) are involved in the reaction (271). Fusion or rejection is governed by a single highly polymorphic locus called the *FuHC* (for fusion/histocompatibility; 10 wild-type individuals collected from around the Monterey Bay area yielded 18 cFuHC alleles). When two colonies share one or both FuHC alleles, they will fuse; rejection occurs if no alleles are in common. The FuHC is highly polymorphic, with most populations containing tens to hundreds of alleles. However like in *Hydractinia*, the situation is not that straightforward since intermediary pathways have been reported in the past and have not been entirely elucidated.

The painstaking development of inbred lines of *Botryllus* homozygous for different FuHC alleles has resulted in a molecular characterization of the polymorphic FuHC locus (272). The deduced C-terminal region of the molecule consists of a nectinlike segment with 3 Ig domains, showing best homology to chicken IgSF4 and related members conserved in all vertebrates as well as to one of the *Ciona* nectins. Those members are found in a tetrad of paralogues in vertebrates but not linked to the tetrad of MHC paralogues ([11] discussed later). The N-terminal region contains an EGF domain and some other unrecognizable regions not conserved among ascidians. Any two alleles differ by an average of 4% at the nucleotide level. Unlike MHC class I and class II, polymorphic residues in FuHC alleles are not concentrated in particular regions.

Some 200 kb away from FuHC, on the same chromosome, is a second polymorphic (and polygenic) locus, *fester*, which is inherited in distinct haplotypes. Diversified through extensive alternative splicing, with each individual expressing a unique repertoire of splice forms, it potentially exists as both membrane-bound and secreted forms, all expressed in tissues intimately associated with histocompatibility. After *fester* knockdown, the histocompatibility reaction is blocked at the stage of initiation as if the colonies ignored each other. In contrast, when *fester* is blocked with specific mAbs, fusion reactions were unaffected, but rejection reactions were turned into fusions in an allele-dependent manner. These data combined with its genetic location suggest that *fester* encodes the FuHC ligand. *Fester* contains a short consensus repeat (SCR, or sushi domain) often found in vertebrate complement receptors (273).

Solitary Ascidians

In *Halocynthia roretzi*, a "polymorphism of color" has been observed, and histocompatibility reset by a mixed hemocyte technique *in vitro*, resulting in a melanization reaction likely to involve the PPO cascade (274). Depending on the strains, the percentage of positive reaction varied

from ∼55% to 70%, indicative of polymorphism. Grafting experiments had already shown the existence of allorecognition in solitary ascidians and investigation at the cellular level had demonstrated the occurrence of cytotoxic cells in such organisms (275). As mentioned earlier, in order to shed light on allorecognition in urochordates and on the molecules involved in preventing self-fertilization, gonadal cDNAs of three genetically unrelated *Ciona intestinalis* individuals were compared by suppression subtractive hybridization (SSH). This led to the discovery of the highly polymorphic VCLR1 (variable complement receptor–like 1) gene coding for a TM protein with several short consensus repeat domains (SCR/CCP), a motif shared with the variable fester receptor of *Botryllus* described earlier (276).

The Meaning and Selection of Histocompatibility Reactions

The association between allorecognition in *Botryllus* and fertilization led to the proposal that histocompatibility systems were selected during evolution to avoid inbreeding. The hypothesis made sense in the case of sessile colonial invertebrates that might have difficulty dispersing their gametes and therefore are susceptible to inbreeding depression. Indeed the partial matching mentioned earlier is a general characteristic of fusion compatibility in colonial invertebrates, perhaps driven by "selection operating on an error-prone genetic system for self-recognition that is perhaps constrained by derivation from a gametic function selected to reduce inbreeding." Further, even for mammals, there is a large literature suggesting a selection both at the mate-choice and pregnancy levels for preserving heterozygocity at the MHC (see Flajnik, Miller and Du Pasquier in the 5th edition of *Fundamental Immunology*). However, the possibility of a common genetic system, or linked systems, governing fusion and gametic compatibility awaits confirmation. Animals that are neither sessile nor unable to disperse their gametes can possess alloimmune responses, which is inconsistent with the general hypothesis. Moreover, inbreeding avoidance can only explain the selection of histocompatibility alleles if the histocompatibility loci are genetically linked to a large fraction of its genome (277). This is inconsistent with the tight linkage of histocompatibility genes to a single major locus, especially in invertebrates. So inbreeding avoidance is unlikely to contribute significantly to the selection of histocompatibility alleles, although in jawed vertebrates, selection for heterozygocity at the MHC itself has obvious advantages.

Another hypothesis is that alloimmunity was selected because it avoided intraspecific parasitism or competition for attachment sites (278). Indeed, after fusion of compatible colonies, bloodborne germline or totipotent stem cells are transferred between colonies and can expand

and differentiate in the newly arising, asexually derived individuals of the vascular partner (279). This can result in a situation where only one genotype is represented in the gametic output of the fused individuals. The FuHC polymorphism in *Botryllus* could function to restrict to compatible individuals the vascular fusion and the germline parasitism. The high allelic polymorphism characteristic of all invertebrate recognition systems may have evolved in response to selection for fusion with self rather than kin. Fusion with self will allow the development of a colony that benefits from fusion while eliminating the possible cost of somatic cell parasitism, and thus would be the *raison d'être* of the allorecognition mechanisms (280).

However, most animals are not sessile and thus are neither prone to intraspecific competition nor to competition for limited substrate attachment sites. Tunicates besides *Botryllus* have evolved differently—for example, in *Diplosoma*, large numbers of chimaeras are encountered in nature (281). In addition, the intraspecific competition hypothesis demands that individuals maintain expression of histocompatibility alleles, even when the expression of these alleles enables their own destruction during intraspecific competition. These considerations suggest that intraspecific competition might affect histocompatibility allele frequencies in some organisms under certain conditions but is unlikely to have broad relevance for the evolution of alloimmunity.

Both previous hypotheses are essentially based on observations made in colonial tunicates, but colony living has evolved several times independently. Urochordates are more ancient than the vertebrates, but the evidence argues against any of the systems being ancestral to MHC class I and class II. That all these studies show a general pressure for polymorphism is quite clear, but the evidence from all systems studied to date suggests strong pressures to evolve similar systems via convergence. However, as described earlier, genetic regions with homology to the vertebrate MHC have been detected in the invertebrates (282), yet are (most likely) unrelated to the reactions detailed here.

As described, in all of the allorecognition systems convergent mechanisms have been encountered to reach an analogous end, and thus it is unlikely that a unique "cause" arose for selecting them in diverse organisms. However in an attempt to find an ultimate and general explanation to the selection during evolution of highly polymorphic allorecognition systems, it has been suggested that pathogen and retroviruses are the force behind the selection of allopolymorphism (277). The hypothesis that places itself at the level of a general selection pressure exerted by pathogens has the advantage of not predicting one given genetic system but a general strategy of adaptation. It does not imply intimate phylogenetic relationships between the systems observed, but points to analogous solutions when facing similar pressures.

ORIGINS OF ADAPTIVE IMMUNITY

The immune system of vertebrates is unique because the antigen-specific receptor expressed by lymphocytes, which initiates cascades leading to activation of the adaptive immune system, is not the product of a complete germline inherited gene. Rather, receptors are generated somatically during lymphocyte ontogeny from gene segments scattered at a particular locus. As described earlier, jawed vertebrate are IgSF members composed of variable (V) and constant (C) domains, with the C domains being of the rare "C1" type, which is shared by MHC class II and class I molecules (Figure 3.3). There are many specific questions: 1) Did MHC class I or class II come first? 2) What is the origin of the MHC PBR? 3) Was the MHC involved with innate immunity before the emergence of adaptive immunity? 4) Did somatic rearrangement or somatic mutation come first to diversify antigen receptors? 5) Which of the extant antigen receptors, α/β TCR, γ/δ TCR, or IgH/L (if any) resembles the primordial receptor? The answers to these questions will always remain speculative, but deductions can be made based on the wealth of genetic data accrued over the past few years. We base many of our arguments on the large-scale duplications that were noticed for MHC by Kasahara in 1996 (Figure 3.13). The remarkable syntenies of paucicopy genes on the paralogous regions, and the recent finding that an animal that predated the duplications (Amphioxus and *Ciona*) has only single-copy genes in the same syntenic group orthologous to the four mammalian copies, make it incontrovertible that at least *en bloc* duplications were involved (282); recent evidence examining essentially all genes in the human genome strongly support the 2R hypothesis (161). Further analysis of this region in Amphioxus and other deuterostomes will begin to answer at least the first three questions in the preceding paragraph. Genetic analyses in protostome lineages have not been very informative, but we must have a second look once we piece together data from more deuterostome species.

MHC Origins

Class I and class II molecules have been found only on the jawed vertebrates—so far, painstaking screenings of the lower deuterostome or lamprey/hagfish databases have yielded no indication of these proteins. Based on phylogenetic analyses and thermodynamic arguments, most investigators believe that class II preceded class I in evolution. However, as stated earlier, class I is much more plastic than class II, as there are many different types of class I molecules, some that do not even bind to peptides. Because class I genes may be on two or three MHC paralogues, and they can have functions outside the immune system, this is evidence that the primordial PBR may not have even bound to anything. If this is true, and because class I and class II do bind peptides, it would suggest class I arose first.

Again, genome scans of jawless fish and lower deuterostomes should be informative on this point, but to date we have had no luck.

From the paralogue data, genes encoding the complement components C3 and Bf, TNFSF members, the signaling molecule Vav, and proteasome subunits, among other genes, should have been present in the proto-MHC before emergence of the adaptive immune system (Figure 3.13). Some of these genes were found in the Amphioxus MHC linkage groups, and C3 and Bf genes are linked in the sea urchin. A fifth paralogous region on human chr 12p13 contains the α2-macroglobulin gene (recall the C3/4/5 homologue), a tapasin homologue, the C3a-receptor, and this "complex" is linked to the NKC. Taken together, the data suggest that the proto MHC included vital nonhomologous genes of the innate immune system, which perhaps were linked to allow coordinate regulation of expression (283). After the *en bloc* duplications, Pontarotti has suggested that "functional restraints upon the complex were relaxed" and hence the duplicated members could evolve new functions, including features indispensable to the adaptive system (284). If indeed innate immunity genes were already linked to allow upregulation at times of infection, it is no surprise that the adaptive immune system piggybacked on such a gene complex. A final point: Why did the duplicate genes survive rather well over hundreds of millions of years? Cis duplicates have been shown to degenerate rapidly over evolutionary time. Evidence suggests that duplicates arising from polyploidy (and by inference large *en bloc* duplications) survive better than cis duplicates, most likely because they cannot be inactivated by unequal crossovers (285); the ability of the genes to survive over very long periods, perhaps combined with strong selection pressures, would allow for subspecialization.

Origins of Rearranging Receptors

The Rearranging Machinery

Most models propose that the generation of somatically rearranging receptors occurred abruptly in evolution via the generation of the RAG machinery made of two lymphocyte-specific proteins, RAG1 and RAG2. *RAG* genes have so far been isolated in all classes of jawed vertebrates, excluding reptiles, and have been quite conserved. In every case examined, *RAG1* and *RAG2* genes are closely linked and in opposite transcriptional orientation. Some regions of RAG1 and RAG2 are similar to bacterial recombinases or to molecules involved in DNA repair (e.g., RAD16), or the regulation of gene expression (e.g., rpt-1r). Similarities to prokaryotic proteins and the gene structure suggest that vertebrates acquired the RAG machinery by horizontal transfer and transposition from bacteria (286). Indeed, *RAG* genetic organization has some transposon characteristics: The RSS are reminiscent of sequences involved in targeting excision of transposons (287). A new class of

transposons has been detected in several protostome and deuterostome invertebrate species that shows similarity to the catalytic domain of RAG1 (288). It is believed that RSS were derived from the terminal inverted repeats of this new transposon, called *transib*. In the sea urchin genome, there are many of such "RAG1 core regions," but only one has an open reading frame throughout the core and shows similarity to vertebrate RAG1 in other regions as well. Further, a *RAG2* homologue is adjacent to the urchin *RAG1* gene, in a similar orientation as is found in gnathostomes (289). This finding was a big surprise and suggests that both *RAG* genes were in place ~100 million years before the origin of the Ig/TCR system. Their precise tissue distribution and expression during ontogeny are not known; nor have there been any candidate genes recognized to date with RSS that might be recognized by the echinoderm homologues. It must be admitted that it is unclear how this new result fits into the puzzle of the origins of adaptive immunity.

Another source of somatic antigen receptor diversity shared by all gnathostomes characterized to date is a unique DNA polymerase, TdT, which diversifies CDR3 during Ig and TCR gene rearrangement through the addition of nucleotides in a template-independent fashion. Further, as detailed earlier, its expression serves as an unambiguous developmental marker for the sites of lymphopoiesis. TdT has been highly conserved in both sequence (>70% aa similarity, >50% aa identity) and overall structure during vertebrate evolution (32). An amino acid alignment of all known TdT sequences reveals that some, but not all, structural motifs believed to be critical for TdT activity are particularly well conserved in all vertebrates studied. TdT protein alignments and the crystal structure for rat β-polymerase support the hypothesis that both evolved from a common ancestral DNA repair gene. In addition, four protein kinase C phosphorylation sites are conserved and hence may be involved in TdT regulation. Homologues related to the ancestor of polymerase β and TdT have been found in sea urchin and other lower deuterostomes. Thus, unlike RAG, TdT has evolved by gradual evolution from a polymerase family and was recruited for immune system function.

As described, somatic rearrangement is dependent on RAG1/2. It seems that a "horizontal" acquisition of a RAG-laden transposon occurred at some point during the history of the vertebrates. In principle, RAG activity is confined to lymphocytes, but the existence of germline rearrangements of shark Ig genes suggests that RAG can remain an active force, modifying the genome in some vertebrates (150). As the enzyme itself is not so informative for phylogenetic analysis of origins of the adaptive immune system, one must turn to the history of the substrate (i.e., the V(J)C IgSF domains, [discussed later]). Introduction of RAG genes from a unicellular organism would be a unique example of a modification of the primordial immune system by horizontal transfer. In this case,

microorganisms that interacted with ancestral vertebrates (or lower deuterostomes) would not simply select the variation derived from the species on which it exerts its pressure, but it would introduce a new source of variation in the immune system. One must think of the cellular lineage in which somatic rearrangement was introduced. Such a dangerous innovation could not be tolerated under conditions where it would be ubiquitously expressed, because it might jeopardize the whole genome. Most likely the introduction was into a gene that controlled a lymphoid cell lineage where a mistake would not threaten the whole individual (perhaps one that already was part of an adaptive immune system governed by SHM; discussed later). Another scenario postulates that RAG was inactive until specific factors coevolved to permit lymphocyte-specific expression. The discovery that neighboring *RAG1/2* genes are controlled by a single switch in a small piece of DNA next to one end of the RAG2 gene may explain why, over the 450 million years since the genes first appeared, they have remained closely linked (290). What was important is that the original transposon became controlled by regulatory regions active in only specific cell types. Perhaps there were several "attempts" at transposition in evolution, resulting in catastrophes or in other activities such as translocation or deletions. An ideal candidate would be a locus control region regulating expression of activating receptors with VC1 domains in NK-like cells, perhaps in the proto MHC or the second set of paralogues (chr 1, 3, 11, 21) before the second duplication (11). The MHC paralogous region described earlier is near the NKC on chr 12p13 (Figure 3.13) and could be derived from the ancestral gene complex, and the *Xenopus* MHC-linked *XMIV* genes are also excellent candidates (160). In the same way as *RAG1/2* genes remain linked because of regulatory elements close to *RAG2,* an NK cell-specific region under the control of a regulatory region might have controlled expression of a set of genes.

Rearrangement or SHM First?

Since all antigen receptor genes use somatic rearrangement of V genes to generate diversity in CDR3 regions as well as to promote combinatorial diversity, there is no doubt that this mechanism is at the heart of adaptive immunity. Indeed, as described, most investigators believe that the introduction of the transposable element into a V gene was *the* driving force in the abrupt appearance of vertebrate adaptive immunity (291); the finding of the RAG genes in sea urchins challenges this notion at some level. However, it cannot be overemphasized that SHM is also at the origins of the immune system; further, all evidence to date suggests a gradual evolution of the hypermutation machinery (the AID/APOBEC family and associated polymerases/mismatch repair proteins) rather than the "hopeful monster" generated by the famous RAG transposon. Thus, diversity generated via SHM or gene conver-

sion may have existed in an adaptive immune system prior to rearrangement, and V gene rearrangement was superimposed onto this already-existing system (217,221). The RAG-induced rearrangement break and subsequent repair provided something new, not only diversity in sequence but heterogeneity in size; this was a remarkable innovation and likely indeed heralded the sophistication of jawed vertebrate adaptive immunity. Perhaps it is no accident that the one gene discovered so far to be indispensable for SHM, AID, or activation-induced deaminase is encoded in the aforementioned chr 12p13 region. Further, the possibility that the VLR genes are pieced together under the influence of an APOBEC family member also suggests that conversion/mutation may have preceded rearrangement— a rare example of a homologous molecule functioning in an analogous system. If mutation indeed came first, we may find examples of it today in extant prochordates and invertebrates (though, as described earlier, no APOBEC family members have been found in the nonvertebrate deuterostomes to date.)

Which Antigen Receptor First?

Phylogenetic analyses have suggested that a γ/δ TCR-like ancestor may have predated α/β TCR and Ig H/L (292). This would suggest that direct antigen recognition, perhaps by a cell surface receptor, arose first in evolution followed by a secreted molecule and an MHC-restricted one. Hood and colleagues argue that phylogenetic analyses over such large evolutionary distances obscure true relationships among the antigen receptor genes (e.g., the relationships of the molecules in the phylogenetic trees has to impose multiple loss/gain of D segments in the different antigen receptor families) and suggests a model based on genomic organization, not so different from the Kasahara model (293). They propose an alternative phylogeny in which there exists an ancestral chromosomal region with linked genes encoding both chains of an ancestral antigen receptor heterodimer, one having D segments and one not. One *en bloc* duplication gave rise to the Ig and TCR divergence, and a second to the α/β and γ/δ TCR gene complexes. The α and δ loci are still closely linked in all vertebrates analyzed (human chr 14), and a pericentric inversion is suggested to have separated the TCR β and γ loci (linked on human chr 7). This model predicts that D segments only emerged once, and also explains the existence of inverted V elements in the TCR β and δ loci. This model does not predict which antigen receptor is oldest but does provide a "simple view" of receptor evolution, consistent with the Kasahara/Ohno model.

For the origin of the rearranging receptors, IgSF lineages have to be traced back through phylogeny, because such receptors generated by somatic rearrangement do not exist outside the jawed vertebrates. In a quest for molecules related to elusive ancestors, without focusing on genes expressed in the immune systems of various phyla (i.e.,

structure is more important than function in this case), the most homologous sequences and gene architectures in the various metazoan phyla must be scrutinized.

V(J) and C1 Domains

C1 domains are found in the antigen receptors, MHC class I and class II, and very few other molecules (Figures 3.3, 3.11). This IgSF domain is so far most prevalent in gnathostomes, as if C1 domains arose concurrently with the adaptive immune system and coevolved with it. What was the value of the C1 domain and why is it found almost exclusively in adaptive immune system-related molecules? All of these molecules interact with coreceptors such as CD3 (TCR), Igα and β chains (Ig on B cells), CD4, and CD8 (with MHC on opposing cells), and it is conceivable that in sections of IgSF domain in which C1 differs from the C2 there is a specific region favoring interaction with other molecules.

The G strand of Ig/TCR V domains is encoded by the J gene segment, separated from the V region-encoded A-F strands (Figure 3.3), and rearrangement is necessary to assemble a complete V gene. The primary structure of each Ig/TCR chain bears hallmarks of the dimeric nature of the receptor in which it participates. A diglycine bulge (Gly-X-Gly), present in all V domains, is thought either to be a beneficial adaptation, or to promote dimer formation by inducing a twist in the G strand that results in V domain pairing that appropriately orients the CDR. Monitoring this feature, therefore, might reveal genes that had the ability to form dimers similar to that of modern antigen specific receptors. In V genes that do not somatically rearrange, the G strand is an integral part of the V exon. In other remotely related IgSF genes, introns have invaded the V domain exon creating a variety of V gene families. Many examples of such events can be found in the history of the IgSF, for example in the genes encoding CD8 and CTX (294).

As described, no Ig/TCR genes have been isolated from hagfish or lampreys, although there are some tantalizing molecules potentially related to their ancestors (e.g., APAR, see earlier). Were Ig and TCR "invented" in a class of vertebrates now extinct (e.g., the placoderms, which are more primitive than cartilaginous fish but more advanced than agnathans)? It is not known whether agnathans have C1 domains, although from the study of the mammalian MHC paralogous regions, a relatively recent jawed vertebrate ancestor should have had such domains. The discovery of the three tapasin paralogues, all with C1 domains, suggests an origin prior to the full establishment of the vertebrate genome (11).

V domains, either alone (e.g., IgNAR) or in association with another V domain (e.g., Ig H/L), recognize the antigenic epitope and are therefore the most important elements for recognition. For this reason, they will be the first to be traced back in metazoan evolution by asking whether V domains exist in invertebrates. Domains with the typical V fold, whether belonging to the true V set or the I set, have been found from sponges to insects (although not necessarily involved in immune reactions; the first ones were discovered by nonimmunologists among molecules involved in nervous system differentiation in invertebrates—e.g., amalgam, lachesin, and fascicilin). Invertebrates also use IgSF members in immunity, but so far they are not V domains, but more I or C2 set (Figure 3.3, e.g., MDM, hemolin, DSCAM). However, the mollusk FREPS have a V domain at their distal end, associated with a fibrinogenlike domain. As described, they are involved in antiparasitic reactions and form a multigenic family with polymorphism (295).

Besides searching for VC1-encoding genes in nonvertebrates, surveying the human genome for such genes has been fruitful. Indeed, nonrearranging V-containing molecules, either VJ alone, VC1, or C1 alone, have been found in the human genome. Interestingly, many of them are present in the MHC class III region (human chromosome 6p21) or its paralogues (Figures 3.12, 3.13). Two MHC-linked gene segments stand out: a single V, NKP30, and a gene containing a VJC1 core, tapasin, involved in antigen processing. NKP30, made of a single Ig domain of the VJ type, is an NK cell activating receptor, and it may offer a link to cell types encountered (analogue or homologue?) in invertebrates. It could be a relative of an ancient receptor whose history is linked to the emergence of MHC class II and class I. To resemble an ancestor, the NKP30 V domain need only be associated with a C1 domain. In fact, a C1 single domain gene, pre-TCRα, is also encoded in the MHC. Besides Ig and TCR, tapasin is one of the rare cases, if not the only other case, of a gene segment with a VJC1 structure existing on several paralogous linkage groups (6, 9q33, 19q13). In other words, while this gene is related to the rearranging receptor structure, it is undoubtedly very old and probably predated the ancient block (genomewide) duplications. It could have acted as a donor of C1 to a V domain-containing gene in the MHC class III region (e.g., the XMIV), which then could have been the first substrate of the rearrangement. Another set of molecules with distal VJC1 segments, the signal-regulatory proteins (SIRPs, VJ C1 C1), and the poliovirus receptor (VJ C1 C2) could represent another group linked to the history of the Ig and TCR. For example, SIRPs may be involved in clearance of dead cells via binding to TREM1 and TREM2 receptors on monocytes/neutrophils involved in inflammatory responses that are composed of single VJ domains whose genes are MHC-linked. MOG and P0, two single V domains involved in the synthesis of myelin sheath, are encoded in the MHC paralogous region on chromosome 1. Chicken BG, which is related to MOG but probably having a different function, is encoded in the chicken MHC. Butyrophilin, CD83, and tapasin all have VJ domains, and butyrophilin also has a C1-type domain. More distant relatives with

VJC2-based architectures are also found in MHC (RAGE, CTX, lectin-related genes; Figure 3.12), and some of these genes related to the rearranging receptor ancestors are found on several paralogues (whether the MHC paralogues or other), suggesting that the V-C1 core was generated early in vertebrate evolution subsequent to the emergence of the chordate superphylum. Among all these molecules, butyrophilin is perhaps not on the direct track to antigen specific receptors. Its C domain, although proven to be C1 through its crystal structure, is more like a C2 at the primary sequence level and belongs to the CD80/86 family, rather than the TCR (296). Finally, tracing the VJ NITR gene family, described earlier, in evolution may lead us to an understanding of the original NKC/LRC/MHC, as well as identifying candidate genes related to the ancestral gene invaded by the RAG transposon (9).

Many invertebrate molecules not involved in immune responses are present as a distal V domain associated with one or more C2-type domains. In the vertebrates, many molecules have retained this feature, such as CD2 and CTX. Some members resemble "primitive" antigen receptors, and several of them map to the MHC or its paralogous regions. Many form dimers and are expressed in lymphocytes, where they form a family of adhesion molecules. A recent crystal structure analysis of a CTX-related molecule (JAM, or junctional-adhesion molecule) revealed a unique form of dimerization, suggesting that the diversity of ligand binding and domain-interactions used by different IgSF domains is extensive. Two JAM molecules form a U-shaped dimer with highly complementary interactions between the N-terminal domains. Two salt bridges are formed in a complementary manner by a novel dimerization motif, R (V, I, L) E. The RAGE gene (receptor for advanced glycosylation end products) has a rather "generic" receptor function, because it recognizes aged cells exposing particular carbohydrate motifs. CD47, another conserved IgSF member with a CTX-like V domain (297), suggests an ancient function. Perhaps such nonrearranging VJC1 genes that regulated cytotoxicity/phagocytosis were predecessors of the antigen receptors (298). Some molecules with VJ/C1 cores involved in cell-cell interactions often serve as ports of entry for viruses. In a move from "property to function," an arms race consequence could result in a virus receptor developing into an immune receptor. The best examples of such molecules are in the CTX/JAM family in which receptor interactions with viruses may trigger apoptosis, a primitive form of antiviral immunity (11,299).

CONCLUSIONS

Since the last edition of *Fundamental Immunology* was published 5 years ago, there have been several stunning findings, as well as other interesting discoveries and integrations, regarding the evolution of the structure and function of the immune system. Further, there have been many genome and EST projects that have allowed us to determine whether particular genes or gene families are present in different taxa. Here, we briefly describe these findings and discuss their broad relevance and relationship to future studies.

—As predicted in the previous edition, adaptive cytokines such as γIFN, IL-2, and IL-4 are not present outside of jawed vertebrates, nor are the vast array of chemokines seen in gnathostomes. However, at the moment it appears that almost all of the cytokines/chemokines discovered in mammals are also present in basal jawed vertebrates. IL-17, a cytokine garnering great attention in basic immunology, and TNF, a central cytokine in both innate and adaptive immunity, seem to be the first cytokines to have emerged in evolution based on studies of lower deuterostomes (32). If, as suggested from studies in mammals, IL-17 is important for responses to extracellular bacteria (300), nonvertebrate deuterostomes may hold the key to understanding the physiology of the entire system (i.e., in the absence of the competing TH1, TH2, and Treg cells, one may be able to study the dynamics of IL-17 development and function).

—A new defense system in *Drosophila*, previously recognized to be important for nervous system specialization by generating an enormous number of splice variants, is also used for immunity (with a different set of splice variants). A model for a primitive type of selection has been proposed to select for the splice variants that bind to particular invaders (301). This system is found in all insects studied to date, and importantly in parasitic vectors such as mosquitoes. Snail FREPs, shrimp penaedins, and sea urchin 185/333 have also shown that nonvertebrates can generate extraordinary levels of diversity in defense molecules. Studies of the mechanisms of diversity generation will not only provide new insights into how immune defense can be obtained (e.g., in economically important insects and agriculturally vital seafood), but also may permit new therapeutic strategies for certain diseases. In addition, "memory" or transfer of immunity from parent to offspring has been encountered in the invertebrates, without an understanding of the mechanisms involved.

—One of the great triumphs in the field of comparative immunology was the discovery that similar mechanisms are used to recognize extracellular pathogens and initiate immune responses (302). It has been ~10 years since the *Drosophila* Toll/IMD systems and their relationship to vertebrate TLR and TNFR was uncovered. By contrast, studies of viral and intracellular pathogen responses have lagged far behind in the protostomes (90,303). Now studies of viral responses in arthropods have shown that an IFN-like response working through a JAK/STAT pathway occurs (analogous, not

homologous to IFN). Thus, the Toll/IMD/JAK/STAT pathways go back at least to the triploblastic ancestor about a billion years ago. Further, an RNAi-like system exists as well, consistent with previous studies of plants and other protostomes. Manipulating these defense pathways will be quite important in "immunization schedules" for commercially important aquatic species. In addition, the general breakthroughs in the study of intracellular recognition of all pathogens in eukaryotic systems, by NOD, TLR, RIG, etc., have changed our gestalt views of immune defense. Finally, similar basic strategies and gene members involved in hematopoiesis are encountered throughout the animal kingdom (23); it would be surprising if this knowledge did not permit a greater universal understanding of the differentiation and maintenance of pluripotent and restricted stem cells.

—The long-awaited molecular mechanisms of histocompatibility in nonvertebrates have been uncovered in *Botryllus* and several plants (and soon in *Hydractinia*). The common themes thus far are that the genes encoding the polymorphic receptors/ligands are closely linked and that the genes all appear to be unrelated to the vertebrate MHC. New theories have arisen concerning the physiological significance of these histocompatibility reactions (277), and in the next five years there may be some consensus on their origins and the selective pressures that maintain them.

—A totally unexpected, convergent system of adaptive, lymphocyte-based defense was discovered in jawless fish (100). While the stitching together of LRR cassettes to produce a functional VLR is definitely not RAG-based, it has been proposed that an AID/APOBEC family member is involved in the generation of diversity. If this is true, then either AID/APOBEC was recruited twice to generate diversity, or there are some cis-acting elements in both systems that were likely present in an ancestral antigen receptor gene (304).

—The sea urchin genome project exposed enormous expansions of many gene families involved in immune defense (32). The significance of these expansions is unclear; sea urchins are long-lived, and in the absence of adaptive immunity a large arsenal of defense molecules may have been selected for. Yet how an organism can use all of this innate diversity (and perhaps adaptive diversity with 185/333) is a conundrum for which we have no framework. The discovery of the Transib family in many invertebrates and of sea urchin RAG1/2 have modified our perception of the "RAG transposon," but the basic idea of an invasion of a VJ IgSF exon by such a transposon lives on.

—The central role of the complement factor and its partner C3 and Bf in the complement pathway, as well as in animal evolution, has been further emphasized by studies of protostomes and cnidarians over the past 5 years (75). The loss of C3 in many protostomes has been compensated by the emergence of the TEPs, which after all have quite similar (and apparently expanded) functions.

—The genomewide duplications early in the evolution of the vertebrates (the 2R hypothesis) have been confirmed in a variety of studies, and they were indeed important in the "Big Bang" emergence of the adaptive immune system (7). The 2R paradigm is useful for studying any gene family found on multiple chromosomes in the vertebrates; good examples of how it has aided in our understanding of immunity were the study of IgSF members involved in cell-cell interaction/costimulation (11) and the evolution/emergence of chemokines (259) and TNF family members (305). An emerging paradigm is the possibility that genes encoding NKC, LRC, and MHC, as well as the antigen receptors and costimulatory molecules (and other immune genes), were all linked at an early point in evolution.

—Finally, with the genome projects and advances in molecular biology, we have made strides in understanding old problems in vertebrate adaptive immunity (99), such as: 1) when did the L chains emerge and what is the significance of more than one isotype; 2) which antigen receptor (if any of the extant ones) came first, and how did all of them evolve to their present state; 3) when did IgD emerge and what is its function in different vertebrate phyla; and 4) how do γ/δ T cells recognize antigen? We propose that there are two arms of the γ/δ T cell lineage, one innate and the other adaptive, similar to B cells and α/β T cells.

In the next 5 years we will make inroads to answering all of these questions. Invariably, new, interesting molecules/mechanisms will be discovered, but we hope that this chapter makes card-carrying immunologists realize that we are nearing the end of the "gene-discovery period" in comparative immunology, and we are entering a new phase in which integration of mechanisms and pathways will open new doors to a comprehensive view of immunity.

Immunoglobulins and B Lymphocytes

Immunoglobulins: Structure and Function

Harry W. Schroeder, Jr., David Wald, and Neil S. Greenspan

INTRODUCTION

Immunoglobulins (Igs) are marked by a duality of structure and function (1). They provide a polyclonal set of receptors for the B cell that permit the cell to produce a highly diverse range of ligand binding sites. This diversity allows Igs to recognize an almost unlimited array of self and nonself antigens, ranging from compounds as fundamental to life as DNA to manmade molecules that could not have played a role in the evolution of the immune system. Igs also provide the immune system with a conserved set of effector molecules. They can activate and fix complement, and they can bind to Fc receptors on the surfaces of granulocytes, monocytes, platelets, and other components of the immune response. Both activation of complement and binding to Fc receptors can contribute to the induction or maintenance of inflammation. The receptor and effector functions of each individual immunoglobulin can be localized to a separate region or domain of the molecule.

Immunoglobulins Are Heterodimers

Immunoglobulins are heterodimeric proteins, consisting of two heavy (H) and two light (L) chains (Figures 4.1, 4.2). The eponymous Ig domain serves as the basic building block for both chains. Each of the chains contains a single amino-terminal variable (V) Ig domain and one, three, or four carboxy-terminal constant (C) Ig domains. H chains contain three or four C domains. L chains contain only one. H chains with three C domains tend to include a spacer *hinge* region between the first (C_H1) and second (C_H2) domains (2). Each V or C domain consists of approximately 110–130 amino acids, averaging 12,000 kD–13,000 kD. A typical L chain will thus mass approximately 25 kD, and a three C domain $C\gamma$ H chain with its hinge will mass approximately 55 kD.

At the primary sequence level, immunoglobulins are marked by the interspersion of regions of impressive sequence variability with regions of equally impressive sequence conservation. The V domains demonstrate the greatest molecular heterogeneity, with some regions including near random variability and others exhibiting extensive conservation across 500 million years of evolution (3). The molecular heterogeneity of the V domains permits the creation of binding sites, or *paratopes,* which can discriminate between antigens that may differ by as little as one atom. Thus, it is the V domains that encode the receptor function and define the monovalent specificity of the antibody. The H chain C_H1 domain, which is immediately adjacent to the V, associates with the single L chain C domain. Together, the C_H1 and C_L domains provide a stable platform for the paired set of V_H and V_L domains, which together create the antigen binding site. The distal C_H2 and C_H3 domains, for those antibodies with a hinge, or the C_H3 and C_H4 domains, for those with an extra (C_H2) domain, typically encode the effector functions of soluble antibody. Each of these Ig C_H domains is encoded by a separate exon. Although the sequences of the individual C_H domains are constant within the individual (and nearly constant within a species), they can vary greatly across species boundaries. The carboxy-terminal C_H domain encodes a secretory tail, which permits the antibody to exit the cell.

Also encoded within the germline sequence of each C_H gene are two membrane/cytoplasmic tail domain exons, termed M1 and M2. Alternative splicing removes the secretory sequence typically encoded by the terminal C_H3 or C_H4 domain and replaces it with the peptides encoded by the M1 and M2 exons, converting a secretory antibody to a membrane-embedded receptor (4). The membrane/cytoplasmic tail region is the portion of the C_H domains that is most highly conserved between species, which befits its role as a link to the intracellular signal transduction pathways that ultimately regulate B cell function.

Paratopes and Epitopes

The immunoglobulin–antigen interaction takes place between the paratope, the site on the Ig at which the antigen binds, and the *epitope,* which is the site on the antigen that is bound. It is important to appreciate that antibodies do not recognize antigens, they recognize epitopes borne on antigens (5). This makes it possible for immunoglobulins to discriminate between two closely related antigens, each of which can be viewed as a collection of epitopes.
FIGURE 4.1 Model of a secretory IgG. The germline exonic derivation of the sequence is shown at the top, and the protein structure is shown at the bottom. The location of the various cysteine residues that help hold both the individual domains and the various Ig subunits together are illustrated. Papain digests IgG molecules above the cysteine residues in the hinge that holds the two H chains together, yielding two Fab molecules and an Fc, whereas pepsin digests below, releasing an (Fab)$'_2$ fragment and two individual Fcs (which are typically degraded to smaller peptide fragments). The location of some allotypic variants is illustrated. C_H2 domains can be variably glycosylated, which can also affect Ig protein structure and effector function.

It also is one scenario that permits the same antibody to bind divergent antigens that share equivalent epitopes, a phenomenon referred to as *cross-reactivity*.

It has been estimated that triggering of effector functions in solution typically requires aggregation of three or more effector domains, and thus tends to involve the binding of three or more epitopes (5). For antigens encoding repeating epitope structures such as polysaccharides or antigen aggregates, binding of a single polymeric Ig molecule carrying multiple effector domains, such as pentameric IgM, can be sufficient to induce effector function. For antigens encoding diverse epitopes, which is more typical of monodisperse single-domain molecules in solution, triggering of inflammatory effector functions may require the binding of a diverse set of Ig molecules, all binding the same antigen but at different epitopes (6).

Membrane and Secretory Immunoglobulin

Alternative splicing allows immunoglobulins to serve either as soluble antibodies or as membrane-bound antigen receptors. In their role as antibodies, Igs are released into the circulation from where they may traffic into the tissues and across mucosal surfaces. In their role as the B cell antigen receptor (BCR), they are anchored to the membrane by means of their M1:M2 transmembrane domain. However, soluble antibodies can also be pressed into service as heterologous cell surface antigen receptors by their attachment to membrane-bound Fc receptors (7). This permits the power of antibody recognition to be extended to nonlymphoid cells such as Fc-expressing granulocytes, macrophages, and mast cells. The major difference between these two forms of cell surface receptors is that immunoglobulins as BCRs provide a monoclonal receptor for each B cell, whereas antibodies bound to Fc receptors endow the cell with a polyclonal set of antigen recognition molecules. This gives greater flexibility and increases the power of the effector cells to recognize antigens with multiple nonself epitopes.

Isotypes and Idiotypes

Immunoglobulins can also serve as antigens for other immunoglobulins. Immunization of heterologous species with monoclonal antibodies (or a restricted set of immunoglobulins) has shown that immunoglobulins contain both common and individual antigenic determinants. Epitopes recognized within the V portion of the antibodies used for immunization that identify individual determinants are termed *idiotypes* (Figure 4.3), whereas
FIGURE 4.2 Ribbon diagram of a complete IgG1 crystal (1 hzh in PDB from data of Harris et al. [190]). The major regions of the immunoglobulin are illustrated. The heavy-chain constant regions (green) also include the hinge (yellow) between the first two domains. CH2 is glycosylated (also seen in yellow). The heavy- and light-chain variable regions (red and dark blue, respectively) are N terminal to the heavy-(green) and light-chain (light blue) constant regions. CDR loops in the heavy- and light-chain variable regions (yellow and white) are illustrated as well. (See color insert.)

epitopes specific for the constant portion are termed *isotypes*. Recognition of these isotypes first allowed grouping of immunoglobulins into recognized classes. Each class of immunoglobulin defines an individual set of C domains that corresponds to a single heavy chain constant region gene. For example, IgM utilizes μ H chain C domains and IgE utilizes ε C domains.

Some V domain epitopes derive from the germline sequence of V gene exons. These shared epitopes, commonly referred to as *public idiotopes* or *cross-reactive idiotypes* (Figure 4.3), are, from a genetic perspective, isotypic because they can be found on many immunoglobulins of different antigen binding specificities that derive from the same germline V region. Examples include the cross-

reactive idiotypes found on monoclonal IgM rheumatoid factors derived from individuals with mixed cryoglobulinemia, each of which can be linked to the use of individual V gene segments (8).

Classes and Allotypes

Each of the various classes and subclasses of immunoglobulins has its own unique role to play in the immunologic defense of the individual. IgA, for example, is the major class of immunoglobulin present in all external secretions. It is primarily responsible for protecting mucosal surfaces. IgG subclasses bind Fc receptors differently, and thus vary in effector function (9). Determinants common to subsets
FIGURE 4.3 Electron micrographs (above; ×350,000) and interpretive diagrams (below) of murine mAb HGAC 39 (specific for the cell wall polysaccharide of *Streptococcus pyogenes*) in complex with antiidiotypic mAb Fab fragments. HGAC 39 is represented in the diagrams as an open figure and the Fab anti-Id probes are represented as solid figures. The Fab arms of the antibody targets and probes are drawn to indicate their rotational orientation as planar (oval with open center), intermediate (bone shape with or without central opening), or perpendicular ("dumbbell shaped"). Different complexes illustrate the range of Fab-Fab angles made possible by segmental flexibility. **Abbreviations:** 39, HGAC 39; 2, anti-IdI-2 Fab; 3a, anti-IdI-3a Fab; 1, anti-IdI-1 Fab; X, anti-IdX Fab; K, anti-Cκ Fab. IdI designates an individual idiotope, and IdX a crossreactive idiotope. Antibody complexes were stained with 2% uranyl formate as described Roux et al. (98). Reproduced from Proceedings of the National Academy of Sciences (from Roux et al. [98] with permission).

of individuals within a species, yet differing between other members of that species, are termed *allotypes* and define inherited polymorphisms that result from allelic forms of immunoglobulin C (less commonly, V) genes (10).

Glycosylation

N-linked carbohydrates can be found in all constant domains as well as in some variable domains (11). The structure of the attached N-linked carbohydrate can vary greatly, depending on the degree of processing. These carbohydrates can play a major role in Ig function. Human IgG molecules contain a conserved glycosylation site at Asn 297, which is buried between the C_H2 domains (12). This oligosaccharide structure is almost as large as the C_H2 domain itself. O-linked sugars are also present in some immunoglobulins (11). Human IgA1, but not IgA2, possesses a 13 amino acid hinge region that contains three to five O-linked carbohydrate moieties (13). A deficiency in proper processing of these O-glycans can contribute to IgA nephropathy, which is a disease that is characterized by the presence of IgA1-containing immune complexes in the glomerular mesangium (14).

A HISTORICAL PERSPECTIVE

The identification of immunoglobulin as a key component of the immune response began in the 19th century. This section describes the history of the identification of immunoglobulin and introduces fundamental terminology.

Antibodies and Antigens

Aristotle and his contemporaries attributed disease to an imbalance of the four vital humors: the blood, the phlegm, and the yellow and black biles (15). In 1890, Behring (later, von Behring) and Kitasato reported the existence of an activity in the blood that could neutralize diphtheria toxin (16). They showed that sera containing this humoral antitoxin activity would protect other animals exposed to the same toxin. Ehrlich, who was the first to describe how diphtheria toxin and antitoxin interact (17), made glancing reference to "Antikörper" in a 1891 paper describing discrimination between two immune bodies, or substances (18). The term *antigen* was first introduced by Deutsch in 1899. He later explained that antigen is a contraction of "Antisomatogen+Immunkörperbildner," or that which induces the production of immune bodies (antibodies). These operational definitions of antibody and antigen create a classic tautology.

Gamma Globulins

In 1939, Tiselius and Kabat immunized rabbits with ovalbumin and fractionated the immune serum by electrophoresis into albumin, alpha-goblulin, beta-globulin,

▶ **TABLE 4.1**   Definitions of Key Immunoglobulin Structure Nomenclature

Fc	A constant region dimer lacking C_H1
Fab	A light chain dimerized to V_H-C_H1 resulting from papain cleavage; this is monomeric since papain cuts above the hinge disulfide bond(s)
F(ab)'₂	A dimer of Fab' resulting from pepsin cleavage below the hinge disulfides; this is bivalent and can precipitate antigen
Fab'	A monomer resulting from mild reduction of F(ab)'₂: an Fab with part of the hinge
Fd	The heavy chain portion of Fab (V_H-C_H1) obtained following reductive denaturation of Fab
Fv	The variable part of Fab: a V_H-V_L dimer
Fb	The constant part of Fab: a C_H1-C_L dimer
pFc'	A C_H3 dimer

From Carayannopoulos and Capra (188), with permission.

and gamma-globulin fractions (19). Absorption of the serum against ovalbumin depleted the gamma-globulin fraction, hence the terms *immunoglobulin* and *IgG*. "Sizing" columns were used to separate immunoglobulins into those that were "heavy" (IgM), "regular" (IgA, IgE, IgD, IgG), and "light" (light chain dimers) (1). Immunoelectrophoresis subsequently permitted identification of the various immunoglobulin classes and subclasses.

Fab and Fc

In 1949, Porter first used papain to digest IgG molecules into two types of fragments, termed Fab and Fc (Table 4.1) (20,21). Papain digested IgG into two Fab fragments, each of which could bind antigen, and a single Fc fragment. Nisonoff developed the use of pepsin to split IgG into an Fc fragment and a single dimeric F(ab)₂ that could cross-link antigens (22). Edelman broke disulfide bonds in IgG and was the first to show that IgG consisted of two H and two L chains (23).

Two Genes, One Polypeptide

The portion of the constant domain encoded by the Fc fragment was the first to be sequenced and then analyzed at the structural level. It could be readily crystallized when chilled. The heterogeneity of the V domain precluded sequence and crystallographic analysis of an intact Ig chain until Bence-Jones myeloma proteins were identified as clonal, isolated Ig light chains. These intact chains could be purified and obtained in large quantities, which finally permitted rational analysis of antibody structure and function (24). Recognition of the unique nature of a molecule consisting of one extremely variable V domain and one highly conserved C domain led to the then-heretical Dreyer-Bennett proposal of "two genes—one polypeptide" (25), which was subsequently and spectacularly confirmed by Tonegawa (26).

THE IG DOMAIN

The immunoglobulin domain is the core unit that defines members of the immunoglobulin superfamily (IgSF) (reviewed in Williams and Barclay [27] and Harpaz and Chothia [28]). This section describes the Ig domain in detail.

The Immunoglobulin Superfamily

Each Ig domain consists of two sandwiched β-pleated sheets "pinned" together by a disulfide bridge between two conserved cysteine residues (Figure 4.4). The structure of the β-pleated sheets in an Ig domain varies depending on the number and conformation of strands in each sheet.
FIGURE 4.4 The Ig domain. **A:** A typical V domain structure. Note the projection of the C-C' strands and loop away from the core. **B:** A typical compact C domain structure. **C:** The cysteines used to pin the two β-sheets together are found in the B and F strands. **D:** The folding pattern for V and C domains. From (27).

Two such structures, V and C, are typically found in immunoglobulins. C-type domains, which are the most compact, have seven antiparallel strands distributed as three strands in the first sheet and four strands in the second. Each strand has been given an alphabetical designation ranging from amino-terminal A to carboxy-terminal G. Side chains positioned to lie sandwiched between the two strands tend to be nonpolar in nature. This hydrophobic core helps maintain the stability of the structure to the point that V domains engineered to replace the conserved cysteines with serine residues retain their ability to bind antigen. The residues that populate the external surface of the Ig domain and the residues that form the loops that link strands can vary greatly in sequence. These solvent exposed residues offer multiple targets for docking with other molecules.

The V Domain

V-type domains add two additional antiparallel strands to the first sheet, creating a five strand–four strand distribution. Domain stability results from the tight packing of alternately inward-pointing residue side chains enriched for the presence of hydrophobic moieties to create a hydrophobic domain core. The H and L variable domains are held together primarily through noncovalent interaction between the inner faces of the β sheets (29,30).

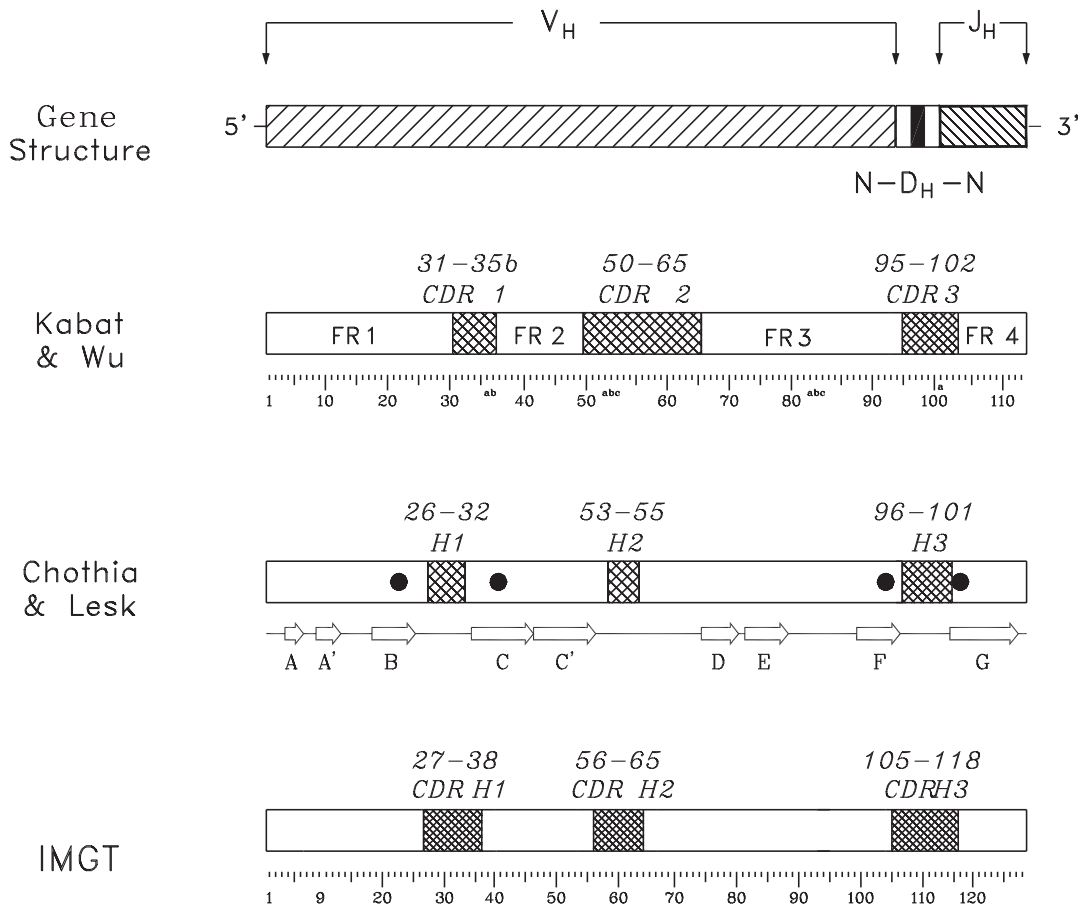
Early comparisons of the primary sequences of the V domains of different antibodies identified four intervals of relative sequence stability, termed *framework regions,* or FRs, which were separated by three hypervariable intervals, termed *complementarity determining regions,* or CDRs (Figures 4.5, 4.6) (31). The exact location of these


FIGURE 4.5 Sequence conservation and hypervariability within an H chain V domain. The primary sequence of the V domain can be divided into four regions of sequence conservation, termed *frameworks*, or FRs, and three regions of hypervariability, termed *complementarity determining regions*, or CDRs. A schematic of the genomic origin of the variable domain is shown at the top of the figure. The classic separation of the sequence into FR and CDR by Kabat and Wu (31) is shown below the gene structure. The letter designation for individual β strands is given beneath the Chothia and Lesk nomenclature (32), which focused more on structure. The positions of each of the four invariant residues of the V_H chain (FR1 Cys22, FR2 Trp36, FR3 Cys92, and FR4 Trp103) are shown as darkened circles on the Chothia and Lesk model. The IMGT designation has attempted to rationalize sequence variability with structure and is the current nomenclature of choice (33).

FIGURE 4.6 The structure of an Fab. The antigen binding site is formed by the H and L chain B-C, C′-C″, and F-G loops. Each loop encodes a separate complementarity determining region, or CDR. The location of CDRs H1, H2, H3, L1 L2, and L3 are shown. The opposing H and L chain C-C′ strands and loop help stabilize the interaction between VH and VL. This C-C′ structure is encoded by the second V framework region, FR2. The inclusion of this structure permits the V domains to interact in a head-to-head fashion. The E-F strands and loop are encoded by the FR3 region and lie directly below the antigen binding site. The A-B strands and loop encode FR1 and lie between the C_H1 and CL domains and the rest of the Vs. The beta sheet strands of the C_H1 and CL domains rest crosswise to each other. The illustration is modified from (191). (See color insert.)

intervals has been adjusted over the years, first by a focus on the primary sequence (31), then by a focus on the three-dimensional structure (32), and, more recently, by a consensus integration of the two approaches by the international ImMunoGeneTics information system®, or IMGT [33] (Figure 4.5). (For students of the immunoglobulin repertoire, IMGT maintains an extremely useful web site, http://imgt.cines.fr, that contains a large database of sequences as well as a multiplicity of software tools.)

The C and C′ strands that define a V domain form FR2. These strands project away from the core of the molecule (Figures 4.4 and 4.6), where they take on a conserved structure that is parallel and opposite to the FR2 of the companion V and adjacent to the FR4 of the complementary chain. Approximately 50% of the interdomain contacts in the hydrophobic core of the V domain are formed by contacts between the FR2 of one chain and the FR4 of the complementary chain (30). Another 30%–45% is contributed by

contacts between the CDR3 and the FR2 or CDR3 of the complementary domain. The overall interdomain contact includes between 12 and 21 residues from the L chain V domain and 16–22 residues from H chain V domain, most of which are contributed by the FR2, CDR3, and FR4 regions.

There are approximately 40 crucial sequence sites that influence variable domain inter- and intradomain interactions (32,34). Four of these sites are relatively invariant—the two cysteines that form the disulfide bridge between the beta sheets, and two tryptophan (phenylalanine in Jκ) residues, one near the beginning of the C strand and the second near the beginning of the G strand, that pack against the bridge to add stability. Beyond these and other common core residues, Ig domains can vary widely in their primary amino acid sequences. However, a common secondary and tertiary structure characteristic of the core Ig V domain tends to be preserved.

FAB STRUCTURE AND FUNCTION

Introduction

It is the Fab domain that allows immunoglobulin to discriminate between antigens. Each developing B cell manufactures its own, largely unique, Fab. The Fab shows an amazing array of binding capabilities while maintaining a highly homologous scaffold. This section describes the characteristics of the Fab domain, its component V domains, and the paratope, which is the part of the Fab that actually binds antigen.

Fab, Fv, and Fb

The antigen-binding fragment (Fab) is a heterodimer that contains a light chain in its entirety and the V and C_H1 portions of the H chain (Figures 4.1, 4.6). In turn, the Fab can be divided into a variable fragment (Fv) composed of the V_H and V_L domains, and a constant fragment (Fb) composed of the C_L and C_H1 domains (Table 4.1). Single Fv fragments can be produced in the laboratory through genetic engineering techniques (35). They recapitulate the monovalent antigen-binding characteristics of the original parent antibody. Other than minor allotypic differences, the sequences of the constant domains do not vary for a given H chain or L chain isotype. The eponymous variable (V) domain, however, is quite variable.

Generation of Ig V Domains by Recombination

Ig variable domain genes are assembled in an ordered fashion by a series of recombination events (26,36–39). The elegant mechanisms used for the assembly of these genes and the Fvs they create are fully discussed in Chapter 6.

However, to understand the relationship between antibody structure and function, a brief review is in order.

In mice, immunoglobulin V assembly begins with the joining of one of 13 diversity (D_H) gene segments to one of four joining (J_H) gene segments. This is followed by the joining of one of 110 functional variable (V_H) gene segments (40–42). (These numbers come from common strains of laboratory mice. The number of gene segments often varies between strains.) Each D_H gene segment has the potential to rearrange in any one of six reading frames (RFs), three by deletion and three by inversion. Thus, these 127 gene segments can come together in 3.4×10^4 combinations. The V_H gene segment encodes FRs H1-H3 and CDRs H1 and H2 in their entirety (Figures 4.1, 4.5), and the J_H encodes FR-H4. CDR-H3 is created *de novo* in developing B cells by the joining process. CDR-H3 contains the D_H gene segment in its entirety, as well as portions of the V_H and J_H gene segments.

After a functional H chain has been created, light chain assembly begins. Mice contain two L chain loci, κ and λ. The κ locus includes five Jκ gene segments and 140 Vκ gene segments, of which 4 and 73 have been shown to be functional, respectively (43–45). This provides 292 combinations. There is only one Cκ (46). The λ locus contains 3 Vλ, three functional Jλ, and two or three functional Cλ chains (47,48). The λ–constant domains are functionally indistinguishable from each other. Due to gene organization, the λ repertoire provides at most seven combinations. Each V_L encodes FRs L1-L3, CDR L1 and L2, and two thirds of CDR-L3 (Figure 4.1). Each J_L encodes one-third of CDR-L3 and FR4 in its entirety. Any one H chain can combine with any one L chain, thus 211 V, D, and J gene segments can provide approximately 1×10^7 different H:L combinations.

At the V→D and D→J junctions, the potential for CDR-H3 diversity is amplified by imprecision in the site of joining, allowing exonucleolytic loss as well as palindromic (P junction) gain of terminal V_H, D_H, or J_H germline sequence. B cells that develop after birth express the enzyme terminal deoxynucleotidyl transferase (TdT) during the H chain rearrangement process (26,36). TdT catalyzes the relatively random incorporation of nongermline-encoded nucleotides between V_H and D_H, and between D_H and J_H. Each three nucleotides of N addition increase the potential diversity of CDR-H3 20-fold. Thus sequences with nine nucleotides of N addition each between the V→D and D→J junctions would enhance the potential for diversity by $(20)^6$, or by 6×10^7; sixfold greater than the potential diversity provided by VDJ gene segment combinations. These genomic gymnastics permit the length of CDR-H3 to vary from 5 to 20 amino acids among developing B cells in mouse bone marrow (49). Together, imprecision in the site of VDJ joining and N addition provides the opportunity to create nearly random CDR-H3 sequences, potentially freeing the CDR-H3 repertoire from germline sequence

constraints. Although a limited amount of N addition is observed between V_L and J_L in human chains (50,51), N addition in murine L chains is distinctly uncommon. Moreover, the length of CDR-L3 appears to be under relatively strict control, greatly limiting the potential for somatic L chain junctional diversity (48,50). Thus, CDR-H3 represents the greatest focus for the initial somatic diversification of the antibody repertoire.

Segmental Conservation and Diversity within the V Domain

Although the large numbers of V gene segments might give the impression of a smooth incremental range of available diversity, multigene families are thought to evolve in concert through mechanisms of gene conversion, and V gene segments are no exception. Sequence relationships allow grouping them into families and clans of sequences that share nucleotide sequence homology (52), as well as structural features. Close inspection of the V_H gene repertoire has shown that these family relationships reflect segmental gene conversion coupled with selection for function (3,53,54).

Due to the need to maintain a common secondary and tertiary core Ig V domain structure capable of associating randomly with a complementary V chain to form a stable Fv, the core sequence of FR2, which is encoded by the V_H gene segment, and the core sequence of FR4, which is encoded by the J_H gene segment, are highly conserved among all Ig V domains. Conversely, the need to generate a diverse repertoire of antigen-binding sites has led to extensive diversity in the CDR1 and CDR2 intervals. One might presume that the FR1 and FR3 intervals, which form the external surface of the antibody, would not be under any particular constraints, but sequence comparisons would suggest otherwise.

Given the need to diversify the CDRs and the need to preserve FR2, it is not surprising that family identity, which might reflect ancestral relationships, can be assigned by the extent of FR1 and FR3 similarity (55). Of these, FR1 appears to be under the greatest constraints, with V_H gene segments belonging to different families both within and across species barriers exhibiting extensive similarities in FR1 sequence (Figure 4.7). Sequence similarities in FR1 and, to a lesser extent, FR3 allow grouping of V_H families into three clans of related sequences, presumably reflecting an early divergence in sequence from a primordial V_H gene sequence (Figure 4.8).

Constraints on the Sequence and Structure of V-Encoded CDRs

The antigen-binding site of an immunoglobulin is formed by the juxtaposition of the six hypervariable H and L chain V domain intervals: CDRs-H1, -H2, and -H3, and CDRs-L1, -L2, and -L3 (31). The CDR sequences of V gene
FIGURE 4.7 A comparison of two human Clan I V_H sequences that belong to different V_H families (modified from [3]). Shown is a comparison of the DNA and amino acid sequences of the V5-51 and V1-2 gene segments. Each line depicts a divergence in the identity of the nucleotide or amino acid at that position. Shown below is a replacement/silent site substitution analysis by interval. Random mutation tends to exhibit an R/S ratio of 2.9. The smaller the ratio, the greater the preservation of sequence. The intervals identified by the arrows predict the family and clan of origin.

segments tend to be enriched for codons where mutations maximize replacement substitutions (56). This includes the RGYW motif that facilitates somatic hypermutation (57,58). While evolution appears to favor CDR1 and CDR2 sequences that facilitate codon diversity, it also appears to preserve specific loop structures.

Although there is great variation in the sequences and sizes of these CDRs, it has been shown that five of them,

CDR-H3 being the notable exception, possess one of a small set of main-chain conformations termed canonical structures (32,34,59,60). Each canonical structure is determined by the loop size and by the presence of certain residues at key positions in both the loop and framework regions. For example, three canonical structure types have been identified for CDR-H1, four for CDR-H2, five for CDR-L1, one for CDR-L2, and five for CDR-L3 (32,34,61). From
FIGURE 4.8 Evolutionary relationships among vertebrate V_H families. The sizes or relative placements of the evolutionary connecting lines are not to scale. V_H sequences from all mammalian species analyzed to date can be placed into one of these three clans. (Modified from [3].)

these types, it can be calculated that the total number of possible combinations of canonical structures, or structure classes, is 300 (62). However, only 10 of these combinations, or classes, are sufficient to describe seven-eighths of human and mouse Fab sequences. Of these, CDR-H1, -L2, and -L3 always appear with the same canonical structure type, and thus do not contribute to the variation in the structure of the most frequent classes of antigen binding sites. Only CDR-H2 and -L1 change from one class to another. Among specific classes, the lengths of CDR-H3 and -L1 appear to correlate with the type of recognized antigen. Antibodies with short loops in -H2 and -L1 appear to be preferentially specific for large antigens (proteins); whereas antibodies with long loops in -H2 and -L1 appear to be preferentially specific for small molecules (haptens) (62).

Given that the sequences and structures of the framework regions, which define families, influences the canonical structure of V_H-encoded CDRs, it is not surprising that the structure repertoire of canonical structures is both family- and clan-specific (63). This implies restrictions to the random diversification of the hypervariable loop structures (canonical structures) and their combinations within the same V_H gene segment (canonical structure classes). It further suggests evolutionarily- and structure-imposed restrictions operating to counteract the random diversification of these CDRs.

Diversity and Constraints on the Sequence and Structure of CDR-H3

The combination of VDJ assortment, variation in the site of gene segment rearrangement, and N nucleotide addition makes CDR-H3 the most variable of the six hypervariable regions. Correspondingly, it has not yet been possible to define, much less assign, canonical structures to the CDR-H3

loops similar to those observed for the V-encoded CDRs. However, insight into a gradient of possible structures has been gained.

CDR-H3 can be separated into a base, which is adjacent to the frameworks, and a loop. The base tends to be stabilized by two common residues, an arginine at Kabat position 94 (IMGT 106) and an aspartic acid at Kabat 101 (IMGT 116) (32). These form a salt bridge that, together with the adjacent residues, tends to create one of three backbone conformations, termed *kinked, extra-kinked,* and *extended* (64). In approximately one-quarter of sequences with kinked or extra-kinked bases, it is also possible to predict whether an intact hydrogen-bond-ladder may be formed within the loop of the CDR-H3 region, or whether the hydrogen bond-ladder is likely to be broken (65). However, for the majority of CDR-H3 sequences, especially those that are longer, current tools do not allow prediction of potential structures.

In spite of the potential for totally random sequence provided by the introduction of N nucleotides, close inspection has shown that the distribution of amino acids in the CDR-H3 loop is highly biased for tyrosine and glycine (31,66) and relatively depleted of highly polar (charged) or nonpolar (hydrophobic) amino acids. This pattern of amino acid utilization is established early in B cell development, prior to the expression of immunoglobulin on the surface of the cell (Figure 4.9) (49,67,68) and reflects evolutionary conservation of J_H and D_H gene segment sequences. In particular, although the absolute sequence of the D_H is not the same, the pattern of amino acid usage by RF is highly conserved. Of the six potential RFs, RF1 by deletion is enriched for tyrosine and glycine. RF2 and RF3 by deletion are enriched for hydrophobic amino acids, as are RF2 and RF3 by inversion. RF1 by inversion tends to encode highly polar, often positively charged, amino acids (66). Various species use different mechanisms to
FIGURE 4.9 A preference for tyrosine and glycine in CDR-H3 begins early and intensifies with B cell development. V_H7183DJC transcripts were cloned and isolated from fractions B (pro-B cells) through F (mature B cells) from the bone marrow of 8 to 10 week-old BALB/c mice (49,67,68). The amino acids are arranged by relative hydrophobicity, as assessed by a normalized Kyte-Doolittle scale (186,187). Use is reported as the percent of the sequenced population. The number of unique sequences per fraction is shown.

bias for use of RF1 by deletion, to limit use of hydrophobic RFs, and to restrict or prevent use of RFs enriched for charged amino acids. Forced rearrangement into RFs with charged amino acids yields an altered repertoire enriched for charge and depleted of tyrosine and glycine (67). Mice forced to use a repertoire enriched for charged CDR-H3s exhibit disruptions in B cell development, reductions in serum IgG, and decreased responses to specific antigens.

The distribution of CDR-H3 lengths can also be regulated both as a function of differentiation and as a function of ontogeny (49,69). In association with long V-encoded CDRs, short CDR-H3s create an antigen binding cavity at the center of the antigen binding site, and CDRs of intermediate length can create an antigen binding groove. Each species appears to prefer a specific range of CDR-H3 lengths (70). Long CDR-H3s, which can create "knobs" at the center of the antigen binding site, are unevenly distributed between species and reflect both divergence in germline sequence and somatic selection.

The Antigen Binding Site Is the Product of a Nested Gradient of Regulated Diversity

The tension between the need to conserve essential structure and the need to emphasize diversity in an environment subject to unpredictable antigen challenge appears to create a gradient of regulated diversity in the Fv. The most highly conserved components of the Fv are FR2 and FR4, which form the hydrophobic core of the $V_H:V_L$ dimer (Figures 4.4, 4.5). FR1, which in the H chain presents with three conserved structures, helps form the ball and socket joint between the V_H and C_H1. FR3, which in the H chain defines the family and provides 7 different structures in human versus 16 different structures in mouse, frames the antigen binding site (Figure 4.10). The V-encoded CDRs, -H1, -H2, -L1, -L2, and most of -L3, are programmed for diversity. However, conserved residues within these CDRs, which interact with V family-associated FR3 residues, constrain diversity within a preferred range of canonical structures. CDR-H3, the focus of junctional diversity, lies at the center of the antigen binding site. The conformation of its base tends to fit within three basic structures. The loop varies greatly in sequence, yet still maintains a bias for the use of tyrosine and glycine. Thus, diversity increases with proximity to the center of the antigen binding site but appears to be held within regulated limits.

Somatic Hypermutation and Affinity Maturation

Following exposure to antigen and T-cell help, the V domain genes of germinal center lymphocytes can undergo mutation at a rate of up to 10^{-3} changes per base pair per cell cycle (71), a process termed *somatic hypermutation*. Somatic hypermutation allows *affinity maturation* of the antibody repertoire in response to repeated immunization
FIGURE 4.10 Location and generation of CDR-H3. A cartoon of the classic antigen binding site (modified from [3]). Due to its central location, most antigens bound to the antibody will interact with CDR-H3.

or exposure to antigen. Although affinity maturation often preserves the canonical structure of the CDR loops, the distribution of diversity appears to differ between the primary and antigen-selected repertoire (72). In the primary repertoire, diversity is focused at the center of the binding site in CDR-H3. With hypermutation, somatic diversity appears to spread to the V-encoded CDRs in the next ring of the binding site (Figure 4.10), enabling a more "custom-tailored" fit.

Binding of 'Superantigens' to Nonclassic V Domain Antigen Binding Sites

Not all antigens bind to the paratope created by the classic antigen binding site. Antigens that can bind to public idiotopes on V domain frameworks (73) and recognize large portions of the available repertoire are termed superantigens. There are indications that B cell superantigens influence the pathogenesis of some common infections, such as those caused by *Staphylococcus aureus*.

ANTIGEN–ANTIBODY INTERACTIONS

Technological advances in biomolecular structure determination, analysis of molecular dynamics, protein expression and mutagenesis, and biophysical investigation of receptor–ligand complex formation have facilitated significant advances in the understanding of antigen–antibody interactions. Particularly valuable has been the integration of high-resolution structural data with thermodynamic

and kinetic analyses on a number of antigen–monoclonal antibody complexes. In this section, some of the key insights arising from these studies will be reviewed.

Molecular Flexibility

Like many other protein domains, V domains exhibit varying degrees and modes of molecular flexibility. Evidence suggests that some V modules (i.e., V_L-V_H pairs) can adopt two or more conformations with meaningful frequencies in the unbound state. Since these different conformational states can exhibit distinguishable binding proclivities, molecular flexibility provides monoclonal antibodies with a mechanism for polyspecificity (74). Molecular flexibility can also play a role in binding a single ligand, which, in such instances, may be better understood as a process of binding rather than as a simple event (75,76). The extent of conformational adjustment by antibody or antigen required for complex formation can influence both the thermodynamics and kinetics of that process.

Role of H$_2$O

A significant role for water molecules has become clear from the study of high-resolution structures and thermodynamic analyses of antigen–antibody complexes. Water molecules exhibit a broad range of association times with protein surfaces. Thus, some of the more tightly protein-associated of these solvent molecules effectively behave as parts of the protein (77). Water molecules found in the antigen–antibody interface, whether constitutively bound or newly recruited, can make important contributions to both the intrinsic (i.e., monovalent) affinity of the complex and to the differential affinities for different ligands (i.e., specificity) (78). Amino acid residues of antigen and antibody can interact, indirectly, through hydrogen bonds to one or more water molecules (78).

Thermodynamics and Antigen–antibody Interactions

Specific residues in the antibody V domains or the antigen can contribute to complex formation in different ways, and some residues can contribute in multiple ways (79). In addition to making van der Waals contact, residues can be important due to contributions to the free energy of complex formation or to the differential free energy of complex formation for two or more different ligands. Some residues may contribute primarily to modulation of the association rate, the "relaxation" of the forming complex, or the dissociation rate (75,80). Other contact residues contribute minimally to the energetics of complex formation, and yet other noncontact residues can be significant thermodynamic contributors (81,82).

Structural and thermodynamic/kinetic comparisons of antibodies possessing germline V domain sequences with somatically mutated V domain sequences have provided new insights into the structural and energetic bases for affinity maturation (81,82). Mutations in both contact and noncontact residues can have major consequences, positive or negative, for the affinity with which an antibody binds an antigen. They can also favor tighter binding by enhancing V domain rigidity, thereby reducing the entropic penalty associated with complex formation (82). Antibodies derived from secondary or later responses that have incorporated somatic mutations have been shown to exhibit less than absolute specificity. Even these "mature" antibodies can bind multiple ligands when screened on libraries of peptides or proteins (83,84), a lesson likely to be relevant to most biomolecules.

IMMUNOGLOBULIN 'ELBOW JOINTS' AND 'HINGES'

The structures of the constant domains can affect antibody–antigen interactions by influencing the range of molecular flexibility permitted between the two Fabs. In this section, the role of the immunoglobulin hinge will be discussed.

Elbow Joints

Individual Ig V and C domains tend to create rather rigid dimers. However, the antibody molecule as a whole, which consists of four or more such dimeric modules linked like beads on a string, can be viewed as a paradigm of molecular flexibility (85). Flexibility begins between the Fv and the Fb of the Fab at what is termed the *elbow bend* or *elbow angle* (86). This reflects both a ball and socket interaction between the FR1 of the H chain and the C_H1 domain (87) and the identity of the L chain (86). Five residues (three in V_H and two in C_H1) that are highly conserved in both antibodies and T-cell receptors make the key contacts that constitute this "joint." Elbow angles, assessed from crystal structures of homogeneous Fab fragments, range from 130° to 180°. λ light chains appear to permit an Fv to adopt a wider range of elbow angles than their κ chain counterparts.

Hinges

Some immunoglobulin isotypes contain a structural element that does not strictly correspond to the canonical structural motifs of IgSF V and C domains, which is termed the *hinge*. Where it occurs, it is located between the C-terminus of the C_H1 and the N-terminus of the C_H2 domains. In isotypes such as IgG and IgA, the hinge is encoded by one (or more) separate exon(s). In isotypes with four C_H domains (i.e., IgM and IgE), the C_H2 domain serves in place of a classical hinge.

The hinge, or the C_H2 domain in Igs that lack a hinge, permits a Fab arm to engage in an angular motion relative
FIGURE 4.11 Illustration of the motions and flexibility of the immunoglobulin. Axial and segmental flexibility are determined by the hinge. The switch peptide (elbow) also contributes flexibility to the Fab. The measure of the elbow angle is defined with respect to the Fv and Fb axes of two-fold symmetry. (From Carayannopoulos and Capra [188] with permission.)

both to the other Fab arm and to its Fc stem (Figures 4.3, 4.11). This permits the two Fab arms to cover a range from maximal extension to an almost parallel alignment. The range of motion of the Fab arms reflects the nature of the hinge region, which in some C genes is rigid and in others, such as human IgA1, functions more as a tether than as a support for each individual Fab. This flexibility has major implications for antibody function, because it enables a bivalent antibody molecule to bind epitopes in a variety of relative spatial arrangements.

Among human IgG subclasses, the most unusual hinge region is that of IgG3. Unlike other human IgG hinge re-

gions, the IgG3 hinge is encoded by a quadruplicated hinge exon, making it the longest hinge (62 amino acids) by far (see Table 4.2). The primary structure of this hinge has been divided into upper, core (or middle), and lower hinge regions with somewhat different functional associations. The upper hinge in particular has been associated with the magnitude of segmental flexibility as assessed by fluorescence emission anisotropy kinetics (88) and with the magnitude of Fab-Fab flexibility by immunoelectron microscopy (89). The core or middle hinge appears to serve, at least in part, a spacer function. The lower hinge functions primarily to facilitate C_H2-C_H2 interactions.

Segmental flexibility of the Ig molecule, conferred mainly by the hinge, permits or facilitates simultaneous binding through two or more Fab arms. Such monogamous bivalency or multivalency, which enhances overall binding (90,91), is a crucial factor permitting biosynthetically feasible antibody concentrations to offer adequate immunity against replicating pathogens. Although it is more speculative why the Fab-Fc geometry needs to vary, it may have to do with optimizing effector function activation when antigen is bound, such as maintaining antigen binding when Fc receptors are simultaneously engaged.

The attribution of flexibility control to the hinge is supported by protein engineering studies in which V domain-identical IgGs of different subclasses were analyzed (88,92). This basic conclusion is also supported by studies in which hinge regions have been selectively mutated or swapped among human or mouse IgG subclasses (93–95). One of these studies indicated that structural variation among subclasses in the C_H1 domain also influenced segmental flexibility as assessed by nanosecond fluorescence polarization measurements (93). Early suggestions that IgG subclass-related differences in activating the classical pathway of complement were explained by differences in segmental flexibility (88) were not confirmed by the studies in which mutant hinge regions were created (93–95).

TABLE 4.2 Properties of Hinges in Human IgG, IgA, and IgD

Ig Type	Upper Hinge Length	Middle Hinge Length	Lower Hinge Length	Genetic Hinge Configuration (Amino Acids/Exon)	Susceptibility to Proteolysis	Special Features
IgG1	4	10	6	15		
IgG2	3	8	6	12		
IgG3	12	49	6	17-15-15-15		
IgG4	7	4	6	12		
IgA1	1	23	2	19	high	Heavily O-linked glycosylation
IgA2	1	10	2	6		
IgD				34-24	high	Extensive charged amino acids; heavy O-linked glycosylation at N terminus

Note: Lengths represent amino acids.

There are several types of molecular motion attributable to the hinge region that contribute to overall segmental flexibility (see Figure 4.11). These include flexing between Fab arms (motion toward or away from one another in the same plane), Fab arms moving in and out of the same plane, Fab arms rotating along their long axes, and Fab arms moving in or out of the same plane as the Fc region (96,97). The inter-Fab angles observed by electron microscopy range from 0° to 180° (98,99). Similarly, Fab arm long-axis rotations can extend up to 180° (100).

Another key role of the hinge is the maintenance of the C_H2-C_H2 interaction (i.e., effectively constraining molecular mobility within the Fc region itself). The lower hinge stabilizes C_H2-C_H2 contacts by providing the key cysteine residues involved in inter-heavy chain disulfide bonds. Experiments in which IgG molecules were modified to eliminate the hinge region demonstrate that covalent linkage between the hinge regions just "upstream" of the two C_H2 domains is critical for the preservation of IgG effector function (101).

HEAVY CHAIN STRUCTURE AND FUNCTION

What might be termed *the fundamental strategy of humoral immunity* is a two-step process that begins with the identification by antibodies (of appropriate binding specificity) of the molecules or molecular complexes that should be eliminated. Following such identification (i.e., noncovalent complex formation), antibodies can then trigger other molecular systems (e.g., complement) or cells (e.g., phagocytes) to destroy or remove the antigenic material—guilt by association at the molecular level. Thus, antigen specificity, determined primarily by the V domains in the Fab arms, is physically and functionally linked to effector function, the activation of which is primarily attributable to the C domains of the Fc region. The effector functions associated with the humoral immune response primarily involve either complement or Fc receptor-bearing cells, such as neutrophils, macrophages, and mast cells. As might be expected, therefore, the Fc contains sites for noncovalently interacting with complement components, such as C1q, and with Fc receptors. This section focuses on the structures and functions of the Fc regions of the various Ig classes and subclasses.

Structure and Function of the Fc

The necessity for interacting effectively with relatively conserved molecules such as C1q and Fc receptors provides a selective basis for maintaining the primary structures of the Fc region, at least where changes would undermine such intermolecular contacts. The degeneracy possible in noncovalent molecular recognition events permits selected primary sequence variations without catastrophic alterations in function. However, there are allotypic differences in the heavy chain constant domains among both human and mouse immunoglobulins. In some cases, these allotypic differences are associated with variation in function, at least *in vitro*. For example, two recombinant V domain-identical IgG3 antibodies, of different allotypes, exhibited differential abilities to bind C1q or initiate antibody-dependent cell-mediated cytotoxicity (102). Nevertheless, the heavy chains of the human IgG subclasses are particularly well conserved, with >90% identity of amino acid sequences. In other mammalian species that have two or more IgG subclasses, they tend to exhibit less amino acid sequence identity than the human IgG subclasses.

By convention, the heavy chain constant domains are numbered from N-terminal to C-terminal, with C_H1 residing in the Fab arm and the remaining two (IgG, IgA, IgD) or three (IgM, IgE) C domains (C_H2, C_H3, and, if relevant, C_H4) residing in the Fc. In IgM and IgE, the C_H2 domain largely plays the role of the hinge region. The C domains of different isotypes and from different species share several key structural features. In distinction from V domains, which consist of four- and five-stranded β-pleated sheets linked through an intrachain disulfide bond, C domains consist of three- and four-stranded β-pleated sheets linked through an intrachain disulfide bond (Figure 4.4). Across isotypes amino acid sequence identity for CH domains is approximately 30%, while for subclasses (within an isotype), the amino acid sequence identity for C_H domains is in the range of 60%–90%. Important physical and biological properties of the human Ig isotypes are summarized in Table 4.3.

As alluded to earlier, the traditional and accepted functional anatomy of immunoglobulins attributes antigen binding (both specificity and affinity) to the V modules in the Fab arms and effector function activation to the Fc region. While this scheme is both well-supported and appealing, there is considerable (perhaps not widely appreciated) evidence that in some cases structural variations in heavy chain domains (i.e., C domains and hinge) can influence both the affinity of the antibody for antigen and the discrimination among antigens (103–108). Although these instances of C domain influence on ligand binding (through the V domains) primarily involve multivalent antigens, there are also reports that suggest C domain influence in instances of monovalent recognition (109–111). Mechanisms for these effects in the context of binding multivalent antigens include isotype-related differences in segmental flexibility, as well as the tendency for self-association. Results from a study comparing resistance to pneumococcal infection for IgG3-deficient and IgG3-producing mice are consistent with the notion that the cooperative binding permitted by murine IgG3 antibodies contributes to the effectiveness of humoral immunity (112).

▶ **TABLE 4.3 Properties of Immunoglobulin Isotypes**

Class or Subclass Properties	IgM	IgD	IgG1	IgG2	IgG3	IgG4	IgA1	IgA2	IgE

Fc Glycosylation

All Igs contain N-linked oligosaccharides, and it is becoming increasingly clear that this glycosylation plays significant roles in Ig structure and function. Though the type and extent of glycosylation varies among isotypes, an N-linked oligosaccharide on ASN 297 in the C_H2 domain is conserved on all mammalian IgGs and homologous portions of IgM, IgD, and IgE. As the average serum IgG contains 2.8 oligosaccharides, there is often glycosylation present in the V domain as well (113). The consensus sequence for the V domain N-linked oligosaccharides is not present in the germline, but it can be created during somatic hypermutation (114). Glycosylation in the Fc region has been shown to be important for antibody half-life and effector functions (115–117). Glycosylation of the Fc domain influences complement activation as Ig hypoglycosylation influences affinity for C1q as well as Ig binding to the FcR, possibly due to its affects on Ig structure (118). Differential sialylation of the core Fc polysaccharide has recently been shown to have dramatic effects on the proinflammatory versus antiinflammatory activity of IgG (119). Further, IgD N-linked glycans are necessary for IgD to bind to the IgD receptor on T cells (120).

V domain glycosylation potentially affects the affinity for antigen, antibody half-life, antibody secretion, and organ targeting. Interestingly, glycosylation has been shown to be capable of both positively and negatively affecting antigen binding (121–124). The biologic significance of Ig glycosylation can be seen from studies demonstrating that IgG from patients with rheumatoid arthritis is galactosylated to a lesser extent (termed IgG G0) than IgG from normal controls. In some cases, hypogalactosylation correlates with disease activity (125). Hypogalactosylation of IgG has also been found to occur in other chronic inflammatory diseases such as Crohn's disease and systemic lupus erythematosus (126).

IgM

IgM is an isotype of firsts. It is ontogenetically primary, being expressed first on developing B lineage cells. IgM is also the isotype that initially dominates the primary humoral immune response. It is probably, along with IgD, a phylogenetically primitive isotype in jawed vertebrates (an almost first) and may be the most phylogenetically stable isotype (127).

IgM serves important immunological functions both on the surfaces of B lymphocytes and in the fluid phase in the blood and in the mucosal secretions. On the cell surface, IgM consists of two identical μ heavy chains and two identical light chains (μ_2L_2). It is initially expressed on B lineage cells in noncovalent association with surrogate light chains, and subsequently, following successful light chain gene rearrangement, with κ or λ light chains. On the mature B cell surface, IgM is noncovalently associated with two other polypeptide chains, Ig-α (CD79a) and Ig-β (CD79b) (128–130). These integral membrane proteins serve to transduce signals when surface IgM binds to and is cross-linked by cognate antigen.

In the secreted form, IgM can consist of either pentamers $(\mu_2L_2)_5$ or, less often, hexamers $(\mu_2L_2)_6$ (131). The μ_2L_2 monomers of the pentameric form are linked one to another by disulfide bonds in the C_H4 domains. Two of these monomers are, on one side, disulfide bonded not to another μ chain but to a 15,000 Da-polypeptide, called J chain. J chain is also found in polymeric IgA. There may be multiple patterns of such disulfide bonding, such that different cysteines participate in different monomeric units (132).

Application of electron microscopy to polymeric IgM molecules has suggested that IgM can adopt two different quaternary arrangements: star and staple (133,134). All of the antigen binding sites are arrayed in radial fashion, in the same plane as one another and the Fc regions, in the star arrangement. In the staple form, the Fab arms bend out of the plane of the Fc regions. It has been conjectured that the staple form is utilized in binding simultaneously to two or more epitopes on multivalent antigens, such as bacterial or viral surfaces.

A major pathway through which soluble IgM mediates immunity or immunopathology is the activation of the classical pathway of complement. On a per molecule basis, relative to other isotypes, IgM is highly effective at activating the classical pathway and can thereby opsonize bacterial pathogens. In select cases (e.g., *Neisseria meningitidis*), binding of IgM to bacterial surfaces, followed by complement activation, can cause direct lysis of the bacteria through the insertion of the membrane attack complex into the bacterial membrane (135). IgM, like polymeric IgA, can reduce the effective number of colony- or plaque-forming units for, respectively, bacteria and viruses, through agglutination. Significant physical and biological properties of IgM and the other Ig isotypes are shown in Table 4.3.

IgD

IgD is primarily of interest in its membrane form, as the soluble form of IgD is found in relatively modest concentrations in the blood and other body fluids. The cell surface form of IgD is found along with IgM on all mature, naïve B cells, where it appears capable of transducing activating and tolerizing signals (136). As is true for IgM, the membrane form of IgD associates noncovalently with Ig-α (CD79a) and Ig-β (CD79b). Simultaneous cell surface expression of two heavy chain isotypes expressing the same V_H domains and the same light chains occurs via differential RNA splicing (137).

IgD exhibits greater sensitivity to proteolytic cleavage than IgM, which is consistent with a relatively short serum

half-life of only 2.8 days. The relatively long hinge region is a primary target for proteolysis. Little is known about the roles of serum IgD in immunity or immunopathology.

IgG

IgG is the predominant isotype (approximately 70%–75% of the total Ig) in the blood and extravascular compartments. The four human IgG subclasses (IgG1, IgG2, IgG3, and IgG4) are named in order of their relative serum concentrations, with IgG1 the most prevalent and IgG4 the least. There are differences in effector functions (e.g., complement activation and Fc receptor binding) and other biological properties (e.g., serum half-life) among these subclasses. However, there are also crucial functional commonalities, such as placental passage (see Table 4.3).

IgG antibodies are the hallmark of immunological memory in the humoral immune response. In addition to the isotype switch from IgM to IgG in a secondary antibody response, somatic hypermutation can lead to affinity maturation, a process by which the average affinity of antibody for the antigen eliciting the immune response can increase.

IgG antibodies contribute to immunity directly and through the activation of complement or FcR-bearing cells. Important examples of immunity mediated directly through antibody binding include neutralization of toxins (e.g., diphtheria toxin) and viruses (e.g., poliovirus). Medically important examples of IgG-induced complement activation include immunity to encapsulated bacterial pathogens leading either to opsonization and destruction within phagocytes (e.g., *Streptococcus pneumoniae*) or to direct complement-mediated lysis (e.g., *Neisseria meningitidis*). Activation of FcR-bearing cells by IgG antibodies has also been implicated in immunity to pathogens (e.g., *Cryptococcus neoformans*) (138). The consensus view is that human IgG1 and IgG3 isotypes are effective activators of the classical complement pathway. Although some older sources state that IgG2 and IgG4 are weak or nonactivators of the classical complement pathway, more recent evidence suggests that when epitope density is high, IgG2 is effective in activating complement (139,140). One possible source for the isotype-related variation in complement-activating ability is variation in affinity for C1q (IgG3>IgG1>IgG2>IgG4), the portion of the first component in the classical pathway that physically contacts the C_H2 domains of antibodies. However, isotype-associated differences in complement activation have also been found to occur at steps of the cascade subsequent to the binding of C1q to antibody (102,141). For example, in one study of chimeric monoclonal antibodies engineered to express identical V domains and representing all four human IgG subclasses, the IgG3 antibody fixed C1q better than the IgG1 antibody, but the IgG1 molecule was more effective in mediating complement-dependent cell lysis than

the IgG3 molecule (141). Thus, it is probably not possible to rank the relative abilities of the IgG subclasses to activate complement in a single absolute hierarchy.

The affinities of IgG subclasses for Fc receptors vary from about 5×10^5 M^{-1} to about 10^8 M^{-1} (see Chapter 5). Recent studies in the mouse suggest that the relative contributions of IgG subclasses to various immunopathological processes depend on their relative affinities for the activating versus inhibiting isoforms of FcR (142).

A remarkable attribute of IgG (for three of the four subclasses) is its serum half-life of about 23 days. This property, attributable to the Fc region and its interaction with the neonatal Fc receptor (FcγRn), has been exploited for therapeutics through the genetic fusion of solubilized receptors (e.g., CTLA4) to IgG Fc regions (143).

IgA

Although IgG is the clearly predominant isotype in the blood, IgA is the dominant immunoglobulin isotype in the mucosal secretions, as well as in breast milk and colostrum (144).

In the blood, 10%–15% of the Ig is IgA (versus 65%–75% IgG). Moreover, IgA has a shorter half-life than IgG in serum. The predominant form of IgA in human serum or plasma is monomeric (i.e., α_2L_2), but there are small quantities of dimers [$(\alpha_2L_2)_2$], and fewer still trimers and tetramers. Secretory IgA consists of dimers and lesser amounts of trimers and tetramers associated with one joining (J) chain (distinct from the J region in the heavy chain V domain) and one secretory component (SC) chain (see below). The latter is the extracellular portion of the polymeric Ig receptor (pIgR), which is expressed by mucosal epithelial cells and transfers polymeric IgA or IgM from basolateral to apical surfaces, thereby providing most of the Ig content of the mucosal secretions. The J chain is disulfide bonded to the tail pieces, short C-terminal extensions of the C_H3 domains, of the two IgA monomers of a dimer, while SC forms a disulfide bond to a cysteine in one C_H2 domain of one monomer.

The two α heavy chain constant region genes correspond to two IgA subclasses, IgA1 and IgA2. IgA1 is the predominant (>80%) IgA subclass in the serum. Although IgA2 is the major form in some human mucosal secretions, such as those in the large intestine and the female genital tract, there is variation in the relative proportion of IgA1 and IgA2 in different secretions. The shorter hinge region of IgA2 confers increased resistance to bacterial proteases that might be encountered in the mucosal environment. The extended hinge region of IgA1 is believed to permit molecules of this isotype to accommodate variable epitope spacings on multivalent antigens. Although the long hinge region of IgA1 molecules might be expected to confer relatively high susceptibility to proteolysis, relative protection against the activity of bacterial proteases is provided by
FIGURE 4.12 A comparison of an x-ray and neutron-solution-scattering theoretical model (human IgA1) and x-ray crystal (murine IgG1 and IgG2a) structures. Light chains (yellow), heavy chains (red and dark blue), and glycosylation (light blue) are illustrated. The extended length of IgA1 over that of IgG can be seen along with extensive glycosylation that characterizes this isotype. (From Boehm et al. [192], with permission. See color insert.)

heavy O-linked glycosylation in the hinge (see Figure 4.12). Nevertheless, the IgA1 hinge is uniquely susceptible to IgA proteases produced by certain pathogenic bacteria (145).

Secretory IgA (S-IgA) has been shown to participate in immunity against a range of viral, bacterial, and parasitic pathogens at mucosal surfaces. The relative absence of functional complement and phagocytes in mucosal secretions is consistent with a different mix of mechanisms for mediating immune effects associated with S-IgA versus, for example, serum IgG. Mechanisms associated with IgA are less dependent on inflammation-producing molecules or cells. Among these mechanisms are inhibition of microbial adherence through V module-mediated specific binding to microbial adhesins, agglutination of microbes, blocking of microbial receptors for cell surface carbohydrates with IgA-associated glycans, and mucus trapping (in which binding of S-IgA to bacteria makes them more adherent to host-generated mucus). There is also evidence that polymeric IgA can neutralize viruses in some circumstances by interfering with steps postattachment, such as internalization. In some cases, posttranslational modifications of viral surface molecules, related to proteolytic events associated with epithelial cell transit, lead to IgA antibodies expressing protection-related antigen specificities that have no parallel in the IgG pool (146,147). Some of the contributions of IgA to immunity are mediated

through binding to FcαRI (CD89) on human neutrophils, monocytes/macrophages, and eosinophils. For example, cells bearing FcαRI on their plasma membranes can phagocytose IgA-antigen complexes. FcαRI binds to the IgA Fc region between the Cα2 and the Cα3 domains (148). Amino acid residues in the IgA Fc region critically involved in the interaction with FcαRI are indicated in Figure 4.13.

The ability of IgA to activate complement is controversial. At present, the preponderance of evidence suggests that IgA does not activate the classical complement pathway and only weakly, and under some pathophysiological circumstances, activates the alternative complement pathway. However, there is evidence suggesting that, *in vitro* at least, polymeric, but not monomeric, IgA can activate the complement pathway dependent on mannose-binding lectin (149).

Additional properties of the polymeric forms of IgM and IgA are considered in the following sections.

IgE

IgE is best known for its association with hypersensitivity reactions and allergy, but this isotype is also of interest in the context of immunity to parasites. In the blood, IgE is present at the lowest concentration of any of the immunoglobulin isotypes (with roughly five orders of
FIGURE 4.13 Illustration of the residues essential for the binding of IgA to FcαR (CD89). Residues represent mutations made in IgA C$_H$ regions as mapped on an Fcγ fragment. Of the residues mutated, L465 and L266 were found to be important for binding to CD89. (From Carayannopoulos et al. [148] with permission.)

magnitude less IgE than IgG) and has the shortest half-life. The unimpressive quantitative representation of IgE in the blood is related to the high affinity of IgE antibodies for FcεRI, often referred to as the high-affinity Fc receptor for IgE. FcεRI is expressed on mast cells, basophils, Langerhans cells, and eosinophils. Due to the high affinity of FcεRI for its IgE ligand, mast cells and basophils are covered with relatively long-lived FcεRI-IgE complexes.

The interaction between IgE and FcεRI has an affinity of $\sim 10^{10}$ L/M. It primarily involves contacts between FcεRI and amino acids in the C$_H$3 domains, with some contributions from amino acids in the C$_H$2 domains. Although each IgE potentially has two sites for interacting with the FcεRI, the stoichiometry has been shown to be 1:1. Further, it has been suggested that IgE binds to FcεRI in a kinked conformation (150).

Upon ligation with bivalent or multivalent antigens specifically recognized by the bound IgE molecules, the FcεRI molecules transduce signals that activate the mast cells or basophils to secrete potent mediators of inflammation, such as histamine. These mediators are responsible for the symptoms associated with asthma, allergic rhinitis, and anaphylaxis.

There is a second receptor for IgE. FcεRII (CD23), a type II membrane protein, is expressed on monocytes/macrophages, B lymphocytes, natural killer (NK) cells, follicular dendritic cells, Langerhans cells, eosinophils, acti-

vated epithelial cells, and platelets. It binds monomeric IgE with an affinity of $\sim 10^7$ L/M, roughly three orders of magnitude lower than the affinity of FcεRI for IgE. Functional consequences of FcεRII-IgE interaction on macrophages include secretion of mediators of immediate hypersensitivity, as well as cytokines and chemokines. There is also evidence suggesting that the FcεRII-IgE interaction can contribute to antigen capture and presentation to both B and T cells.

Fc Receptor Immunoglobulin Interactions

There are four receptors that bind the Fc regions of IgG molecules in humans and five such receptors in mice. Three of the human receptors are expressed primarily on hematopoietic cells directly involved in immune responses: FcγRI, FcγRII, and FcγRIII. Among the FcγR involved in antibody effector functions, there is important variation in affinity for IgG molecules. FcγRI binds IgG with relatively high affinity, permitting the binding of monomeric IgG. In contrast, FcγRII and FcγRIII bind to IgG with relatively low affinity. Consequently, these latter two receptors do not bind significant quantities of monomeric IgG but preferentially interact with IgG that has been effectively aggregated through interaction with bivalent or multivalent antigens (i.e., immune complexes). Key amino acid residues involved in the binding FcγRs and FcεR1 with their corresponding Ig can be seen in Figure 4.14. Allotypic variations in FcγRIIA can also influence affinity for IgG ligands and subsequent effector function (151).

There are different isoforms of FcγRII and FcγRIII. Of particular functional relevance, FcγRIIA is activating, whereas FcγRIIB is inhibiting. In mouse models, deficiency of FcγRIIB can be associated with an autoimmune syndrome similar to human lupus (152). Studies in mice have also suggested that the effectiveness of antibodies of the various murine IgG subclasses in mediating FcγR-dependent effector functions are correlated with the ratio of affinities of antibodies of those subclasses for activating versus inhibiting FcγR (142).

FcγRIIIA is expressed on NK cells, while FcγRIIIB is expressed on neutrophils. The former receptor is attached to the membrane by a standard transmembrane polypeptide, while the latter is attached via a glycophospholipid tail.

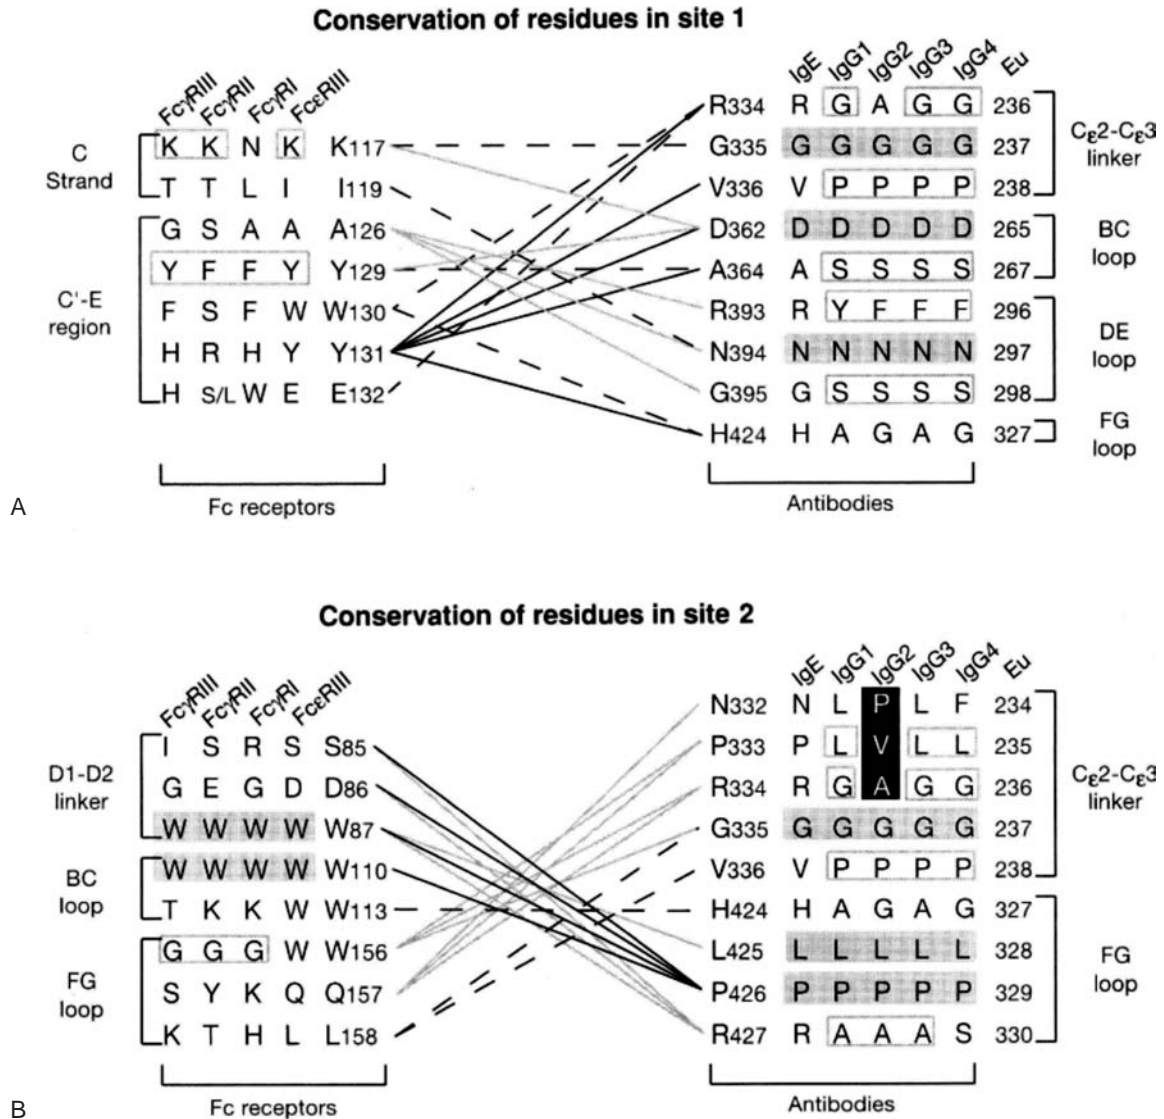
The fourth human receptor, the neonatal FcγR, or FcγRn (sometimes referred to as the *Brambell receptor*), transports IgG across the placenta. It also plays a crucial role in protecting IgG from proteolytic degradation, thereby prolonging serum half-life. While FcγRI, FcγRII, and FcγRIII are members of the immunoglobulin superfamily, FcγRn is structurally similar to MHC class I molecules, including noncovalent association with β_2-microglobulin. The interaction between FcγRn and IgG involves amino acid residues in the C$_H$2-C$_H$3 interface (153)


FIGURE 4.14 Certain residues are conserved between FcγRs and FcεRl as well as between IgG and IgE that facilitate binding. Two sites participate: site 1 in (a) and site 2 in (b). Heavy lines indicate the highest number of contacts and dashed lines indicate the least. Of considerable note are residues W87 and W110 in site 2 of the receptors and P426 in the immunoglobulin that form a core "praline sandwich" in the interaction between immunoglobulin and receptor. (From Garman [189] with permission.)

and is pH-sensitive. This latter property is consistent with the ability of FcγRn to bind IgG in acidic vesicular compartments and then release it into the neutral-pH environment of the blood. A crystallographic structure of the rat FcγRn in a 1:1 complex with a heterodimeric Fc (containing only one FcγRn-binding site) reveals that there are conformational changes in the Fc on binding to FcγRn (154). The investigators also identified three titratable salt bridges that confer pH-dependent binding of the IgG Fc to the FcγRn.

There are other FcR that interact with the non-IgG isotypes: IgM, IgD, IgA, and IgE. The FcR for IgA and IgE are covered in the respective sections devoted to the corre-

sponding isotypes. An additional Fcα/μR binds both IgA and IgM. Functional attributes of this receptor and the FcRδ are in the process of being characterized in detail.

There are functional as well as structural parallels among FcR for IgG and non-IgG isotypes. Some of the features of Fc-FcR interaction that are conserved across isotypes are illustrated in Figure 4.14.

Transmembrane and Cytoplasmic Domains

Igs are expressed in both membrane and secreted forms. In contrast to the secreted form, the membrane Ig contains a transmembrane and a cytoplasmic domain. The

transmembrane domain is a typical single-pass polypeptide segment consisting of 26 hydrophobic residues, extending from the C-terminus end of the C-terminal C_H domain and forming an alpha-helix followed by a variable number of basic amino acids. The cytoplasmic portion of the IgH chain ranges in length from 3 amino acids for IgG to 30 amino acids for IgE.

Both membrane expression of Ig and the integrity of the cytoplasmic domain are important in antibody function. As the cytoplasmic domain is rather short, membrane bound IgM is not thought to "signal" directly, but through the associated Ig-α and Ig-β molecules (155). However, disruption of either membrane expression of IgG1 in mice or the cytoplasmic tail results in the failure to generate an effective IgG1 response and IgG1 memory (156). Mice lacking IgE membrane expression exhibit significant impairment in IgE responses and have extremely low levels of secreted IgE (157). Thus, for those Igs with longer membrane:cytoplasmic tails, membrane Ig affects signaling beyond its association with Ig-α and Ig-β. Thus, specific residues in the transmembrane domain have been identified that are crucial for signal transduction while having no effect on the association with Ig-α and Ig-β (158).

HIGHER ORDER STRUCTURE

Many of the biological functions of IgA and IgM are dependent on their ability to form multimeric structures. This section will discuss the role of multimeric immunoglobulin in immune function.

Dimers, Pentamers, and Hexamers

The majority of multimeric IgA exists as dimers and, less commonly, trimers and tetramers, while IgM forms pentamers and occasionally hexamers. The polymeric structure of these antibodies enhances their functional affinity (avidity) for antigen, is essential for their active transport (both IgA and IgM) across epithelial cells to mucosal secretions, and, in the case of IgM, enhances the activation of the classical pathway of complement. Once multimerized, IgA or IgM in a complex with J chain can bind to pIgR and cross mucosal epithelial cells ([159], reviewed in [160]). Although IgM can undergo transcytosis to the mucosal secretions, its principal action is in the serum.

The ability of IgA and IgM to multimerize is due to a tailpiece (tp), an additional C-terminal segment of 18 amino acids in the secreted forms of the μ and α heavy chains. Tailpieces of both IgM and IgA contain a penultimate cysteine (residue 575 in IgM and 495 in IgA) that forms two different disulfide bonds important for multimer formation. In an Ig monomeric unit containing two identical heavy chains, one cysteine residue forms intermonomeric subunit bonds, while the remaining cysteine residue on the other heavy chain bonds to a cysteine on the J chain (161–164).

Another cysteine residue, Cys414, also forms intermonomeric subunit disulfide bonds in IgM and this bond is important in hexamer formation (165). Besides disulfide bonds, the highly conserved glycan linked to Asn563 in IgM (and the homologous region in IgA) is also important for multimerization (166).

Domain-swapping experiments demonstrate that the tp regulates multimerization in the context of the specific heavy chain. While addition of the α tp to IgM has little effect on IgM polymerization, the introduction of the μ tp to IgA leads to higher-order IgA polymers (167). Based on this finding, it has been proposed that IgM polymerization is more efficient than IgA polymerization.

The J Chain

The J chain, an evolutionarily conserved 137-amino-acid polypeptide produced by B lymphocytes, functions to regulate multimer formation and to promote linkage of multimeric Ig to pIgR on epithelial cells. The J chain consists of a single domain in a beta barrel conformation and does not show sequence similarity to Ig domains (168). It contains eight cysteine residues that participate in disulfide bonds with two tp cysteines, as described earlier, as well as function to stabilize its own structure through intramolecular bonds (167,169). The J chain influences the polymerization of the multimers, because in the absence of J chain, IgA forms fewer dimers and IgM forms fewer pentamers (170).

The J chain exists in all polymeric forms of IgA and is important in IgA polymerization and secretion across the mucosa. J chain is not required for IgM polymers, but is required for external secretion. While IgM pentamers contain J chain, hexamers almost always lack it. The makeup of IgM is biologically significant since IgM hexamers have about 20-fold greater ability to activate complement than IgM pentamers. The presence of increased levels of hexameric IgM has been postulated to play a role in the pathogenesis of Waldenstrom's macroglobulinemia and cold agglutinin disease (171).

Immunoglobulin Transport

Transport of dimeric IgA and pentameric IgM to the mucosal secretions occurs after binding to pIgR that is present on the basolateral surface of the lining epithelial cells. The J chain is essential for the secretion of IgA and IgM and, as described earlier, influences the polymeric structure of the Ig (159). pIgR is a transmembrane receptor synthesized by mucosal epithelial cells that contains seven domains, including five extracellular V-like domains, a transmembrane domain, and a cytoplasmic domain (172). Once bound to pIgR, polymeric Ig is endocytosed and

transported to the apical surface of the cell. pIgR is then proteolytically cleaved between the fifth and sixth domains to release a complex (termed *secretory Ig*) containing the H, L and, J chains, and the secretory component (SC), which represents the cleaved extracellular portion of pIgR (173,174). As pIgR undergoes constitutive transcytosis in the absence of polymeric Ig, free SC is also released into the mucosal secretions. SC has several biological functions, including protecting the Ig from degradation by proteases and binding bacterial antigens such as the *Clostridium difficile* toxin A (175,176). SC also functions to localize sIgA to the mucus layer to help protect against invasion by pathogens (177). Results from pIgR-null mice demonstrate that alternate pathways exist to transport polymeric Ig to the mucosal secretions as some secretory Ig still crosses the epithelial cells in the absence of pIgR (178). Results from pIgR-null mice also demonstrate the importance of high levels of secretory antibodies, as these mice are more susceptible to mucosal infections with pathogens such as *Salmonella typhimurium* and *Streptococcus pneumoniae* (179,180).

The epithelial transcyotosis of polymeric Ig has several biological implications. First by delivering the Ig to the mucosal surface, it enables antibodies to bind to pathogenic agents and prevent them from penetrating the mucosa, a process termed *immune exclusion*. Second, transcytosing antibody can neutralize viruses intracellularly (181,182). Finally, polymeric Ig can bind to antigens in the mucosal lamina propria and excrete them to the mucosal lumen (where they can be removed from the body) by the same pIgR-mediated transcytosis process (183,184). Some pathogens can exploit the pIgR-mediated transcytosis process in reverse to penetrate the mucosa. For example, the pneumococcal adhesin, CbpA, can bind pIgR at the epithelial apical surface, leading to bacterial penetration of the mucosa (185).

CONCLUSION

Immunoglobulins are extremely versatile molecules that can carry out many biological activities at the same time. The need to be able to recognize unique antigen structures prior to any previous exposure, coupled with the need to maintain host cell receptor or complement recognition properties, presents a truly unique challenge for the system. As has been described, the system incorporates diversity within specific constraints. The precise biological niches may differ, but the overall design for these molecules is the same.

The flexibility and biologic properties of immunoglobulins have made them a major focus of molecular engineering. Immunoglobulins are being used as therapeutic agents, as well as for biotechnology applications. These opportunities have led to a resurgence of interest in the structure–function aspects of antibodies as we approach "designer antibodies." Both the variable and constant portions of these molecules are current substrates for engineering purposes, offering the potential for altering both receptor and effector function. The study of antibodies began with the need to understand how sera could neutralize toxins. It is likely that antibodies will continue to be a major focus for those who seek to take fundamental principles of protein chemistry to the bedside.

Antigen–antibody Interactions and Monoclonal Antibodies

Jay A. Berzofsky, Ira J. Berkower, and Suzanne L. Epstein

INTRODUCTION

The basic principles of antigen–antibody interaction are those of any bimolecular reaction. Moreover, the binding of antigen by antibody can, in general, be described by the same theories and studied by the same experimental approaches as the binding of a hormone by its receptor, of a substrate by enzyme, or of oxygen by hemoglobin. There are several major differences, however, between antigen–antibody interactions and these other situations. First, unlike most enzymes and many hormone-binding systems, antibodies do not irreversibly alter the antigen they bind. Thus, the reactions are, at least in principle, always reversible. Second, antibodies can be raised, by design of the investigator, with specificity for almost any substance known. In each case, one can find antibodies with affinities as high as and specificities as great as those of enzymes for their substrates and receptors for their hormones. The

interaction of antibody with antigen can thus be taken as a prototype for interactions of macromolecules with ligands in general. In addition, these same features of reversibility and availability of a wide variety of specificities have made antibodies invaluable reagents for identifying, quantitating, and even purifying a growing number of substances of biological and medical importance.

Another feature of antibodies that in the past proved to be a difficulty in studying and using them, compared to, say, enzymes, is their enormous heterogeneity. Even "purified" antibodies from an immune antiserum, all specific for the same substance and sharing the same overall immunoglobulin structure (see Chapter 4), will be a heterogeneous mixture of molecules of different subclass, affinity, and fine specificity and ability to discriminate among cross-reacting antigens. The advent of hybridoma monoclonal antibodies (1–3) has made available a source of homogeneous antibodies to almost anything to which antisera can be raised. Nevertheless, heterogeneous antisera are still in widespread use and even have advantages for certain purposes, such as precipitation reactions. Therefore, it is critical to keep in mind throughout this chapter, and indeed much of the volume, that the principles derived for the interaction of one antibody with one antigen must be modified and extended to cover the case of heterogeneous components in the reaction.

In this chapter, we examine the theoretical principles necessary for analyzing, in a quantitative manner, the interaction of antibody with antigen and the experimental techniques that have been developed to study these interactions and to make use of antibodies as quantitative reagents. Further, we discuss the derivation, use, and properties of monoclonal antibodies.

THERMODYNAMICS AND KINETICS

The Thermodynamics of Affinity

The basic thermodynamic principles of antigen–antibody interactions, as indicated earlier, are the same as those for any reversible bimolecular binding reaction. We review these as they apply to this particular immunological reaction.

Chemical Equilibrium in Solution

For this purpose, let S = antibody binding sites, L = ligand (antigen) sites, and SL = the complex of the two. Then for the reaction

$$S + L \rightleftharpoons SL \tag{1}$$

the mass action law states

$$K_A = \frac{[SL]}{[S][L]} \tag{2}$$

where K_A = association constant (or affinity) and square brackets indicate molar concentration of the reactants enclosed. The import of this equation is that, for any given set of conditions such as temperature, pH, and salt concentration, the ratio of the concentration of the complex to the product of the concentrations of the reactants at equilibrium is always constant. Thus, changing the concentration of either antibody or ligand will invariably change the concentration of the complex, provided neither reactant is limiting—that is, neither has already been saturated—and provided sufficient time is allowed to reach a new state of equilibrium. Moreover, because the concentrations of antibody and ligand appear in this equation in a completely symmetrical fashion, doubling either the antibody concentration or the antigen concentration results in a doubling of the concentration of the antigen–antibody complex, provided the other reactant is in sufficient excess. This proviso, an echo of the one just above, is inherent in the fact that $[S]$ and $[L]$ refer to the concentrations of free S and free L, respectively, in solution, not the total concentration, which would include that of the complex. Thus, if L is not in great excess, doubling $[S]$ results in a decrease in $[L]$ as some of it is consumed in the complex, so the net result is less than a doubling of $[SL]$. Similarly, halving the volume results in a doubling of the total concentration of both antibody and ligand. If the fraction of both reactants tied up in the complex is negligibly small (as might be the case for low-affinity binding), the concentration of the complex quadruples. However, in most practical cases, the concentration of complex is a significant fraction of the total concentration of antigen or antibody or both, so the net result is an increase in the concentration of complex, but by a factor of less than 4. The other important, perhaps obvious but often forgotten, principle to be gleaned from this example is that since it is concentration, not amount, of each reactant that enters into the mass action law (Equation 2), putting the same amount of antigen and antibody in a smaller volume will increase the amount of complex formed, and diluting them in a larger volume will greatly decrease the amount of complex formed. Moreover, these changes go approximately as the square of the volume, so volumes are critical in the design of an experiment.

The effect of increasing free ligand concentration $[L]$ at constant total antibody concentration on the concentration of complex $[SL]$ is illustrated in Figure 5.1. The mass action law (Equation 2) can be rewritten

$$[SL] = K_A[S][L] = K_A([S]_t - [SL])[L] \tag{3}$$

or

$$[SL] = \frac{K_A[S]_t[L]}{(1 + K_A[L])} \tag{3'}$$

where $[S]_t$ = total antibody site concentration; that is, $[S] + [SL]$. Initially, when the complex $[SL]$ is a negligible fraction of the total antibody $[S]_t$, the concentration of
FIGURE 5.1 Schematic plot of bound ligand concentration as a function of free ligand concentration at a constant total concentration of antibody combining sites, $[S]_t$. The curve asymptotically approaches a plateau at which [bound ligand] $= [S]_t$.

complex increases nearly linearly with increasing ligand. However, as a larger fraction of antibody is consumed, the slope tapers off, and the concentration of complex, $[SL]$, asymptotically approaches a plateau value of $[S]_t$ as all the antibody becomes saturated. Thus, the concentration of antibody-binding sites can be determined from such a saturation-binding curve (Figure 5.1), taking the concentration of (radioactively or otherwise labeled) ligand bound at saturation as a measure of the concentration of antibody sites.[1] This measurement is sometimes referred to as *antigen-binding capacity*.

The total concentration of ligand at which the antibody begins to saturate is a function not only of the antibody concentration but also of the association constant, K_A, also called the *affinity*. This constant has units of M^{-1} or liters/mol, if all the concentrations in Equation 2 are molar. Thus, the product $K_A[L]$ is unitless. It is the value of this product relative to 1 that determines how saturated the antibody is, as can be seen from Equation 3′. For example, an antibody with an affinity of 10^7 M^{-1} will not be saturated if the ligand concentration is 10^{-8} M (product $K_A[L] = 0.1$), even if the total amount of ligand is in great excess over the total amount of antibody. From Equation 3′, the fraction of antibody occupied would be only 0.1/1.1, or about 9% in this example. These aspects of affinity and the methods for measuring affinity are analyzed in greater detail in the next section.

Free Energy

With regard to thermodynamics, the affinity, K_A, is also the central quantity, because it is directly related to the free energy, ΔF, of the reaction by the equations

$$\Delta F^\circ = -RT \ln K_A \tag{4}$$

$$K_A = e^{-\Delta F^\circ / RT} \tag{4'}$$

where R is the so-called gas constant (1.98717 cal/$^\circ$K $\cdot$ mol), T is the absolute temperature (in degrees Kelvin), ln is the natural logarithm, and e is the base of the natural logarithms. The minus sign is introduced because of the convention that a negative change in free energy corresponds to positive binding. ΔF° is the standard free-energy change defined as the ΔF for 1 mol antigen + 1 mol antibody sites combining to form 1 mol of complex at unit concentration.

It is also instructive to note an apparent discrepancy in Equations 4 and 4′. As defined in Equation 2, K_A has dimensions of M^{-1} (i.e., liters/mol), whereas in Equation 4′ it is dimensionless. The reason is that for Equation 4′ to hold strictly, K_A must be expressed in terms of mole fractions rather than concentrations. The mole fraction of a solute is the ratio of moles of that solute to the total number of moles of all components in the solution. Because water (55 M) is by far the predominant component of most aqueous solutions, for practical purposes, one can convert K_A into a unitless ratio of mole fractions by dividing all concentrations in Equation 2 by 55 M. This transformation makes Equation 4′ strictly correct, but it introduces an additional term, $-RT \ln 55$ (corresponding to the entropy of dilution), into Equation 4. This constant term cancels out when one is subtracting ΔF values, but not when one discusses ratios of ΔF values.

An important rule of thumb can be extracted from these equations. Because ln 10 = 2.303, a 10-fold increase in affinity corresponds to a free-energy change ΔF of only 1.42 kcal/mol at 37°C (310.15°K). (The corresponding values for 25°C and 4°C are 1.36 kcal/mol and 1.27 kcal/mol, respectively.) This is less than one-third the energy of a single hydrogen bond (about 4.5 kcal/mol). Looked at another way, a very high affinity of 10^{10} M^{-1} corresponds to a ΔF of only 14.2 kcal/mol, approximately the bonding energy of three hydrogen bonds. (Of course, since hydrogen bonds with water are broken during the formation of hydrogen bonds between antigen and antibody, the net energy per hydrogen bond is closer to 1 kcal/mol). It is apparent from this example that of the many interactions (hydrophobic and ionic as well as hydrogen bonding) that occur between the contact residues in an antibody-combining site and the contacting residues of an antigen (e.g., a protein), almost as many are repulsive as attractive. It is this small difference of a few kilocalories between much larger numbers corresponding to the total of attractive and the total of repulsive interactions that leads to net "high-affinity" binding. If ΔF were any larger, binding reactions would be of such high affinity as to be essentially irreversible. Viewed in this way, it is not surprising that a small modification of the antigen can result in an enormous change in affinity. A single hydrogen bond can change the affinity many-fold, and similar arguments apply to hydrophobic interactions and other forms of bonding. This concept is important when we discuss specificity and antigen structure later.

---

[1] This point is strictly true only for univalent ligands, but most multivalent ligands behave as effectively univalent at large antigen excess, where this plateau is measured.

Effects of Temperature, pH, Salt Concentration, and Conformational Flexibility

It was mentioned earlier that K_A is constant for any given set of conditions such as temperature, pH, and salt concentration. However, it varies with each of these conditions. We have already seen that the conversion of free energy to affinity depends on temperature. However, the free energy itself is also a function of temperature

$$\Delta F^\circ = \Delta H^\circ - T\Delta S^\circ \qquad (5)$$

where ΔH is change in enthalpy (the heat of the reaction)[2] and ΔS is the entropy (a term related to the change in disorder produced by the reaction),[2] and T is the absolute temperature (in degrees Kelvin).

It can be shown that the association constant K_A will thus vary with temperature, as follows:

$$\frac{d\ln K_A}{dT} = \frac{\Delta H^\circ}{RT^2} \qquad (6)$$

or equivalently,

$$\frac{d\ln K_A}{d(1/T)} = \frac{-\Delta H^\circ}{R} \qquad (6')$$

The derivation of these equations is beyond the scope of this book (see [4]). However, the practical implications are as follows: First, one can determine the standard enthalpy change ΔH° of the reaction from the slope of a plot of $\ln K_A$ versus $1/T$. Second, for an interaction that is primarily exothermic (i.e., driven by a large negative ΔH, such as the formation of hydrogen bonds and polar bonds), the affinity decreases with increasing temperature. Thus, many antigen–antibody interactions have a higher affinity at 4°C than at 25°C or 37°C, so maximum binding for a given set of concentrations can be achieved in the cold. In contrast, apolar or hydrophobic interactions are driven largely by the entropy term, $T\Delta S$, and ΔH° is near zero. In this case, there is little effect of temperature on the affinity.

As for the effects of pH and salt concentration (or ionic strength) on the affinity, these vary depending on the nature of the interacting groups. Most antigen–antibody reactions are studied near neutral pH and at physiologic salt concentrations (0.15 M NaCl). If the interaction is dominated by ionic interactions, high salt concentration lowers the affinity.

Conformational flexibility of an antigen can also affect the affinity by affecting the entropy term in Equation 5. An outstanding example comes from the thermodynamics of binding of a series of broadly neutralizing monoclonal antibodies to the HIV envelope protein gp120. The energetics of binding between HIV gp120 and its cellular receptor CD4 (5) or to a panel of monoclonal antibodies (6) has been studied in detail. The results provide insight into the

[2] For a more complete description of these concepts, see a physical chemistry text, such as Moore (4).

TABLE 5.1 Energetics of Antibody Binding to gp120 Core Structure (Based on [6])

Ligand	ΔF	ΔH	$-T\Delta S$
CD4	−10.4	−48.4	38.2
F105	−11.4	−30.0	18.6
b12	−12.3	−18.0	5.7
2G12	−7.8	−6.2	−1.6

ways protein flexibility can help the virus to evade antibody immunity. They may also explain part of the difficulty in eliciting antibodies of this type when immunizing with the native protein.

Gp120 is a glycoprotein that exhibits at least two conformational states: One exists on the virus, and it changes to the other when it binds the CD4 receptor on the cell surface. Monoclonal antibodies F105 and b12 bind residues within the CD4 binding site on gp120, while monoclonal 2G12 binds the opposite surface. The CD4 binding site defines a neutralizing surface that is conserved among a broad range of HIV isolates.

As shown in Table 5.1, CD4 and each antibody demonstrated a strongly negative ΔF, corresponding to high-affinity binding. However, as shown by microcalorimetry, they arrived at the affinity in different ways. CD4 and F105 have a strong negative ΔH of binding, but they also have a large, negative entropy due to the conformational change required, as shown by strongly positive values for $-T\Delta S$. This entropy effect greatly reduces the overall ΔF of binding, so they depend on a very large negative ΔH to bind. In contrast, monoclonal b12 has moderate levels of both ΔH and $-T\Delta S$, resulting in a nearly identical ΔF. Monoclonal 2G12 binds gp120 with a less favorable ΔH but no entropy cost.

The two discrete conformations of gp120 may be called the open and closed forms. The excursion between these two conformations affects the entropy of binding. CD4 and F105 only bind the open form, which reduces randomness and creates an entropy barrier. Monoclonal b12 is less dependent on one conformation, so it binds with less entropy cost, and 2G12 is indifferent to the two forms, so it has no entropy effect at all.

The strong entropy effect observed for these monoclonals may illustrate one way for the virus to evade antibody binding through a mechanism called *conformational masking*. The randomness of gp120, as found on the virus, means that it is rarely in the open conformation, making it difficult for most antibodies like F105 to bind. Only the rare antibody that is b12-like can bind multiple forms and eventually pull gp120 into its most favorable conformation.

The same effect may explain the difficulty in eliciting antibodies to this site using native gp120. If it is rarely in the open form, it will be unable to trigger B cells to make antibodies that require this form, and it will deliver only a

weak antigenic stimulus to those that bind partially to different conformations, such as b12. These considerations suggest that a more favorable vaccine antigen could be made if gp120 could be anchored in the open conformation, so it could stimulate B cells to make antibodies that require this form. The hallmark of this structure would be its ability to bind F105 and b12 with a good ΔH and reduced values of $-T\Delta S$.

Kinetics of Antigen–antibody Reactions

A fundamental connection between the thermodynamics and kinetics of antigen–antibody binding is expressed by the relationship

$$K_A = \frac{k_1}{k_{-1}} \tag{7}$$

where k_1 and k_{-1} are the rate constants for the forward (association) and backward (dissociation) reactions.

The forward reaction is determined largely by diffusion rates (theoretical upper limit 109 liters/mol·sec) and the probability that a collision will result in binding—that is, largely the probability that both the antigen and the antibody will be oriented in the right way to produce a good fit, as well as the activation energy for binding. The diffusive rate constant can be shown (7) to be approximated by the Smoluchowski equation

$$k_{\mathrm{dl}} = 4\pi a D(6 \times 10^{20}) \tag{7a}$$

where a is the sum of the radii in centimeters of the two reactants, D is the sum of the diffusion constants in cm^2/sec for the individual reactants, and the constant 6×10^{20} is necessary to convert the units to $M^{-1} \cdot sec^{-1}$. For example, if $a = 10^{-6}$ cm and $D = 10^{-7}$ cm^2/sec, then $k_{\mathrm{dl}} \approx 7.5 \times 10^8$ $M^{-1} \cdot sec^{-1}$. Association rates will generally be slower for large protein antigens than for small haptens. This observation may be due to the smaller value of D, the orientational effects in the collision, and other non-diffusional aspects of protein–protein interactions. Therefore, association rates for protein antigens are more frequently on the order of 10^5 to 10^6 $M^{-1} \cdot sec^{-1}$ (see below). However, this observation can also be partly understood from diffusion-limited rates alone. If the radii of hypothetically spherical reactants are r_1 and r_2, then in Equation 7a, $a = r_1 + r_2$, whereas D is proportional to $1/r_1 + 1/r_2$. The diffusive rate constant is, therefore, proportional to

$$(r_1 + r_2) \left(\frac{1}{r_1} + \frac{1}{r_2} \right) = \frac{(r_1 + r_2)^2}{r_1 r_2} \tag{7b}$$

From this result, it can be seen that if $r_1 = r_2 = r$, then r cancels out and the whole term in Equation 7b is simply equal to 4. Thus, for the interaction between two molecules of equal size, the diffusive rate constant is the same regardless of whether those molecules are large or small (8). However, if one molecule is large and the other small, the rate is greater than if both molecules are large. This difference occurs because reducing the radius r_1 while keeping r_2 constant (and larger than r_1) has a greater effect on increasing the diffusion constant term D, proportional to $(1/r_1 + 1/r_2)$, in which the smaller radius produces the larger term, than it has on the term a, which is still dominated by the larger radius r_2. For example, if $r_2 = r$ as above, but $r_1 = 0.1r$, then the numerator in Equation 7b is only reduced from $4r^2$ to $1.21r^2$, whereas the denominator is reduced from $1r^2$ to $0.1r^2$. Thus, the ratio is increased from 4 to 12.1. Viewed another way, the greater diffusive mobility of the small hapten outweighs its diminished target area relative to a large protein antigen, since the larger target area of the antibody is available to both.

The dissociation rate (or "off rate") k_{-1} is determined by the strength of the bonds (as it affects the activation energy barriers for dissociation) and the thermal energy kT (where k is Boltzmann's constant), which provides the energy to surmount this barrier. The activation energy for dissociation is the difference in energy between the starting state and the transition state of highest energy to which the system must be raised before dissociation can occur.

As pointed out by Eisen (9), if one compares a series of related antigens, of similar size and other physical properties, for binding to an antibody, the association rates are all very similar. The differences in affinity largely correspond to the differences in dissociation rates.

A good example is that of antibodies to the protein antigen staphylococcal nuclease (10). Antibodies to native nuclease were fractionated on affinity columns of peptide fragments to isolate a fraction specific for residues 99 to 126. The antibodies had an affinity of 8.3×10^8 M^{-1} for the native antigen and an association rate constant, k_{on}, of 4.1×10^5 $M^{-1} \cdot sec^{-1}$. This k_{on} was several orders of magnitude lower than had been observed for small haptens (11), as discussed earlier. A value of k_{off} of 4.9×10^{-4} sec^{-1} was calculated using these results in Equation 7. This is a first-order rate constant from which one can calculate a half-time for dissociation (based on $t_{1/2} = \ln 2/k_{\mathrm{off}}$) of 23 minutes. These rates are probably typical for high-affinity ($K_A \approx 10^9$ M^{-1}) antibodies to small protein antigens such as nuclease ($MW \approx 17,000$). The dissociation rate is important to know in designing experiments to measure binding, because if the act of measurement perturbs the equilibrium, the time one has to make the measurement (e.g., to separate bound and free) is determined by this half-time for dissociation. For instance, a 2-minute procedure that involves dilution of the antigen–antibody mixture can be completed before significant dissociation has occurred if the dissociation half-time is 23 minutes. However, if the on rate is the same, but the affinity 10-fold lower, still a respectable 8×10^7 M^{-1}, then the complex could be 50% dissociated in the time required to complete the procedure. This caution is very relevant in the following discussion of methods of measuring binding and affinity below.

Because knowledge of the dissociation rate can be so important in the design of experiments, a word should be said about techniques to measure it. Perhaps the most widely applicable one is the use of radiolabeled antigen. After equilibrium is reached and the equilibrium concentration of bound radioactivity determined, a large excess of unlabeled antigen is added. Because any radioactive antigen molecule that dissociates is quickly replaced by an unlabeled one, the probability of a radioactive molecule associating again is very small. Therefore, one can measure the decrease in radioactivity bound to antibody with time to determine the dissociation rate.[3]

AFFINITY

It is apparent from our earlier discussion that a lot of information about an antigen–antibody reaction is packed into a single value: its affinity. In this section, we examine affinity more closely, including methods for measuring affinity and the heterogeneity thereof, the effects of multivalency of antibody and of antigen, and the special effects seen when the antigen–antibody interaction occurs on a solid surface (two-phase systems).

Interaction in Solution with Monovalent Ligand

The simplest case is that of the interaction of antibody with monovalent ligand. We may include in this category both antihapten antibodies reacting with truly monovalent haptens and antimacromolecule antibodies, which have been fractionated to obtain a population that reacts only with a single, nonrepeating site on the antigen.[4] In the latter case, the antigen behaves as if monovalent in its interaction with the particular antibody population under study. The proviso that the site recognized (antigenic determinant) be nonrepeating—that is, occur only once per antigen molecule—of course, is critical.

If the combining sites on the antibody are independent (i.e., display no positive or negative cooperativity for antigen binding), then for many purposes one can treat these combining sites, reacting with monovalent ligands, as if they were separate molecules. Thus many, but not all, of

FIGURE 5.2 Equilibrium dialysis. Two chambers are separated by a semipermeable membrane that is freely permeable to ligand but not at all to antibody. Antibody is placed in one chamber (B), and ligand in one or both chambers. Regardless of how the ligand is distributed initially, after sufficient time to reach equilibrium, it will be distributed as follows: The concentration of free ligand will be identical in both chambers, but chamber B will have additional ligand bound to antibody. The concentration of bound ligand is thus the difference between the ligand concentration in the two chambers, whereas the free concentration is the concentration in chamber A. Since these concentrations must obey the mass action law, Equation 2, they can be used to determine the affinity K_A, from Equations 3 or 3′, by any of several graphical procedures, such as Scatchard analysis (described in the text).

the properties we discuss can be analyzed in terms of the concentration of antibody-combining sites, independent of the number of such sites per antibody molecule (2 for IgG and IgA, 10 for IgM).

To determine the affinity of an antibody, one generally determines the equilibrium concentrations of bound and free ligand at increasing total ligand concentrations but at constant antibody concentration. Alternatively, one can vary the antibody concentration, but then the analysis is slightly more complicated. Perhaps the theoretically most elegant experimental method to determine these quantities is equilibrium dialysis (12,13), depicted and explained in Figure 5.2, in which ligand (antigen) is allowed to equilibrate between two chambers, only one of which contains antibody, separated by a semipermeable membrane impermeable to antibody. The important feature of this method, as opposed to most others, is that the concentrations of ligand in each chamber can be determined without perturbing the equilibrium. The disadvantage of this method is that it is applicable only to antigens small enough to permeate freely a membrane that will exclude antibody. Another technical disadvantage is that bound antigen, determined as the difference between bound plus free antigen in one chamber and free antigen in the other, is not measured independently of free antigen.

Another category of method uses radiolabeled ligand in equilibrium with antibody and then physically separates

---

[3] This method assumes that all binding sites are independent, as is generally true for antibodies and monovalent ligands. If there were either negative or positive cooperativity in binding, then the change in receptor occupancy that occurs when a large excess of unlabeled antigen is added would probably perturb the dissociation rate of radiolabeled antigen molecules already bound to other sites.

[4] Such fractionated antibodies may contain mixtures of antibodies to overlapping sites within a domain on the antigen, but as long as no two antibody molecules (or combining sites) can bind to the same antigen molecule simultaneously, the antigen still behaves as effectively monovalent.

FIGURE 5.3 Scatchard analysis of the binding of [³H]-sperm whale myoglobin by a monoclonal antibody to myoglobin (A) and by the serum antibodies from the same mouse whose spleen cells were fused to prepare the hybridoma (B). The monoclonal antibody (clone HAL 43-201E11, clone 5) produces a linear Scatchard plot, whose slope, -1.6×10^9 M^{-1}, equals $-K_A$, and whose intercept on the abscissa gives the concentration of antibody-binding sites. In contrast, the serum antibodies produce a curved (concave up) Scatchard plot, indicative of heterogeneity of affinity. From (15), with permission.

free antigen from antigen bound to antibody and quantitates each separately. The methods used to separate bound and free antigen are discussed below in the section on radioimmunoassay. These methods generally allow independent measurement of bound and free antigen but may perturb the equilibrium.

Scatchard Analysis

Once data are obtained, there are a number of methods of computing the affinity; we shall discuss two. Perhaps the most widely used is that described by Scatchard (14) (Figure 5.3 [15]). The mass action equilibrium law is plotted in the form of Equation 3

$$[SL] = K_A([S]_t - [SL])[L] \qquad (3)$$

and B is substituted for $[SL]$ and F for $[L]$, referring to bound and free ligand, respectively. Then the Scatchard equation is

$$\frac{B}{F} = K_A([S]_t - B) \qquad (8)$$

Note that a very critical implicit assumption was made in this seemingly simple conversion. The $[SL]$ within the parentheses in Equation 3 was intended to be the concentration of bound antibody sites, so that $([S]_t - [SL]) =$ free $[S]$. However, in Equation 8, we have substituted B, the concentration of bound ligand. If the ligand behaves as monovalent, then this substitution is legitimate, since every bound ligand molecule corresponds to an occupied antibody site. However, if the ligand is multivalent and can bind more than one antibody site, then Equation 8 is valid only in ligand excess where the frequency of ligands with more than one antibody bound is very low. In this section

we are discussing only monovalent ligands, but this proviso must be kept in mind when the Scatchard analysis is applied in other circumstances.

From Equation 8, we see that a plot of B/F versus B should yield a straight line (for a single affinity), with a slope of $-K_A$ and an intercept on the abscissa corresponding to antibody-binding site concentration (Figure 5.3). This is the so-called Scatchard plot. An alternative version that is normalized for antibody concentration is especially useful if the data were obtained at different values of total antibody concentration, $[A]_t$, instead of constant $[A]_t$. However, for this version one requires an independent measure of total antibody concentration, other than the intercept of the plot. Then one divides Equation 8 by the total concentration of antibody molecules (making no assumptions about the number of sites per molecule) to obtain

$$\frac{r}{c} = K_A(n - r) \qquad (9)$$

where r is defined as the number of occupied sites per antibody molecule, n is defined as the total number of sites per antibody molecule, and c is free ligand concentration; that is, $c = F$. Thus,

$$r = \frac{B}{[\text{total antibody}]} = \frac{B}{[A]_t}$$

$$n = \frac{[\text{total sites}]}{[\text{total antibody}]} = \frac{[S]_t}{[A]_t}$$

where $[A]_t =$ total molar antibody concentration. In this form of the Scatchard plot, r/c versus r, the slope is still $-K_A$, and the intercept on the r axis is n. Thus, one can determine the number of sites per molecule. Of course,

if one determines $[S]_t$ from the intercept of Equation 8, one can also calculate the number of sites per molecule by dividing $[S]_t$ by any independent measure of antibody concentration. Thus, the only advantage of normalizing all the data points first to plot the r/c form arises when the data were obtained at varying antibody concentrations. If the antibody concentration is unknown but held constant, then the B/F form is more convenient and actually provides one measure of antibody (site) concentration. Since today we know the value of n for each class of antibody (2 for IgG and serum IgA, 10 for IgM), the concentration of sites and that of antibody are easily converted in many cases.

Heterogeneity of Affinity

The next level of complexity arises when one is dealing with a mixture of antibodies of varying affinity for the ligand. This is the rule, rather than the exception, when one deals with antibodies from immune serum, even if they are fractionated to be monospecific—that is, all specific for the same site on the antigen. Contrast, for example, the linear Scatchard plot for a homogeneous monoclonal antibody to myoglobin (Figure 5.3A) with the curved Scatchard plot for the serum antibodies from the same mouse used to prepare the hybridoma monoclonal antibody (Figure 5.3B). This concave up Scatchard plot is typical for heterogeneous antibodies. In a system such as hormone receptor–hormone interaction in which negative cooperativity can occur between receptor sites (i.e., occupation of one site lowers the affinity of its neighbor), a concave up Scatchard plot can be produced by negative cooperativity in the absence of any intrinsic heterogeneity in affinity. However, in the case of antibodies, where no such allosteric effect has been demonstrated, a concave up Scatchard plot indicates heterogeneity of affinity.

Ideally, one would like to imagine that the tangents all along the curve correspond (in slope) to the affinities of the many subpopulations of antibodies. Mathematically, this is not strictly correct, but it is true that the steeper part of the curve corresponds to the higher-affinity antibodies and the shallower part of the curve to the lower-affinity antibodies. Graphical methods have been developed to analyze more quantitatively the components of such curves (16,17), and a very general and versatile computer program, LIGAND, has been developed by Munson and Rodbard (18) that can fit such curves using any number of subpopulations of different affinity. For purposes of this chapter, we discuss only the case of two affinities and then examine the types of average affinities that have been proposed when one is dealing with much greater heterogeneity. We also examine mathematical estimates of the degree of heterogeneity (analogous to a variance).

When an antibody population consists of only two subpopulations of different affinities, K_1 and K_2, then we can add the component Equations 3′ to obtain

$$r = r_1 + r_2 = \frac{n_1 K_1 c}{(1 + K_1 c)} + \frac{n_2 K_2 c}{(1 + K_2 c)} \qquad (10)$$

so that

$$\frac{r}{c} = \frac{n_1 K_1}{(1 + K_1 c)} + \frac{n_2 K_2}{(1 + K_2 c)} \qquad (10')$$

where the subscripts correspond to the two populations. Then the graph of r/c versus r can be shown to be a hyperbola whose asymptotes are, in fact, the linear Scatchard plots of the two components (Figure 5.4). This situation has been analyzed graphically by Bright (19). Taking the limits as $c \to 0$ and as $c \to \infty$, it can easily be shown that the intercept on the abscissa is just $n_1 + n_2$ (or, in the form B/F versus B, the intercept is the total concentration of binding sites $[S]_t$), and the intercept on the ordinate is $n_1 K_1 + n_2 K_2$. Thus, one can still obtain the total value of
FIGURE 5.4 Analysis of a curved Scatchard plot produced by a mixture of two antibodies with different affinities. The antibodies have affinities K_1 and K_2 and have n_1 and n_2 binding sites per molecule, respectively. r is the concentration of bound antigen divided by the total antibody concentration (i.e., bound sites per molecule), and c is the free antigen concentration. The curve is a hyperbola that can be decomposed into its two asymptotes, which correspond to the linear Scatchard plots of the two components in the antibody mixture. The tangents to the curve at its intercepts only approximate these asymptotes, so that the slopes of the tangents estimate but do not accurately correspond to the affinities of the two antibodies. However, the intercept on the r axis corresponds to $n_1 + n_2$. Note that in this case n_1 and n_2 must be defined in terms of the total antibody concentration, not that of each component.

n or $[S]_t$ from the intercept on the abscissa. The problem is in obtaining the two affinities, K_1 and K_2, and the concentrations of the individual antibody subpopulations (corresponding to n_1 and n_2). If K_1 is greater than K_2, one can approximate the affinities from the slopes of the tangents at the two intercepts (Figure 5.4), but these will not, in general, be exactly parallel to the two asymptotes, which give the true affinities, so some error is always introduced, depending on the relative values of n_1 and n_2 and K_1 and K_2. A graphical method for solving for these exactly has been worked out by Bright (19) and computer methods by Munson and Rodbard (18).

Average Affinities

In practice, of course, one rarely knows that one is dealing with exactly two subpopulations, and most antisera are significantly more heterogeneous than that. Therefore, the previous case is more illustrative of principles than of practical value. When faced with a curved Scatchard plot, one usually asks what the average affinity is, and perhaps some measure of the variance of the affinities, without being able to define exactly how many different affinity populations exist.

Suppose one has m populations each with site concentration $[S_i]$ and affinity K_i, so that at free ligand concentration $[L]$, the fraction of each antibody that has ligand bound will be given by an equation of the form of Equation 3′:

$$B_i = \frac{K_i[S_i]_t[L]}{(1 + K_i[L])} \quad (11)$$

Then the bound concentrations sum to give

$$B = \sum_{i=1}^{m} B_i = \sum_{i=1}^{m} \frac{K_i[S_i]_t[L]}{(1 + K_i[L])} \quad (11')$$

Substituting F for $[L]$ and dividing through by this quantity, one obtains

$$\frac{B}{F} = \sum_{i=1}^{m} \frac{K_i[S_i]_t}{(1 + K_i F)} \quad (12)$$

or equivalently

$$\frac{r}{c} = \sum_{i=1}^{m} \frac{K_i n_i}{(1 + K_i c)} \quad (12')$$

These can be seen to be generalizations of Equations 10 and 10′. Taking the limits as $F \to 0$ and $F \to \infty$, one again sees that the

$$\text{intercept on ordinate} = \sum_{i=1}^{m} K_i[S_i]_t \quad (13)$$
FIGURE 5.5 Types of average affinities for a heterogeneous population of antibodies, as defined on a Scatchard plot. K_0 is the slope of the tangent to the curve at a point where $B = [S]_t/2$, that is, where half the antibody sites are bound. Thus, K_0 corresponds to a median affinity. K_{av} is the slope of the chord between the intercepts and corresponds to a weighted average of the affinities, weighted by the concentrations of the antibodies with each affinity. Adapted from (20).

and the

$$\text{intercept on abscissa} = \sum_{i=1}^{m} [S_i]_t = [S]_t \quad (14)$$

Therefore, one can still obtain the total antibody site concentration from the intercept on the abscissa (Figure 5.5) (20).

Two types of average affinity can be obtained graphically from the Scatchard plot (20). Perhaps the more widely used K_0 is actually more accurately a median affinity rather than a mean affinity. It is defined as the slope of the tangent at the point on the curve where half the sites are bound—that is, where $B = [S]_t/2$ (Figure 5.5). A second type of average affinity, which we call K_{av}, is a weighted mean of the affinities, each affinity weighted by its proportional representation in the antibody population. Thus, we take the ratio

$$K_{av} = \sum_{i=1}^{m} \frac{K_i[S_i]_t}{[S]_t} \quad (15)$$

From Equations 13 and 14, it is apparent that K_{av} is simply the ratio of the two intercepts on the B/F and B axes—that is, the slope of the chord (Figure 5.5). This type of weighted mean affinity, K_{av}, is, therefore, actually easier to obtain graphically in some cases than K_0, and we shall see that it is useful in other types of plots as well.

Indices of Heterogeneity: The Sips Plot

For a heterogeneous antiserum, one would also like to have some idea of the extent of heterogeneity of affinity. For instance, if the affinities were distributed according to a normal (Gaussian) distribution, one would like to know the variance (21,22). More complex analyses have been developed that do not require as many assumptions about the shape of the distribution (23–25), but the first and most widely used index of heterogeneity arbitrarily assumes that the affinities fit a distribution, first described by Sips (26), that is similar in shape to a normal distribution. This was applied to the case of antibody heterogeneity by Nisonoff and Pressman (27) and is summarized by Karush and Karush (28). One fits the data to the assumed binding function

$$r = \frac{n(K_0 c)^a}{(1 + (K_0 c)^a)} \tag{16}$$

which is analogous to Equations 3′ and 11 (the Langmuir adsorption isotherm) except for the exponent a, which is the index of heterogeneity. This index, a, is allowed to range from 0 to 1. For $a = 1$, Equation 16 is equivalent to Equation 3, and there is no heterogeneity. As a decreases toward 0, the heterogeneity increases. To obtain a value for a graphically, one plots the algebraic rearrangement of Equation (16):

$$\log\left(\frac{r}{n-r}\right) = a \log c + a \log K_0 \tag{17}$$

so that the slope of $\log[r/(n-r)]$ versus $\log c$ is the heterogeneity index a.

  C. DeLisi (personal communication) has derived the variance (second moment) of the Sips distribution in terms of the free energy $RT \ln K_0$, about the mean of free energy. The result (normalized to RT) gives the dispersion or width of the distribution as a function of a:

$$\frac{\sigma^2_{\text{Sips}}}{R^2 T^2} = \frac{\pi^2 (1 - a^2)}{3a^2} \tag{18}$$

This is useful for determining a quantity, σ_{Sips}, which can be thought of as analogous to a standard deviation, if one keeps in mind that this is not a true Gaussian distribution. In addition, as noted earlier, the use of the Sips distribution requires the assumption that the affinities (really the free energies) are continuously distributed symmetrically about a mean, approximating a Gaussian distribution. This assumption frequently is not valid.

The Plot of B/F versus F or T

Another graphical method that is useful for estimating affinities is the plot of bound/free versus free or total ligand concentration, denoted F and T, respectively (20) (Figure 5.6). To simplify the discussion, let us define the bound/free ratio, B/F, as R, and define R_0 as the intercept, or limit,
FIGURE 5.6 Schematic plot of R, the bound/free ratio, as a function of free (F) or total (T) antigen concentration. The curves have a similar sigmoidal shape, but the midpoint (where $R = R_0/2$) of the plot of R versus T has a term dependent on antibody site concentration ($[S]_t$), whereas the midpoint of the plot of R versus F is exactly $1/K$, independent of antibody concentration. Adapted from (20).

as free ligand $F \rightarrow 0$. First, for the case of a homogeneous antibody, from Equation 3′,

$$R = \frac{B}{F} = \frac{K[S]_t}{(1 + KF)} \tag{19}$$

and

$$R_0 = \lim_{F \rightarrow 0} \frac{B}{F} = K[S]_t \tag{20}$$

Let us define the midpoint of the plot (Figure 5.6) as the point at which R decreases to half its initial value, R_0—that is, at which $R = K[S]_t/2$. For the case of homogeneous antibody (i.e., a single affinity), simple algebraic manipulation (20), substituting $K[S]_t/2$ (i.e., $R_0/2$) for B/F in Equation 8, will show that at this midpoint[5]

$$F = \frac{1}{K} \tag{21}$$

and

$$B = \frac{[S]_t}{2} \tag{22}$$

so that the total concentration, T, is

$$T = B + F = \frac{[S]_t}{2} + \frac{1}{K} \tag{23}$$

---

[5] It is important to note that R_0 must be the limit of B/F as F truly approaches zero. In an RIA in which the concentration of tracer is significant compared to $1/K$, reducing the unlabeled ligand concentration all the way to zero will still not yield the true limit R_0. The tracer concentration must also be negligible. If not, R_0 will be estimated falsely low, and the affinity will also be underestimated.

Thus, if one plots B/F versus F, the midpoint directly yields $1/K$. However, it is frequently more convenient experimentally to plot B/F versus T. In this case, the midpoint is no longer simply the reciprocal of the affinity. As seen from Equation 23, the assumption that the midpoint is $1/K$ will result in an error equal to half the antibody-binding site concentration. Thus, in plots of B/F versus T, the midpoint will be a good estimate of the affinity only if $[S]_t/2 \ll 1/K$—that is, if the antibody concentration is low compared to the dissociation constant. In fact, if the affinity is so high that $1/K \ll [S]_t/2$, then one will merely be measuring the antibody concentration, not the affinity at all (20) (Figure 5.6).

In the case of a heterogeneous antiserum, we have already seen that

$$R_0 = \sum_i K_i [S_i]_t \tag{13}$$

Therefore, at the midpoint, when $B/F = R_0/2$, it is easy to see that

$$K_{av} = \left(\frac{B}{F}\right)\left(\frac{2}{[S]_t}\right) = \frac{R_0}{[S]_t} \tag{24}$$

Thus, one can still obtain the average affinity, as defined above (20).

Regardless of average affinities, the effect of affinity heterogeneity is to broaden the curve, or to make the slope shallower. This can be seen by visualizing the curve of B/F versus F as a step function. Each antibody subpopulation of a given affinity, K_i, will be titrated to 50% of its microscopic B/F at a free ligand concentration $F = 1/K_i$. The high-affinity antibodies will be titrated at low F, but the low-affinity antibodies will require much higher F to be titrated. The resulting step function is analogous to the successive transitions corresponding to different pK values in a pH titration.

Intrinsic Affinity

The affinity, K_A, that we have been discussing so far is what has been termed the *intrinsic affinity*—that is, the affinity of each antibody-combining site treated in isolation. We have been able to do this, regardless of the valence of the antibodies, by using the concentration of combining sites, $[S]$, in our equations rather than the concentration of antibody molecules, $[A]$, which may have more than one site. Even without any cooperativity between combining sites, there is a statistical effect that makes the actual affinity different from the intrinsic affinity if the antibody is multivalent and one uses whole antibody concentration rather than site concentration. The way this difference arises can best be seen by examining the case of a bivalent antibody, such as IgG. We assume that the two sites are equivalent and neither is affected by events at the other. The ligand, as in this whole section, is monovalent. Then there are two binding steps

$$A + L \overset{K_1}{\rightleftharpoons} AL, \qquad AL + L \overset{K_2}{\rightleftharpoons} AL_2 \tag{25}$$
and the corresponding actual affinities are

$$K_1 = \frac{[AL]}{[A][L]}, \qquad K_2 = \frac{[AL_2]}{[AL][L]} \tag{26}$$

If the intrinsic affinity of both equivalent sites is K, then K_1 will actually be twice K, because the concentration of available sites $[S]$ will be twice the antibody concentration when the first ligand is about to bind, in step 1. However, once one site is bound, the reverse (dissociation) reaction of step 1 can occur from only one site—namely, that which is occupied. Conversely, for the second step, the forward reaction has only one remaining available site; however, in the reverse reaction, $AL_2 \rightarrow AL + L$, either site can dissociate to go back to the AL state. The second site bound need not be the first to dissociate, and since the sites are identical, one cannot tell the difference. Thus, for step 2, the apparent concentration of sites for the reverse reaction is twice that available for the forward reaction, so the affinity K_2 for the second step will be only half the intrinsic affinity, K.

It is easy to see how this statistical effect can be extrapolated to an antibody with n sites (29):

$$K_1 = nK \qquad \text{and} \qquad K_n = \left(\frac{1}{n}\right) K \tag{27}$$

For the steps in between, two derivations are available (9,29), which yield

$$K_i = \frac{(n - i + 1)}{i} K \tag{28}$$

The actual affinity, rather than the intrinsic affinity, becomes important with monovalent ligands when one is interested in the effective affinity (based on a molar antibody concentration) under conditions where $[L]$ is so low that only one site can bind antigen. Then for IgG or IgM (with 2 or 10 sites per molecule, respectively), the apparent affinity will be theoretically 2 or 10 times the intrinsic affinity. For most purposes, it is easier to use site concentrations and intrinsic affinities. The analyses given earlier, such as B/F versus F or the Scatchard plot, whether B/F versus B or r/c versus r, will all yield intrinsic affinities. It is the intrinsic affinity that tells us something about the nature of the antibody–ligand interaction.

Once one enters the realm of multivalent ligands, the actual affinity or effective affinity involving multipoint binding between multivalent antibody molecule and multivalent ligand molecule can be much greater than the intrinsic affinity for binding at each site. This case is the subject of the next section.

Interaction with Multivalent Ligands

So far, we have discussed only situations in which the ligand is monovalent, or effectively monovalent with respect to the particular antibody under study. However, in many situations the ligand molecule has multiple repeating identical determinants, each of which can bind independently to the several identical combining sites on a divalent or multivalent antibody.[6] Although the intrinsic affinity for the interaction of any single antibody-combining site with any single antigenic determinant may be the same as that discussed in the preceding section, the apparent or effective affinity may be much higher, due to the ability of a single antibody molecule to bind more than one identical determinant of a multivalent antigen molecule. Karush (30) has termed this phenomenon "monogamous bivalency." Such monogamous binding can occur between two molecules in solution, or between a molecule in solution and one on a solid surface, such as a cell membrane or microtiter plate. We first discuss the situation in solution and then discuss the additional considerations that apply when one of the reactants is bound to a solid surface.

Monogamous Bivalency

Suppose a divalent antibody molecule reacts with antigen that has two identical determinants. This situation has been treated in detail by Crothers and Metzger (31) and by Karush (30). Let us call the two antibody sites S and S', and the antigenic determinants D and D', with the understanding that, in actuality, we cannot distinguish S from S' or D from D'. The interaction can be broken up into two steps, a bimolecular reaction

$$
\begin{array}{ccc}
S & D & S \!-\! D \\
| + | & \overset{K_1}{\rightleftharpoons} & | \quad | \\
S' & D' & S' \quad D'
\end{array}
\tag{29}
$$
followed by an intramolecular reaction

$$
\begin{array}{ccc}
S \!-\! D & & S \!-\! D \\
| \quad | & \overset{K_2}{\rightleftharpoons} & | \quad | \\
S' \quad D' & & S' \!-\! D'
\end{array}
\tag{30}
$$
The association constant for the first step, K_1, is related to the intrinsic affinity, K, simply by a statistical factor of 4 due to the degeneracy (equivalence) between S and S' and between D and D'. This is a typical second-order reaction between antigen and antibody. However, the second step (Equation 30) is a first-order reaction, since it is effectively an interconversion between two states of a single molecular complex, the reactants S' and D' being linked chemically (albeit noncovalently) through the S—D bond formed

in the first step. Thus, the first-order equilibrium constant, K_2, is not a function of the concentrations of S—S and D—D in solution, as K_1 would be. Rather, the forward reaction depends on the geometry of the complex and the flexibility of the arms; in other words, the probability that S' and D' will encounter each other and be in the right orientation to react if they do come in contact depends on the distances and freedom of motion along the chain S'—S—D—D' rather than on the density of molecules in solution (i.e., concentration).

The reverse reaction for step 2, on the other hand, will have a rate constant similar to that for the simple monovalent S—$D \to S + D$ reaction, since the dissociation reaction depends on the strength of the S'—D' (or S—D) bond and is not influenced by the other S—D interaction unless there is strain introduced by the angles required for simultaneous bonds between S and D and S' and D'. Note that K_2 will inherently have a statistical factor of 1/2 compared to the intrinsic K'_2 for the analogous reaction if the S'—S—D—D' link were all covalent, since in the forward reaction of Equation 30 only one pair can react, whereas in the reverse reaction either S'—D' or S—D could dissociate to produce the equivalent result.

We would like to know the apparent or observed affinity for the overall reaction

$$
\begin{array}{ccc}
S & D & S \!-\! D \\
| + | & \overset{K_{\text{obs}}}{\rightleftharpoons} & | \quad | \\
S & D & S \!-\! D
\end{array}
\tag{31}
$$
Since the free energies, ΔF_1 and ΔF_2, for the two steps are additive, the observed affinity will be the product of K_1 and K_2

$$
K_{\text{obs}} = K_1 K_2
\tag{32}
$$

where we have defined K_1 and K_2 to include the statistical degeneracy factors.[7] The equilibrium constants K_1 and K_2 are each the ratios of forward and reverse rate constants, as in Equation 7. Of these four rate constants, all are directly related to the corresponding terms for the intrinsic affinity between S and D except for the intramolecular forward reaction of step 2, as noted above. Thus, the difficulty in predicting K_{obs} is largely a problem of analyzing the geometric (steric) aspects of K_2, assuming one already knows the intrinsic affinity. K. Crothers and Metzger (31) have analyzed this problem for particular situations. Qualitatively, we can say that whether K_2 will be larger or smaller than K will depend on factors such as the enforced proximity of S' and D' in step 2 and the distance between D and D' compared to the possible distances accessible between S and S', which in turn depends on the length of the antibody arms and the flexibility of the hinge between them (see Chapter 4).

---

[6] If only the antigen is multivalent and the antibody monovalent, such as an Fab fragment, the situation can be analyzed using the same statistical considerations discussed earlier.

[7] In some treatments where these statistical factors are not included in K_1 and K_2, the equivalent equation may be given as $K_{\text{obs}} = 2K_1 K_2$.

Thus, since K_1 can be approximated by K, except for statistical factors, the apparent affinity for this "monogamous bivalent" binding interaction, K_{obs}, may range from significantly less than to significantly greater than K^2. If K_2 is of the same order of magnitude as K, then K_{obs} will be of the order of K^2, which can be huge (e.g., if $K \approx 10^9$ M^{-1}, K_{obs} could be $\approx 10^{18}$ M^{-1}). The half-time for dissociation would be thousands of years. It is easy to see how such monogamous bivalent interactions can appear to be irreversible, even though in practice the observed affinity is rarely more than a few orders of magnitude larger than the K for a single site, possibly due to structural constraints (32).

If apparent affinities this high can be reached by monogamous bivalency, even greater ones should be possible for the multipoint binding of an IgM molecule to a multivalent ligand. Although IgM is decavalent for small monovalent ligands, steric restrictions often make it behave as if pentavalent for binding to large multivalent ligands. However, even five-point binding can lead to enormously tight interactions. Therefore, even though the intrinsic affinity of IgM molecules tends to be lower than that of IgG molecules for the same antigen (30), the apparent affinity of IgM can be quite high.

Two-phase Systems

The same enhanced affinity seen for multipoint binding applies to two-phase systems. Examples include the reaction of multivalent antibodies with antigen attached to a cell surface or an artificial surface (e.g., Sepharose, or the plastic walls of a microtiter plate), the reaction of a multivalent ligand with antibodies on the surface of a B cell, a Sepharose bead, or a plastic plate, and the reaction of either component with an antigen–antibody precipitate. For the reasons outlined earlier, "monogamous" binding can make the apparent affinity of a multivalent antibody or antigen for multiple sites on a solid surface be quite large, to the point of effective irreversibility.

However, another effect also increases the effective affinity in a two-phase system. This effect applies even for monovalent antibodies (Fab fragments) or monovalent ligands. The effect arises from the enormously high effective local concentration of binding sites at the surface, compared to the concentration if the same number of sites were distributed in bulk solution (33). Looked at another way, the effect is due to the violation, at the liquid–solid interface, of the basic assumption in the association constants, K_A, discussed earlier, that the reactants are all distributed randomly in the solution. (To some extent, the latter is involved in the enhanced affinity of multivalency as well.) This situation has been analyzed by DeLisi (34) and DeLisi and Wiegel (35), who break the reaction down into two steps, the diffusive process necessary to bring the antigen and antibody into the right proximity and orientation

to react, and the reactive process itself. The complex between antigen and antibody, when positioned but not yet reacted, is called the "encounter complex." The reaction can then be written

$$S + D \underset{k_-}{\overset{k_+}{\rightleftharpoons}} S \cdots D \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} SD \tag{33}$$
where S is antibody site, D is antigenic determinant, k_+ and k_- are the forward and reverse diffusive rate constants, and k_1 and k_{-1} are the forward and reverse reactive rate constants once the encounter complex is formed. If the encounter complex is in a steady state, the overall rate constants will be given by

$$k_f = \frac{k_1 k_+}{(k_1 + k_-)} \tag{34}$$

$$k_r = \frac{k_{-1} k_-}{(k_1 + k_-)} \tag{35}$$

where subscripts f and r stand for forward and reverse (34). The association constant, according to Equation 7, is the ratio of these two, or

$$K_A = \frac{k_1 k_+}{k_{-1} k_-} \tag{36}$$

The relative magnitudes of k_1 and k_- determine the probable fate of the encounter complex. Is it more likely to react to form SD or to break up as the reactants diffuse apart?

Now suppose that k_- is slow compared to k_1. Then the SD bound complex and the encounter complex, $S \cdots D$, may interconvert many times before the encounter complex breaks up and one of the reactants diffuses off into bulk solution. If the surface has multiple antigenic sites, D, then even a monovalent antibody (Fab) may be much more likely, when SD dissociates to $S \cdots D$, to rereact with the same or nearby sites than to diffuse away into bulk solution, again depending on the relative magnitudes of these rate constants. This greater probability to rereact with the surface rather than diffuse away is the essence of the effect we are describing. A more extensive mathematical treatment of reactions with cells is given in DeLisi (34) and DeLisi and Wiegel (35).

A somewhat different, and very useful, analysis of the same or a very similar effect was given by Silhavy et al. (36). These authors studied the case of a ligand diffusing out of a dialysis bag containing a protein for which the ligand had a significant affinity. Once the ligand concentration became low enough that there was an excess of free protein sites, then the rate of exit of ligand from the dialysis bag was no longer simply its diffusion rate; nor was it simply the rate of dissociation of protein–ligand complex. These authors showed that under these conditions the exit of ligand followed quasi–first order kinetics, but with a half-life longer than the half-life in the absence of protein by a factor of $(1 + [P]K_A)$

$$t_+ = t_-(1 + [P]K_A) \tag{37}$$

where $[P]$ is the protein site concentration, K_A the affinity, and t_+ and t_- the half-lives in the presence and absence of protein in the bag.

In this case, the protein was in solution, so the authors could use the actual protein concentration and the actual intrinsic affinity, K_A. In the case of protein on a two-dimensional surface, it is harder to know what to use as the effective concentration. However, the high local concentration of protein compartmentalized in the dialysis bag can be seen to be analogous to the high local concentration attached to the solid surface. The underlying mechanism of the two effects is essentially the same and so are the implications. For instance, in the case of dialysis, a modest 10 μM concentration of antibody sites with an affinity of 10^8 M^{-1} can reduce the rate of exit of a ligand 1,000-fold. A dialysis that would otherwise take 3 hours would take 4 months! It is easy to see how this "retention effect" can make even modest affinities appear infinite (i.e., the reactions appear irreversible). This retention effect applies not only to immunological systems, but also to other interactions at a cell surface or between cell compartments where the local concentration of a protein may be high. In particular, these principles of two-phase systems should also govern the interaction between antigen-specific receptors on the surface of T cells and antigen–MHC molecule complexes on the surface of antigen-presenting cells, B cells, or target cells.

One final point is useful to note. Since these retention effects depend on a localized abundance of unoccupied sites, addition of a large excess of unlabeled ligand to saturate these sites will diminish or abolish the retention effect and greatly accelerate the dissociation or exit of labeled ligand. This effect of unlabeled ligand can be used as a test for the retention effect, although one must be aware that in certain cases the same result can be an indication of negative cooperativity among receptor sites.

RADIOIMMUNOASSAY AND RELATED METHODS

Since it was first suggested in 1960 by Yalow and Berson (37), radioimmunoassay (RIA) has rapidly become one of the most widespread, widely applicable, and most sensitive techniques for assessing the concentration of a whole host of biological molecules. Most of the basic principles necessary to understand and apply RIA have been covered earlier in this chapter. In this section, we examine the concepts and methodological approaches used in RIA. For a detailed methods book, we refer the reader to Chard (38), Rodbard (39), and Yalow (40).

The central concept of RIA is that the binding of an infinitesimal concentration of highly radioactive tracer antigen to low concentrations of a high-affinity, specific antibody is very sensitive to competition by unlabeled anti-

gen and is also very specific for that antigen. Thus, concentrations of antigen in unknown samples can be determined by their ability to compete with tracer for binding to antibody. The method can be used to measure very low concentrations of a molecule, even in the presence of the many impurities in biological fluids. Accomplishment of this requires an appropriate high-affinity antibody and radiolabeled antigen, a method to distinguish bound from free-labeled antigen, optimization of concentrations of antibody and tracer-labeled antigen to maximize sensitivity, and generation of a standard curve, using known concentrations of competing unlabeled antigen, from which to read off the concentrations in unknown samples, as well as the best method for representing the data. We review all these steps and pitfalls in this procedure, except the preparation of antibodies and labeled antigens.

Separation of Bound and Free Antigen

Whatever parameter one uses to assess the amount of competition by the unlabeled antigen in the unknown sample to be tested, it will always be a function of bound versus free, radiolabeled antigen. Therefore, one of the most critical technical requirements is the ability to distinguish clearly between antibody-bound radioactive tracer and free radioactive tracer. This distinction usually requires physical separation of bound and free ligand. If the bound fraction is contaminated by free ligand, or vice versa, enormous errors can result, depending on the part of the binding curve on which the data fall.

Solution Methods

Solution RIA methods have the advantage that binding can be related to the intrinsic affinity of the antibody. However, bound and free antigen must be separated by a method that does not perturb the equilibrium. Three basic types of approaches have been used: precipitate the antibody with bound antigen, leaving free antigen in solution; precipitate the free antigen, leaving antibody and bound antigen in solution; or separate free from antibody-bound antigen molecules in solution on the basis of size by gel filtration. This last method is too cumbersome to use for large numbers of samples and is too slow, in general, to be sure the equilibrium is not perturbed in the process. Therefore, gel filtration columns are not widely used for RIA.

Methods that precipitate antibody are perhaps the most widely used. If the antigen is sufficiently smaller (MW <30,000) than the antibody that it will remain in solution at concentrations of either ammonium sulfate (41) or polyethylene glycol, MW 6,000 (10% W:W) (42), which will precipitate essentially all the antibody, then these two reagents are frequently the most useful. Precipitation with polyethylene glycol and centrifugation can be accomplished before any significant dissociation has occurred

due to dilutional effects (43). However, if the antigen is much larger than about 30,000 MW to 40,000 MW, then these methods will produce unacceptably high background control values in the absence of specific antibody. If the antibody is primarily of a subclass of IgG that binds to staphylococcal protein A or protein G, one can take advantage of the high affinity of protein A or G for IgG by using either protein A (or G)-Sepharose or formalin-killed staphylococcal organisms (Cowan I strain) to precipitate the antibody (44). Finally, one can precipitate the antibody using a specific second antibody, an antiimmunoglobulin raised in another species. Maximal precipitation occurs not at antibody excess but at the "point of equivalence" in the middle of the titration curve where antigen (in this case, the first antibody) and the (second) antibody are approximately equal in concentration. Thus, one must add carrier immunoglobulin to keep the immunoglobulin concentration constant and determine the point of equivalence by titrating with the second antibody. Worse, the precipitin reaction is much slower than the antigen-antibody reaction itself, allowing re-equilibration of the antigen-antibody interaction after dilution by the second antibody. Some of these problems can be reduced by enhancing precipitation with low concentrations of polyethylene glycol.

The other type of separation method is adsorption of free antigen to an agent, such as activated charcoal or talc, that leaves antigen bound to antibody in solution. Binding of antigen by these agents depends on size and hydrophobicity. Although these methods are inexpensive and rapid, they require careful adjustment and monitoring of pH, ionic strength, and temperature to obtain reproducible results and to avoid adsorption of the antigen-antibody complex. Further, because these agents have a high affinity for antigen, they can compete with a low-affinity antibody and alter the equilibrium. Also, since charcoal quenches beta scintillation counting, it can be used only with gamma-emitting isotopes such as ^{125}I.

Solid-phase Methods

Solid-phase RIA methods have the advantages of high throughput and increased apparent affinity due to the effects at the solid-liquid interface noted earlier. However, they have the concomitant disadvantage that one is not measuring the true intrinsic affinity because of these same effects. The method itself is fairly simple. One binds the antibody in advance to a solid surface such as a Sepharose bead or the walls of a microtiter plate well. To avoid competition from other serum proteins for the solid phase, one must use purified antibody in this coating step. Once the wells (or Sepharose beads) are coated, one can incubate them with labeled tracer antigen with or without unlabeled competitor, wash, and count directly the radioactivity bound to the plastic wells or to the Sepharose. The microtiter plate method is particularly useful for process-

ing large numbers of samples. However, because the concentration, or even the amount, of antibody coating the surface is unknown, and because the affinity is not the intrinsic affinity, one cannot use these methods for studying the chemistry of the antigen-antibody reaction itself. A detailed analysis of the optimum parameters in this method is given by Zollinger et al. (43).

A variation that does allow determination of affinity, based on the Enzyme-Linked Immunosorbant Assay (ELISA) described below, but equally applicable to RIA, was described by Friguet et al. (45). This uses antigen-coated microtiter wells and free antibody but measures competition by free antigen to prevent the antibody in solution from binding to the antibody on the plate (Figure 5.9B). Thus, the antibody bound to the plastic is antibody that was free in the solution equilibrium. The affinity measured is that between the antibody and antigen in solution, not that on the plastic, so it is not directly influenced by the multivalency of the surface. However, as pointed out by Stevens (46), the determination of affinity is strictly accurate only for monovalent Fab fragments, because a bivalent antibody with only one arm bound to the plastic and one bound by antigen in solution will still be counted as free. Therefore, there will be an underestimate of the ligand occupancy of the antibody combining sites, and thus an underestimate of affinity. Stevens also points out a method to correct for this error based on binomial analysis. Subsequently, Seligman (47) showed that the nature and density of the antigen on the solid surface can also influence the estimate of affinity.

Optimization of Antibody and Tracer Concentrations for Sensitivity

The primary limitations on the sensitivity of the assay are the antibody affinity and concentration, the tracer concentration, and the precision (reproducibility) of the data. In general, the higher the affinity of the antibody, the more sensitive the assay can be made. Once one prepares the highest affinity antibody available, this parameter limits the extent to which the other parameters can be manipulated. For instance, since the unlabeled antigen in the unknown sample is going to compete against labeled tracer antigen, the lower the tracer concentration, the lower the concentration of the unknown, which can be measured, up to a point. That point is determined by the affinity, K_A, as can be seen from the theoretical considerations earlier (38). The steepest part of the titration curve will occur in the range of concentrations around $1/K_A$. Concentrations of ligand much below $1/K_A$ will leave most of the antibody sites unoccupied, so competition will be less effective. Thus, there is no value in reducing the tracer concentration more than a few-fold lower than $1/K_A$. Therefore, although it is generally useful to increase the specific radioactivity of the tracer and reduce its concentration, it is important

to be aware of this limit of $1/K_A$. Increasing the specific activity more than necessary can result in denaturation of antigen.

Similarly, lowering the antibody concentration will also increase sensitivity, up to a point. This limit also depends on $1/K_A$ and on the background "nonspecific binding." Decreasing the antibody concentration to the point that binding of tracer is too close to background will result in loss of sensitivity due to loss of precision. In general, the fraction of tracer bound in the absence of competitor should be kept greater than 0.2, and in general closer to 0.5 (see ref. 48).

A convenient procedure to follow to optimize tracer and antibody concentrations is first to choose the lowest tracer concentration that results in convenient counting times and counting precision for bound values of only one-half to one-tenth the total tracer. Then, keeping this tracer concentration constant, one dilutes out the antibody until the bound/free antigen ratio is close to 1.0 (bound/total $= 0.5$) in the absence of competitor. This antibody concentration in conjunction with this tracer concentration will generally give near-optimal sensitivities, within the limits previously noted. It is important to be aware that changing the tracer concentration will require readjusting the antibody concentration to optimize sensitivity.

Analysis of Data: Graphic and Numerical Representation

We have already examined the Scatchard plot (bound/free versus bound) and the plot of bound/free versus free or total antigen concentration as methods of determining affinity. The latter lends itself particularly to the type of competition curves that constitute a RIA. In fact, the independent variable must always be antigen concentration, because that is the known quantity one varies to generate the standard curve. Let us use B, F, and T to represent the concentrations of bound, free, and total antigen, respectively. Earlier, we saw that the plot of B/F versus F is more useful for determining the affinity, K_A, than the plot of B/F versus T. However, in RIA, the quantity one wants to determine is T, and, correspondingly, the known independent variable in generating the standard curve is T. Another difference between the situation in RIA and that discussed earlier is that, in RIA, one has both labeled and unlabeled antigen. The dependent variable, such as B/F, is the ratio of bound tracer over free tracer, because only radioactive antigen is counted. B/F for the unlabeled antigen will be the same at equilibrium, assuming that labeled and unlabeled antigen bind the antibody equivalently—that is, with the same K_A. This assumption is not always valid and requires experimental testing.

The sigmoidal shape of B/F versus F or T, when F or T (the "dose") is plotted on a log scale, can be seen in Figure 5.6. The shape for B/T versus F or T would be similar.
FIGURE 5.7 Schematic plot of B/F or B/T (the bound/free or total antigen concentration) as a function of free (F) or total (T) antigen concentration, when plotted on a linear scale. Contrast with similar plot on a log scale in Figure 5.6.

Note that since $B + F = T$,

$$\frac{B}{F} = \frac{B}{(T - B)} = \frac{B/T}{(1 - B/T)} \qquad (38)$$

and

$$\frac{B}{T} = \frac{B/F}{(1 + B/F)} \qquad (39)$$

These transformations can be useful. If one plots B/F or B/T versus F or T on a linear scale, then the shape is approximately hyperbolic, as in Figure 5.7. The plot of B/F versus T (log scale) was one of the first methods used to plot RIA data and is still among the most useful. The most sensitive part of the curve is the part with the steepest slope.

It has been shown by probability analysis that if the antigen has multiple determinants, each capable of binding antibody molecules simultaneously and independently of one another, then the more such determinants capable of being recognized by the antibodies in use, the steeper will be the slope (49). This effect of multideterminant binding on steepness arises because, in RIA, an antigen molecule is scored as bound whether it has one antibody molecule or several attached. It is scored as free only if no antibody molecules are attached. Thus, the probability that an antigen molecule is scored as free is the product of the probabilities that each of its determinants is free. The effect can lead to quite steep slopes and has been confirmed experimentally (49).

A transform that allows linearization of the data in most cases is the logit transform (50,51). To use this, one first expresses the data as B/B_0, where B_0 is the concentration of bound tracer in the absence of competitor. One then takes the logit transform of this ratio, defined as

$$\text{logit}\,(Y) = \ln\left[\frac{Y}{(1 - Y)}\right] \qquad (40)$$
FIGURE 5.8 Schematic logit–log plot used to linearize RIA data. B and T are bound tracer and total antigen concentration, respectively, and B_0 is the value of B when no unlabeled antigen is added to tracer. The logit function is defined by Equation (40), logit $(Y) = \ln[Y/(1-Y)]$.

where ln means the natural log (log to the base e). The plot of logit (B/B_0) versus ln T is usually a straight line (Figure 5.8). The slope is usually -1 for the simplest case of a monoclonal antibody binding a monovalent antigen. The linearity of this plot obviously makes it very useful for graphical interpolation, which one would like to do to read antigen concentration off a standard curve. One additional advantage is that linearity facilitates tests of parallelism. If the unknown under study is identical to the antigen used to generate the standard curve, then a dilution curve of the unknown should be parallel to the standard curve in this logit-log coordinate system. If not, the assay is not valid.

These and other methods of analyzing the data are discussed further by Feldman and Rodbard (52) and Rodbard (39), including statistical treatment of data. While a number of computer programs have become available for rapid analysis of RIA data without using manual plots of standard curves, they are all based on these and similar methods, and their accurate interpretation depends on an understanding of these concepts.

Corrections for B, F, and T

Before we leave this section on analysis of RIA data, we must point out a few controls and corrections to the data without which the results may be fallacious.

First, in any method that precipitates antibody and bound antigen (or uses a solid-phase antibody), there may always be a fraction of antigen that precipitates or binds nonspecifically in the absence of specific antibody. Thus, one must always run controls with normal serum or immunoglobulin to determine this background. The nonspecific binding usually increases linearly with antigen dose; that is, it does not saturate. This control value should be subtracted from B but does not affect F when measured independently, only F determined as T minus B. The total antigen that is meaningful is the sum of that which is

specifically bound and that which is free. Nonspecifically bound antigen should be deleted from any term in which it appears.

A second correction is that for immunologically inactive radiolabel, either free radioisotope or isotope coupled to an impurity or to denatured antigen. The fraction of radioactive material that is immunologically reactive with the antibodies in the assay can be determined by using a constant, low concentration of labeled antigen and adding increasing concentrations of antibody. If there is no contamination with inactive material, all the radioactivity should be able to be bound by sufficient antibody. If the fraction of tracer bound reaches a plateau at less than 100% bound, then only this fraction is active in the assay. The importance of this correction can be seen from the example in which the tracer is only 80% active. Then, when the true B/F is 3 ($B/T = 0.75$), applying only to the active 80% of the tracer, the remaining 20%, which can never be bound, will mistakenly be included in the free tracer, doubling the amount that is measured as free. Thus, the measured B/F will be only 1.5 (i.e., 0.6/0.4) instead of the true value of 3 (i.e., 0.6/0.2). This factor of 2 will make a serious difference in the calculation of affinity, for instance, from a Scatchard plot. It will also result in a plateau in the Scatchard plot at high values of B/F, since with 20% of the tracer obligatorily free, B/F can never exceed 4 (i.e., 0.8/0.2). To correct for this potentially serious problem, the inactive fraction must always be determined subtracted from both F and T.

Nonequilibrium RIA

So far, we have assumed that tracer and unlabeled competitor are added simultaneously and sufficient incubation time is allowed to achieve equilibrium. To measure the affinity, of course, equilibrium must be assured. However, suppose one's sole purpose is to measure the concentration of competitor by RIA. Then one can actually increase the sensitivity of the assay by adding the competitor first, allowing it to react with the antibody, and then intentionally adding the tracer for too short a time to reach a new equilibrium. One is essentially giving the competitor a competitive advantage. It can be shown that the slope of the dose-response curve, B/T versus total antigen added, is increased in the low-dose range—a mathematical measure of increased sensitivity. A detailed mathematical analysis of this procedure may be found in Rodbard et al. (53). Note, however, that use of such nonequilibrium conditions requires very careful control of time and temperature.

Enzyme-linked Immunosorbent Assay (ELISA)

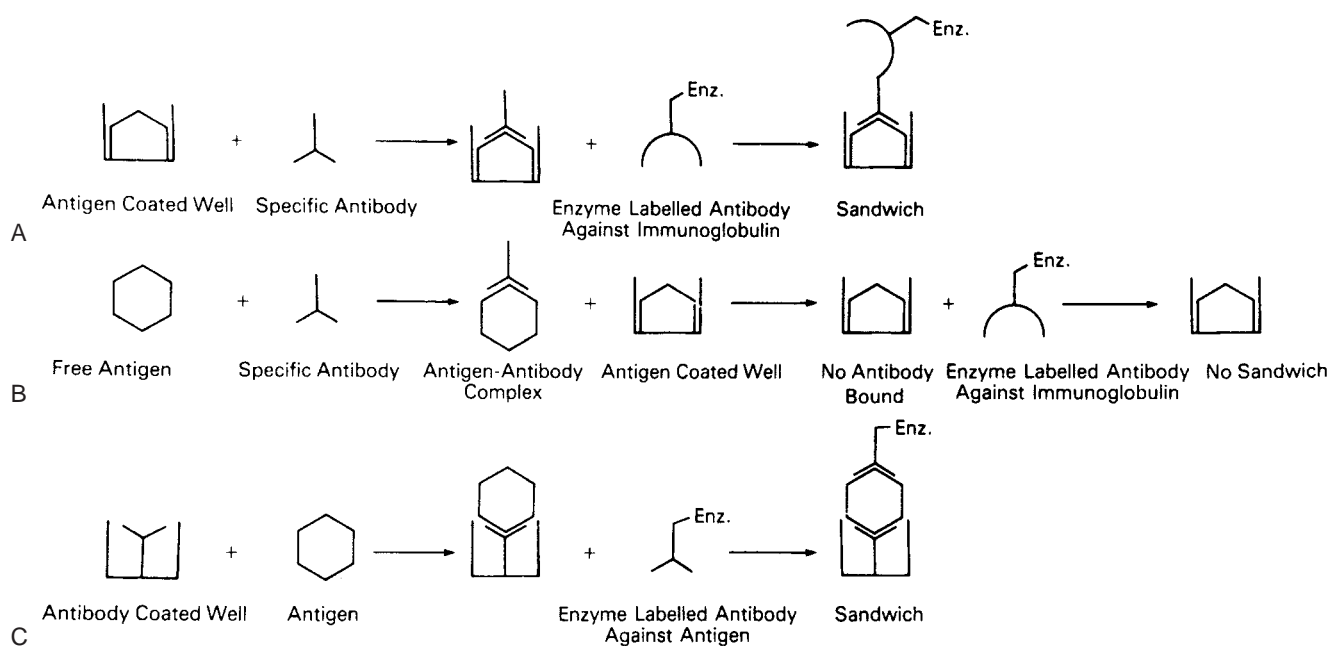
An alternative solid-phase readout system for the detection of antigen–antibody reactions is the ELISA assay (54). In principle, the only difference from RIAs is that antibodies


FIGURE 5.9 Three strategies for the detection of specific antibody–antigen reactions using the ELISA technique. **A:** Direct binding. **B:** Hapten inhibition. **C:** Antigen sandwich.

or antigen are covalently coupled to an enzyme instead of a radioisotope, so that bound enzyme activity is measured instead of bound cpm. In practice, the safety and convenience of nonradioactive materials and the commercial availability of plate readers that can measure the absorbance of 96 wells in a few seconds account for ELISA's widespread use. Since both ELISA and RIA are governed by the same thermodynamic constraints, and the enzyme can be detected in the same concentration range as commonly used radioisotopes, the sensitivity and specificity are comparable. We consider three basic strategies for using ELISA assays to detect specific antibody or antigen.

As shown in Figure 5.9A, the indirect antibody method is the simplest way to detect and measure specific antibody in an unknown antiserum. Antigen is noncovalently attached to each well of a plastic microtiter dish. For this purpose, it is fortunate that most proteins bind nonspecifically to plastic. Excess free antigen is washed off, and the wells are incubated with an albumin solution to block the remaining nonspecific protein binding sites. The test antiserum is then added, and any specific antibody binds to the solid-phase antigen. Washing removes unbound antibodies. Enzyme-labeled anti-immunoglobulin is added. This binds to specific antibody already bound to antigen on the solid phase, bringing along covalently attached enzyme. Unbound antiglobulin-enzyme conjugate is washed off, then substrate is added. The action of bound enzyme on substrate produces a colored product, which is detected as increased absorbance in a spectrophotometer.

Although this method is quick and very sensitive, it is often difficult to quantitate. Within a defined range, the

increase in optical density is proportional to the amount of specific antibody added in the first step. However, the amount of antibody bound is not measured directly. Instead, the antibody concentration of the sample is estimated by comparing it with a standard curve for a known amount of antibody. It is also difficult to determine affinity by this method, since the solid-phase antigen tends to increase the apparent affinity. The sensitivity of this assay for detecting minute amounts of antibody is quite good, especially when affinity-purified antiglobulins are used as the enzyme-linked reagent. A single preparation of enzyme-linked antiglobulin can be used to detect antibodies to many different antigens. Alternatively, class specific antiglobulins can be used to detect how much of a specific antibody response is due to each immunoglobulin class. Obviously, reproducibility of the assay depends on uniform antigen coating of each well, and the specificity depends on using purified antigen to coat the wells.

Figure 5.9B shows the competition technique for detecting antigen. Soluble antigen is mixed with limiting amounts of specific antibody in the first step. Then the mixture is added to antigen-coated wells and treated as described in Figure 5.9A. Any antigen-antibody complexes formed in the first step will reduce the amount of antibody bound to the plate and hence will reduce the absorbance measured in the final step. This method permits the estimate of affinity for free antigen, which is related to the half-inhibitory concentration of antigen. Mathematical analysis of affinity by this approach was described by Friguet et al. (45), with modification by Stevens (46), as discussed earlier in the "RIA Solid-phase Methods" section. In

addition, some estimate of cross-reactivity between the antigen in solution and that on the plate can be obtained.

Figure 5.9C shows the sandwich technique for detecting antigen. Microtiter plates are coated with specific antibody. Antigen is then captured by the solid-phase antibody. A second antibody specific for the antigen and coupled to enzyme is added. This binds to the solid-phase antigen-antibody complex, carrying enzyme along with it. Excess second antibody is washed off and substrate is added. The absorbance produced is a function of the antigen concentration of the test solution, which can be determined from a standard curve. Specificity of the assay depends on the specificity of the antibodies used to coat the plate and detect antigen. Sensitivity depends on the affinity as well as amount of the first antibody coating the well, which can be increased by using affinity-purified antibodies or monoclonal antibodies in this step. The sandwich method depends on divalency of the antigen, or else the two antibodies must be specific for different antigenic determinants on the same antigen molecule. When comparing two monoclonal antibodies to the same antigen, this technique can be used to ascertain whether they can bind simultaneously to the same molecule or whether they compete for the same site or sites close enough to cause steric hindrance (55).

When antibodies are serially diluted across a plate, the last colored well indicates the titer. Specificity of binding can be demonstrated by coating wells with albumin and measuring antibody binding in parallel with the antigen-coated wells. Because it can be used to test many samples in a short time, ELISA is often used to screen culture supernatants in the production of hybridoma antibodies. The sensitivity of the method allows detection of clones producing specific antibodies at an early stage in cell growth.

An important caution when using native protein antigens to coat solid-phase surfaces (Figure 5.9A) is that binding to a surface can alter the conformation of the protein. For instance, using conformation specific monoclonal antibodies to myoglobin, Darst et al. (56) found that binding of myoglobin to a surface altered the apparent affinity of some antibodies more than others. This problem may be avoided by using the solution phase methods of Figure 5.9B or 5.9C.

ELIspot Assay

The normal ELISA assay can be modified to measure antibody production at the single cell level. In this method, called the *ELIspot assay,* tissue culture plates are coated with antigen, and various cell populations are cultured on the plate for four hours. During that time, B cells settle to the bottom and secrete antibodies, which bind antigen nearby and produce a footprint of the antibody-secreting cell. The cells are then washed off, and a second antibody, such as enzyme labeled goat antihuman IgG, is added. Finally, unbound antibody is washed off, and enzyme sub-strate is added in soft agar. Over the next 10 minutes, each footprint of enzyme activity converts the substrate to a dark spot of insoluble dye, corresponding to the localized zone where the B cell originally secreted its antibody.

Using this method, it is possible to detect as few as 10 to 20 antibody-producing B cells in the presence of 10^6 spleen cells, and typical results for immunized mice range from 200 to 500 spot-forming cells per 10^6 spleen cells (57,58). Clearly, to work at all, this assay must be capable of detecting the amount of antibody secreted by a single immune B cell and be specific enough to exclude nonspecific antibodies produced by the vast majority of nonimmune B cells. Sensitivity depends on the affinity and amount of antibodies secreted and may be optimized by titering the amount of antigen on the plate.

This type of assay is useful in analyzing the cellular requirements for antibody production in vitro, because the number of responding B cells is measured directly. It can also be used to detect antibodies made in the presence of excess antigen. For example, during acute infections (59) and in autoimmunity (60), when antigen may be in excess over antibody, this assay makes it possible to measure antibody-producing B cells, even though free antibody may not be detectable in circulation. It can also be used to measure local production of self-reactive antibodies in a specific tissue, such as synovium. By using two detecting antibodies, each specific for a different immunoglobulin class and coupled to a different enzyme, and two substrates producing different colored dyes, cells secreting IgA and IgG simultaneously can be detected (61). In this way, ELIspot was used to show that bacterial DNA containing CpG sequences is a polyclonal B cell mitogen (62).

ELIspot can also detect secreted cytokines, as opposed to antibodies, by coating the plate with a capture antibody and detecting antigen with an enzyme-coupled second antibody (as in a sandwich ELISA, Figure 5.9C). For example, using plates coated with monoclonal antibody to IL-4, T cells secreting IL-4 could be detected (63), providing one measure of T helper 2 cells.

SPECIFICITY AND CROSS-REACTIVITY

The specificity of an antibody or antiserum is defined by its ability to discriminate between the antigen against which it was made (called the *homologous antigen,* or *immunogen*) and any other antigen one might test. In practice, one cannot test the whole universe of antigens, but only selected antigens. In this sense, specificity can only be defined experimentally within that set of antigens one chooses to compare. Karush (30) has defined a related term, *selectivity,* as the ability of an antibody to discriminate, in an all-or-none fashion, between two related ligands. Thus, selectivity depends not only on the relative affinity of the antibody for the two ligands, but also on the experimental

lower limit for detection of reactivity. For instance, an anticarbohydrate antibody with an affinity of 10^5 M^{-1} for the immunogen may appear to be highly selective, because reaction with a related carbohydrate with a 100-fold lower affinity, 10^3 M^{-1}, may be undetectable. However, an antibody with an affinity of 10^9 M^{-1} for the homologous ligand may appear to be less selective because any reaction with a related ligand with a 100-fold lower affinity would still be quite easily detectable.

Conversely, cross-reactivity is defined as the ability to react with related ligands other than the immunogen. More usually, this is examined from the point of view of the ligand. Thus, one might say that antigen Y cross-reacts with antigen X because it binds to anti-X antibodies. Note that in this sense, it is the two antigens that are cross-reactive, not the antibody. However, the cross-reactivity of two antigens, X and Y, can be defined only with respect to a particular antibody or antiserum. For instance, a different group of anti-X antibodies may not react at all with Y, so that with respect to these antibodies, Y would not be cross-reactive with X. One can also use the term in a different sense, saying that some anti-X antibodies cross-react with antigen Y.

In most cases, cross-reactive ligands have lower affinity than the immunogen for a particular antibody. However, exceptions can occur, in which a cross-reactive antigen binds with a higher affinity than the homologous antigen itself. This phenomenon is called *heterocliticity,* and the antigen that has a higher affinity for the antibody than does the immunogen is said to be heteroclitic. Antibodies that manifest this behavior are also described as heteroclitic antibodies. A good example is the case of antibodies raised in C57BL/10 mice against the hapten nitrophenyl acetyl (NP). These antibodies have been shown by Mäkelä and Karjalainen (64) to bind with higher affinity to the cross-reactive hapten, nitroiodophenyl acetyl (NIP), than to the immunogen itself. Another example is the case of retro-inverso or retro-D peptides (65–69). By reversing the chirality from L to D amino acids and simultaneously reversing the sequence of amino acids, one can produce a peptide that is resistant to proteolysis and has its side chains approximately in the same position as the original L amino acid peptide, with the exception of some amino acids with secondary chiral centers, such as Thr and Ile. However, the backbone NH and CO moieties are reversed. Antibodies that interact with only the side chains might not distinguish these peptides, whereas antibodies that interact with the main chain as well as side chains might distinguish them and have potentially higher or lower affinity. In a study of monoclonal antibodies to a hexapeptide from histone H3, some bound the retro-D form with higher affinity than the native sequence and some did not (67,68). The former are an example of heterocliticity. In addition to greater binding affinity, the retro-D peptides may have even greater activity in vivo because of their resistance to

proteolysis (65–69). This stability makes them more useful as drugs as well (65,66,70).

Cross-reactivity has often been detected by methods such as the Ouchterlony test, or hemagglutination (descriptions of both of these appear later) or similar methods, which have in common the fact that they do not distinguish well between differences in affinity and differences in concentration. This practical aspect, coupled with the heterogeneity of immune antisera, has led to ambiguities in the usage of the terms "cross-reactivity" and "specificity." With the advent of RIA and ELISA techniques, this ambiguity in the terminology, as well as in the interpretation of data, has become apparent.

For these reasons, Berzofsky and Schechter (71) have defined two forms of cross-reactivity and, correspondingly, two forms of specificity. These two forms of cross-reactivity are illustrated by the two prototype competition RIA curves in Figure 5.10. In reality, most antisera display both phenomena simultaneously.

Type 1 cross-reactivity, or true cross-reactivity, is defined as the ability of two ligands to react with the same site on the same antibody molecule, possibly with different affinities. For example, the related haptens dinitrophenyl (DNP) and trinitrophenyl (TNP) may react with different affinity for antibodies raised to dinitrophenyl hapten. In protein antigens, such differences could occur with small changes in primary sequence (e.g., the conservative substitution of threonine for serine), or with changes in conformation, such as the cleavage of the protein into fragments (Figure 5.11) (71–75). If a peptide fragment contained all the contact residues in an antigenic determinant (i.e., those which contact the antibody-combining site), it
FIGURE 5.10 Schematic RIA binding curves for homologous ligand L and cross-reacting ligands. Cross-reacting ligand C_A manifests type 1 or true cross-reactivity demonstrated by complete inhibition of tracer ligand binding and a lower affinity. Ligand C_B displays type 2 cross-reactivity or determinant sharing, as recognized from the plateau at less than 100% inhibition, but not necessarily a lower affinity. The ordinate R is the ratio of bound/free radiolabeled tracer ligand, and R_0 is the limit of R as the concentration of all ligands, including tracer, approaches zero. From (71), with permission.
FIGURE 5.11 An artist's drawing of the amino terminal region of the ß chain of hemoglobin. **A:** The first 11 residues of the ß^A chain. **B:** The comparable regions of the ß^S chain. The substitution of valine for the normal glutamic acid at position 6 makes a distinct antigenic determinant to which a subpopulation of antibodies may be isolated (72,73). **C:** A schematic diagram of the sequence in A unfolded as occurs when the protein is denatured. This region may be cleaved from the protein, or the peptide synthesized (74), resulting in changed antigenic reactivity. An antiserum prepared to hemoglobin (or the ß chain thereof) might exhibit cross-reactivity with the structures shown in B and C, but the molecular mechanisms would be different. Polypeptide backbone atoms are in white in the side chains, oxygen atoms are hatched, nitrogen atoms are black, and carbon atoms are lightly stippled. Adapted from (71,75).

might cross-react with the native determinant for antibodies against the native form, but with lower affinity because the peptide would not retain the native conformation (see Chapter 21). This type of affinity difference is illustrated by competitor C_A in Figure 5.10, in which complete displace-

ment of tracer can be achieved at high enough concentrations of C_A, but higher concentrations of C_A than of the homologous ligand, L, are required to produce any given degree of inhibition.

A separate issue from affinity differences is the issue of whether the cross-reactive ligand reacts with all or only a subpopulation of the antibodies in a heterogeneous serum. This second type of cross-reactivity, which we call *type 2 cross-reactivity* or *shared reactivity,* therefore, can occur only when the antibody population is heterogeneous, as in most conventional antisera. In this case, the affinity of the cross-reactive ligand may be greater than, less than, or equal to that of the homologous ligand for those antibodies with which it interacts. Therefore, the competition curve is not necessarily displaced to the right, but the inhibition will reach a plateau at less than complete inhibition, as illustrated by competitor C_B in Figure 5.10. As an example, let us consider the case of a protein with determinants X and Y and an antiserum against this protein containing both anti-X and anti-Y antibodies. Then a mutant protein in which determinant Y was so altered as to be unrecognizable by anti-Y, but determinant X was intact, would manifest type 2 cross-reactivity. It would compete with the wild-type protein only for anti-X antibodies (possibly even with equal affinity), but not for anti-Y antibodies.

Of course, both types of cross-reactivity could occur simultaneously. A classic example would be the peptide fragment discussed earlier in the case of type 1 cross-reactivity. Suppose the fragment contained the residues of determinant X, albeit not in the native conformation, but did not contain the residues of a second determinant, Y, which was also expressed on the native protein. If the antiserum to the native protein consisted of anti-X and anti-Y, the peptide would compete only for anti-X antibodies (type 2 cross-reactivity) but would have a lower affinity than the native protein even for these antibodies. Thus, the competition curve would be shifted to the right and would plateau before reaching complete inhibition.[8]

In the case of a homogeneous (e.g., monoclonal) antibody in which only type 1 or true cross-reactivity can occur, one can quantify the differences in affinity for different cross-reactive ligands by a method analogous to the B/F versus F method described earlier. Suppose that ligands X and Y cross-react with homologous ligand L for a monoclonal antibody. If one plots the bound/free ($B/F = R$)

---

[8] An ambiguous case could occur experimentally in which the distinction between the two types of cross-reactivity would be blurred. For example, in the case of antibodies that all react with determinant X but have a very wide range of affinities for X, some such antibodies may have such a low affinity for cross-reactive determinant X′ that they would appear not to bind X′ at all. Then a competition curve using X′ might appear to reach a plateau at incomplete inhibition even though all the antibodies were specific for X, and the only difference between X and X′ was affinity.
FIGURE 5.12 Schematic RIA binding curves showing the effect of affinity on the midpoint and the slope at the midpoint and the value of using free [ligand] rather than total [ligand]. Ordinate R is the ratio of bound/free radiolabeled tracer ligand, and R_0 the limit of R as all ligand concentrations approach zero. If x and y are the concentrations of ligands X and Y that reduce R to exactly $R_0/2$, then if the abscissa is total ligand concentration, $x = 1/K_X + [S]_t/2$ and $y = 1/K_Y + [S]_t/2$, where $[S]_t$ is the concentration of antibody binding sites and K_X and K_Y the affinities of the antibody for the respective ligands. However, if the abscissa is free ligand concentration, $x = 1/K_X$ and $y = 1/K_Y$ so that the ratio x/y (or the difference $\log x - \log y$ on a log plot) corresponds to the ratio of affinities K_Y/K_X. Note that the slopes at the midpoints are the same on a log scale, but that for Y would be only K_Y/K_X that for X on a linear scale. From (71), with permission.

ratio for radiolabeled tracer ligand L as a function of the log of the concentration of competitors X and Y, one obtains two parallel competition curves (Figure 5.12) (71), under the appropriate conditions (below). The first condition is that the concentration of free tracer be less than $1/K_L$, the affinity for tracer. In this case, it can be shown (71) that

$$K_X \approx \frac{1}{[X]_{\text{free}}} \tag{41}$$

at the midpoint where $R = R_0/2$, where K_X is the affinity for X. This is analogous to Equation 21 for the case in which unlabeled homologous ligand is the competitor. Also, in analogy with Equation 23, it can be shown that if the total concentration of competitor, $[X]_t$, is used instead of the free concentration, $[X]_{\text{free}}$, an error term will arise, giving

$$[X]_t \text{ (at } R = R_0/2) = \frac{1}{K_X} + \frac{[S]_t}{2} \tag{42}$$

Thus, with competitor on a linear scale, the difference in midpoint for competitors X and Y will correspond to the difference $1/K_X - 1/K_Y$, regardless of whether free or total competitor is plotted, but the ratio of midpoint concentrations will equal K_X/K_Y only if the free concentrations are used. This last point is important if one plots the log of competitor concentration, as is usually done, because the

horizontal displacement between the two curves on a log scale corresponds to the ratio $[X]/[Y]$, not the difference (71).

If a second condition also holds, namely, that the concentration of bound tracer is small compared to the antibody site concentration $[S]_t$, then the slopes (on a linear scale) of the curves at their respective midpoints (where $R = R_0/2$) will be proportional to the affinity for that competitor, K_X or K_Y (71). (Both conditions can be met by keeping tracer L small relative to both K_L and $[S]_t$.) When $[X]_{\text{free}}$ and $[Y]_{\text{free}}$ are plotted on a log scale, the slopes will appear to be equal (i.e., the curves will appear parallel), since a parallel line shifted m-fold to the right on a log scale will actually be $1/m$ as steep, at any point, in terms of the antilog as abscissa.

When the antibodies are heterogeneous in affinity, the curves will be broadened and in general will not be parallel. When heterogeneity of specificity is present, and type 2 cross-reactivity occurs, it should be pointed out that the fractional inhibition achieved at the plateau in a B/F versus free competitor plot will not be proportional to the fraction of antibodies reacting with that competitor but will be proportional to a weighted fraction, where the antibody concentrations are weighted by their affinity for the tracer (71).

These two types of cross-reactivity lead naturally to two definitions of specificity (71). The overall specificity

of a heterogeneous antiserum is a composite of both of these facets of specificity. Type 1 specificity is based on the relative affinities of the antibody for the homologous ligand and any cross-reactive ligands. If the affinity is much higher for the homologous ligand than for any cross-reactive ligand tested, then the antibody is said to be highly specific for the homologous ligand; that is, it discriminates very well between this ligand and the others. If the affinity for cross-reactive ligands is below the threshold for detection in an experimental situation, then type 1 specificity gives rise to selectivity, as was discussed above (cf. ref. 30). The specificity can even be quantitated in terms of the ratio of affinities for the homologous ligand and a cross-reactive ligand (cf. ref. 76). It is this type 1 specificity that most immunochemists would call true specificity, just as we have called type 1 cross-reactivity true cross-reactivity.

The common use of the term *cross-reactivity* to include type 2 or partial reactivity leads to a second definition of specificity, which applies only to heterogeneous populations of antibodies such as antisera. We call this type 2 specificity. If all the antibodies in the mixture react with the immunogen, but only a small proportion react with any single cross-reactive antigen, then the antiserum would be said to be relatively specific for the immunogen. Note that it does not matter whether the affinity of a subpopulation that reacts with a cross-reactive antigen is high or low (type 1 cross-reactivity). As long as that subpopulation is a small fraction of the antibodies, the mixture is specific. Thus, type 2 specificity depends on the relative concentrations of antibodies in the heterogeneous antiserum, not just on their affinities. Also note that one can use these relative concentrations of antibody subpopulations to compare the specificity of a single antiserum for two cross-reactive ligands. However, it would not be meaningful to compare the specificity of two different antisera for the same ligand by comparing the fraction of antibodies in each serum that reacted with that ligand. Although type 2 specificity may appear to some to be a less classic concept of specificity than type 1, it is type 2 specificity that one primarily measures in such assays as the Ouchterlony double immunodiffusion test, and it carries equal weight with type 1 specificity in such assays as hemagglutination, discussed later. Type 2 specificity also leads naturally to the concept of "multispecificity" described in the following section.

Multispecificity

The theory of multispecificity, introduced and analyzed by Talmage (77) and Inman (78,79) and discussed on a structural level by Richards et al. (80), suggests a mechanism by which the diversity and specificity of antisera can be expanded and also understood. The idea is that each antibody may actually bind, with high affinity, a variety of diverse antigens. When one immunizes with immunogen A, one selects for many distinct antibodies that have in common only that they all react with A. In fact, each antibody may react with other compounds, but if fewer than 1% of the antibodies bind B, and fewer than 1% bind C, and so on, then by type 2 specificity, the whole antiserum will appear to be highly specific for A. Note that the subpopulation that binds B may react with an affinity for B as high as or higher than that for A, so that the population would not be type 1 specific for A. This same population would presumably be selected if one immunized with B. The net result would be that the diversity of highly (type 2) specific antisera an organism could generate would be even greater than the diversity of B cell clones (or antibody structures). This principle can explain how polyclonal antisera can sometimes appear paradoxically more specific than a monoclonal antibody.

OTHER METHODS

We mention only a few of the other methods for measuring antigen–antibody interactions. Other useful techniques include quenching of the tryptophan fluorescence of the antibody by certain antigens on binding (81) (a sensitive method useful for such experiments as fast kinetic studies), antibody-dependent cellular cytotoxicity, immunofluorescence including flow cytometry, immunohistochemistry, and inhibition by antibody of plaque formation by antigen-conjugated bacteriophage (82) (a method as sensitive as RIA since inhibition of even a few phage virions can be detected).

Quantitative Precipitin

Among the earliest known properties of antibodies were their ability to neutralize pathogenic bacteria and their ability to form precipitates with bacterial culture supernatants. Both activities of each antiserum were highly specific for the bacterial strain against which the antiserum was made. The precipitates contained antibody protein and bacterial products. The supernatants contained decreased amounts of antibody protein and, under the right conditions, had lost the ability to neutralize bacteria. However, quantitation of the antibody precipitated was difficult, since the precipitate contained antigen protein as well as antibody protein. Heidelberger and Kendall (83,84) solved this problem when they found that purified pneumococcal cell wall polysaccharide could precipitate with antipneumococcal antibodies. In this case, the amount of protein nitrogen measured in the precipitate was entirely due to antibody protein, and the amount of reducing sugar was mostly due to the antigen. Plotting the amount of antibody protein precipitated from a constant volume of antiserum by increasing amounts of carbohydrate antigen gives the curve shown in Figure 5.13.

As shown in Figure 5.13A, the amount of antibody precipitated rises initially, reaches a plateau, and then
FIGURE 5.13 Quantitative immunoprecipitation. To a fixed amount of specific antibody are added increasing amounts of nonprotein antigen. The figure shows the amount of antibody protein (**A**) and the ratio of antibody to antigen (**B**) found in the precipitate. At antigen excess, soluble immune complexes are found in the supernatant, and the precipitate is decreased.

declines. The point of maximum precipitation was found to coincide with the point of complete depletion of neutralizing antibodies and is called the *equivalence point*. The amount of antibody protein in the precipitate at equivalence is considered to equal the total amount of specific antibody in that volume of antiserum. The rising part of the curve is called the *antibody excess zone* (antigen limiting), and the part of the curve beyond the equivalence point is called the *antigen excess zone.*

Supernatants and precipitates were carefully analyzed for each zone of antibody or antigen excess, as shown in Figure 5.13B. When antigen was limiting, the precipitate contained high ratios of antibody to antigen. The supernatant in this zone contained free antibody with no detectable antigen. As more antigen was added, the amount of antibody in the precipitate rose, but the ratio of antibody to antigen fell. At equivalence, no free antibody or antigen could be detected in the supernatant. As more antigen was added, the precipitate contained less antibody, but the ratio of antibody to antigen remained constant. The supernatant now contained antigen–antibody complexes, since the complexes at antigen excess were small enough to remain in solution. No unbound antibody was detected.

The lattice theory (83,84) is a model of the precipitation reaction that explains these observations. It assumes that antibodies are multivalent and antigens are bi- or polyvalent. Thus, long chains can form consisting of antibody linked to antigen linked to antibody, and so on. The larger the size of the aggregate, the less soluble the product, until a precipitate is formed. In the antibody excess zone, branch points can form whenever three antibodies bind to a single antigen, giving a large and insoluble product. For example, at the antibody to antigen ratio 2:1, every antigen molecule can bind three antibody molecules in a three-dimensional lattice structure. However, when equimolar amounts of antibody and antigen are mixed (the equivalence zone), the likelihood of more than two antibodies binding each antigen molecule decreases. The number of branch points decreases, and the product consists of longer chains of alternating antibody and antigen molecules. As the antigen concentration reaches excess, the precipitate approaches linear chains with molar ratio 1:1. At even higher antigen ratios, more antigen molecules will have 0 or 1 antibody bound. One antibody bound is equivalent to a chain termination, so shorter chain lengths are found, until the product is small enough to remain in solution. Such soluble antigen–antibody "immune complexes" are detectable in the antigen excess zone, where no free antibody is found.

Besides explaining the observed precipitation phenomena on a statistical basis, the lattice theory made the important prediction that antibodies are bivalent or multivalent. The subsequent structural characterization of antibodies (see Chapter 4) revealed their molecular weight and valency. Antibodies are indeed bivalent, except for IgM, which is functionally pentavalent and forms precipitates even more efficiently.

Antigens can be polyvalent either by having multiple copies of the same determinant or by having many different determinants, each of which reacts with different antibodies in a polyclonal antiserum. A good example of the former case, is described in Chapter 21. The predominant antigenic determinants of polysaccharides are often the nonreducing end of the chain. Branched chain polysaccharides have more than one end and are polyvalent. Nonbranched chains such as dextran (polymer of glucose) are monovalent for end-specific antidextran antibodies and do not precipitate them (85). However, a second group of antidextran antibodies is specific for internal glucose moieties. Since each dextran polymer consists of many of these internal units, it is polyvalent for internal $\alpha(1 \rightarrow A\ 6)$ linked glucose specific antibodies. Thus, unbranched dextran polymer can be used to distinguish between end-specific and internal-specific antibodies, as it will precipitate with the latter antibodies but not the former (85,86). Monomeric protein antigens, such as myoglobin (see Chapter 21) or lysozyme, are examples of the second case, because they behave as if they were polyvalent for heterogeneous antisera but monovalent for

monoclonal antibodies. This results from the fact that each antigen molecule has multiple antigenic determinants but only one copy of each determinant. Thus, a polyspecific antiserum can bind more than one antibody to different determinants on the same molecule and form a lattice. However, using antibodies directed against a single determinant (e.g., a monoclonal antibody), no precipitate will form. In this case, antigen–antibody reactions must be measured by some other binding assay, such as RIA or ELISA.

Immunodiffusion and the Ouchterlony Method

One of the most useful applications of immunoprecipitation is in combination with a diffusion system (87). Diffusion could be observed by gently adding a drop of protein solution to a dish of water, without disturbing the liquid. The rate of migration of protein into the liquid is proportional to the concentration gradient times the diffusion coefficient of the protein according to Fick's law,

$$\frac{dQ}{dt} = -DA \frac{dc}{dx} \tag{43}$$

where Q is the amount of substance that diffuses across an area A per unit time t, D is the diffusion coefficient, which depends on the size of the molecule, and dc/dx is the concentration gradient. Since antibody molecules are so large, their diffusion coefficients are quite low, and diffusion often takes 1 day or more to cover the 5 mm to 20 mm required in most systems. In order to stabilize the liquid phase for such long periods of time, a gel matrix is added to provide support without hindering protein migration. In practice, 0.3% to 1.5% agar or agarose will permit migration of proteins up to the size of antibodies while preventing mechanical and thermal currents. By carefully adjusting the concentration of antibody and antigen, these systems can provide a simple analysis of the number of antigenic components and the concentration of a given component. By adjusting the geometry of the reactants entering the gel, immunodiffusion can provide useful information concerning antigenic identity or difference, or partial cross-reaction, as well as the purity of antigens and the specificity of antibodies.

In single diffusion methods (88–91), antibody is incorporated in the gel, and antigen is allowed to diffuse from one end of a tube gel or from a hole in a gel in a Petri dish in one or two dimensions, respectively. Over time, the antigen concentration reaches equivalence with the antibody in the gel, and a precipitin band forms. As more antigen diffuses, antigen excess is achieved at this position, so the precipitate dissolves and the boundary of equivalence moves farther. By integrating Fick's law, we find that the distance moved is proportional to the square root of time. If two species of antigen a and b are diffusing and the antiserum contains antibodies to both, two independent bands will

form. These will move at independent rates, depending on antigen concentration in the sample, diffusion coefficient (size), and antibody concentration in the agar. Similarly, in the two-dimensional method, at a given radius of diffusion, antigen concentration will be equivalent to the antibody in the gel, and a precipitin ring will form. The higher the initial antigen concentration, the farther the antigen will diffuse before precipitating and the wider the area of the ring will be. The area of the ring is directly proportional to the initial antigen concentration. This method provides a convenient quantitative assay that can be used to measure immunoglobulin classes by placing test serum in the well and antiserum to each class of human immunoglobulin in the agar. Sensitivity can be increased by lowering the concentration of antiserum in the gel, giving wider rings, because the antigen must reach a lower concentration to be at equivalence. However, the antiserum cannot be diluted too far, or no precipitate will form.

The double diffusion methods use the same principles, except that instead of having one reactant incorporated in the gel at a constant concentration, both antigen and antibody are loaded some distance apart in a gel of pure agarose alone and allowed to diffuse toward each other. At some point in the gel, antigen diffusion and antibody diffusion will provide sufficient concentrations of both reactants for immunoprecipitation to occur. The line of precipitation becomes a barrier for the further diffusion of the reactants, so the precipitin band is stable. If the antigen preparation is heterogeneous and the antiserum is a heterogeneous mixture of antibodies, different bands will form for each pair of antigen and antibody reacting at positions dependent on concentration and molecular weight of each. The number of lines indicates the number of antigen–antibody systems reacting in the gel. The ability of immunodiffusion to separate different antigen–antibody systems gives a convenient estimate of antigen purity or antibody specificity.

In the most widely used Ouchterlony method of double diffusion in two dimensions (87), three or more wells are cut in an agarose gel in a dish in the pattern shown in Figure 5.14. Antigen a or b is placed in the upper wells, whereas antiserum containing anti-a or anti-b is placed in the lower well. Each antigen–antibody reaction system will form its own precipitin line between the wells. As shown in Figure 5.14A, this should extend an equal distance to the left and right of the wells. When different antigens are present in different wells (Figure 5.14C), the precipitating systems do not interact immunochemically, so the precipitin lines cross. However, when the same antigen is present in both wells (Figure 5.14B), each line of precipitation becomes a barrier preventing the antigen and antibody from diffusing past the precipitin line. This shortens the precipitin line on that side of the well. In addition, antigen diffusion from the neighboring wells shifts the zone of antigen excess, causing the equivalence line to deviate downward and meet between the two wells. Complete fusion
FIGURE 5.14 Immunodiffusion of two components in two dimensions. Cross-reactions produce inhibition (shortened bands) or deviation (curved bands). Lines of identity are shown in **B** and **D** (87).

of precipitin lines with no spurs is called a *line of identity,* indicating that the antigen in each well reacts with all antibody capable of reacting with antigen in the other well.

The analytical power of this method is shown in Figure 5.14D. When a mixed antigen sample is placed in one well, and pure antigen b is placed in the other well, antiserum to a plus b gives the pattern shown. Two precipitin lines form with the left well and one precipitin line with the right well. The line of complete fusion allows us to identify the second band as antigen b; the first band is antigen a. From their relative distance of migration, we can conclude that antigen a is in excess over antigen b, assuming their diffusion coefficients are comparable and both antibodies are present in equal amounts. Finally, since the precipitin line of antigen a-anti-a is not shortened at all, there is no contamination of the right sample with antigen a, and the two antigens do not cross-react.

The type of cross-reactivity detected by this Ouchterlony double immunodiffusion in agar is what we defined earlier as type 2 cross-reactivity. The method is not suitable for measuring affinity differences, required for quantitating type 1 cross-reactivity. Sensitivity can be increased by use of radioactive antigen and detection of the precipitate by autoradiography.

Immunoelectrophoresis

Some antigen–antibody systems are too complex for double immunodiffusion analysis, either because there are too many bands or they are too close together. Immunoelec-

trophoresis combines electrophoresis in one dimension (Figure 5.15) with immunodiffusion in the perpendicular direction. In the first step, electrophoresis separates the test antigens according to charge and size, in effect separating the origin of diffusion of different antigens. This is equivalent to having each antigen start in a different well, as shown in the right-hand panel. A horizontal trough is then cut into the agar and filled with antiserum to all the components. Immunodiffusion occurs between the separated antigens and the linear source of antibody. The results for a mixture of three antigens approximate those shown for three antigens in separate wells (87). Fusion, deviation, and inhibition between precipitin lines can be analyzed as described earlier. The resolution of each band is somewhat decreased, due to widening of the origin of diffusion during electrophoresis. However, the immunodiffusion of unseparated human serum proteins, for example, is greatly facilitated by prior electrophoresis. Starting from a single well, only the heavier bands would be visible. However, prior electrophoresis makes it possible for each electrophoretic species to make its own precipitin line. Monospecific antiserum can be placed in a parallel horizontal trough, so that each band of precipitation can be identified. Immunoelectrophoresis is commonly used to diagnose myeloma proteins in human serum. The unknown serum is electrophoresed, followed by immunodiffusion against antibodies to human immunoglobulin heavy or light chains. A widening arc of IgG suggests the presence of an abnormal immunoglobulin species. At this same electrophoretic mobility, a precipitin line with
FIGURE 5.15 Immunoelectrophoresis. A sample containing multiple components is electrophoresed in an agarose gel, separating the antigens in the horizontal dimension. Then a horizontal trough is cut into the gel and antiserum is added. Immunodiffusion between the separated antigens and the trough is equivalent to having separate wells, each with a different antigen (87). This technique is used to identify a myeloma protein in human serum. Sera from the patient or normal individual were placed in the circular wells and electrophoresed. Antisera were then placed in the rectangular troughs and immunodiffusion proceeded perpendicular to the direction of electrophoresis. The abnormally strong reaction with anti-IgG and anti-κ, but no reaction with anti-λ antibodies, indicate a monoclonal protein (IgG,κ), because polyclonal Ig should react with both anti–light-chain antisera. Failure to form a band with anti-IgM and a reduced band with anti-IgA show typical reduction of normal immunoglobulins in this disease. Photographs courtesy of Theresa Wilson, NIH Clinical Chemistry Section.

anti-κ, but not anti-λ reactivity, strongly suggests the diagnosis of myeloma or monoclonal gammopathy, since these proteins arise from a single clone that synthesizes only one light chain. All normal electrophoretic species of human immunoglobulins contain both light chain isotypes, although κ exceeds λ by the ratio of 2:1 in humans. As shown in Figure 5.15C, the abnormal arc with γ mobility reacts with anti-IgG and anti-κ but not anti-λ antiserum. Thus, it is identified as an IgG-κ monoclonal protein.

Hemagglutination and Hemagglutination Inhibition

Hemagglutination

A highly sensitive technique yielding semiquantitative values for the interaction of antibody with antigen involves the agglutination by antibodies of red blood cells coated

with the antigen (92). For exogenous antigens that are adsorbed to the red blood cell surface, the reaction is called *passive hemagglutination*. Untreated red blood cells are negatively charged, and electrostatic forces keep them apart. Following treatment with tannic acid (0.02 mg/ml for 10 minute at 37°C), however, they clump readily.

Untreated red blood cells are easily coated with polysaccharide antigens, which they adsorb readily. After tanning, the uptake of some protein antigens is good, giving a sensitive reagent, whereas for others it tends to be quite variable; coating red blood cells has been the limiting factor in the usefulness of this method for certain antigens. Apparently, slightly aggregated or partially denatured protein antigens are adsorbed preferentially (92).

The test for specific antibodies is done by serially diluting the antiserum in the U-shaped wells of a microtiter plate and adding antigen-coated red cells. When

cross-linked by specific antibodies, agglutinated cells settle into an even carpet spread over the round bottom of the well. Unagglutinated red cells slide down the sides and form a much smaller button at the very bottom of the well. The titer of a sample is the highest dilution at which definite agglutination occurs. With hyperimmune antisera, inhibition of agglutination is observed at high doses of antibody, termed a *prozone effect*. Two interpretations have been offered: One is that, at great antibody excess, each cell is coated with antibody, so cross-linking by the same antibody molecule becomes improbable. The second interpretation is the existence of some species of inefficient or "blocking" antibodies that occupy antigen sites without causing aggregation of cells (9). To ensure antigen specificity, the antiserum should be absorbed against uncoated red cells prior to the assay, and an uncoated red cell control should be included with each assay. IgM is up to 750 times more efficient than IgG at causing agglutination, which may affect interpretation of data based on titration. The titer may vary by a factor of 2 simply due to subjective estimates of the endpoint.

Once the titer of an antiserum is determined, its interaction with antigen-coated red blood cells can be used as a sensitive assay for antigen. To constant amounts of antibody (diluted to a concentration twofold higher than the limiting concentration producing agglutination) are added varying amounts of free antigen. Agglutination will be inhibited when half or more of the antibody sites are occupied by free antigen. In a similar fashion, the assay can be used for the detection and quantitation of anti-idiotype antibodies that react with the variable region of antibodies and sterically block antigen binding.

Immunoblot (Western Blot)

A most useful technique in the analysis of proteins is polyacrylamide gel electrophoresis (PAGE), in which charged proteins migrate through a gel in response to an electric field. When ionic detergents such as sodium dodecyl sulfate are used, the distance traveled is inversely proportional to the logarithm of molecular weight. The protein components of complex structures, such as viruses, appear as distinct bands, each at its characteristic molecular weight. Because antibodies may be unable to diffuse into the gel, it is necessary to transfer the protein bands onto a nitrocellulose membrane support first, where they are exposed for antibody binding (93).

The immunoblot is often used to detect viral proteins with specific antibodies that bind these proteins on the nitrocellulose blot. Then a second antibody, which is either enzyme conjugated or radiolabeled, is used to detect the antigen–antibody band. Crude viral antigen preparations can be used, because only those bands that correspond to viral antigens will be detected.

Typical results are shown in Figure 5.16. Human immunodeficiency virus type 1 (HIV-1) was cultured in susceptible H9 cells. The viral proteins were separated by PAGE and detected by immunoblot, using the serum of infected patients. Each antigen band recognized by the antiserum has been identified as a viral component or
FIGURE 5.16 A: Western blot technique. The antigen preparation is run through a polyacrylamide gel, which separates its components into different bands. These bands are then transferred to paper by electrophoresis in the horizontal dimension. The paper is cut into strips. Each strip is incubated with test antibodies, followed by further incubation with enzyme-labeled second antibodies. If the test antibodies bind to the component antigens, they will produce discrete dark bands at the corresponding positions on the strip. **B:** Clinical specimens from AIDS patients tested on strips bearing HIV-1 viral antigens, showing antibodies to viral gag (p15/17, p24, and p55 precursor), pol (p66 and possibly p32), and env (gp41 and gp120) proteins. Lane 1 is the negative control, and lanes 2 to 4 are sera from three different patients.

precursor protein. The gp160 precursor is processed to mature gp120 and gp41 envelope proteins, while a p66 precursor is processed to the p51 mature form of reverse transcriptase, and a p55 precursor becomes the p24 and p17 gag and matrix proteins of the virus (94). The practical uses of the HIV western blot include diagnosing infection, screening blood units to prevent HIV transmission, and testing new vaccines.

Surface Plasmon Resonance (SPR)

SPR uses the electromagnetic properties of light to measure the binding affinity of a variety of biological molecules, including antigen–antibody pairs. In this method, polarized light passes through a glass plate coated on the back surface with a thin metal film, usually gold. Biological materials binding to the metal film behind the plate can alter its refractive index in ways that affect the angle and intensity of reflected light.

At angles close to perpendicular, light will pass through the glass, although it will bend at the interface due to differences in the refractive index of glass and what is behind it. Above a certain angle, called the *critical angle,* bending will be so great that total internal reflection will occur. Small changes in refractive index behind the glass can be

detected as significant changes in the critical angle, where light reflection occurs, and in the intensity of reflected light at this angle. By reading the reflected light intensity in a diode array detector, the critical angle and intensity can be determined simultaneously. Due to the wave nature of light, the effect of refractive index in the gold film extends about one wavelength beyond the glass, or about 300 nm to 700 nm (95). Within this layer, if an antigen is covalently attached to the gold, then antibody binding can be detected as a change in refractive index, resulting in a different critical angle and intensity of the reflected light.

SPR systems have three essential features (96): an optical system that allows determination of the critical angle and light intensity at the same time; a coupling chemistry that links antigen or antibody to the gold surface; and a flow system that rapidly delivers the binding molecule in the mobile phase, so SPR can measure the rate of binding, rather than the rate of diffusion. Because binding causes a physical change in the gold film, there is no need to detect binding with radioactive labels or enzyme conjugates. Molecular binding interactions can be followed in real time.

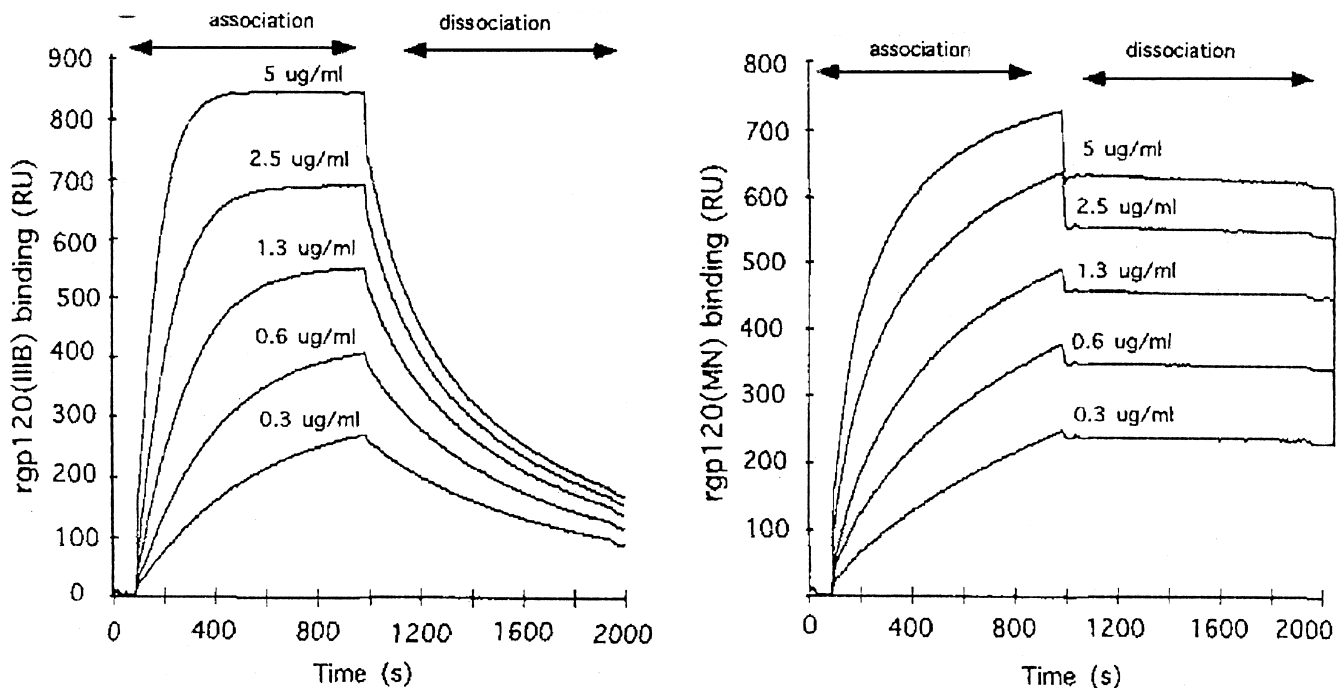
A typical SPR experiment is shown in Figure 5.17. HIV gp120 of type IIIB (left panel) or MN (right panel) were fixed to the gold layer, and various concentrations of


FIGURE 5.17 Monoclonal antibody to gp120 was introduced into the flow cell at time 0, and antibody binding was followed over time as a change in the critical angle, measured in response units. After 1,000 seconds, free antibody was washed out, and the release of bound antibody was measured as a decrease in refractive index. Lower-affinity binding to gp120 from the IIIB strain (left) was shown as a faster "off rate," as compared to the very slow rate of antibody release from the MN strain (right). These results, obtained under nonequilibrium conditions, provide direct measurement of the forward and reverse rate constants for antibody binding, and the ratio of these two gives the affinity constant. Modified from (97), with permission.

monoclonal antibody to gp120 were added to the flow cell (97). Over the first 1,000 seconds, antibody binding was measured as a change in reflected light (in response units), allowing a calculation of the rate constant for the forward reaction of antibody binding. Once the signal reached a plateau, antibody was washed out of the flow cell, and the decrease in SPR signal over time indicated the rate at which antibody came off the antigen. The "on rate" for antibody binding to IIIB gp120 (left) was about twice as fast as for MN (right) at each antibody concentration. However, the "off rate" was about 50-fold less for MN than for IIIB. Combining these kinetic results indicates much greater binding affinity for gp120 of MN type, which may explain the observation that MN type virus was 10-fold more sensitive to neutralization by this antibody than was the IIIB strain.

MONOCLONAL ANTIBODIES

Homogeneous immunoglobulins have long played important roles in immunological research. Starting in the 1950s, Kunkel and colleagues studied sera from human patients with multiple myeloma and recognized the relationship between abnormal myeloma proteins and normal serum globulins (98). Potter and colleagues characterized numerous mouse myeloma tumors and identified some of their antigenic specificities (99). Human and mouse myeloma proteins were studied as representative immunoglobulins and recognized for the advantages they had with proteins as diverse as antibodies, for studies of immunoglobulin structure, function, and genetics. It was not yet possible, however, to induce monoclonal immunoglobulins of desired specificity.

This goal was achieved by the introduction of hybridoma technology by Köhler and Milstein (1,100) and by Margulies and colleagues (101) in the 1970s. Since that time, monoclonal antibodies have come to play an enormous role in biological research and applications. They offer as advantages the relative ease of the production and purification of large quantities of antibody, the uniformity of antibody batches, and the ready availability of Ig mRNA and DNA from the hybrid cell lines.

Derivation of Hybridomas

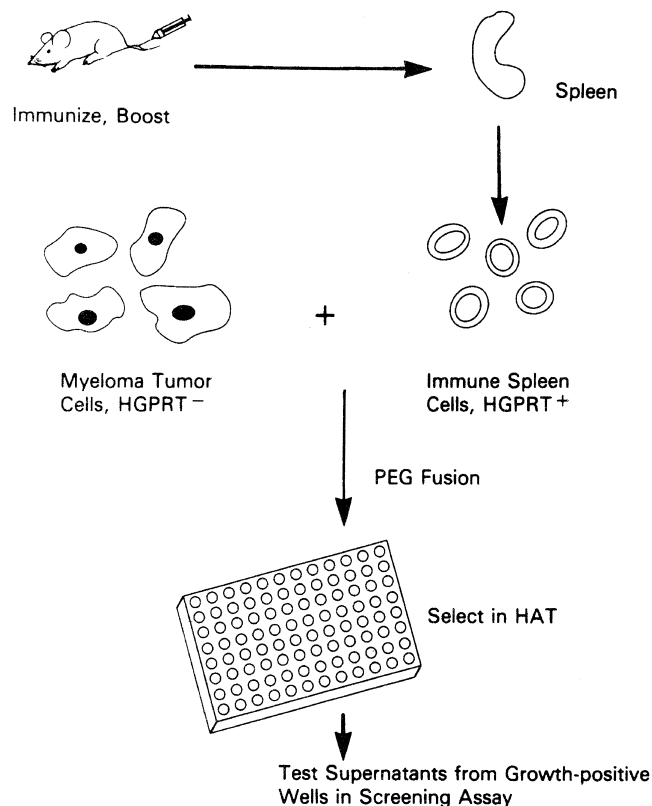
Hybridomas producing monoclonal antibodies are generated by the somatic cell fusion of two cell types: antibody-producing cells from an immunized animal, which by themselves die in tissue culture in a relatively short time, and myeloma cells, which contribute their immortality in tissue culture to the hybrid cell. The myeloma cells are variants carrying drug selection markers, so only those myeloma cells that have fused with spleen cells providing the missing enzyme will survive under selective conditions. Initial work used myeloma cells that secreted their


FIGURE 5.18 Production of hybridomas. Steps in the derivation of hybridomas can be outlined as shown. Spleen cells from immunized donors are fused with myeloma cells bearing a selection marker. The fused cells are then cultured in selective medium until visible colonies grow, and their supernatants are then screened for antibody production.

own immunoglobulin products, but later such fusion partners were replaced by myeloma variants that fail to express Ig (102,103), so that the fused cell secretes exclusively antibody of the desired specificity. Successful hybridoma production is influenced by the characteristics of the cell populations (immune lymphocytes and myeloma fusion partner), the fusion conditions, and the subsequent selection and screening of the hybrids. A diagrammatic version of the overall process of hybridoma derivation is presented in Figure 5.18.

This section will not attempt to provide a detailed, step-by-step protocol for laboratory use. For that purpose, the reader is referred to monographs and reviews on the subject, including a detailed lab protocol with many hints and mention of problems to avoid (104).

Hybridomas Derived from Species Other than Mice

Laboratory mice are the most common species immunized for hybridoma production, but for a variety of reasons, other animal species often have advantages. If an antigen

of interest is nonpolymorphic in the mouse, the mouse component might be immunogenic in other species, while mice would be tolerant to it. In the case of hybridomas for clinical use, mouse antibodies have the drawback of inducing anti–mouse immunoglobulin immune responses with possible deleterious effects.

Several approaches have been taken to the derivation of hybridomas in species other than mouse. First, interspecies hybridization can be performed using mouse myeloma fusion partners. The resulting hybrids are often unstable and throw off chromosomes, but clones can sometimes be selected that produce antibody in a stable fashion. Examples of this would be rat–mouse fusion to produce antibody to the mouse Fc receptor (105), and hamster–mouse fusion to produce antibody to the mouse CD3 equivalent (106). Rabbit–mouse hybridomas have also been described (107).

A second approach is the use of fusion partner cells from the desired species. Myeloma variants carrying drug selection markers are available in a number of species. A rat myeloma line adapted for this purpose, IR983F, was described by Bazin (108). Production of human hybridomas is of special importance, because their use in therapies would avoid the problem of human immune responses to Ig derived from other animal species, as discussed in detail in the later section on applications.

Use of Gene Libraries to Derive Monoclonal Antibodies

Monoclonal antibodies produced by hybridoma technology are derived from B cells of immunized animals. A recent alternative technology uses gene libraries and expression systems instead. This approach has the advantages of avoiding labor-intensive immunizations of animals and the screening of antibody-containing supernatants. Another advantage of the approach is circumventing tolerance. One can derive mAbs to antigens expressed in the animal species that donated the gene library, including highly conserved antigens for which there may be no available responder that does not express the antigen.

The first version of such an approach involved preparation of V_H and $V\kappa$ libraries and expression of the libraries in bacteria. Further development of the system led to use of V_H and V_L libraries made separately, and then preparation of a combinatorial library by cleaving, mixing, and religating the libraries at a restriction site (109,110). A linker can be used so that V_H and V_L can both be expressed on one covalent polypeptide; the flexibility of the linker allows association of the V_H and V_L in a normal three-dimensional configuration and thus formation of an antigen-binding site (110).

Another innovation involves expression of V_H and $V\kappa$ genes on the surface of bacteriophage as fusion proteins with a phage protein, to permit rapid screening of large numbers of sequences (110–112). Adsorption of antibody-bearing phage on antigen-coated surfaces allows positive selection of phage containing DNA encoding the desired variable region fragment (Fv) from combinatorial variable region gene libraries (111,112).

Human antibody gene sequences can be recovered by PCR from peripheral blood cells (113), bone marrow (114), or human cells reimmunized in SCID-hu mice (115). The phage display technique can then be used to select antigen-binding clones and derive human reagents of desired specificity, such as antibody to hepatitis surface antigen (113) or HIV envelope (114).

One limitation in the phage library technique initially was low affinity of the mAbs derived, because they were generated by a random process and not subject to further somatic mutation. Several approaches have now been used to improve affinities. Hypermutation and selection has now been achieved *in vitro* by a strategy using a bacterial mutator strain (116). The process involves multiple rounds of mutation followed by growth in nonmutator bacteria and then selection for high-affinity binding led to an overall 100-fold increase in affinity (116). Improved affinity has also been achieved by use of site-directed mutagenesis to alter residues in hypervariable regions affecting dissociation rates (117).

Applications of Monoclonal Antibodies

Since monoclonal antibodies can be made easily and reproducibly in large quantities, they allow many experiments that were not possible or practical before. Affinity chromatography based on monoclonal antibodies can be used as a step in purification of molecular species that are difficult to purify chemically. Homogeneous antibody can be crystallized and can also be crystallized together with antigen to permit the study of the structure of antibody and of antigen–antibody complexes by x-ray diffraction. Homogeneous antibodies are also very valuable in the study of antibody diversity. Such analyses have revealed much about the roles of somatic mutation, changes in affinity, and changes in clonal dominance in antibody responses.

Catalytic Antibodies

One area of recent interest is the use of antibody molecules to catalyze chemical reactions (118). In this role, antibodies serve as an alternative to enzymes, an alternative that can be customized and manipulated more easily in some cases.

The concept of antibodies as catalysts had been proposed a long time ago by D. W. Woolley (cited in ref. 118). Use of homogeneous antibodies permitted identification of some with significant catalytic effects; MOPC167 accelerates the hydrolysis of nitrophenyl-phosphorylcholine by 770-fold (119). Polyclonal antibodies have also been

reported to possess detectable enzymatic activity (120). With the advent of hybridoma technology, purposeful selection of antibodies with potent enzymatic function became possible. Antibodies have been characterized that catalyze numerous chemical reactions, with rates nearing 10^8-fold above the spontaneous rate (reviewed in ref. 118). One common strategy for elicitation of such antibodies is immunization with transition state analogs (121), although there are other strategies (122). Antibodies function as catalysts in a stereospecific manner (123), a valuable property.

Molecular mechanisms of antibody-mediated catalysis vary, as do enzymatic reactions (122,124). To accelerate a reaction, an antibody has to lower the activation energy barrier to the reaction, which means lowering the energy of the transition state by stabilizing it. For this reason, an antibody that recognizes the transition state is favorable, and immunizations with analogs of the transition state have advantages.

Antibodies can serve as what has been termed an entropy trap (118); binding to the antibody "freezes out" the rotational and translational degrees of freedom of the substrate and thus makes a chemical reaction far more favorable energetically. Interactions with chemical groups on the antibody can neutralize charges or bury hydrophobic groups, thereby stabilizing a constrained transition state.

Discovery of such catalytic antibodies opens practical opportunities: antibodies can be customized for an application by appropriate selection and can be produced relatively cheaply and purified easily. Catalytic antibodies can be developed to perform chemical reactions for which no enzyme is available. They can shield intermediates from solvent—for example, allowing reactions that do not occur in aqueous solution (125). They can form peptide bonds (126), suggesting a new approach to polypeptide synthesis. Thus, catalytic antibodies will likely have many practical applications.

Bispecific and Bifunctional Antibodies

Antibodies produced naturally by a single B cell have only one binding site specificity, and their effector functions are determined by the structure of the Fc domain. The availability of monoclonal antibodies made possible the generation in quantity of artificial antibodies as cross-linking reagents, by linking binding sites of two specificities to form bispecific antibodies. A variety of techniques have been used to prepare such hybrid or bispecific antibodies, and they have been put to a variety of uses. In addition, antibody binding sites can be linked to other functional domains, such as toxins, enzymes, or cytokines, to create "bifunctional antibodies" (127).

One of the most powerful uses of hybrid antibodies is in redirecting cytolytic cells to targets of a defined specificity. In one early demonstration of this use (128), a mon-

oclonal antibody specific for the Fcγ receptor and one specific for the hapten DNP were chemical cross-linked. In the presence of this hybrid antibody, FcγR-bearing cells were able to lyse haptenated target cells specifically. The FcγR played a critical role; antibody to MHC class I antigens on the cell could not be substituted. Antibody to the T cell receptor complex has also been used extensively to redirect T cell lysis to desired targets. For example, anti-CD3 was cross-linked to antitumor antibodies and mixed with effector cells. These "targeted T cells" were able to inhibit the growth of human tumor cells *in vivo* in nude mice (129). Bispecific antibodies have also been used recently to alter the tropism of a viral gene therapy vector to target specific cells (130).

Cumbersome cross-linking chemistry can now be replaced by genetic engineering for creation of designer antibodies (127). Bifunctional and bispecific antibodies can be engineered as single chain variable fragment (scFv) constructs or by specialized strategies using two chains. A wide variety of configurations are possible and can be used to make multivalent reagents as well as reagents with one site of each specificity. Tags can be built in by fusion of additional sequence such as streptavidin, or, as mentioned earlier, antibody domains can be combined with other functional domains, such as toxins, enzymes, or cytokines.

Clinical Applications

The possible clinical uses of monoclonal antibodies are many. *In vitro,* they are widely used in RIA and ELISA measurements of substances in biological fluids, from hormones to toxins. They are also extremely valuable in flow cytometric assays of cell populations using antibodies specific for differentiation antigens expressed on cell surfaces. Monoclonal antibodies plus complement or toxin-conjugated monoclonal antibodies have also been used to remove T cells from bone marrow prior to transplantation (131).

In vivo, although it took more than two decades for the original promise of hybridoma technology to be translated into widespread clinical applications, a number of monoclonal antibodies are now in use or in trials for a variety of purposes (reviewed in 132–134). Monoclonal antibody OKT3 directed to a marker on human T lymphocytes is used as a treatment for rejection reactions in kidney transplant patients (135). Other monoclonal antibodies, for example, ^{111}In-labeled CYT-103 referred to as *Oncoscint* (136), are used as diagnostic tumor-imaging reagents. Monoclonal antibodies are have now been approved for a variety of therapeutic uses (134,137). Cancer therapies use either unconjugated monoclonal antibody (132,138–142) or toxin-coupled (143,144) or radiolabeled monoclonal antibody (138,142,145). Molecules targeted in cancer therapies include CD25 (IL-2 receptor alpha chain) in adult T cell leukemia (132,134,142,146–148); CD20 in

non-Hodgkin lymphoma using either unlabeled (141,149) or more recently, radionuclide-labeled anti-CD20 (150,151); the HER-2/neu oncoprotein in breast and ovarian cancer (139,140,152,153); CD22 in hairy cell leukemia (144); vascular endothelial growth factor to limit angiogenesis in diverse tumors, especially colorectal, renal, and non–small-cell lung cancer (154–159); antiepidermal growth factor receptor in colorectal carcinoma and others (160); anti-CD52 in chronic lymphocytic leukemia (161); and anti-CD33 in acute myelogenous leukemia (162). Other therapies studied include anti-LPS for treatment of sepsis, anti-IL-6 receptor for treatment of multiple myeloma, and anti-IgE for treatment of allergy (surveyed in 133), and anti-TNF for treatment of arthritis (163,164), anti-RSV for prevention of RSV morbidity and mortality in infants (165,166), and anti-IL-2 receptor (CD25) for prevention of graft rejection (142,167), as well as for treatment of autoimmune diseases such as uveitis (168) and multiple sclerosis (169).

In the specialized case of B cell lymphoma, monoclonal anti-idiotypes against the idiotype expressed by the patient's tumor have been tested as a "magic bullet" therapy (170). Active immunization of the patient with idiotype (171–175) has the advantage that escape mutants (176) are less likely to emerge because multiple idiotopes are recognized. Another approach under study is immunization using not idiotype as protein but plasmid DNA encoding patient idiotype (177). This approach would have additional advantages, such as ease of preparing customized reagents for each patient.

Production of Human or Humanized Monoclonal Antibodies

Many of the side effects of monoclonal antibodies in clinical use are due to the foreign Ig-constant regions. Recognition of foreign Ig epitopes can lead to sensitization and so preclude subsequent use in the same individual of different monoclonal antibodies. Thus, monoclonal antibodies with some or all structure derived from human Ig have advantages. Several approaches have been taken employing fusion of human cells with animal myelomas or with human tumor cells of various kinds (178,179), and use of Epstein-Barr virus to immortalize antibody-producing cells (180). Production of populations of sensitized human cells to be fused presents another special problem, since the donors cannot be immunized at will. In one example, *in vitro* stimulation of lymphocytes with antigen followed by fusion with mouse myeloma cells has been used to generate a series of antibodies to varicella zoster (181).

Another approach to production of monoclonal antibodies with human characteristics involves application of genetic engineering. The part of the antibody structure recognized as foreign by humans can be minimized by combining human constant regions with mouse variable regions (182,183) or even just mouse hypervariable segments (184) by molecular genetic techniques. Antigen-binding specificity is retained in some cases, and the "humanized" chimeric molecules have many of the advantages of human hybridomas.

Production of fully human mAbs in transgenic mice has now been achieved by multiple laboratories. The strategy has involved insertion into the mouse germline of constructs containing clusters of human Ig V, D, J, and C genes to generate one transgenic line, and targeted disruption of the mouse heavy chain and κ chain loci to generate another transgenic line. From these two lines, mice are then bred that express only human antibodies.

To show feasibility of this approach, cosmids carrying parts of the human heavy chain locus were used to make transgenic mice (185). The next step was to produce mice carrying human genes for both heavy and light chains to generate a functional human repertoire. Several groups using different technologies constructed heavy chain miniloci containing functional V segments representing several major V region families, D and J segments, constant and switch regions, and enhancers. κ chain constructs were made that contained multiple functional Vκ segments, the J segments, Cκ, and enhancers (186,187). Mice were bred that were homozygous both for the transgene loci and for disruption of the mouse heavy chain and κ light chain loci; note that the mouse λ locus was left intact. The human Ig genes could rearrange in the mouse genome, and expression of human Ig resulted. If these mice were immunized with a fragment of tetanus toxin, resulting antibodies included some that were fully human (187). In one of the studies (186), serum contained human μ, $\gamma 1$, and κ, as well as mouse λ and γ. Immunization of such mice with various antigens led to class switching, somatic mutation, and production of human antibodies of affinities of almost 10^8 m^{-1}.

Ig expression in these mice demonstrates cross-species compatibility of the components involved in antibody gene rearrangement and diversification. The mice also provide a responder able to provide fully human antibodies to clinically important antigens, and they have the advantage that they are not tolerant to human antigens, such as the human IgE and human CD4 used by Lonberg, et al. (186).

Nucleotide Aptamers: An Alternative to mAbs

Antibodies are not the only biological macromolecules that have evolved to permit an enormous range of specific structures. Oligonucleotides selected for ability to bind a ligand with high affinity and specificity are termed *aptamers* and can be used in many of the ways antibodies have been used. Selection, properties, and uses of aptamers have been reviewed (188). Aptamers have the advantage that their production does not require animals or cell culture. These

well-defined reagents may be used increasingly in diagnostic testing and are also being tested in clinical trials for use as imaging agents or therapeutics.

Specificity and Cross-reactivity

Specificity of Monoclonal Antibodies

Because all the molecules in a sample of monoclonal antibody have the same variable region structure, barring variants arising after cloning, they all have the same specificity. This uniformity has the advantage that batches of monoclonal antibody do not vary in specificity as polyclonal sera often do. The most obvious fact about cross-reactions of monoclonal antibodies is that they are characteristic of all molecules and cannot be removed by absorption without removing all activity. An exception would be an apparent cross-reaction due to a subset of denatured antibody molecules, which could be removed on the basis of that binding. The homogeneity of monoclonal antibodies allows refinement of specificity analysis that was not possible with polyclonal sera. A few examples follow.

First, one can use monoclonal antibodies to distinguish closely related ligands in cases where most antibodies in a polyclonal serum would cross-react and so absorption of a serum would not leave sufficient activity to define additional specificities. This ability is useful in designing clinical assays for related hormones, for example. Such fine discrimination also allows the definition of new specificities on complex antigens. When large numbers of monoclonal antibodies specific for class I and class II MHC antigens were analyzed, some defined specificities that could not be defined with existing polyclonal antisera (189–191).

However, monoclonal antibodies are also a powerful tool for demonstrating similarities rather than distinctions between two antigens. In some cases, only a minor portion of an antibody response detects a cross-reaction, and so it is not detected by polyclonal reagents. For example, determinants shared by the I-A and I-E class II MHC antigens in the mouse were demonstrated using monoclonal antibodies (191), while they had been suspected but were difficult to demonstrate using polyclonal sera.

Another type of fine specificity analysis possible only with monoclonal antibodies is the discrimination of spatial sites (epitope clusters) by competitive binding. In some cases, such epitope clusters correspond to specificities that are readily distinguished by other means. However, in other cases, the epitope clusters may not be distinguishable by any serologic or genetic means. An example is the splitting of the classical specificity Ia.7 into three epitope clusters by competitive binding with monoclonal antibodies (191). The epitopes cannot be distinguished genetically, because all three are expressed on cells of all Ia.7-positive mouse strains. Thus, polyclonal sera cannot be absorbed to reveal the different specificities. Only with the use of mon-

oclonal antibodies were the epitopes resolved from each other.

The importance of this type of analysis is shown by another example—the definition of epitope clusters on CD4, a surface molecule on a subset of human T cells that also functions as the receptor for HIV. Monoclonal antibodies to CD4 can be divided into several groups based on competitive inhibition (192). The cluster containing the site recognized by OKT4A is closely related to virus infection, since antibodies to this site block syncytium formation. The cluster recognized by OKT4, however, is not related to infection because antibodies to it do not block syncytium formation (192), and cells expressing variant forms of the CD4 molecule lacking the OKT4 epitope can still be infected by HIV (193). This information about the sites on the molecule is important in understanding the molecular interactions of virus with its receptor and may be useful in designing vaccine candidates.

Although most antibodies are not MHC-restricted in their recognition of antigens, distinguishing them from T cell receptors, antibodies can be selected that recognize peptide-MHC complexes (MHC-restricted antipeptide antibodies or peptide-dependent anti-MHC class I antibodies) (194–196). Several monoclonal antibodies have been selected that require both a certain MHC class I antigen and a particular peptide for reactivity. Such mAbs are useful reagents capable of detecting cells presenting the appropriate peptide-MHC complexes on their surfaces (194). Such mAbs may also be useful in dissection of T cell responses. In one study, the mAbs could inhibit IL-2 secretion by a T cell hybridoma of corresponding specificity and could also block induction of CTL recognizing that epitope when given in vivo during priming (196). Such mAbs have been used to address structural questions about antigen recognition by T and B cells (195). Such antibodies also appeared to skew the repertoire of T cells for this particular HIV peptide–MHC complex to specific TCR Vβ types and T cell avidities (197). However, only very rare mAbs have this type of specificity, and they were purposely selected in the fusions, so they do not provide a general comparison of TCR and Ab characteristics.

Cross-reactions of Monoclonal Antibodies

Monoclonal antibodies display many type 1 cross-reactions, emphasizing that antibody cross-reactions represent real similarities among the antigens, not just an effect of heterogeneity of serum antibodies. Even antigens that differ for most of their structure can share one determinant, and a monoclonal antibody recognizing this site would then give a 100% cross-reaction. An example is the reactivity of autoantibodies in lupus with both DNA and cardiolipin (198).

It should be emphasized that sharing a "determinant" does not mean that the antigens contain identical chemical

structures; instead, they bear a chemical resemblance that may not be well understood—for example, a distribution of surface charges. Antibodies to the whole range of antigens can react with immunoglobulins in idiotype anti-idiotype reactions, showing a cross-reactivity of the same antibodies with proteins (the anti-idiotypes) and with the carbohydrates, nucleic acids, lipids, or haptens against which they were raised.

Polyclonal versus Monoclonal Antibodies

When monoclonal antibodies first became available, some people expected that they would be exquisitely specific and would be superior to polyclonal sera for essentially all purposes. Further thought about the issues discussed here, however, suggests that this is not always the case and depends on the intended use of the antibodies. Not only do monoclonal antibodies cross-react, but when they do, the cross-reaction is not minor and cannot be removed by absorption. A large panel of monoclonal antibodies may be needed before one is identified with the precise range of reactivity desired for a study.

In polyclonal sera, however, each different antibody has a distinct range of reactivity, and the only common feature would be detectable reactivity with the antigen used for immunization or testing. Thus, the serum as a whole may show only a low-titered cross-reaction with any other particular antigen, and that cross-reaction can be removed by absorption, leaving substantial activity against the immunizing antigen. For the purposes of an experiment, a polyclonal serum may be "more specific" than any one of its clonal parts and may be more useful. This concept is the basis of the theory of multispecificity (see earlier discussion).

Polyclonal sera also have advantages in certain technical situations such as immunoprecipitation in which multivalency is important. Many antigens are univalent with respect to monoclonal antibody binding but display multiple distinct sites that can be recognized by different components of polyclonal sera. Thus, a greater degree of crosslinking can be achieved.

The ultimate serological reagent in many cases may well be a mixture of monoclonal antibodies that have been chosen according to their cross-reactions. The mixture would be better defined and more reproducible than a polyclonal antiserum and would have the same advantage of overlapping specificities.

CONCLUSION

In conclusion, antibodies, whether monoclonal or polyclonal, provide a unique type of reagent that can be made with high specificity for almost any desired organic or biochemical structure, often with extremely high affinity.

These can be naturally divalent (e.g., in the case of IgG) or multivalent (e.g., in the case of IgM) or can be made as monovalent molecules, such as Fab or recombinant Fv fragments. They serve not only as a major arm of host defense, playing a major role in the protective efficacy of most existing antiviral and all antibacterial vaccines, but also as very versatile tools for research and clinical use. RIAs and ELISAs have revolutionized the detection of minute quantities of biological molecules, such as hormones and cytokines, and thus have become indispensable for clinical diagnosis and monitoring of patients, as well as for basic and applied research. Current solid-phase versions of these take advantage not only of the intrinsic affinity and specificity of the antibodies, but also of the implicit multivalency and local high concentration on a solid surface. Cross-reactivity of antibodies often provides the first clue to relationships between molecules that might not otherwise have been compared. Conversely, methods that use antigens to detect the presence of antibodies in serum have become widespread in testing for exposure to a variety of pathogens, such as HIV. Antibodies also provide specific reagents invaluable in the rapid purification of many other molecules by affinity chromatography. They have also become indispensable reagents for other branches of biology—for example, in histocompatibility typing and phenotyping of cells using a myriad of cell-surface markers that were themselves discovered with monoclonal antibodies, and for separating these cells by fluorescence activated cell sorting, panning, or chromatographic techniques. Monoclonal antibodies have also finally emerged as clinically important therapeutics in cancer, arthritis, organ graft rejection, and infectious diseases. Thus, antibodies are among the most versatile and widely used types of reagents today, and their use is constantly growing. Understanding the fundamental concepts in antigen–antibody interactions thus has become essential not only to an understanding of immunology, but also to the effective use of these valuable molecules in many other fields.

Immunoglobulins: Molecular Genetics

Edward E. Max

INTRODUCTION

From the millions of naïve B cells circulating in an individual, a foreign antigen triggers a specific antibody response by activating the small fraction of B lymphocytes displaying antibody as a B cell receptor (BCR) that can bind the antigen; these B cells proliferate and mature into antibody-secreting cells, manufacturing large amounts of antibody specific for the triggering antigen. To be effective against a universe of diverse pathogens, this "clonal selection" mechanism requires that the diversity of immunoglobulin species expressed on naïve B cells prior to antigen exposure be huge enough so that virtually any antigen finds B cells displaying a cognate antibody (i.e., an antibody capable of binding that antigen). Indeed, in the 1960s the number of different antibody sequences in the repertoire of typical mouse was estimated in the millions; to encode this many sequences would seem to require an unreasonably high percentage of the mammalian genome (now estimated to contain only about 30,000 genes). Understanding the genetic source of immunoglobulin diversity—variable (V) region assembly recombination—was the first major challenge and achievement of the molecular biological investigations of antibody genes and will be discussed first in this chapter.

A week or so after antigen administration, the antibody response changes in two ways that generally improve the protective functions of antibodies. B cells initially express antibodies of the IgM isotype, but those cells that migrate into germinal centers receive stimuli that can induce them to switch to production of IgG, IgA, or IgE without changing the antigen specificity of the protein; this switch results from a DNA recombination event known as class switch recombination (CSR). In addition, over the course of an immune response, the affinity of antibody for antigen gradually improves as a result of somatic hypermutation (SHM) of antibody genes, with subsequent selection for B cells expressing high-affinity antibodies. CSR and SHM are discussed later in this chapter.

In this chapter, well-established facts about immunoglobulin genes are summarized concisely, while areas currently under investigation are considered in more detail, with particular attention to topics expected to interest immunologists.

OVERVIEW OF IMMUNOGLOBULIN V GENE ASSEMBLY

The three immunoglobulin gene loci—κ, λ, and heavy chain—each undergo similar V region assembly recombination during B lymphoid development, a novel form of DNA acrobatics that was initially discovered by Tonegawa's lab (1). The κ locus (murine or human) is conceptually the simplest, containing a single constant (C) region and a cluster of multiple upstream V region genes. During the development of an antibody-producing cell, one of the V region sequences rearranges to associate with the C region sequence, leading to a complete (V + C) gene, which the cell can then express. The difference between recombined DNA in a Ig-expressing B lymphocyte and the precursor "germline" DNA can be demonstrated by comparing these DNAs using Southern blotting or sequence analysis of cloned Ig genes (now often obtained by polymerase chain reaction [PCR]).

The general structures of the germline V genes are similar for the three Ig loci. Each V gene begins with sequence encoding a signal peptide of about 22 amino acids. Within codon –4 (numbering backward from the beginning of the

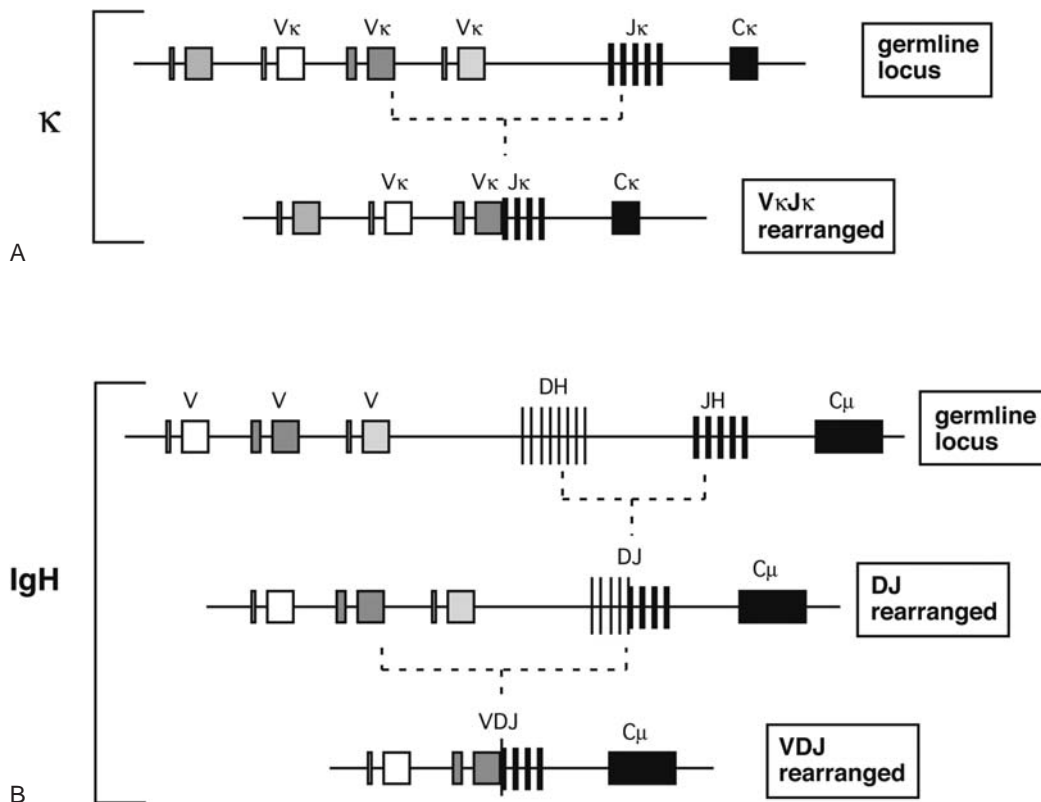
mature protein sequence), the coding sequence is interrupted by an intron, usually roughly 0.1 kb to 0.3 kb long. Each V region gene as it exists in the germline is incomplete, and recombination is necessary to assemble a complete V gene as expressed in a B lymphocyte. For example, most murine κ chains have variable regions 108 amino acids in length, but murine germline Vκ genes encode only about 95 of these. The remaining 13 amino acids are encoded by segments known as J ("joining") regions that lie at some distance upstream of the Cκ gene. The murine κ locus contains four Jκ regions (plus an additional nonfunctional J sequence). An assembled Vκ gene thus results from recombination that joins one of many germline Vκ genes to one of four Jκ gene segments (Figure 6.1A). A similar recombination event is necessary to assemble a complete Vλ chain sequence from germline Vλ and Jλ genes. For heavy chains, recombination assembles a V region from three types of germline elements; between the residues encoded by germline VH and JH elements are extra amino acids—usually from two to eight residues—encoded by a D ("diversity") region. The assembly of a complete heavy chain V region occurs in two separate steps (Figure 6.1B): initially one of several germline DH regions joins with one


FIGURE 6.1 V assembly recombination. **A:** In the κ locus a single recombination event joins a germline Vκ region with one of the Jκ segments. **B:** In the IgH locus an initial recombination joins a D segment to a JH segment. A second recombination completes the V assembly by joining a VH to DJH.

FIGURE 6.2 Vκ-Jκ recombination at single base resolution. **A:** The sequence of the recombined MOPC41 κ gene around the VJ junction is shown (center) with the sequences of the two germline precursors (Vκ41 and Jκ1) shown above and below. The germline origins of the recombined gene are indicated by the vertical lines and the shading of the V-derived sequence. **B:** The consequences of joining the same germline sequences (from part A) at four different positions are shown. Of the four alternative recombination products illustrated, the top one is that actually found in MOPC41. The second example has a single nucleotide difference but no change in encoded amino acid sequence. The third and fourth alternatives yield Arg or Pro at position 96; both of these amino acids have been found at this position in sequenced mouse κ chains.

of the JH regions; then a germline VH region is added to complete the assembled VDJ heavy chain gene.

Several PCR strategies can detect V(D)J recombination, depending on the needs of the experiment. An upstream sense primer can be specific to a particular V region or represent a consensus V primer (or primer mixture), while the downstream antisense primer may target the 3′-most J region. If the template DNA derives from a clonal B cell line, a single amplified band should result, or perhaps two bands if both alleles in the cell have undergone V(D)J rearrangement using different J regions. DNA from a mixed B cell population usually produces a "ladder" of bands, each corresponding to rearrangements of a different J region. No amplification product would be expected from germline DNA, because before recombination the primer sequences lie too far apart to allow efficient amplification.

How Recombination Contributes to Diversity

The V assembly recombination contributes in two significant ways to the diversity of antigen binding specificities. First, because there are multiple germline V regions and multiple D and J regions, the number of possible combinations of VL, JL, VH, DH, and JH is the multiplication product of the numbers of each of these five classes of germline sequence elements. This repertoire is vastly larger than could be achieved by devoting the same total lengths of DNA sequence to preassembled V regions. A second factor that increases diversity was recognized by comparing nucleotide sequences of various myeloma genes to their germline precursors. For example, as shown in

Figure 6.2A, a comparison between the Vκ gene expressed in the murine myeloma MOPC41 and the corresponding germline Vκ and Jκ genes shows that the myeloma gene matches the germline precursor through the second nucleotide of codon 95; the VJ recombination junction occurs exactly at this point, because sequence beyond this position in the myeloma gene clearly derives from Jκ1. Similar analyses of other myelomas reveal that the recombination junctions can occur at several different positions within codon 95 or 96. As shown in Figure 6.2B, this "flexibility" of the position of the recombination junction increases the diversity of the affected codons. Heavy chain V regions exhibit this imprecision at both VD and DJ junctions. In addition, many heavy chain VDJ junctions (and a smaller percentage of light chain VJ junctions) contain insertions of a few extra nucleotides not present in the germline precursors; the mechanism of these insertions—known as N regions—is discussed later in this chapter. Significantly, the three-dimensional structure of immunoglobulins established from X-ray crystallography reveals that the VL-JL junction and the VH-DH-JH junction both form one of the three "complementarity determining region" loops (CDR3) that can contact antigen; thus this junctional diversity is functionally relevant for diversifying antigen binding.

The imprecision of V(D)J recombination increases Ig diversity, but at a cost. Because the precise boundaries between V, D, and J result from independent stochastic events (discussed later), only about one third of recombination events maintain the correct reading frame between V and J. In myelomas with rearrangements on both allelic copies of an immunoglobulin gene locus, the unexpressed recombination is generally out-of-frame or "nonproductive." For
FIGURE 6.3 Conserved elements flank germline V, D, and J region genes. Conserved heptamer and nonamer RSSs lie adjacent to V, D, and J coding sequences and are important for targeting V(D)J recombination. The heptamer and nonamer elements are separated by spacer regions of about 12 bp (illustrated by thin lines in the figure) or 23 bp (thick lines). Depending on the locus, V regions may be flanked by 12 bp or 23 bp RSS, and similarly for J regions. But one of each type of element must be present for recombination to occur, a requirement that prevents futile recombination events (e.g., J to J).

heavy chain VDJ recombination, one could theoretically retain the correct reading frame between V and J while allowing the interposed D region segments to be used in all three reading frames; human B lymphocytes exploit this extra diversity *(2)*. In murine heavy chains, however, only a single D region reading frame is generally expressed, and several mechanisms prevent expression of antibodies with D regions in the other two reading frames (3).

Recombination Signal Elements

Analysis of DNA sequences flanking the germline V, D, and J region sequences revealed two conserved sequence elements that have subsequently been shown to define targets for V(D)J recombination: a heptamer adjacent to the coding sequence and a more distal nonamer. (These sequences are diagrammed in Figure 6.3.) For example, in the κ locus the consensus heptamer CACTGTG occurs 5′ of the Jκ coding sequences, with its (reverse) complement CACAGTG appearing 3′ to Vκ coding sequences. The consensus nonamer GGTTTTGT appears about 23 nucleotides 5′ of the Jκ heptamer, and its complement ACAAAAACC appearing about 12 nucleotides 3′ of the Vκ heptamer. Similar sequences flank Vλ and Jλ, as well as VH, DH, and JH (as shown in Figure 6.3). These "recombination signal sequences" (RSSs) have been shown to be critical in the recombination, serving as recognition sequences for the recombination activating gene proteins RAG1 and RAG2, as discussed later in this chapter. Similar RSSs are present flanking light and heavy chain Ig genes throughout phylogeny, as well as in T cell receptor genes (see Chapter 8), which undergo similar V assembly recombinations. In all of these systems, the length of the spacer between the heptamer and nonamer (Figure 6.3) appears significant. Recombination apparently occurs almost ex-

clusively between one coding sequence associated with a ~12 bp spacer and another coding sequence with a ~23 bp spacer, a requirement referred to as the "12/23" rule. This requirement may serve to prevent futile recombinations, such as between two Vκ or two Jκ gene segments. Although the heptamer and nonamer are the primary elements necessary for V(D)J recombination, a computerized alignment of several hundred spacer sequences has detected some preferred nucleotides at specific positions *(4)*, and different spacer sequences can affect recombination frequency *(5)*. For example, when T cells rearrange Vβ, Dβ, and Jβ regions, direct Vβ to Jβ rearrangements (omitting Dβ) would be consistent with the 12/23 rule, but are largely prevented by specific features of the Dβ RSS and spacer, a restriction known as "beyond 12/23" (reviewed in ref *[6]*).

After the DNA is cut by the RAG proteins, the two coding ends (e.g., V and J) undergo several processing steps and are eventually ligated together to create the assembled V gene; the two RSS ends are also joined, generally creating a circular DNA "excision product," as discussed later.

THE THREE IMMUNOGLOBULIN GENE LOCI

This section presents an overview of the three immunoglobulin loci (heavy chain, κ, and λ), mainly considering C regions. The V regions of these loci are described later in this chapter in the section on germline diversity.

Heavy Chain Genes

Murine and human genomic clones encoding constant region heavy chain (CH) genes include separate exons encoding the ~100 to 110 amino acid Ig domains that were

independently identified by internal homologies of amino acid sequences and by three-dimensional structural analysis (X-ray crystallography); these exons are separated from each other by introns of roughly 0.1 kb to 0.3 kb. Thus, for example, the mouse $\gamma2b$ protein has three major domains (CH1, CH2, and CH3) with a small hinge domain between CH1 and CH2. The gene structure may be summarized:

CH1—intron—**hinge**—intron—**CH2**—intron—**CH3**
(292) (314) (64) (106) (328) (119) (322)

where the numbers in parentheses represent the number of nucleotides in each segment. As an interesting contrast, the hinge region of the α gene is encoded contiguously with the CH2 domain with no intervening intron, while the unusually long human $\gamma3$ hinge is encoded by three or four hinge exons.

About 7 kb upstream from the murine $C\mu$ gene lies a cluster of four JH segments that participate in VDJ recombination (the human locus has six JH segments). Further upstream lie 13 D segments (about 27 in human) and beyond them the VH regions.

Genomic Organization of CH Gene Loci

Each B lymphocyte initially produces IgM by expressing an assembled V region with $C\mu$, but may use CSR to replace $C\mu$ with one of the several CH regions lying downstream, thereby allowing expression of IgG, IgA, or IgE (Figure 6.4A). These downstream CH genes were cloned by a variety of investigators, and all eight murine CH genes—spanning about 200 kb of DNA on chromosome 12—were linked by contiguous clones in 1982 (7) as shown in Figure 6.4B, where the numbers indicate the approximate distance in kilobases between the genes. All the CH genes are oriented in the same 5′-3′ direction. Several γ pseudogenes lie within the clustered γ genes (8).

The human CH genes were similarly cloned, and then eventually completely linked by the Human Genome Project. The human IgH locus contains a large duplication, with two copies of a γ-γ-ε-α unit separated by a γ pseudogene (Figure 6.4B). One of the duplicated ε sequences is also a pseudogene in which the CH1 and CH2 domains have been deleted. In addition, the human genome contains a third closely homologous ε-related sequence—a "processed" pseudogene retroposed to chromosome 9. The map presented in Figure 6.4B also indicates several known deletions in the human heavy chain locus. The sequences of the entire human and mouse IgH loci are now available online at www.ncbi.nlm.nih.gov.

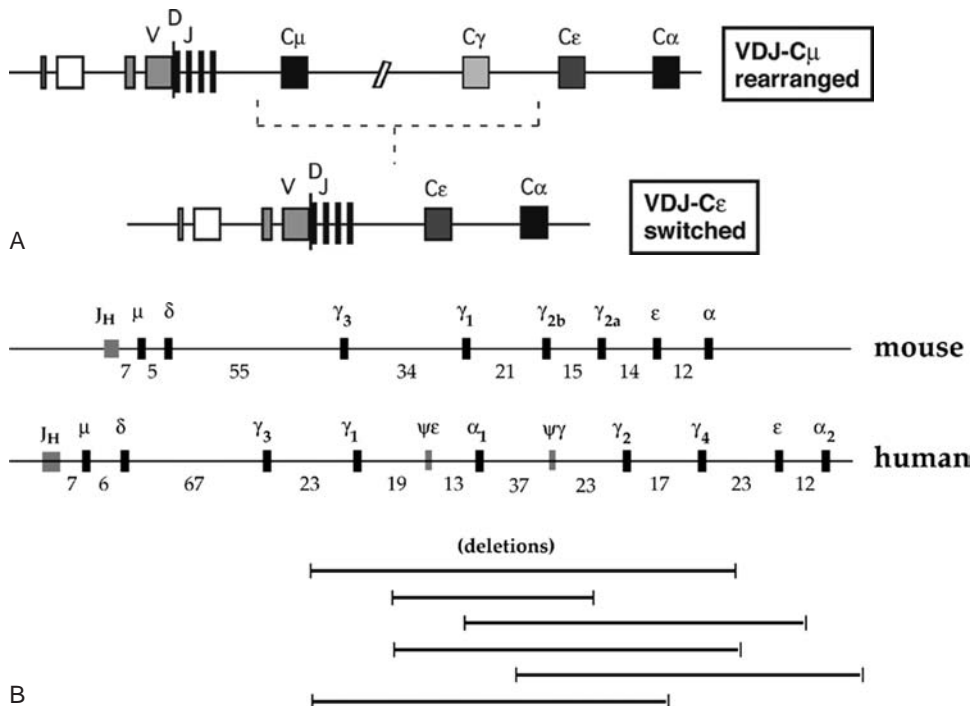
The IgH locus has also been examined in several other species besides mouse and human, and several notable differences have been observed. Rabbits, for example, have 13 $C\alpha$ sequences and only a single $C\gamma$ gene (9); this unusual expansion of genes contributing to mucosal immunity may be related to the peculiar habit of coprophagy in these animals. In contrast to the multiplicity of rabbit $C\alpha$ genes, pigs have only one $C\alpha$ gene and eight $C\gamma$ genes. Camels are unusual in having heavy chains that function in the absence of light chains (10). Heavy chain Ig genes (VH or CH) have been cloned from a number of other species, including rat (which is highly homologous with mouse), cow, dog, chicken, horse, shark, bony fish, crocodile, frog, and axolotl.


FIGURE 6.4 Deletional isotype switch recombination. **A:** The expression of "downstream" heavy chain genes is accomplished by a recombination event that replaces the $C\mu$ gene with the appropriate heavy chain C gene ($C\varepsilon$ is shown as an example), deleting the DNA between the recombination breakpoints. **B:** The murine and human heavy chain constant region genes are diagrammed with the approximate intergene distance indicated below (in kb); various literature values for these distances differ somewhat, possibly due to allelic polymorphisms. The human locus shows a large duplication of γ-γ-ε-α sequences. Deletions observed in various human alleles are shown below the map of the human locus.

Membrane vs. Secreted Ig

Studies of IgH gene and cDNA structure have provided an explanation for how a single heavy chain gene can encode both the soluble form of the H chain secreted by plasma cells and the alternative membrane-bound immunoglobulin displayed as BCR on the surface of B cells. The membrane-bound Ig H chains are slightly larger than the secreted forms owing to an additional C-terminal hydrophobic segment that anchors the protein in membrane lipids. In the case of the μ chain, the membrane and secreted forms are products of two different mRNAs of 2.7 kb and 2.4 kb, which can be separated by gel electrophoresis. Sequence comparisons between a genomic μ clone and μ cDNA clones corresponding to these two RNA species demonstrated that the two RNAs represent transcripts of the identical gene that have been spliced differently at their 3′ or C-terminal ends (Figure 6.5). The nucleotide sequence encoding the 20 C-terminal residues of the secretory (μs) form is derived from DNA contiguous with the CH4 domain of the μ gene, whereas in the membrane mRNA (μm), the sequence following CH4 derives from two exons (M1 and M2) lying about 2 kb further 3′. These membrane exons encode 41 residues, including a stretch of 26 uncharged residues that span the membrane to stabilize the Ig in the cell membrane. The same general gene structure has been found for the other CH genes, suggesting that the differential splicing mechanism accounts for the two forms of Ig of all isotypes.

Early B cells make roughly similar quantities of both μm and μs, whereas maturation to the plasma cell stage is associated with strong predominance of μs production, facilitating high-level secretion of circulating Ig. The balance between the two RNA splice forms of μ has been interpreted as a competition between CH4-M1 splicing versus the cleavage/polyadenylation at the upstream μs poly(A) addition site. These processes are mutually exclusive because CH4-M1 splice removes the μs poly(A) site, while cleavage at the μs poly(A) site removes the membrane exons. The cis elements influencing the balance between these processes have been studied by transfecting either early or late B cells (or nonlymphoid cells) with μ gene sequences or constructs in which the splice sites, coding exons, or cleavage/polyadenylation sites have been mutated, placed different distances apart, or replaced with other sequences.

The μm poly(A) site appears to be intrinsically more active than the μs poly(A) site when tested in separate plasmids, and some evidence suggests competition between these sites *(11,12)*. Their relative usage is influenced by cis-acting sequences near the μs poly(A) site of the RNA, including a hexamer polyadenylation signals (AAUAAA) upstream of the μs poly(A) addition site and GU-rich sequences downstream of the site *(12)*. The binding of a cleavage stimulator factor CstF64K to GU-rich sequences can apparently stimulate the strength of the μs poly(A) site, because the μs/μm ratio was increased when CstF64K was artificially increased in a B cell line (13). The binding of this protein to the μs GU-rich sequences may be suppressed prior to the secretory stage of B lymphoid development by inhibitory factors. One such inhibitor is the U1A protein, which binds to the RNA and prevents both CstF64K binding and μs poly(A) site cleavage *(14,15)*. A reduction in the level of free U1A fraction during maturation to secretory plasma cells apparently releases the μs poly(A) site from the block in CstF64K binding and allows RNA cleavage at that site *(16)*. The shift to μs expression has been found to require the activity of the "master regulator" of plasma cell differentiation Blimp-1 (B lymphocyte–induced maturation protein-1; discussed in Chapter 7) *(17)*. Cis-acting sequences affecting the ratio of alternative splice forms have been described for other isotypes besides Cμ, particularly Cα (18).

Membrane Ig serves as the antigen-specific component of the BCR that is critical for initiating the signal for lymphocyte activation following contact with antigen, as described in Chapter 8. The segments of membrane immunoglobulins (of all isotypes) that penetrate into the cytoplasm are too short to encode functional signal transduction domains. Instead, transduction is mediated by an associated protein dimer composed of the
FIGURE 6.5 Two RNAs generated from the μ gene by alternative processing. The top line illustrates the exons of the μ gene (black rectangles) in an expressed, rearranged μ gene. A primary transcript including all the exons present in the DNA can be processed as shown to yield either μs RNA (containing a C-terminal "secreted" [S] sequence) or μm RNA (containing the two membrane [M] exons).

BCR components Ig-α and Ig-β (CD79a and CD79b) whose cytoplasmic domains contain immunoreceptor tyrosine-based activation motifs (ITAMs) similar to those found in the CD3 chains mediating T cell receptor (TCR) signaling. The Ig-α-Ig-β dimer also plays important signaling roles during B cell development before the mature BCR is assembled, as discussed later in this chapter.

Kappa Light Chain Genes

In comparison to the heavy chain genes, the κ locus is relatively simple. A single Cκ gene with a single exon and no reported alternative splice products is found in both mice and humans. Upstream of the murine Cκ gene lie the five Jκ gene segments mentioned earlier, spaced about 0.3 kb apart. The third of these Jκ segments encodes an amino acid sequence never observed in κ chains and is believed to be nonfunctional owing to a defect in the splice donor site that would join the corresponding RNA sequence to Cκ. The human locus is quite similar, with five functional Jκ regions upstream of Cκ. Upstream of the Jκ segments in both species are the Vκ genes, which will be described later in this chapter.

Apart from Vκ-Jκ rearrangement, an additional recombination event occurs uniquely in the κ locus, apparently mediated by the same heptamer/nonamer signal elements involved in V(D)J recombination. This event, which involves deletion of the Cκ gene segment, was initially suggested by the observation that Southern blots of DNA from λ-expressing human lymphoid cells generally show no detectable Cκ sequence *(19)*. Apparently in most B cells the Cκ genes are deleted from both chromosomes before λ gene rearrangement begins. When the boundaries of the deleted segment of DNA were examined in several human and mouse cell lines, a common sequence element was found at the downstream boundary; this element was designated RS (recombining sequence) in the mouse studies *(20)* and kde (kappa deleting element) in the human studies *(21)*. The human kde in germline DNA is located 24 kb downstream of the Cκ gene and is flanked by a heptamer/nonamer RSS similar to that found flanking the Jκ regions—that is, with a 23 bp spacer. The similar murine RS is about 25 kb downstream from murine Cκ. The kde element can apparently recombine either with a Vκ gene segment (leading to a deletion of the entire Jκ-Cκ locus) or with an isolated heptamer element that is located in the Jκ-Cκ intron (leading to deletion of Cκ but retention of the Jκ locus). The heptamer in the Jκ-Cκ intron is 30 bp 5′ from a poorly conserved nonamerlike sequence, a spacing that seems to violate the usual 12/23 rule. The significance of this unusual spacer is not understood, but possibly the heptamer in these recombinations is active without a functional nonamer, as seems to be the case for secondary VH recombinations (discussed in a later section).

Lambda Light Chain Genes

Murine λ Locus

In laboratory mouse strains, λ chains represent only about 5% of L chains, and this diminished abundance is associated with remarkably meager diversity. In contrast to the κ system with its multiple V region families, amino acid sequence analysis of monoclonal λ chains detected only two sequences that appeared to represent germline Vλ regions. Further, in contrast to the single mouse Cκ region, three nonallelic mouse Cλ isotypes are known from secreted λ chains; these are designated λ1, λ2, and λ3, in decreasing order of abundance.

Complete sequence analysis *(22)* (Figure 6.6) of the murine locus reveals four Cλ genes, each with its own Jλ region gene located about 1.3 kb 5′ of the C. The J-Cλ2 and J-Cλ4 genes are arranged in one cluster about 3 kb apart with the Vλ2 gene lying about 60 kb upstream. (At the 3′ end of Jλ4 a mutation has destroyed the "GT" found at almost all known "donor" splice sites, so that an RNA transcript of this gene would not be properly processed, reminiscent of the mouse Jκ3.) A second Cλ cluster lying about 110 kb downstream of the Cλ2-Cλ4 locus contains J-Cλ3 and J-Cλ1. The gene order (V2-Vx-JC2-JC4-V1-JC3-JC1) explains the common expression of Vλ2 (or Vx) in association with Cλ2, and Vλ1 with Cλ1 or Cλ3. The Vλ2 has been found in rare association with the Cλ1 locus, which lies 180 kb downstream in the germline; but the "backward" recombination of Vλ1 with Cλ2 has not been observed. The similarities between the four J-C genes suggest that the two clusters arose by a duplication of an ancestral V-J-Cλx-J-Cλy unit that in turn was the result of a prior J-Cλ duplication event. The ancestry of the Vx gene is uncertain, as this gene is rather dissimilar to the other Vλ genes; indeed it resembles Vκ as much as Vλ. Anti-Vλx antisera detect expression of this Vλ in all laboratory mice tested, but it may have a particular restricted function. Analyses of λ genes in wild mice by Southern blotting have indicated more complex and varied loci than that seen in typical laboratory strains.

The Jλ gene segments are all flanked on their 5′ side by sequences similar to the nonamer and heptamer signal elements observed in the heavy chain and κ system. The 12/23 rule discussed in relation to spacing between the signal elements applies as well to λ, but in the λ locus the RSS elements are spaced about 23 bp apart for V regions and about 12 bp apart for J regions (the opposite of the arrangement in κ genes) as shown in Figure 6.3. The decreased abundance of λ2 and λ3 relative to λ1 may be related to discrepancies between their nonamer homology elements and the consensus nonamer element.

Human λ Locus

Lambda L chains are much more abundant in man than in mouse (about 40% of human light chains versus about 5% in mouse). Four forms of human λ chains have been
FIGURE 6.6 Germline λ genes. The maps in this figure are schematic, i.e., not to scale. A. The murine λ gene system includes four JC complexes and three V genes as shown. B. The human λ locus includes multiple V genes, of which only three are shown. The human VpreB "surrogate" light chain gene is located within the Vλ cluster. The Cλ locus includes a segment of seven JC complexes plus three additional unlinked sequences. The hatched JC complexes diagrammed above the seven linked λ sequences represent polymorphic variants with additional duplications of the JC unit. The 14.1 sequence—the human λ5 "surrogate" light chain homolog—lies downstream of the JC cluster. Exon 1 of the 14.1 gene is homologous to an exon upstream of Jλ1 (as indicated by the unlabeled white rectangle).

characterized serologically, with differences residing in a small number of amino acids in the constant region. The serological classification of Kern$^+$ depends on Gly at position 152 versus Ser in Kern$^-$. The Oz$^+$ designation depends on Lys at #190 vs. an Arg on Oz$^-$. And Mcg$^+$ λ chains (versus Mcg$^-$) have Asn112 (versus Ala), Thr114 (versus Ser) and Lys163 (versus Thr).

Seven human Jλ-Cλ segments are clustered within an approximately 33 kb region of DNA. As shown in Figure 6.6, genes for four major expressed human λ isotypes have been localized within the major cluster and correspond to JCλ1, JCλ2, JCλ3 and JCλ7. JCλ7 was originally interpreted as encoding the Kern$^+$Oz$^-$ serologic form of λ, but more recent data suggest that the latter is an allele of Cλ2, and that JCλ7 encodes an isotype provisionally designated Mcp (23). The other three homologous J-C segments found in most haplotypes are apparently pseudogenes, with either in-frame stop codons or frame-shifting deletions. However, JCλ6 may be functional in some individuals, and the common allele—which has a 4 bp insertion leading to a deletion of the C-terminal third of the Cλ region—can nevertheless undergo Vλ-Jλ recombination, encoding a truncated protein that can associate with heavy chains. A variety of polymorphic variants of the human λ locus have been detected, apparently the result of gene duplication; as shown in Figure 6.6, one to three extra λ segments have been detected on Southern blots of human DNA, and some have been sequenced (24).

Three Cλ-related sequences have been discovered near the major Jλ-Cλ cluster. One of these, designated λ14.1, represents the human homolog of the murine "surrogate" light chain λ5 (see below). Finally, an additional weakly hybridizing DNA segment outside the linked cluster has been characterized as a "processed" pseudogene. V genes of the human λ system have been completely characterized, as discussed in a later section.

λ-related "Surrogate" Light Chains

In mature B cells, Ig heavy chains cannot reach the cell surface if light chain synthesis is interrupted. However, immunoglobulin μ heavy chains can be detected on the surface of pre-B cells that do not make light chains. In these cells a "surrogate light chain" (SLC) composed of two smaller proteins facilitates the surface expression of μ protein. One component of SLC was identified as the product of a gene expressed exclusively in pre-B cells that showed high sequence similarity to the J and C regions of the λ locus. It was designated λ5, because four murine Cλ genes were already known *(25)*. The genomic λ5 gene includes three exons: exon 1, which appears to encode a signal peptide; exon 2, whose 3′ end is homologous to Jλ; and exon 3, homologous to Cλ. The second component of SLC was found as a transcribed segment about 4.7 kb 5′ of λ5 in the mouse genome. Sequence analysis of the latter region revealed similarities to both Vλ and Vκ; for this reason (and because of its expression in preB cells),

it is called VpreB1. A second, nearly identical sequence in the mouse genome is named VpreB2 and appears to be functional *(26)*, and a less similar VpreB3 has also been described. Neither λ5 nor VpreB genes show evidence of gene rearrangement in B or pre-B cells. Both genes appear functional, and homologs have been found in every mammalian species examined.

The two SLC proteins have been found to associate with μ heavy chains to permit surface μ expression prior to the availability of light chains. Thus, when a μ heavy chain gene was transfected into an Ig-negative myeloma line, no surface μ expression was observed unless λ5 and VpreB genes were also transfected *(27)*. The surface μ chains were found to be covalently linked to the 22 kD product of the λ5 gene, while the 16 kD VpreB product was noncovalently associated. A similar complex is observed in pre-B cell lines and in normal bone marrow pre-B cells. The V-like VpreB gene product apparently associates with the Cλ-like λ5 product to form a light-chain-like heterodimer that is able to fulfill some functions of a true light chain.

One likely role for a μ-SLC complex is suggested by the observation that most Vκ-Jκ recombination occurs only in cells expressing a functional μ heavy chain; apparently μ-SLC expression on the cell surface can trigger the onset of Vκ-Jκ rearrangement. Evidence for this view comes from experiments in which a pre-B line that normally does not rearrange its κ locus was transfected with a construct encoding the membrane form of μ heavy chain (28); when the transfected μ gene was expressed in a complex containing VpreB and λ5, Vκ rearrangement was induced.

As mentioned earlier, three λ5-like sequences are located downstream of the human Cλ cluster on chromosome 22 (Figure 6.6), but only one—designated 14.1—appears to be functional, possessing the three-exon structure of λ5. The human VpreB homolog lies within the Vλ cluster *(29)*, in contrast to murine VpreB, which lies close upstream of λ5.

V GENE ASSEMBLY RECOMBINATION

The mechanism by which germline variable region constituents (VL and JL, or VH, D, and JH) assemble in the DNA to form a complete active V gene has been pursued ever since Ig gene recombination was first discovered. In this section we will address (1) the topology of the recombinations from a macro viewpoint, (2) the components of the recombinase machinery (a micro view), and (3) the regulation of that machinery in B cell development.

Topology of V Assembly Recombination

Deletion vs. Inversion

For V segments and J segments oriented in the same direction of transcription, the DNA between the recombining V and J segments can be simply deleted and religated as
FIGURE 6.7 The same "micro" mechanism of recombination can join Vκ and Jκ by deletion or inversion, depending on the relative orientation of the two precursors in germline DNA. **A:** When V coding sequence (shaded rectangle) and J coding sequence (white rectangle) are oriented in the same 5′→3′ direction in germline DNA (as indicated by the internal arrowheads), the recombination yields a VJ coding joint plus a DNA circle containing the signal joint (apposed triangles). **B:** If V is oriented in the opposite direction in germline DNA then an identical recombination reaction at the "micro" level (inside shaded circle) leaves the signal joint linked to the recombined VJ coding joint.

an excision circle, as described previously (and illustrated in Figure 6.7A). Such a DNA circle would not be attached to the main chromosome and, failing to replicate, it would be diluted out as cells divide after V(D)J recombination. Such circles are therefore generally absent in B lineage cell lines and in mature B lymphocytes that have undergone several rounds of proliferation after Ig expression. By isolating circular DNA from cells actively undergoing Vκ-Jκ rearrangement it has been possible to clone the predicted circular molecules bearing signal joints *(30)*. More recent experiments have used PCR to detect signal joints, especially those generated by V(D)J recombination of T cell receptor genes; a high content of TCR excision circles (TRECs) in a population has been interpreted as reflecting "recent" V(D)J recombination with relatively little subsequent proliferation (31).

However, some Vκ genes (both mouse and human) are oriented in the opposite direction from the Jκ-Cκ region, a topology that causes the VJ recombination to occur by an inversion of the DNA between the recombining V and J segments (Figure 6.7B), leaving both RSS heptamers retained on the chromosome. The same recombinase machinery can presumably rearrange the germline elements by either inversion or deletion—depending on the relative orientations of the sequences—because this enzymatic machinery "sees" only the DNA in the immediate vicinity of the recombination site (circled in Figure 6.7) and is insensitive to the topology of the DNA strands far from this site. Indeed retained "signal joints" (also known as "flank

products" and "reciprocal joints") have been detected in several cell lines.

In contrast to the κ system, in the heavy chain or λ loci, there is no evidence for inverted V genes or retained signal joints, so these loci apparently recombine only by deletion (and this is also true for all the TCR gene loci).

Nonstandard Joints

Investigations of V(D)J recombination have documented several "nonstandard" recombination joints, which, though not contributing to physiological V gene assembly, may reflect features of the recombination mechanism *(32)*. These nonstandard joints can be understood by appreciating that there are three topologies in which DNA that has been cut twice—generating four ends—can be rejoined. If the four ends are coding (V), signal (V), signal (J), and coding (J), the three possibilities can be defined by considering the three different ends that may join to the coding (V) end (assuming that the remaining two ends must join to each other). The possibilities are

coding(V)-coding(J) plus signal(V)-signal(J)

This is the standard reaction product in which the coding(V)-coding(J) product encodes the assembled VJ gene and the signal(V)-signal(J) represents the signal joint.

coding(V)-signal(V) plus signal(J)-coding(J)

These products (i.e., open and shut joints) look like the starting DNAs, but can be distinguished from them if nucleotides have been added or deleted at the junctions so that they no longer hybridize to oligonucleotide probes specific for the coding/signal junction.

coding(V)-signal(J) plus signal(V)-coding(J)

These are "hybrid joints," in which the signal ends have switched places.

Hybrid and open and shut joints have been observed to form both in transfected plasmids bearing RSSs *(32)* and in endogenous immunoglobulin loci in vivo *(33)*.

Secondary Recombinations

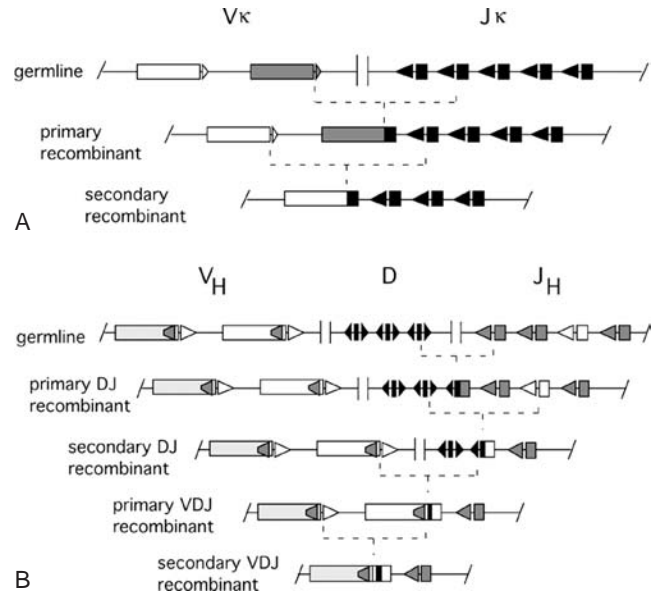
As discussed in an earlier section, the imprecision of VJ or VDJ joining causes nonproductive, out-of-frame junctions in about two thirds of recombination products. A B lymphocyte that rearranged its κ genes nonproductively on both parental chromosomes might be thought to have no further avenue for making a functional light chain, but the availability of upstream Vκ genes and downstream Jκ segments could allow additional recombinations to occur as shown in Figure 6.8A. More complex events are possible as a consequence of the inverted orientation of some Vκ genes. The occurrence of such secondary recombinations has in fact been reported for κ genes and would be implied by the recovery of a chromosomal signal joint that is


FIGURE 6.8 Secondary recombinations. **A:** In the κ light chain system, a primary recombination can be followed by recombination between an upstream V and a downstream J. **B:** Analogous secondary recombinations can occur in the heavy chain system between upstream D and downstream J segments. After VDJ recombination eliminates all "short spacer" signal elements from the chromosome, secondary recombination can still occur between VH (long spacer signal) and an internal heptamer within the VH coding sequence of the VDJ unit.

not reciprocal to a coding joint in the same cell. The preponderance of Jκ1-derived nonreciprocal flank products observed in myelomas may result from initial nonproductive recombinations between this J segment and inverted V genes, followed by successive recombinations involving more downstream J segments; by the time a productive rearrangement occurs, many myelomas will carry signal joint relics of earlier recombinations involving Jκ1. Secondary recombination may also occur in cells that have assembled a productive VκJκ joint if the resulting VH-VL pair recognizes an autoantigen. This type of secondary recombination, known as "receptor editing," is considered in more detail later in this chapter.

For H chain genes, secondary D-J rearrangements should be possible before VH-D recombination removes unrearranged upstream DH segments (Figure 6.8B), and indeed this has been shown to occur. Even though VDJ rearrangement must eliminate all the 12 bp-spaced signal elements from the VH locus, upstream germline VH genes can sometimes recombine with an established VDJ unit, displacing most of the originally assembled V gene *(34)*. This type of recombination (sometimes called *VH replacement*) is apparently mediated by a heptamerlike sequence that appears near the 3' end of the coding region in about 70% of VH genes (Figure 6.8B). The internal heptamer is not generally found in light chain genes. After VH

replacement, the few nucleotides remaining from the originally assembled VH could potentially contribute to diversity; such nucleotides would be difficult to distinguish from N-region nucleotides. Secondary recombination, thus, represents an escape mechanism for cells with nonproductive rearrangements on both heavy chain chromosomes, or, as alluded to earlier, for cells whose antibody can interact with an autoantigen. The fact that the isolated heptamer is apparently able to function in VH replacement recombinations without an associated nonamer implies that the heptamer is the more critical recombination signal, although it has been suggested that in VH regions an additional consensus sequence upstream of the internal heptamer may contribute to VH replacement recombination *(35)*.

Mechanism of V Assembly Recombination

As mentioned earlier, the same recombination machinery mediates all four types of immunoglobulin V gene assembly recombinations (Vκ-Jκ, Vλ-Jλ, VH-D and D-JH) as well as similar recombinations in the four TCR gene loci; this fact has allowed investigators to pool mechanistic knowledge from studies of B and T cell systems. However, the assumption of a common recombinase raises the question of how B cells preferentially rearrange Ig genes (and T cell TCR genes) when both gene systems are present in both cell lineages. This issue will be addressed later in this section.

Recombination Model Overview

A model for the detailed mechanism of the recombination event must account for the observed features of the recombination products—that is, the coding and signal joints—and of their germline precursors. In the germline precursors, the heptamer and nonamer RSS with appropriate spacing (12 bp and 23 bp) are necessary and sufficient to create efficient recombination targets; model substrates containing these elements are competent to undergo recombination even in the absence of normal V, D, or J coding regions. However, the efficiency of recombination can be influenced by features of the sequences replacing the coding regions. In the recombination products, the features of the signal joints are relatively simple: the RSS heptamers are joined "back-to-back," with only rare nucleotide additions or deletions. The features of the coding joints are more complex, due to the imprecision discussed earlier: (1) A variable number of bases are deleted from the ends of the coding regions (in comparison to the "complete" sequence in the germline precursor). (2) Nongermline nucleotides (N regions) unrelated to the germline precursor sequences are added in some coding joints; these are generally rich in G and C nucleotides. (3) Less frequently, extra bases are added that can be interpreted as "P" nucleotides; these are nucleotides that are joined to the end of an undeleted coding sequence and that form a palindrome (hence the P) with the end of that

sequence (36). P nucleotides are generally only one or two base pairs, but they can be longer, especially in mice with the SCID (severe combined immunodeficiency defect) disorder.

The model shown in Figure 6.9 can serve as a framework for discussion of the recombination mechanism. The
FIGURE 6.9 Model for V assembly recombinations. All V assembly recombination reactions (in Ig and TCR genes) may proceed by a common mechanism, illustrated here by D-J recombination. The RSS sequences are included in triangles, which is the conventionally used RSS graphic. Hairpin loops are created on coding ends dependent on the action of RAG1 and RAG2. After the opening of the hairpin loops the pictured D coding sequence shows the effects of "nibbling" by exonuclease but the J coding sequence is spared and shows P nucleotide generation; N region addition is pictured in this example as occurring only on the D region end. In reality, exonuclease digestion and N nucleotide addition can occur on either (or both) ends. The steps in the proposed mechanism are discussed in the text.

recombination is thought to begin with binding of the RAG1 and RAG2 proteins to the heptamer-nonamer RSS adjacent to the two segments to be recombined. Both DNA segments are then cleaved at the border of the two heptamers, and the two heptamer ends are joined together without modification. In contrast, the ends bearing the coding sequences form transient "hairpin" loops, which are then nicked open and digested to varying extents by an exonuclease activity. Recessed DNA strands may be lengthened with complementary nucleotides by a DNA polymerase, and a variable number of untemplated nucleotides may be added to the 3′ ends through the action of terminal deoxynucleotide transferase (TdT). Then the ends are ligated together, completing the recombination event.

Recombination Intermediates: Blunt Signal Ends, Hairpin Coding Ends

To study broken DNA ends as intermediates in V(D)J recombination, several labs have employed ligation-mediated PCR (LM-PCR) to detect signal ends. This technique involves ligating blunt genomic DNA ends with a double-stranded oligonucleotide, followed by amplification extending from a primer sequence near the genomic signal end to the ligated oligonucleotide sequence; amplified products can then be cloned and their sequence determined. LM-PCR analyses of both TCR and Ig genes have defined the signal ends as blunt-ended cuts, usually exactly at the heptamer border, leaving 5′ phosphate and 3′ hydroxyl groups *(37)*.

Even with less sensitive Southern blot assays, signal ends were detectable in cells undergoing intensive V(D)J recombination (e.g., thymus DNA rearranging TCR genes), but in these experiments the coding ends could not be visualized at all, perhaps because of rapid processing of these ends into coding joints. Based on the known defect of SCID lymphocytes in forming coding joints, Roth et al. (38) reasoned that SCID thymocytes might accumulate the cut coding ends that could not be visualized in normal thymocytes. Indeed, coding ends were detected in the SCID thymocyte DNA and, moreover, were found to have several properties suggestive of a hairpinlike structure. First, the coding ends in SCID thymocyte DNA were resistant to exonuclease treatment. Further, restriction fragments bearing these *in vivo*–generated ends on one side were found to move on a denaturing electrophoresis gel as if they were twice as long as predicted from the size of the double-stranded fragment before denaturation. Finally, LM-PCR experiments failed to detect the coding ends unless they were pretreated with a single strand–specific endonuclease, consistent with the impossibility of ligation to a hairpin unless it were first opened. The sequences of LM-PCR products obtained after endonuclease treatment suggested that the hairpins contained the entire sequence of the coding element, usually without loss or gain of a single nucleotide (39).

These hairpin ends apparently represent normal V(D)J recombination intermediates that—in wild-type cells—are opened at variable positions within the hairpin loop by an endonuclease activity that is dependent on the normal allele of the SCID gene. P nucleotides could then result from opening the loop at an asymmetric position (Figure 6.9); this model would explain the absence of P nucleotides from coding ends that have been "nibbled" after opening of the hairpin. Unusually long P nucleotide segments observed in the rare coding joints assembled in SCID mice might then be interpreted as resulting from resolution of hairpins by nonspecific nicking enzymes that—unlike the exonuclease activity dependent on the normal allele of the SCID gene—do not focus on the hairpin loops but nick in variable positions in the double-stranded hairpin "stem" (38). Hairpins have also been found in a non-SCID B lymphoid line engineered to sustain a high level of κ gene recombination *(40)*.

RAG Proteins: Mediators of Early Steps in V(D)J Recombination

A major advance in the investigation of V(D)J recombination was the identification of two genes whose products are critical for this process in B and T lineages. In the pioneering experiments, Schatz and Baltimore (41) stably transfected fibroblasts with a construct containing a selectable marker whose expression was dependent on V(D)J recombination; as expected, no measurable recombination occurred in this nonlymphoid cell. However, when either human or murine genomic DNA was transfected into these fibroblasts, a small fraction of recipient cells stably expressed recombinase activity, activating the selectable marker. This suggested that a single transfected genomic DNA fragment was able confer recombinase activity in a fibroblast. (Presumably the fibroblast contained endogenous copies of the same genes, but their expression was repressed by mechanisms that could not repress the transfected genes.) After successive rounds of transfection and selection for recombinase activity, the critical genomic fragment was identified. This fragment turned out to contain two genes, designated RAG1 and RAG2. Both RAG1 and RAG2 are required for recombination; therefore, these genes would not have been discovered by this transfection technique if they had chanced to lie too far apart in the genome for both to be transferred on a single DNA fragment. The genes are notable for having no introns in most species (certain fish are exceptions) and for their close association and opposite transcriptional orientation in all species examined.

A crucial role for the RAGs in V assembly recombination was supported by the conservation of these genes in a variety of Ig-producing vertebrate species from man through shark. RAG1 and RAG2 are expressed together in pre-B and pre-T cells, specifically at the stages expressing V(D)J recombinase activity. Moreover, mouse strains in which either gene has been eliminated by homologous

recombination (gene "knockouts") have no mature B or T cells, as the result of abrogation of V(D)J recombination *(42,43)*. A subset of human patients with a SCID syndrome and no T or B lymphocytes have been found to have null mutations in RAGs *(44)*. Patients with less complete defects often have a complex of features (oligoclonal T cells, hepatosplenomegaly, eosinophilia, decreased serum immunoglobulin but elevated IgE) known as the Omenn syndrome, which can also be caused by defects in other genes involved in V(D)J recombination. The same RAG mutation can in different patients cause either Omenn syndrome or SCID, depending on unknown factors *(45)*.

Attempts to demonstrate activities of the RAG proteins on recombination substrates in vitro were initially hampered by poor solubility of the proteins, but functional analyses of truncated RAGs—using RAG expression vectors cotransfected into fibroblasts along with recombination substrate plasmids—revealed that surprisingly large segments of both proteins could be deleted without eliminating recombinase activity; and some of the remaining core regions were soluble and could be handled relatively easily as fusion proteins. This work allowed the demonstration that in a cell-free *in vitro* system core regions of the two RAG proteins together are capable of carrying out cleavage of substrate DNAs as well as hairpin formation on the coding end *(46)*.

Murine RAG1 is a 1040-residue protein, with a central core (residues 384 to 1008) that includes all the known enzymatic activities of the whole protein as well as a nuclear localization signal. The protein exists as a dimer, which shows intrinsic binding affinity for the RSS nonamer sequence in the absence of RAG2. This binding is dependent on residues 389 to 486, known as the nonamer-binding domain (NBD). Mutational analysis has revealed regions of the protein necessary for binding to RAG2, as well as three amino acids critical for enzymatic activity: D600, D708, and E962 *(47,48)*.

Murine RAG2 is a 527-residue protein, with a core (residues 1 to 382) sufficient for activity. This protein has little intrinsic binding affinity for RSS elements, but improves the strength and specificity of RAG1 binding *(49)*. The binding of RAG2 also extends the nucleotide sequence over which DNA-protein interactions can be detected (by DNA footprinting or ethylation interference experiments) beyond the nonamer and into the heptamer *(50)*. In the presence of divalent cations, the two RAG proteins can form a stable signal complex with an RSS having a 12 bp spacer (12-RSS), but efficient complex formation with a 23-RSS requires the addition of a high-mobility group (HMG) protein, either HMG1 or HMG2 *(51)*. These abundant and ubiquitous proteins are known to bind DNA in a non–sequence-specific manner and to cause a local bend in DNA. They apparently facilitate RAG1/2 binding by stabilizing bending induced by the RAG proteins themselves *(52)*.

The RAG-induced cleavage occurs in two steps: first a nick occurs on one strand adjacent to the heptamer—the top strand as drawn in Figure 6.9; then the 3′ hydroxyl created at the nick causes transesterification by nucleophilic attack on the phosphodiester bond adjacent to the heptamer on the bottom strand (Figure 6.9), yielding a hairpin on the coding end and a new 3′hydroxyl on the 3′ end of the bottom heptamer strand *(53)*. RAG1 is apparently necessary for both steps, because some RAG1 mutants can nick at the heptamer efficiently but show impaired hairpin formation. After DNA cleavage, the RAG proteins remain in a complex with the DNA. RAG proteins likely facilitate steps beyond cleavage and hairpin formation, since mutant forms of RAG1 or RAG2 have been reported that are competent for cleavage but show impairment in coding or signal joint formation.

The activities of the RAG proteins are regulated by divalent ions in the medium *(54,55)*. In Mn^{++}, the RAG proteins catalyze cleavage of substrates with a single RSS, but in Mg^{++}, cleavage requires two RSSs and occurs most efficiently if the substrates conform to the 12/23 rule regarding the spacing between heptamer and nonamer elements. Thus, this rule may be enforced by the RAG proteins, though other proteins, including HMG1/2, seem to contribute to 12/23 specificity, perhaps by promoting an optimal molecular "architecture." *In vivo* experiments suggest that RAG proteins may bind to an RSS-12 and create a nick but do not complete DNA cleavage until an RSS-23 is captured *(56)*. Further, experiments using thymocytes undergoing TCRβ V(D)J recombination indicate that cleavage at one signal end does not occur unless a "partner" DNA segment with a compatible RSS is available *(57)*. These constraints would prevent creation of a potentially dangerous double-strand break (dsb) until DNA with a compatible RSS is present to complete the recombination.

In addition to the activities of RAG proteins on DNA segments containing RSSs, these proteins can act on several other "nonstandard" substrates:

(1) *In vitro*, core RAG proteins can catalyze the insertion of a DNA fragment with signal ends into foreign DNA, acting essentially like a transposase *(58,59)*. This transposase activity lends support to the early speculation that the V(D)J recombination system may have originated by insertion of transposonlike DNA fragment encoding RAG genes (and bearing RSSs at its ends) into a primordial V region, thereby separating J region sequence from the remainder of the V sequence upstream. This model is consistent with the many mechanistic similarities between V(D)J recombination and transposition (e.g., *[60]*), and the recent detection of RAG1 homologs in a transposon family found in of insect, echinoderm, helminth, coelenterate, and fungus genomes (61). (However, the recent finding of apparent homologs of both RAGs in a

sea urchin genome complicates the view that the two RAGs entered the vertebrate genome via a transposon [62].) The transposase activity may also be the cause of certain oncogenic recombinations *(63,64)*.

(2) As mentioned earlier, VH replacement recombination utilizes a nonconsensus RSS heptamer within VH coding sequences. An *in vitro* model suggests that in VH replacement, the RAG proteins nick on both DNA strands without forming a hairpin coding end (65).

(3) The RAG complex also generates two nicks in cleaving within the major breakpoint region (Mbr) of the Bcl2 gene. This 150 bp segment is the target of a common RAG-catalyzed translocation between the IgH locus and the Bcl2 gene that occurs in most follicular lymphomas. In this segment, there are no RSSs, and the RAG proteins recognize an unusual sequence-dependent DNA conformation different from the normal B-form double helix (66).

Although the "core" RAG proteins have been useful for studying the biochemistry of V(D)J recombination, it is clear that the "noncore" portions of each protein confer important functions, as expected from their sequence conservation across species. These functions have been inferred by studying *in vivo* recombination in cells carrying core RAGs versus full-length copies, and by *in vitro* studies using full-length RAG proteins solubilized by various techniques. The N-terminal region of RAG1 is required *in vivo* for optimal RAG1 activity and for the formation of precise signal joints in D-J recombination (67). The C-terminal region of RAG2 has multiple functions, many of which are conferred by a PHD (plant homeo domain) finger structure (68). This region is required for precise signal joints in both D-J and V-D recombination (67), for achieving normal numbers of B and T lymphocytes *in vivo (69)* and to protect against RAG-mediated DNA transposition *(70,71)*. The RAG2 C-terminus binds directly to all four histones, and point mutations that disrupt this interaction inhibit V(D)J recombination (72). Finally the RAG2 C-terminus regulates RAG2 protein levels across the cell cycle to prevent double-strand breaks during DNA synthesis or mitosis, when such breaks could lead to chromosomal deletions *(37)*. Although the RAG1 protein and mRNA transcripts of both RAGs vary little across the cell cycle, a specific phosphorylation at Thr490 of RAG2 by a cyclin-dependent kinase mediates its destruction via ubiquitination and proteasomal degradation during S phase (73). In RAG2 knockout (KO) mice carrying a transgenic RAG2 gene with an alanine replacing the phosphorylatable threonine, RAG2 protein and double-stranded DNA breaks were found throughout the cell cycle, demonstrating the importance of the RAG2 degradation signal in cell-cycle control of V(D)J recombination *(74)*.

Apart from the obvious importance of the RAG proteins in understanding the initial steps of V(D)J recombination, knowledge of these proteins and their genes has allowed two major technical advances that have opened the way to many additional experiments. First, several nonlymphoid cell lines with known defects in various DNA repair genes have been transfected with the RAGs to see whether these gene defects impair V(D)J recombination; these experiments have revealed several other proteins required for V(D)J recombination, as described later. The second major technical fall-out from the RAGs has been the availability of the RAG1 and RAG2 KO mice. These mice have no functional B cells or T cells and are not "leaky" like SCID mice, which develop some functional B and T cells, especially as the animals age. The RAG KOs can be used to study the importance of the "innate" immune system (i.e., responses that occur in the absence of antigen-specific lymphocytes) in particular immune responses. The KOs can be used as recipients for various lymphocyte subsets to explore the roles of different cell types. They can be used to study the signals for B cell development by introducing transgenes with specific functionally recombined immunoglobulin genes and characterizing the phenotypes of lymphocytes that develop (as discussed later). Finally, they can be used in "RAG complementation" experiments designed to assess the phenotype—in lymphocytes—of various other gene KOs (75). In RAG complementation, embryonic stem (ES) cells in which the gene of interest has been knocked out by homologous recombination are injected into homozygous RAG KO (RAG $^{-/-}$) blastocysts. This procedure yields chimeric mice in which all B and T cells derive from the ES cells deleted for the gene of interest, because these are the only source of intact RAGs to support lymphocyte development. Such animals can be made more easily than a KO mouse line and can be used to study the effect of gene deletion in lymphocytes independent of effects the deletion may have in other cells. In particular, for cases where the gene KO causes embryonic lethality due to effects on nonlymphoid cells, RAG complementation allows the selective KO in lymphocytes to be studied in the background normal gene expression in nonlymphoid cells.

Nonhomologous End Joining Components

The RAGs are the critical lymphocyte-specific participants in the first steps in V(D)J recombination (recognition of RSS, cleavage, hairpin formation, and perhaps hairpin cleavage), but additional components are required to complete the reaction. The other known components function not only in V(D)J recombination but also in the ubiquitous DNA repair pathway known as nonhomologous end joining (NHEJ), which is the major pathway for repair of double-strand DNA breaks (e.g., those induced by ionizing radiation or reactive oxygen species) during the G0-G1 phases of the cell cycle. (In the S and G2 phases, the additional chromatid genome copy enables breaks to be repaired by homologous recombination.) There are six classical components of NHEJ—Ku70, Ku80, DNA-PK,

XRCC4, ligase IV, and artemis—but additional proteins play a role in some models of NHEJ. Presumably these nonlymphoid-specific proteins are engaged in the postcleavage steps of V(D)J recombination.

The Ku Complex.   The first gene for an NHEJ component to be recognized as participating in V(D)J recombination was the SCID gene described earlier. This mutation was originally identified in a mouse strain that was immunodeficient as a result of a marked impairment in V(D)J recombination of both immunoglobulin and T cell receptor genes. SCID lymphocytes are able to perform the RAG-mediated reactions of cleavage and hairpin formation and can form signal joints, but are markedly defective in coding joint formation. Subsequently it was found that the SCID mutation also impairs NHEJ, causing radiosensitivity.

The gene mutated in the mouse SCID model encodes DNA-PK, a DNA-dependent protein kinase that is part of a heterotrimer known as the Ku complex. Originally described as the autoantigen recognized by a patient antiserum, Ku is composed of an approximately 70 kD protein (Ku70) and an approximately 86 kD protein (Ku86, often called Ku80). Together these two very abundant proteins form a heterodimer that can bind to DNA. The DNA-Ku complex can then recruit DNA-PK. (In an alternative terminology, the Ku-DNA-PK complex is designated DNA-PK, and the protein kinase is designated DNA-PK$_{CS}$ [catalytic subunit].) Ku genes are conserved in drosophila, yeast, and even bacteria, consistent with a function in NHEJ not restricted to V(D)J recombination. Targeted DNA-PK murine KO strains show a phenotype resembling the original SCID mutation (i.e., defective coding but not signal joint formation *[76,77]*). Ku80 mutant cell lines are defective in both signal and coding joint formation, and mice with a KO of the Ku80 gene are severely impaired in B and T cell development *(78)*. Cells with homozygous disruption of Ku70 are also defective in V(D)J recombination induced by RAG gene transfection *(79)*.

The Ku complex had previously been studied as an activity with an unusual DNA binding specificity: rather than recognizing particular nucleotide sequences, it recognizes topological features of DNA, particularly double-stranded DNA ends such as might be generated by X-rays or by recombinases. Indeed, Ku may be the primary detector of broken DNA. Once bound to an end, Ku can translocate down the length of the DNA. These properties can be interpreted in light of the three-dimensional structure of the protein (80). DNA bound to the Ku heterodimer resembles a finger wearing two adjacent rings, with the negatively charged DNA "finger" contacting positive charges on the interior surface of the rings. Continuous unbroken DNA is topologically inaccessible to unbound Ku "rings," but a DNA end could be threaded into the ring, which could then slide along the DNA axis. How the Ku protein "ring" might be removed after a DNA break has been resealed is not known.

DNA-PK is a large protein (460 kD) with a domain near its C-terminus that is related to phosophoinositide-3-kinase (PI3K) and that contributes to activation and autophosphorylation of the protein. *In vitro* kinase activation of the DNA-PK in the presence of DNA fragments was found to be efficient when the DNA ends either were at high concentration or, if at low concentration, were on DNA fragments long enough to circularize readily; but when the DNA-PK was located on the ends of DNA fragments too short to circularize (and too dilute to interact efficiently with other DNA ends), the DNA-PK activation was much reduced. This implies that autophosphorylation, kinase activation, and exposure of DNA ends can only occur after two DNA ends are brought together by DNA-PK in "synapsis" (81,82). Further phosphorylation of DNA-PK inactivates the protein and may prepare it for removal once DNA ends have been sealed.

Ligase IV and XRCC4.   An important role of activated Ku-DNA-PK complex is to recruit the additional components of NHEJ. One such component is DNA ligase IV, which is recruited to the Ku complex and activated by the protein XRCC4 *(83,84)*. The evidence suggests that ligase IV is the essential ligase that joins DNA ends in V(D)J recombination and NHEJ. Human patients with ligase IV deficiency have a severe phenotype including chromosomal instability, developmental and growth retardation, radiosensitivity and immunodeficiency with a T-B-NK$^+$ phenotype. The rare DH-JH junctions detected show extensive nucleotide deletion consistent with delayed ligation and prolonged exonuclease digestion (85). In mice, disruption of either the XRCC4 or the ligase IV genes causes embryonic lethality associated with neuronal apoptosis. Crossing these mice with p53 mutants does not improve V(D)J recombination but does rescue the mice from embryonic lethality, suggesting that neuronal cells may be unusually susceptible to p53-triggered apoptosis induced by normal low-level DNA damage (a similar mechanism may explain the severe human phenotype) (86). The importance of ligase IV for V(D)J recombination is supported by the ability of this protein to accomplish *in vitro* ligation of DNA ends. Indeed this is the only NHEJ component necessary to join compatible sticky DNA ends *in vitro*, though XRCC4 can stimulate this joining significantly *(84)*.

Recently two laboratories independently discovered a new protein required for V(D)J recombination and NHEJ. One group used yeast two-hybrid screening to search for proteins interacting with XRCC4 (87). The other group searched for the gene causing a syndrome of T+B lymphocytopenia, increased radiosensitivity, and microcephaly in a Turkish family; these investigators used functional cDNA

rescue of a patient's cell line from a radiomimetic drug to identify the gene (88). The protein identified by both groups is a 299 amino acid nuclear protein, which was named Cernunnos or XRCC4-like factor (XLF). The protein has a predicted secondary structure similar to that of XRCC4, to which it binds in cells *(89)* as expected from its isolation via two-hybrid screen. When Cernunnos/XLF-deficient fibroblasts were transfected with RAGs and a recombination substrate, imprecise signal joining was observed, similar to the defect in patients with hypomorphic ligase IV mutations. These experiments all suggest a role for Cernunnos/XLF linked to the function of XRCC4 and ligase IV.

Artemis. Since the coding ends generated by RAG cleavage are not directly ligatable because of their hairpin structure, V(D)J recombination requires a single-strand endonuclease activity to cleave the hairpins. This activity is conferred by the protein named Artemis, which was discovered through positional cloning in a group of human SCID patients carrying normal genes for the then-known V(D)J recombination proteins *(90)*. Patients with homozygous null mutations of Artemis survive (no embryonic lethality) and show radiosensitivity as well as defects in coding joint—but not signal joint—formation, similar to the phenotype of DNA-PK mutations. Hypomorphic Artemis mutations can cause features of the Omenn syndrome similar to those observed with hypomorphic RAG gene mutations (91). Purified recombinant Artemis protein has an intrinsic exonuclease activity *in vitro*; however, in the presence of DNA ends, it gains a single-strand endonuclease activity when it binds to DNA-PK and, in an ATP-dependent step, becomes phosphorylated at multiple sites in the C-terminal region of the protein (92,93). The Artemis endonuclease activity can cleave synthetic and RAG-generated hairpin ends as well as other single-strand DNA near a transition to double-strand DNA (94).

DNA Polymerase X Family Members

If hairpin opening leaves blunt ends or compatible sticky ends (like, the ends generated by restriction enzymes), *in vitro* joining experiments suggest that these ends can be joined by ligase IV without any additional processing (95). However, since Artemis opens hairpins at variable positions and may engage in exonuclease "nibbling" of opened DNA ends, further processing of DNA ends generally occurs before ligation completes the recombination. This processing may include further nuclease digestion and apparently also involves variable DNA extension by three DNA polymerases—polymerase λ, polymerase μ, and terminal deoxynucleotide transferase TdT—all of which are members of the polymerase X family. All three proteins contain a Brca1-C-terminus (BRCT) domain, which confers binding to Ku (96).

N Regions and TdT. Terminal deoxynucleotide transferase, the apparent source of untemplated "N region" additions in VDJ junctions, is an enzyme found in thymus and bone marrow; in the B lineage, it is expressed almost exclusively in pro-B cells. It catalyzes the addition of nucleotides onto the 3′ end of DNA strands. Though no template specificity determines the nucleotides added, the enzyme adds dG residues preferentially, consistent with N region sequences observed between V and D and between D and J. Both N region addition and TdT are characteristically absent from fetal lymphocytes *(97)*. N region addition is common in heavy chain genes (recombined in pro-B cells) but rare in murine light chain genes (recombined in pre-B cells), though perhaps somewhat less rare in human *(98)*.

As evidence that TdT is the primary source of N nucleotides, lymphocytes with engineered defects in their TdT genes produced rearranged immunoglobulin V regions with almost no N additions. Conversely, when TdT expression was engineered in cells undergoing κ or λ light chain rearrangement, the normally low level of N region insertion in these recombinations was dramatically increased. This result suggests that the low frequency of N region sequences in normal κ or λ recombinations is not due to the inability of these coding sequences to accept N region nucleotides, but to the loss of TdT as cells progress to the stage of light chain recombination; indeed, mice engineered to undergo premature Vκ-Jκ joining in pro-B cells show an increased frequency of N region nucleotides in their recombined Vκ genes *(99)*. In normal mice, the expression of a μ heavy chain may down-regulate TdT expression (100), contributing to the reduced level during the stage of light chain recombination.

In TdT mutant mice, as well as in normal fetal lymphocytes, which express minimal TdT activity, absence of N region addition is associated with an increase in the frequency of recombination junctions in which short stretches of nucleotides could have derived from either germline element because of an overlap of identical sequences at the coding ends. These junctions suggest a recombination intermediate in which the complementary single-stranded regions from the two coding ends hybridize to each other, much as "sticky ends" generated by restriction endonucleases can facilitate ligation of DNA fragments. Such "microhomology-mediated" recombination may restrict the diversity of neonatal antibodies; possibly the resulting antibodies are enriched in specificities for commonly encountered pathogens, or have broadened specificity, as has been reported for TCRs lacking N regions (101). Decreased N region nucleotides and a high incidence of homology-mediated recombination have also been found in the rare coding joints formed in Ku80 KO mice, consistent with a role for Ku in recruiting TdT or supporting its action *(102)*.

Polymerase μ and Polymerase λ. Pol μ and pol λ are ubiquitously expressed polymerases. Both readily fill in single-strand gaps in DNA and apparently participate in V(D)J recombination by filling in single-strand 3′ overhangs generated by asymmetric hairpin opening. Without this filling in, such overhangs might be destroyed by nucleases. Indeed, when *in vitro* NHEJ reconstitution experiments are performed using purified proteins and DNA fragments with overhanging ends, the omission of pol μ or pol λ increases the deletional trimming observed in recombined sequences (96). Similar excessive deletions at V(D)J junctions are observed in mice lacking pol μ or pol λ. Remarkably, however, pol μ KO mice show abnormalities only in their light chains (103), while the deletions in pol λ KOs are restricted to their heavy chains (104). This selectivity may be explained by corresponding changes in the relative mRNA levels for these two polymerases at different stages of B lineage maturation.

Other Possible Participants in V(D)J Recombination

Proteins that Bind to DNA Breaks. In eukaryotic cells, DNA breaks initiate signals that halt cell division, induce repair, and in some cases trigger apoptosis. Several proteins can be detected at dsbs induced by V(D)J recombination or irradiation, including: γ-H2AX, a phosphorylated form of the histone H2AX; ATM, the product of the gene mutated in the disease ataxia telangiectasia; and Nbs1 (or nibrin), the product of the gene mutated in Nijmegen breakage syndrome. The importance of these proteins in V(D)J recombination is not clear because defects in all three are compatible with near normal V(D)J recombination, possibly due to compensation by related proteins.

BSAP/Pax5. Pax5 (also known as B cell specific activator protein, or BSAP) is a transcription factor required for normal B cell development. Pax5$^{-/-}$ mice are able to complete DJH recombination, but VH to DJH recombination is impaired except for certain genes located proximal to the D regions. Surprisingly, 94% of human and mouse VH coding genes were found to have potential Pax5 binding sites. Pax5 was found to coimmunoprecipitate with RAG proteins, to potentiate *in vitro* cleavage of a VH gene RSS, and to enhance VH to DJH recombination in RAG-transfected fibroblasts; the latter enhancement required intact Pax5 binding sites in the VH sequence (105).

Regulation of V(D)J Recombination in B Cell Development

The recombination events that occur between immunoglobulin gene segments are carefully regulated so that most B cells expresses only one L chain isotype (isotype exclusion) and use only one of the two homologous chromosomal loci for H and L chain genes (allelic exclusion). Isotype and allelic exclusion ensure that each lymphocyte expresses a single H_2L_2 combination, and thus a single antigen binding specificity, a crucial feature of the clonal selection model of the immune response. Current evidence suggests that V(D)J recombination is controlled at two levels: regulation of the RAG protein levels and regulation of accessibility of the germline V, D, and J elements to the recombinase machinery. Both of these factors are affected by the stage of B cell development; and conversely, the expression of immunoglobulin provides a signal critical for regulating maturation of B cells. A brief scheme of B cell development is presented below as background; a detailed account is in Chapter 7.

As shown in Figure 6.10, B and T lymphocytes differentiate from pluripotent hematopoietic stem cells in the fetal liver and bone marrow. The primordial lymphoid progenitor has the potential to differentiate into B or T lymphocytes or natural killer (NK) cells. Among the earliest markers that indicate B lineage specificity are the non-immunoglobulin components of the pre-BCR: Ig-α, Ig-β and λ5. CD19, which functions as a coreceptor in signal transduction, first appears in large proliferating pro-B cells, which also express several other distinguishing surface markers including c-kit (receptor for the stem cell factor SCF), B220 (a B lineage form of the phosphatase CD45), TdT, and CD43 (a sialoglycoprotein known as leukosialin). In the absence of heavy chain protein, most of the SLC protein remains cytoplasmic, but some SLC is displayed on the surface membrane in association with a complex of glycoproteins (represented by a hook shape in Figure 6.10), which has sometimes been called a surrogate heavy chain. This includes a cadherin-related protein of 130 kD protein (p130 in Figure 6.10) *(106)*. RAG gene expression in these cells causes DJ rearrangements on both chromosomes. Subsequently, recombination with germline VH genes occurs; and, if the recombination is "productive" (i.e., yielding an "in-frame" VDJ junction), then μ heavy chain can be produced. The μ protein appears on the B cell surface along with SLC in a pre-BCR or μ-SLC complex that also includes Ig-α and Ig-β. The resulting large pre-B cells proliferate, with RAG gene expression down-regulated. After several rounds of division, the cells become smaller, stop dividing, turn up RAG gene expression once more, undergo light chain rearrangement, and express surface IgM ("immature B cells"), again turning down RAG expression. In IgM$^+$IgD$^-$ immature B cells, contact with autoantigens may up-regulate RAG expression again to facilitate receptor editing (discussed below). When immature B cells eventually also express surface IgD they become "mature B cells" and migrate into the periphery, ready to be triggered by antigen exposure.

Regulation of RAG Expression

A complete explanation of RAG gene expression would elucidate the mechanisms conferring lymphoid specificity, the two waves of RAG expression (during IgH and IgL rearrangements), and the autoantigen-induced up-regulation
FIGURE 6.10 Ig gene recombination in B cell development. A simplified scheme of B cell development is presented as a background for discussion of Ig gene recombination. The stages occurring in the bone marrow vs. in the periphery (e.g., lymph nodes, spleen) are shown, along with the status of IgH and IgL genes at each stage. A graphic depicting the Ig-related proteins displayed on the surface at each stage is presented; and, at the bottom, the stage-dependent expression of RAGs and TdT—both important in V(D)J recombination—is schematically depicted, as well as the expression of several other marker proteins.

associated with receptor editing. Although current knowledge is incomplete, several cis elements involved in regulating RAG expression have been characterized. RAG1 and RAG2 are transcribed toward each other in opposite directions and are regulated by individual promoters and by two enhancers lying 5′ of the RAG2 genes. A RAG2 proximal enhancer designated Erag supports normal expression in B cells, and the more distal enhancer is required for expression in T cells (107,108). In addition, a silencer located between RAG1 and RAG2 inhibits expression of both RAGs in certain T cell subsets; this silencer is normally repressed by an antisilencer more than 70 kb 5′ of RAG2 (109). The B cell–specific function of many of these cis regulatory regions is explained by the intersecting specificities of transcription factors that interact with them, including Pax5, E2A, Runx, and Ikaros. Recently NFκB, which binds at

several locations in the RAG enhancers, was found to be an important mediator of the up-regulation of RAG expression in cells undergoing receptor editing (110).

Parameters Affecting Recombinational Accessibility and Transcription

What maintains the locus specificity of V(D)J rearrangement in cells expressing RAG proteins—that is, why is Ig gene recombination confined to B cells, with heavy chain rearrangement before light chain, and why is TCR gene recombination exclusive to T cells? One clue is the observation that susceptibility to recombination seems to be correlated with transcriptional activity of germline gene elements. For example, many germline VH genes are transcribed at the pre-B cell stage, just at the time when these genes are targets for recombination (111); these

transcripts—designated "sterile" transcripts because they do not encode a functional immunoglobulin chain—are not seen in more mature B cells in which H chain recombination has been terminated. Similar sterile transcripts have been reported for other germline Ig gene elements during the period when they are actively rearranging. Susceptibility of a segment of DNA to both transcription and recombination might be a reflection of a common chromosomal state—"accessibility"—required for both processes, or transcription itself might be a prerequisite for recombination, perhaps by partially unwinding the DNA. Heavy chain CSR is also associated with prerecombinational "sterile" transcription, as discussed later in this chapter.

The accessibility model has received support from the finding that RAG proteins incubated in vitro with nuclei from pro-B cells (which generate sterile transcripts in the IgH locus) were capable of cleaving DNA at an endogenous nuclear JH RSS, but not at a TCRδ RSS, while conversely in pro-T nuclei the TCRδ RSS but not an Ig gene RSS was cleaved (112). The differential chromatin accessibility of Ig versus TCR gene loci in B versus T lymphocytes appears to be regulated in part by the same regulatory regions that control transcription. For example, in the heavy chain locus, one enhancer (Eμ) is located in the intron between JH and Cμ. Deletion of this enhancer markedly decreased sterile transcription and V(D)J recombination *(113)*.

Ig gene expression and recombinational accessibility are regulated at several interrelated levels: (1) cis regulatory DNA sequences (e.g., promoters, enhancers and silencers) and the nuclear proteins that they recruit; (2) the chromatin context of the DNA, including covalent alterations of the histones in the nucleosomes associated with the immunoglobulin genes; (3) epigenetic DNA alterations, specifically methylation of CpG dinucleotides, which alters the binding of nuclear regulatory proteins; (4) movement of Ig genes to different subcompartments within the nucleus; (5) physical looping or contraction of the Ig loci prior to recombination; and (6) antisense transcription in the loci. A detailed account of the regulation of Ig gene expression and accessibility is beyond the scope of this chapter (see reviews, e.g., [114]), but topics will be outlined briefly to highlight recent developments.

Cis Control Sequences. Promoters, DNA regulatory regions that are generally located just upstream of the transcription initiation site, stimulate transcription in one direction—into the associated gene—by recruiting nuclear proteins that stimulate formation of a transcription complex. Each germline V gene has an upstream promoter, as do all other DNA segments that produce sterile transcripts, including DH regions, the Jκ and JH clusters, I regions (exons involved in CSR, as discussed later in this chapter), and the κ RS sequence. In contrast to promoters, enhancers and silencers may be located upstream, downstream, or

within introns of genes, whose transcription they either up-regulate (enhancers) or down-regulate (silencers). They generally act in either orientation, rather than directionally like promoters. In the three Ig gene loci of mouse and human, several enhancer sequences are located downstream of each locus, and (except for the λ locus) one enhancer lies in the J-C intron. An additional region with enhancer activity was reported in the intron between the human Cδ3 and Cγ3 genes. The enhancers have been extensively studied to deduce the functional sequence motifs in these sequences (summarized in [114]). In κ-expressing cells, the κ intron enhancer (iEκ and 3' enhancers 3'Eκ and Ed) were recently shown to loop around to associate with each other and with Vκ promoters in B cells (115); similar interactions may occur at the λ and heavy chain loci.

Although enhancers and promoters were originally discovered by placing them near reporter genes in transient transfection studies, recent experiments have used knockout or knockin replacement technologies to examine function of these elements more physiologically in their endogenous locations in the mouse genome. The deletion of either iEκ (116,117) or Eμ (118) substantially impaired germline transcription and V(D)J recombination in the respective loci. Moreover, insertion of Eμ into the κ locus in place of iEκ caused the κ locus to behave more like the heavy chain locus, in that VκJκ recombination now occurred in pro-B cells (when heavy chain VDJ recombination normally occurs) and occurred at reduced efficiency in pre-B cells, the normal stage for VκJκ recombination (119).

Sequences with silencer activity have been described upstream (120) and downstream (121) of the entire heavy chain locus, where they might play a role in insulating the locus from the regulation of neighboring genes. In the κ locus, a downstream silencer has been reported, as well as another silencer in the Vκ-Jκ intron (122).

The activity of all cis regulatory sequences depends on the nuclear content of specific transcription factors that bind to short motifs within these sequences; activities of these factors are in turn regulated by the developmental stage and the environmental milieu of the cell.

Histone Interactions. In mammalian nuclei, DNA is highly compacted at several levels, most fundamentally by being wrapped around a nucleosome composed of eight histone proteins. Several groups have shown that when purified DNA is reconstituted *in vitro* with histones, its susceptibility to RAG cleavage at RSSs is reduced *(123,124)*. Nucleosome reconstitution is also associated with decreased template activity for RNA transcription. *In vivo,* enhancer- or promoter-dependent acetylation of histones by histone acetyltransferases is associated with increased template activity of many genes, possibly because acetylation of histone tails loosens the association between DNA and the histones. In addition, methylation of specific

residues in histone tails may, by providing binding targets for particular nuclear proteins, "mark" chromatin for silencing or activation. Experimentally, learning which covalent histone modifications are associated with a specific gene locus depends on the technique of chromatin immunoprecipitation (ChIP). In this technique, nucleosomes (with attached DNA) carrying a particular histone modification are precipitated with an antibody specific for that modification; DNA in the precipitate is then assayed for the presence of specific target sequences, commonly by PCR. Several groups have used ChIP to document the distribution of chromatin marks in Ig genes and have correlated changes with V(D)J recombination (e.g., 125,126).

For example, the extent of *in vivo* histone acetylation in the IgH (127) and κ (128) loci was found to correlate with developmentally regulated activation of susceptibility to V(D)J recombination, including a fall in acetylation as the IgH locus is deactivated during the κ locus recombination at the pre-B stage *(129)*. Trichastatin A, an inhibitor of the histone deacetylases (which remove the acetyl "marks" from chromatin), increased histone acetylation as well as VκJκ recombination in a pre-B cell line *(130)*. In an examination of *in vitro* (RAG + HMG1)–mediated cleavage of RSS-containing DNA, the inhibitory effect of nucleosome reconstitution was found to be relieved by acetylation of the histones and, additively, by adding ATP plus the ATP-dependent remodeling complex known as SWI/SNF; the inhibition was also relieved by complete removal of the histone tails *(131)*.

Apart from accessibility changes, V(D)J recombination has another link to histones through a direct interaction between the C-terminal domain of RAG2 and the histones. As described earlier, this interaction is required for efficient V(D)J recombination, but the mechanism is unknown (72).

DNA Methylation. Most cytosine residues within CpG dinucleotides are methylated in mammalian DNA, but genes that are actively expressed in a particular cell are generally relatively undermethylated in that cell type, suggesting that DNA methylation inhibits transcription. DNA methylation also seems to inhibit V(D)J recombination. Thus, the developmental maturation from pro-B cell to pre-B is associated with progression from a κ locus that is methylated, nontranscribed, and nonrearranging to one that is hypomethylated, transcribed, and rearranging *(132,133)*. Further, plasmid templates containing Ig RSSs were found to undergo V(D)J recombination when transfected into a recombination competent B cell line, but prior methylation of the DNA impaired recombination *(134)*, and V(D)J recombination of a transgenic construct occurred only when it was unmethylated *(135)*. Demethylation thus appears necessary for V(D)J recombination, though it is not sufficient. Methylation and histone acetylation are interrelated—for example, the methyl-

CpG-binding protein MeCP2 recruits histone deacetylases, which reduce acetylation of histones.

Compartmentalization. Several studies using fluorescence in situ hybridization (FISH) have indicated that inactive genes tend to be located in the periphery of nuclei, while active genes are recruited to a more central nuclear location (*e.g., 136*). In multipotential progenitors and in T cells, most FISH signals of Ig genes were found in a peripheral region, but in a high percentage of pro-B cells both κ and IgH were in central nuclear positions, even though in pro-B cells, only the heavy chain and not the κ chain genes are being transcribed and rearranged (137). In addition, formerly active genes that are no longer being transcribed have been reported to localize near centromeric heterochromatin associated with the protein Ikaros *(138,139)*. In pre-B cells the nonfunctional IgH allele was found associated with centromeric heterochromatin and with deacetylated nucleosomes, a combination that might shut off VHDJH recombination of the nonfunctional IgH allele at a time when RAGs are rearranging the light chain genes (140). Similarly in pre-B cells, one κ allele is associated with centromeric heterochromatin and Ikaros, while the other allele appears open to transcription and VJ recombination (128), a mechanism that may contribute to allelic exclusion.

Locus Contraction. By FISH analysis with C-region probes of one color and distal V-region probes of another color, investigators using confocal microscopy have reported that in recombining cells, both the IgH and κ loci undergo a locus contraction that moves the fluorescence signals for V and C physically close to each other in the interphase nucleus (137,140,141). This contraction occurs in RAG$^{-/-}$ mice, and thus precedes recombination. Such contraction could facilitate recombination by looping together recombining segments that are quite distant in linear DNA. For both IgH and κ loci, contraction peaks at the stage when the respective genes are undergoing recombination: pro-B cells for IgH and pre-B cells for κ. Contraction requires Pax5 (142); in Pax5$^{-/-}$ pro-B cells no IgH contraction or V$\rightarrow$DJ recombination occurs, although the locus moves normally to a central nuclear location and VH regions are transcriptionally active.

Antisense Transcription. Bidirectional RNA transcription is increasingly being recognized as a mechanism that can affect chromatin structure and function *(143)*. Recently an investigation of transcripts in the distal VH region in pro-B cells revealed abundant antisense transcripts including coding and noncoding segments between distal VH regions, but not from 3′ D through the Cμ region B. These transcripts were detected in RAG1$^{-/-}$ pro-B cells along with sense transcripts, so transcription from either strand does not depend on recombination. In a study of

normal B lineage cells at different stages, the antisense transcripts were found almost exclusively in pro-B cells, fueling the speculation that they might be involved in preparing chromatin in the IgH locus for recombination. Further research will be necessary to clarify the relationship of these transcripts to V(D)J recombination.

Allelic Exclusion and Regulated V(D)J Recombination

A model to explain allelic exclusion first proposed by Alt and colleagues (145) suggests that the functional rearrangement of an L (or H) chain gene in a particular B cell would inhibit further L (or H) chain gene rearrangement in the same cell. If the inhibition occurred promptly after the first functional rearrangement, then two functional immunoglobulins could never be produced in the same cell. An initial nonproductive rearrangement would have no inhibitory effect, so recombination could continue until a functional product resulted or until the cell used up all its germline precursors. This model has received considerable experimental support.

In B lineage maturation, the first Ig gene rearrangements join D to JH segments (commonly on both chromosomes) in pro-B cells, when most κ and λ genes are in germline configuration. The next recombination step is VH→DJH. According to the model, if the initial VDJ junction is nonfunctional (e.g., out of frame), then H chain gene recombination can continue on the other chromosome. If the VDJ recombination on the second chromosome is also nonfunctional, then the cell may have reached a dead end leading to death by apoptosis. Indeed, mice transgenic for the apoptosis suppression gene $bcl\text{-}x_L$ harbor an expanded population of bone marrow pro-B cells with almost all nonproductive VDJ joints (146). In normal mice, approximately 40% of mature B cells carry a nonproductive VDJ segment on the nonexpressed IgH allele, remnants of the initial recombination events in those cells.

In contrast, if the first VH→DJH recombination in a pro-B cell produces a functional VDJ gene, then its expression will lead to the synthesis of μ heavy chain. This heavy chain is expressed in the surface of pre-B cells as a pre-BCR in association with the "surrogate" light chains (SLC) VpreB and $\lambda5$ (as discussed earlier) and the Ig-α-Ig-β heterodimer. In the model, expression of this pre-BCR complex has two predicted regulatory consequences. The first is that it blocks further H chain recombination. Consistent with this prediction, functionally rearranged μ transgenes generally suppress the rearrangement of endogenous heavy chain genes in B lymphocytes, suggesting that the transgene-encoded protein can shut off V(D)J recombination of endogenous genes. A transgene encoding the membrane form of μ(μ_m) can confer this suppression, but one encoding only the secreted form (μ_s) cannot, demonstrating that a membrane form of μ protein is required for allelic exclusion (147). The suppression signal is mediated by the Ig-α-Ig-β heterodimer (148,149) and includes the down-regulation of RAG gene expression (150), as well as reduced target accessibility, as reflected in decreased VH gene transcription (151). Continued inaccessibility of the IgH locus would prevent further VH→DJH recombination during the subsequent stage when RAG proteins are up-regulated to activate light chain recombination.

The second consequence of pre-BCR expression is that κ chain recombination is activated. This effect was originally deduced from the rarity of κ-expressing cells without H chain gene rearrangement, suggesting that H chain expression is required for κ expression. As additional evidence, a functional μ gene introduced into early B lineage cells can cause RAG gene expression, sterile κ gene transcription, and Vκ-Jκ rearrangement. (A few cells are apparently able to initiate light chain recombination in the absence of heavy chain synthesis [152].)

When κ recombination begins in μ-expressing cells, the possibilities for functional and nonfunctional Vκ-Jκ rearrangements resemble those discussed earlier for the heavy chain. As soon as κ gene rearrangement leads to expression of a functional κ chain that can associate with μ to form a surface-expressed IgM molecule—that is, a mature BCR—then further κ rearrangement is suppressed. This regulatory influence would explain the observation of allelic exclusion in κ-expressing myelomas, and it has been supported by the finding that functional rearranged VJ-Cκ transgenes can suppress rearrangement of endogenous κ genes. This occurs in part by suppressing RAG gene expression (153).

Although this scheme of regulatory pathways may seem sufficient to explain allelic exclusion, an additional level of control is suggested by the observation that in developing B cells only a single allele of the κ locus is initially demethylated, and that allele is the target for Vκ-Jκ recombination (154). How demethylation might occur on only a single chromosome is unknown, but the mechanism may be similar to that causing monoallelic expression of other genes such as IL2, IL4 and odorant receptor genes (reviewed in [155]). The inactive methylated allele is the one associated with heterochromatin, as previously discussed.

Most B cells show isotypic exclusion—that is, express either κ or λ but not both. Further, κ rearrangement seems to occur before λ. Thus, in normal and malignant human B lymphoid cells, κ-expressing cells generally have their λ genes in germline configuration, while in λ-expressing cells, κ genes are either rearranged (rarely) or deleted (most commonly) (19). The κ deletions reflect the RS recombination event discussed earlier in this chapter. It may be that λ gene recombination is suppressed until κ genes rearrange nonproductively or are deleted, but it is not clear how this suppression would be mediated. An alternative possibility is that κ and λ rearrangement occur independently, but in the B lineage developmental program κ is simply activated for recombination earlier than the λ locus (156). Some overlap between the stages of κ and λ rearrangement might explain rare cells expressing both isotypes.

Regulation of B Cell Maturation by BCR and pre-BCR

The signals mediated by the pre-BCR (μ-SLC) and the mature BCR (IgM) are critical not only for regulating V(D)J recombination, but also for being checkpoints controlling other features of B lymphocyte differentiation. Thus, in the bone marrow of RAG or JH KO mice, the absence of BCR signaling leaves B lymphopoiesis blocked at the earliest pro-B stage—large cells staining positive for B220, CD43, and c-kit; and cells with surface markers typical of mature B cells are absent from the periphery. When a recombined VDJ-Cμ heavy chain transgene is introduced into a RAG KO background (157), the resulting μ protein allows the progression of B lineage cells to the stage of small pre-B-II cells where light chain recombination would normally occur (similar to the phenotype of a double KO of κ and λ loci [158]). RAG$^{-/-}$ pre-B cells cannot undergo VL$\rightarrow$JL recombination in the absence of RAG proteins, but do show the up-regulation of sterile κ transcription discussed previously. If, in addition to the μ gene, a functional recombined light chain transgene is also added to the genome of the RAG KO mice, then B cell development is restored, with normal numbers of B cells in the periphery, expressing mature B cell surface markers. The permissive effect of the pre-BCR or BCR on developmental progression appears to be mediated by the Ig-α-Ig-β heterodimer, based on results with the mutant or chimeric μ transgenes linked to Ig-α or Ig-β cytoplasmic domains, as described earlier *(148,149)*. Indeed, when a chimeric molecule containing the cytoplasmic signaling domains of Ig-α and Ig-β without an extracellular domain was targeted to the inner leaflet of the plasma membrane, it was capable of driving developmental maturation beyond the pro-B stage, apparently through a basal unstimulated level of signaling (159). Even in mature circulating B cells the BCR apparently provides a tonic signal necessary for survival of B cells, since *in vivo* ablation of the BCR of adult mice by inducible Cre-lox gene targeting induces rapid B cell death (160). The BCR signal delivered by Ig-α-Ig-β thus can lead to the following outcomes: it permits progression from pro-B to pre-B or from pre-B to mature B; on ligation to an autoantigen the BCR, triggers anergy or receptor editing (discussed below); in mature cells, it prevents the cell death observed with BCR ablation; and on ligation to foreign antigen, induces proliferation and maturation to the plasma cell stage. How the same Ig-α-Ig-β can trigger such different outcomes is not completely understood (see Chapter 8), though the maturation stage, the strength of the BCR signal and the presence of other costimuli seem to contribute to selectivity of the response *(161,162)*.

Late RAG Expression: Receptor Editing and Receptor Revision

Although the RAGs are generally down-regulated by a signal mediated by the appearance of IgM at the end of the pre-B cell stage, RAG gene expression and V(D)J recombination can recur later during "receptor editing" of autoreactive B cells in the bone marrow. One estimate suggests that about 25% of immunoglobulin are products of receptor editing (163). After production of an initial IgM-κ protein, receptor editing by light chain rearrangement can take three forms: an initial VκJκ junction could be deleted by recombination between an upstream V and downstream J on the same chromosome; VκJκ recombination could occur on the other chromosome; or Vλ Jλ recombination could be activated.

Most replacement of productively rearranged light or heavy chain genes likely serves to extinguish an antibody that was autoreactive, thus complementing two other mechanisms to silence autoantibodies: anergization and cell deletion by apoptosis. Early studies with transgenic autoantibodies suggested that anergy or deletion were the main fates of self-reactive B cells, but these conclusions may have depended on the nonphysiologic inability of the cells to silence the transgenic autoantibody by receptor editing. More recent studies involving autoantibody genes "knocked in" to the physiological position in the IgH and Igκ loci have shown that receptor editing is the major mechanism for B cell tolerance (164,165). This conclusion was also supported by a study of mice expressing a transgenic antibody against the murine Cκ constant region, a model of a self-superantigen; these mice provided evidence of receptor editing leading to virtually 100% λ light chain expression (166).

As compared with light chain editing, V gene replacement of the heavy chain seems to occur less frequently, probably because it depends on an incomplete RSS, a lone heptamer embedded in the 3' end of some VH coding regions, as described in an earlier section. An analysis of normal heavy chain sequences for "footprints" of VH replacement yielded an estimate that at least 5% of the sequences derived from VH replacement (167), possibly higher in autoimmune diseases *(168)*. Also, VH replacement was readily observed in mice engineered with a nonproductive VDJ gene knocked in at the physiological position in the heavy chain locus (169). However, one report has cautioned that some VHDJH genes that appear to have arisen by VH replacement may in fact be products of gene conversion mediated by activation-induced deaminase. This protein is known to participate in somatic hypermutation (SHM) in mammals and gene conversion in chickens, as discussed later in this chapter.

GERMLINE DIVERSITY

To understand the contribution of the germline V region repertoire to immunoglobulin diversity, several groups undertook cloning and sequence analysis of individual V region genes from the μ, κ, or λ loci of human or mouse. More recently, the complete sequences of all human and mouse Ig loci have been determined as part of the high-throughput genome sequencing projects for

these two species, though annotation that describes function and refers to earlier literature is incomplete. Several Internet resources are devoted to providing convenient updated access to immunoglobulin germline gene sequences. The IMGT (international ImMunoGeneTics) database (http://imgt.cines.fr/), coordinated by Marie-Paule Lefranc, includes a database for Ig and T cell receptor genes from a variety of species and includes maps, sequences, lists of chromosomal translocations, and multiple helpful links. IgBLAST (http://www.ncbi.nlm.nih.gov/igblast/) is a service of the National Center for Biotechnology Information and allows a submitted sequence to be searched against germline V, D, and J sequences.

Germline Diversity of the Murine Igh Locus

VH Segments. The murine VH locus extends over about 2.5 megabases on chromosome 12 and includes 110 genes and 85 pseudogenes, all in the same transcriptional orientation as the D, JH and CH regions (170). These VH segments can be classified into related groups based on sequence similarity; two VH gene sequences are considered to be in the same group or family if they show more than about 80% nucleotide sequence identity and in different families if their sequences are less than 70% identical. (Empirically, few VH comparisons yield identities between 70% and 80%.) Sixteen families are now recognized, one of which (VH16) was discovered only when the complete nucleotide sequence of the VH locus revealed a single novel VH that did not match any recognized family (170). The largest and most upstream family, designated J558, contains 52 functional genes in the C56BL/6 strain, making up almost half of the repertoire, though this family is smaller in some other strains. The VH families have been further classified into three "clans" based on sequence conservation primarily in the framework I region (FR1; codons 6 to 24) and FR3 (codons 67 to 85). (Framework amino acids are the non-CDR parts of the Ig V region that hold the CDR loops in position to contact antigen.) The clans are conserved between man, mouse, and frog, suggesting that several fundamental steps in germline VH diversification preceded the amphibian-reptile divergence (171). Unlike the organization of the human VH locus, members of a given murine VH family tend to be clustered together on the chromosome, though some interdigitation of families occurs even in the mouse locus (Figure 6.11). The map order is of interest because the most proximal family cluster (designated 7183), and in particular its most proximal member (designated VH81X), were found to be significantly overrepresented in the VDJ rearrangements occurring in fetal liver pre-B cells of BALB/c mice, but this bias is not observed in C57BL/6, and its significance is uncertain. The VH RSS spacers are about 23 bp.

JH and D Segments. Four germline JH sequences were identified about 5 kb upstream of the murine Cμ

gene. All appear to be functional in that the sequences they encode are found in secreted H chains. Upstream of each JH lies a typical RSS with 22 bp to 23 bp spacers.

D regions were initially hypothesized based on the highly diverse amino acid sequences in myeloma proteins between the V and J regions, as briefly discussed earlier in this chapter. The 13 murine D regions span about 80 kb upstream of the four JH segments. Eleven of the genes fall into two families: SP2 (nine Ds) and FL16 (two Ds). The most 3′ D region, DQ52 lies only 0.7 kb upstream of JH1. Although D regions could theoretically contribute to Ig diversity by being read in all three frames in different VDJ recombinants, the mouse has evolved mechanisms that strongly favor the reading frame known as RF1 (3). Rare rearranged VDJ sequences seem to be interpretable as V-D-D-J products, even though D-D recombination would violate the 12/23 rule *(172)*.

Germline Diversity of the Human Igh Locus

VH Segments. The human VH locus spans 1.1 Mb at the telomeric end of chromosome 14 (14q32.33). Essentially the entire locus (957 kb) was sequenced in 1998 (173) and more recently overlapping sequence has become available through the public database of the Human Genome Project. The original sequence includes 123 VH segments, including about 40 functional genes whose mRNA or protein products have been identified. Of the remaining sequences, 79 are clearly pseudogenes and 4 show no apparent defect but have not been documented to be expressed. The human VH sequences are all in the same orientation and fall into seven families, which are extensively interdigitated, in contrast to the family clusters characteristic of the murine locus (Figure 6.11). The families can be further classified into the same clans found in the murine VH locus. Some human VH sequences are polymorphic owing to VH insertions or deletions in different allelic chromosomes. In addition to the VH sequences on chromosome 14, 24 additional germline VH sequences have been mapped to chromosome 15 and 16 and represent nonfunctional "orphons" that were apparently duplicated from the functional locus on chromosome 14.

Human JH and DH Regions. Upstream of the human Cμ gene lie six functional JH regions interspersed with three JH pseudogenes. The pseudogenes encode amino acid sequences never found in human H chains and lack the RNA splice signal found at the 3′ end of all active JH genes. All of the JH segments and pseudogenes demonstrate ~23 bp RSS spacing (as in the mouse).

Most human D regions lie in a 92 kb region upstream of the JH segments *(2)*. One germline D gene is located in a position roughly homologous to that of the mouse DQ52—that is, 5′ to the human JHI. This human D gene, initially designated DHQ52, bears striking homology to
FIGURE 6.11 Maps of the murine and human VH loci. The fifteen known murine VH gene families are shown in their approximate map positions. Each rectangle represents a cluster of VH genes of the indicated family; the clan identification of the VH families is indicated by the color of the rectangle: black for clan I, gray for clan II, and white for clan III. Although some interdigitation is shown by overlapping families (e.g., the Q52 and 7183 families), the murine VH families are largely clustered. In contrast all human VH genes (vertical lines) of a prototypic haplotype are shown in the right panel; extensive interdigitation of families is apparent.

its murine counterpart, but is the only human D segment showing such human/mouse homology. All of the other human D regions fall into six families and lie in a cluster of duplicated domains beginning about 22 kb upstream of JH1. There are 27 D regions. Twenty-four of these are accounted for by four tandem approximate duplications of a 9.5 kb segment containing a representative of the six D families. Three D regions are apparently nonfunctional as a result of mutations in RSS heptamers, and there are two pairs of D regions with identical coding sequences (including one of the D segments with a heptamer mutation), so there are 23 distinct D regions that can contribute to human immunoglobulin diversity. All of these sequences appear in the expressed immunoglobulin VDJ regions, many in all three reading frames. In general, one reading frame encodes primarily hydrophilic residues, one encodes hydrophobic residues, and one includes frequent stop codons. Some D regions that contain stop codons can be used if these codons are removed by nuclease trimming before VDJ assembly is complete.

Germline Diversity of Light Chain Genes

Murine Germline κ Locus. The murine Vκ locus spans about 3.2 Mb upstream of the Cκ gene on chromosome 6 (174). Of the 140 Vκ sequences in the locus, 95 are potentially functional and 75 are known to be functional, as their mRNA or protein products have been detected. Of the remaining sequences, 44 are clearly pseudogenes, 21 are apparently defect-free but have not been demonstrated to be expressed, and the rest have minor defects that might not preclude function *(175)*. Of the 95 potentially functional genes, 61 lie in a transcriptional orienta-

tion opposite to that of the Jκ genes (174) and must recombine by inversion, as discussed earlier. A classification of the Vκ sequences by similarity (based on the criteria described above) recognizes about 20 Vκ families. As described for VH genes, some families are shared by human and mouse, suggesting that the family divisions preceded primate-rodent species divergence. Many related Vκ sequences within a family are found to lie clustered together in the locus, although some interspersion of families also exists. A few Vκ sequences have been localized to other chromosomes (chromosome 16 and 19), where they could not contribute to diversity and are thus considered orphons. As described previously, there are five Jκ regions, of which four are functional.

Human Germline κ Locus. The human Vκ locus is located on the short arm of chromosome 2 (2p11-2) within a sequence contig of about 1 Mb (10^6 bp) of DNA (176). This is composed of a proximal segment including the Jκ-Cκ region and about 500 kb upstream and a distal segment of about 430 kb further upstream. These two segments are separated by a spacer of about 0.8 Mb that is apparently devoid of Vκ sequences. The distal and proximal segments represent a large inverted repeat, so most Vκ sequences on the proximal segment have duplicated copies in the opposite orientation on the distal segment. The average sequence similarity between the corresponding distal and proximal sequences is 98.9%, suggesting a duplication event less than 5 million years old. Consistent with this, the locus is not duplicated in chimpanzees, a species that is estimated to have diverged from the human lineage approximately 6 million years ago. About 5% of human alleles also lack the distal duplication.

The sequenced region contains 132 Vκ sequences, including 87 unambiguous pseudogenes and 46 open reading frames. Of these, 29 Vκ sequences have been found expressed in proteins; these 29 include 25 unique sequences plus four that derive from identical gene pairs. Among all examined B lymphoid cell lines, those with VκJκ rearrangements involving the distal inverted Vκ segments contained retained signal joints, consistent with Vκ-Jκ recombination by inversion. Outside the duplicated region, the two Jκ1-proximal Vκ genes are also in inverted orientation. The locus contains numerous insertions of retroposed elements (about 35% of the sequence) but no recognized interspersed non-Ig genes or pseudogenes. Multiple internal repeats suggest ancient duplications.

Apart from the Vκ sequences in the cluster near the Jκ-Cκ locus, at least 25 orphons have been identified. One orphon cluster is located in the long arm of chromosome 2; perhaps it was separated from the major locus—on the short arm of this chromosome—by a pericentric inversion (which must have occurred rather recently in evolution since it is absent from chimpanzee and gorilla). Other orphons are located on chromosomes 1 and 22, and at least one probably nonfunctional Vκ lies about 1.5 Mb downstream from Cκ.

Human Germline Vλ Locus

The human Vλ has also been characterized by intensive cloning, sequencing, and mapping of Vλ regions and ultimately by the complete sequence analysis of 1,025,415 bp covering the entire locus (177). The locus contains about 36 potentially functional Vλ genes (in 10 families), 56 pseudogenes, and 13 "relics," containing <200 bp of Vλ-like sequences. (As noted for other loci, exact numbers may differ depending on the haplotype and method of analysis.) Of the potentially functional genes, only about 30 have been documented to be expressed by comparison with cDNA sequences. Within the clustered Vλ sequences lies the human VpreB gene, as well as several genes and pseudogenes unrelated to the λ system. All the Vλ sequences (except a few pseudogenes) are in the same transcriptional orientation as the J-C cluster. Analysis of the ~1 Mb sequence reveals several segments of internal duplications, some including Vλ regions. The largest and most frequently expressed Vλ gene families lie relatively close to the J-C cluster, mostly within the proximal 400 kb.

Combinatorial Diversity Estimates

Before the era of recombinant DNA technology, the source of antibody diversity was so mysterious that it was whimsically referred to as "the problem of G.O.D." (generation of diversity). Knowledge of antibody genes gained over the past 20 years has elucidated the diversity inherent in the germline V repertoire plus the diversity contributed by recombinational mechanisms (combinatorial multipli-

cation, "flexibility" of recombination site, N and P nucleotides) as already discussed. Together these diversity elements provide an immense potential repertoire, one so large that to some investigators it seemed sufficient to account for observed antibody diversity. As an exercise in estimating the contribution of germline and recombinational diversity in the human, consider the number of different antibodies that could be formed using the germline human V, D, and J sequences that are known to be functional. From 40 VH regions, 27 D regions, and 6 JH, regions we can obtain 6,480 combinations, but taking into account the three reading frames available for the D regions, the total comes to 19,440 combinations of amino acid sequences. For the light chain, we have the 145 κ combinations (29 Vκ × 5 Jκ) plus the 120 λ combinations (30 Vλ × 4Jλ), or 265 total light chain combinations. Assuming that H_2L_2 pairing occurs randomly, we can calculate a total of 19,440 × 265, or about 5 million combinations. This estimate has neglected additional sources of diversity that are substantial but difficult to quantitate: the variable "nibbling" of coding sequences and the insertion of N and P nucleotides. Yet even neglecting these factors the exercise demonstrates how nature has greatly enlarged the potential sequence diversity available from a limited number of total nucleotides by allowing flexible recombination between different sequence elements.

Although it is clear that these mechanisms imply a vast repertoire, it is worth considering some qualifications that tend to reduce the actual combinatorial diversity, especially early in ontogeny. It seems unlikely, for example, that every possible combination of L and H chains yields a functional antibody molecule, since in vitro L and H reassociation experiments show that certain hybrid molecules (formed from L and H chains derived from different antibodies) are relatively unstable. Similarly, association of V and J (or V, D, and J) is conceivably not completely random. Evidence of striking bias in the selection of VH genes in fetal pre-B hybridomas has been mentioned, and other biases have been reported in J usage. In addition, fetal and newborn VDJ junctions show a paucity of N nucleotides and a tendency to form VDJ junctions across short stretches of sequence identity between the recombining sequences ("homology mediated" recombination, discussed earlier in this chapter). Factors that reduce diversity in early VDJ recombination may facilitate the production of certain antibodies that are advantageous for young individuals.

IG GENE ALTERATIONS IN GERMINAL CENTERS

Several days after exposure to an antigen, B cells accumulate in local lymph nodes, gut-associated lymphoid tissue, and spleen and begin additional maturation steps in

germinal centers (GC). During the GC response, antigen-driven B cells undergo cycles of proliferation and their Ig genes undergo two unique alterations: CSR and affinity maturation through SHM and selection. For many years, these two processes were considered to be mechanistically unrelated, but more recent evidence, although not completely clarifying either process, has suggested mechanistic similarities between them. These similarities will be discussed in more detail later, but can be briefly mentioned here. First, while double-strand DNA breaks are expected intermediates for DNA recombinations such as CSR, such breaks have also been detected as likely intermediates in SHM. Second (and conversely), in addition to the mutations occurring in V regions as part of SHM, mutations have also been observed surrounding the recombination junctions of CSR. Third, transcription is required for both processes. Fourth, some evidence suggests that palindromic DNA structures may be important for targeting both CSR and SHM to specific sequences.

Activation-induced Deaminase. A fifth and dramatic link between CSR and SHM was the discovery that both processes require the protein known as *activation-induced deaminase* (AID). The gene for AID (known as AICDA) was identified (178) by a subtractive strategy designed to screen for transcripts that were expressed in a murine B cell line when induced to undergo CSR, but that were not expressed when uninduced. AID is expressed almost exclusively in GC B cells and in B cells activated in vitro, though there are reports of expression in certain nonlymphoid cells *(179,180)*. Mice engineered with a targeted defect in the AICDA gene show profound defects in both CSR and SHM. The same defects are seen in patients with a homozygous defect in the human AICDA gene, a condition known as *hyper-IgM syndrome-2* (HIGM2) (181). These patients have elevated serum levels of IgM because their B cells are profoundly impaired in CSR. AID is not only necessary for CSR and SHM, but apparently sufficient (in a mammalian cell at least), because overexpression of AID in fibroblasts can confer transcription-dependent CSR of an artificial switch construct (182) and transcription-dependent SHM of a transfected model mutation target sequence (183). These experiments suggest that AID is the only B-cell-specific protein required for SHM and CSR. AID is also required for somatic gene conversion in those species (e.g., chicken) that use that process to somatically diversify Ig genes.

As translated from the cDNA, AID is a 198 amino acid protein that forms homodimers. AID shows 34% amino acid identity with the RNA editing enzyme APOBEC1, which catalyzes the deamination of a cytosine residue to uracil in a specific position in the mRNA encoding apolipoprotein B. (This change produces a UAA stop codon that shortens the translated protein to yield apoB48.) The human APOBEC1 and AICDA genes appear to be genetically linked, both lying at chromosome 12p13. Both are members of a cytidine deaminase family, including proteins (e.g., human APOBEC3G and AID itself) that destructively mutate unwelcome DNA sequences to protect against retroviral infection and against the spread of endogenous parasitic retroposons *(184–186)*. Like APOBEC1, recombinant AID protein has a cytidine deaminase activity in vitro, and it was initially proposed that, by analogy with APOBEC1, AID functions in vivo by editing specific RNAs to produce novel mRNA encoding one or more proteins required for CSR and SHM. Since a novel edited mRNA would need to be translated into protein before it could enable CSR, proponents of the RNA deamination model have found support in the observation that inhibitors of protein synthesis block CSR (187,188), though it is possible that this block reflects a requirement for a novel but unedited protein, or for maintenance of an existing protein with short half-life. In any case, no evidence of novel AID-dependent edited RNAs has been reported, nor does AID deaminate RNA cytidines *in vitro*.

An alternative hypothesis that has received considerable experimental support is that AID acts by deaminating cytidines in DNA to uracil—in V regions for SHM, and in Switch regions (discussed later) for CSR. The resulting uracil would be then recognized as an abnormal DNA base by the cell's genetic surveillance machinery, which might trigger error-prone repair of V regions to produce SHM, or DNA cleavage to mediate CSR. This DNA-deamination model for AID is consistent with various properties reported for this protein *in vitro* or in cells:

(1) AID is found by ChIP analysis to be associated with IgH genes *in vivo* in B cells undergoing CSR (189,190).
(2) AID can deaminate cytosines to uracil in single-strand DNA *in vitro* (191–193) or in double-strand DNA that is being transcribed *in vitro*, presumably because transcription causes localized regions of single-strandedness (193–195).
(3) Defective SHM and CSR are observed with inhibition or genetic inactivation of uracil-N-glycosylase (UNG), an enzyme that removes uracil residues from DNA (196,197), consistent with the idea that CSR and SHM require a step in which AID-produced uracil in DNA is removed by UNG.
(4) A DNA sequence motif WRC (where W is A or T and R [pu**R**ine] is A or G) that has been recognized as a hotspot target of SHM is also a preferred target for AID deamination *in vitro* (192,195). (Several related sequences have been proposed as the consensus hotspot, now generally recognized as WRCH [H = T/C/A] or its complement DGYW [D = A/G/T] [198].)
(5) In transfected E. coli cells, AID mutates cytosines to uracil in DNA, a result that would be unexpected by the RNA-deamination model because bacteria

presumably lack the specific mammalian RNA targets predicted by that model (199,200).

In light of these observations, most investigators accept the DNA-deamination model as a working hypothesis, but alternative interpretations of these observations consistent with the RNA-deamination model have been proposed (201).

Preparations of AID purified from transfected E. coli or nonlymphoid eukaryotic cells can deaminate single-strand DNA in vitro, as mentioned earlier, but deamination of transcribed double-strand DNA requires association of AID with replication protein A (RPA), a single-strand DNA binding protein (190). This association requires phosphorylation of AID by protein kinase A (PKA), a kinase activated by cAMP (202,203). When the AID gene was mutated by replacing the phosphorylated amino acids with alanine to prevent RPA association, the resulting protein could still deaminate cytosines on single-strand DNA but was impaired in deaminating transcribed double-strand DNA and in carrying out SHM and CSR in cells (202,204), indicating the physiologic relevance of the phosphorylation and RPA interaction. These results suggest that AID activity may be fine-tuned by cytokines and other mediators that regulate cAMP levels and thereby affect PKA activity, AID phosphorylation, and thus AID activity.

Regulation of AID activity is important because inappropriate mutations or DNA breakage could be dangerous. Indeed, constitutive expression of an AID transgene causes tumors in mice *(205)*, and even normal expression of AID in B cells may contribute to tumorigenic translocations and oncogenic mutations *(206)*. Early studies showed that AID expression in B cells is upregulated by IL4 and CD40 engagement. More recent investigations of AICDA regulatory regions have led to identification of a promoter, an enhancer lying within the first intron, and two other candidate regulatory regions showing patches of significant mouse/human sequence conservation *(207–209)*. Outside the B cell lineage, AID has been found only in embryonic germ cells and in spermatocytes, where it could play a role in the widespread deamination of methyl-cytosine to thymine, thereby causing the most frequent point mutation observed in mammals: the transition from CpG to TpG *(180)*.

Structure-function relationships of AID have been probed by examining cross-species sequence comparisons and the effects of natural and engineered mutations in the protein. Remarkably, mutations in the N-terminus of AID impaired SHM but not CSR, whereas mutations or deletion in the C-terminus selectively impaired CSR (210–212), suggesting the possibility that the N- and C-terminal regions of the protein contact specific cofactors required for SHM or CSR function. DNA-PK is a possible candidate for the latter cofactor; it is required for CSR but not SHM,

and it has been found to bind to AID but not to C-terminal deletion mutants of AID (213). The C-terminus of AID also contains a conserved leucine/phenylalanine-rich nuclear export signal (NES), which mediates active transport of AID from the nucleus to the cytoplasm in association with exportin-1 *(214,215)*, but the CSR-specific function of the C-terminus requires more than an active NES *(216)*. Interestingly, agents causing nuclear DNA breaks were found to shift AID into the nucleus *(217)*. AID is highly conserved from fish to human, with all species having approximately 200 amino acids and sequence similarities throughout the protein. Sharks and bony fish show evidence of SHM but not CSR, while amphibians and all higher vertebrates are capable of both SHM and CSR. However, zebrafish AID expressed in murine cells can support CSR, implying that the lack of CSR in fish may be due to the structure of Ig genes rather than to a limitation in their AID *(218,219)*.

AID will be discussed further in the context of its function in SHM and CSR.

Somatic Hypermutation

The idea that antibody genes inherited in the germline might be subject to somatic mutation in lymphocytes during the life of an individual was suggested as an explanation for the diversity of antibodies several years before recombinant DNA technology became available and helped clarify the role of V(D)J recombination. Persuasive evidence for somatic mutation was reported in the 1970s: analyses of Vλ1 amino acid sequences of murine myeloma antibodies showed many instances of a particular prototype sequence, plus several variant sequences containing unique single amino acid substitutions that could be explained by single nucleotide changes. The prototype was interpreted as reflecting the germline sequence, with the variants arising by somatic mutation *(220)*. Subsequent investigations at the DNA level revealed myeloma V region sequences that deviated from their germline counterparts, verifying the principle of somatic mutation.

Somatic mutations are much rarer in IgM than in antibodies with "switched" isotypes (IgG, IgA, and IgE) made by B cells that have been exposed to AID in GCs, but they do occur; antibodies with "switched" isotypes without mutations are also found. These observations suggest that though both SHM and CSR normally occur in the same population of B cells in germinal centers, the two processes are unlinked.

It should be mentioned that, although SHM has been generally described as occurring in normal animals exclusively in germinal centers, some reports suggest that T cell–independent SHM may occur in a population of less mature cells, which may populate the splenic marginal zone and which may increase the repertoire of circulating lymphocytes prior to antigen exposure, especially in young individuals (221,222). Also, mice lacking histologically

detectable GCs as a result of lymphotoxin-α-deficiency are capable of somatic hypermutation and affinity maturation *(223)*. T cell–independent antigens can undergo a low level of SHM (224).

Role of Hypermutation in Immune Responses

To understand the role of somatic mutation in the antibody response, several groups have studied the extent of somatic mutation at different times after the immunization of mice. Studies of the responses to p-azophenylarsonate (Ars), phosphorylcholine, influenza hemagglutinin, oxazalone, and several other antigens have all indicated that the initial response after primary immunization is contributed by antibodies showing no somatic mutation. About one week after immunization, mutated sequences begin to be observed, increasing during the next week or so. Booster immunizations yield sequences showing additional mutations.

Many hybridomas made late in the immune response produce mutated antibodies with a higher antigen affinity than the unmutated (sometimes loosely called "germline") antibodies made early after immunization. The shift to higher affinity is a phenomenon long recognized at the level of (polyclonal) antisera and has been termed *affinity maturation*. This phenomenon can now be explained as the result of an "evolutionary" mechanism selecting antibodies of progressively higher affinity from the pool of randomly mutated V sequences. According to this model, at the time of initial antigen exposure, an animal has a set of naïve B lymphocytes expressing IgM with germline (unmutated) versions of Ig variable regions resulting from gene rearrangements that occurred prior to immunization. Because of the diversity of available VH, D, JH, VL, and JL sequences as well as the impressive recombinational potential described earlier, some B cells will express Ig molecules capable of binding the antigen with modest affinity. These cells are stimulated—by antigen binding—to proliferate, to secrete antibody and to move to lymphoid follicles, where they form germinal centers. In this environment, AID is expressed and somatic hypermutation machinery is activated, generating random mutations in the Ig genes of stimulated GC B cells. Many of these mutations reduce the resulting affinity of the encoded antibody for antigen *(225,226)*, and some may acquire autoantibody specificity *(227)*. As antigen clearance reduces antigen concentrations seen by the lymphocytes, only the cells displaying high affinity for antigen will be stimulated effectively; cells displaying lower-affinity antibodies or antibodies with affinity for self-antigens are subjected to programmed cell death (apoptosis) *(228,229)*. The preferential proliferation of the high-affinity cells and their maturation to secreting plasma cells will be reflected in an increase in the average affinity of the antibodies in the serum. These high-affinity cells will be left as the predominant population to be represented as memory cells when antigen exposure ceases; they thus can induce the rapid, high-affinity antibody response seen on secondary antigen exposure. In this model the driving force for affinity maturation—analogous to natural selection in the evolution of species—is selection for high antibody affinity in the face of falling antigen concentration. The importance of this selective force is suggested by the observation that affinity maturation can be inhibited by repeated injection of antigen (which removes the selective pressure for high affinity) *(230)* or by overexpression of the antiapoptotic protein Bcl-XL (which allows survival of B cells expressing low-affinity antibody) *(231)*.

Cellular Context of Somatic Mutation

Within the GC, SHM occurs in a subpopulation of B cells known as *centroblasts*. These cells proliferate in the "dark zone" of the germinal center and bear characteristic surface markers including IgD, CD38, and the receptor for peanut agglutinin *(232)*. Each GC appears to be populated by a small number of antigen-specific founder B cells *(233)* and an unusual Thy-1 negative T cell population, also antigen-specific *(234)*. The GC environment promotes contact between the B cell and follicular dendritic cells (FDCs)—which store, process and present antigen—and T lymphocytes, which activate somatic mutation in part via CD40-CD40L interaction *(235)*. Other critical signals promoting SHM have been investigated using *in vitro* systems, which implicate CD80:CD28 engagement *(236)* and cytokines *(237)*. Proliferating GC centroblasts give rise to centrocytes in the "light zone" of the GC; there, centrocytes are programmed for apoptosis unless they are rescued by FDC-presented antigen and T cell activation via CD40 engagement *(228,238)*. It is at this stage where positive selection for high-affinity antibodies occurs via apoptosis of cells expressing low-affinity antibodies, yet paradoxically apoptosis is also promoted by soluble antigen, perhaps functioning to select against autoantibodies *(239)*. As mentioned earlier, receptor editing may be another fate for autoantibody-producing cells in germinal centers. The features of antigen signaling that select for survival versus apoptosis or editing are not fully understood. Susceptibility of GC cell populations to apoptosis is correlated with their expression of Fas, Bax, p53, and c-myc, all of which promote apoptosis, and down-regulation of the apopotosis suppressors Bcl-2 and c-FLIP *(229)*. As mentioned previously, B cells of mice with engineered overexpression of Bcl-2 or Bcl-XL can escape selection against autoreactivity *(231)*.

SHM is apparently unusually active in IgM$^-$IgD$^+$ cells, as this subset of GC B cells from human tonsils was found to accumulate extremely high numbers of somatic mutations *(240)*. An important role for IgD in somatic mutation is also suggested by the observations that mice with a homozygous targeted disruption of their Cδ gene were impaired in affinity maturation *(241)* and that anti-IgD antiserum is an effective stimulant for triggering SHM *(242)*.

Germinal center B cells may undergo several successive cycles of mutation and proliferation followed by selection. Such a scheme has been supported by the sequence analysis of mutated Ig genes PCR-amplified from single cells microdissected from a histologic section of a germinal center *(243)* or from mutations in copies of an engineered transgene that is unusually susceptible to SHM *(244)*; in these and other systems, the mutated sequences can be organized into genealogical trees consistent with repeated mutation and selection cyles. Cyclical movement of the B cells from the dark zone to the light zone of the GC may be mediated by cyclically changing chemotactic responses to chemokines *(245,246)*. A computer simulation has affirmed the high efficiency of alternating periods of somatic mutation and mutation-free selection as a strategy for generating high-affinity antibodies *(247)*.

Targeting and Distribution of Mutations

The mutation rate of Ig genes undergoing SHM may reach as high as 10^{-3} mutations/bp/generation, or about 10^6 times higher than the normal genomic mutation rate *(248,249)*, a rate that could be lethal if it were not carefully targeted specifically to Ig genes. The molecular nature of this targeting is a critical question closely related to understanding the molecular mechanism of SHM. However, it should be noted that some non-Ig genes that are transcribed in GC B cells (BCL6 and CD95) may be also subject to mutation, though several other genes expressed in GC B cells at comparable levels are not *(250)*. One possible interpretation is that some of the features that target SHM to Ig genes may be shared by a few other genes.

Exactly what feature of the V(D)J locus targets the hypermutation machinery to the expressed V(D)J gene is not understood. Unrearranged Vκ, VH regions and DJ regions are generally not mutated, suggesting that the V(D)J recombination generates a hypermutation target from elements contributed by both V and J, possibly by moving the V region promoters close to enhancers lying in the J-C intron. (In contrast to the κ and heavy chain loci, the λ locus lacks an enhancer between J and C; unrearranged Vλ regions are transcribed in B cells *[251]* and can be mutated *[252]*.) The specific chromosomal location of Ig genes does not seem to be necessary for hypermutation, since transgenic mice carrying a rearranged expressible Ig gene—presumably inserted randomly in the genome—show somatic mutations, as do stably transfected Ig genes in cell lines. Therefore investigators have been able to study the sequence requirements for SHM using transgenes and stable transfectants. More recent studies have examined the effects of altering gene structure at the endogenous Ig loci by homologous recombination (i.e. KOs and knock-ins).

The importance of transcription in targeting hypermutation is consistent with *in vitro* dependence of AID deamination on transcription of double-strand DNA targets.

One striking confirmation of the correlation between transcription and SHM was reported in which a tetracycline-inducible reporter gene encoding Green Fluorescent Protein (GFP) was engineered with an internal stop codon. When this construct was stably transfected into a B cell line, the rate of reversion of the stop codon by SHM was found to be directly related to the transcription rate regulated by a tetracycline analog (253). A possible mechanistic explanation for the role of transcription is that DNA behind the advancing RNA polymerase complex becomes negatively supercoiled, which can facilitate access of the DNA to AID (254). The relationship between SHM and transcription is reinforced by studies showing that transgenes engineered with known transcriptional enhancers generally experienced more SHM than those without such enhancers. However, enhancers could theoretically regulate SHM independently of their transcriptional regulation, a possibility that is often hard to evaluate in these experiments. Further, recent studies have reported unexpected and sometimes conflicting differences in SHM effects of enhancer deletions in endogenous genes versus transgenes. For example, rearranged κ transgenes including intronic and 3′Eκ enhancers were more highly transcribed and better somatic mutation targets than similar constructs lacking these regions *(255)*. However, a targeted deletion of the endogenous 3′Eκ enhancer was found to minimally affect SHM in one study *(256)*, whereas another study reported greater effects from deletion of this enhancer than from the intronic enhancer (119). In another discrepancy, the downstream IgH enhancers HS3b and HS4 were found important for SHM in transgenes *(257)* but dispensable in the context of endogenous genes *(258)*. Even non–Ig enhancers could support SHM in a stably transfected cell line *(259)*, and so could non-Ig promoters such as the β-globin promoter *(260)*, though it cannot be concluded that every promoter or enhancer would have this property.

The V coding sequence can be replaced by a human β-globin gene or prokaryotic *neo* or *gpt* gene without affecting the hypermutation rate downstream of the promoter *(261)*. However, other constructs show little SHM despite high levels of transcription *(262,263)*. In studies probing differing SHM levels of similar transgene constructs, SHM was found to be enhanced by two repeats of the E box motif CAGGTG, the binding site for E2A transcription factors (264), even though transcription did not seem to be affected. Moreover, E2A proteins were found to strongly stimulate SHM of Ig genes in the chicken B cell line DT40 without significant effects on Ig gene (or AID) transcription (265). To summarize, it appears that transcription is necessary but not sufficient for targeting hypermutation, but the additional elements required for SHM have not been defined as of this writing (though E2A function seems likely to be among them).

A parameter related to transcription of Ig genes (−) their context in chromatin (−) has also been studied in

relation to SHM targeting. Culture of a B cell line under conditions that upregulate SHM (in the presence of T cells and anti-IgM) led to increased acetylation of histone H3 and H4 at V region but not C region DNA, as assessed by ChIP analysis *(266)*, paralleling the distribution of mutations. The increased histone acetylation was not a consequence of AID action since it occurred when AID expression (and SHM) was inhibited by antisense treatment; moreover, when cells were treated with the deacetylase inhibitor trichostatin A, the C region was both acetylated and subjected to SHM. Another histone modification that may be even more tightly correlated with SHM is phosphorylation of histone H2B (267).

Within a specific V sequence, mutations seem to be targeted to a region beginning about 0.1 kb downstream of the transcription start site, peaking within the V region and tapering off downstream to define a mutation target domain of about 1.5 kb to 2 kb. Therefore, for VDJ units involving the downstream JH5 segment, mutations extend further towards the $C\mu$ region than for units involving JH1. This distribution has suggested a model *(268)* in which a "mutator factor"—likely AID (269)—is loaded onto the transcription initiation complex as transcription elongation begins. The mutator factor then remains attached to the transcription machinery—and competent to induce mutations—for a period of time as this machinery moves downstream to extend the transcript; but eventually the mutator falls off, so that further transcription procedes without mutations. Consistent with this model, a $V\kappa$ Jκ-Cκ transgene bearing a second $V\kappa$ promoter engineered upstream of the $C\kappa$ region was found to incur mutations over over a second domain extending into the $C\kappa$ region, in addition to the usual V region mutations *(268)*. Conversely, the insertion of an irrelevant 2 kb DNA fragment between a $V\kappa$ promoter and the leader (signal peptide) exon prevented mutation within the $V\kappa$ transgene, which now apparently was downstream of the mutational domain *(270)*. Remarkably, a similar envelope of AID-dependent cytidine deamination has been observed in an *in vitro* system, where AID binds to E. coli RNA polymerase transcribing a plasmid DNA *(271)*.

Mutations in V region genes observed in B cells *in vivo* may be highly selected for antigen-binding function of the expressed antibody. To better analyze the spectrum of mutations produced by SHM unbiased by selection, investigators have studied nonproductively rearranged VDJ alleles or "passenger" transgenes engineered with stop codons to prevent expression as a protein. In these genes, mutational "hot spots," as well as "cold spots," have been recognized, apparently due to local DNA features that may promote or suppress somatic mutation. The consensus sequence WRC (i.e., [A/T][G/A][C]) is the most consistent hotspot for mutation, presumably reflecting the predilection of AID for *in vitro* deamination of this sequence, and different triplet codons are mutation targets at differing but largely consistent frequencies. It is possible that evo-

lution has concentrated mutational hotspot frequencies in CDR regions to enhance the potential for diversity generation in the parts of the protein critical for antigen contact *(272)*. All four nucleotides are targets for mutation, and all are found as products. Transitions (purine-purine and pyrimidine-pyrimidine interchanges) are somewhat more frequent than transversions (purine-pyrimidine interchanges), with some preferential targeting of G-C basepairs *(273)*. Small insertions and deletions occur rarely. In an unselected passenger $V\kappa$ transgene, A and G nucleotides were mutated more frequently on the coding strand than on the noncoding strand *(274)*. This "strand polarity" was also observed in human VH regions *(275)*, but is not universally found. Such polarity would suggest that the mutation mechanism may be affected by a process that can distinguish between the strands, such as transcription through the V region.

Molecular Mechanism of Hypermutation

A model of SHM has been formulated by Neuberger and colleagues (196) based on abnormalities in SHM that are observed in various mutant B cells (Figure 6.12). In brief, the model proposes that after AID-catalyzed deamination creates a uracil residue in the target DNA, there are several possible outcomes depending stochastically on which of several mechanisms engage the DNA and in what order they act. (1) The U:G mismatch may be replicated without correction, in which case the fact that uracil forms a Watson-Crick basepair with adenine means that the original C:G basepair will be mutated to T:A in progeny of the cell that receives the uracil-bearing DNA strand. These are referred to as *phase 1A mutations*. (2) The uracil base may be removed by UNG, creating an abasic site. As DNA is replicated, the strand with the abasic site may directly engage translesional polymerases (which are error-prone) to insert an unpaired nucleotide (i.e., any nucleotide) to replicate past the abasic lesion, creating phase 1B mutations. (3) The original U:G mismatch (or possibly the abasic site created by UNG action) may be recognized by the mismatch repair (MMR) system of the cell; MMR triggers nucleolytic digestion of the strand bearing the abasic site, and repair by error-prone polymerases, which create mutations (designated *phase 2*) near the position of the original U:G mismatch.

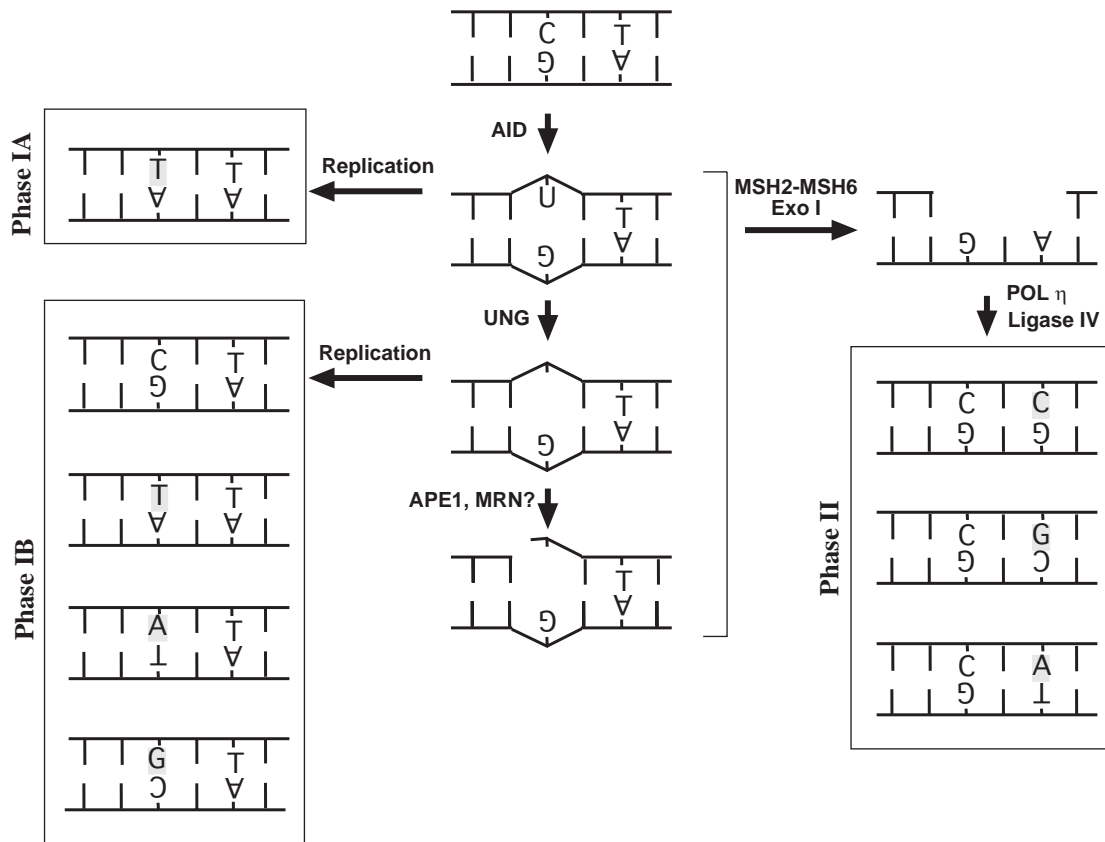
Role of Uracil-N-Glycosylase in SHM. The UNG gene encodes two proteins that differ in their N-termini as a result of alternative promoters that generate different initial coding exons. UNG1 is expressed ubiquitously in mitochondria, whereas UNG2 is specific to activated B cells. There are three other mammalian enzymes with uracil glycosylase activity, but they do not appear to contribute significantly to SHM or CSR. Hydrolytic deamination of cytosines to uracil occurs at a significant rate in all eukaryotic and prokaryotic cells, and misincorporation of dUTP


FIGURE 6.12 Mechanistic model of somatic hypermutation. The graphic depicts a small region in a VH gene showing a targeted C:G basepair and a nearby T:A pair. After AID-catalyzed deamination of a C residue, the DNA may be subjected to various modifications as shown, leading to mutations indicated by nucleotides in gray rectangles. The model is described in the text.

during replication further contributes to the load of uracil in DNA. UNG2 plays a major role in mitigating this load by initiating base excision repair (BER) in which the abasic site created by UNG2 activity is faithfully repaired to a cytosine by complex of recruited factors.

In SHM, the faithful repair of uracil is somehow subverted to introduce mutations. UNG$^{-/-}$ mice and human patients with a rare form of hyper-IgM immunodeficiency due to UNG mutations have similar immunological phenotypes. First, UNG$^{-/-}$ individuals are profoundly defective in CSR (discussed in more detail later), as expected if this process requires AID-catalyzed deamination of cytidine followed by UNG-catalyzed removal of uracil. Although SHM is roughly normal quantitatively, UNG-deficient individuals show a striking decrease in the frequency of transversions from C nucleotides (i.e., mutations at C are almost exclusively transitions to T). As suggested by Figure 6.12, UNG$^{-/-}$ individuals would not create the abasic sites that lead to C→G and C→ mutations by replication, though some mutations of these kinds could be produced by MMR. Indeed, the frequencies of mutations from the A, T, and G in these individuals are normal, apparently resulting from MMR engaged by the U:G mismatch in many cells.

Mismatch Repair in SHM. MMR is a highly conserved mechanism that detects abnormalities in DNA—including mispaired nucleotides and abnormal bases—and repairs them. The well-studied *E. coli* MMR system has three main components. MutS binds tightly and specifically to DNA defects. MutL then binds and recruits MutH (for which there is no mammalian homologue) and other components. The Mut complex then activates a latent nuclease activity to remove a segment of the DNA strand including the mismatched base; this gapped strand is then resynthesized by a DNA polymerase. Mammals have several MutS homologs, including three reported in somatic cells—MSH2, MSH3 and MSH6—which exist in the cell as heterodimers. MSH2-MSH6 (also known as MutSα) is the most abundant form and is specialized for recognizing single base gaps or mismatches, while MSH2-MSH3 (MutSβ) recognizes larger gaps and insertion/deletion loops. The mammalian homologs of MutL are heterodimers consisting of MLH1 paired with PMS1, PMS2, or MLH3. Apart from their effects on SHM and CSR, mutations in MMR genes, especially MSH2 and MLH1, underly hereditary nonpolyposis colorectal cancer. Recent efforts in several labs have led to *in vitro* reconstitution of mammalian MMR with purified components, enabling powerful analysis of this

complex mechanism (reviewed in *[276]*). In addition to the MutS and MutL homologs, the system requires the following: Exo1 to excise the gap; RPA, which binds to the single strand DNA in the gapped region (and is known to bind to phosphorylated AID, as discussed earlier); PCNA (proliferating cell nuclear antigen), which promotes processivity by encircling DNA in a sliding ring clamp and recruiting other components; DNA polymerase δ; ligase 1; and several other proteins.

An early speculation that SHM might be caused by localized abrogation of MMR has been investigated by one group who found that GC centroblasts have an intact MMR system, as judged by an in vitro MMR assay and Western blot for MMR components *(277)*. If MMR normally operates to minimize mutations, KOs of MMR components might have been expected to increase mutation frequencies in immunoglobulin V regions, as they do in non-Ig genes. In fact, MMR KOs generally show normal or modestly decreased frequencies of mutation in SHM, but show interesting qualitative abnormalities in the spectrum of mutations observed.

KOs of MSH2 have been studied by several labs and show consistent decrease in SHM from A:T basepairs (with a corresponding increase in the percentage of mutations from G:C basepairs). KOs of MSH6 (but not MSH3) show similar decreased A:T mutation (278,279). These results, in the context of the model of Figure 6.12, suggest that MMR, triggered by the MSH2-MSH6 heterodimer, primarily introduces mutation at A:T basepairs. The predilection for mutating A:T basepairs matches the activity of polymerase η, as discussed in the next section, implying that this polymerase may by the one most frequently engaged by the MMR machinery in repairing AID-generated lesions. Indeed, MSH2-MSH6 is capable of binding to a U:G mismatch, MSH2 can bind to pol η in cell extracts, and MSH2-MSH6 can stimulate the activity of pol η *in vitro* (280).

Compared with the effects of MutS mutations, KOs of MutL homologs have shown less striking abnormalities in SHM, perhaps because of some redundancy in these proteins.

Exonuclease 1 is another important component of the MMR machinery. The human Exo1 protein interacts *in vitro* with human MSH2 and MutL homologs *(281)*, which may recruit Exo1 to Ig V regions. Exo1 KO mice were found to show a slight decrease in SHM frequency, with a significant decrease in mutation at A:T as seen in KOs of other MMR components (282). In addition, the protein was found by ChIP analysis to be strikingly enriched in VH region DNA, but not Cμ region, of a B cell line stimulated by anti-IgM and T cells to initiate SHM (282). The same study reported similar association of MLH1 with the VH region undergoing SHM.

These results are all consistent with the model of Figure 6.12, in which AID-catalyzed creation of a U:G mismatch has three possible fates. The DNA strand bearing U may be simply replicated, the U may be removed by UNG, or the U:G mismatch may be recognized by MMR, which is the only route for mutations at T:A or A:T positions. This model makes the strong prediction that a double KO UNG$^{-/-}$ MSH2$^{-/-}$ should only be capable of phase 1A transitions at C:G. In fact, SHM in this double KO was found to be limited almost exclusively to C:G→T:A transitions (283), although an alternative interpretation of these results has been proposed (201).

Error-prone Polymerases. Although avoidance of error is a high priority for most DNA replication, error-prone DNA synthesis served an important function long before SHM evolved to mutate Ig genes; indeed error-prone polymerases have been most thoroughly studied in E. coli and yeast. These polymerases are useful in all cells for replication of DNA containing focal lesions that would block replication of stringent high-fidelity polymerases. A panel of these polymerases has evolved, each specializing in different aspects of "translesion DNA synthesis" (TLS) and showing differing spectra of infidelity in replication of normal DNA. Evidence for participation of four specific TLS polymerases in SHM has come from comparing the known activities of a particular polymerase with the SHM abnormalities seen in mice or humans with mutations in the corresponding polymerase gene. Some polymerase KOs are homozygous lethals, requiring evaluation by gene knockdown or inhibition in B cells.

Polymerase η characteristically inserts mismatches at A or T nucleotides, and individuals lacking this polymerase show the predicted abnormality: decreased mutations at A:T basepairs. This was first demonstrated in patients with xeroderma pigmentosum variant (XP-V) disease, whose defects in pol η make them susceptible to sunlight-induced skin cancers (284); a similar defect in mutations from A:T basepairs was subsequently shown for pol η KO mice (285,286). Pol η binds to MSH2-MSH6, as mentioned earlier, and is up-regulated in cells undergoing SHM.

In addition to pol η, three other polymerases have been implicated in SHM by experiments in which their diminished expression was associated with abnormalities in SHM: pol ζ (287,288), pol θ (289), and REV1 (290). Several other polymerases have been studied and do not appear to play important roles in SHM; minor contributions might be difficult to detect unless tested in cells deficient in multiple other SHM components.

A fundamental question about the action of error-prone polymerases is how they are specifically engaged for SHM, given that most spontaneous cytosine deamination in nonlymphoid cells is accurately repaired. A recent investigation using the chicken B cell line DT40 showed that inactivation of RAD18, an E3 ubiquitin ligase of PCNA, inhibited SHM frequency by about 60%, and suggested that RAD18 may contribute to recruitment of error-prone TLS polymerases in SHM (291). Further work will be necessary to understand the upstream regulation of Rad18

in SHM and to clarify which MMR components are affected by PCNA ubiquitination.

DNA Breaks in V Regions. Brenner and Milstein proposed in 1966 that Ig V region genes might be cleaved by an endonuclease and that these defects might then be repaired by an error-prone polymerase that introduced mutations into the DNA *(292)*. Clearly error-prone polymerases participate importantly in SHM, but the role of double-strand breaks (dsbs) is less clear. DNA breaks are implied by the occurrence of insertions and deletions, which are found in about 5% of V regions undergoing SHM in normal human GC B cells isolated by flow cytometry *(293)*. Further, transfection of the SHM-competent human Burkitt lymphoma line Ramos with TdT was found to lead to many insertions in mutated immunoglobulin VH genes, insertions that were found (like typical somatic mutations) in the V but not C region *(294)*. These insertions are most easily interpreted as the result of TdT-catalyzed nucleotide addition at dsbs. Breaks are also suggested by the enrichment of phosphorylated histone H2B at V regions undergoing SHM (mentioned earlier), as this histone modification seems to be associated with dsbs *(295)*.

More direct evidence for such breaks has come from two laboratories using LM-PCR to amplify blunt DNA ends within Ig genes undergoing SHM *(296,297)*. However, the role of dsbs in SHM is unclear because both labs have subsequently reported that these V region dsbs were found at similar frequency in B cells from normal mice and from AID$^{-/-}$ mice, in which SHM does not occur *(298,299)*; this was surprising because it had been assumed that the V region dsbs were triggered by AID-catalyzed deamination, as has been reported for dsbs associated with CSR (discussed below). Perhaps dsbs play a role in only a small fraction of V region mutations, conceivably as low as the ~5% of mutations involving insertions or deletions. Consistent with a minimal contribution of dsbs to SHM is the observation that the variant histone H2AX, which rapidly accumulates in a phosphorylated form (γH2AX) at and near dsbs, was found to be enriched broadly in a heavy chain gene undergoing CSR and SHM, but not in a Vλ gene undergoing only SHM, as though dsbs may be widespread in CSR but not in SHM. Moreover, B cells lacking H2AX are impaired for CSR but undergo normal SHM (300), as are mice lacking Ku and DNA-PK.

Heavy Chain Switch

Switch Regions and Switch Junctions

As briefly mentioned earlier in this chapter, isotype switching involves removal of Cμ from downstream of the rearranged heavy chain VDJ gene and its replacement by a new downstream CH region. This occurs by a deletional recombination—CSR—between repetitive DNA sequences known as *switch* (or *S*) *regions* that lie 5′ of each CH region (except Cδ). While most switch breakpoints fall in the S regions, some are in nearby nonrepetitive DNA. The S region of the mouse μ gene, Sμ, is located about 1 kb to 2 kb 5′ to the Cμ coding sequence and is composed of numerous tandem repeats of sequences of the form (GAGCT)$_n$(GGGGT), where n is usually 2 to 5 but can range as high as 17. All of the S regions of downstream isotypes include pentamers similar to GAGCT and GGGGT embedded in larger repeat units, rather than precisely tandemly repeated as in Sμ. The 10 kb murine Sγ1 region has an additional higher order structure: two direct repeat sequences flank each of two clusters of 49 bp tandem repeats. In support of the critical role of S regions for CSR, KO of Sγ1 by homologous recombination essentially abolished expression of IgG1 from that allele (301). However, mice with a complete deletion of the Sμ tandem repeats were still able to accomplish CSR, although at a reduced level (302). These mice still retained a few scattered G-rich pentamers flanking the tandem repeat region, and these may have supported CSR. Mice with a larger deletion removing most of the flanking G-rich pentamers had a more profound impairment in CSR (303).

A switch recombination between, for example, μ and ε genes produces a composite Sμ-Sε sequence (Figure 6.13). From a comparison between the sequence of an Sμ-Sε composite switch region and the sequences of the germline Sμ and Sε, one can localize the exact recombination sites between Sμ and Sε that occurred in each allele. Such comparisons have indicated that there is no specific site, either in Sμ or in any other S region, where the recombination always occurs, although clusters of recombination sites have been reported at two specific regions within the tandem repeats of murine Sγ3 region *(304)*. Thus, unlike the enzymatic machinery of VJ recombination, the switch machinery can join sequences in a broad target region. Often both IgH alleles in a single cell undergo switching to the same downstream isotype. Some alleles undergo sequential switching events; for example, a common pathway to IgE expression is an initial $\mu \rightarrow \gamma$1 switch, followed by a CSR between the composite Sμ-Sγ1 region and the Sε region *(305)*. Although most CSR occurs as a deletion within a single IgH allele, switching between two allelic chromosomes can be detected at a frequency of roughly 7% to 10% in mouse and rabbit (306,307).

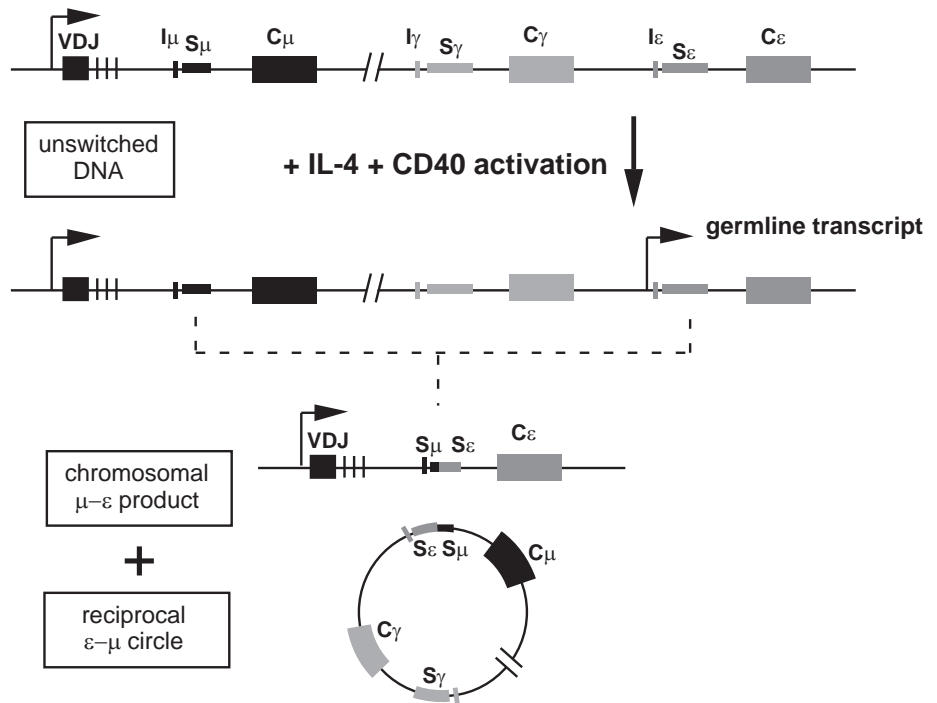
DNA fragments excised by switch recombination have been cloned from fractions of circular DNA isolated from cells actively undergoing isotype switch recombination. Thus, at least some of the excised DNA segments ligate their ends to form "switch circles," which contain composite switch junctions that are in theory reciprocal to the composite switch junction retained on chromosomal DNA (Figure 6.13). Because switch circles are not linked to centromeres and may not contain origins of replication, they are not efficiently replicated. Therefore, they are not found in cells that have divided many times after switching (e.g., in myelomas or hybridomas).


FIGURE 6.13 Switch regions and composite switch junctions. The recombination breakpoints in isotype switch recombination fall within repetitive "switch" (S) regions. Stimuli that activate switch recombination (IL-4 and CD40 activation in the example shown) generally promote transcription across the target S region, initiating just upstream at the "I" exon. Recombination between $S\mu$ and $S\varepsilon$ produces two composite switch junctions: an $S\mu$-$S\varepsilon$ junction retained in chromosomal DNA, and a reciprocal $S\varepsilon$-$S\mu$ junction found in fractions of circular DNA. PCR amplification across either composite junction can be used to study switch recombination.

Many composite switch junction sequences show mutations near the recombination breakpoint when compared to the corresponding germline switch sequences; these mutations have been interpreted as reflecting an error-prone DNA synthesis step that may be a component of the switch recombination mechanism *(308)*. Mutations are also observed in unrecombined $S\mu$ regions in activated cells, but are much rarer in $S\gamma$ regions (309). Internal deletions also occur within individual S regions in cells undergoing CSR (310). Like functional CSR, both the mutations and internal deletions in the switch regions seem to be AID-dependent.

Regulation of Isotype Switching by CD40

Isotype switching occurs physiologically in animals about 1 week after immunization with T-dependent antigens, at about the same time that somatic mutation of Ig genes begins. Both processes normally occur in germinal centers of lymphoid organs—a location that facilitates interactions between B cells, T cells, and follicular dendritic cells presenting antigen. As demonstrated by *in vitro* switching experiments, T cells promote switching by secretion of cytokines (especially IL-4 and TGF-β), as well as by cell-to-cell contact.

A major component of the cell contact signal is mediated by an interaction between the B cell surface marker CD40 and its ligand—designated CD40L, CD154, or gp39—expressed on activated T cells (primarily CD4$^+$). CD40 is a member of the TNF-receptor family, while CD40L belongs to the TNF ligand family. The dependence of switching on the CD40-CD40L interaction is highlighted by the ge-

netic disease known as the *X-linked hyper-IgM syndrome-1,* which was found to be caused by a defect in the human gene encoding the CD40L/gp39 (311). Like AID-deficient HIGM2 patients described earlier, patients with HIGM1 have elevated concentrations of IgM in their serum and almost no immunoglobulins of other isotypes. In addition, their antibodies fail to show affinity maturation or evidence of B cell memory responses. Similar defects are seen in humans with mutations in their CD40 gene, an autosomal recessive disease designated HIGM3 (312). CSR impairment may also be caused by abnormal function of CD40 signaling pathway components, including IKKγ (also known as *NEMO*), NFκB proteins, and c-Jun N-terminal kinase (JNK). Mouse strains with engineered defects in CD40 are defective in SHM and T-dependent CSR, but respond with normal isotype switching to T-independent antigens *(313)*; little is known about this T-independent switching pathway.

The discovery of the importance of the of CD40-CD40L interaction has facilitated in vitro switching experiments in which B cells are incubated with stimuli designed to engage their CD40 molecules (i.e., with CD40L$^+$ T cells, with nonlymphoid cells engineered to display surface CD40L, or with antibodies to CD40).

One role of the CD40 engagement is to induce B cell proliferation. Indeed, other proliferative stimuli—for example, LPS or IgM or IgD crosslinking—can support cytokine-induced isotype switching in vitro in the absence of T cells and CD40 activation. The relationship of CSR to cell division is supported by evidence that switching is linked to the cell cycle *(313)* and to the number of cell divisions

after stimulation *(314)*, a phenomenon that may reflect cell division–related regulation of AID expression (315). However, apart from activating proliferation, CD40 has additional effects that may facilitate switching, including upregulation of IL-4 responsiveness and IL-4 receptor number *(316)*, upregulation of sterile "switch transcripts" (discussed later), and upregulation of AID expression. Activated B cells also express CD40L, which can not only trigger CD40 signaling but also transduce a "reverse" signal affecting B cell function *(317)*.

The CD40-CD40L interaction appears to be opposed by an interaction between two other members of the same protein families: CD30 and its ligand CD153. CD30 expression on B cells is induced by CD40L, but inhibited by ligation of the BCR *(318)*. Engagement of CD30 by its ligand—CD30L—down-regulates several of the effects of CD40 ligation, apparently by inhibiting the action of NFκB *(319)*. This effect may represent a feedback mechanism to limit the activation of B cells that have not been stimulated effectively through their BCR by antigen. "Reverse" signaling by B cell-expressed CD30L has also been reported as an additional inhibitory influence on CSR *(320)*. Pathologic activation of CD30-CD153 signaling in chronic lymphocytic leukemia may contribute to the impairment in IgG and IgA production that leads to infection in these patients (321).

Isotype-specific Regulation of Germline Transcripts

Different isotypes are known to predominate in different immune responses depending on the antigen, route of antigen administration, and several other parameters. These different parameters act in part by influencing the cytokine milieu of the B cells. IL-4, for example, promotes the expression of IgE (and IgG1 in mouse), whereas TGFβ promotes switching to IgA. These lymphokines have been proposed to act by making the C region of the target isotype "accessible" to switch recombinase machinery that may be largely non–isotype-specific. The accessibility is associated with expression of a "sterile" or "germline" RNA transcript that initiates upstream of a target S region (Figure 6.13) and extends through the target C region. This transcript is spliced so that a noncoding upstream exon known as an *I* (or *intron*) *region* is joined to the first coding exon of the C region. The same experimental conditions—particularly the same cytokines—that favor the accumulation of sterile transcripts from a particular isotype generally also stimulate switch recombination involving the corresponding S region. In some cases, the signals transduced by the cytokine receptor have been elucidated. For example, IL-4 stimulates germline transcription by activating the transcription factor STAT6, which attaches to one of several nuclear protein binding motifs in the promoter region upstream of Iε and Iγ1. CD40 engagement also acts in part through NFκB-mediated binding to I region promoters *(322)*.

Apart from I region promoters, sterile transcription and isotype switching are also regulated by IgH enhancers.

A combined deletion of the murine 3′α enhancers HS3b and HS4 was found to cause a significant impairment in switching to most isotypes, although switching to IgG1 was unaffected (and IgA only moderately decreased) (323). The diminished switching was associated with diminished sterile transcription of the same isotypes, suggesting that one major function of the enhancers in CSR is to increase sterile transcription. The relative independence of γ1 from regulation by enhancers may be related to the putative LCR region associated with that gene *(324)*. The intronic enhancer also seems to play a role in CSR, since IgH loci with a targeted deletion of the Eμ enhancer showed decreased switching when tested in RAG-complementation mice *(325)*.

The importance of sterile transcription for CSR has been highlighted by experiments in which an artificial switch substrate was constructed bearing an Sμ sequence, an Sα sequence whose transcription was driven by a tetracycline-regulatable promoter, and a GFP gene whose expression required recombination between the two S regions (326). When this plasmid was stably transfected into the switch-competent cell line CH12F3-2, and transcription across the Sα sequence was manipulated by adjusting the tetracycline concentration, higher transcription levels were associated with more CSR.

Although cytokines and CD40 ligation clearly affect CSR by regulating sterile transcription, it is likely that the B cell milieu regulates other aspects of the switching mechanism as well, because several examples have been reported of cytokines up- or down-regulating switch recombination without a parallel effect on sterile transcripts *(327)*. Further, when certain cell lines capable of switching their endogenous IgH loci to only one particular isotype were transfected with a panel of plasmid CSR substrates with different S regions, the isotype specificity of the cells for plasmid CSR matched that for their endogenous genes, even though all S regions of the engineered constructs were strongly transcribed; this observation suggests that the CSR machinery might show isotype specificity based on recognition of features specific to certain S region sequences (328). For example, *in vivo* footprinting demonstrated that NFκB p50 binds specifically to a motif in Sγ3, and this protein is required for efficient $\mu \rightarrow \gamma$3 switching of both endogenous genes and plasmid substrates (329). In a related example, the protein Suv39h1, a histone methyltransferase, specifically increases $\mu \rightarrow \alpha$ CSR of plasmid substrates and endogenous genes, possibly by repressing a sequence-specific binding protein *(330)*. In principle the activity of isotype-specific switching factors could be regulated by the environment of the B cell.

Role of Transcription in the Mechanism of CSR

Gene targeting experiments have shown that mouse strains lacking the I region (and its promoter) of a particular isotype do not switch to that isotype, reinforcing the idea that sterile transcription is necessary for CSR

(reviewed in ref *[331]*). The low extent of sequence conservation of the I exons and the lack of consistent open reading frames suggest that these transcripts do not encode a functional protein. Indeed, the exact sequence of the I region may be irrelevant since an I region can be replaced by an unrelated sequence and still support CSR *(332)*. However, the transcribed exon upstream of the S region may need a splice donor site allowing the S region to be removed from the transcript, because a targeted construct lacking such a splice donor site was reportedly unable to support CSR even though transcription through the S region occurred *(333)*.

One possible role for sterile transcripts in CSR involves the formation of an RNA:DNA complex known as an R loop, a structure in which RNA complementary to one strand of a DNA molecule binds to that strand with Watson-Crick base-pairing, displacing the other DNA strand, which forms a single-stranded loop. In support of the R loop model, cell-free transcription across switch regions was found to generate a stable association of the transcript RNA with the template DNA (334,335); significantly, no substantial association occurred when the switch region was transcribed in reverse orientation, leading to a C-rich transcript, or when the transcribed template was a DNA fragment other than an S region. The displaced DNA strand in S region R loops was susceptible to cleavage *in vitro* by nucleases that recognize single-strand DNA or junctions between single- and double-stranded DNA; *in vivo,* such cleavage could be a step in CSR. To probe whether R loops might exist *in vivo,* DNA was extracted (along with any R loops) from LPS-stimulated B cells switching to Sγ3 and was treated with sodium bisulfite, which efficiently deaminates cytosines to uracil only in unpaired single-strand DNA. The Sγ3 regions were then amplified from the genomic DNA by PCR and cloned. The clone sequences revealed long stretches in the upper strand where all the C residues were replaced by Ts (336,337), presumably marking regions of single-strand DNA that were displaced as stable R loops *in vivo*. In the lower DNA strand, only short patches of C→T mutations were found, suggesting short single-strand regions in that strand; such regions might be transiently created during transcription, or perhaps result from misalignment of repeats in the two strands when an R loop collapses. Regions of single-strand DNA on either strand might provide targets for deamination by AID *in vivo,* given that AID apparently deaminates only single-stranded DNA (or DNA regions transiently rendered single-stranded by transcription), as shown by *in vitro* experiments described earlier.

Apart from the formation of R loops, transcription may also facilitate access to AID by altering the supercoiling of the transcribed DNA, as previously discussed in the context of SHM (254).

A model in which AID loads onto an RNA polymerase complex and acts on DNA as the complex travels downstream was discussed earlier in the context of AID function in SHM. Some evidence consistent with a similar polymerase-loading model has been described in the context of CSR. Because uracils generated in S regions through AID-catalyzed deamination are apparently processed by UNG and MMR (as discussed below), double KO mice defective in both processes produce uracils that can by resolved only by replication, causing C:G → A:T mutations. A study of the distribution of such mutations in clones from these double KO B cells found that a domain of mutations began about 150 bp 3′ of the transcription start site of Iμ and extended 4 kb to 5 kb downstream, with diminishing mutation frequency near Cμ *(338)*. Within this domain, the overall frequency of C→T mutations was similar on the two strands, but individual sequences showed clustering of C→T mutations on one or the other strand, suggesting that AID may confine its action to one strand as the polymerase moves processively downstream. Cytokine conditions associated with sterile transcription of particular downstream isotypes increased the frequency of C:G→A:T mutations in the corresponding S regions. Another study supporting the concept of a promoter-initiated domain of CSR found that recombination breakpoints near Sμ extended further downstream than normal in mice with a deletion of the Sμ tandem repeats, as though a constant CSR domain length were maintained with a fixed upstream end (339).

Features that Target CSR to Switch Regions

Mammalian IgH switch regions have several notable properties: they are G rich on the nontranscribed "upper" strand, and they contain multiple repeated sequences, possibly including motifs that could serve as targets for the CSR machinery. To investigate which characteristics might be critical in targeting CSR, several laboratories have studied CSR in two main contexts: (1) in B cells transfected with model CSR targets, often containing reporter genes whose expression depends on a CSR event; or (2) in B cells of mice in which endogenous S regions have been modified by "knocking in" engineered constructs. In either context investigators can test how variant S regions affect CSR.

One study reported that replacement of a natural murine Sμ sequence with the chicken or frog Sμ sequences—neither of which are G rich—supported somewhat reduced but still substantial frequencies of CSR, while a randomly chosen sequence, even if G rich, did not support CSR *(340)*. These investigators proposed that palindromic sequences (which seem to be present in all S regions, including those of frogs) may contribute to CSR. In support of this, they reported that switch junctions tend to lie closer to boundaries of DNA stem-loops (which might be formed by palindromes) than statistically expected, an observation that has not been universally confirmed. However, they also tested the CSR potential of a synthetic palindrome-rich tandem repeat (derived from the multiple cloning site of a commercial Bluescript plasmid containing

palindromic recognition sites for restriction enzymes) and found, surprisingly, that it supported a modest but clearly significant level of CSR.

In another study (mentioned earlier) homologous recombination was used to delete the endogenous ~10 kb Sγ1 region and replace it shortened versions. The efficiency of CSR to γ1 correlated well with length of the engineered Sγ1 region (301). When the Sγ1 region was inverted, it retained about 25% of the wild-type activity (341). Since this inverted, and now C-rich, DNA segment could not form an R loop, this result suggests that the R loop contributes to CSR, but other features of the S region that are preserved in the inverted sequence also play a role.

The nature of the other features is suggested by an analysis of switch junctions occurring between a knocked in frog Sμ and the endogenous murine Sγ1 (342). As mentioned earlier, the AT-rich frog S region is not prone to R-loop formation, but it was able to support efficient CSR when it was swapped into the position of the murine Sμ, and it functioned equally well in either orientation. Significantly, in either orientation the recombination junctions were clustered in a portion of the S region that is rich in repeats of the sequence AGCT, which is a special case of the WRCH/DGYW consensus sequence for AID targeting. Indeed, the AGCT-rich region was a good substrate for *in vitro* deamination by AID when transcribed in association with RPA. The AGCT motif is enriched in all mammalian S regions (and is also enriched in the Bluescript multiple cloning site). Among WRCH motifs, AGCT may be particularly effective as a target for CSR because of the potential for deamination on either strand, creating closely spaced nicks, or even a dsb with a single base overhang if the cytosines in same AGCT motif are targeted on both strands. The density of AGCT in S regions correlates with the location of switch junctions better than the density of WRC or the boundaries of G richness or R loops (337). These results all suggest that clusters of AGCT may represent a target for CSR that evolved in amphibians, with R-loop formation evolving later in mammals to further enhance AID accessibility to the "upper" G-rich strand of S regions.

DNA Breaks in CSR

The recombination event that underlies isotype switching includes DNA breaks and rejoining events that must involve both strands of DNA. Although the RAG-induced DNA breaks that initiate V(D)J recombination occur at the corresponding position on the two strands (yielding a blunt end and a hairpin), the nature of the ends in the initial CSR cleavage is not clear. An early compilation of switch junctions *(308)* found only rare instances of microhomology at the junction. Because these microhomology examples would be consistent with invasion of one DNA strand from Sμ targeting a short homologous region in a downstream S region (or vice versa), the rarity of such junctions has
FIGURE 6.14 Mechanistic model of CSR. This figure incorporates features of the most widely accepted models, but some aspects are controversial at present. Two strands of DNA near the 5′ boundary of a Switch region are shown in black, with the S region repeats indicataed by dots. DNA with normal Watson-Crick base-pairing is indicated by the gray shading between the DNA strands. RNA Polymerase moves to the right, transcribing the sequence into an RNA strand; multiple other proteins accompany the RNA pol, but only AID (black circle) is shown. AID may deaminate C residues to U either in the negatively supercoiled DNA behind the transcription complex or in the single-strand R-looped DNA displaced by the RNA-DNA complex. Cleavage of the U-bearing DNA strand can lead to dsbs in pathways dependent or independent of MMR components as shown.

been interpreted as an indication that CSR usually proceeds by ligation of blunt DNA ends rather than by strand invasion. However, DNA cuts with staggered—not blunt—ends would generally be the result of the widely discussed mechanism shown in Figure 6.14: a DNA break on one strand might result from AID-catalyzed cytosine deamination, removal of the resulting uracil by UNG, and cleavage 5′ to the abasic site by an endonuclease, possibly APE1 (apurinic-apyridinic endonuclease 1). The initial staggered ends could be converted to blunt ends through trimming of a 5′ or 3′ single-strand overhang, or through filling in the shorter strand by a DNA polymerase, or through a combination of both processes. Filling in by error-prone polymerases could explain the mutations commonly

observed around the switch junction, mentioned previously.

Evidence supporting staggered DNA breaks in CSR was reported from the switch junctions observed in a model CSR substrate designed with two oppositely oriented S regions such that CSR would occur by inversion, preserving both recombination junctions on the same chromosome. Several duplications at the ends of inverted DNA after CSR suggested that complementary overhangs at dsbs had been filled in before joining (343). Additional evidence for staggered breaks has come from several investigators using LM-PCR to detect double-strand DNA ends at switch regions in cells undergoing CSR (344–346). LM-PCR protocols involving ligation of a blunt linker directly to blunt ends from genomic DNA was successful in amplifying blunt ends from DNA of B cells activated for CSR, but when the DNA was pretreated with T4 polymerase—which would convert staggered end cuts to blunt—the yield of amplified bands after LMPCR was significantly increased, suggesting that most of the ends in the isolated genomic DNA (before T4 polymerase treatment) were staggered.

As discussed earlier, SHM-associated dsbs in V regions occurred independently of AID. When the CSR-associated dsbs in $S\mu$ were examined by LM-PCR in B cells from normal and $AID^{-/-}$ individuals, the dsbs were significantly fewer in $AID^{-/-}$ B cells, though not completely absent. Further, γH2AX foci (which mark dsbs, as mentioned earlier) were found at IgH genes marked by FISH in B cells undergoing CSR, and these foci were strikingly diminished in $AID^{-/-}$ B cells, consistent with AID-dependence of dsbs in CSR (347). However, a provocative recent report suggests that AID may play an additional role after dsbs have been created. Two unrelated human HIGM2 patients were observed to have a particular heterozygous mutation in AICDA: a premature stop codon replacing Arg190 (i.e., in the C-termininal region known to be important for CSR). Although other AICDA mutations cause an HIGM phenotype only when homozygous, this R190X mutation acted as a dominant negative for CSR; but significantly, there was no dramatic decrease in dsbs in the patients' activated B cells (348). This result suggests that after the creation of dsbs, the C-terminal residues of AID may be required for an additional step to complete CSR.

Ubiquitously Expressed Components of CSR Machinery

Role of Uracil-N-Glycosylase in CSR. The model of Figure 6.14 suggests that after AID-catalyzed deamination of a cytidine residue, the resulting uracil is removed by UNG, creating an abasic site that leads to a single-strand DNA break (nick), which can become double-stranded if there is a nearby nick on the opposite strand. This model predicts that both CSR and the creation of dsbs would be severely impaired in the absence of UNG. Indeed, B cells from $UNG^{-/-}$ mice showed almost complete inability to switch *in vitro* to IgG1and IgG3 secretion and significant impairment in IgA secretion (197). Double-strand breaks in $UNG^{-/-}$ B cells, as detected by LM-PCR, were also significantly impaired, but not abolished (346). Human patients with homozygous UNG deficiency due to mutations in both UNG alleles showed an HIGM phenotype, with a more profound defect than in $UNG^{-/-}$ mice: the patients showed essentially no IgG, IgE, or IgA secretion by stimulated B cells, and no dsbs (by LM-PCR) in $S\mu$ (349). A role for UNG in CSR is also suggested by the fact that UNG expression was found to be upregulated in normal B cells stimulated for CSR (349).

These data support an important role for UNG in CSR as outlined in Figure 6.14, but several lines of evidence from Honjo's lab have challenged this model. First, mutant UNG proteins with profoundly impaired uracil deglycosylase enzymatic activity were able to rescue CSR in $UNG^{-/-}$ murine B cells (350); second, expression of the specific UNG inhibitor protein Ugi at concentrations sufficient to inhibit UNG enzymatic activity did not inhibit dsb formation in CSR as assessed by formation of γH2AX foci (351); and third, IgM$^+$ B cells from $UNG^{-/-}$ mice stimulated to undergo CSR showed a normal frequency of internal deletions in $S\mu$, deletions that depend on AID-induced recombination (352). These authors suggested that UNG may act in CSR by binding other CSR components rather than by removing uracils enzymatically, and that the step where UNG is required may be after, rather than before, DNA cleavage. One caveat is that a small residual amount of UNG activity remaining in the mutants or in the presence of Ugi might have confounded some results. A full reconciliation of the evidence on UNG function will require additional data.

Role of MMR in CSR. The complementary pathways of UNG and MMR action in SHM were discussed earlier (Figure 6.12); current evidence suggests a similar participation of both UNG and MMR in CSR. Although CSR was dramatically impaired in $UNG^{-/-}$ B cells (e.g., *in vitro* switching to IgG1 was reduced to about 6% of wild type), the double KO $UNG^{-/-}$, $MSH2^{-/-}$ caused significant further impairment (to 1.5% of wild type IgG1 switching) (283). Single KOs of MMR components (MSH2, PMS2 or MLH1) inhibit CSR efficiency by only two- to five-fold, but cause significant differences in the characteristics of switch junctions, including alterations in the extent of microhomology at the junctions *(353,354)*. Notably, $S\mu$ junction breakpoints in $MSH2^{-/-}$ B cells were found to cluster in the $S\mu$ tandem repeat sequences of $S\mu$ ($S\mu$TR), with significantly fewer breakpoints upstream of the tandem repeats *(355)*. $MSH2^{-/-}$ B cells in which the $S\mu$ tandem repeats were knocked out by homologous recombination ($S\mu$TRΔ), showed profoundly impaired CSR efficiency (to 0.6% of wild type) (356), whereas CSR efficiency in B cells carrying the $S\mu$TRΔ allele but wild type MSH2 was only

modestly impaired (two- to three-fold reduced efficiency), as discussed earlier. These results suggest that MSH2 is primarily important for mediating CSR at positions outside the Sμ tandem repeats; presumably UNG can act without MSH2 to mediate the recombinations within the repeats. Perhaps the frequent AGCT motifs in the tandem repeats cause single-strand DNA nicks that lie close enough together to act as staggered double-strand breaks, able to participate in CSR with minimal further processing; whereas in the sparsely scattered hotspots flanking the tandem repeats, AID generates uracils that lie too far apart to engage in CSR without processing by MMR components.

As discussed previously, Exo1 is a component of MMR machinery that participates in SHM. Exo1 KO mice show a significantly decreased efficiency of CSR, from roughly 15% to 30% of normal (depending on isotype), with some decrease in microhomology at CSR junctions (282).

Nonhomologous End Joining Components in CSR. If AID triggers cleavage at switch regions, ubiquitous DNA repair and ligation enzymes may accomplish the subsequent DNA repair steps of CSR as in V(D)J recombination. This possibility has been tested for several proteins whose role in V(D)J recombination was discussed earlier in this chapter. Because KOs of NHEJ components are impaired in V(D)J recombination, investigators have studied NHEJ in CSR using mouse strains with "knock-ins" of recombined heavy and light chain genes, allowing normal B cell development up to the point of CSR. Whereas "knock-in" mice with intact Ku genes switched to downstream isotypes, the corresponding Ku-70– or Ku-80–deficient mice were dramatically impaired in CSR *(357,358)*. A role for the Ku complex in CSR is also suggested by the fact that incubation conditions favoring CSR (IL4 and CD40 engagement) increased the amount of Ku complex detectable in nuclear extracts of splenic B cells *(359)*.

Treatment with IL4 plus CD40 engagement also increased the level of nuclear DNA-PK, but the evidence for a role of this protein in CSR is complex. Although an early report indicated dramatically reduced CSR in pro-B cells from SCID mice—the classic DNA-PK mutant described earlier—more recent studies of conventional CSR in mature B cells of SCID mice with "knock-in" recombined Ig genes have found that the SCID mutation causes only modest (two- to three-fold) reductions CSR efficiency, differing for different isotypes *(360)*. In contrast, a null (KO) mutant of DNA-PK essentially abolished CSR to all isotypes except IgG1 (361). The reason for the more severe effect of KO versus the SCID mutation is not fully understood, but it is possible that the SCID mutant protein, while truncated and lacking kinase activity, may still retain a scaffolding function that facilitates switching by recruiting other CSR components, and that loss of this scaffolding function in the DNA-PK KO mouse accounts for the more severe phe-

notype. The sparing of CSR to IgG1 in the DNA-PK KO remains mysterious.

DNA Damage Response Proteins in CSR. Several additional proteins known to participate in the damage response to dsbs in DNA seem to participate in CSR. A complex of three proteins—Mre11, Rad50, and Nibrin (also known Nbs1, product of the abnormal gene in the human disease Nijmegen Breakage Syndrome, NBS)—is conserved in eukaryotes from yeast to mammals and has been implicated in telomere maintenance, cell cycle checkpoint signaling, meiotic recombination, and dsb repair. The Nibrin component binds rapidly to dsbs induced by irradiation and forms foci coincident with IgH gene FISH fluorescence in B cells undergoing CSR (347). Nibrin-deficient mouse B cells show impairments in CSR (to 30% to 50% of normal efficiency) (362,363), while human NBS patients show lower than normal concentrations of IgG and IgA in serum, consistent with a CSR defect *(364)*. The Mre11 protein has a nuclease activity and may contribute to dsb formation, since Mre11/RAD50 complex was found to cleave an AP site in *in vitro* experiments (365). Human patients with Mre11 deficiency (ataxia telangiectasia-like disorder, ATLD) also show evidence of decreased CSR efficiency and evidence of abnormal switch junctions, with increased microhomology and abnormal mutations (366).

An important function of the MRN complex is to recruit and activate ATM—product of the gene mutated in the human disease <u>a</u>taxia <u>t</u>elengectasia (AT). ATM is a member of the phosphatidylinositol-3'-kinase family and participates in the DNA damage response by phosphorylating a number of critical protein targets including p53, Chk2, and Nibrin. Human AT patients have a complex disease similar to NBS, including an immunodeficiency with T cell abnormalities as well as variably low IgG and IgA levels. B cells from AT patients undergo $\mu \rightarrow \alpha$ *in vitro* switching at reduced efficiency, and the Sμ-Sα switch junctions formed show a very high frequency of microhomology with abnormally infrequent mutations near the junctions (367). ATM-deficient mouse B cells show impaired CSR with normal germline transcripts (368,369). One group reported an increase in microhomology at switch junctions, similar to that observed in human AT patients (368). While CSR between different S regions was impaired in the ATM KOs, internal deletions within Sμ occurred in IgM-secreting cells at a frequency similar to that in wild type, suggesting that the loss of ATM specifically impaired long-range joining; this may indicate a role for ATM in synapsis of DNA ends (369).

As discussed previously in the context of V(D)J recombination, γ-H2AX—the phosphorylated form of histone H2A—rapidly accumulates in foci at dsbs and may help assemble other proteins at dsbs to prevent the breaks from progressing to chromosome translocations. H2AX$^{-/-}$ B cells show a CSR defect very similar to that in ATM$^{-/-}$:

significantly decreased CSR efficiency with normal frequency of deletions within Sμ (300).

53BP1 (p53 binding protein 1) was originally discovered as a protein binding to the tumor suppressor p53 but was subsequently found to function in checkpoint control and to localize rapidly to DNA breaks *in vivo*. 53BP1$^{-/-}$ murine B cells show significant impairment in CSR (to 5% to 25% of wild type) depending on isotype, without defects in cell proliferation, germline transcription in the IgH loci or V(D)J recombination (370,371).

Although the exact functions of ATM, the MRN complex, γ-H2AX and 53BP1 are unknown in dsb repair and specifically in CSR, the emerging evidence suggests that they have mutual interactions and distinct but related roles, so that the elimination of any one protein reduces CSR efficiency but permits residual CSR to occur by pathways that remain intact.

Other Possible CSR Components. Several other proteins implicated in CSR may be mentioned. Rare human patients lacking functional ligase IV have recently been described; they suffer a severe phenotype including immunodeficiency with dramatic decreases in T and B cell numbers, as discussed earlier in the context of their defect in V(D)J recombination. Abnormal Sμ-Sα switch junctions were amplified from patients' blood cells, suggesting that ligase IV normally participates in CSR (372). ERCC1-XPF is an endonuclease that nicks double-strand DNA several nucleotides 5$'$ of a gap in one strand. ERCC1$^{-/-}$ murine B cells showed slightly decreased CSR efficiency and subtle abnormalities in switch junctions, suggesting a possible role in CSR (373). Additional as yet unidentified components of CSR are suggested by reports of patients with an HIGM phenotype unexplained by defects in known components (374).

In summary, a consensus model for CSR would be that cytokines and CD40 ligation trigger AID expression and isotype-specific sterile transcription. As a result of transcription, DNA strands in S regions become separated (either by a helicase activity associated with transcription, or perhaps as a result of R-loop formation), allowing AID to deaminate cytosines on the exposed single-strand DNA. The resulting uracils serve as a target either for removal by UNG or for initiation of mismatch repair. If UNG removal creates an abasic site, that strand may be nicked by APE1 or by the MRN complex. Alternatively, MMR may be engaged and digest away several nucleotides surrounding the abasic site. Closely apposed single strand cuts on opposite strands may effectively become dsbs, as may more distant cuts after single-strand cuts are converted to single-strand gaps by MMR components. Dsbs quickly recruit repair factors of the MRN complex, ATM, 53BP1, γ-H2AX, and NHEJ components, which either seal internal gaps within one S region, or through synapsis with a dsb from a distant S region, complete a recombination event. This model leaves unanswered many questions about mechanisms that target these events to S regions and about the precise role of all the components; undoubtedly some of these questions will be clarified by future investigations.

CONCLUSION

Recombinant DNA technology has revolutionized the study of the antibody response. Initial investigations used powerful cloning and sequencing methods to define the structure of the Ig genes as they exist in the germline and in actively secreting B lymphocytes. Subsequent experiments have begun to shed light on the mechanisms of the processes unique to these genes: V(D)J recombination, CSR, and somatic hypermutation.

The knowledge of Ig genes gained so far has answered some of the most puzzling mysteries about antibody diversity, as discussed earlier, and has also led to many practical ramifications exploiting these genes that are beyond the scope of this chapter (reviewed in ref [375]). As one example, cloned Ig genes have allowed the production of recombinant monoclonal antibodies in bacteria and the bioengineering of Ig-fusion proteins that exploit the exquisite specificity of antibody V region binding (e.g., antibody-toxin fusions) or the ability of Ig constant region domains to extend serum half-life (e.g., immunoadhesins). Other engineered derivatives utilizing Ig genes include single-chain antibodies (e.g., *[376]*), bispecific antibodies (e.g., *[377]*), and "intrabodies" designed not to be secreted from a cell but rather to bind to intracellular targets (e.g., *[378]*. Ig V gene fragments cloned into bacteriophage so as to express single-chain V regions on the phage surface (phage display libraries) can be used to obtain specific monoclonal antibodies without immunization or use of mammalian cells, and *in vitro* mutation and selection protocols can mimic affinity maturation to yield high-affinity antibodies (reviewed in *[379]*). Even Ig gene regulatory regions have been exploited to achieve B cell–specific expression of oncogenes *(380)* and of intracellular toxins that could be used to target B lymphomas *(381)*. Apart from these biotechnology applications, Ig gene probes of Southern blots and library clones from lymphomas have led to the identification of numerous proto-oncogenes that become activated by translocation into Ig gene loci (reviewed in [382]). For instance, Bcl2 was initially discovered as the target of Ig heavy chain translocation in follicular lymphoma and provided an entrance into an entire family of apoptosis-related genes. A final example of medical benefit from Ig gene technology has been the amplification of unique Ig gene rearrangements by PCR to diagnose (or monitor minimal residual disease in) leukemias or lymphomas (383,384).

Further practical applications of Ig genes can be anticipated in the future, as well as a deeper scientific

understanding of their molecular biology and their contribution to the immune system.

B Lymphocyte Development and Biology

Richard R. Hardy

INTRODUCTION

B lymphocytes constitute one of the major arms of the immune system, being responsible for humoral immunity. B cells in humans and mice are produced throughout life, primarily in the fetal liver before birth and in the bone marrow afterward. B lymphocytes development from hematopoietic stem cells has been extensively characterized in mice, and the generation of numerous gene-targeted and transgenic lines in many cases has provided crucial information about the role of transcription factors, cellular receptors, and interactions that are critical in their generation. The complexity of this process is now apparent, and their differentiation into multiple peripheral subsets with distinctive functions is also widely appreciated. This chapter will focus on B cell development and function in the mouse, touching more briefly on aspects of human B cells that are similar or distinctive with a focus on immunodeficiency. It will conclude with a brief description of novel aspects of B lymphocyte development in other species, highlighting differences from development in mouse and human.

B CELL DEVELOPMENT IN MICE

In mice, B cells are produced from hematopoietic stem cells through a complex process of differentiation that is gradually becoming understood. One of the goals of clas-sical hematology is the delineation of differentiation pathways for different lineages of blood cells, and this is rapidly being achieved. Over the past decade, there has been considerable progress in utilizing the ordered expression of a diverse set of cell surface and internal proteins, some with known functions, others whose roles are only suspected, to construct a description of the intermediate stages that cells transit as they develop into B lymphocytes. A simplified example of such a description is presented in Figure 7.1. Thus, hematopoietic stem cells with the capacity to generate all the cell types in blood create progeny with a more restricted capacity, recognizable in this example by expression of the IL-7Rα. These in turn produce yet more restricted progenitor cells identified by expression of CD45R/B220 (and, importantly, by absence of CD19).

This kind of pathway is constructed based on isolation and short-term culture of intermediate stages, allowing progression to occur, which helps to define the order. This framework for development serves as a starting point for analysis of the effects of transcription factors, microenvironmental interactions, cytokines, and natural or engineered mutations. It can also be extended by analysis of gene or protein expression at distinct intermediate stages. Critical processes, such as D-J rearrangement and immunoglobulin (Ig) heavy chain expression, can also be mapped onto this framework. Progress in this work allows additional questions, such as key regulatory interactions,

developmental checkpoints, and the mechanism of B lineage commitment to be approached.

The following sections will cover the sites of B lineage development at different stages of ontogeny, then focus on what is known about their development in the bone marrow of adult mice, highlighting the function of the pre-B cell receptor and the crucial role of Ig heavy and light chains in guiding development. Later sections will consider their differentiation into various specialized peripheral populations and emphasize insights into B cell selection gained from various transgenic models of tolerance.

Early Development

Sites of B Lymphopoiesis During Ontogeny

In the mouse, hematopoiesis occurs predominantly in the fetal liver prior to birth, in the spleen just prior to and shortly after birth, and in the bone marrow thereafter. Prior to liver hematopoiesis, the blood islands of the yolk sack (YS) contain the first identifiable hematopoietic cells, nucleated erythrocytes with embryonic forms of hemoglobin *(1)*. However, these early YS precursors appear incapable of generating other blood cell lineages, and generation of all blood cell types, including lymphocytes *(2,3)*, initiates

at around 9 to 10 dpc in an embryonic region referred to as the *splanchnopleura/aorta-gonads mesonephros (AGM)* (or simply Sp/AGM). Cells from this site are capable of long-term repopulation of lethally irradiated adult recipients with all blood lineages *(4,5)*. These cells colonize the fetal liver at about 11 dpc, initiating hematopoiesis there. Thus, there are two sites of very early hematopoietic precursors, with one in the YS largely limited to erythropoiesis and the other in the Sp/AGM capable of complete (referred to as *definitive*) hematopoiesis. However, it may be that precursors in the YS have a broader lineage potential in the fetal microenvironment, as when they are injected directly into the newborn liver *(6)*.

Hematopoietic stem cells (HSC) capable of developing into all the blood cell types are produced in the Sp/AGM and migrate to the fetal liver at about d10. Thereafter, B lineage cells develop largely in a wave, with earlier stages present at earlier times and later stage predominating at later times, close to (and shortly after) birth *(7,8)*. This progression with gestation day is easily visualized by staining with antibodies that delineate B cell development as shown in Figure 7.2. Early precursors can also be found in the fetal omentum *(9)*. In contrast with the bone marrow, cells at most differentiation stages in the fetal liver appear to be rapidly proliferating, so larger and larger numbers of B lineage cells are detected at progressive days of

Fetal Liver Gestation Day
FIGURE 7.2 Phenotypic progression of developing B lineage cells in mouse fetal liver analyzed at different days of gestation. Note that B220$^+$CD43$^+$cells precede B220$^+$CD43$^-$cells and that within the B220$^+$CD43$^+$ fraction HSA$^-$ cells precede HSA$^+$ cells, and BP-1$^-$ cells precede BP-1$^+$ cells. Within the B220$^+$CD43$^-$ fraction, the IgM$^+$ percentage increases until birth (at about day 20).

gestation. Another distinction of fetal liver from bone marrow development in the adult is the absence of terminal deoxynucleotidyl transferase (TdT) (10,11), an enzyme that mediates nontemplated addition of nucleotides at the D-J and V-D junctions of Ig heavy chain *(12,13,14)*. Therefore, heavy chains produced during fetal development have little or no N-region addition, and CDR3 diversity is constrained even further by favoring of short stretches of homology at the V-D and D-J junctions (15,*16*). Rearrangement of certain V or D elements may also differ between fetal and adult development—such as, for example, the reported high utilization of the DFL16.1 segment in fetal liver *(17)*. Differential expression of genes other than TdT also distinguish B cell development during fetal life from that in the adult, including precursor lymphocyte regulated myosin light chain like PLRLC transcripts (11,*18*) and major histocompatibility complex (MHC) class II (19,*20*). Interestingly, while absence of the cytokine IL-7 completely eliminates bone marrow B linage development *(21)*, it nevertheless spares some fetal development (22), suggesting a difference in growth

requirements. The B cell progeny of this early fetal wave may largely consist of B cell quite distinct from adult-derived cells, populating the B-1 subset (23).

At birth, B cell development can also be detected in spleen, but development at this site gradually decreases to very low levels by 2 to 4 weeks of age. Over this same period, B cell development shifts to the bone marrow, and thereafter it continues for the life of the animal. B lymphopoiesis decreases in aged mice, and this may be due to diminished responsiveness of precursors to IL-7 *(24,25)*.

Stem Cells, Commitment, and Early B Cell Progenitors in Bone Marrow

B cells are continually generated from HSCs in the bone marrow of adult mice. Considerable effort has focused on evaluating the functional capacity of fractions of bone marrow cells to repopulate different lineages of blood cells, and this work has progressed to the stage of defining a phenotype for such cells, with expression of c-KIT constituting an important marker in the so-called "lineage negative"

subset (26,27). This is the small fraction of bone marrow cells (less than 5%) that lacks expression of a panel of "differentiation markers," cell surface molecules that are expressed on later stages of various hematopoietic cell lineages. Careful analysis of this HSC fraction using additional markers has shown that it represent perhaps 1/30,000 of nucleated bone marrow cells with as few as 10 mediating multilineage repopulation in cell transfer assays (28,29,30). An important capacity of "true" or "long-term repopulating" HSC is their ability to give rise to cells in a recipient mouse that can also repopulate all the blood cell lineages upon retransfer into a second host, indicating a capacity for extensive self-renewal without differentiation into more restricted progenitors.

In the past decade, a great deal of interest has focused on defining and characterizing lineage-restricted progenitors, such as the common myeloid and common lymphoid progenitors (CLP) (31,32,33). The CLP cell fraction was identified by lack of a panel of "lineage markers," expression of the IL-7Rα chain, and distinctive intermediate levels of c-KIT, compared to higher levels on HSC. Initial characterization of these cells in various functional assays suggested that these cells could generate B, T, NK, and a subset of dendritic cells, but no other blood cell lineages. The reason for this restriction has been intensively studied, and down-regulation of the receptor for granulocyte-myeloid stimulating factor has been suggested to be a key event in this process (34). Cells with the phenotype of CLP constitute about 1/3,000 of bone marrow cells. Prior to the CLP stage, multipotent progenitors exhibit low-level expression of genes characteristic of diverse cell lineages, leading to the idea that such promiscuous expression indicates chromatin accessibility that facilitates flexibility in cell fate decisions (35).

CLP cells can give rise in short-term cultures to cells of the B lineage, naturally raising the issue of when cells become restricted to the B lineage. The majority of cells growing in stromal cultures give rise only to B cells upon transfer into mice, and the phenotype of these cells has been well characterized (36). Most have at least some heavy chain rearrangement and bear the B lineage marker CD19 (37,38). There is less certainty concerning the cells isolated directly from primary lymphoid tissues, as such cells are quite rare, similar to the CLP and HSC. Most of the CD45R/B220$^+$ cells in bone marrow are also CD19$^+$, and such cells appear to be irreversibly committed to the production of B cells (39). However, a subset of B220$^+$ cells lacks detectable CD19 expression, and cells within this fraction can generate CD19$^+$ cells in short-term stromal culture with IL-7. Such cells are found within the CD43$^+$CD24^{low} fraction (Fr. A, 1% of bone marrow) of B220$^+$ cells in bone marrow, but this fraction also contains other cell types, including natural killer (NK)-lineage precursors (38,40). Thus, it is necessary to exclude cells lacking AA4.1 (about half [38]) and recent analysis (41) suggests that exclusion of Ly6c$^+$ cells

(about half of the AA4.1$^+$ cells) is another useful criterion for purifying this subset. Many of these Ly6c$^+$ cells also express CD4, and recent work suggests that these are plasmacytoid dendritic cells (42,43). A phenotypic approach for enriching and fractionating very early B lineage subsets is shown in Figure 7.3a.

Careful analysis of the LIN$^-$ (including CD19) IL7Rα^+c-KIT$^+$ CD45/B220$^-$ (CLP) and CD45/B220$^+$ (Fr. A), as delineated in Figure 7.3, suggests that our understanding of the earliest stages of B cell development in bone marrow needs some revision (44). First, while CLP stage cells fail to efficiently generate myeloid cells upon transfer into irradiated hosts, they nevertheless retain significant capacity to produce such cells in short-term cultures, likely due to continued (albeit reduced) expression of receptors for myeloid growth factors. In contrast, this myeloid capacity is greatly reduced as cells begin to express CD45R/B220 (i.e., become Fr. A), concomitant with reduced expression of receptors for myeloid growth factor receptors. Yet these Fr. A cells, while poorly reconstituting T cells in cell transfer assays, nevertheless retain the capacity to generate T lineage cells in culture, mediated by engagement of Notch by its ligand DL1 (45). Thus, the loss of potential for alternate hematopoietic lineages appears to be lost somewhat later in progression down the B lineage pathway in mouse bone marrow than previously thought. However, it appears that initiation of Ig rearrangement is initiated earlier than some studies have indicated. Determination of the extent of germline DNA segments lost upon DJ rearrangement and the formation of such DJ segments in individual cells isolated by electronic cell sorting showed that 30% to 50% of cells in CLP and more than 80% of cells in Fr. A contained a DJ rearrangement on at least one chromosome (44). This is consistent with high-level expression of genes important in Ig rearrangement, including TdT, Rag-1, and Rag-2, in CLP (46) and Fr. A stage cells.

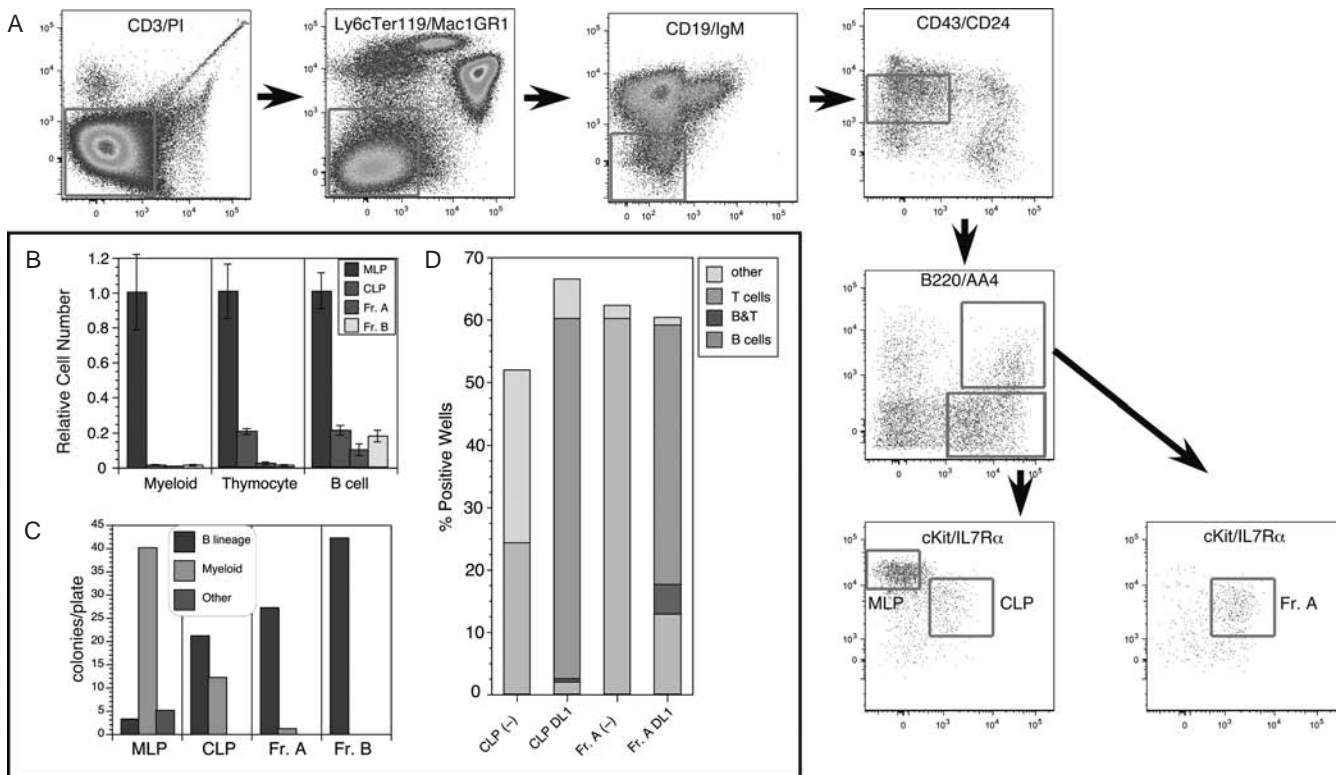
An emerging view of CLP (and possibly even the earlier multi lineage progenitor (MLP)) stage cells considers them to be early B lineage precursors, rather than branch points in the production of other hematopoietic cell lineages. Thus, analysis of CD4/CD8/CD3 "triple-negative" cells in thymus failed to identify cells with a surface phenotype comparable to CLP, and mutant mice lacking CLP in bone marrow nevertheless have relatively intact thymic development, leading to the suggestion of a distinct "early T progenitor" (ETP), different from CLP (47). It seems reasonable to hypothesize that MLP, CLP, and Fr. A stage cells occupy a distinctive microenvironmental niche in bone marrow, where they receive signals that guide them along the early stages of B lineage development, culminating in CD19$^+$ pro-B cells that are irreversibly committed to becoming B cells, due to expression of PAX-5 (39; and see following section). Identifying this niche and characterizing the key signals that lead to specification of the B cell fate are areas of continuing research.


FIGURE 7.3 A: An approach for purifying the earliest stage of B lineage cells in mouse bone marrow. Bone marrow cells expressing cell surface proteins characteristic of differentiated stages of T, myeloid, erythroid, and B lineages are depleted sequentially by electronic gating in the first three panels. Cells with low-level expression of CD24/HSA and intermediate levels of CD43(S7) are selected in the fourth, and the distribution of Cd45R/B220 versus CD93/AA4 is shown in the fifth. AA4$^+$B220$^-$ cells contain MLP and CLP, resolved by analysis for cKit versus IL7Rα in panel six. AA4$^+$B220$^+$ cells, shown in the final panel, are enriched for cKit$^+$IL7Rα^+ cells, termed Fr. A. CLP stage cells resemble Fr. A, but lack detectable expression of CD45R/B220. In contrast with CLP and Fr. A, MLP stage cells have higher levels of cKit and lack IL7Rα expression. **B:** Functional analysis of early B lineage cells by *in vivo* competition assay, showing absence of myeloid or T lineage generation, but production of B lineage cells from Fr. A. In contrast, CLP stage cells generate B and T cells, whereas MLP repopulate B, T, and myeloid lineage cells. MLP, CLP, and Fr A as identified in A. Fr. B stage cells are DJ/DJ rearranged pro-B cells, identified as CD19$^+$CD43$^+$CD24(HSA)$^+$. **C:** Functional analysis of early B lineage cells by *in vitro* S17 stromal cell assay, showing predominant B lineage colony formation from Fr. A, but some myeloid generation from CLP stage cells. **D:** Functional analysis of early B lineage cells by *in vitro* DL1-OP9 stromal cell culture, revealing very significant T lineage potential in Fr. A stage cells.

Additional issues remain with regard to the lineage restriction of cells at these early stages in B cell development. For example, there is evidence that cells restricted to generating B and myeloid/macrophage (but not T) lineage may exist, in the fetal liver (48) and even in bone marrow *(49)*. There is also apparently a different dependence of fetal liver B lymphopoiesis on expression of the transcription factor BSAP compared to bone marrow, as determined by analysis of PAX-5 null mice *(50)*. Further comparison of B cell development in fetal liver with that in bone marrow is needed to clarify this point. Finally, the precise delineation and characterization of B cell precursors earlier than CLP, prior to IL-7 expression, remains imprecise. It seems likely that at least some of the MLP stage cells mentioned earlier are initiating a B lineage program, based on their expression of E2A, Rag-1, Rag-2, and TdT (44). However, potential heterogeneity in this fraction needs to be assessed. Determination of Rag-1 transcriptional activity at the single cell level by a GFP reporter, used for identification of the early lymphoid progenitor (ELP) fraction (51), may provide a key approach for such studies.

Transcription Factors Important in B Lineage Development (Figure 7.4)

The GATA-2 and Runx1/AML1 transcription factors are required for the development of hematopoietic stem cells that are the precursors of all the blood cell lineages,
FIGURE 7.4 Transcription factors important at different stages in B cell development in mouse bone marrow. Some regulatory networks are also shown. Positive/activating activity is indicated by arrows, while negative or blocking activity is indicated by bars. The rapidly cycling stage, early pre-B, is also indicated. Predominant stages of expression are indicated below the diagram.

including B cells *(52–56)*. Somewhat later acting, but still very early in development, is the Ikaros transcription factor (57,*58,*59). Ikaros and the related transcription factor Aiolos (60) play important roles in lymphocyte development. Ikaros is expressed very early in hematopoietic precursors. Ikaros null mice lack B lineage cells (59) and a different Ikaros mutant that acts as a dominant negative completely blocks lymphoid development (57). Ikaros activates numerous early B lineage genes, including TdT, Rag-1, λ5, and VpreB. Aiolos is detected somewhat later in development, at about the stage of B lineage commitment, and its expression increases further at later stages.

PU.1, an ets family transcription factor, is critical for progression to the earliest stage of lymphoid development, as demonstrated by the inability of PU.1 null precursors to generate lymphocytes (61,62). An important target of PU.1 for B lineage development is the gene for Ig-β, known as MB-1. The level of PU.1 appears to be critical for development along the B lineage, as, while low-level expression

induced in PU.1 null mice allowed B lineage development, high-level expression blocked this and fostered myeloid lineage development (63), likely due to differential induction of the IL-7Rα and M-CSF receptor chains *(64)*. In fact, retroviral mediated expression of the IL-7Rα chain complements defective B lymphopoiesis in PU.1 null bone marrow hematopoietic precursor cells (65). Surprisingly, recent work from several groups indicates that some B cell development can occur in the absence of PU.1 expression *(66)*. Further, analysis of conditional PU.1 knockout mice showed that expression of this transcription factor was not required after the pre-B cell stage *(67)*.

E2A codes for two proteins, E12 and E47, members of the basic helix-loop-helix family of transcription factors, and its induction is crucial from the earliest stages of B linage development, because all stages after CD19 expression are absent from E2A null mice (68,69). These mice lack detectable DJ rearrangements and, interestingly, such rearrangements can be induced in nonlymphoid cells by introduction of the Rag genes and ectopic expression

of E2A *(70)*, implicating this transcription factor in the process of chromatin remodeling of the Ig heavy chain locus that permits accessibility by the recombinase machinery (71). The regulation of E2A is crucial for B lineage development, as negative regulators such as Notch1 and ID2 have been show to block this lineage and induce alternate cell fates, to the T and NK lineages (72,73–75). Consistent with this picture, ectopic expression of genes that negatively regulate Notch1, Lunatic Fringe, and Deltex1, induce the B cell fate (76,77,78).

Expression of the early B cell factor, EBF1, a member of the O/E protein transcription factor family, is requisite for progression of early B lineage progenitors to the DJ-rearranged pro-B stage (Fr B), as shown in EBF1 null mice (79). EBF1 and E2A act at a similar stage in early in B lineage development, and these two transcription factors can act together to up-regulate a family of early B lineage–specific genes, including Ig-α/β, VpreB/λ5, and Rag-1/2 (80,*81*). There is evidence that E2A up-regulates expression of EBF1, found by transfection of E2A in a macrophage cell line (82), suggesting an ordering of these two in development. Further, recent studies showed that there are two distinct promoters for EBF1 that are regulated differently (83). A distal promoter is activated by IL-7 signaling, E2A, and EBF1, whereas a proximal promoter is regulated by PAX5, Ets1, and PU.1. Such complex regulation indicates that B cell development occurs through the action of several feedback loops in a regulatory network that is gradually being uncovered (*84*,85).

BSAP, the product of the PAX5 gene, is expressed throughout B cell development until the plasma cell stage *(86)*. PAX5/BSAP transcriptional targets include CD19 and BLNK and expression of this transcription factor acts to up-regulate V to DJ heavy chain rearrangement *(50)*. Analysis of chromatin structure around the Ig heavy chain locus revealed that PAX5 induces V to DJ locus contraction, thereby promoting rearrangement *(87)*. PAX5 null mutant mice show an arrest in bone marrow development at the pro-B stage, likely due to the lack of complete heavy chain rearrangements and also due to the absence of the critical B cell adaptor protein BLNK that serves to link the pre-B cell receptor (BCR) to the intracellular signaling pathway via the tyrosine kinase syk *(88)*. BSAP/PAX5 also acts to repress alternate cell fates, because pro-B phenotype cells isolated from PAX5 null bone marrow can generate diverse hematopoietic cell lineages, in contrast with such cells from wild-type mice that are B lineage restricted (39,*89*). This occurs by repression of the myeloid growth factor receptor gene c-fms (90) and by repression of the Notch1 signaling pathway (91), critical for T cell fate specification (*45*,92). Finally, as mentioned earlier, in contrast with bone marrow, the absence of BSAP/PAX5 arrests B cell development prior to the B220$^+$ stage in fetal liver, suggesting a crucial difference in the early dependence on this transcription factor *(50)*.

Lymphoid enhancer binding factor (LEF-1) shows a pattern of expression restricted to the pro-B and pre-B stages of B cell development *(93)*. Targeted inactivation of the LEF-1 gene allows B cell development, but with reduced numbers (94). This is because LEF-1 regulates transcription of the Wnt/β-catenin signaling pathway whose activation increases proliferation and decreases apoptosis of early B lineage cells. In fact, exposure of normal pro-B cells to Wnt protein induces their proliferation (94). Interestingly, there is a counter-proliferative signal that can act at the pre-B proliferative stage, mediated by TGF-β1 (95). It appears that this occurs due to induction of the Id-3 inhibitor that negatively regulates the activity of E2A *(96)*. Another transcription factor whose expression is similar to LEF-1 is SOX-4 and its inactivation also results in the inability of normal early B lineage cell expansion and a block at the pro-B stage *(97)*.

Several forms of NF-κb subunits are expressed throughout B cell development, and this transcription factor can regulate kappa light chain expression and also growth factor signaling (98). Mice lacking the p65 subunit die before birth, and so development must be analyzed by transfer of fetal liver precursors into wild-type recipients. Such experiments showed diminished B lineage cell numbers, but the major defect was in mature B cell mitogenic responses (99). Mice lacking the p50 subunit showed relatively normal B cell development, but again poor response to mitogen by mature B cells (99). However, mice lacking both the p50 and p65 subunits failed to generate any B220$^+$ B lineage cells. Curiously, when mixed with wild-type fetal liver cells, normal numbers of mature B cells could be generated from the double-defective precursors, suggesting that the defect could be overcome by secreted or membrane-bound signals provided by the wild-type precursors. Another double mutant, p50p52, showed a late stage defect in B cell development, with a failure to generate mature B cells in spleen *(100)*.

Inactivation of the Oct-2 transcription factor results in neonatal lethality, but transfers of fetal precursors can reconstitute lymphoid cells in wild-type recipients, allowing assessment of effects on the B lineage. Such studies have shown that fewer mature follicular B cells are generated in these mice, and B-1 (CD5$^+$) B cells are completely eliminated *(101–103)*. Similarly, the Oct binding factor, OBF-1, also known as OCA-B and BOB-1, appears to function in the maturation of newly formed B cells in the bone marrow to become follicular B cells in the periphery, because inactivation of this gene resulted in a significant deficit in mature B cells *(104–106)*. Both of these transcription factors have been shown to regulate the follicular B cell chemokine receptor CXCR5, and this may explain at least part of the defect *(107)*. Curiously, unlike Oct-2 null mice, there was reportedly no deficit in B-1 B cells in OBF-1 null mice. Interestingly, when the OBF-1 mutant mouse is crossed with Bruton's tyrosine kinase (Btk)–deficient mice, then there

is a complete lack of peripheral B cell generation *(108)*, suggesting that this transcription factor may function in the BCR-mediated selection of mature B cells.

Bone Marrow Developmental Stages

Functional Definition

Distinct stages of developing B lineage cells can be delineated based on their capacity for growth under different culture conditions. That is, the earliest precursors require cell contact with the stromal microenvironment, in addition to specific cytokines, notably IL-7 (95,109). This stromal cell/precursor adhesive interaction is mediated, at least in part, by binding of VLA-4 to ICAM-1 (*110*,111). Later stage cells do not require cell contact, but maintain a need for cytokines (112,113). Both cell types can undergo considerable cell proliferation in culture. Interestingly, the difference between cell contact requirement and independence is linked to the expression of heavy chain protein (112,*114*). A population of cytoplasmic heavy chain expressing B lineage cells later than either of these, the so-called *late* or *small pre-B cells,* does not proliferate in culture. These cells likely require different culture conditions for survival, as they usually do not persist for extended periods, but rather die with a half-life of less than 24 hours, unless protected from apoptosis by a Bcl-2 transgene *(115)*.

Phenotypic Definition

Further clarification of the heterogeneity in bone marrow can be achieved by analysis using fluorescent staining reagents and either microscopic or flow cytometric analysis. For example, the earliest determination that there were both heavy chain surface-positive B cell and cytoplasmic-positive pre-B cells was through microscopic examination using anti-Ig staining *(116,117)*. Later studies in mice

showed that there were specific surface proteins or "markers" that could be useful in identifying these populations, notably a restricted isoform (CD45Ra) of the common leukocyte antigen, CD45 (118). This largely B lineage–restricted 200 kDa molecular mass isoform is often referred to as *B220*. Some highly B lineage–restricted monoclonal antibodies, such as RA3-6B2, recognize a specific glycosylation of the CD45Ra isoform *(119)*. However, as described earlier, even highly specific antibodies such as 6B2 may also recognize other cell types, such as particular differentiation stages or subsets of NK or dendritic cells.

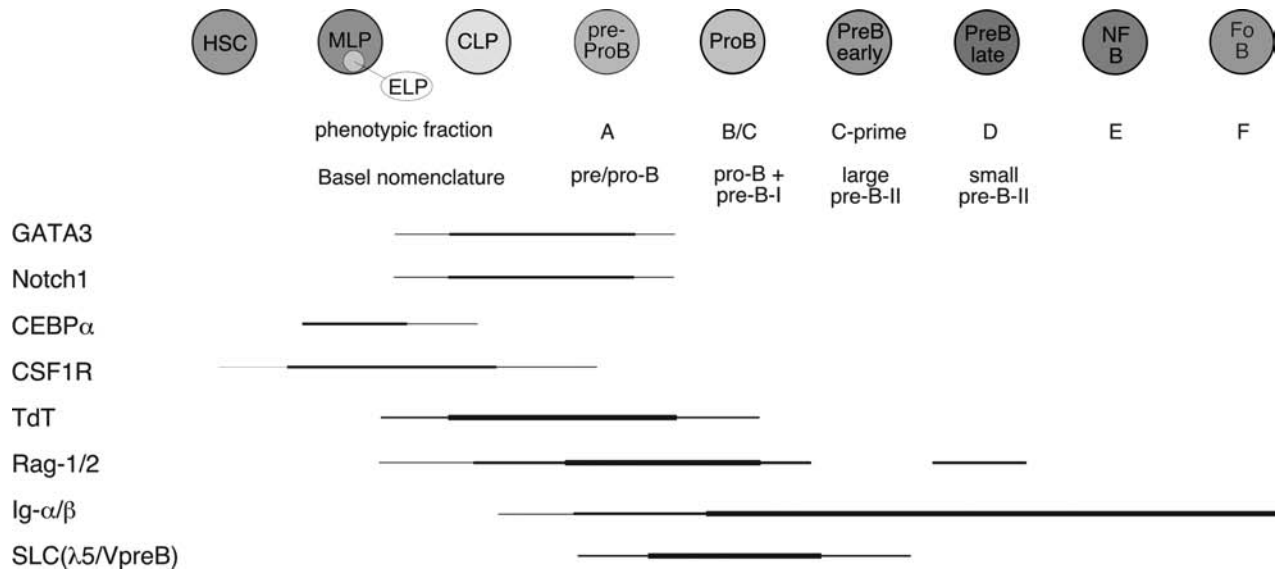
The application of multiparameter/multicolor flow cytometry and additional monoclonal antibodies specific for other cell surface proteins differentially expressed during B lineage development has facilitated delineation of multiple additional intermediate stages in this pathway (113). For example, the B220$^+$ population in bone marrow can be further fractionated into an earlier subset expressing CD43 (about 3% to 5% of marrow cells) and a later fraction with much lower CD43 expression (20% to 30% of marrow). The precursor/progeny relationship of cells in these two fractions can be readily demonstrated by short-term culture, with CD43$^+$ cells giving rise to CD43$^-$ cells. These two populations can be further sub-fractionated based on additional developmentally regulated surface proteins, such as CD24/HSA (heat stable antigen), BP-1 (a zinc-dependent cell surface metallopeptidase also known as *aminopeptidase A [120]*), and the surface Ig molecules IgM and IgD (113). This is shown in Figure 7.5. Again, these cell populations can be isolated and short-term culture used to determine their order in the pathway. Alternative approaches based on other developmental markers can be correlated with this framework of cell stages, notably the system developed by Melchers' group using expression of CD45R/B220, CD19, c-KIT, and the IL-2 receptor
FIGURE 7.5 Flow cytometry approach for analyzing different stages of CD19$^+$ B cell development in mouse bone marrow. Note that the antibody used for CD24/HSA staining, 30F1, is important, as other monoclonal antibodies that recognize HSA do not resolve high from low-level expression as well. The cells expressing low levels of CD24/HSA, labeled "A," are CD19$^-$ and enriched for very early B lineage precursors, but also contaminated by other cell types that can be detected by staining for AA4, NK1.1, DX5, and Ly6c; early B lineage precursors are AA4$^+$NK1.1$^-$DX5$^-$Ly6c$^-$.


FIGURE 7.6 Diagram of distinct phenotypic stages and characterization of TdT, biphasic Rag expression, Ig-α/β, and surrogate light chain (SLC) expression. Genes characteristic of myeloid and T cell lineage are also shown. The cell type descriptions are cross-referenced to the alphabetic phenotypic fraction nomenclature and also to the Basel nomenclature. The early lymphoid progenitor (ELP) population is identified by activation of the Rag-1 locus in a GFP reporter mouse.

alpha chain *(121)*. A diagram summarizing this type of phenotypic subdivision and relating different nomenclatures is shown in Figure 7.6.

Culture Systems and Critical Microenvironmental Interactions

The combination of phenotypic characterization coupled with analysis of growth and differentiation in culture has provided a very powerful approach for the further understanding of B cell development, as employed by many different investigators. Bone marrow cultures developed by

Whitlock and Witte (122,*123*,124) and fetal liver cultures developed by Melchers' group *(125,126)* have allowed determination of the critical cytokines and some of the cell adhesion molecules important in the *in vivo* development of these cells. Many of these are summarized in Table 7.1. A typical B lineage colony proliferating on S17 stromal cells in the presence of IL-7 is shown in Figure 7.7.

Survival and growth of the earliest stages of developing B lineage cells require cell contact with nonlymphoid-adherent cells that can be isolated from bone marrow, cells referred to generically as *stromal cells*. A number of lines

▌ **TABLE 7.1 Regulators of Growth of Early B Lineage Cells**

Mediator	Effect	Reference
IL-7	Stimulates CLP and B precursor proliferation	95, 132, *133, 523*
TSLP	Alternate IL-7–like cytokine	140, *141*
IGF-1	Stimulates accumulation of cμ^+ cells in culture	168
FLT-3/FLK2-L	Critical for earliest stages of B lineage development	*151*, 155, *524, 525*
c-KIT-L	Synergizes in IL-7–induced proliferation	26, 149
IL-3	Substitute for IL-7–in proliferation of pre-B clones	159
CXCL12/CXCR4	Crucial chemokine interaction for early B-lineage precursors	177, *179*, 181, *182*
Hemokinin	Novel regulator of B lymphopoiesis	170
VLA4/VCAM-1	Adhesive interaction; antibodies to either block B lymphopoiesis	*110*, 111, 526
CD44/hyaluronate	Adhesive interaction; mediates association of B lineage/stromal cells	128, *130*
TGF-β	Inhibits proliferation stimulated by IL-7	95
Sex steroids	Decrease B lineage precursors in bone marrow	527, 528
Growth hormones	Required for normal B lymphopoiesis	171, *172, 529*
TLRs	Innate immune system regulation	173
FIGURE 7.7 Photomicrographs of B lineage colony proliferating on S17 stromal layer (in the well of a 96 well microplate) in the presence of IL-7. Day 10 colony derived from a single Fr. A phenotype (Figure 7.3A) cell. Low- and high-power views. All of these cells now express CD19 and many have progressed to BP-1[+].

have been derived from primary cultures of bone marrow adherent cells and characterized in terms of their capacity to support B lymphopoiesis *in vitro* (127). This work has led to the discovery of adhesion molecules that play important roles in mediating the organization of clusters of developing B lineage cells on stromal layers, including CD44 interacting with hyaluronate and VLA-4 interacting with VCAM-1 (*110*,111,128,*129*). Both of these interactions could be disrupted by addition of blocking antibodies to CD44 and VLA-4 on B cell precursors, resulting in a disruption of normal pre-B proliferation *in vitro (130)*. Such adhesion interactions may serve to transmit signals directly to the stromal cells or B precursors or both. There is some evidence that stromal cells are induced to elaborate specific growth mediators after interaction with B cell precursors or soluble regulators *(131)*.

Another function of the stromal cells is to produce growth factors critical to B lineage survival, proliferation, and differentiation, and the most important of these for mouse B cell development is IL-7 (95,109,132,*133*). IL-7 promotes the survival and proliferation of pro-B and pre-B stage cells, both *in vivo* and *in vitro (134,135)*. Neutralizing antibody to IL-7 can block B cell development *in vitro* (113), and IL-7 expressed as a transgene can deregulate normal B cell development, leading to B cell lymphadenopathy *(136)*. The IL-7 receptor consists of a unique IL-7Rα chain *(137)* paired with the common gamma chain (γc) that is also found in the receptors for IL-2, IL-4, IL-9, IL-15, and IL-21 *(138)*. IL-7Rα null mice have a severe deficit of both B and T cells in the periphery and lack most B lineage cells in bone marrow (139). Mice with targeted inactivation of the γc or IL-7 do have some B lineage development, suggesting an alternate cytokine, and this appears to be TSLP. This protein was first identified as a pre-B cell growth factor produced by a thymic stromal line (140) and shows some of the same effects in culture as IL-7, although possibly inducing less proliferation and more differentiation *(141)*. Its receptor has been cloned and requires the IL-7Rα chain for function (142). It shares both sequence homology and genomic exon organization with the common gamma chain *(143)*. Signaling through the IL-7 receptor requires JAK3 and activates the transcription factor STAT5, whereas signaling through TSLP is JAK3 independent, but also activates STAT5 *(141,144)*. Unexpectedly, the growth response to TSLP requires synergy with the pre-BCR in bone marrow, but not in fetal liver (145), leading some to propose that this might be a marker for distinctive B-1 B cell development in bone marrow *(146)*.

The earliest precursors in the B lineage pathway, probably including cells that are not B lineage committed but that can efficiently give rise to B cells in a short time *in vitro,* have receptors for SCF/c-KIT-ligand (26,*27,147,148,*149,*150*) and FLK2/FLT3-ligand (*151–154*,155). Thus, the most permissive cultures for expanding precursors of B lineage cells will include these cytokines, in addition to IL-7 and a stromal adherent cell layer, such as S17 (156,*157,158*). IL-3 has also occasionally been suggested as playing a support role for pre-B cells *in vitro* (159), although its role *in vivo* may be at a much earlier stage. Although culture conditions have been reported that can support B lineage development in the absence of stromal cells *(160,161)*, the clear-cut alteration of contact dependence prior and post–heavy chain expression (112,113,*114,162*,163) argues that the most physiological model for early B lineage growth will include stromal cells. Besides providing important cell–cell contacts that may signal survival, proliferation, and differentiation, it is also likely that stromal cells bind at least some cytokines to their surface, providing higher local concentrations to the clusters of B lineage precursors that adhere *(164,165)*.

B lineage development may be modified by exposure to hormones and considerable interest has focused on sex steroids released during pregnancy that serve to depress B lymphopoiesis, particularly the pre-B cell pool (166).

This may be important to avoid autoimmune responses by the mother, but could have negative consequences due to possible transient immunodeficiency. Interestingly, fetal B lymphopoiesis is not similarly depressed, due to the absence of hormone receptors on fetal B lineage cells *(167)*. Insulinlike growth factor (IGF-1) has been reported to potentiate progression *in vitro* to the $c\mu^+$ stage (168,*169*), and more recently, there is a report of a bioactive peptide, a type of tachykinin, that synergizes with IL-7 to enhance the growth of IL-7 dependent cultures (170). Besides IGF-1, other pituitary hormones, thyroxine and growth hormone (GH) have effects on B lymphopoiesis (171). For example, thyroxine treatment can restore normal B cell development in dwarf Pit-1 mutant mice with deficient pituitary function *(172)*. Recent work has highlighted the effect that activation of Toll-like receptors during infection may have on altering development (173). Thus, it is likely that more detail remains to be filled in to complete our picture of the growth requirements and modulating influences of B lineage cells in mouse bone marrow.

Another function of cell–cell interaction is cell fate determination during the lineage commitment stage, very early in development of B lineage cells. The Notch signaling pathway is implicated in cell fate determination in invertebrates and more recently has been shown to function in lymphoid lineage specification (*45*,72,174). Notch family transmembrane receptors regulate transcription by being cleaved upon ligand binding to release an intracellular cytoplasmic domain that translocates to the nucleus where it interacts with the transcriptional repressor CSL *(175)*. Recent studies have shown that Notch1 can play a pivotal role in commitment of common lymphoid progenitors to the T cell lineage (72). That is, expression of Notch1 by retroviral transduction has been shown to redirect B lineage differentiation in bone marrow along the T lineage. Further, a reciprocal result was found in conditional Notch1 null mice, blocking T cell development in the thymus, to be replaced by B cell development (92). Finally, altering the Notch1 modifier, Lunatic Fringe, by overexpressing this molecule under regulation of an lck promoter resulted in B cell development in the thymus (76). Differentiation of lymphoid precursors to NK or dendritic cell lineages was unaffected in Notch1 null CLP cells, so Notch apparently affects only the B/T lineage decision.

Role of Chemokines in Migration of B Cell Precursors

One of the most distinctive features of B cell development in bone marrow is the migration of developing precursors from early stages nearest the bone endosteum layer to latter stages progressively closer to the central arteriole, where they will eventually exit *(176)*. This migration is likely due to differential expression of specific adhesion molecules and also to expression of chemokine re-

ceptors. Analysis of B cell migration has identified a critical chemokine that is important in this process, SDF-1, now known as CXCL12 (177,*178*), and its receptor CXCR4 *(179)*. CXCL12 is expressed by fetal liver and bone marrow stromal cells, while CXCR4 is found on hematopoietic precursors and B cell progenitors *(180)*. Deletion of either the receptor or ligand results in severely impaired B lymphopoiesis (181,*182*,183). Interestingly, the critical defect appears to be failure to retain precursors in the primary lymphoid organ, as progenitors and precursors can be found in the blood of mutant mice *(184)*.

Gene Expression and Ig Rearrangement (Figure 7.8)

In addition to delineation of developmental stages based on changes in protein surface expression, B lineage cells can also be characterized for expression of internal proteins related to critical processes in their progression along this pathway, specifically those related to rearrangement and expression of the B cell antigen receptor. Thus, expression of μ heavy chain constant region, prior to Ig rearrangement, from a cryptic promoter generates a "sterile transcript" that likely reflects an open chromatin structure important for the onset of rearrangement *(185–187)*, and so analysis of sterile μ expression can be used to investigate very early stages of B cell development. Classical Northern analysis can be done with transformed lines, but much work analyzing RNA levels in B lineage cell fractions, whether directly isolated or cultured, has depended on PCR amplification of cDNA (38). For example, using this approach, sterile μ can be detected in a very early fraction of $B220^+CD43^+CD19^-$ (Fr. A) cells. Expression of the recombinase activating genes Rag-1 and Rag-2, that together make the double-strand breaks in DNA required for Ig rearrangement (188,*189*,190), also occurs in Fr. A stage cells, which also have high levels of TdT, the enzyme responsible for adding nontemplated nucleotides at the D-J and V-D junctions of the heavy chain (*12*,191).

The extent of heavy chain or light chain rearrangement can be quantitated, either in bulk-isolated populations (113) or in individual cells *(121,192,193)*. At the heavy chain locus, D-J rearrangement occurs prior to V-DJ rearrangement, and cells with extensive D-J but little V-DJ rearrangement can be detected at the $B220^+CD43^+CD19^-$ (Fr. A) stage, where Rag-1/2 and TdT are strongly expressed (44). V-DJ rearrangements are readily detected in the abundant $B220^+CD43^-$ (Fr. D) stage small pre-B cells, although productive rearrangement has already completed by the large pre–B (Fr. C-prime) stage (discussed later). Single cell sequence analysis of rearrangements in Fr. C stage cells shows a large proportion with nonproductive rearrangements on both chromosomes, suggesting that this may represent a dead-end fraction *(192)*. Some light chain rearrangement is detectable in early stage $B220^+CD43^+$
FIGURE 7.8 A: Profiles of Ig rearrangement-related gene expression. Cells isolated using fractionation scheme in Figure 7.3 for MLP and Fr. A; in Figure 7.5 for Fr. B through Fr. F. Relative mRNA levels assessed by performing semiquantitative RT-PCR using limited numbers of cycles, blotting, then probing and quantitating the probe signal. Note the biphasic expression of Rag genes and the early expression of sterile μ (labeled μ_0) during the first wave, where heavy chain rearranges, and the up-regulation of sterile kappa transcripts (κ_0) during the second Rag wave, when most light chain rearrangement takes place. **B:** Single cell PCR analysis of Ig heavy chain rearrangement in four early stages of developing B lineage cells. DNA prepared from individual cells isolated following the scheme shown in Figure 7.3 was divided into two aliquots and analyzed for retention of a DNA segment lost upon any DJ rearrangement (labeled GL, germline) and also for DJ rearrangement. Note that DJ rearrangement initiates at the CLP stage, where 30% to 50% of cells show a rearrangement.

(Fr. B) cells, and this is consistent with the observation that low-level kappa light chain rearrangement is detectable in bone marrow of mice where μ heavy chain has been crippled by deletion of the membrane exon *(194)*. However, much higher levels of kappa rearrangement can be detected in B220$^+$CD43$^-$ (Fr. D) stage cells, consistent with the finding of sterile kappa mRNA increase just prior to this stage likely induced by pre-BCR signaling (discussed later).

Role of Ig Heavy Chain and the pre-BCR

Careful analysis of SCID mouse (195) bone marrow revealed the presence of a population of B220$^+$ cells, all with a very early CD43$^+$ phenotype, suggesting a block in B cell development at this stage *(196)*. SCID mice have a defect in the catalytic subunit of the DNA-dependent protein kinase DNA-PKcs (197,*198*), and as a result B linage cells in these mice are very ineffective at completing even initial DJ rearrangements at the heavy chain locus. This block could be overcome by introduction of an Ig heavy chain transgene, supporting the model of a critical role for μ protein in progressing past an early developmental checkpoint *(199)*. An early gene targeting experiment eliminated the membrane

exon of μ heavy chain (μ-mt), and such mice also showed a block at this stage (200,*201*).

μ heavy chain can be shown in coimmunoprecipitation experiments to associate with a set of B cell–specific peptides at the early pre-B cell stage (202), and this complex is referred to as the *pre-BCR,* or *pre-B cell receptor.* It seems clear that this complex mediates a type of signaling function, analogous to the BCR in mature B cells. Prior to light chain expression, two peptides known as λ5 and VpreB, originally isolated as B lineage–specific cDNAs (203,*204*), associate with heavy chain. λ5 shows homology to a lambda-constant region, and VpreB is so-termed because it has homology to a variable region domain, so together these peptides constitute a pseudo- or surrogate light chain (SLC). The critical role of λ5 was demonstrated unambiguously in gene-targeted mice, where B cell development was blocked at the B220$^+$CD43$^+$ stage (205). The production of some mature cells that accumulate in this mutant is likely due to early kappa rearrangement, with light chain substituting for SLC, as demonstrated in light chain transgenic experiments (206).

μ heavy chain has a very short cytoplasmic region consisting of only three amino acids, and an important finding has been that signal transduction through the BCR is mediated by accessory peptides, similar to the CD3

components of the T cell receptor, known as Ig-α and Ig-β (207,208,*209,210*). As predicted by the pre-BCR signaling developmental checkpoint hypothesis, inactivation of Ig-β (211) results in a block at the B220$^+$CD43$^+$ stage in mouse bone marrow, similar to the μ-mt and λ5 null mice. Finally, the syc tyrosine kinase plays a critical role in transducing BCR cross-linking signals in mature B cells, and inactivation of this gene results in a "leaky" block at this same stage (212,*213*). Thus, any mutation that affects this pre-BCR complex (see the following section and Figure 7.10a) precludes efficient progression past the earliest stages of B cell development.

Careful examination of B cell development in normal mice shows that heavy chain is first expressed in a late fraction of B220$^+$CD43$^+$ stage cells, termed *Fr. C-prime* (Figure 7.9a). This fraction is also interesting because it shows a much higher proportion of cells in cycle (revealed by a high frequency of cells with greater than 2N DNA content; Figure 7.9b), compared with any other B220$^+$ stage in bone marrow (113). Mice unable to assemble a pre-BCR, due to inability to rearrange heavy chain (Rag-1 null) show a block in development at the CD43$^+$ stage that can be complemented by introduction of a functionally rearranged μ heavy chain as a transgene ([163] Figure 7.9c). Analysis of several types of pre-BCR defective mutant mice shows a complete absence of Fr. C-prime stage cells, suggesting that pre-BCR signaling results in the up-regulation of CD24/HSA and also entry into rapid cell proliferation.

Thus, a model of pre-BCR function is that it signals the clonal expansion phase of pre-B cell development, amplifying cells with in-frame VDJ rearrangements capable of making heavy chain protein.

The precise nature of pre-BCR signaling remains to be completely understood. An early model suggested that crosslinking of heavy chain was mediated through interaction of SLC with a bone marrow–expressed ligand. However, subsequent experiments showed that normal light chain could substitute for SLC and that even a V$_H$ truncated μ heavy chain could mediate progression past this stage. Further, intensive searches for the putative ligand over a 10-year period have been fruitless, leading to the model that pre-BCR signaling is more akin to "tonic" signaling in mature B cells (*214*,215,216). That is, simple assembly of the complex (or possibly some degree of multimerization fostered by the self-aggregating nature of SLC [*217*]) probably is sufficient for the cell to pass this developmental checkpoint (Figure 7.10b). One clear-cut finding is that pre-BCR signaling in a transformed pro-B cell model system can occur in the absence of any additional cell type, suggesting that if a ligand exists, it must be expressed on B lineage cells, rather than stromal cells (218).

Mutations in other molecules in the pre-BCR signaling pathway have been shown to affect B cell development and pre-B cell clonal expansion. While the Btk mutation is less severe in mouse than in human, there nevertheless is an alteration in pre-B cell expansion in Btk-deficient mice
FIGURE 7.10 A: Diagram of the pre-BCR, μ heavy chain with surrogate light chain (λ5 and VpreB) in place of conventional light chain. As in the BCR, Ig-α and Ig-β serve to couple signals between the receptor and cytoplasmic components, such as BLNK and syk. Starred m transmembrane residues are important in mediating interaction with Ig-α/Ig-β, as mutation of these diminishes BCR function. **B:** Clonal expansion mediated by pre-BCR assembly. Association of newly generated μ heavy chain with preexisting surrogate light chain leads to a burst of proliferation at the pre-B stage.

(219). Also, xid B cells (deficient in Btk) have been reported to proliferate more in stromal cell cultures, possibly due to decreased differentiation to later nonproliferative stages *(220,221)*. The role of Btk is thought to modulate BCR signaling strength *(222)*, and this is probably also the case for pre-BCR signaling, allowing only strongly signaling pre-BCRs to progress in the mutant mice. BLNK serves to link the pre-BCR to the syk kinase, critical in BCR signaling *(223,224)*. Mutant mice lacking BLNK show a partial block in B cell development at the pro-B to pre-B transition *(225)*. Curiously, while pre-BCR signaling is thought to mediate allelic exclusion (expression of a single heavy chain allele), this remains intact in BLNK-deficient mice (226). Syk deficient mice show a more severe block at the pro-B to pre-B transition and a lack of allelic exclusion (212,*213*,226).

Outcomes of pre-BCR signaling, in addition to pre-B proliferation, are down-regulation of the Rag genes (227), down-regulation of TdT (218), and transcriptional activation of the kappa locus, detected as up-regulation of sterile kappa transcripts (228). A control element for regulating Rag expression has been identified *(229*,230). Extinction of recombinase activity is probably important for chromosomal stability during the clonal burst period of B cell development *(231,232,233)* and is also at least a part of the mechanism that assures allelic exclusion, the expression of a single heavy chain by any given B cell *(234)*. There is evidence that pre-BCR selection requires low levels of IL-7

(235) and probably occurs naturally as the developing precursors migrate through different stromal cell microenvironments in bone marrow.

The function of the pre-BCR may be more complex than simply to sense whether an in-frame VDJ rearrangement has occurred. This possibility is suggested by the observation that heavy chains with different VDJ segments vary in their capacity to assembly with SLC components (*236*,237–239). V regions are classified into families based on sequence homology and many members of two of these families, the 7183 and Q52, appear to frequently generate heavy chains that assemble poorly with surrogate light chain (238). A consequence of this will likely be poor pre-BCR signaling and little clonal expansion, so such cells will become under-represented at later stages of B cell development relative to cells containing heavy chains that signal effectively. One explanation of the reason for this SLC assembly-mediated clonal expansion is that it serves a quality-control function to test heavy chain V regions for their potential to fold with real Ig light chain, a critical requirement if the cell is to express a complete BCR. An alternative (not necessarily mutually exclusive) explanation is that making pre-B cell proliferation dependent on pre-BCR expression provides a simple mechanism for regulating the extent of clonal expansion, since an immediate consequence of pre-BCR signaling is to terminate SLC expression. Thereafter, SLC protein levels decay and are diluted by cell division, so that after several rounds of proliferation, pre-BCR levels will decrease to below the threshold required to provide the signal to maintain the cell in cycle. Figure 7.11 illustrates a model for bone marrow B cell development, showing the pre-BCR checkpoint.

One of the most striking examples of pre-BCR selection is seen with the D-proximal V_H gene, V_H81X, where early precursors show biased over-utilization, due to preferential rearrangement of this V_H gene (11,*240,241*). V_H81X had also been identified as frequently rearranged in Abelson virus transformed pre-B cells (242), even though it was rarely seen in the mature B cell compartment. The demonstration of the decrease in representation of cells with V_H81X rearrangements at the pre-B clonal expansion phase in bone marrow (*243,244*), together with the demonstration that heavy chains utilizing V_H81X frequently fail to assemble functional pre-BCRs (*236,237,245*), explained this paradox. However, it is still curious that the most frequently rearranged V_H gene is so strongly selected *against* at the clonal expansion stage. A possible explanation may lie in comparisons of V_H utilization during fetal development. That is, in contrast with bone marrow precursor cultures, the ratio of productive/nonproductive V_H81X does not decrease during cultures of fetal precursors (*246,247*). Further, the proliferative burst that pre-BCR assembly provides to bone marrow pre-B cells may instead result in exit from cell cycle in fetal precursors (239), leading to
FIGURE 7.11 Model of mouse bone marrow B cell development showing relationship of Ig rearrangement with progression and proliferation.

selection of very different BCR repertoires during fetal and adult B lymphopoiesis. The possible significance of this is discussed below in the section on B-1 B cells.

Light Chain Rearrangement and Generation of Immature B Cells

Besides termination of TdT and SLC gene expression, pre-BCR signaling also results in the down-regulation of Rag-1 and Rag-2 expression, and protein levels rapidly drop as cells enter the rapidly cycling stage. However, as pre-BCR levels decrease and cells exit from cycle, the Rag genes are reexpressed at high levels. Sterile kappa transcripts become detectable during the cycling stage, likely reflecting chromatin remodeling to make the kappa light chain locus accessible (228), so induction of Rag expression together with the rest of the recombinase machinery will initiate kappa light chain V to J rearrangement. An interesting feature of the Vκ locus is that the approximately 100 genes are in both transcriptional orientations, and so these genes can rearrange either by deletion (generating an extrachromosomal excision circle) or by inversion *(248)*. The absence of intervening D segments also means that it is possible for upstream V kappa genes to rearrange to downstream J kappa segments, "leap-frogging" the initial rearrangement, assuming it was to any Jκ other than Jκ5. The successive association of different kappa chains with the same heavy chain in a B cell is referred to as BCR "editing" and was originally observed in the context of autoreactivity, which maintains Rag expression even at the B cell stage ([249,*250*]; see the following section on B cell tolerance). Since assembly and expression of a complete BCR (that is not self-reactive) terminates Rag expression, an additional reason for light chain editing in the bone marrow may be to replace an initial light chain that fails to assemble effectively with the particular heavy chain present in

that pre-B cell. This is probably the explanation for multiple light chain rearrangements detected in single early B lineage cells *(251)*.

Newly formed B cells can be distinguished from mature B cells on the basis of their inability to proliferate in response to BCR cross-linking—that is, they are functionally immature. This is also the stage where negative selection is reported in transgenic models of autoreactivity (252,*253*). Cells at this stage have a short half-life, only a few days, compared to mature follicular B cells with a half-life measured in months. They can be distinguished by surface phenotype from other B cells based on expression of certain combinations of markers, such as IgM$^+$IgD$^-$, absence of CD23, and high-level expression of CD24/HSA (254). Recently, there are reports of single markers that are useful in distinguishing newly formed cells from any mature subset, such as the molecules recognized by monoclonal antibodies 493 (255) and AA4.1 (256). The AA4.1 target molecule has been cloned and identified as the mouse ortholog of a component of the human C1q receptor *(257)*.

Cells similar to newly formed B cells can be generated to varying extent during stromal cell culture of B cell precursors, although the more primitive cycling pre-B or pro-B cells are usually more abundant and tend to increase in frequency with prolonged culture. It is possible to induce differentiation of B cells in these cultures by withdrawing IL-7, which induces a wave of small pre-B and then newly formed B cell generation. Such cells do not persist for more than a day, unless the cultures are established from Bcl-2 transgenic mice *(115)*, suggesting that the short half-life of newly formed cells in these cultures, and possibly also *in vivo*, is due to their low level of antiapoptotic mediators. Both Bcl-2 and Bcl-X$_L$ mRNA are present at only very low levels in these cells, in contrast with other B lineage stages where either one or the other predominates. Over-expression of Bcl-X$_L$ from a transgene results

in accumulation of a population of pro-B phenotype cells with nonfunctional rearrangements *(258)*, implicating this protein in the process of pre-BCR selection of cells with functional rearrangements.

Peripheral Maturation Stages and Functional Subsets

Transitional B Cells

Newly formed immature B cells migrate to the spleen where they either die or undergo further maturation to a mature B cell. These maturing B cells can be subdivided based on differential expression of several surface proteins, including CD21, CD23, CD24/HSA, and AA4.1. These subdivisions have been referred to as *transitional B cells* (259). One recent subdivision based on CD21, CD23, AA4.1, and IgM level has shown progression from an AA4.1⁺CD21⁻CD23⁻ T1 stage to an AA4.1⁺CD21⁻CD23⁺ T2 stage, followed by down-regulation of IgM as a T3 stage,

and finally loss of AA4.1 with up-regulation of CD21 to yield the mature follicular phenotype (256). As shown in Figure 7.12, this approach also resolves two AA4.1⁻ subsets that lack CD23, the B-1 subset with low CD21 and the marginal zone (MZ) subset with very high CD21 (see following). The transitional stage cells are all short-lived, as shown by bromodeoxyuridine incorporation (256,260). They are also not functionally competent, as shown by inability to proliferate after BCR cross-linking (254,261). Another well-characterized functional distinction is that B cell tolerance, rather than an immune response, is induced by BCR cross-linking of immature B cells *(262–264)*. More recent studies with transgenic models of self-reactivity have shown that these B cells can be deleted, undergo receptor editing, or are rendered functionally unresponsive (anergic) by BCR signaling at the immature stage (249,252,265–269). One group has suggested that the "T3" stage is not an intermediate in production of follicular B cells, but rather a population of autoreactive anergic cells *(270)*, so clearly additional work needs to be done to
FIGURE 7.12 Flow cytometry approach for resolution of transitional (T1-T3) and mature (Fo, B-1, MZ) populations of B cells in mouse spleen. Left panels show the distribution of AA4.1 and CD23 on B cells (defined as CD19⁺IgM⁺). Cell in the boxed regions are then analyzed for correlated expression of CD21 and IgM, facilitating resolution of three AA4.1⁺ fractions (T1-T3), the follicular subset (AA4.1⁻CD23⁺CD21⁺), the marginal zone subset (AA4.1⁻CD23⁻CD21⁺⁺), and the B-1 subset (AA4.1⁻CD23⁻CD21^low).

establish the identities of all the B cell subpopulations present in spleen.

It is not simply the inability to receive T cell help due to differences in microenvironment or receptor expression that makes immature B cells incapable of responding as mature B cells. Crosslinking the BCR on purified populations of immature, but not mature, B cells has been shown to induce apoptosis, suggesting distinctions in the signaling pathways between these two stages (271,272). Studies with transgenic mice suggest that this apoptosis is not mediated through the Fas/Fas-ligand pathway, because central deletion is intact in Fas-mutant mice (273,274). Prior to induction of apoptosis, immature B cells have been shown to complete some of the early events associated with entry into cell cycle, while failing to complete this program *(275)*. Distinct stages in maturation appear more or less capable of responding to BCR cross-linking by reinduction (or maintenance) of Rags to facilitate receptor editing *(253)*. Further, it appears that immature B cells are more sensitive to smaller changes in intracellular free calcium, compared to mature B cells (276). It is possible that the capacity to up-regulate antiapoptotic molecules, such as A1, may play a critical role in the inability of immature B cells to survive and complete a normal response *(277,278)*. The characterization of signaling pathways in different immature stages of developing B cells is ongoing and should eventually provide insights into the detailed mechanism for immature B cell tolerance.

Analyses of various normally occurring or engineered mutant mice have provided approaches for investigation of the process of progressing from a newly formed B cell to a mature follicular B cell. B cell populations and B cell function has been studied for many years in CBA/N mice, bearing the x-linked immunodeficiency (xid) mutation. This mouse has a mutation in the Btk gene that produces a milder phenotype than the complete absence of peripheral B cells seen in humans. The Btk gene likely plays a role at several stages of B cell development and activation which complicates the analysis, but it appears clear that one major consequence is altered BCR signaling that has a profound effect on progression through the various transitional stages in spleen. A likely consequence of diminished strength of BCR signaling is a compensatory requirement for higher surface BCR expression that eventually produces at decreased frequency a type of "mature" B cell that is still functionally handicapped *(279,280)*. Several groups have produced xid mice on a nu/nu T cell–less background that results in a more profound absence of mature B cells, suggesting a requirement for T cells or T cell–produced factors in the maturation of xid B cells *(281,282)*. A more recent variation of this type of investigation is the production of xid/CD40 deficient mice that show a similar deficit in mature B cells, suggesting a role for the CD40/CD40L interaction in the generation of mature B cells from transitional B cells, particularly when the BCR is handicapped by defective Btk (283).

Lyn is a src family protein kinase that is associated with the BCR and functions in signaling in mature B cells (284). Lyn-deficient mice exhibit defects in maturation of immature cells, suggesting a positive role for BCR/Lyn signaling at this stage, but these mice also develop a severe autoimmune condition, suggesting an additional negative regulatory role for Lyn in maintaining tolerance in mature B cells *(285,286)*.

CD72 is a predominantly B lineage restricted C-type lectin, and ligating this molecule was recognized for many years (when it was known as Lyb2) as having functional consequences *(287)*. Recent analyses of a CD72 null mouse has clarified its function in B cell development and activation *(288)*. CD72 has been shown to recruit SHP-1 to the BCR, supporting a negative regulatory role in BCR activation *(289)*. Consistent with this model for CD72 function, null gene-targeted mice have been shown to produce B cells that are hyper-responsive *(288)*. Interestingly, late stages of B cell development are affected, with fewer mature B cells and relatively normal numbers of immature B cells in spleen *(288)*. Thus, too intense signaling may also delay maturation of immature B cells.

Follicular B Cells

The major population of mature recirculating B cells in the spleen is located in the B cell follicle region, hence the term *follicular B cells*. Entry into this anatomical site appears to constitute a final stage in maturation for developing bone marrow B cells, as competition for this site is compromised in several transgenic models of B cell tolerance (290,*291*,*292*,293). Cells in this compartment do not proliferate, but persist in the resting state for several months. A conditional knockout study, eliminating expression of the BCR (by deleting the V region), revealed that expression of the BCR is required for cell survival (215,216). It is not yet established whether this is due to "tonic signaling" (simple assembly of the BCR signaling complex), or instead reflects signaling by low-affinity binding to cross-reactive self-determinants, a kind of "positive selection." It is interesting to note that ablation of heavy chain from the immature B cell, thereby eliminating any possibility of pre-BCR or BCR tonic signaling, results in a "reversion" of cell phenotype to an earlier developmental stage *(294)*. Finally, the maintenance of follicular B cells has been found to depend on the function of the c-Myb transcription factor, due to its role in BAFF signaling ([295] see following section).

The repertoire of the follicular B cell pool appears to differ from the earlier immature splenic B cell population, as assessed by sequence analysis of the light chain repertoire in heavy chain transgenic mice *(296)*. The approach of fixing the heavy chain and then examining the light chain

repertoire simplifies the analysis, and the results of this study were interpreted to indicate that BCR-mediated antigen selection is indeed operating. However, the resolution of the analysis probably could not have rigorously excluded populations known to show V gene biases, such as B-1 or MZ B cells (see following sections), so further work will be required to provide convincing evidence of antigenic selection in the follicular B cell pool.

B Cell Migration and Maintenance

Newly formed B cells migrate from the bone marrow to the spleen, undergo further maturation in the red pulp, and eventually enter the follicle where they constitute the mature B cell pool that recirculates. Their migration is dependent on chemokines/receptor interactions, notably the SLC(CCL21)/CCR7 interaction, as demonstrated by the inability of mature B cells to be retained normally in spleens of CCR7 null mice *(297)*. The role of the CXCR5 receptor on B cells in homing to the lymphoid follicle due a gradient of the B lymphocyte chemoattractant CXCL13 is also well known and additionally CXCL13 can directly induce Lt$\alpha1\beta2$ on the recruited cells (298). Finally, it is also possible that the SDF1(CXCL12)/CXCR4 interaction, critical for normal B lymphopoiesis, may also be important at this later stage, although investigation of this issue is complicated by the early defect. This is an ongoing area of investigation and may eventually be clarified by developmentally regulated gene targeting studies.

Recently, considerable interest has focused on the role of a TNF family member cytokine known variously as BAFF, BLyS, TALL-1, zTNF4, or THANK in the process of peripheral B cell maturation *(299)*. BAFF is a TNF family member found to enhance survival of B cells or even produce autoimmunity in transgenic mice constitutively expressing it *(300,301)*. Initially two receptors defined for BAFF, BCMA and TACI, provided a complex picture, as targeted inactivation of BCMA yielded no B cell defect and deletion of TACI had increased B cell numbers (suggesting that TACI might be a negative regulator). This puzzle was resolved by identification of a third receptor, BAFF-R/BR3 (302,*303*), that was mutated in the A/WySnJ strain of mice, known to lack most mature B cells (304). A second ligand, APRIL, can bind to BCMA and TACI, but not to BAFF/BR3, and this binding is proliferative rather than survival-promoting *(305)*. Thus, the critical interaction for maintenance of follicular B cells is BAFF/BLyS with its receptor. B-1 cells are not deficient in A/WySnJ mice (304), suggesting that their maintenance does not depend on this pathway, but instead is more BCR-dependent.

B Cell Turnover

It is estimated that 10 million to 20 million B cells are produced in bone marrow of the mouse each day *(306)*, yet it appears that only about 10% of this number reach the periphery *(260)*. Thus, there is considerable loss at this bone marrow emigration stage/spleen entry stage, possibly due to elimination of autoreactive cells (B cell tolerance) or to homeostatic regulation. The latter possibility is supported by the observation that depletion of the mature B cell population results in a relatively rapid recovery of this pool, suggesting that most of the immature B cell population can enter the mature follicular subset in this situation *(307)*.

Once functionally mature B cells are generated, it has been difficult to unambiguously determine their half-life, although accumulating data from several laboratories using bromodeoxyuridine labeling has led to the idea that follicular B cells have a relatively long half-life, on the order of months (*260*,308). A recent elegant study provided definitive confirmation of this by conditional elimination of Rag-2 expression, allowing termination of B cell development in adult mice (309). This study showed that follicular B cells have a half-life of about 4.5 months. This same analysis showed that two other subsets of B cells, B-1 and MZ B cells, did not diminish over time, consistent with their well-known capacity for self-renewal and life-long persistence.

Germinal Center B Cells

T cell dependent immune responses usually give rise to anatomically distinctive structures in spleen and lymph nodes that are referred to as germinal centers (GC) containing large numbers of rapidly cycling B cells (310,*311*). These cells can be recognized in stained sections of spleen by binding of high levels of peanut agglutinin (PNA) and by the absence of IgD (312,*313*). Many of the B cells with this phenotype have down-regulated-BCL-2/upregulated-Fas expression and, in the absence of strong BCR signaling, will likely die by apoptosis (*314*,315,*316*,317). The termination of IgD expression means that surface BCR expression decreases at least 10-fold and so limiting amounts of antigen will favor the cells with increased affinity for antigen, generated by a process termed *somatic hypermutation*, or SHM. The molecular details of this mechanism are still unclear, but a major advance has been the recent discovery that activation-induced cytidine deaminase (AID), a putative DNA or RNA-editing enzyme that can induce class switch recombination in fibroblasts (318,*319*,*320*), is also a key player in the process of hypermutation (321,*322*). In fact, a third means for Ig gene diversification used in non-mammalian species, V gene conversion, is also dependent on AID *(323,324)*.

A potential means for repertoire diversification in the GC, distinct from SHM, has been suggested by the finding that the Rag genes are induced in at least some GC B cells *(325–328)*. Receptor editing is a potential consequence of this induction, but to date, it is unclear that there is any physiological relevance for the induction of

Rag in the periphery. Considering the important role that the pre-BCR and BCR play in regulating Rag expression in bone marrow development, it seems quite possible that the reexpression of Rag may be a consequence of hypermutation of the heavy or light chain (or both), resulting in generation of nonfunctional receptor genes. This could occur either from truncation by stop codons or by less severe alterations that result in an inability of Ig HL pairing. Consistent with this notion, it appears that much of the Rag expression by GC B cells is coincident with apoptotic cells in the GC *(329)*. Recent Rag-reporter approaches have failed to indicate significant Rag reinduction in mature B cells *(330,331)*. An alternative explanation for some peripheral Rag expression may be an influx of immature cells into the spleen induced as a consequence of immunization (332).

The precise mechanism of selection for higher affinity B cells generated by hypermutation of the BCR V regions remains to be fully understood, but regulation of pro- and antiapoptotic genes likely plays a major role. B cells able to bind antigen with high affinity can present antigen to $CD4^+$ T cells that then signal the B cell through a CD40/CD40L interaction, resulting in the up-regulation of $Bcl-X_L$ *(314,315,316)*. Most GC B cells have sharply down-regulated levels of Bcl-2 and up-regulated levels of Fas *(316*,317), and so in the absence of rescue by expression of the alternative antiapoptotic mediator $Bcl-X_L$, cell death by apoptosis will be the fate of most B cells in the GC. Careful regulation of selection is critical to affinity maturation, and elimination of self-reactive cells that potentially could be generated during this process must also occur efficiently to avoid the potential of autoimmune disease. This is an active area of investigation, and more players in this selection process are continuing to be identified *(333)*.

Memory B Cells

Memory B cells were initially defined functionally as cells that could respond rapidly by production of high-affinity antibody when challenged in a host reconstituted with B cells and T cells from a primed animal *(334–338*,339). Subsequently, such cells have been purified based on their antigen-binding properties *(340)* and shown to consist primarily of isotype-switched (IgG^+) B cells that continue to express CD45R/B220 and have distinctively lower levels of cell surface BCR (341). They arise during the T cell–dependent immune response, probably only from follicular B cells, in the GC. They are very long-lived or self-regenerating, as cell transfer assays have shown that memory responses can be detected for long periods after the primary immunization (341,*342)*.

It is not clear whether all B cells are capable of giving rise to memory B cells. Memory or "secondary" B cells were originally described as expressing distinctively low levels of CD24/HSA, recognized by the monoclonal antibody J11d *(343)*. Some years later, fractionation of naïve

spleen B cell precursors into $J11d^{low}$ and $J11d^{high}$ subsets in a spleen focus assay system showed that while rapid antibody secretion derived from $J11d^{high}$ cells, memory came largely from the $J11d^{low}$ subset *(344)*. Subsequent experiments demonstrated that GCs (the sites where most memory B cells are generated) were only produced in cell transfers of $J11d^{low}$ B cells and not with $J11d^{high}$ or $CD5^+$ B cells *(345)*. Considering the rapid Ig secretory response of B-1 B cells and MZ B cells, both contained in the $CD24/HSA^{high}$ fraction, and the fact that most other $CD24/HSA^{high}$ cells are immature (transitional) B cells, likely to be highly susceptible to apoptosis, it seems quite reasonable that memory B cells would not be a major product of this fraction. Rather, the most likely candidate for the memory B cell precursor is the follicular B cell subset (Fo), which has variable, but lower expression of CD24/HSA. Whether there is heterogeneity for GC formation or memory B cell generation within the Fo population remains to be determined.

Whether the maintenance of memory requires periodic restimulation by antigen has been a longstanding, controversial issue. On the one hand, transfer of B cells and T cells into irradiated recipients usually required simultaneous challenge with antigen to elicit the full response and maintain B cell memory in recipients *(346)*. Antigenic fragments can persist for very extended periods on follicular dendritic cells, very potent antigen-presenting cells, and so in this model the memory B cells are periodically triggered to self-renew by interaction with antigen on FDC. However, on the other hand, memory B cells can be maintained in the apparent absence of T cells or FDCs *(347,348)*. Further, analysis by bromodeoxyuridine labeling of memory B cell populations showed that they were nondividing *(342)*. This issue has recently been addressed in elegant experiments that used the inducible cre recombinase system to switch the BCR on memory cells away from the immunizing antigen (349). Such antigen-negative memory cells still persisted for extended periods, clearly demonstrating that this was a physiological property of the cell type, independent of the presence of antigen.

B-1 B Cells

B-1 B cells, initially described as $Ly-1/CD5^+$ B cells, are distinguished from follicular B cells by phenotype, anatomical distribution, and function (23,*350)*. The B-1 B cell phenotype encompasses both $CD5^+$ and $CD5^-$ B cells that are IgM^{high}, $IgD^{low/-}$, $CD23^-$, and $CD43^+$. They constitute a large proportion of the B cells found in the peritoneal and pleural cavities (30% to 50% of B cells, around 10^6 cells), but are also found in spleen where they are present at numerically similar levels, but constitute a much lower proportion of the total B cell pool (2% of B cells, around 10^6 cells). The B-1 B cells in the peritoneal cavity are also $CD11b/Mac-1^+$, unlike those in spleen. They appear early

in ontogeny, representing 30% or more of the B cells in spleen of 1-week-old animals. They also have a distinctively higher frequency of λ light chain usage compared to follicular B cells (20% versus 5%). Also, unlike follicular B cells, they maintain their population in adult animals largely by self-renewal (possibly dependent on periodic stimulation by self-antigen, discussed later), rather than by input from precursor cells, as shown in cell transfer studies *(351)*.

Perhaps the most distinctive feature of CD5$^+$/B-1 B cells is their enrichment of certain self-reactive specificities, notably for branched carbohydrates, glycolipids, and glycoproteins, including phosphorylcholine, phosphatidylcholine (PtC), the Thy-1 glycoprotein, and bacterial cell wall constituents (352,353,354,*355*). These antibodies, while autoantibodies, are not pathogenic, but rather referred to as *natural autoantibodies* whose existence has been recognized in serum for several decades *(356–358)*. Their function is still under active investigation, but at least some natural autoantibodies are thought to function in clearance of senescent cells or proteins and to provide an initial immunity to common bacterial or viral pathogens, serving as a kind of "hard-wired" memory B cell population (359,360,*361*,362).

Under physiologic conditions in normal mice, most of the CD5$^+$ B cells in the B-1 population (so called *B-1a B cells*) arise from precursors in fetal liver, as cell transfer studies showed many years ago that B cells with this phenotype were inefficiently generated from bone marrow precursors in adult mice, compared to fetal or neonatal precursors (363). This is very clearly shown by repopulation of SCID mice by pro-B stage cells isolated from fetal liver and adult bone marrow (Figure 7.13). Part of the reason for this difference may be that novel BCRs are enriched by distinctive mechanisms of fetal B lymphopoiesis, including recombination in the absence of TdT (thereby favoring rearrangement of certain D-J and V-D junctions possessing short regions of homology [16]) and distinctive pre-BCR selection (239,247,*364*). It is also possible, although not yet tested, that the threshold for elimination of self-reactive B cells at the newly formed stage may be less stringent during fetal development. Forced expression of transgenic BCRs cloned from CD5$^+$ B cells can give rise to CD5$^+$ B cells from bone marrow of adult animals, but the physiological relevance of this remains to be carefully assessed. The development of B cells in bone marrow of such transgenic mice often appears handicapped, and the precise reason for this requires further study.

The development of B-1/CD5$^+$ B cells is thought to be more dependent on antigenic selection compared to follicular B cells. This idea was first suggested by the finding of particular specificities enriched in this population and strengthened by the observation of repeated occurrences of particular V_H/V_L pairs *(365)*. Thus, for example, the anti-PtC specificity is predominantly encoded by $V_H11V_\kappa9$ and $V_H12V_\kappa4$, utilizing two V_H genes rarely found in con-
FIGURE 7.13 Generation of B cells in SCID mice shows the distinctive phenotypes produced from fetal and adult pro-B cells. Similar numbers of pro-B cells, isolated as in Figure 7.5, Fr. B/C, were injected i.v. into sublethally irradiated adult SCID mice, then recipients were analyzed 3 weeks later for spleen cell lymphocytes by staining as shown in the figure.

ventional T-dependent immune responses *(353,366)*. These cells appear to participate in T-independent responses, but in normal physiology may in fact provide an initial low-affinity "first wave" response to many pathogens that eventually will also elicit a T-dependent response *(362,367)*.

The observation of their self-reactive bias, their capacity for self-renewal, and their restricted repertoire of distinctive BCRs all are consistent with an important role for BCR–antigen interaction in generation and maintenance of this population. This has been formally confirmed recently by studying mice bearing a BCR transgene specific for a glycosylation present only on the Thy-1 membrane protein *(368)*. In these mice, transgene-encoded serum anti-Thy-1 autoantibody (354) was readily detected, and there was a corresponding accumulation of a population of CD5$^+$ transgene BCR$^+$ B cells in the peritoneal cavity. Importantly, in Thy-1 null mice generated by gene targeting, neither serum autoantibody nor the B cell population was found, demonstrating the critical role for antigen in selection of this B cell population (369).

Consistent with the importance of antigen selection in the generation and maintenance of these cells, this population is often severely affected in mice bearing mutations that alter BCR signaling intensity. The loss of negative mediators such as PTP1C/SHP-1 in "motheaten" mice *(370)*, of CD72 that recruits this phosphatase *(370)*, and of the CD22 co-receptor *(371,372)*, all result in an increased frequency of B-1/CD5$^+$ B cells relative to follicular B cells. However, the loss of critical BCR signaling components or positive mediators in this pathway such

as an Ig-α tail mutant *(373)*, Btk deficiency (in xid or btk null mice [374,375]), CD19 null mice (*376,377*), CD21 null mice *(378)*, CD45 null mice (367), and vav null mice *(379)* all negatively affect this B cell population. A further indication of a signal-dependent selection model is the accumulation of B-1 type B cells with high-level expression of a BCR surrogate, LMP2A, but only B-2 B cells and MZ B cells with low level expression (380).

Marginal Zone B Cells

MZ B cells are localized in a distinct anatomical region of the spleen that represents the major antigen-filtering and scavenging area (by specialized macrophages resident there). It appears that they are preselected to express a BCR repertoire similar to B-1 B cells, biased toward bacterial cell wall constituents *(381)* and senescent self-components (e.g., oxidized low density lipoprotein (LDL) [*382,383*]). Similar to B-1 B cells, they respond very rapidly to antigenic challenge, likely independently of T cells, but participating in the early phase of T-dependent responses (*384,385,386*). Uniquely, among all populations of B cells, MZ B cells are dependent on Notch2 signaling for their development (387,*388*).

There are similarities and differences in the cell surface phenotype of MZ and B-1 B cells. Thus, they both are IgM^{+++}IgD$^{-/+}$, CD23^{-}, and CD9^{+} *(389)*. However, while B-1/CD5^{+} B cells express CD5 and CD43, MZ B cells do not, and MZ B cells express distinctively high levels of CD21, while B-1 cells have distinctively low levels (Figure 7.12). Also, MZ B cells have high levels of CD1, while B-1 B cells do not *(390)*. Certain mutant mice show similar effects on MZ and B-1 B cells, distinct from Fo B cells. For example, most of the mutations described for B-1 B cells that alter BCR signaling have similar consequences for MZ B cells (391), although cells that resemble MZ B cells are present in xid/Btk-deficient mice, leading to some controversy in their origins (392). Both are decreased by a mutation in the Ig-α tail that weakens overall BCR signaling *(393)*. They are also both decreased in the Aiolos transcription factor null mouse (60). Interestingly, deletion of the Pyk-2 tyrosine kinase results in elimination of MZ B cells, while B-1 cells are still found *(394)*.

MZ B cell development can be studied in a heavy chain transgenic mouse model system where large numbers of such cells are produced (*381*,395). In this V$_H$81X heavy chain mouse, B cells with a specific light chain accumulate with a marginal zone phenotype. This MZ population is eliminated by deletion of CD19, Btk, or CD45, all genetic changes that weaken BCR signaling (391).

B Cell Tolerance and Receptor Editing (Table 7.2)

The past decade has seen the development of several transgenic models for the study of B cell tolerance. In two of these systems, high-affinity BCRs are expressed as IgM-IgD transgenes, one specific for the antigen hen eggwhite lysozyme (HEL), the other for a specific polymorphic determinant on MHC class I (249,265–267,*396,397,398*). The advantage of these systems is that they utilize antigens that can be regulated: Transgenic B cells can develop in either the presence or absence of antigen, and cell transfer experiments can be employed to alter the B cell's antigenic milieu. These have been used initially to confirm ideas on B cell tolerance that originated in work with nontransgenic B cells, namely that exposure to antigen is generally deleterious to developing B cells, resulting in their elimination or failure to mature (instead entering an "anergic" state). However, the resolution of these systems, coupled with advances in gene targeting and other molecular technologies have uncovered important new details regarding the way that self-reactive B cells develop (or fail to develop). For example, studies in the anti-H-2 model uncovered an alternative to deletion in response to immature B cell encounter with antigen, BCR editing to escape autoreactivity (249).

In the HEL system, differences have been uncovered in immature B cell responses to soluble versus membrane-bound antigen, suggesting that differences in the extent of BCR cross-linking can influence cell fate (266). Further, studies with this system on different mutant backgrounds that shift BCR signaling thresholds up or down has shown that such alterations can result in striking alterations in selection outcomes (399,400). More recently, work in this system has shown that one consequence of B cell tolerance may be arrest of B cell migration, so that follicular entry is inefficient (290,*291*). Presumably, failure to reach such follicular niches contributes to handicapping the autoreactive B cells, resulting in their relatively speedy elimination.

Another major line of investigation has focused on a more "physiologic" example of pathogenic autoreactivity, the anti-DNA antibodies produced in lpr (Fas-deficient) mice that are generally considered to model the human disease of systemic lupus erythematosus (SLE). Analysis of transgenic mice bearing a heavy chain transgene known to be capable of generating anti-dsDNA reactivity with numerous light chains showed that only light chains with ssDNA activity were tolerated in the periphery, and even these did not contribute to the serum antibody pool (268). Follow-up work uncovered receptor editing in this model (269,*401–403*) and also showed that when such editing was blocked, the B cells were eliminated in the bone marrow at an immature stage (252). More recent work analyzing transgenic B cells expressing lambda light chain (or in kappa null mice) where B cells have dsDNA binding, has shown the failure of follicular entry previously described in the HEL system (*292,*293). Interestingly, similar analyses on an "autoreactive" (Fas-deficient) background have shown that this follicular exclusion is lost and production of pathogenic autoantibodies ensues, providing a powerful model for the further characterization of the development of autoimmunity due to breakdown of B cell tolerance.

▶ **TABLE 7.2 Transgenic Models of B cell Tolerance**

Ig Transgene	Antigen	Background	Effect	Reference
3-83 $\mu\kappa$	MHC class I	H-2Kk	Deletion, receptor editing	249, 267, 398
	H-2Kk,b	H2-Kd	Normal development	
3-83 $\mu\kappa$	""	H-2Kk lpr autoimmune-prone	Deletion unaffected	274
anti-HEL $\mu\delta$	HEL	sHEL-Tg	Anergy	265, *396, 397*
		Wildtype	Normal development	
anti-HEL $\mu\delta$	""	mHEL-TG	Deletion	266
anti-HEL $\mu\delta$	""	HEL-Tg lpr autoimmune-prone	Deletion unaffected	273
anti-HEL $\mu\delta$	HEL	sHEL-Tg CD45 null	Self-antigen promoted development	400
anti-HEL $\mu\delta$	HEL	sHEL-Tg motheaten	Deletion by lower-valency autoantigen	399
3H9 μ-only	ssDNA with many light chains	BALB/c	No anti-DNA autoantibodies	268
3H9 μ-only	""	lpr autoimmune-prone	Anti-DNA autoantibodies	530
3H9 $\mu\kappa$	dsDNA	BALB/c	Deletion, editing	269
3H9 $\mu\kappa$	dsDNA	J_H^-/J_κ^-	Deletion	252
3H9 $\mu\lambda$	""	Wild-type and lpr autoimmune-prone	Anergy	*292*, 293
3H9-R/Vκ4-R	dsDNA	BALB/c	Deletion, editing anergy	531
3H9-R/Vκ8-R	ssDNA			
3H9-R/Vκ4-R	dsDNA, ssDNA	Rag-2$^-$	Deletion, activation	532
3H9-R/Vκ8-R				
3H9/56R	dsDNA, ssDNA	BALB/c	Deletion, editing	533
3H9/56R76R				
anti-erythrocyte	Red blood cell		Tg$^+$ cells only in peritoneal cavity	404, *405, 406*
V$_H$11μ, V$_H$12μ	PtC, BrMRBC	Wildtype	Increased number of B-1 B cells	534, 535
6C10μ	ATA determinant (glycosylation of Thy-1)	Wildtype	ATA B cells ATA serum	369
		Thy1 null	Normal development; no ATA	
ATA $\mu\kappa$ (6C10μVκ21c)	ATA determinant	Wildtype	Receptor editing or development block in BM; ATA in serum	409, 410
		Thy1 null	Normal development	

A different model of a pathogenic anti–erythrocyte autoantibody has shown another possible mechanism whereby self-reactive B cells may escape deletion or receptor editing, by sequestration from self-antigen (404,*405*). In this system, the transgenic B cells are largely absent from spleen, but instead survive in the peritoneal cavity, where exposure to the distinctive microenvironment may also contribute to the persistence of these cells. Eventual activation of the B cells by mitogen or antigen can lead to an autoimmune condition in these mice *(406)*.

A common thread in all of the studies described earlier is the negative impact that the B cell experiences upon interaction with self-antigen, an expected result for systems that model the regulation of pathogenic autoantibodies. However, a class of autoantibodies is produced in healthy individuals, and these "natural autoantibodies" may play a role in early responses to certain classes of pathogens (359,360,362,*407*). Such a natural autoantibody has been used to construct a transgenic model system where the self-antigen can be regulated. Most natural self-antigens are common glycosylations or cell constituents such as PtC that cannot be eliminated, but a class of natural autoantibodies binds to thymocytes (antithymocyte autoantibody, ATA), and many of these recognize a glycolylation that is only present on the abundant thymocyte cell surface glycoprotein CD90/Thy-1 (369). Thy-1 null mice have already been generated *(408)*, so production of ATA-BCR μ-only transgenic mice enabled the study of the role of antigen in the generation of this natural autoantibody. Interestingly, both production of serum ATA and accumulation of B cells with the appropriate light chain (by rearrangement of endogenous Ig light chain locus) for the ATA BCR required the presence of Thy-1 self-antigen (369). Thus, at least some B cells are selected for binding to self-antigen,

although these may belong exclusively to specialized B cell compartments, such as the B-1 B cell subset.

This ATA-BCR/Thy-1 tolerance model has been extended by the production of ATA $\mu\kappa$ transgenic mice, where most developing B cells express the natural autoreactive specificity (409). In such mice, most B cells developing from bone marrow become arrested in spleen and either cease maturation or else "edit" their BCR by replacing the transgene-encoded light chain by a different light chain, as a consequence of rearranging the endogenous light chain locus. This resembles typical "negative selection," as seen with other transgenic models (249,265–267,*396,398*). Nevertheless, some B-1 B cells are detected, and high levels of serum autoantibody are produced, suggesting that some B cells with this BCR are capable of maturing, perhaps in specialized microenvironments or at distinctive (fetal/neonatal) times.

The role of BCR signaling intensity in directing B cells to various specialized subpopulations has been studied using the ATA $\mu\kappa$ BCR transgenic model, by altering the levels of Thy-1 self-antigen, and then examining B cell development (410). This analysis observed follicular B cell development in the absence of antigen, but MZ B cell production in the presence of very low levels of autoantigen. As shown earlier, normal physiologic levels of the Thy-1 autoantigen results in a block in bone marrow development, but allowed B-1 production, with concomitant generation of ATA detected in serum. This work led the authors to propose a model of B cell development where strong BCR signaling produces B-1 B cells (particularly during fetal development), intermediate BCR signaling yields MZ B cells, and weak (or negligible) BCR signaling results in follicular B cell generation.

Role of Complement, Serum Antibody, and CD5 in B Cell Tolerance and Response

The importance of complement in the immune system has long been recognized, based on classic experiments showing that cobra toxin decreased responses *(411–413)*. Over the past 10 years, the importance of complement in immune responses, explaining the function of adjuvants, has become clearer (414). In the context of B cell development, components of the complement system also play a role in modulating BCR responses and negative selection of B cells. At least in the HEL-Ig/sHEL system, altering the strength of the BCR signal, by CD45R or PTP1C/SHP1 inactivation, could either reduce or enhance B cell deletion (400). Similar results could be obtained by altering the BCR-associated chain CD19 (415). The capacity of HEL double Tg mice that also are Cr2 (CD21/CD35) null to respond to HEL challenge *(416)* implies a role for complement as a modulator of BCR signaling. This could be due to an inefficient retention of antigen (sHEL) on stromal/dendritic cells and therefore weaker signaling by a

monomeric soluble antigen to developing/transitional B cells in the bone marrow or spleen. Potentially a major role for complement would be to localize self-antigens on bone marrow stromal and dendritic cells, facilitating tolerance at the newly formed B cell stage. An implication of these findings is that complement deficiency could result in accumulation of functional autoreactive cells, possibly leading to autoimmunity.

Natural autoantibody, a major component of the serum, may have a role (together with complement) in maintaining tolerance to highly conserved self-antigens (414). It also appears that it plays a role in amplifying immune responses, as suggested by studies with a mutant mouse lacking the μ heavy chain secretory exon *(417)*. The deficit due to a lack of serum IgM was particularly severe in an acute peritonitis model, where some restoration of responsiveness could be obtained by injection of a monoclonal IgM antibody derived from CD5$^+$ B cells *(417)*. Finally, in infection with influenza virus, it appears that early presence of natural autoantibody was equally as important as antibody induced during the course of infection in mediating viral clearance and survival (362). This work has led to the proposal off a two-phase description of immune responses, with an early T cell–independent phase dominated by natural autoantibody, likely critically dependent on innate immune recognition and activation of complement, leading to a later T cell–dependent phase culminating in the GC reaction, producing high-affinity antibody and memory B cells *(418)*.

The presence of CD5 on many of the B-1 B cells has led to the question of whether it plays a direct role in maintaining such self-reactive B cells, particularly in light of its role in altering T cell selection thresholds as demonstrated in the CD5 null mouse *(419)*. Analysis of B cell responses to BCR cross-linking in CD5 null mice suggested that the presence of CD5 makes the normal population less likely to respond by secreting IgM *(420)*, effectively "raising the threshold" for their response, possibly by promoting interaction of the BCR with SHP-1 *(421)*. Analysis of the effect of CD5 expression on tolerance in the HEL-Ig/sHEL system also suggested a modulating role, with absence of CD5 leading to a loss of B cell tolerance and production of serum anti-HEL autoantibody *(422)*.

B CELL DEVELOPMENT IN HUMANS—SIMILARITIES AND DIFFERENCES FROM MOUSE

Fetal Development

As described for mouse, human B cell development can be broadly divided into that taking place prior to birth and that operating after birth, throughout life. The liver and spleen are major sits of fetal B lymphopoiesis in humans and, as in mouse, the bone marrow is the predominant site

in adults, with production continuing over most of an individual's lifespan, with some decrease in the aged. The fetal omentum has also been described as a site for B cell development, similar to mouse *(9,423)*. There is some indication that VH gene usage is more restrictive in fetal development *(424)*. TdT, absent from mouse fetal development, is similarly missing very early in human fetal development, but is expressed by the eigth or ninth week of gestation, based on detection of N-region addition *(424)*. In general, there is more N-addition (and consequently longer CDR3 regions) in human antibodies compared to mouse at all stages of development, including the adult, although the significance of this is not known.

Bone Marrow Development

B cell development can be detected in human bone marrow from 20 weeks of gestation and continues throughout life (425,*426*). Phenotypic subdivisions similar to those in the mouse have been described for developing bone marrow cells (427) (Figure 7.14). Thus, CD19 identifies B lineage cells at all stages, with the earliest stages also expressing CD34, a molecule found on multilineage progenitors *(428)*. These $CD19^+CD34^+$ cells have been shown to express TdT, Rag-1 and Rag-2, the surrogate light chain orthologs, and Ig-α/Ig-β (427). They contain D-J, but not productive VDJ rearrangements. The next stage can be defined by loss of CD34, with a fraction that is still IgM^- (pre-B cells) and another subset that is IgM^+. The pre-B cells express heavy chain in their cytoplasm and have down-regulated expression of TdT (427). All of the IgM^+ cells express a marker lost upon final maturation, CD10, so they are immature B cells.

Human early B lineage cells have proven much more difficult to grow in culture than mouse cells, although conditions have now been defined that allow their expansion *in vitro*. One of the most surprising differences between mouse and human B precursor growth has been much less dependence on IL-7, suggesting that a different cytokine

may substitute in humans *(429,430*,431). The finding that lack of the cytokine common gamma chain (γc) in mouse blocks B cell development, but spares T cell development, while the reverse is the case in humans *(138,432)*, demonstrates clear differences in cytokine dependence between mouse and human lymphopoiesis.

Human B precursors also express orthologs of λ5 and VpreB, although their organization and number differ from the mouse (433,*434,435*). Their expression occurs at a corresponding stage and analysis of the human EBF gene has shown that its targets are similar to those of mouse EBF, including Ig-α, Ig-β and 14.1 (the human ortholog of λ5) *(436)*. Importantly, mutations in components of the pre-BCR lead to immunodeficiency diseases in humans, pointing out the similar and crucial role that pre-BCR signaling plays in human B cell development (437,*438,439)*.

Germinal Center Differentiation

As in mice, GCs in humans are anatomical structures in secondary lymphoid organs where T-dependent immune responses occur, selecting high-affinity clones during the process of SHM and eventually generating memory B cells. The GC consists of B cells at a variety of differentiation states, from early activated B cells through the plasmablast stage. Therefore, study of this process has benefited significantly from resolution of intermediate stages using multiparameter flow cytometry and carefully chosen cell surface markers. In one study, this allowed definition of two IgD^+ stages, two GC stages, and a memory stage in tonsilar B cells *(440)*. This work focused on the levels of somatic mutations accumulating as cells passed through this pathway, finding that it was first detected in the initial GC stage (centroblast). Subsequent work has shown that IgD^+ somatically mutated cells can be detected in peripheral blood, based on expression of CD27, suggesting that they are IgM^+IgD^+ memory B cells *(440)*.

Recent work has found an interesting link between SHM and certain B cell lymphomas. Bcl-6 is a
FIGURE 7.14 Stages of developing B lineage cells in human bone marrow can be delineated, based on expression of combinations of cell surface proteins, similar to mouse.

transcriptional repressor that is linked to both GC B cells and to B lymphomas that likely derive from GC B cells *(441,442)*. Bcl-6 expression is high in GC B cells and is required for formation of the GC *(443)*. Strikingly, its 5′ regulatory region is mutated as a consequence of hypermutation in GC B cells, the first example of hypermutation targeted outside the Ig regions *(441,442)* and links this process to deregulated cell growth and lymphomagenesis. Subsequently, mutations have also been found, albeit at a lower level, in CD95/Fas, suggesting this as another potential cause for lymphomas of GC origin *(444)*.

Abnormalities of Development

A key discovery in the past decade has been the finding that a well-known immunodeficiency, X-linked immunodeficiency (XLA), characterized by inability to respond to bacterial infections and a severe deficit in peripheral B cells *(445)*, is due to mutations in Btk, or Bruton's tyrosine kinase (446). Shortly after this finding, the mouse ortholog of Btk was shown to be the cause of murine xid, an extensively studied mutation originally identified in CBA/N mice (447). Btk deficiency in humans is more severe than xid, with little B cell development past the early B cell stage, in contrast with an absence of normal peripheral B cell development in mouse and inability to respond to certain types of T-independent antigens *(448)*. This difference is not simply due to specific difference in the mutations, as a complete null mutation in mouse is indistinguishable from xid (375). Thus, human B cell development, likely at the pre-BCR signaling stage, is much more dependent on Btk.

While XLA is by far the most common B cell deficiency, amounting to more than 80% of those identified, non-X-linked mutations have also been observed. These correspond to mutations in the pre-BCR signaling complex, and in most cases similar effects had been observed in the mouse. For example, deletions or mutations in the μ constant regions accounted for another 5% *(439)*. Examples have been found of mutations in the 14.1 gene, the human ortholog of the mouse surrogate light chain $\lambda 5$ protein (437) and also in Ig-α *(438)*. In both of these cases, early B lineage cells, identified as $CD19^+CD34^+$, were present in normal numbers in bone marrow, but $CD19^+CD34^-$ $c\mu^+$ cells (pre-B cells) and all later stages were absent. Finally, a patient with a mutation in BLNK, an adaptor protein that links pre-BCR signaling from syk to the rest of the signaling cascade, showed a similar phenotype (449).

Very few peripheral B cells are detected in any of these disorders, which suggests that pre-BCR signaling is more critical in human than in the mouse, where mutations in $\lambda 5$ and BLNK allow the generation of variable numbers of peripheral B cells. The reason for this difference is not yet understood. Interestingly, common variable immunodeficiency has been shown to result from mutations in the common gamma chain *(138)* or in the JAK3 gene *(450)*,

consistent with IL-7 playing a much less critical role in human pre-B cell growth than in mouse, as had already been determined from culture studies *(429,430)*, B cell development is relatively intact, whereas T cells are ablated. The reverse is true for mouse *(451,452)*.

New Insights into Treatment of B Cell Malignancies

One of the principle reasons for studying the regulation of B cell development is that defects in this process may result in lymphoma. Human B lineage neoplasias can be viewed as transformed counterparts of normal B cell developmental stages, such as pro-B, pre-B, immature B, mature B, or plasma cell, based on rearrangement status and surface phenotype (433). In some cases, transformed cells may even retain growth characteristics of the normal counterpart. This type of classification scheme, correlating features of neoplasias with their normal counterparts, has been useful in diagnosis and prognosis of B lineage neoplasias. For example, B precursor acute lymphoblastic leukemia (ALL), the most common type of ALL in children (ALL accounts for 25% of childhood cancer), is a clonal expansion of a cell defined by surface phenotype and Ig rearrangement status as representing the pro-B stage *(453–455)*. Recent analyses of B precursor ALL suggests that it can be subdivided into a pro-B type, predominant in pediatric patients, and a pre-B type, more frequent in adults *(456)*.

Whereas traditional chemotherapeutic agents typically target proliferating cells without specificity for malignant cells, the identification of molecular abnormalities that result in the abnormal survival and proliferation of leukemic cells may lead to the design of novel therapies that specifically target these cells. For example, the successful treatment of mice carrying human B precursor leukemias with antisense strategies and tyrosine kinase inhibitors holds promise for efficacy in humans *(457,458)*. The identification of novel translocations in B-precursor ALL also holds promise in understanding this disease at the molecular level *(459–462)*.

Another therapeutic approach makes use of knowledge of the surface phenotype of the transformed cell, as in the recent development of anti-CD20 therapy for several types of B lymphomas *(463)*. CD20 is a 33 kDa phosphoprotein expressed highly on the surface of mature B cells *(464–466)*. Antibodies to CD20, originally called *B*1, were initially characterized by their stimulatory and inhibitory effects on human B cells, indicating the importance of CD20 in regulating B cell proliferation and differentiation *(467–469)*. Therapeutic anti-CD20, called *Rituximab,* is a chimeric antibody derived by fusing the V regions of a mouse antibody to the human IgG1 constant segment *(470)*. The precise mechanism of depletion is not yet fully understood but likely includes contributions

from antibody-dependent cell-mediated cytotoxicity, complement mediated cytotoxicity, and direct antibody binding effects, including sensitization to apoptosis *(463)*.

As most of the cells in many indolent B cell neoplasms, such as non-Hodgkin's lymphoma or chronic lymphocytic leukemia (CLL), are not predominantly in cycle, the problem may be more a failure to die appropriately, rather than a failure to regulate proliferation. A greater understanding of the growth and sensitivity to apoptosis of different types of lymphomas and leukemias may allow more specific targeting using this approach *(471)*. For example, while CLL cells express relatively low levels of CD20, likely requiring higher doses of anti-CD20 for a response, a combination with another antibody recognizing a molecule that is highly expressed on CLL, CD52, has shown promise *(472)*. Alternatively, treatment with anti-CD20 may render the cells generally more sensitive to apoptosis, so that use in combination with more conventional chemotherapeutic agents will be efficacious. These combination therapies are already in clinical trials. Finally, new insights into distinctive growth properties of transformed B cells, such as the role of Wnt signaling in CLL (473), may suggest new approaches to treat such disorders.

Novel technologies may revolutionize our understanding of B cell development and the relationship between normal and transformed cells. For example, recent gene profiling analysis suggests that CLL can be subdivided into two types of diseases, with different severity and different response to therapies (474). This analysis also challenges the earlier classification of the disease as a transformation of normal CD5$^+$ B cells, since there are more similarities with normal memory B cells. It is likely that advances in our understanding of the growth and differentiation of cells that represent transformed counterparts of normal developmental stages will suggest novel therapeutic approaches. In the case of CLL, the development of gene therapy has allowed introduction of a gene product, CD40, into patient leukemia cells that can then serve as stimulators for induction of antitumor responses (475). Analysis of the V gene repertoire of CLL has also revealed recurrent BCR usage, reminiscent of mouse B-1 B cells, potentially a therapeutic target for anti-idiotypic antibodies (476).

ALTERNATIVE STRATEGIES FOR B CELL DEVELOPMENT

The broad outlines, and even many of the details of B cell development are quite similar in mouse and man, but there are striking differences in other species. There is a notable common alternative approach that involves generation of Ig$^+$ cells during fetal/neonatal development with a relatively restricted repertoire that is then diversified by novel approaches (gene conversion or SHM) in specialized lymphoid organs that are associated with the gut. In these species, most development from Ig$^-$ precursors appears to cease by birth, and the B cell population is maintained by self-renewal of mature B cells. Here we consider the development and diversification of B cells in chicken and rabbit.

Chicken

B cell development in the avian occurs in the bursa of Fabricius *(477,478)*. In fact, the term *B cell* refers to "bursa-derived," reflecting the historical origins of research in lymphocyte development. That is, removal of the bursa just after hatching eliminated the ability to mount an antibody response, demonstrating the importance of this organ in generating cells capable of antibody formation *(477)*. In contrast with the bone marrow, the bursa, being associated with the gut *(479)*, facilitates exposure of developing cells to external antigens and bacterial flora. B cell development in chicken is usually divided into three stages: pre-bursal, bursal, and post-bursal (480).

During pre-bursal development, at day E5, early precursors can be identified in the para-aortic foci *(481)*, likely corresponding with similar precursor stages localized in this anatomic site in mammals *(2)*. B lineage commitment, as indicated by DJ rearrangements, is detected in the YS at day E5/6, and V gene rearrangement is found 3 days later *(482)*. Unlike mammalian ordered development, light chain rearrangement is detected at about the same time as heavy chain and light chain can precede heavy chain *(483)*. This means that there is no pre-B stage, per se, and also probably no requirement for surrogate light chain. Rearranging B lineage precursors migrate into the bursal mesenchyme at about day E12, and thereafter these cells begin to proliferate in bursal epithelial buds. This proliferation selectively expands cells that have BCR. These receptors have very limited diversity, since the heavy chain is formed by rearrangement of a single VH, several Ds and a single JH pairing with a light chain generated by rearrangement of a single VL with a single JL *(484,*485). As in mouse fetal development, there is no TdT-mediated N-region addition at the junctions (485).

This "pre-bursal" receptor is diversified by gene conversion by a set of V pseudo-genes during this proliferative phase. At about hatching, these cells become exposed to the contents of the bursal lumen that is connected to the gut lumen via the bursal duct, similar to the appendix. Thus, these proliferating B cells are exposed to the contents of the digestive tract, and there is also reverse peristalsis at the end of the gut that transports external antigens into the bursal duct *(479)*. At about this time, the level of apoptosis increases dramatically, and it is possible that only 5% of the cells generated in the bursa eventually emerge *(486)*. This death may be due to generation of nonfunctional receptors during the course of gene conversion or it may reflect antigenic selection.

At hatching, emigration of B cells from the bursa increases, but most of these cells constitute a population with a relatively short half-life, measured in days *(487)*. The long-lived pool colonizes the peripheral lymphoid organs over several weeks as the bursa atrophies. By 3 weeks after hatching bursectomy no longer results in agammaglobulinemia, indicating that the post-bursal phase has become established.

Rabbit

B cell development in rabbit is similar to chicken, in that B cells initially are produced with a limited BCR diversity (488,*489,490*) during fetal life, with little new production after birth (*491*,492). This repertoire is then expanded through gene conversion (488,*493*) and SHM *(493,494)* in a specialized gut-associated organ, the appendix (495). However, unlike chicken, this diversification process is dependent on antigen availability *(496–498)*.

Pre-B cells can be found in rabbit before birth in the liver, bone marrow, and omentum *(491,499–501)*, but B lymphopoiesis decreases at birth and is negligible in adult animals (492). Ig rearrangement during fetal and neonatal times is dominated by usage of the most D-proximal V_H gene paired with multiple V_L genes in the light chain *(489,490,502–505)*. In contrast with chicken and mouse, there is significant N-addition *(490,504)*. From 4 to 8 weeks after birth, there is a striking increase in the diversity of this primary repertoire that occurs during proliferation of B cells in the gut-associated lymphoid tissues (GALT) (492, *493*). V genes are diversified by both gene conversion (488) and also by SHM *(493,494)*. Importantly, surgical removal of GALT organs, appendix, saccutus rotundus, and the Peyer's patch, from neonatal rabbits led to unresponsiveness to many antigens, suggesting that this diversification was crucial for normal immune function *(506)*. This finding has been confirmed by sequence analysis, demonstrating that removal of the GALT blocks diversification (495).

Considering the relatively late diversification in rabbit compared to the chicken, these gut areas will provide a milieu of microbial antigens, and this appears to be a critical aspect of the diversification process (507). For example, surgery to prevent access of intestinal flora to the appendix blocked diversification in this organ *(508,509)* that could be restored by reversing the ligation *(508)*. Further, analysis of rabbits reared in germ-free conditions revealed abnormal cellular development in the GALT *(497)* and a lack of responsiveness to certain antigens *(496)*. The dependence of V gene diversification on antigen has been directly demonstrated in animals where the sacchus rotundus and Peyer's patches were removed at birth and the appendix ligated. Testing the peripheral blood B cell V gene repertoire showed an absence of diversification, in contrast to controls *(498)*. Although the mechanism for this stimulation remains to be established, possibilities include

B cell activation by a BCR superantigen (*510,511*,512) or through a B cell Toll-like receptor *(513)*.

Two B Cell Developmental Pathways?

The similarities of chicken and rabbit B cell development with that in other species, such as sheep, swine, and cow, suggests that the initial production of a limited BCR repertoire during fetal/neonatal life, diversification at a later time, and maintenance of the B cell pool in adult life by self-renewal (rather than *de novo* generation from unrearranged precursors) is a major pattern in the design of the immune system (Figure 7.15). This pattern contrasts with that described for mouse and man, where ordered heavy and light chain rearrangement, pre-BCR selection, and replacement of senescent B cells by newly generated B cells are major aspects of development. This raises the interesting question of whether there is an analogous B cell development pathway in humans or mouse, perhaps as a vestige.

The idea of two pathways in bone marrow development was suggested previously, based on the observation that heavy and light chain ordering is not absolute: Light chain rearrangements are detected in mice incapable of making heavy chain rearrangements and can be detected in cells early in B cell development *(514)*. In one pathway, heavy chains rearrange first, the pre-BCR is assembled and signals down-regulation of Rag-1/2 expression (ending heavy chain rearrangement), clonal expansion, and accessibility of the kappa locus. Cessation of proliferation is coincident with reinduction of Rag-1/2 and light chain rearrangement. Expression of a complete BCR signals a final termination of Rag expression. In this model, pre-BCR and BCR mediates allelic exclusion by a feedback mechanism regulating Rag expression. Thus, most B cells have DJ or even VDJ rearrangements on both alleles. In the alternative pathway, heavy and light chains rearrange stochastically and allelic exclusion is mediated by relative inaccessibility of the loci (and thereby low frequency of rearrangement). If this is the major pathway in chicken and rabbit, it is consistent with the observation that most chicken B cells have only one allele rearranged (485,515,516). Further, the careful ordering of TdT expression, being down-regulated at the light chain rearranging stage, is apparently not the case for rabbit, where a large percentage of light chains have N-regions *(505)*.

Most rabbit B cells express CD5 *(517)*. In mouse, much of the CD5[+] B cell population is generated during fetal/neonatal development and persists in the adult through self-renewal *(351)*. Further, these cells express a relatively restricted BCR repertoire that is dependent on antigen selection (23). Finally, the pre-BCR selection phase of several heavy chains abundant in CD5 B cells appears to follow different rules than classical pre-BCR mediated expansion (239). In fact, the process of development in mouse fetal

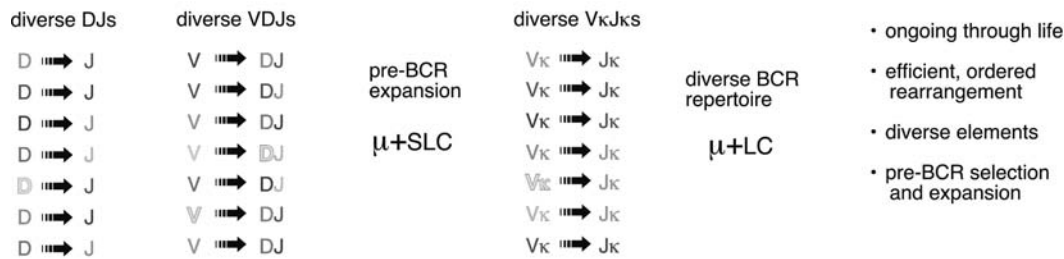
Human/Mouse Primary Pathway Bone Marrow B Cell Development


FIGURE 7.15 Alternative strategies of repertoire diversification and B cell development. In both mouse and human bone marrow B cell development, ordered rearrangement predominates, with a pre-BCR selection phase dividing heavy and light chain rearrangement. The eventual outcome is a population of newly formed B cells with a diverse set of BCRs, produced throughout life. In chicken and rabbit, Ig rearrangement appears less efficient (usually the other allele is germline) and much less diverse, with a single BCR for chicken. However, these cells proliferate and undergo gene conversion during fetal/neonatal life, followed by selection, eventually generating a set of B cells with a more diverse repertoire that persist for the life of the animal.

liver may predominantly follow this alternative pathway *(364)*. Thus, in mouse, fetal development, culminating in production of B-1 B cells, may represent a type of alternative or "primitive" B cell development, as has been proposed previously *(518)*. It is less clear whether a similar distinction exists in human B cell development, as data are lacking. Nevertheless, one can envision a primordial pathway, randomly combining heavy and light chains and simply selecting cells that express BCRs with weak reactivity to self- or environmental antigens as an alternative to ordered rearrangement, pre-BCR selection, and BCR selection, an elaborate process fine tuned to generate more variation.

CONCLUSION

There has been considerable progress over the past decade in understanding the mechanisms that regulate B cell development, with important insights coming from application of the novel genetic approaches of transgenesis and gene targeting. In a sense, this has allowed progression from research with simple model systems using cell lines to analysis of "normal B cells" in whole animals. The use of such mutant mouse "reagents," together with much higher resolution of normal development made possible by multiparameter flow cytometry, has proven a powerful combination for unraveling much of the complexity of this process. It is daunting to attempt to predict where new advances in the field will come, but undoubtedly the completion of the genome sequence for both mouse and human will provide impetus to large-scale gene profiles of B cell development, as have already begun (519,520). A complementary approach to gene targeting based on such profiling will involve characterizing new mutant mice generated by chemical mutagenesis (521,*522*). Considering the recent unanticipated discoveries of AID in isotype switching and BAFF in peripheral B cell development, it seems likely that the coming decade will provide many surprises. A goal will be to eventually understand how the interplay of the innate and adaptive immune systems generates protective responses, while avoiding autoimmune pathologies, at the organism level.

B Lymphocyte Signaling Mechanisms and Activation

Anthony L. DeFranco

OVERVIEW

During an immune response, the B cell antigen receptor (BCR) plays a critical role in the activation of the B cell and in this way ensures that only B cells recognizing antigen are induced to become antibody-secreting cells. The BCR also plays an essential role in the development of B cells, in the maturation of newly generated B cells into long-lived mature B cell subtypes, in the survival of B lineage cells at various stages, and in a variety of mechanisms promoting tolerance in the B cell compartment. Most of these biological effects are mediated by signaling events generated by the BCR, some of which may be generated at a low level by expression of the BCR on the cell surface, a process called *tonic signaling,* and others of which require oligomerization of the BCR to enhance its signaling. This chapter focuses primarily on the mechanisms of signaling and what is known about the biological relevance of this signaling. In addition, the BCR serves as an endocytic receptor for uptake of antigen, allowing efficient presen-

tation of antigenic peptide-major histocompatability complex (MHC) complexes to helper T cells, which is essential to T-dependent antibody responses.

In addition to responding to soluble proteins and small particulate antigens derived from degraded virus particles and microbes, B cells may recognize and respond to antigen bound to other immune cells, such as dendritic cells, macrophages, and follicular dendritic cells (1). Such antigens or fragments of microbes may be held on the immune cell surface by Fc receptors, complement receptors, and innate immune receptors such as C-type lectin receptors. Such means of presentation likely influence the nature of activation signals the B cell receives from antigen contact, although little is understood about this aspect of B cell activation. Some of these cells secrete BAFF (B cell activating factor of the tumor necrosis factor (TNF) family), which is a strong survival signal for unstimulated mature B cells and may also promote B cell activation through the BCR (2).

B cells can mount some antibody responses without helper T cells, and these have been divided into two sub-groupings, called *T-independent type I* and *T-independent type II* antibody responses. This distinction is generally based on the responsiveness of a mutant mouse strain, the *xid* mouse. Mice with this mutation have a complete loss of function of the Btk protein tyrosine kinase, which plays an important role in BCR signaling, as is described below. These mice still make antibody responses to T-independent type I antigens, which include molecules containing Toll-like receptor (TLR) ligands and highly polymeric structures such as certain types of virus particles (3), but fail to make responses to T-independent type II antigens, which typically are polysaccharide antigens (4). Recent work demonstrates that B cell TLRs are likely to have importance for many antibody responses, not just the T-independent type I responses (5–7). Polysaccharide antigens induce robust and sustained BCR signaling, probably due to their multimerization of epitopes on a flexible backbone (4). Interestingly, capsular polysaccharides of certain bacterial pathogens have been purified for use as vaccines, and these vaccines behave as T-independent type II antigens. The vaccines are often poorly efficacious in young children, younger than the age of 2, and in addition they generate relatively little memory. As a response to these limitations, in the early 1990s, conjugate vaccines were developed in which capsular polysaccharides are chemically coupled to protein antigens (e.g., tetanus toxoid, etc.). These vaccines have the property that they can promote antibody responses by both T-independent type II and T-dependent mechanisms.

T-independent antibody responses are typically quite rapid and serve the purpose of generating a rapid IgM response to provide early protection against infection, whereas T-dependent antibody responses, as described in more detail in the next chapter, can lead to vigorous germinal center responses that generate high-affinity isotype-switched antibody, and also generate long-lived plasma cells and memory B cells, both of which are of great value for protection from infection at a later date.

BCR signaling participates in T cell-dependent antibody responses in multiple ways. BCR signaling changes the responsiveness of the B cell to chemokine signals that position the B cell within secondary lymphoid organs and, in this way, the antigen-recognizing B cell is induced to move to the edge of the T cell areas, where T cells are scanning B cells for peptide-MHC complexes (8). BCR signaling also changes the adhesive properties of the B cell, enhancing its binding to T cells, and it induces expression of molecules the B cell needs to activate T cells. In particular, BCR signaling increases the expression of MHC class II molecules and induces expression of costimulatory molecules, particularly B7-2 (CD86). BCR signaling also protects B cells from Fas-mediated killing, which can be induced by acti-

vated helper T cells, by the action of FasL, in combination with CD40L (9,10).

BCR FUNCTION AND B CELL DEVELOPMENT

Although the focus of this chapter is on B cell activation, defects in B cell development often result from genetic alterations in mice of BCR components or individual BCR signaling components (11). This is because BCR-signaling reactions play multiple roles in the development of B cells. The first of these reactions occurs following the successful rearrangement of the Ig heavy chain locus, when the resulting heavy chain protein assembles with two proteins, λ5 and VpreB, called *surrogate light chain,* and the signaling chains Ig-α and Ig-β to form the pre-BCR, which is structurally similar to the BCR. Pre-BCR signaling promotes development from the pro-B cell stage to the pre-B cell stage. Subsequent successful rearrangement of one of the Ig light chain loci promotes the next developmental step, to the immature B cell stage in the bone marrow. If a bone marrow immature B cell is not self-reactive, it can leave the bone marrow and transit to the spleen, where it is called a transitional 1 (T1) B cell (12). T1 cells mature further to the T2 developmental stage and eventually to either of two mature B cell types, the marginal zone B cell or the follicular B cell. This choice is also influenced by BCR signaling, with low signaling in response to weak reactivity to self-antigens probably favoring development to the follicular B cell type and even lower signaling favoring development to the marginal zone B cell (13), although some investigators have argued for the opposite relationship between signaling and choice between follicular and marginal zone B cells. Selection of T2 cells into the long-lived follicular B cell population on the basis of a low level of self-reactivity may resemble positive selection of thymocytes in T cell development. Notch-2 signaling also influences the long-lived choice of cell type between follicular and marginal zone B cell, promoting development of marginal zone B cells.

In fetal life and immediately after birth, B cell precursors access a third type of mature B cell, the B1 cell. B1 cells reside primarily in the peritoneal and plural cavities, where they make rapid T-independent antibody responses to microbes that enter these locations (14). In addition, early in life, B1 cells spontaneously secrete polyreactive IgM antibodies, called *natural antibody,* and this antibody has been shown to be protective in the case of several infections in mice (15). B1 cells appear to require a higher level of self-reactivity to enter and survive in this compartment than what is needed to develop into a follicular B cell (14,16). Indeed, some signaling defects that do not greatly affect development of marginal zone or follicular B cells result in loss of B1 cells (13,14).
FIGURE 8.1 Functions of signaling by the BCR and pre-BCR. BCR signaling regulates the development and maturation of B cells, B cell survival, B cell activation, and B cell tolerance.

FIGURE 8.2 Structure of the BCR. The BCR consists of two moieties, the antigen binding membrane immunoglobulin, consisting of a two heavy chain, two light chain structure, and the signal transducing Ig-α/Ig-β heterodimer. The two component parts are weakly associated with one another through hydrophilic amino acid side chains in their transmembrane domains and probably also through interactions of heavy chain Ig domains with Ig domains of Ig-α or Ig-β. Surprisingly, experimental evidence indicates that only one Ig-α/Ig-β heterodimer pairs with a H_2L_2 membrane immunoglobulin.

B cells with reactivity to self antigens generate moderate to high levels of BCR signaling, which induce biological responses promoting immunological tolerance in the B cell compartment. The response varies depending on the developmental stage of the B cell when it contracts self antigen. If immature B cells bind well to self antigens, then the resulting BCR signaling causes maturation arrest and further Ig light chain rearrangements, which may replace the first light chain with a new one, in which case self-reactivity may be erased. This process is called *receptor editing,* and it appears to occur in at least 25% of B cells (17). Self-reactive T1 cells begin the receptor editing process like immature B cells in the bone marrow but die due to lack of protective signals provided to immature B cells by bone marrow stromal cells (18).

BCR signaling above the level that promotes follicular B cell development induces T2 or follicular B cells to enter a tolerized but alive state referred to as *anergy* (19). In most cases, anergic B cells are characterized by chronic low-level BCR signaling (20). This level of signaling is sufficient to induce relocalization from the follicles to the T cell zone (8), but is insufficient to protect from Fas-mediated killing (21). In addition, the lifespan of anergic B cells is shorter than that of follicular B cells due to an increased requirement for BAFF (22). Analysis of normal mice indicates that anergic B cells are present in substantial numbers (23), so anergy likely represents an important mechanism for establishing and maintaining tolerance in the B cell compartment.

The functions of the pre-BCR and BCR in B cell development, choice of mature cell type, tolerance, and activation are summarized in Figure 8.1.

STRUCTURE OF THE B CELL ANTIGEN RECEPTOR

The BCR is a multimeric complex containing membrane Ig (mIg) of any of the five isotypes noncovalently associated with a disulfide-linked heterodimer of two signaling chains

called Ig-α and Ig-β, also known as CD79a and CD79b, respectively (Figure 8.2). Ig-α and Ig-β are the products of the *mb-1* and *B*29 genes (24). Ig-α and Ig-β have structures similar to those of the CD3 chains that pair with the T cell receptor (TCR)—namely, they each have an N-terminal Ig-like domain, a single hydrophobic transmembrane domain, and a C-terminal cytoplasmic domain of 61 and 48 amino acid residues in length. These cytoplasmic domains each contain an amino acid sequence motif referred to as the *Immunoreceptor Tyrosine-based Activation Motif* (*ITAM*), which is also present in the CD3 and ζ chains of the TCR and in several other polypeptides of activating Fc receptors of myeloid cells and activating natural killer cell receptors. The ITAM plays a central role in BCR signaling, as described in the next section.

The association between mIgM and Ig-α/Ig-β is rather weak and is maintained if B cell membranes are solubilized in very gentle, nonionic detergents such as digitonin, but is disrupted by more commonly used nonionic detergents such as NP-40 and Triton X-100. There is a striking number of hydrophilic amino acid residues within the Ig heavy chain transmembrane domains, particularly serine, threonine, and tyrosine residues. Mutagenesis data indicates that these –OH-containing side chains contribute importantly to the association between mIgM and Ig-α/Ig-β (25,26). This association is probably also stabilized by interactions of extracellular Ig domains of the different components.

Given that membrane forms of Ig are composed of two heavy chains and two light chains, symmetry considerations originally led to the proposal that the BCR would contain two dimers of Ig-α and Ig-β. Co-immunoprecipitation experiments using two distinct epitope tags, however, indicate that a single BCR complex contains only one Ig-α/Ig-β heterodimer (Figure 8.2). Fluorescence resonance energy transfer (FRET) studies in intact B cells have supported

this conclusion (27) and, moreover, have indicated that the BCR complexes are single units (H_2L_2 + 1 Ig-α/Ig-β dimer) rather than higher order structures.

Although most evidence favors the view of BCRs as independent units dispersed in the plasma membrane, one study (28) suggested the possibility that BCRs may form into a lattice in the membrane that has tonic signaling properties that are perturbed by binding to antigen to induce the stronger signaling seen upon acute stimulation. Fluorescence imaging studies have not supported the idea of large preformed lattices of BCRs in the membranes of B cells, but the possibility of small microclusters cannot be ruled out by light microscopic techniques. The FRET studies mentioned earlier also did not find evidence for clustering of BCRs prior to cross-linking. In addition, electron microscopy studies have supported the view that BCRs are dispersed in the plasma membrane (29). As will be discussed later, tonic signaling is a feature of the BCR and is important for promoting B cell survival (30,31), but it seems likely that this low-level signaling in the absence of ligand results from the equilibrium between protein tyrosine kinases and protein tyrosine phosphatases acting on the BCR and its signaling components, rather than by formation of multimeric complexes in the absence of antigen.

INITIATION OF SIGNALING

Cross-linking of the BCR by antigen or experimentally by anti-Ig antibodies induces rapid and robust signaling, including activation of protein tyrosine kinases, elevation of intracellular free calcium, activation of mitogen-activated protein (MAP) kinases, and activation of several transcription factors, including NF-κB. The magnitude of signaling is generally related to the extent of BCR clustering achieved. The signaling reactions are all dependent upon the ITAM sequences in the cytoplasmic domains of Ig-α and Ig-β. An ITAM has two tyrosines in a conserved sequence context and with a conserved spacing (D/E $XXYXXL/IX_7YXXL/I$). Tyrosine kinase-based signaling systems typically involve phosphorylation-induced assembly of multiprotein complexes (32), and this is also true for BCR signaling. Each half of the ITAM (YXXL/I) is, when phosphorylated, a binding site for several signaling proteins containing Src-homology 2 (SH2) domains, especially tyrosine kinases involved in the early steps of BCR signaling, the Src-family tyrosine kinases, and Syk (Figure 8.3).

The BCR contains two ITAMs, one each in the cytoplasmic domains of Ig-α and Ig-β. These ITAMs are largely redundant: Mice in which either the Ig-α or the Ig-β ITAM is ablated by tyrosine to phenylalanine mutations have defects that are subtle, but mice in which both ITAMs are ablated have a strong block in B cell development at the stage where pre-BCR signaling is required for progression (33).
FIGURE 8.3 Three families of intracellular protein tyrosine kinases are involved in BCR signaling. The Src-family kinases Lyn, Fyn, and Blk each have an N-terminal unique region that has fatty acid addition sites, myristic acid in all cases and an additional palmitic acid in the case of Lyn and Fyn. The former fatty acid targets these kinases to membranes, whereas the latter additionally targets them to lipid raft membrane subdomains. Blk is also preferentially localized to lipid rafts, but this is achieved by a different mechanism. In addition, Src-family kinases all have three conserved domains, called Src-homology 1 (the kinase domain), Src-homology 2 (SH2), and Src-homology 3 (SH3) domains and also have a negative regulatory tyrosine phosphorylation site near the C-terminus. Syk lacks lipid modifications and has two SH2 domains and a kinase domain. Btk has an architecture similar to Src-family kinases, but lacks the lipid modification and negative regulatory tyrosine and instead at the N-terminus has a pleckstrin homology (PH) domain, which can bind to PIP_3.

In addition, Ig-α has two tyrosines outside of its ITAM, and one of these (Y204) has been shown to be important for downstream signaling reactions, as is described later.

The first step in the BCR signaling cascade is tyrosine phosphorylation of the Ig-α and Ig-β ITAM tyrosines by Src-family tyrosine kinases. B cells express primarily three members of the Src family, Lyn, Fyn, and Blk. These three tyrosine kinases function redundantly for ITAM phosphorylation, as indicated by analysis of development between the pro-B cell stage and the pre-B cell stage in single, double and triple knockout (KO) mice (34): triple KO mice exhibit a strong block at this early stage of development, presumably reflecting a defect in pre-BCR signaling, whereas the single and double KO mice exhibit normal B cell development. The strong block in B cell development in these mice suggests that pre-BCR signaling requires Lyn, Fyn, or Blk acting redundantly to initiate pre-BCR signaling.

Exactly how antigen binding to the BCR leads to ITAM tyrosine phoyphorylation and initiation of signaling is not fully understood. Three explanations have been proposed. Originally, it was proposed that Src-family tyrosine kinases were noncovalently associated with Ig-α/Ig-β cytoplasmic domains prior to stimulation in a way that did not allow them to efficiently phosphorylate the ITAMs of the Ig-α and Ig-β to which they were associated, but allowed them to phosphorylate ITAMs of other BCRs brought nearby by antigen-induced clustering. Although attractive in its simplicity, this model has little experimental support. Immunoprecipitation of BCRs from unstimulated B cells does bring down Lyn, Fyn, and Blk, but the amounts are quite small, a few percent of the amount of these kinases present in the cell. Immunoprecipitation of the BCR from B cell lines expressing transfected mIgM demonstrated
FIGURE 8.4 Model for BCR tonic signaling mediated by equilibrium between tyrosine kinases and protein tyrosine phosphatases. According to the model shown, Src-family tyrosine kinases are responsible for phosphorylating BCR ITAM tyrosines, which creates a binding site for Syk (via its tandem SH2 domains) and also for Src-family kinases (via their single SH2 domain) to bind to the receptor and initiate a low level of signaling. Dissociation of Syk or Src family SH2 domains from ITAM phosphorylated tyrosines exposes them to allow phosphatases (SHP1, CD45, or others) to dephosphorylate the ITAMs and terminate tonic signaling from that receptor.

that a small amount of Fyn is specifically associated with mIgM, but the amounts of Lyn or Blk detected were not above the negative control (35). Since Fyn KO mice have no defect in BCR signaling (36), it seems likely that pre-association of Src kinases with the BCR is not important for BCR signaling. It should be noted, however, that Lyn and Fyn were found to associate specifically with the BCR after cross-linking (35), possibly reflecting an association between the SH2 domains of Lyn and Fyn and one half of one of the ITAMs, since phosphorylated YXXL/I represents a consensus sequence for binding of Src-family SH2 domains. Although Lyn and Fyn bound in this way would presumably not be responsible for initiating BCR signaling, they could function to amplify it.

A second hypothesis is that the initiation of BCR signaling involves a change in location of the BCR within the plasma membrane that takes it from the nonlipid raft region of the membrane to the lipid raft region, which is highly enriched in the Src-family kinases. Indeed, cross-linked BCRs have been shown by both biochemical means (37) and by fluorescent microscopy (38) to associate with lipid rafts after antigen– or anti–Ig-induced BCR clustering, but not before. Originally, it was argued that this change in location occurred independently of signaling reactions (37), although not all data are consistent with this possibility, and more recent data has suggested that this change of localization may occur after signaling has initiated (39), in which case its function may be to amplify signaling or allow efficient association with adaptor molecules required for downstream signaling. Another problem with the hypothesis that BCR signaling is initiated by a movement of the BCR into lipid rafts is that, in immature B cells, this movement appears not to occur and yet clearly BCR cross-linking induces signaling in imma-

ture B cells, although perhaps not as robustly as in mature B cells (40,41). The relationship of BCR signaling to lipid rafts is discussed additionally in the next section.

Finally, a third hypothesis for how ITAM signaling is initiated is that cross-linking alters the equilibrium between kinases phosphorylating the ITAMs and phosphatases dampening signaling by removing phosphates from ITAM tyrosines (Figure 8.4). According to this view, dispersed BCR complexes in the plasma membrane are being phosphorylated by Src-family tyrosine kinases frequently, and this allows some recruitment of Syk and downstream signaling, as described below. This tonic signaling is maintained at a low level by the action of tyrosine phosphatases (perhaps SHP-1 or CD45) that remove phosphates from phosphorylated ITAMs, attenuating signaling. Interesting in this regard is the observation that addition of inhibitors of tyrosine phosphatases (e.g., pervanadate) results in a pattern of signaling reactions that closely mimics what is seen upon treatment of B cells with anti-Ig antibodies (42). Moreover, it is likely that antigen-induced clustering of BCRs changes the dynamic equilibrium between tyrosine kinases and protein tyrosine phosphatases, because when BCRs are clustered, Src-family tyrosine kinases and Syk bound to phosphorylated ITAMs are now close to other ITAMs and can efficiently phosphorylate them and in that way promote sustained signaling.

Evidence that Syk can propagate signaling of cross-linked BCRs comes from studies of ITAM signaling in the absence of Src-family kinases. For example, Lyn-deficient DT-40 chicken B cells, which apparently lack other Src-family kinases, exhibit substantial BCR signaling upon treatment with anti-Ig, although the calcium response is somewhat delayed compared to parental cells (43). Similarly, mouse macrophages genetically lacking Src-family

kinases have greatly delayed ITAM signaling through their activating Fc receptors, but once signaling is initiated, it is sufficient to mediate internalization of antibody-coated red blood cells (44). These observations have been interpreted as indicating that Syk is sufficient to mediate ITAM signaling in the absence of Src-family tyrosine kinases, but it is inefficient at doing so due to inefficient initiation of signaling. Signaling ability of the BCR expressed with Syk in an epithelial cell line that has endogenous Fyn (45) or of the BCR expressed with Lyn and Syk in Drosophila S2 cells (46) support these conclusions.

The ability of Syk to promote ITAM signaling in the absence of Src-family tyrosine kinases is in contrast to ZAP-70, which is primarily expressed in T cells and NK cells. ZAP-70 absolutely requires a Src-family kinase to become activated (47). Thus, the ITAM signaling machinery in B cells and myeloid cells is more flexible than its counterpart in T cells, perhaps to accommodate the greater variety of antigen types that B cells must respond to in contrast to T cells, which primarily respond to MHC-peptide ligands.

LIPID RAFTS AND BCR SIGNALING

BCR signaling in mature B cells is probably enhanced by compartmentalization into subdomains of the plasma membrane, called *lipid rafts* or *glycolipid-enriched membrane microdomains* (GEMMs). Lipid rafts are highly dynamic self-assembling lipid structures within membranes. They contain glycosphingolipids, cholesterol, and various lipid-modified proteins. The lipids in these structures pack together more closely than do the lipids in the rest of the plasma membrane, giving these structures a "liquid-ordered" structure, as opposed to the more fluid structure of the other parts of the plasma membrane. It should be emphasized that lipid rafts, particularly in unstimulated cells, are very small, highly dynamic structures in which individual components, both lipid and protein molecules, are continually exchanging between the rafts and the surrounding membrane.

Another point that should be emphasized about lipid rafts is that some of the methods for analyzing them have significant limitations, and hence there is some disagreement about their importance for immunoreceptor signaling (48,49). The association of molecular components with lipid rafts is typically assessed by extraction of cellular membranes with nonionic detergents such as NP-40 or Triton X-100 at 0°C, a condition that solubilizes the majority of the plasma membrane, but not glycosphingolipids, GPI-linked proteins, or many lipid-modified membrane proteins, and hence is believed not to solubilize lipid rafts. These unsolubilized structures are typically isolated by sucrose density gradient centrifugation, as the unsolubilized membranes are of lighter density than are detergent-solubilized proteins. This approach is less than perfect,

as the concentration of detergent used can affect the spectrum of proteins obtained in the lipid raft fraction, perhaps because some membrane proteins are less tightly associated with lipid rafts, and hence are more easily extracted, than others. It is also theoretically possible that some proteins in the nonraft part of the membrane join the lipid raft structures after extraction, although there is not strong evidence for this possibility. Lipid rafts can also be studied by fluorescence microscopy of intact cells, but this approach has the limitation that, in unstimulated cells, most lipid rafts are sufficiently small as to be below the resolution limit of light microscopy. However, in lymphocytes, as in many other cell types, receptor stimulation causes lipid rafts to come together into larger structures, such that in stimulated B cells, distinguishable lipid rafts become increasing prominent within several minutes of BCR ligation, and the association of particular proteins with these structures can readily be visualized (38).

With regard to addressing the biological significance of lipid rafts for particular cellular events, there are two methods that have been used to disrupt lipid rafts. There are antifungal components such as filipin that intercalate into membranes and disrupt lipid rafts, and it is also possible to extract cholesterol from membranes of cells with methyl β-cyclodextrin, and this is believed to cause the remaining lipid raft components to disperse in the plasma membrane. Although interesting data have been collected with these methods, it is possible that some functions of the non–lipid raft plasma membrane are perturbed as well, so the specificity of these effects is not entirely clear. Finally, in some cases, it is possible to convert a lipid raft resident membrane protein to a nonlipid raft distribution by mutating it to remove lipid addition sites. In this case, the role of lipid raft localization of a particular protein within the membrane can be assessed. For example, this has been done with the T cell adaptor protein LAT (linker for activation of T cells), which is necessary for TCR signaling. LAT function is greatly decreased by mutations that prevent its palmitoylation, which is the modification that targets it to lipid rafts (50,51). This observation argues strongly that TCR signaling occurs primarily in lipid rafts, and it is likely that BCR signaling is similar.

Among components involved in BCR signaling, the Src-family tyrosine kinases are enriched in lipid rafts. The BCR itself is not detectably associated with lipid rafts prior to ligation, but once cross-linked by antigen, it rapidly associates with lipid rafts. The mechanism by which this occurs is not well established, but one possibility is that this is the result of association between phosphorylated ITAMs of the BCR and the SH2 domain of Src-family tyrosine kinases (39). Alternatively, the association of the BCR with lipid rafts may be favored by the coalescence of lipid rafts from smaller structures into larger ones that become visible in the light microscope. This coalescence is facilitated by BCR signaling induced dephosphorylation

of ezrin (52). Prior to stimulation, ezrin binds to both lipid raft–associated proteins (PAG1 and possibly others) and to the cortical actin cytoskeleton. This linkage of lipid raft proteins to the cytoskeleton may keep lipid rafts in a dispersed state by limiting their mobility. Dephosphorylation of ezrin causes it to release from actin and from lipid rafts and, preventing this release by expressing a mutant form of ezrin that is constitutively linked to lipid rafts and to actin, attenuates the coalescence of lipid rafts that is otherwise observed following BCR cross-linking (52).

Interestingly, stimulation-dependent association of the BCR with lipid rafts occurs in mature B cells but not in immature B cells (40,41). This difference appears to be due to changes in the cholesterol content of the membranes of immature versus mature B cells (53). The functional significance of this change is not well established, but it is striking that BCR engagement of immature B cells in the spleen leads to rapid cell death, whereas engagement of the BCR of mature B cells promotes their activation. It may be that one or more signaling reaction is particularly dependent upon localization to lipid rafts and that this signaling reaction is required for production of prosurvival or proliferative signals. Activation of the transcription factor NF-κB is an attractive candidate for such a signaling event, as described later, although further studies will be required to address this point.

TONIC SIGNALING BY THE BCR

Expression of the BCR and the pre-BCR result in a constitutive low level of "tonic" signaling even without interaction with a ligand (33). This conclusion is supported by a number of experimental strategies. For example, plasma membrane expression of chimeric proteins containing the ITAMs of Ig-α and/or Ig-β is sufficient to drive several of the B lineage developmental transitions that require the pre-BCR or the BCR. This tonic signaling could be the result of an equilibrium between, on the one hand, ITAM phosphorylation, recruitment of Syk, and activation of some downstream signaling reactions (described below), and, on the other hand, dissociation of Syk, dephosphorylation of ITAM tyrosines, and inactivation of signaling reactions. In the absence of ligand binding, this equilibrium favors the dephosphorylations and, therefore, the amount of signaling is low. Nonetheless, this low-level tonic signaling may be sufficient to mediate some biological effects, including promotion of the pro-B cell to pre-B cell transition or export of immature B cells from the bone marrow. It should be noted that there is evidence both for ligands for the pre-BCR and for surrogate light chain-induced oligomerization of the pre-BCR, so pre-BCR signaling may not rely solely on low-level tonic signaling (33). Similarly, chronic low-level BCR signaling is required for survival of mature B cells (31), but whether this signaling is truly independent of ligand or is stimulated by a low degree of reactivity to one or more self-antigens is not known. Thus, the significance of tonic signaling for normal B cell biology remains unclear at this time, although it is likely to be important in some contexts.

AMPLIFICATION OF SIGNALING

The association of Syk and Src-family tyrosine kinases with phosphorylated ITAMs and the ability of these tyrosine kinases to phosphorylate adjacent ITAMs on antigen-clustered BCRs represents a positive feedback loop that can convert tonic BCR signaling to ligand-induced amplified signaling. This is only one of several amplification mechanisms that promote robust, high-level signaling by cross-linked BCRs.

A second amplification mechanism may result from the association of clustered BCRs with lipid rafts, which occurs in mature B cells but not in immature B cells (33). Src-family kinases are highly enriched in lipid rafts by virtue of their N-terminal lipid modifications, particularly the palmitate groups present in Lyn and Fyn, so localization of the BCR to lipid rafts presumably increases the amount of phosphorylation of BCR ITAM tyrosines. In addition, the assembly of the CARMA1/Bcl-10/MALT1 complex, which is necessary for activation of the transcription factor NF-κB, occurs primarily in lipid rafts, and this may be enhanced by localization of the BCR to lipid rafts. Thus, a key function of lipid rafts for BCR signaling may be to concentrate together key signaling components to enhance the efficiency of signal propagation from the receptor to downstream events.

A third mechanism for amplifying signaling has recently been proposed in which reactive oxygen species such as H_2O_2 are generated and transiently inactivate tyrosine phosphatases near the signaling BCRs, further tipping the balance between the tyrosine kinases, which are not inhibited, and the tyrosine phosphatases, which are inhibited (42,54). In this regard, it is noteworthy that protein tyrosine phosphatases have highly reactive cysteine residues in their active sites, which are selectively oxidized in a reversible fashion with low levels of reactive oxygen species generated at the plasma membrane (55). Thus, the generation of low levels of reactive oxygen species may be a novel mode of receptor signaling with highly selective effects that amplify BCR signaling.

DOWNSTREAM SIGNALING REACTIONS

Signaling by the BCR and the pre-BCR mediates a remarkable diversity of cellular responses, including developmental progression or arrest, change in location within peripheral lymphoid tissues, survival or apoptosis, and
FIGURE 8.5 Activation of multiple signaling reactions by the BCR. BCR signaling activates the signaling pathways shown, which are each described in detail in the text.

FIGURE 8.6 Phosphatidylinositol lipid signaling reactions. Phosphatidylinositol (PI) is a major lipid found on the cytoplasmic side of the plasma membrane. The inositol head group is a cyclic hexose sugar that can be phosphorylated on any of the six positions other than the 1 position, which is connected to diacylglycerol. Enzymes within the cell convert a small fraction of PI to $PI4,5P_2$ by adding phosphates to the 4 position and then to the 5 position of the inositol ring. The second step is positively regulated downstream of Vav signaling, which serves to keep $PI4,5P_2$ levels high in the context of phospholipase C (PLC) action to hydrolyze this lipid. PIP_2 hydrolysis generates the second messengers inositol 1,4,5-trisphosphate (IP_3), which induces opening of calcium channels in the endoplasmic reticulum, and diacylglycerol, which activates protein kinase C isoforms, and which promotes activation of Ras via RasGRP3. BCR signaling activates $PLC\gamma2$. $PI4,5P_2$ can also be converted to PIP_3 by the action of PI 3-kinase, which is activated by BCR signaling. PIP_3 is a membrane-bound phospholipid that activates the protein kinase Akt and aids in the activation of $PLC\gamma2$. PIP_3 phosphates are removed by two phosphatases, PTEN, which removes the 3 phosphate, and SHIP, which removes the 5 phosphate, creating a new second messenger $PI3,4P_2$, which serves as a membrane-recruiting ligand for some signaling proteins via their PH domains.

proliferation. Which particular response ensues depends on the developmental stage of the B lineage cell and the context of other signals coming from TLRs, cytokines, or helper T cells. Therefore, it is not surprising that the BCR triggers a wide variety of intracellular signaling events. Interactions with helper T cells are promoted by up-regulation of integrin adhesion, changes in chemokine responsiveness, regulation of intracellular organelle function promoting antigen presentation, and changes in the transcription of many genes. Key signaling reactions triggered by the BCR or pre-BCR that mediate one or more of these cellular responses include activation of phosphoinositide 3-kinase (PI 3-kinase), hydrolysis of phosphatidylinositol 4,5-bisphosphate (PIP_2) resulting in elevation of intracellular free calcium and production of diacylglycerol (DAG), activation of small molecular weight GTP-binding proteins including Ras, Rac and Rap, activation of the Erk MAP kinase, and to a lesser extent the JNK and p38 MAP kinases, and activation of transcription factors including NFAT, AP-1, and NF-κB (Figure 8.5). In this regard, BCR signaling closely resembles signaling by other ITAM-containing receptors, including the TCR, and also signaling by many transmembrane tyrosine kinase receptors, such as the platelet-derived growth factor receptor and epidermal growth factor receptor.

To connect with these signaling reactions, the BCR and its associated intracellular tyrosine kinases require adaptor proteins that efficiently connect the kinases to the targets that mediate particular signaling reactions (56,57).

The PI 3-Kinase Pathway

Activation of PI 3-kinase is an early signaling event that promotes many of the other BCR-induced signaling events and also promotes B cell survival. PI 3-kinases are a diverse family of enzymes, but the isoform activated downstream of the BCR is a dimeric enzyme composed of a regulatory subunit, p85α, which contains an SH2 domain that recruits PI 3-kinase to tyrosine-phosphorylated adaptor molecules, and a catalytic domain, p110δ. Mice with

targeted mutations in the genes encoding either of these subunits have a loss of B1 cells and also a substantial decrease in the number of mature follicular B cells or of marginal zone B cells (11). Low-level expression of other isoforms of these subunits may attenuate the defects seen in the knockout mice, allowing some B cell development.

The product of PI 3-kinase, PIP_3 (Figure 8.6), serves as a membrane-bound ligand for a subset of signaling proteins with pleckstrin homology (PH) domains. PH domains often mediate interactions with phosphorylated phosphatidylinositols and in that way contribute to signaling reactions. Thus, elevation of PIP_3 in the membrane adjacent to signaling receptors aids in the recruitment to this location of other signaling molecules and, in that way, promotes signaling. Key signaling molecules with PIP_3-binding PH domains include Btk, $PLC\gamma2$, and Akt (58). Btk and $PLC\gamma2$ are discussed in more detail in the next section. Akt is a serine-threonine protein kinase that is activated by PI 3-kinase action to promote enhanced protein synthesis, which is a preparation for proliferation, and to promote cell survival. Akt is both recruited to the plasma membrane by binding PIP_3 and is activated by phosphorylation by an upstream protein kinase, called PDK1 (phosphoinositide-dependent protein kinase 1), which is itself activated by PIP_3. The growth promoting actions of Akt involve activation of mTOR (mammalian target of rapamycin), which regulates protein synthesis (59), and phosphorylation and

inactivation of the transcription factors of the FoxO family, which promote quiescence (60). In addition, Akt promotes cell cycle progression by blocking GSK3 (glycogen synthase kinase 3), which is an inhibitor of cell cycle regulators cyclin D and Myc. Akt promotes cell survival by phosphorylating and inactivating the BH3-only pro-apoptotic regulator Bad and probably also by other, less understood mechanisms. Thus, Akt is a key regulator in B cells as well as in many other cell types.

Activation of PI 3-kinase by the BCR is thought to occur by the participation at least three adaptor molecules: CD19, BCAP, and Gab-1. The most important of these is the transmembrane coreceptor molecule CD19, which is present in a complex with the CR2 complement receptor (also called CD21) and the tetraspan protein CD81 (61). The cytoplasmic tail of CD19 has 9 conserved tyrosines, two of which are consensus sites for binding by $p85\alpha$ of PI 3-kinase (YXXM). These sites are required for CD19 to mediate the activation of PI 3-kinase and are the primary sites responsible for CD19 signaling function (62,63). The CR2/CD19 complex greatly potentiates BCR signaling when an antigen has C3b-derived fragments attached to it, as is described later, but CD19 clearly participates in BCR signaling even when the antigen has not been decorated with C3 fragments. Mice deficient in CD19 exhibit a complete defect in B1 cell development and also lack marginal zone B cells. There also appears to be a partial deficiency in maturation of follicular B cells. T-independent type 2 antibody responses are highly deficient, perhaps due to the lack of B1 and marginal zone B cells. T cell-dependent antibody responses are also partially defective in germinal centers, and this deficiency is also seen in mice expressing CD19 with the two PI 3-kinase binding sites mutated (63).

Despite the striking defects in CD19-deficient mice, there are stronger defects in mice lacking the $p85\alpha$ component of PI 3-kinase (58). This observation suggests that there are alternative mechanisms by which the BCR activates PI 3-kinase, perhaps to a lesser degree than CD19. Two cytoplasmic adaptors, BCAP (B cell adaptor for PI3K) and Gab-1 (Grb2-associated binder 1), may promote activation of PI 3-kinase downstream of BCR ligation, but this is not clearly established in primary mammalian B cells. Disruption of the gene encoding BCAP in the DT-40 chicken B cell line ablates PI 3-kinase signaling, leading to the view that a primary function of BCAP is to mediate activation of PI 3-kinase. In mice, mutation of the BCAP gene results in clear B cell defects, including loss of B1 cells, an increase in the number of immature B cells in the spleen, a corresponding decrease in the number of follicular B cells, and a strong defect in T-independent type 2 antibody responses (64). Surprisingly, biochemical studies failed to reveal a clear defect in PI 3-kinase activation or in activation of Akt, which is dependent upon PIP_3 but not other signaling reactions. In contrast, there was a partial decrease in PIP_2 hydrolysis and calcium elevation, al-

though the mechanism of these decreases was not defined. Thus, BCAP clearly participates in BCR signaling, but its exact role in primary B cells is not clear.

Another adaptor that may participate in PI 3-kinase activation is Gab-1 (or the closely related Gab-2) (65,66). Gab-1 and Gab-2 have PH domains that are thought to bind to PIP_3. BCR stimulation leads to Gab-1 recruitment to the plasma membrane, and this recruitment is dependent on its PH domain and on PIP_3. Once recruited, Gab-1 becomes phosphorylated and associates with PI 3-kinase and also with the SH2-domain-containing protein tyrosine phosphatase SHP-2. It has been proposed that Gab-1 may represent a positive feedback loop that amplifies PIP_3 production, but genetic evidence has suggested that primary effect of Gab-1 is to attenuate BCR signaling via SHP-2.

PI 3-kinase signaling is countered by two enzymes that remove phosphates from PIP_3, PTEN, which removes the phosphate that PI 3-kinase adds, and SHIP (SH2-containing polyphosphoinositide 5 phosphatase), which removes the 5-phosphate, generating phosphatidylinositol 3,4 bis-phosphate (Figure 8.6). This molecule does bind to some PH domains, including that of an adaptor involved in BCR signaling, Bam32 (see below), so it may continue to promote certain signaling reactions, although Akt and $PLC\gamma2$ action both require PIP_3. SHIP is recruited to sites of BCR signaling via SH2-domain interactions and is particularly important for inhibitory coreceptor function, as described below.

The Phospholipase Cγ2 Pathway

Phospholipase Cγ (PLCγ) is the second major BCR-stimulated signaling enzyme that generates second messengers of importance for B cell responses to antigen (Figure 8.6) and most biological responses to the BCR require this signaling reaction. PLCγ1 and PLCγ2 are the primary isoforms of PLC that are activated by tyrosine phosphorylation-based signaling receptors, including the BCR, and of these PLCγ2 is the major form expressed in B cells. PLCs hydrolyze PIP_2 to generate two second messengers, inositol 1,4,5- trisphosphate (IP_3) and diacylglycerol (DAG). The former second messenger is a soluble molecule that diffuses to the endoplasmic reticulum (ER), where there are IP_3 receptors that release calcium stores (67). This is responsible for the initial elevation of intracellular free calcium released upon BCR stimulation. Maintenance of elevated intracellular calcium in response to sustained generation of IP_3 is mediated by poorly understood signals released from the ER when its calcium stores are depleted. These signals act upon plasma membrane calcium channels to cause them to open to keep intracellular free calcium high. Recently some of the components of this system have been identified in T cells (68,69), and a similar system probably operates in B cells. Elevated intracellular free calcium activates NFAT (nuclear factor

of activated T cells) through removal of inhibitory phosphate by the calmodulin-regulated protein phosphatase, calcineurin. Elevation of intracellular free calcium also can stimulate calcium-activated protein kinases, such as CaM kinase 2 (calmodulin-regulated protein kinase 2).

The other second messenger generated by PLCγ2 action is the lipid DAG, which activates isozymes of the protein kinase C (PKC) family, often in conjunction with elevated intracellular calcium, and also activates Ras-activating proteins of the RasGRP family, as is discussed in more detail below. PKCβ participates positively in signaling to Ras and to NF-κB, whereas another isoform, PKCδ appears to be critical for signaling in anergic cells and mice lacking PKCδ exhibit loss of self tolerance, suggesting that PKCδ generates signals that establish or maintain the anergic state of B cells (70–72).

Activation of PLCγ2 by the BCR is largely dependent on the signaling scaffold molecule BLNK (B cell linker), which is also called SLP-65 (SH2-containing leukocyte protein of 65kDa) and BASH (B cell adaptor containing SH2 domain). BLNK is required for B cell development in humans (73), probably reflecting a role for this molecule in pre-BCR signaling. Mouse B cells lacking BLNK exhibit a substantial but less complete block at the pro-B cell to pre-B cell stage and exhibit a further block at the immature to mature B cell stage (74).

BLNK has an N-terminal region containing a short putative leucine-zipper structure, a central region with at least five tyrosines that become phosphorylated upon BCR stimulation, and a C-terminal SH2 domain. Although BLNK appears to be a soluble cytoplasmic protein, a fraction of the molecules associate with the plasma membrane of B cells prior to antigen stimulation via the leucine zipper (75), and this association appears to be important for BLNK function. Full BLNK function also requires its SH2 domain, which binds to phosphorylated Y204 in Ig-α and thereby localize BLNK to the signaling BCRs (Figure 8.7). Mice in which Ig-α contains a Y204F mutation exhibit clear defects, including decreased BCR-induced proliferation and decreased T-independent type II antibody responses in vivo (76).

Recruitment of BLNK to the BCR leads to phosphorylation of 5 tyrosines that are important for signaling function (77). Three of these (Y84, Y178, and Y189 in human BLNK) are responsible for recruiting PLCγ2 via an SH2 domain in the latter, perhaps reflecting an amplification mechanism (one BLNK molecule attracting three PLCγ2 molecules). Recruitment to the membrane of PLCγ2 is also promoted by its PH domain binding to PIP$_3$, generated by PI 3-kinase. Once recruited to BLNK, PLCγ2 becomes tyrosine phosphorylated by Syk, but this is insufficient for PLCγ2 enzymatic activation. Additional tyrosine phosphorylation of PLCγ2 on two sites (Y753 and Y759) is required for enzymatic activity, and these phosphorylations are provided by a third type of intracellular protein tyrosine kinase, Btk.
FIGURE 8.7 Adaptor molecules involved in PLCγ2 signaling in B cells. BLNK binds via its SH2 domain to phosphorylated Y204 of Igα. BLNK then becomes phosphorylated on tyrosines, which allows it to bind to PLCγ2 and Btk and thereby scaffold a complex for activation of PIP$_2$ hydrolysis. Syk phosphorylates BLNK; Btk is necessary to activate PLCYγ2.

Btk is recruited to BLNK by binding to a distinct tyrosine (Y96 in human BLNK) from those that recruit PLCγ2. Interestingly, for BLNK to be functional for inducing calcium signaling, it must have an intact Btk recruitment site, as well as at least one PLCγ2 recruitment site. Expression of two mutant forms of BLNK, one lacking the Btk-binding site and the other lacking the PLCγ2-binding sites, is insufficient for restoring function (77), indicating that BLNK must scaffold a complex between Btk and PLCγ2 (Figure 8.7) to promote the activation of the latter. The fifth tyrosine site on BLNK appears to recruit Vav and Nck, which may also contribute to PIP$_2$ breakdown and are discussed below.

Mice deficient in Btk, PLCγ2, or BLNK all exhibit significant defects in B cell development, probably reflecting defects in pre-BCR or BCR signaling, although the severity of the defects differ to some degree. There may be some redundancy between Btk and other Tec family kinases, and similarly there could be some redundancy between PLCγ2 and PLCγ1, accounting for small differences in phenotypes. Mice expressing the Y204F mutant form of Ig-α, which is responsible for recruiting BLNK to the signaling BCR, have some defects, but they are clearly lesser defects than those that are seen in mice deficient in Btk, PLCγ2 or BLNK, so it seems likely that either membrane localization of BLNK mediated by the leucine zipper motif is sufficient for some function, or there is another molecule that can recruit BLNK to the vicinity of signaling BCRs. The latter possibility has been suggested by analogy with SLP-76, which is similar to BLNK in some ways. Recruitment of SLP-76 is mediated by the transmembrane lipid raft-associated protein LAT (linker for activation of T cells). B cells express a molecule similar to LAT, called NTAL (non-T cell activation linker) or LAB (linker for activation of B cells), but genetic evidence argues against it playing a necessary role in the activation of BLNK in B cells (78).

Mice lacking this transmembrane adaptor molecule have close to normal B cells, although they may have a slight increase in BCR signaling to calcium elevation and in T-independent antibody responses. Moreover, convincing association of BLNK with NTAL/LAB has not been reported.

Thus, surprisingly, the activation of PLC by the antigen receptors of B cells and T cells appears to be significantly different: In B cells, PLCγ2 is recruited to a scaffold (BLNK) that is recruited directly to signaling BCRs, whereas in T cells PLCγ1 is recruited to the LAT-SLP-76 complex, which is not believed to bind directly to the TCR. It may be that the signaling architecture in T cells has greater potential for amplification, since many LAT/SLP-76 complexes can be phosphorylated, bind and activate PLCγ1, even if only a small number of TCRs are engaged. Such an amplification may explain how T cells can generate a robust calcium elevation when only 1 to 10 TCRs are engaged with foreign peptide-MHC ligands (79). In contrast, the recruitment of BLNK directly to the BCR suggests that the calcium response would be more nearly proportional to the number of BCRs engaged. Thus, B cells may only be able to generate a biologically meaningful calcium signal if many antigen receptors are engaged and signaling.

The Ras-Raf-Erk Pathway

The Ras-Raf-Erk signaling pathway controls several steps in the developmental progression of B cell and is also critical for BCR-stimulated proliferation of mature B cells. Receptor stimulation activates guanine-nucleotide exchange factors (GEFs) that convert Ras from the inactive GDP-bound form to the active GTP-bound form by inducing it to release bound GDP and thereby allowing GTP to bind. GEFs are countered in the cell by GTPase-activating factors (GAPs) that induce Ras to hydrolyze the bound GTP and release phosphate, leaving GDP bound to Ras in the inactive conformation (Figure 8.8). Active Ras binds to and activates a series of Ras effectors, of which the best understood is the serine-threonine protein kinase Raf, which activates MEK1 and MEK2, which in turn activate the Erk1 and Erk2 MAP kinases (80). Among the major functions of Erk is phosphorylation and activation of various transcription factors. For example, in B cells, the Ras pathway activates Ets-family transcription factors acting at Serum Response Elements (SREs) in the Egr1 gene to induce its expression, which in turn promotes expression of adhesion molecules ICAM-1 and CD44 (81–84). Also, in mature B cells, MEK1 and MEK2 inhibitors strongly interfere with anti-Ig-induced B cell proliferation (84). Transgenic expression in B lineage cells of dominant negative forms of Ras block developmental progression to the pre-B cell and immature B cell stages (85,86), demonstrating that Ras also has developmental roles in developing B cells, probably via Erk activation.
FIGURE 8.8 Control of Ras activity in B cells. Ras exists in two conformations, an inactive conformation bound to GDP and an active conformation bound to GTP. Conversion from the inactive to the active conformation is achieved by guanine nucleotide exchange factors (GEFs) that induce release of GDP, allowing GTP to bind and induce the active conformational. The most important GEF for BCR regulation of Ras is Ras guanine nucleotide releasing factor 3 (RasGRP3), which is activated by diacylglycerol (DAG) and by phosphorylation by protein kinase C. Ras is inactivated by GTPase activating factors (GAPs), neurofibromin, which acts constitutively, and RasGAP, which is controlled by signaling reactions, including those downstream of the negative coreceptor FcγRIIb, which recruits RasGap via SHIP and the adaptor Dok1. Ras effectors include the serine-threonine protein kinase Raf, which activates the Erk MAP kinase, and other effectors of unknown function in B cells.

BCR-induced activation of Ras primarily results from activation of RasGEFs and, in particular, RasGRP3 (Ras guanine nucleotide releasing protein 3), and to a lesser extent RasGRP1 (87,88). RasGRPs have domains structurally related to the C1 DAG-binding domains found in protein kinase C (PKC) isoforms, and their activation is correspondingly dependent on DAG, which is generated by PLC action. Indeed, BCR activation of Ras is highly dependent on PLCγ2. RasGRP3 is found in the cytoplasm of unstimulated B cells, and it is recruited to the membrane in response to PLCγ2 action (87). However, forced recruitment to the membrane of RasGRP3 only activates Ras to a small degree. Recent studies have identified BCR-induced phosphorylation of T133 of RasGRP3 as a key regulatory step in full activation of Ras. It appears that conventional isoforms of PKC (which in B cells would be PKCα or PKCβ) are responsible for this phosphorylation (89,90), which means that DAG acts in two ways to promote RasGRP3 activation and also that calcium elevation contributes importantly to Ras activation, because conventional PKCs are dependent on both calcium and diacylglycerol for their activation (Figure 8.8).

Ras-Raf-Erk signaling is attenuated in several ways following BCR signaling. One mechanism by which this pathway is attenuated is by the recruitment of RasGAP to the membrane by the formation of a tyrosine phosphorylation/SH2-based multiprotein complex

including SHIP, Dok1 (downstream of kinase 1), and Ras-GAP (19). This complex likely also contains the adaptor Shc (91,92). This pathway is strongly engaged by the inhibitory coreceptor FcγRIIb (93,94) and is discussed further below. In addition, among the early response genes induced by BCR signaling is a MAP kinase phosphatase, MKP1, which can directly inactivate Erk and other MAP kinases (95).

The Vav-Rac Pathway

Rac is a small molecular weight GTP-binding protein related to Ras, but more closely related to Rho, Cdc42, and a handful of other Rho family members. Rho family members function in the regulation of actin polymerization, which is important for cell shape and cell migration. Rho family members also are important for activation of two types of MAP kinases, JNK (c-Jun N-terminal kinase) and p38 MAP kinase. BCR signaling activates Rac through the Vav family of GEFs, which are recruited into signaling complexes via BLNK and CD19 (Figure 8.9). B cells express all three members of this family (Vav1, Vav2, and Vav3), and the phenotypes of mice lacking one or more forms of Vav suggests that all three of these Vav isoforms participate in B cell function, largely in nonredundant ways (96). Rac appears to enhance PIP$_2$ hydrolysis by activation of a PIP 5-kinase, which replenishes PIP$_2$ to allow its hydrolysis to continue at a high level (97). Rac also activates production of reactive oxygen species to amplify BCR signaling at an early stage as described earlier. Rac also promotes activation of a protein kinase called HPK1 (hematopoietic progenitor kinase 1), which appears to be upstream of JNK activation. JNK in turn phosphorylates and activates the c-Jun transcription factor, promoting transcription of early response genes. An adaptor Bam32 (B lymphocyte adaptor

FIGURE 8.9 The Vav-Rac pathway activated by BCR signaling. BCR signaling results in recruitment to the membrane and activation of Vav, which is a guanine nucleotide exchange factor for Rac. Rac promotes actin polymerization, JNK activation, and probably production of reactive oxygen species (ROS) that amplify BCR signaling in general. Rac also activates PIP 5-kinase, which replenishes PI4,5P$_2$ levels, promoting high-level generation of second messengers from this compound. HPK1: hematopoietic progenitor kinase 1; MEKK1: MAPK/Erk kinase kinase 1.

molecule of 32kDa) also contributes to this pathway (98). B cells from mice genetically ablated for this adaptor exhibit defects in BCR-induced activation of HPK1 and JNK, as well as MEKK1, which is likely an intermediate in this signaling cascade (Figure 8.9). These B cells also exhibit decreased anti-Ig-induced proliferation in vitro. Bam32-deficient mice have normal development of follicular and marginal zone B cells, but had defective development of B1 cells in one study and an inability to make antibodies in response to T-independent type II antigens (98).

The Rap-Integrin Pathway

BCR stimulation leads to increased binding by integrins expressed on B cells, particularly LFA-1 (αLβ2), which binds to ICAM-1, and α4β1 which binds to VCAM-1 and to fibronectin. Integrins promote adhesion between the B cell and a variety of immune cells that may have antigen bound to their surface (1) or to helper T cells and, therefore, likely promote the prolonged recognition and response to antigen in many circumstances. The ability of integrins to promote adhesion is controlled both by conformational changes between a low-affinity state and one or more higher affinity states (99) and by release from the actin cytoskeleton, which gives integrins the freedom to cluster and more efficiently bind to ligands fixed in the extracellular matrix or on the surface of another cell. The former is referred to as *affinity regulation,* whereas the latter is sometimes called *avidity regulation,* although more properly, the term *avidity* refers to the combination of the effects of affinity and multivalency on binding strength. In the case of BCR activation of integrins, there may be regulation of either or both integrin conformation and integrin mobility within the membrane.

A key regulator of integrin activation in B cells, as well as in other cells is the Rap family of Ras-like small GTP-bindings proteins (100,101). Both BCR and chemokine receptor stimulation of B cells induce activation of Rap1 and Rap2 and blocking this activation by overexpressing a highly specific Rap GTPase-activating protein blocks the increase in integrin adhesion (101). Recent evidence demonstrates that two adaptor proteins, ADAP (adhesion and degranulation-promoting adaptor protein) and SKAP55 (Src kinase-associated phosphoprotein of 55kD) are required for the TCR to induce integrin activation in T cells and suggests that this is mediated by targeting of activated Rap to the correct location at the plasma membrane (102). B cells likely use related but distinct molecules, as gene knockouts for these two molecules do not exhibit clear B cell defects, but B cells from mice lacking SKAP-HOM, which is closely related to SKAP55, do show a strong defect in BCR-induced integrin activation (103). Recent evidence suggests that Rap may act by promoting the binding of talin to the cytoplasmic domains of integrin β chains,

FIGURE 8.10 Activation of the NF-κB pathway downstream of the BCR. BCR signaling induces phosphorylation and oligomerization of the scaffold molecule CARMA1 and its association with adaptors Bcl-10 and MALT1, which then activate TNF receptor–associated factors TRAF2 and TRAF6. TRAFs activate the IκB kinase (IKK) complex to phosphorylate IκB. Phosphorylated IκB is then ubiquitinylated and degraded, freeing NF-κB to enter the nucleus and induce transcription.

which promotes their unfolding into the higher affinity conformation (104).

The NF-κB Pathway

The transcription factor NF-κB is central to inflammatory, innate immune, and adaptive immune responses. In B cells, NF-κB is activated by the BCR, by TNF receptor family members, including CD40 and BAFF receptor, and by TLRs (105). In mature B cells, BCR-induced survival and proliferation pathways are particularly dependent on NF-κB signaling, and mice genetically defective for signaling components that connect the BCR (but not TLRs or cytokine receptors) to NF-κB activation have a severe defect in lymphocyte activation (105,106).

NF-κB is a family of transcription factors originally discovered as binding to a site in the Ig κ intronic enhancer and is composed of homo- and heterodimers of five different related members, called p50 (NFKB1), p52 (NFKB2), p65 (RelA), c-Rel, and RelB (105). NF-κB can be held in an inactive form in the cytoplasm by an inhibitor called IκB, of which there are several isoforms. The activation of NF-κB generally follows phosphorylation, ubiquitination, and proteasome-mediated degradation of IκBs (Figure 8.10). Although different types of receptors activate NF-κB via distinct mechanisms, in most cases, referred to as the *classical* or *canonical pathway,* activation occurs via the IκB kinase (IKK) complex, which is a high molecular weight complex of multiple copies of three different subunits, called IKKα, IKKβ and IKKγ (or NEMO). IKKα and IKKβ are serine/threonine protein kinases and in this pathway IKKβ is essential for the phosphorylation and subsequent ubiquitination and degradation of IκB, IKKα plays a less important role and IKKγ is a scaffold that holds together the IKK complex and mediates its association with upstream activators. A second pathway of NF-κB activation, the *alternative* or *noncanonical pathway,* is mediated primarily by IKKα downstream of a subset of TNF receptor family members including BAFF receptor (105).

Antigen receptors utilize a unique set of signaling components to activate the IKK complex, although they ultimately use components from the TNF receptor, IL-1 receptor, and TLR pathways in the terminal steps leading to IKK activation. BCR signaling induces the assembly of a plasma membrane lipid raft–associated complex between the scaffold molecule CARMA1 and two adaptor proteins, Bcl-10 and MALT1, which then binds to TRAF2 (TNF receptor associated factor 2) or TRAF6. In the pathway connecting the BCR to IKK activation, TRAF2 and TRAF6 are thought to be alternative and equivalent components, although there are subtle mechanistic differences (106). TRAF2 also participates in NF-κB signaling downstream of TNF receptor family members, whereas TRAF6 also participates in NF-κB signaling from TLRs, IL-1 receptor family members, and CD40 (107). TRAFs are E3 ubiquitin ligases that catalyze ubiquitinylation reactions forming K63-linked polyubiquitin chains on themselves (TRAF6) or on associated proteins (RIP1 in the case of TRAF2). The K63-polyubiquitin chains are recognized by ubiquitin-binding domains on IKKγ and on the adaptor proteins TAB2 (TAK1-binding protein 2) or TAB3, and in this way TRAF action nucleates formation of a larger signaling complex that includes TRAF2 or TRAF6, the IKK complex and the TAK1 (TGFβ-activated protein kinase 1) complex with TAB1 and TAB2 or TAB3 (Figure 8.10). Once this complex forms, IKKγ also becomes decorated with a K63-polyubiquitin chain that appears to be necessary for IKK enzymatic activation, as is phosphorylation of IKKβ by TAK1.

How antigen receptors trigger this sequence of signaling reactions leading to IKK complex activation is not completely understood, but a key event is phosphorylation of CARMA1 by PKCβ in B cells (108) and PKCθ in T cells (Figure 8.10). PKCβ is a conventional PKC that is activated by calcium and DAG, both of which are generated downstream of PLCγ2 action. In contrast, PKCθ is activated by DAG alone, without a requirement for calcium elevation. The significance of this difference in signaling to NF-κB in B cells versus T cells is not known at this time. Phosphorylation of CARMA1 has been proposed to promote its multimerization and binding to Bcl-10, which in turn multimerizes MALT1 and TRAF2 or TRAF6, which appears to be how TRAFs become activated. CARMA1 multimerization occurs at the plasma membrane in areas of

coalesced lipid rafts (108,109). CARMA1 is mostly cytosolic in resting lymphocytes, so its multimerization at the plasma membrane likely reflects binding to an unknown membrane protein. The significance of CARMA1 lipid raft localization is also not known, although it may reflect the localization of the putative binding protein. In any case, it is clear that NF-κB is triggered by PKCβ activation in B cells (106), possibly with involvement of additional signaling reactions.

CORECEPTORS FOR BCR SIGNALING

The term "coreceptors" has been given to CD4 and CD8 in T cells because these molecules also bind to the peptide-MHC ligand that is bound by the TCR. As described in Chapters 10 and 11, CD4 and CD8 aid T cell activation by promoting the binding between TCR and peptide-MHC and also by cooperation of their intracellular domains with the intracellular domains of the TCR subunits, particularly with the ITAMs in the CD3 and ζ chains. The cytoplasmic tails of CD4 and CD8 bind to the Src-family tyrosine kinase Lck, so the simultaneous binding of a TCR and CD4 or CD8 to the same peptide-MHC complex results in juxtaposition of Lck with ITAMs, promoting efficient ITAM phosphorylation. Thus, CD4 and CD8 effectively tell the T cell that the TCR has bound to the correct type of ligand.

Analogously, the B cell expresses at least three different molecules that can bind to the same molecular complex bound by the BCR and, if this happens, modulate BCR signaling. These B cell coreceptors provide additional information about the nature of the antigen that is relevant to B cell activation. One of these B cell coreceptors, the complement receptor 2 (CR2) complex, functions positively to promote B cell activation, whereas two of these coreceptors, FcγRIIb and CD22, function negatively to inhibit B

cell activation (Figure 8.11). Complement deposited on an antigen provides an indication to the B cell that the innate immune system or preexisting antibody has tagged the molecular complex as foreign, whereas the presence of antigen in an IgG-containing immune complex is an indication that sufficient antibody has already been made to counter the threat. The logic of the coreceptor role for CD22 is less well established, but this molecule binds to α2, 6-linked sialic acid oligosaccharides, which are expressed on most host cells but less commonly on microbe surfaces, so this coreceptor may act to decrease antibody responses to cell surface self-antigens (110,111).

Complement receptor 2 (CR2, also called CD21) is found in a complex with CD19 and the tetraspanin protein CD81 (61). When CR2 is coligated with the BCR, CD81 promotes prolonged association of the BCR with lipid rafts, which may enhance its signaling (111a). CD19, the other component of the CR2 complex, is a major adaptor molecule for activation of PI 3-kinase signaling, as described above, and it is thought to be responsible for the major coreceptor signaling function of the CR2 complex. Lyn binds to CD19 after the latter becomes activated, so this association may amplify signaling. Genetic studies indicate that the PI 3-kinase binding sites in the cytoplasmic tail of CD19 (Y482, Y513) are responsible for most of the signaling function of CD19 (62,63). Curiously, in its signaling mechanism, CD19 is more closely analogous to signaling by the T cell costimulatory receptor CD28 than to signaling by the T cell coreceptors CD4 and CD8. For both CD28 and the CR2 complex, the ligands are molecules related to innate immune recognition: In T cells, the B7 ligands for CD28 can be induced on dendritic cells by TLR signaling, and in B cells, the fragments of C3 may be deposited on antigenic particles due to the alternative or lectin pathways of complement, or due to complement activation by weak reactivity to preexisting

FIGURE 8.11 Coreceptors and BCR signaling. The complement receptor 2 (CR2) complex with CD19 and CD81 serves as a positive coreceptor for BCR signaling (left). When an antigen is coated with C3b-derived complement fragments, CR2 is brought adjacent to the BCR, where the cytoplasmic tail of CD19 can be phosphorylated on several tyrosines. Phosphorylated CD19 serves as a binding site for signaling proteins including PI 3-kinase and Vav. CD19 also participates in BCR signaling in the absence of complement activation, although less efficiently. FcγRIIb is a negatively acting coreceptor (right). If the antigen has IgG bound to it, then FcγRIIb is recruited adjacent to the BCR. Lyn associated with the BCR phosphorylates the ITIM tyrosine of FcγRIIb, which attracts SHIP, which counters PI 3-kinase. SHIP also recruits RasGAP via the adaptor Dok1, resulting in inactivation of Ras.
IgM. Thus, whether one considers the CR2 complex to be more analogous to T cell coreceptors or T cell costimulatory receptors is a matter of choice. In either case, juxtaposition of the signaling BCR with CR2 strongly promotes B cell activation (112).

The inhibitory coreceptors of B cells are part of an extensive family of immune inhibitory receptors characterized by the presence in their cytoplasmic tails of an immunoreceptor tyrosine-based inhibitory motif (ITIM) (113). These inhibitory receptors play critical roles in restraining activation of all immune cells, including B cells. Indeed, in addition to FcγRIIb and CD22, B cell express a variety of other inhibitory receptors whose function is less well understood but that clearly serve to inhibit BCR signaling, including CD72 (114,115), PIR-B (116), and CD5 (117,118).

When a B cell binds to antigen that is in an immune complex with specific IgG, then it engages FcγRIIb as well as the BCR, and this juxtaposition promotes phosphorylation of the ITIM tyrosine in the cytoplasmic tail of FcγRIIb. The phosphorylated ITIM serves as a high-affinity binding site for SHIP (SH2-containing polyphosphoinositide 5 phosphatase), which removes the 5 phosphate from PIP$_3$ (Figure 8.6), thereby countering most of the actions of PI 3-kinase, because the resulting lipid, PI 3,4P$_2$, does not activate Akt or promote activation of PLCγ2, although it does serve as a ligand for some PH domains, including the PH domain of the adaptor Bam32 (98). SHIP also recruits to this inhibitory complex the adaptor Dok-1 and RasGAP, which inactivates Ras (93,94). Thus, coligation of the BCR and FcγRIIb results in some signaling but attenuation of the most important downstream signaling events. Presumably, an antigen with a small amount of IgG bound could still induce B cell activation, whereas soluble antigen in an extensive IgG-containing immune complex or present on a cell surface covered with IgG would likely not induce an immune response from naïve B cells. It should be noted, however, that FcγRIIb on follicular dendritic cells plays a positive role in promoting germinal center B cell responses, so the role of FcγRIIb in antibody responses is complex and depends on the stage of the response.

The role of CD22 in the regulation of antibody responses is less well understood, but a major function of CD22 is to inhibit BCR signaling via its ITIMs (111). In contrast to FcγRIIb, which is thought to only inhibit BCR signaling if coligated with the BCR by a specific immune complex, some CD22 on the cell surface is preassociated with a subset of mIgM molecules on naïve B cells. Alternatively, there is evidence that CD22 function is regulated by it binding to ligands on the B cell surface, perhaps reflecting a mechanism for tuning BCR signaling (119). In either case, CD22 and its ITIM appear to attenuate BCR signaling in a tonic way (111,120). In addition, it has been proposed that CD22 binding to sialic acid-containing glycoproteins on the antigen or antigen-bearing particle would increase the amount

of CD22 coligated with the BCR and thereby attenuate signaling (110). CD22-deficient mice do exhibit some autoantibody production, but it appears to be modest compared to what is seen in mice lacking other molecules involved in these inhibitory pathways, as discussed below. BCR cross-linking leads to phosphorylation of CD22 and recruitment of SHP-1 (SH2-containing tyrosine protein phosphatase 1) and of SHIP (121). Other inhibitory receptors on B cells, including CD72, PIR-B, and CD5 (on B1 cells), also have ITIMs and bind SHP-1 and so likely provide some redundancy that may compensate to some degree for the loss of CD22 in the knockout mice. SHP-1 probably attenuates BCR signaling by dephosphorylating early components in the signaling cascade, including BLNK (122). CD22 also appears to directly regulate calcium influx induced by the BCR (123).

Phosphorylation of the ITIM tyrosines of FcγRIIb, CD22, and other inhibitory receptors of B cells is heavily dependent on the Src-family tyrosine kinase Lyn (124). In contrast, BCR ITAM tyrosine phosphorylation is mediated by all three of the most highly expressed Src-family tyrosine kinases of B cells, Lyn, Fyn, and Blk (34), and probably once started is maintained in part by Syk, as described earlier. The mechanism for the heavy dependence of inhibitory receptor function on Lyn is not understood in detail, although in the case of CD22, Lyn binds to a tyrosine phosphorylation site in the cytoplasmic domain of CD22 distinct from the ITIM, and it has been proposed that Lyn binds and then efficiently phosphorylates the ITIM (125). In any case, the heavy dependence of inhibitory receptor function in B cells on Lyn has made it interesting to examine the effects of Lyn-deficiency on B cell function (124,126). Lyn-deficient mice exhibit elevated levels of serum IgM and IgG, suggesting enhanced activation of B cells during immune responses. In addition, these mice make high levels of antinuclear antibodies and anti–double-stranded DNA antibodies and develop lupus nephritis and kidney disease, which is eventually fatal on a mixed genetic background (127). Autoantibody production in Lyn-deficient mice is attenuated on either a C57BL/6 background or a Balb/c background but still occurs (Gross, A. J. and DeFranco, A. L., unpublished observations). Mice deficient in other elements of the inhibitory receptor pathway in B cells also exhibit autoantibody production, although to variable degrees. Thus, FcγRIIb-deficient mice exhibit autoimmunity, even on some nonautoimmune genetic backgrounds (128), CD22-deficient mice exhibit some autoreactivity, but to a lower degree than that seen in Lyn-deficient or FcγRIIb-deficient mice (126). Finally, SHP-1-deficient mice were originally isolated as motheaten mice, which have a severe autoimmune and inflammatory disease that is fatal early in life. The severe nature of this disease may reflect important roles for SHP-1 in inhibitory receptor function in all lymphocytes and leukocytes, compared to the less dramatic

effects of mutations that affect only B cells or B cells and a few other cell types.

ANTIGEN PRESENTATION BY B CELLS

In addition to being a signaling receptor, the BCR is an endocytic receptor that takes up antigens for presentation to T cells, which in turn promote activation of B cells, as described in detail in the next chapter. Internalization of the BCR is achieved via tyrosine-containing sequences found in the cytoplasmic domains of Ig-α and Ig-β (129,130). Uptake is primarily via a clathrin-mediated pathway, although a second pathway involving lipid rafts also is active (131,132). Studies with chimeric molecules in which the cytoplasmic tails of Ig-α or Ig-β have been fused to heterologous proteins indicate that both cytoplasmic tails can mediate uptake and that they function in a complementary fashion to promote antigen presentation (129,133). In particular, the Ig-β cytoplasmic domain is responsible for targeting the BCR/antigen complex to late endosomes, where antigenic peptide loading onto MHC class II molecules occurs. Recently, internalization of the BCRs have been examined in a more physiological context by the use of targeted gene mutations and analysis of B cells from mice with these targeted mutations (130). B cells in which the Ig-α cytoplasmic tail has been modified to change the two ITAM tyrosines to phenylalanine or in which the Ig-β cytoplasmic tail has been modified to change its two ITAM tyrosines to alanines were examined. B cells with either alteration showed a profound loss of constitutive BCR internalization and clearly slower BCR-cross-linking induced internalization. B cells with mutant Ig-β showed the greater delay in ligand-stimulated internalization and also a decrease in the final extent of internalization, whereas B cells with mutant Ig-α had decreased internalization but to a smaller degree. B cells from both mice had elevated levels of cell surface IgM and IgD, in agreement with decreased constitutive BCR internalization.

In addition to the role of the Ig-α ITAM tyrosines in BCR internalization, there is also evidence for a role for Ig-α Y204 in BCR internalization (133). Y204 is the tyrosine that when phosphorylated binds to BLNK (76,134,135). Interestingly, phosphorylation of Ig-α Y204 appears to block internalization (133). Given the central role of BLNK in BCR signaling, as described earlier, this observation suggests that ligand-engaged BCRs can either signal or be internalized as alternative contributions to B cell activation. Mathematical modeling indicates that a feature of competition between the two BCR functions is that the difference in the amounts of signaling resulting from ligands that bind to the BCR with higher avidity versus those that bind with lower avidity is less than would occur in a situation where signaling and internalization are not antagonistic (133). In other words, antagonism between signaling and

internalization is predicted to allow B cells to respond to a wide variety of ligands of different avidity by promoting signaling at low avidity where there is a low degree of internalization.

Although individual BCRs may signal or be internalized, BCR signaling in the cell contributes positively to antigen presentation and interactions with T cells in multiple ways. BCR signaling induces migration of follicular B cells from the follicles to the boundary of the T cell zone and also induces migration of marginal zone B cells to promote their interactions with helper T cells (8). BCR signaling induces increased adhesion of a B cell's LFA-1 integrin molecules, as described earlier, which promotes binding to helper T cells. In addition, BCR-stimulated B cells induce expression of the costimulatory molecule B7-2 (CD86) and also increase their expression of MHC class II molecules, both of which would promote activation of helper T cells recognizing peptides contained in the antigen internalized via the BCR. BCR signaling also promotes acidification of endosomes, which is important for antigen processing and loading onto class II MHC molecules (129).

LINKAGE OF ANTIGEN PRESENTATION TO ITAM SIGNALING IN B CELLS

Activation of B cells either through the BCR or via IL-4 leads to association of MHC class II molecules with Ig-α/Ig-β heterodimers (136). Subsequent clustering of MHC molecules by anti-MHC antibodies or by recombinant soluble TCRs induces strong ITAM signaling, which promotes B cell activation in vitro. Although the physiological relevance of this pathway is not clearly established, it is striking that in cell-cell conjugates between antigen-presenting B cells and antigen-specific T cells, there is a strong concentration of B cell MHC class II molecules at the interface, suggesting that they are engaged and are likely signaling. Moreover, it is interesting that the association of Ig-α/Ig-β with the class II MHC molecules requires prior B cell stimulation, which may promote antigen specificity of the response, as would the fact that B cell–T cell conjugates generally are only stable if T cells are recognizing cognate peptide-MHC complexes. Thus, although further work is required, the possibility that this signaling process is important for B cell activation in many circumstances is an attractive one.

CONCLUSION

B cells make antibodies in response to a rich diversity of physical forms of antigens, implying the existence of a considerable flexibility in the mechanisms that control B cell activation. In addition, B cells make a wide variety of cellular responses to BCR stimulation, including promotion

or arrest of developmental progression, choice of lineage between marginal zone and follicular types of mature B cells, promotion of survival or of apoptosis, migration to particular places within secondary lymphoid tissues, and entry into cell cycle. This flexibility and variety may explain why BCR signaling employs a large number of signaling pathways and why there is overlap between some of these pathways and signaling pathways induced by other key regulators of B cells, including TLRs and CD40. Clearly we have come a long way in the past two decades in understanding in detail how B cell activation is regulated. Just as clearly, much more needs to be learned to reduce this complexity to a clearer and more complete understanding of how the molecular mechanisms described in this chapter combine to regulate B cell activation in a way that generates rapid and useful antibody responses but largely avoids destructive autoantibody production.

B Lymphocyte Biology

Michael McHeyzer-Williams

OVERVIEW

Preexisting diversity in the antigen receptor repertoire is the central feature of the adaptive immune system. Foreign antigen triggers clonal selection mechanisms that regulate the quantity and quality of adaptive immunity. This chapter will focus on mature B lymphocyte biology and consider the cellular and molecular processes that promote antibody production and the development of high-affinity B cell memory in response to foreign antigen exposure *in vivo*.

There are at least three major subsets of mature B cells that can participate in the adaptive response to foreign antigen, each with different developmental life histories, survival needs, and activation requirements upon antigen receptor triggering. The innate immune system participates in rapid early antigen clearance and communicates the nature of the foreign antigen assault to the adaptive immune system. Dendritic cells (DC) are the most efficient antigen-presenting cells (APC) of innate immunity and will be discussed in some detail. DCs exist in multiple forms that can present antigen to specific B cells and pMHCII complexes to specific helper T (Th) cells. Th cell independent B cell responses will be discussed; however, emphasis remains on antigen-specific mechanisms of Th cell regulated B cell immunity.

In the past few years, experimental access to immune response biology has dramatically shifted with the advent of multiphoton laser–based intravital imaging techniques. These studies provide direct access to the mechanics and cell dynamics of antigen-specific cognate regulation *in vivo*. This information serves to integrate existing knowledge in the field using a real-time scaffold for the developmental progression *in vivo*. This chapter will be broadly

organized across the four major checkpoints in the evolution of high-affinity B cell memory. The first checkpoint defines contact between antigen-experienced pMHCII[+] DC and naïve pMHCII-specific Th cells. Clonal selection within the Th cell compartment underpins effector Th cell differentiation required for regulating B cell fate in this pathway. Cognate control of antigen-primed pMHCII-expressing B cells defines the second major checkpoint in this pathway. Commitment to antibody class switch, short-lived plasma cell (PC) development and entry into the germinal center (GC) reaction to memory B cell development occurs at this stage of the immune response. The GC reaction underpins memory B cell evolution and is discussed in detail. The interaction of the B cell receptor (BCR) and antigen followed by the cognate control of GC B cell fate by GC-Th cells defines the third major checkpoint, determining entry of high-affinity GC B cells into the memory B cell compartment. Little is understood about the cellular heterogeneity within the memory B cell compartment and the memory Th cell compartment and how such heterogeneity affects the response to antigen recall. The fourth major checkpoint defines cognate control of antigen recall responses and is central to the consolidation of antigen-specific B cell responses in all vaccine regimes.

This chapter mainly focuses on what is known of the antigen-specific immune response in mouse models, with reference to work conducted in humans. Further, there is an emphasis on the response to model hapten-protein antigens that is pertinent to our understanding and manipulation of adaptive immunity for preventive vaccination but may not provide a full appreciation of the immune response to infection.

MATURE B CELL SUBSETS

Mature peripheral B cells subdivide into at least three major compartments based on cell surface phenotype, cellular ontogeny and tissue distribution. B1 B cells, marginal zone (MZ) B cells, and follicular (FO) B cells respond characteristically to different sets of foreign antigens, creating a broad subdivision of function in the mature B cell compartment. Differences in BCR repertoire and helper T cell requirements for antigen responsiveness underscore this functional divide and further distinguish the mature B cell subsets. More recently, the identification of separable precursors for B1 and FO B cells support the existence of distinct B cell lineages and provide a mechanism for their differential development *in vivo*. All three subsets are also found in humans with some notable distinctions in overall organization and cellular composition.

B1 B Cells

The B1 B cell subset was first identified by differential expression of CD5, phenotypic similarity to a set of B cell lymphomas and expansion of the CD5[+] (Ly-1[+]) B cells in autoimmune-prone mice strains (1,2). B-1 B cells characteristically express high levels of sIgM, demonstrable CD11b, and low levels of sIgD, CD21, CD23, and the B cell isoform of CD45R (B220). In adult mice, B1 B cells constitute a minor fraction of the spleen and secondary lymphoid tissues but are enriched in the pleural and peritoneal cavities (3,4). B1 B cells were shown to arise from precursors in the fetal liver and neonatal but not adult bone marrow and constitute the earliest wave of mature peripheral B cells.

B1 B cells express a separable BCR repertoire (5). Sequence analysis indicates antibodies with restricted sets of V region genes, no evidence for somatic hypermutation (SHM), and few nontemplated nucleotide (N) sequence insertions, a pattern typical of neonatal B cells. BCR transgenic B cells of known B1 B cell specificities differentially assort into this mature B cell subcompartment (6–8). Further, efficient B1 B cell development appears to be dependent on positive regulators of BCR signaling and the loss of negative regulators promotes greater accumulation of B1 B cells (1,2,9). Hence, there appears to be a role for self or foreign antigen in shaping the repertoire of the B1 B cell compartment (10).

In contrast, the differential propensity of fetal and adult hematopoietic tissue to promote B1 B cells suggests the existence of developmentally separate precursors (11). Recent studies identify a novel CD45R[low/-] CD19[+] B1 B cell precursor whose developmental potential is limited to B1 B cell development (12). These B1 B precursors reach peak levels around day 17 of gestation and rapidly decline postnatally. FO B cell precursors differentially express CD138 and MHC II and dominate the adult bone marrow pro–B cell pool (13). Hence, subspecialization in the mature B cell compartment is also preprogrammed during development due to the distinct attributes of the separable B cell progenitors.

Adoptively transferred B1 B cells self-renew and spontaneously secrete IgM and IgG3 serum antibodies. These natural serum antibodies display extensive polyreactivity and demonstrable self-reactivity and bind to many common pathogen-associated carbohydrates (5). Natural serum antibodies play an important early role in the immune response to many bacteria and viruses but require complement fixation for effective antigen clearance. B1 B cells are the key responders to type II thymus-independent antigens with characteristic repetitive epitopes such as bacterial capsular polysaccharides (8,9). Innate sensing mechanisms can rapidly mobilize B1 B cells regardless of specificity highlighting the innatelike activity of this separate B cell compartment. Peritoneal B1 B cells are also responsible for large numbers of the IgA PCs found in mucosal and intestinal tissue, an important early innatelike defense mechanism.

B1 B cells can be further subdivided into B1a (CD5[+]) and B1b (CD5[−]) subtypes. Unlike B1a B cells, the B1b subtype can be generated from precursors in the adult bone marrow. The B1a and B1b precursors have been

reported to differ in the expression levels of CD138 (13). Recent functional studies indicate a further subdivision of labor assigning B1a cells as the precursors of natural serum antibody (14). In contrast, B1b cells appear to be the primary source of dynamic T cell independent (TI) antibody production and long-term protection after bacterial infection such as *B. hermsii* (15) and *S. pneumonia* (14). These studies indicate preexisting subset differences in BCR specificity and antigen-driven B cell fate that remain important unresolved features of the system.

Marginal Zone B Cells

MZ B cells are noncirculating mature B cells that segregate anatomically into the MZ of the spleen (16). The MZ is located at the perimeter of splenic white pulp beginning with the marginal sinus and bordering the red pulp. This region contains multiple subtypes of macrophages, dendritic cells, and the MZ B cells and is not fully formed until 2 to 3 weeks after birth in rodents and 1 to 2 years in humans (17). The MZ B cells within this region typically express high levels of sIgM, CD21, CD1, CD9 with low to negative levels of sIgD, CD23, CD5, and CD11b that help to distinguish them phenotypically from FO B cells and B1 B cells (Figure 9.1).

Similar to B1 B cells, MZ B cells can be rapidly recruited into the early adaptive immune responses in a TI manner. The MZ B cells are especially well positioned as a first line of defense against systemic blood-borne antigens that enter the circulation and become trapped in the spleen (18). MZ B cells also display a lower activation threshold than their FO B cell counterparts with heightened propensity for PC differentiation that contributes further to the accelerated primary antibody response (19).

In rodents, the MZ B cell compartment expresses largely germline-encoded BCRs supporting the TI status of MZ B cell development. In contrast, MZ B cells from humans express somatically diversified receptors suggesting a difference in the development that results in their resembling IgM$^+$ memory B cells following foreign antigen encounter (20). Further to this thinking, CD27$^+$IgM$^+$IgD$^-$ memory B cells in human peripheral blood display higher levels of CD21 and lower CD23, similar to their MZ counterparts in the spleen. Nevertheless, it is also clear from adoptive transfer experiments in mouse models that MZ B cells can be recruited into typical Th cell dependent (TD) antiprotein responses, diversify their BCR in germinal centers, and be selected into the high-affinity memory B cell compartment (21). Hence, MZ B cells express rapid TI B cell functions resembling B1 B cells but have a capacity for TD responses that overlaps with FO B cells.

The vast majority of IgM$^+$IgD^{lo} B cells exported from the adult bone marrow will not enter the long-lived mature peripheral B cell compartment (22). There is evidence for positive selection of these B cells based on the repertoire of their expressed BCR (23). As discussed for B1 B cells, the specificity of the BCR can impact the propensity of B cells to develop into MZ B cells. However, enlarged MZ B cell compartments are also found in single-chain BCR transgenic animals of diverse specificities, suggesting that specificity may not be the major influence in MZ B cell development. Decreased MZ B cell development is found in the absence of CD79a signaling, CD19, Btk, CD45, PI3K, PKCβ all associated with BCR signal integration. Thus, strength of the positive selecting BCR signal appears to play a role in mature B cell subset assortment.

Earlier alterations in B cell development can preprogram mature B cell fate. There are proportionately enlarged MZ B cell compartments in the absence of IL7, IL7Rα, lambda-5, and Rag-1, all of which also truncate the total peripheral B cell compartment (16). Differential sensitivity of mature B cell subsets to growth factors also regulates the compartment size. While BAFF-deficient mice lack MZ and FO B cells with some sparing of B1 B cells, over-expression of BAFF favors MZ B cells and enlarges the size of this compartment. Disorganized splenic architecture in the absence of LTα, LTβ and LTβR and decreased chemokine responsiveness in the absence of Pyk2, Dock2, and Lsc also leads to reduced MZ B cell numbers in the spleen. Hence, differential access to specialized environmental niches may play an important role in the development and maintenance of mature B cell subsets.

Follicular B Cells

The majority of mature B cells in the spleen express high levels of IgM, IgD, and CD23; lower C21; and no CD1 or CD5, readily distinguishing this FO B cell compartment from B1 B cells and MZ B cells. As the name implies, FO B cells organize into the primary follicles of B cell zones

	B1a	B1b	MZ B	FO B
IgM	+++	+++	+++	++
IgD	+	+	+	+++
CD21	+	+	+++	++
CD23	+	+	+	+++
CD45R	++	++	++	+++
CD5	+++	-	-	-

FIGURE 9.1 Cell surface phenotype of mature B cell subsets.

focused around follicular dendritic cells in the white pulp of the spleen and the cortical areas of peripheral lymph nodes. Multiphoton-based live imaging of lymph nodes indicate continuous movement of FO B cells within these follicular areas at velocities of ~6 μm per min (24). Recent studies indicate movement along the processes of FDC as a guidance system for mature resting B cells in peripheral lymph nodes (25). Unlike their MZ counterpart, FO B cells freely recirculate, comprising >95% of the B cells in peripheral lymph nodes.

The BCR repertoire of the FO B cell compartment also appears under positive selection pressures during final maturation in the spleen; however, diversity is substantially broader than B1 B and MZ B cell compartments. Most important, FO B cells require CD40-CD40L dependent T cell help to promote effective primary immune responses and antibody isotype switch and establish high-affinity B cell memory (26).

INITIATING B CELL IMMUNITY

The initial antibody response to many infectious agents is largely based on the rapid TI expansion of B cells and their subsequent differentiation into PCs. The B1 and MZ B cells are largely responsible for these rapid TI humoral responses, suggesting that some level of "natural memory" function resides in these B cell subsets and may be predetermined in an evolutionarily conserved manner. TI antigens can be separated into two broad categories based on their ability to polyclonally activate B cells (TI-1) or require BCR recognition of multivalent epitopes to induce B cell differentiation in the absence of T cell help (TI-2). TI-2 antigens can activate BCR signaling but require accessory signals to promote the development of antigen-specific PCs.

In contrast, monovalent protein antigens require antigen-specific helper T cell regulation to promote high titer antibody responses and the development of B cell memory. These TD antibody responses take longer to emerge and display a spectrum of affinities and isotypes and engage multiple strategies for antigen-specific clearance *in vivo*. Immune responses to model protein antigens provide experimental access to the complex cascade of cellular and molecular events that underpin long-term protective immunity. The recruitment and behavior of antigen-experienced APCs initiate this program of development and shapes the quality and quantity of peptide-MHCII (pMHCII) specific Th cell responses.

Preexisting Dendritic Cell Diversity

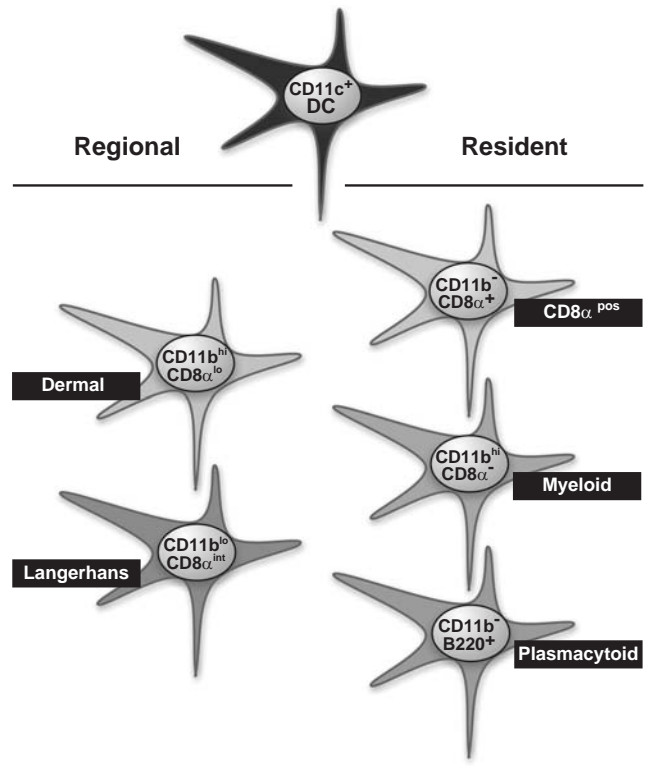
DCs are essential APCs for initiating adaptive immunity and preexist antigen challenge in multiple cellular subsets. Different phenotypic schemes can be used to characterize DC subsets with the origins and developmental relatedness of different DC subsets still subject to debate (27,28). In


FIGURE 9.2 Regional and lymphoid resident dendritic cell subsets in mice.

the murine system, three main bone marrow–derived DC subsets enter via the blood to reside at different levels in all secondary lymphoid organs (Figure 9.2). These blood-derived DC all express CD11c and are distinguishable as CD11b^{high} CD8α^{neg} DC, CD8α^{high} DC, and 6B2^{high} plasmacytoid DC (pDC). In lymph nodes (LN) draining the skin, there are at least two further CD11c$^+$ DC subsets, Langerhans cells (LC) and dermal DC (dDC), that emigrate from the skin, even at homeostasis (29). Thus, before antigen challenge, multiple subsets of DC are available to differentially process and present antigen to the adaptive immune compartment.

pMHCII$^+$ DC

Protein antigen administration without inflammation induces immune tolerance. In contrast, coadministration of immune adjuvant activates facets of innate immunity, induces inflammation, and primes antigen-specific adaptive immunity. Sensing pathogens involves pattern recognition receptors such as the evolutionarily conserved toll-like receptors (TLR) (30,31) and the more recently described nod-like receptors (NLR) (32). Both families of receptors recognize different types of microbial components initiating programs of DC maturation and promote immediate local inflammation and innate effector clearance mechanisms.

The processing and presenting of antigenic peptides in the MHC II pathway of DC is also an elaborate and highly regulated cellular activity that can be influenced by the inflammatory context of antigen stimulus (33). Hence, both the inflammatory context of the immune assault and antigen specificity can be rapidly imprinted on the local innate immune system. While the mechanisms remain poorly resolved, differential activation of DC subtypes provides a powerful means for controlling cell fate decisions in the development of adaptive immunity (34). In this manner, pMHCII$^+$ DC expressing an appropriate spectrum of costimulatory molecules become the critical regulators of antigen-specific adaptive immunity.

Temporal and spatial constraints on DC maturation provide another layer of regulation for the innate system that can impact adaptive immunity. In the steady-state, DCs form dense networks at the T-B borders of LNs. Interestingly, motile lipopolysaccharide (LPS)–activated DC immigrants will rapidly coalesce with this preexisting network *in vivo* (35). In separate studies using genetically tagged LC, the emigrants of LC and dDC were shown to emerge separately in time and colonize separate regions of the T-B border (36). A similar temporal regulation was seen using antibodies to specific pMHCII complexes with resident DC presenting an early wave of pMHCII and dDC emerging later in a second wave (37). In each of these studies, the immune stimulus was varied and the coordinated response of the innate system was also qualitatively and quantitatively different.

Antigen Presentation to B Cells

Categorizing an antigen as TI-I was originally based on the ability to elicit an antibody response in immunocompromised mice with defects in Btk function and BCR signaling. Many such polyclonal activators are compounds of bacterial cell wall, such as LPS, peptidoglycans (PGN), and lipoteichoic acid (LTA) that activate B cell–expressed TLRs (38). In contrast, TI-2 antigens trigger the BCR and are typically repetitive polymers, such as bacterial capsular polysaccharides or repetitive epitopes found in many viral particles. Studies using antigen coupled to polyacrylamide determined that a minimum of 12 to 16 haptens (small chemical antigens) per molecule were required to induce a strong TI-2 antibody response (39). The size of the epitope array indicates the aggregate BCR cluster required to initiate signal transduction at the cellular level.

The backbone flexibility or the density of accessible epitope is also a factor in antigenicity. A high ratio of hapten conjugated to protein molecules still requires T cell help to induce antibody production. Dextran molecules have been used to conjugate anti-IgM and -IgD into potent TI-2 reagents that can stimulate phosphoinositde breakdown and intracellular Ca^{2+} responsiveness at 1,000-fold lower concentrations than the soluble antibody alone. Many TI-2 antigens can also fix complement and thereby co-cross-link the BCR complex and CD21/CD19 molecules.

TI-2 antigens require accessory signals to drive B cell proliferation and PC development. While B cells can recognize soluble antigen, forms of antigen directly conjugated to complement components potently induce B cell immunity. APC-associated bacterial antigen also drives rapid MZ B cell activation in the spleen that appears dependent on the TNF family member, TACI (18). DC can internalize and recycle IgG-opsonized antigen in an FcγRIIB- and complement-dependent manner (40). This nondegradative processing of antigen can activate MZ B cells in the spleen and promote a TI B cell response. In general, B cell recognition of cell-associated antigen can be influenced by the costimulatory factors expressed by the APC that may regulate the outcome of the initial B cell priming event.

Antigen-presenting DC can also drive TD B cell immunity. Injection of DC pulsed with protein antigen can induce isotype switch and promote efficient B cell responses. B cells can form synapselike interactions with antigen pulsed DC (41,42). More recently, two-photon imaging revealed that naïve B cells entering local LNs surveyed protein antigen-pulsed DC before entering the follicular areas (43). In this model, engagement of BCR led to calcium flux, migration arrest, and the local accumulation of the antigen-specific B cells. Further, there is a reticular network of collagen fibers that physically connects the subcapsular and paracortical sinuses of LNs to blood vessels and separates these regions from T and B cell areas (44). This organization facilitates the efficient delivery of soluble antigen toward the lumen of high-endothelial venules (HEV) without it entering the LN parenchyma. While resident DCs can access this conduit transport system, FO B cells may have difficulty accessing soluble antigen.

Nevertheless, in the context of TD protein antigens, B cells must recognize their cognate antigen and internalize, process, and present peptides from this antigen in the context of MHCII to receive pMHCII-specific T cell help. If the TD antigen is cell associated, in the presence of adequate costimulation, some aspects of the B cell response can proceed in a TI manner. B cell proliferation and PC development can occur in the absence of CD40-CD40L interactions with some residual isotype switch induced by the action of TACI and BAFF-R (45). Thus, FO B cells can respond in a TI manner to TD antigens but do not express the characteristic range of outcomes and the full extent of protective immunity that is found with cognate regulation and T cell help.

ANTIGEN-SPECIFIC HELPER T CELL DIFFERENTIATION

Following initial protein immunization, pMHCII$^+$ DC appear in the lymph nodes that drain the site of antigen administration in patterns that depend on the quality of

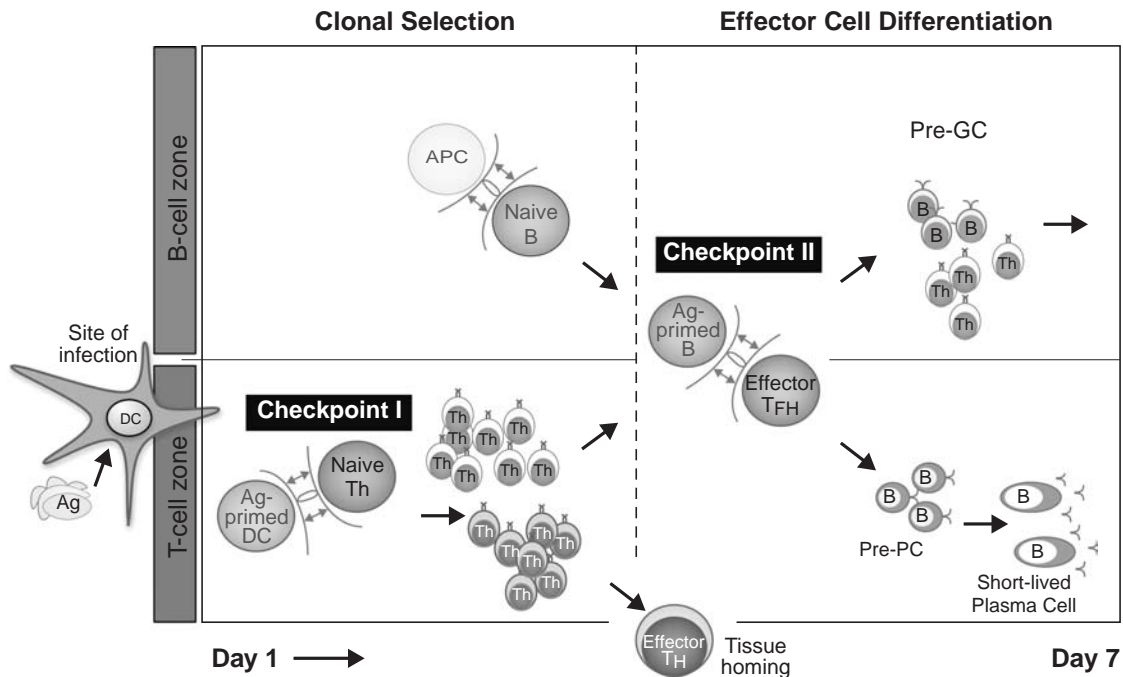
Clonal Selection   **Effector Cell Differentiation**


FIGURE 9.3 Initial helper T cell regulated checkpoints in memory B cell evolution. Protein vaccination induces antigen uptake, processing and presentation of pMHCII complexes and local DC maturation and migration to draining secondary lymphoid tissues. In the T cell zones, pMHCII$^+$ DC will make contact with naïve pMHCII-specific naïve Th cells to define the first major checkpoint in the development of Th cell regulated B cell immunity. Subsets of antigen-specific effector Th cells destined to migrate to the site of initial antigen contact will exit after clonal expansion. Antigen-specific Th clonal expansion and migration of effector T$_{FH}$ cells to the T-B borders will make contact with antigen-primed pMHCII$^+$ B cells at checkpoint II. Antigen-specific B cell then either progress in an extra-FO pathway to switch antibody isotype and become short-lived PCs or pre-GC B cells to enter the GC pathway to memory B cell development.

immune stimulus (Figure 9.3). The antigen-experienced pMHCII$^+$ DC populations then sample the naïve Th cell compartment for clonotypes that express pMHCII-specific TCR. While there are many "bystander" influences in the outcome of adaptive responses, the "cognate" regulation of cell fate focuses primarily on the TCR of the Th cells that bind complexes of foreign peptide in MHC II molecules (pMHCII). These critical recognition events control antigen-specific development *in vivo* and are modified by a multitude of molecular interactions. Importantly, regulation occurs at the cellular interface between antigen-experienced cells as critical checkpoints to the ongoing developmental process that is adaptive immunity.

Priming pMHCII-specific Th Cells

DC maturation proceeds at the site of antigen challenge. Levels of total MHC II and the costimulatory molecules CD40, CD80, and CD86 increase substantially from the immature or resting state (27,28,46). Specific pMHCII levels also increase; however, the capacity for antigen uptake is rapidly truncated as maturation proceeds. Activated DCs also up-regulate CCR7, a chemokine receptor that fa-

cilitates their migration via afferent lymphatics to the T cell zones of draining LNs (47). The concentrations of the CCR7 ligands CCL19 and CCL21 in the T cell zones provide the means to draw these antigen-experienced pMHCII$^+$ DC to the appropriate microenvironment (48). Integrins such as LFA-1 ($\alpha_L\beta_2$) and the expression of matrix metalloproteinase MMP2 and MMP9 also play a role in mature DC migration to LNs.

The recognition of pMHCII complexes by the TCR of specific Th cells is central to the development of adaptive immunity (49–51). Successful cognate interactions occur through organized rearrangement of cell surface molecules at the cellular interface, now commonly referred to as the *immunological synapse* (52,53). Specific TCR-pMHCII interactions cluster toward the center of the immune synapse surrounded by complementary adhesion molecule interactions and excluding negative regulators of TCR signaling. *In vitro,* at least 2h conjugate formation is necessary to promote Th cell proliferation (54) with antigen-specific signaling evident up to 10 h (55). Direct imaging provides outstanding clarity to the dynamic nature of conjugate formation (24,56), resolving the timescale and quality of APC-T cell interactions *in vivo* (57). Two-photon imaging of labeled DCs and Th cell

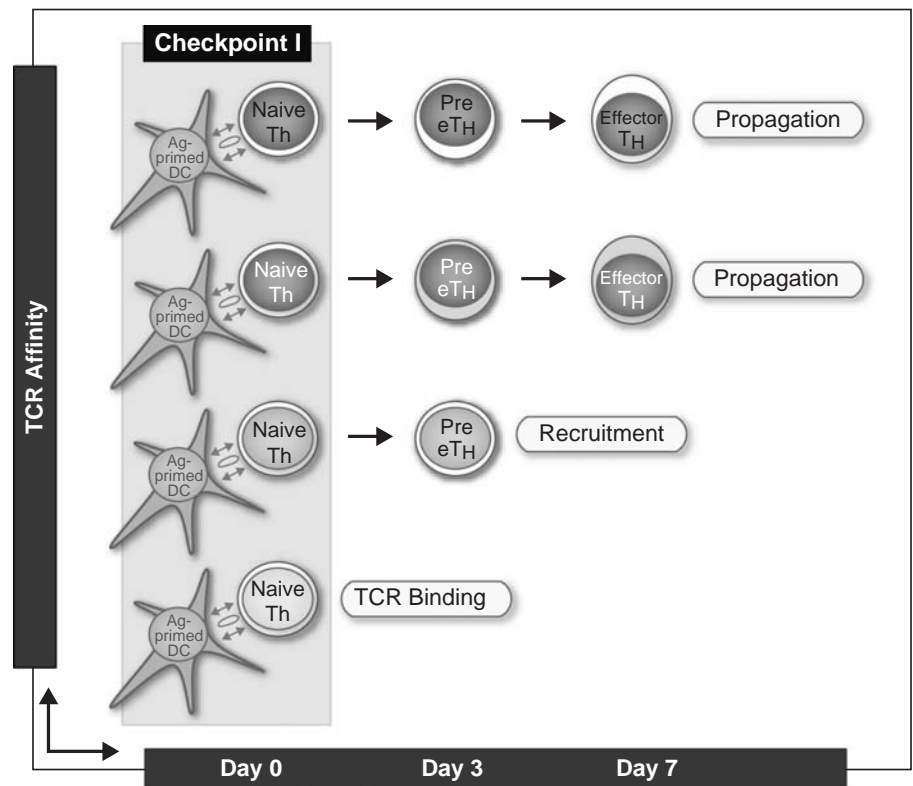
contacts indicates an early phase of short-lived contacts lasting ~10 min with dendrites of DCs (24). Subsequent altered patterns of T cell motility promote serial engagement with several different DCs that lead to clustering and swarming behavior that precedes cell division (58,59). These three phases of initial activation are also found in CD8 T cell responses with transient contacts that precede long-lasting contacts before resumption of dynamic movement (57). Interestingly, early activation and tolerance induction appear broadly similar in this early antigen-specific DC contact (60).

In the draining LNs, chemo-attraction and intercellular adhesion helps to initiate first contact with naïve pMHCII-specific Th cells. Differential expression of Notch ligands, DC production of cytokines, other growth factors, and the expression of a multitude of surface molecules can impact and alter antigen-specific Th cell fate. Recent studies that genetically manipulate cellular expression of pMHCII emphasize the role of persistent antigen in the complete activation of CD4 T cells (61). Two-photon imaging also suggested that there are at least two separate and successive contacts with APC in the activation of CD4 T cells *in vivo* (62). In models of virus infection, activating depots of antigen can be shown to persist for >3 weeks in draining lymphoid tissue (63,64). These elegant sets of studies indicate multiple levels of innate to adaptive control in the earliest phases of an immune response that regulate Th cell fate and function.

Clonal Selection in Th Cells

The central and defining outcome for pMHCII$^+$ DC interactions with naïve Th cells is TCR-driven clonal selection. Helper T cell responses in which a set of dominant TCR are utilized provide access to the mechanisms that underpin Th clonal selection (65–67). Earlier studies indicate the importance of TCR-pMHCII affinity in determining Th cell fate (65,68–70). In this model, selective expansion of clonotypes expressing higher affinity TCR would rely on competition for pMHCII complexes on APC. Alternatively, *in vitro* studies using altered peptide ligands suggested that the duration of TCR-pMHCII contact is critical to cell fate and therefore defined "best fit" *in vivo* (71–74). In support of this model, Th cells expressing TCRs with fast off-rates were lost over time *in vivo* (75). Further, there is evidence for different peptides stabilizing the pMHCII to create a hierarchy of dominant peptides (76). Each and all of these variables would impact what is considered "best fit" and influence the outcome of clonal selection.

More recently, we provide evidence for a model of Th clonal selection that is based on a TCR affinity threshold (77). These studies place emphasis back on overall TCR affinity and define a level of TCR-pMHCII binding above which there was no further skewing of clonal expansion due to TCR affinity. As depicted, multiple affinity-based thresholds underpin cell fate and clonal expansion (Figure 9.4). Importantly, we noted that varying the antigen dose until clonal expansion was compromised did not alter

FIGURE 9.4 Multiple TCR-pMHCII affinity thresholds regulate Th cell fate *in vivo*. Following adoptive transfer of oligoclonal antigen-specific Th cells and priming *in vivo*, Th cells with the lowest affinity TCR bind pMHCII tetramers but do not get recruited into the immune response. Clonotypes expressing the next lowest affinity TCR are recruited into the early phase of the response with substantial clonal expansion but are not found at the peak of the primary response. The final set of clonotypes expressing the highest affinity TCR are recruited to the early response and fully propagated to the peak of the local primary response. Interestingly, based on clonal expansion, above the high-affinity threshold there was no skewing toward clonotypes that expressed even higher affinity TCR and the numbers of antigen-specific Th cells after propagation was directly proportional to the precursor frequency upon transfer. We have labeled checkpoint I as involved in the early selection activity and predict that checkpoint II impacts full propagation of antigen-specific T$_{FH}$ cells *in vivo*.


clonal diversity. These data suggested interclonal competition was not part of the selection process and that TCR recognition and signal strength was a more intrinsic attribute of "good fit." Hence, establishing and perhaps modifying selection thresholds *in vivo* provides another important mechanism for generating antigen-specific clonal diversity that may impact effector Th cell function.

Regulation of B Cell Immunity

Antigen-activated B cells rapidly relocate to the T/B cell interface of secondary lymphoid organs. These earliest events in B cell activation are difficult to access experimentally in nontransgenic animals with polyclonal BCR due to the extremely low preimmune precursor frequency for any known antigens. Adoptive transfer of BCR transgenic B cells and TCR transgenic Th cells allow direct visualization of cognate interactions at these T-B borders (78). Activated B cells up-regulate CCR7 expression to drive them toward T cell areas, while maintaining CXCR5 allows them the appropriate counterbalance for this migration event to the T-B border (79). Two-photon imaging of antigen-specific contact indicates long-lasting 10 min to 60 min interactions (80). Interestingly, the Th-B conjugates appear highly motile, displaying extensive migration lead by the B cells at this early stage of the B cell response.

The range of cognate effector Th cell functions defines a broad spectrum of activities that is still not fully appreciated. B cell expansion in the T cell zones is the prelude to short-lived PC development, while expansion in the follicular regions forms secondary follicles as the precursor to GCs. We recently identified subpopulations of naïve Th cells based on the expression of Ly6C that have a greater propensity to promote PC formation after antigen priming *in vivo* (81). The Ly6C^{high} subset of Th cells also expressed separable TCR repertoires, arguing that the differential capacity to promote PCs was preprogrammed as a consequence of thymic development. Antibody isotype switch occurs in both arms of antigen-driven B cell response and is also likely to be imprinted in a cognate manner by Th cells at this early juncture of B cell development.

There have also been reports of effector Th cells that are specialized to regulate B cell responsiveness. CXCR5 expression was first reported on CD4$^+$CD45RO$^+$ cells in the peripheral blood and secondary lymphoid tissue in humans (82). Gene ablation studies emphasized the role of CXCR5 and CCR7 in the correct positioning of T and B cells in secondary lymphoid tissue that was also needed to support effective Th cell dependent B cell immunity (83,84). Blocking CD28 and OX40 interactions *in vivo* blocked the development of CXCR5$^+$ Th cells and the GC reaction (85). Further, CXCR5 expression was induced in an antigen-specific manner on Th cells *in vivo,* and these cells relocated to follicular areas and the GCs of responding lymphoid tissue (86). CXCR5$^+$ Th cells were sorted from

human tonsil and shown to support antibody production *in vitro* (87,88). The tonsillar CXCR5$^+$ Th cells express high levels of CD40L and ICOS and are found in both the follicular mantle and GC. Adoptive transfers distinguish CXCR5$^+$ B cell helper activity (T$_{FH}$) from P-selectin ligand^{high} tissue homing inflammatory mediators (DTH-promoting Th) that emerge together from the same set of precursors *in vivo* (89). The term *follicular B helper T cells* (T$_{FH}$) was coined to categorize this functionally and phenotypically distinct effector Th cell compartment (87,88).

T$_{FH}$ have also been detected in studies of human tonsil focusing on a subset of CXCR5$^+$ Th cells that also express CD57 and CD69 in the GC (90). These GC-localized T$_{FH}$ exhibit gene expression programs distinct from the more typical Th1 and Th2 type effector Th cells and will be discussed in more detail in a later section. While the nomenclature and identity of the cells under analysis remains somewhat confusing, these studies begin to access the range of specialized effector Th cell activities focused on controlling TD B cell immunity *in vivo*. Figure 9.5 depicts the functional divisions that are predicted to exist within this broad category of T$_{FH}$ cells that will be discussed in detail in the following sections.

Controlling Antibody Class Switch

The initial delivery of cognate T cell help to antigen-experienced pMHCII$^+$ B cells defines the second major checkpoint in the evolution of B cell immunity (Figure 9.3). At this developmental juncture, primed and helped B cells either remain in the T cell zone in a pathway to short-lived PC production or enter the GC pathway toward high-affinity memory B cell development. Antibody class switch occurs synchronously in both pathways of B cell development (91) and requires multiple rounds of cell division in the target cell (92). Thus, it is likely that the commitment to antibody class switch occurs at this critical early checkpoint in B cell differentiation.

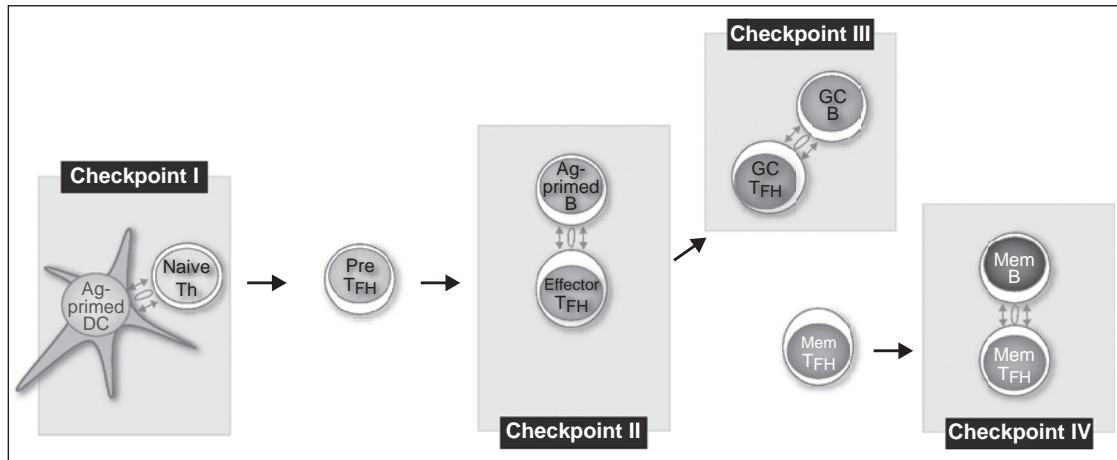
Class switch recombination (CSR) is an intrachromosomal deletional process between the switch (S) regions that reside 5′ of each constant region gene in B cells (except Cδ) (93). Signaling through CD40 and cytokine receptors induces germline transcription through the targeted S regions. The Sμ region and the targeted S region are then cleaved by a putative DNA-cleaving enzyme. The activation-induced deaminase (AID) is required and sufficient for the initiation of the CSR reaction in the activated locus (94). AID-deficient animals (95) and humans (96) display no CSR or SHM of the Ig genes. Repair and ligation through nonhomologous end joining completes the process and results in the looping-out and replacement of the Cμ heavy chain constant region gene (C$_H$) with other downstream C$_H$ genes. Isotype switch can proceed without SHM in the T zone pathway; however, SHM within the GC


FIGURE 9.5 Checkpoints in antigen-specific T_{FH} cell development. Recognition of pMHCII complexes initiates naïve Th cell activation, expansion and development of effector Th precursors. The quantity of pMHCII expressed by mature DC and the coexpressed modifiers of Th cell activation can induce multiple cellular outcomes for the Th cells, one of which will be the effector T_{FH} precursor. Movement to the T-B borders accompanies development of antigen-specific effector T_{FH} functions to allow contact with antigen-primed pMHCII$^+$ B cells. There is evidence indicating that pMHCII B cell contact promotes further T_{FH} expansion at this developmental juncture. We also propose that checkpoint II events precede T_{FH} movement into the GC reaction and may be required for the development of antigen-specific GC T_{FH} cells. There is scant evidence for memory T_{FH} cells or information on the pathway of their development *in vivo*. Nevertheless, we propose that antigen-specific memory T_{FH} cells are related to the primary response T_{FH} compartment and are the regulators of local memory B cell responses that proceed in lymphoid tissues after re-exposure to the same antigen.

reaction is thought to use the same molecular machinery and will be discussed in a later section.

Induced CD40L on effector Th cells and the receipt of this signal through CD40 on B cells is required for antibody class switch (97,98). Animals and humans lacking CD40 display a hyper-IgM syndrome with profound defects in class switch, GC formation, and the development of affinity-matured B cell memory (98). ICOS is an inducibly expressed homologue to CD28 with a distinct ligand-binding motif and cytoplasmic tail and no detectable CD80 or CD86 binding. ICOS expression on activated Th cells is thought to act upstream of CD40L in this temporally orchestrated set of events (99). ICOS-deficient animals also have clear defects in antibody class switch, GC formation, and the development of B cell memory (100–102). Some residual class switch in the absence of CD40/CD40L interactions may be explained by the action of TACI and BAFF-R (45). OX40/OX40L interactions also quantitatively impact class switch, while CD27-CD70 interactions promote PC production (103). Thus, the range of molecules expressed at the effector Th cell surface influences the quality of TCR-pMHCII contact on antigen-primed B cells.

Considering the range of antibodies that can be produced, there must be multiple subtypes of effector T_{FH} that control class switch commitment. Different classes of effector T_{FH} would vary in production of Th cell–derived

cytokines to control antibody isotype. IL-4 and IFN-γ are reciprocal regulators of IgG1 and IgG2a production (104). Animals lacking IL-4 or Stat 6 have decreased IgG1 levels and no IgE (105,106). IL-4 also acts together with IL-21 to control IgG subtypes and IgE levels (107). In contrast, TGFβ is implicated in the induction IgA, while IL-2 and IL-5 augment IgA production(108). Similarly, IL-6 may selectively support IgG2a and IgG2b expressing B cells *in vivo* (109). Each of these factors can exert their effects *in vitro* or in a bystander manner *in vivo*. However, it is thought that the directed delivery of these soluble molecules toward points of TCR-pMHCII contact allows soluble signals to focus locally in an antigen-specific cognate manner.

SHORT-LIVED PLASMA CELL DEVELOPMENT

Under the cognate regulation of effector T_{FH} cells, a cohort of antigen-primed B cells clonally expand within the T cell zones of secondary lymphoid organs and rapidly give rise to short-lived PCs. Within the first few days after antigen exposure, small foci of B cell blasts can be seen within the T cell zones (91). The B cell blasts that have committed to the short-lived PC pathway are depicted as non-GC pre-PCs (Figure 9.3). This plasmablast stage in short-lived

PC development appears transitional and defines pre-PCs that may secrete antibody but also retain the capacity to proliferate. In contrast, PCs are typically considered terminally differentiated and in a postmitotic state. PCs display a marked increase in IgH and IgL mRNA and prominent amounts of rough endoplasmic reticuluum (ER) to accommodate translation and secretion of abundant Ig. They have reduced or lost numerous cell surface molecules including MHC II, B220, CD19, CD21, and CD22 with an increase in the proteoglycan syndecan-1 (CD138), often used as a distinguishing marker for PCs.

In mice deficient for SLAM-associated protein (SAP), the extra-follicular pathway to short-lived PC development remains largely intact, but the GC pathway is blocked (110). Recent studies indicate that SAP deficient Th cells exhibit heightened CD40L expression but decreased ICOS induction that alone can account for this defect (111). It will be important to dissect the separable signals and cellular subsets of effector T_{FH} cells that regulate the rapid but short-lived effector B cell response *in vivo*.

Heterogeneity within the PC Compartment

Short-lived PCs have half-lives of 3 to 5 days (112) and express germline-encoded antigen-specific antibodies (113,114). Newly formed PCs migrate via the MZ bridging channels into the red pulp of the spleen and into the medullary cords of lymph nodes. Migration patterns *in vivo* appear controlled by increased responsiveness to the CXCR4 ligand CXCL12 and decreased expression of CXCR5 and CCR7 (115). There is evidence for BCR affinity-based selection even at this early stage in the response (114). In some studies, B cells expressing low-affinity BCR remain non-GC and high-affinity B cells preferentially enter the GC pathway (116). The converse can also be seen with high-affinity B cells preferentially entering the non-GC short-lived PC pathway (117). While seemingly contradictory, these different outcomes *in vivo* may reflect the plasticity of intercellular control at the Th-B point of contact. Under some circumstances, the capacity to promote the highest germline affinity rapid antibody response may be favored over the development of high-affinity memory B cells. Nevertheless, variations in the strength of initial BCR engagement can also direct B cell fate at this second checkpoint in antigen-specific B cell development.

Currently, there are no phenotypic differences between short-lived and long-lived PCs. Long-lived PCs, as discussed in a later section, are distinguished as the cellular products of the GC reaction that contribute to long-lasting humoral memory. The polyclonal activation of naïve B cells induces short-lived PC that die rapidly *in vitro*. Similarly, the rapid emergence after antigen priming *in vivo* provides one operational means for isolating short-lived PCs (118,119). The expression of germline BCR in these PC provides genotypic support that these cells remain out-side the GC in an extra-follicular pathway of development. However, non-GC B cells and B cells in TI responses can also give rise to long-lived PC (120,121). Similarly, it is possible that the precursors of long-lived PC in TD immune responses exit the GC reaction without diversifying their BCR. Hence, longevity itself provides the best distinguishing attribute for these two types of PC and the basis for this physiological difference remains an important issue to resolve.

Microenvironment is also a key factor controlling longevity in PC populations. The right growth factor niche can potentially convert a short-lived PC into a long-lived PC. Differential migration patterns associated with production of antibodies of different isotype may also contribute to variation and functional subspecialization among the antigen-specific PC compartment. The short-term production of antibody represents different antigen clearance mechanisms, while the deployment of long-lived PCs is a function of B cell memory and a strategy for long-term humoral protection. What controls expansion of particular precursors, migration patterns of progeny, or survival across PC subsets expressing different antibody isotypes remains an important area of research with potentially high impact on the field of vaccine design.

Molecular Regulation of PC Development

The transcriptional control of PC development also exists in multiple layers controlling a cascade of developmental change. The transcriptional repressor prdm-1 (encoding Blimp-1) plays a central role in the regulation of PC development (122). B cells lacking Blimp-1 do not differentiate into short- or long-lived PC, with TI and TD antibody responses profoundly diminished *in vivo* (123). These Blimp-1–deficient animals also display defective levels of serum antibody, suggesting that spontaneous production of antibody by B1 B cells also requires Blimp-1 expression. Structure function analysis indicates the modular action of Blimp-1 integrating a variety of environmental cues that lead to PC development (124,125). Blimp-1 represses proliferation through c-myc as one direct target among many others involved in cell cycle control. Blimp-1 also induces antibody secretion by repressing the transcription factor Pax-5, thereby de-repressing Xbp-1. The transcription factor Xbp-1 controls the unfolded protein response (UPR) and many facets of the cellular secretory mechanism that are critical to PC function and survival (126–128).

The transcriptional coactivator, OBF-1 also appears important for B cells to complete the PC program (129). In the absence of OBF-1, Bcl-6, Pax-5, and AID are not repressed, blocking the induction of Blimp-1 and PC development. In contrast, ablation of the transcription factor MitF leads to the spontaneous development of PC that appears independent of antigen stimuli (130). Interestingly, reexpression of bcl-6 and its cofactor MTA3 reactivates the B cell program

and increases CD19 and MHC II and decreases CD138 in PC cell lines (131). This remarkable study suggests that PC fate is not as terminal and passive as it has been thought to be and that the PC fate remains subject to dynamic gene expression programs.

THE GERMINAL CENTER REACTION

Movement of antigen-primed B cells into the follicular regions of lymphoid organs after effector T_{FH} cell contact initiates the GC pathway to memory B cell development. These pre-GC B cells expand rapidly within the follicular region to form areas of $B220^+IgD^{low}$ antigen-specific B cells referred to as secondary follicles. Secondary follicles polarize into T cell proximal dark zones of cycling centroblasts and opposing light zones of largely noncycling centrocytes among the dense processes of follicular dendritic cells (FDC) and sparse presence of GC Th cells (132,133). This broad anatomical distribution of the GC reaction orients the activities of clonal expansion, BCR diversification, and clonal variant selection that underpin the evolution of high-affinity memory B cells in this pathway (depicted in Figures 9.6 and 9.7).

Under normal physiological conditions the GC reaction emerges as the most efficient means to control affinity maturation and memory B cell development. However, in the disorganized or absent preimmune lymphoid subcompartments of mice lacking $LT\alpha$, $LT\beta$, TNFRI, and $LT\beta R$, the activities of the GC reaction remain disorganized but largely intact (134–137). Vestiges of the GC or small cell aggregates manage the expansion, diversification, and selection steps required for affinity maturation and memory B cell development. Selective reexpansion of high-affinity variants upon antigen recall appears to continue the selection of the best memory B cell compartment in these less than ideal priming conditions.

Memory B Cell Evolution

The GC reaction requires T cell help, as it is absent in athymic nude mice and CD40- and CD40L-deficient mice and is diminished using reagents that block or deplete Th cell function, such as anti-CD4, anti-CD40, and anti-CD28 (138–140). Mice deficient in ICOS also display profound defects in all aspects of TD B cell responses (100–102). Conversely, mice deficient in Roquin, an inhibitor of ICOS expression, produce excessive numbers of T_{FH} cells and

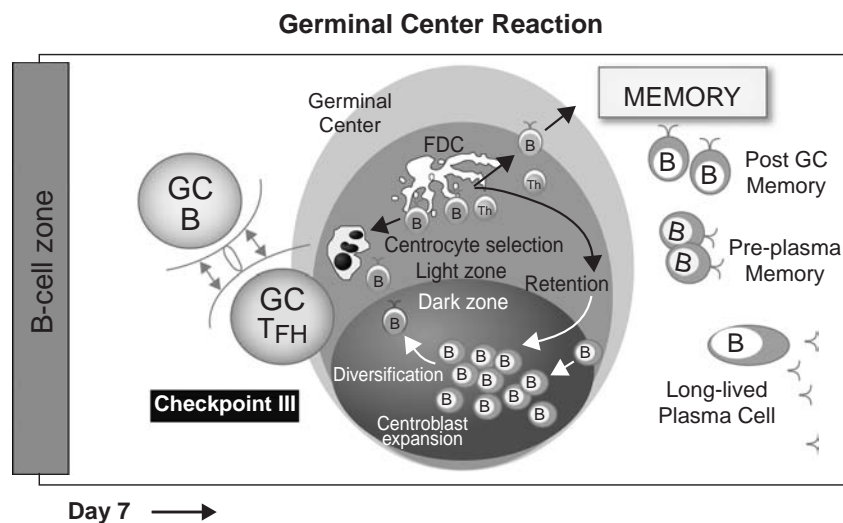
Germinal Center Reaction


FIGURE 9.6 The GC pathway to memory B cell development. The GC pathway for B cells involves clonal expansion, BCR diversification and antigen-driven selection for high-affinity variants. Antigen-specific contact with GC T_{FH} cells at this developmental juncture defines a critical checkpoint in the survival and export of high affinity GC B cells into the memory B cell compartment. Importantly, the unique cellular outcomes at each checkpoint are driven by the quality of TCR-pMHCII interactions and the presence of molecular comodifiers that differ substantially at each progressive stage of development. Multiple subsets of memory B cells emerge from the GC reaction of the primary immune response. 6B2^{high} post-GC memory B cells are the first cellular product that exits the GC. We propose that these cells can give rise to 6B2^{low} pre-plasma memory B cells that are phenotypically and functionally distinct non-secreting memory response precursors. Further, the 6B2^{low} pre-plasma memory B cells appear to be the immediate cellular precursors of long-lived plasma cells that are a terminally differentiated antibody secreting memory B cell compartment. Both pre-plasma memory B cells and the long-lived plasma cells can be found in the spleen but preferentially home to the bone marrow.
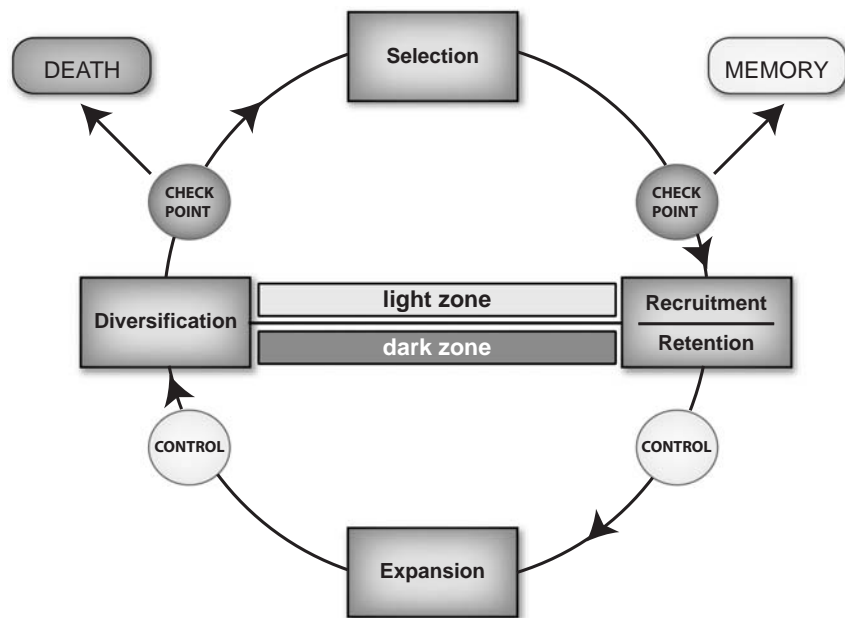

FIGURE 9.7 The GC cycle of activity. Antigen-specific B cells enter the follicular area and rapidly expand into secondary follicles that polarize into the light and dark zones of the GC reaction. Clonal expansion is accompanied by somatic diversification of antibody variable region genes in the dark zone. Exit from cell cycle and expression of variant BCR allows for antigen-specific selection of centrocytes in the light zones. Negative selection leads to apoptosis while positive selection of high affinity variants results in GC cycle reentry or exit from the GC into the memory B cell compartment under the cognate control of GC Th cells.

GCs and are prone to autoimmunity (141). However, TI antigens can also promote GC reactions, but they collapse within the first week after priming with no evidence of BCR diversification (142). In contrast, MZ B cells can be recruited into TD responses and form GCs that diversify and affinity mature (21). Interestingly, in these studies, the MZ B cells responding to antigen challenge expressed a distinctive preimmune BCR repertoire to the FO B cells responding in the same animals. Hence, there is some redundancy to the control of GC formation and flexibility to the origins of the B cells recruited into the GC reaction.

The transcriptional repressor Bcl6 is highly expressed in the GC and is necessary for GC formation (143). However, IgM and IgG1 antigen-specific memory B cells can develop in the absence of Bcl6 (144). These studies were based on direct labeling with antigen and their capacity to respond to soluble low-dose antigen recall. However, there were no GCs formed, and the memory B cells expressed no SHM or evidence for affinity maturation. Bcl6 has been recently shown to repress p53, the tumor-suppressor gene that controls DNA damage–induced apoptosis (145). Regulation of p53 in this manner may protect GC B cells to allow for the DNA breaks that are necessary intermediates in SHM and CSR. Bcl6 also directly represses Blimp-1 (146) and hence must be lost at some point during the GC reaction to allow subsequent development of pre-plasma memory B cells and long-lived PC *in vivo* (123).

The GC cycle of activity regulates clonal evolution within antigen-primed B cell responders. All pre-GC B cells express some measure of antigen specificity and appear preselected into the memory B cell pathway based on germline BCR expression. Massive and rapid clonal expansion with doubling times of 6 h to 8 h underpins secondary

follicle formation and drives clonal expansion in the GC reaction. It is now clear that GC B cells in the light zone also have the capacity to proliferate (147). Further, recent studies using two-photon imaging of established GC *in situ* demonstrate in real-time that GC B cells in the light zone can also reenter the dark zone of GCs (148,149). These studies also emphasize the more open nature of the GC itself, demonstrating the capacity of naïve B cells to traverse the follicular region occupied by the antigen-responsive GC (149). Importantly, antigen-specific B cells could also be recruited into ongoing GCs if they expressed sufficiently high-affinity BCR. While these studies use high frequencies of BCR transgenic B cells pulsed into the ongoing response, it is intriguing to consider the ramifications of such an open network of affinity-based selection and its impact on the composition of the memory B cell compartment.

Somatic Hypermutation

Upon expansion in the GC reaction, antigen-specific B cells down-regulate their germline BCR and diversify their variable region genes through SHM. Single base substitutions, rare insertions, and deletions are introduced into a region spanning 1.5 kb to 2.0 kb downstream of the transcription initiation site; however, activity peaks within the V(D)J region and decreases within the J-C intronic region of IgH and IgL V genes (150). The mutation rate approaches 10^{-3} per base pair per generation, which is $\sim$ 6 orders of magnitude greater than spontaneous mutation frequencies. Approximately one mutation is introduced with each cell division. Analysis of mutation in "passenger" Ig transgenes that are not under selection pressure indicate intrinsic sequence hotspots for the mutator mechanism (151). Hence,

BCR diversification accompanies extensive clonal expansion within the GC reaction generating progeny that express variant antigen-binding BCR.

AID is the central component of the SHM mechanism. Originally discovered through cDNA subtraction focused on novel genes in GC B cells (152), it was then found to be the defect associated with an autosomal recessive form of hyper-IgM syndrome (96). Mice deficient in AID were able to form the GC reaction but were unable to undergo CSR or SHM (95). AID deaminates cytidine to uracil in single-stranded DNA that can be processed by a mutagenic repair pathway (93,153). The processing of these mutagenic changes creates the double-stranded breaks required for CSR and the mutagenic substrate for SHM. AID is the only B cell–specific enzyme that guides this phase of the diversification mechanism. However, distinct DNA damage response and histone modifications may discriminate SHM and CSR targets in this system (154).

Cell Cycle Arrest and Apoptosis

The control of cell cycle in the GC environment is of fundamental importance to the evolution of high-affinity B cell memory. Variant GC B cells exit cell cycle and move toward the light zone to undergo selection. Dysregulated cell cycle arrest promotes enlarged GCs in situ. This phenotype is found in multiple genetic knockout models that also influence the composition of the memory B cell compartment. Large GCs form in the absence of AID and are thought to indicate a negative feedback mechanism that follows SHM or CSR (95). The absence of the CDK inhibitor p18^{INK4c} more directly impacts GC size through blocking cell cycle arrest and also decreases the formation of long-lived PCs (155). The large GCs in the absence of Blimp-1 (123) may also be related to the lack of cell cycle control that may contribute to the pre-plasma memory cell and long-lived PC defect in these mice. The absence of the main regulatory subunit of calcineurin CnB1 results in the large GC phenotype, the loss of late-stage antibody production, and diminution of the memory B cell response to antigen recall (156). It will be important to assess whether these putative cell cycle defects directly impact high-affinity memory B cell evolution or indirectly modifies GC B cell fate and the onset of apoptosis.

It is generally believed that the majority of GC B cells expressing variant BCR will die *in situ*. Extensive local apoptosis is characteristic of the GC reaction. Further, over-expression of antiapoptotic molecules such as Bcl-2 or Bcl-xL prolongs survival of GC B cells without improving selection efficiency (157). In the absence of CD95 (Fas), there is also a dilution of high-affinity clonotypes in the memory B cell compartment (158). Mutations in the co-modifiers of BCR signal also impact GC B cell dynamics. Unlike the CnB1 mutation, defects in CD45 and CD19 reduce proliferation and survival of GC B cells, arguing for a more global impact of these molecules on BCR signal integration (147,159,160). Initiation of the GC development program may also be altered to differing degrees in these animal models in ways that are difficult to dissect. Driving the expression of Cre recombinase at a stage in development when germline Cγ1 transcript provides access to later-stage antigen-responsive B cells and GC B cells without interfering with the early antigen specific events. (161). This model allows the conditional deletion of alleles at a late stage in antigen-driven B cell development that occurs after the first Th-B cell checkpoint in development.

Affinity Maturation

Affinity maturation requires the positive selection of GC B cells expressing high-affinity variant BCRs. The details of this process are still poorly understood. Receipt and integration of signals through the BCR are clearly involved in positive selection and must be based on the affinity for antigen. Ablating BCR signals such as calcineurin-dependent signals and CD19 signaling mutants and loss of CD45 interferes with positive selection and memory B cell development (147,156,159,160). However, as discussed earlier, it is difficult to dissect the GC BCR interactions with antigen from the initial BCR triggers that recruited naïve B cells into the primary response. Most models suggest immune complex (IC) trapping on FDCs as the most likely means for variant BCRs to receive a rescuing signal from native antigen. Antigen appears rapidly in this location and can persist for extended periods of time focused to FDC in lymphoid tissue draining the site of antigen administration (162). In support of this notion, complement receptors CD21/CD35 on FDC are needed to generate long-term serum antibody response (163). However, animals that do not secrete antibody and therefore cannot form IC can still support affinity maturation (164). In the absence of inhibitor of nuclear factor (NF)-κB kinase 2 (IKK2)–dependent activation of the NF-κB pathway, FDCs can still capture ICs but are not stimulated to up-regulate vascular cellular adhesion molecule-1 (VCAM-1) and intercellular adhesion molecule-1 (ICAM-1) (165). In the absence of these adhesion molecules, GC B cells appear more susceptible to apoptosis with evidence for altered gene expression and decreased affinity maturation.

Polarity in the GC microenvironment is partly controlled by the differential expression of chemokines and their receptors (166). Higher expression of CXCL12 in the dark zone assorts CXCR4-expressing centroblasts, while higher CXCL13 in the light zone attracts CXCR5-expressing centrocytes. These studies use flow cytometry and cell cycle status to identify GC B cell subsets and demonstrate the aberrant behavior of GC B cells from various genetically modified host animals. Recent two-photon analysis reveals the movement of GC B cells along FDC processes within the GC (148). These studies emphasize

the lack of dwell time for GC B cells on FDC processes with little change in GC B cell velocity upon FDC contact. Therefore, if antigen binding is associated with GC B cell-FDC contact, there appears to be no evidence for interclonal competition between different GC B cells. In contrast, there was prolonged contact between antigen-specific GC Th cells and GC B cells. As there are also very few GC Th cells in the light zone of GCs, the Th cells create a rate limiting stage within the GC pathway. Thus, competition for cognate GC Th cell interaction may provide a final selection mechanism for the pMHCII-expressing GC B cells and constitutes a third major checkpoint in memory B cell development. These direct imaging strategies provide important clues to the dynamic facets of antigen-driven selection in the GC microenvironment and, importantly, begin to identify the central function of GC Th cells.

As with all *in vivo* studies, there are substantial influences associated with the choice of models, affinities of BCR, type of antigen, and method of immunization that will impact the observations presented in the studies. The issues of antigen receptor monoclonality are self-evident in BCR transgenic models in the context of repertoire studies but less clearly understood in association with the expression of diverse effector functions *in vivo*. More important, in the context of T cell responses, it is now apparent that elevated precursor frequency deviates the dynamics of clonal expansion (167,168) and can alter the development of T cell memory *in vivo* (169). Changing the balance or affinity of regulator populations will impact cell fate of the target populations in ways that remain difficult to assess. Nevertheless, new insights offered by dynamic imaging continue to buttress our appreciation for the workings of the immune system and serve to challenge existing dogma in powerful and productive ways.

GC T_{FH} Cells

In contrast to pre-GC effector T_{FH} cells discussed earlier, CXCR5+ Th in GC will be referred to as "germinal center" T_{FH} cells (Figures 9.5 and 9.6). Many CXCR5+ T_{FH} cells were found very early in the immune response (day 3), at the T-B borders and within follicular regions of LNs (86). These studies also provide further evidence for a circulating compartment of CXCR5+ Th cells. Hence, it is clear that CXCR5 expression is not a reliable marker of GC Th cells only. Further, the expected function of GC T_{FH} cells would be broadly different from those described for pre-GC effector T_{FH} cells. The presence of GC T_{FH} cells among the dense follicular dendritic cell networks of the GC light zone predict a role in the propagation of high-affinity variant GC B cells into the long-lived memory B cell compartment (166).

During antiprotein immune responses, the Th cells within the light zone of the GC express pMHCII-specific TCRs. There appears to be sequential movement of antigen-specific Th cells from the T cell zones into the GC microenvironment (66,170) with evidence that suggests GC Th cells can also move between different GCs (171). Interestingly, all antigen-specific Th cells responding to a protein antigen are not represented within the GC reaction, indicating pre-GC functional differentiation for responding Th cells (172). Further, non-GC Th cells can reemerge in a memory response, indicating that the GC is not required for memory Th cell development (66). Downregulation of CD90 (Thy-1) has been used as a marker of GC Th cells in the mouse, although when this occurs and how well it discriminates only GC Th cells is not clear (171). Interfering with CD40L-CD40 interactions disrupts the GC reaction, while blocking B7-2 interaction impairs memory B-cell development (173). Hence, the cognate control of GC B cell fate appears to be modified by the cellular and molecular context of pMHCII presentation.

The more recent work on human T_{FH} cells use expression of CD57, as well as CXCR5, to define T_{FH} cells that are contained within the GC of tonsils (174,175). Microarray analysis highlights the distantly related functional programs of CD57+ GC T_{FH} cells as compared to naïve Th cells, central memory Th cells (T_{CM}), and effector memory Th cells (T_{EM}) from the peripheral blood (175). Differences in adhesion molecules, chemokine receptors, cytokines, and transcription factors appear as distant as different lineages. Interestingly, the CXCR5 ligand, CXCL13, is highly expressed in GC T_{FH} cells. *In vitro* derived Th1 and Th2 effector Th cells also appear distant in gene expression program to GC T_{FH} cells (174). This analysis associates CD84, CD200, IL-21, and BCL6 with CD57+ GC T_{FH} cells. A separate analysis of T_{FH} cells by function and gene expression demonstrates that T_{FH} activity in human tonsil is independent of CD57 expression (176). These studies highlight ICOS^{high}CXCR5^{high} T_{FH} as CXCL13 secretors and the most potent inducers of antibody production *in vitro*. Therefore, it is clear *in situ* that all GC T_{FH} cells express CXCR5, and many express CD57; however, these molecules are not exclusively expressed on GC T_{FH} cells nor expressed on all T_{FH} cells in the tonsil. Nevertheless, it remains important to clarify GC T_{FH} phenotype so that the details of their function can be pursued *in vivo*.

B CELL MEMORY

It is now clear that centrocytes can undergo proliferation in the light zone (160), and there is direct evidence for movement of centrocytes back into the dark zone of GCs (148,149). Thus, it appears that one outcome of GC B cell-GC T_{FH} interactions is reentry into the GC cycle and reiterative rounds of expansion, diversification, and selection (Figure 9.7). In this model, each subsequent round of clonal expansion and BCR diversification is applied to GC B cell variants that have been positively selected based on

increased BCR affinity. Hence, the introduction of a few mutations in each clonal progeny of selected variants is less likely to destroy BCR specificity and leaves room for further increases in an already high-affinity variant BCR.

The second major outcome of checkpoint III is exit from the GC cycle and entry into the memory B cell compartment (Figures 9.6, 9.8). The GC reaction produces at least two broad categories of affinity-matured memory B cells (26). The most typical memory B cells are the precursors for a memory response to antigen recall. These memory B cells are easily distinguished functionally from the second cellular compartment of memory, the long-lived PCs (177). The long-lived PCs are terminally differentiated cells that continually produce high-affinity antibody and will not be drawn into a secondary response. In both categories of memory B cells, the expression of antibody isotype distinguishes separable memory B cell compartments. By definition, these subsets differ in the antibody they can produce and hence their developmental program and cellular function is distinct. However, these "isotype-specific" memory B cell subsets may also differ in migration patterns, survival needs, and the requirements for reactivation at the time of antigen recall. These issues define a level of heterogeneity that have received very little attention at the current time and remain important features in the organization of B cell memory *in vivo*.

Memory B Cell Subsets

Memory response precursors are affinity-matured BCR[+] post-GC cells that have often isotype-switched and can still respond, in a Th-cell-dependent manner, to low-dose soluble antigen recall. The long-term persistence *in vivo* of antigen-binding BCR[+] B cells, after the decline of the primary response, provides the single best indicator for all memory response precursors. Beyond this particular attribute, antibody isotype and stage of development within the memory B cell compartment introduces a level of cellular heterogeneity that is only recently being appreciated.

As soluble antigen is the ligand for the BCR, most experimental approaches use variations of labeled antigen to identify antigen-specific B cells. While panning techniques used gel-associated antigen (178,179), flow cytometry provided the most reliable access to antigen-specific B cells (180,181). These earliest studies (180,181) coupled cell sorting technology and direct labeling to enrich antigen-specific B cells for adoptive transfer. These early studies helped to demonstrate that B cells with receptors for antigen were the precursors for antibody-forming cells. This approach has been adopted by many groups (182–185) with the subsequent evaluation of specificity and purity demonstrated by the frequency for antibody-forming cells or the enrichment for production of antigen-specific antibodies *in vitro*.

Early studies indicated antigen-binding B cell populations of long-lived cells with slow or no turnover *in vivo* (186). These memory B cells can survive independent of their expressed BCR specificity and hence do not require persistent antigen depots *in vivo* (187). Loss of membrane IgM/IgD and expression of downstream isotype are also indicative of antigen experience but are not required for memory cell development (181,183,188). Further, the expression of mutated BCRs with evidence for affinity increasing changes is the most useful molecular marker for the memory B cell compartment (114,189–191). However, there are also abundant examples of germline-encoded

BCRs expressed by memory response precursors. Location has also been a reliable means for isolating memory B cells from the blood very soon after intentional priming (189). The combination of location, phenotype, genotype, and time after intentional priming has many elements of a comprehensive definition for memory B cells.

Memory response precursors have been typically defined as IgM$^-$IgD$^-$6B2^{high} antigen-binding B cells (183,191–193) that do not secrete antibody until expansion and differentiation into PC after re-challenge with antigen. These 6B2^{high} memory B cells express mutated receptors and can be found in late primary and secondary responses to antigen (114,191,194). There is now evidence for a second subset of antigen-binding memory B cells that down-regulates the CD45 glycoform B220, displaying reduced levels of 6B2 binding (195–197). Upon adoptive transfer, both 6B2^{high} and 6B2^{low} memory B cell subsets give rise to antigen-specific memory responses (197). The pattern of cellular expansion, conversion of cell surface phenotype, and extent of PC development suggests that the 6B2^{high} "post-GC" memory B cells lie developmentally upstream from the 6B2^{low} "pre-plasma" memory B cell compartment.

The 6B2^{low} pre-plasma memory B cells have been seen across a number of different antigen systems following a variety of immunization regimes. Following hapten-protein immunizations, 6B2^{low} memory B cells are found with high-dose antigen (400 μg) using the Ribi adjuvant system (118) but not with low-dose (40 μg) using alum as the adjuvant (189). There is clear evidence of 6B2^{low} antigen-experienced B cells across multiple regimes of BCR transgenic transfer using the B cells from the QM mouse model that express germline-encoded and hapten-specific BCR (195,196). The QM B cells also produce a phenotypically distinct B cell subset of 6B2^{low} pre-plasma cells that can differentiate into plasma cells in an antigen-independent manner (198). This change can be induced upon adoptive transfer into naïve recipients but requires some level of clonal expansion. Cells with a similar 6B2^{low} pre-plasma cell phenotype have been recently described in a mouse model of bacteriophage capsid immunization (199). The 6B2 antibody also recognizes a similar determinant on human B cells with the majority of CD27$^+$ IgM and non-IgM memory B cells in the blood displaying a 6B2^{low} phenotype (200). Hence, the 6B2^{high} and 6B2^{low} memory B cells represent separable subsets of the memory B cell compartment that may describe a linear progression of development as the cellular products of the GC reaction and immediate precursors of high-affinity plasma cells upon antigen recall.

Long-lived Plasma Cells

Long-lived antibody-secreting B cells can also be considered part of the memory B cell compartment. The long-lived PCs do not replenish through turnover, but do secrete isotype-switched antibody and display evidence of SHM with affinity increasing mutation patterns (177,201,202). This post-GC antigen-specific B cell compartment appears during the second week after initial antigen exposure (114) and preferentially homes to the BM for growth factor support of stromal cells (203). Based on gene ablation studies, these cells use a variety of redistribution mechanisms such as up-regulation of CXCR4, $\alpha 4 \beta 1$ integrin binding to its ligand VCAM-1 (115) to get to the BM, where they can persist for the life of the animal (112,204–208). In the BM, long-lived PCs need signals through the TNFR family member, BCMA for survival (209). It has also been proposed that a pre-PC precursor (198) or memory cells themselves (210) produce PCs in a non–antigen-dependent manner as a means of maintaining serum antibody levels for extended periods.

The extended longevity of the long-lived PC can be demonstrated using BrdU incorporation and adoptive transfer (205–208). The extinguished gene programs associated with PC development (128,211,212) support a terminally differentiated end-stage cell that needs to arrest cell cycle progression (155) and will not be reactivated on antigen recall. Nevertheless, based on the evidence of a GC phase in development, the extended longevity of these PCs and the continued production of high-affinity antibody, it is reasonable to consider these end-stage B cells to belong to the memory B cell compartment.

Based on variability in memory B cell formation across different antigen models, it appears likely that different sets of initiating stimuli modify the balance of cells within the different memory B cell compartments. The memory cell balance may be a quantitative "interpretation" of the quality of the initial immunizing signals. Ultimately, memory B cell fate is likely to be controlled by checkpoint III interactions in the GC itself. The strength of BCR signal and costimulatory context serve to select variant BCRs and initiate changes in memory B cell development. Cognate interactions with GC T$_{FH}$ cells may consolidate these functional outcomes. Understanding the role of the different memory B cell subsets in long-term protection and the rules that govern their development *in vivo* remain important unresolved areas in this field.

Memory Response to Recall

Persistent high-affinity serum antibody provides the first layer of protection against a secondary challenge. While antibody binding to antigen is a clearance mechanism, it also serves to increase the efficiency of antigen presentation to memory B cells through rapid IC formation and binding to FcR or complement receptors on cells of the innate system. In this manner, antibody may amplify the sensitivity of the memory B cell response to secondary antigen challenge. Furthermore, antigen re-challenge also seems necessary to establish adequate long-term protection following protein vaccination. The cognate cellular dynamics

and molecular regulation of the memory response boost are important factors in the consolidation of B cell memory that remain poorly understood and inadequately optimized in most vaccine regimes.

Primary response GC persists for around three weeks after initial priming, but this timing may vary substantially depending on the immune stimuli (132,133). There is evidence for continued selection in the memory B cell compartment even after the demise of the GC reaction (202). This selection process represents more typical interclonal competition without further BCR diversification (213). Where this secondary selection occurs and how it relates to the selection mechanisms in the GC remains to be determined. Nevertheless, secondary selection events appear capable of reshaping the memory compartment toward higher affinity clonotypes that can substantially influence the quality of the secondary response and consolidation of the memory compartment (210).

Using priming doses of antigen and adjuvant, antigen-specific memory Th cell responses (66,67,214) and memory B cell response (215) emerge more rapidly than their naïve response counterparts. Memory Th cell responses reach peak levels more rapidly but to similar levels as the primary response. In contrast, memory B cells display accelerated kinetics but reach substantially higher maximal levels compared to the primary response. Even in the presence of priming doses of antigen and adjuvant, the memory responders dominate the recall response (66,197), out-competing naïve lymphocytes that may express specific Ag-R.

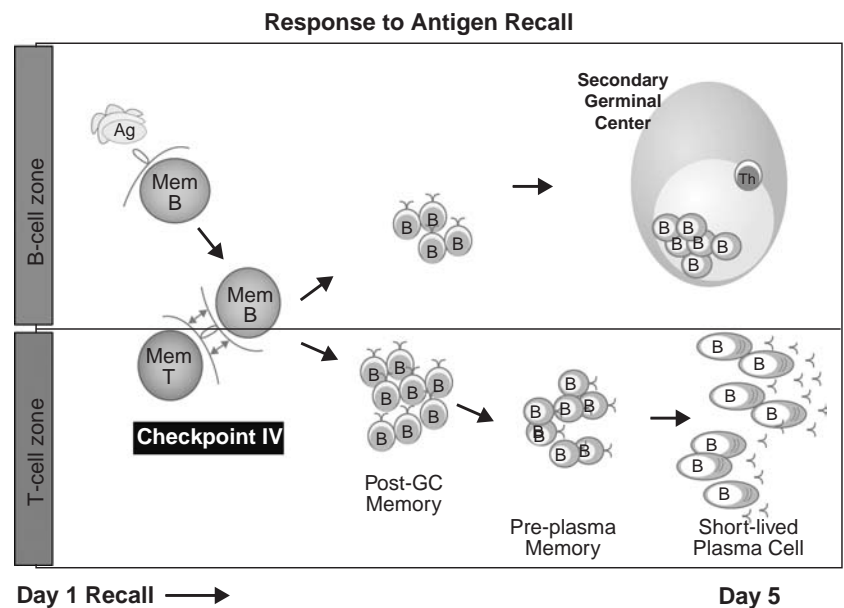
Memory Th Cells

Memory B cell response to TD antigens require antigen-specific T cell help (26). Under normal physiological circumstances, this secondary T cell help must be antigen-specific and is most likely delivered by memory Th cells that are specific to the immunizing antigen. Under typical low-dose antigen re-challenge regime in the absence of immune adjuvant, antigen-specific B cells are likely to be the APC for the memory response. Hence, the cognate interactions of pMHCII$^+$ memory B cells and antigen-specific memory Th cells define a fourth developmental checkpoint in the evolution of long-term immune protection (Figure 9.9). Alternately, circulating antibody and innate immune activation induce an accelerated memory response due to increased frequencies and heightened responsiveness of memory response precursors. In this scenario, the memory Th cell-memory B cell checkpoint may be preceded by an independent series of antigen presentation events prior to checkpoint IV.

The major cellular outcome of the secondary boost is rapid and exaggerated memory B cell expansion and the production of large numbers of high-affinity PCs. While high-affinity B cells can be drawn into GC reactions (149), it is not clear that the GC pathway is operative at the time of the secondary boost. Regardless, there is clear evidence for secondary selection events upon antigen re-challenge that are more likely to be driven by cellular selection without somatic BCR diversification (26). The nature of the selection mechanism for B cells at this stage of the response is also poorly understood. In contrast, the accelerated local reexpansion of antigen-specific memory Th cells occurs with little change in the expressed TCR repertoire (216) or cytokine-secreting potential (214). Hence, the antigen-specific memory Th cell compartment appears to conserve and reexpress many of the functions associated with the initial primary immune response.

There is evidence for a division of labor in the memory T cell compartment that involves the migratory capacity of memory Th cell subsets (217). Recirculating central

Response to Antigen Recall

FIGURE 9.9 The response to antigen recall. Low-dose soluble antigen in the absence of adjuvant can induce a rapid and exaggerated humoral immune response. Hence, antigen-specific B cells are the most likely APC for pMHC II complexes at checkpoint IV interactions between memory Th cells and memory B cells are the critical developmental checkpoint for the memory response. Memory cell expansion is vigorous to produce large numbers of high-affinity memory response plasma cells as the dominant cellular outcome. Secondary GC reactions are also part of the memory response, although more a minor outcome than seen in the primary response.


memory T cells (T_{CM}) and tissue-homing effector memory T cells (T_{EM}) further divide on their readiness to reexpress effector function upon reexposure to antigen. It is reasonable to propose that each antigen-specific effector Th cell subset will produce a memory Th cell counterpart (214). However, the range of Th memory effector attributes required to control antigen-specific memory B cell responses is not well understood. Compartments of tissue-localized memory Th cells provide rapid "reactive" immune protection that is antigen-specific (217). For example, the focal placement of T_{EM} cell subsets at sites of original antigen entry preempts the life history of the pathogen. In this manner, location provides an opportunity to accelerate the recall response, enhancing the capacity of the immune system to block overt infection. As the precursors of the memory response to antigen recall, high-affinity memory B cells belong to a similar "reactive" set of memory cells. However, in contrast to local hypersensitivity responses by Th cells, antigen reexposure promotes rapid and exaggerated memory B cell responses in the lymphoid tissue that drains the site of re-challenge. In this context, we can refer to the memory Th cell compartment that controls memory B cell responses as memory T_{FH} cells.

It is not clear whether memory T_{FH} cells would necessarily express CXCR5$^+$ like their primary response T_{FH} compartment. Further, it is not clear whether both effector T_{FH} and GC T_{FH} produce memory T_{FH} counterparts. Nevertheless, it will be important to unravel the programs of cognate control used by antigen-specific memory T_{FH} to regulate the memory B cell response to antigen re-challenge. It is plausible that manipulating cellular and molecular interactions at checkpoint IV can alter the shape of antigen-specific B cell memory.

Antigen Persistence *in vivo*

Unlike CD8 T cells, CD4 Th cells appear to require continued presence of antigen to reach maximal clonal expansion *in vivo*. The conditional induction and abrogation of pMHCII molecules demonstrate that as soon as a lower threshold level of antigen is breached, Th cell cease to divide (61). Surprisingly, this model induces no form of inflammation and would otherwise be considered a model of tolerance induction. Recent intravital imaging studies also indicate that antigen-responsive Th cells engage multiple DCs at successive early stages after priming (62). These multiple DC-Th cell contacts also impact the development of effector Th cell function *in vivo*. Most surprisingly, there is evidence for persistent depots of pMHCII complexes up to 3 weeks after viral infection (63). These pMHCII depots are present at times after viral clearance *in vivo*. The same persistent depots can be demonstrated for pMHCI with the capacity for local activation of viral-specific naïve CD8 cells (64). While persistent antigen is not required for the maintenance of antigen-specific T cell memory (218,219),

there may be a role for persistent depots of pMHC complexes as local guidance cues for antigen-specific memory T cells.

CONCLUSION

Understanding the cellular and molecular control of memory B cell development remains a high priority for fundamental research with important application to the field of immunotherapeutics and vaccine design. There has been substantial progress in our understanding of this complex developmental cascade *in vivo*, with many of the cellular processes being more carefully defined in their most relevant *in vivo* context. The sophisticated manipulation of mouse genetics provides a powerful set of tools that begin to unravel the regulatory mechanisms operative across each developmental checkpoint controlling cell fate *in vivo*. Real-time intravital imaging provides a major advance to our appreciation of cell dynamics and intercellular communication as it proceeds in the crowded confines of secondary lymphoid tissue.

Clonal selection underpins all adaptive immune activities with significant differences emerging between Th cells and B cells in the antigen-specific pathway to immune memory. Effector Th cell function remains somewhat convoluted and still difficult to fathom *in vivo*, although we are beginning to appreciate the extraordinary heterogeneity that resides among these antigen-specific regulators of adaptive immunity. Antigen-driven B cell development is less divergent than its Th cell counterpart; however, the organization of the antigen-responsive B cell compartment is still difficult to access experimentally *in vivo*. Nevertheless, the progression of cellular and molecular events that underpin immune memory are rapidly coming into focus. Many new antigen-specific models provide high resolution to the nature of effector B cell function and antigen-specific B cell memory that may unravel the rules of immune control and substantially impact the redesign of vaccine formulations.

T Lymphocytes

T Cell Antigen Receptors

Mark M. Davis and Yueh-Hsiu Chien

INTRODUCTION

T lymphocytes expressing $\alpha\beta$ or $\gamma\delta$ T cell receptors (TCRs) are found together with B lymphocytes in all but the most primitive vertebrate animals. These three cell types are the only ones that use random V, D, J, gene rearrangement to generate diverse antigen receptors. During the past two decades, there has been a great deal of progress in identifying the molecules and genes of TCRs, and there is considerable information on their biochemistry and structure. Although TCRs share structural and genetic similarities with B cell receptors (BCRs) (immunoglobulins [Igs]), they also possess a number of unique features pertinent to their specific functions. The first major difference was suggested by the experiments of Zinkernagel and Doherty, who found that the cytotoxic cells could only lyse infected cells expressing certain major histocompatibility complex (MHC) haplotype (1,2). This phenomenon of "MHC restricted recognition" is in marked contrast to the recognition of intact antigens by Igs *(3,4)*. In fact, antigen recognition by T cells has helped to define their functions.

$\alpha\beta$ TCRs are expressed on classical helper and cytotoxic T cells, which predominate in most lymphoid compartments (90%–95%) of humans and mice *(5)*. $\alpha\beta$ TCRs are also expressed on natural killer (NK) T cells *(6)*, regulatory T cells *(7)*, and T cells in the mucosal sites such as the intestinal epithelial compartment (IELs) (8). In most cases, the $\alpha\beta$ TCR ligand is a peptide antigen bound to a class I or class II MHC molecule; but in the case of NKT cells, the antigen is a glycolipid bound to a nonclassical class I MHC molecule, CD1d *(6)*.

T cells bearing $\gamma\delta$ TCRs are less numerous than the $\alpha\beta$ type in most cellular compartments of humans and mice (less than 5%). However, they make up a substantial fraction of T lymphocytes in cows, sheep, and chickens *(9)*. $\gamma\delta$ T cells coexist with $\alpha\beta$ T cells but seem to be better represented in the mucosal compartments *(9,10)*. Although $\alpha\beta$ T cells perform most of the functions classically attributed to T cells, mice lacking $\gamma\delta$ T cells clearly have compromised immune systems, indicating that $\gamma\delta$ and $\alpha\beta$ T cells contribute to host immune defense differently (10,11). $\gamma\delta$ TCRs also have distinct antigen recognition requirements in that no antigen processing is required (12). During the past few years, there have been considerable advances in our understanding of antigen recognition by $\gamma\delta$ T cells. This should lead to a better understanding of how $\gamma\delta$ T cells contribute to host immune competence.

TCR POLYPEPTIDES

The search for the molecules responsible for T cell recognition first focused on deriving antisera or monoclonal antibodies specific for molecules on T cell surfaces. Ultimately, a number of groups identified "clonotypic" sera (13) or monoclonal antibodies (14–18). Several of these antibodies were able to block antigen-specific responses by the T cells they were raised against or, when coated on a surface, could activate the T cells for which they are specific. They were also able to immunoprecipitate 85 to 90,000 MW disulfide-bonded heterodimers from different T cell clones or hybridomas consisting of two 40,000 MW to 50,000 MW glycosylated subunits referred to as α and β. Peptide mapping studies showed that there was a striking degree of polymorphism between heterodimers isolated from T cells of differing specificity, thus suggesting that these antigen recognition molecules might be akin to Igs (19,20).

Work in parallel to these serological studies exploited the small differences (~2%) observed between B and T cell gene expression (21) and isolated both a mouse (22,23) and a human (24) T cell–specific gene that had antibody-like V, J, and C region sequences and could rearrange in T lymphocytes (23). This molecule was identified as TCRβ by partial sequence analysis of immunoprecipitated materials (25). Subsequent subtractive cloning work rapidly identified two other candidate T cell receptors cDNAs identified as TCRα (26,27) and TCRγ (28). It was quickly established that all antigen-specific helper or cytotoxic T cells expressed TCR $\alpha\beta$ heterodimers. Where TCRγ fit in remained a puzzle until work by Brenner et al. (29) showed that it was expressed on a small (5%–10%) subset of peripheral T cells together with another polypeptide, TCRδ. The nature of TCRδ remained unknown until it was discovered within the TCRα locus, between the V_α and J_α regions (30). Formal proof that the TCR α and β subunits were sufficient to transfer antigen/MHC recognition from one T cell to another came from gene transfection experiments (31,32) and equivalent experiments have also been done with $\gamma\delta$ TCRs (33).

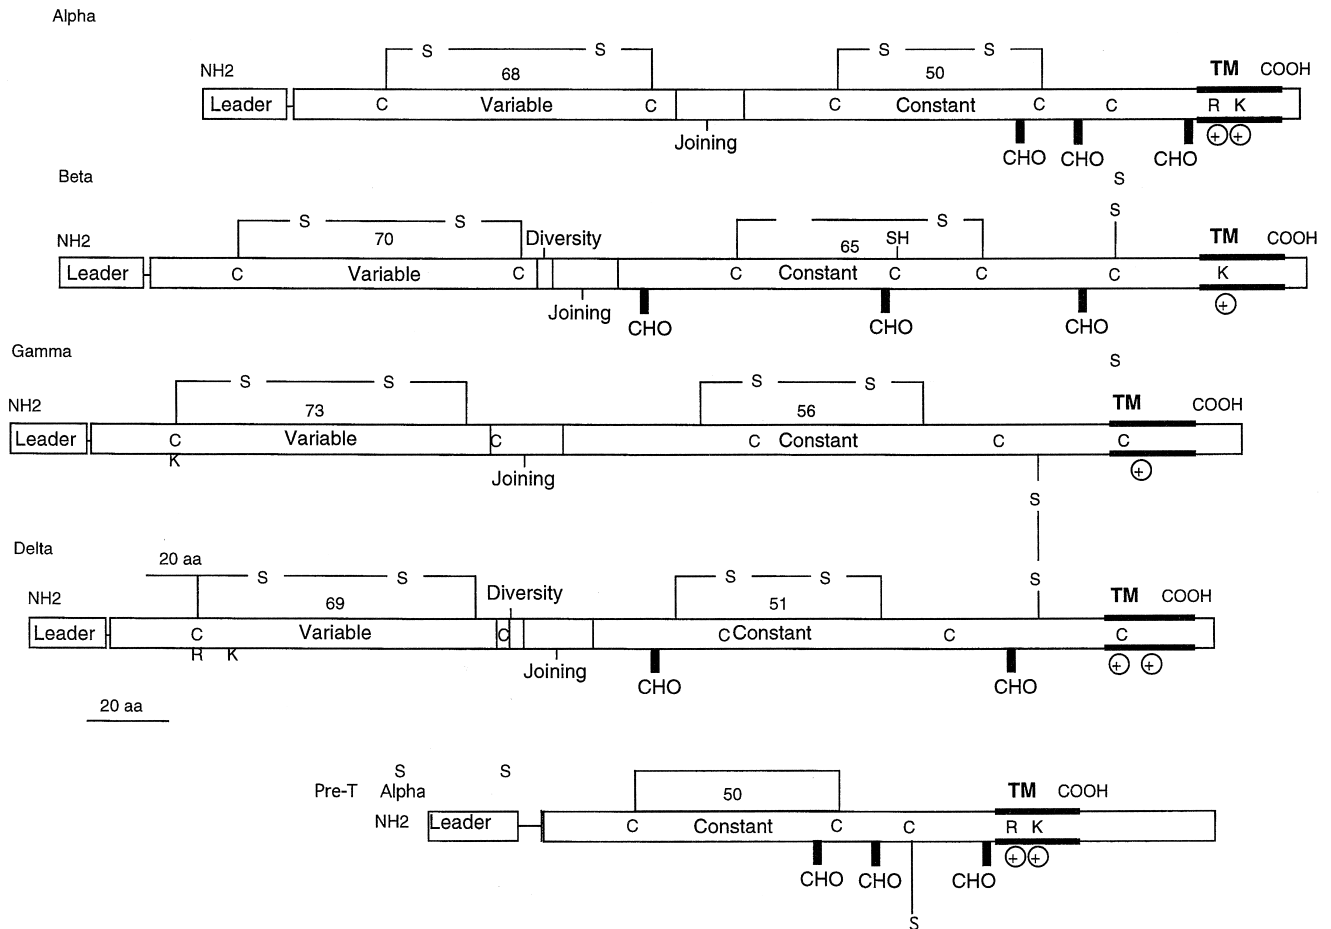
As shown in Figure 10.1, all TCR polypeptides have a similar primary structure, with distinct variable (V), diversity (D) in the case of TCR β and δ, joining (J), and constant (C) regions exactly analogous to their Ig counterparts. They also share many of the amino acid residues thought to be important for the characteristic variable and constant domains of Igs (*34*). The C_β region is particularly homologous, sharing 40% of its amino acid sequences with C_K and C_λ. The TCR polypeptides all contain a single C region domain (versus up to four for Igs) followed by a connecting peptide. These usually contain the cysteine for the disulfide linkage that joins the two chains of the heterodimer (some human TCR $\gamma\delta$ isoforms lack this cysteine and consequently are not disulfide-linked; ref. [35]). N-linked glycosylation sites vary from two to four for each polypeptide, with no indications of O-linked sugar addition. C-terminal to the connecting peptide sequences are the hydrophobic transmembrane regions. These have no similarity to those of the *IgH* genes, but instead have one (TCRβ and γ) or two (TCRα and δ) positively charged residues. As discussed later, these charged residues are critical for the association of the ligand binding TCR polypeptides with the CD3


FIGURE 10.1 Structural features of T cell receptors and pre-T α polypeptides. Leader (L), variable (V), diversity (D), joining (J), and constant region (C) gene segments are indicated. TM and bold horizontal lines delineate the putative transmembrane regions; CHO indicates potential carbohydrate addition sites; C and S refer to cystein residues that form interchain and intrachain disulfide bonds; R and K indicate the positively charged amino acids (arginine and lysine, respectively) that are found in the transmembrane regions.

signaling polypeptides. This is important because the TCR polypeptides themselves have very short cytoplasmic regions with no known role in signaling.

A more recent member of the TCR polypeptide family is the pre-T α chain, which serves as a chaperone for TCRβ in early thymocytes, similar to the role of λ5 in pre-B cells. It was first identified and cloned by von Boehmer and colleagues (*36*,37). It has an interesting structure that consists of a single Ig constant region-like domain followed by a cysteine-containing connecting peptide, a transmembrane region containing two charged residues—an arginine and a lysine spaced identically to the TCRα transmembrane region. The cysteine in the connecting peptide is presumably what allows heterodimer formation with TCRβ, and the similarity to TCRα in the transmembrane region is most likely to accommodate the CD3 polypeptides. In both the mouse and humans, the cytoplasmic tail is much longer than any of the TCR chains (37 and 120 amino acids, respectively) and the murine sequence con-

tains two likely phosphorylation sites and sequences homologous to an SH3 domain binding region. These are not present in the human sequence, however, and so their functional significance is questionable (37). Thus, the pre–Tα molecule could function as signaling intermediate independent of the CD3 polypeptides, and it has recently been shown that at least one CD3 component ($\delta\varepsilon$, discussed later) is not required for it to function normally in early thymocyte differentiation (*38*).

CD3 POLYPEPTIDES

Immunoprecipitation of the human TCR with anti-idiotypic antibodies after solubilization with the nonionic detergent, noniodet P-40 (NP-40), initially revealed only the α- and β-chain heterodimer. However, the use of other detergents, such as digitonin or Triton-X100, revealed four other proteins (as reviewed in (39,*40*,41). These are

known as the CD3γ, δ, ε, and ζ. γ and δ form distinct heterodimers with ε within the TCR/CD3 complex ($\gamma\varepsilon$ and $\delta\varepsilon$), and ζ usually occurs as a disulfide-linked homodimer. In mouse T cells, NP-40 does not dissociate TCR heterodimers from CD3 molecules *(42,43)*. In some cases, the ζ-chain can be part of a heterodimer in at least two forms. In mouse T cells, the ζ-chain can disulfide bond with a minor variant called the η (eta) chain *(44,45)*. This latter chain is an alternate splicing variant of the ζ-chain gene *(46)*. This alternatively spliced species of the ζ-chain is not found in significant quantities in human T cells *(47)*. The second type of ζ-chain containing heterodimer contains the γ-chain associated with the $F_c\varepsilon RI$ ($F_c\varepsilon RI$ γ) and $F_c\gamma RIII$ (CD16) receptors *(48)*. These CD3 subunits, in their various forms, are an integral part of TCR-mediated T cell recognition because only they possess the immunoreceptor tyrosine-based activation motifs (ITAMs) that are necessary for cellular activation when the TCR engages ligand.

Characterization and Structural Features of the CD3 Polypeptides

Figure 10.2 illustrates the principal structural features of the CD3 γ-, δ-, ε-, and ζ- polypeptides as derived from gene cloning and sequencing (as reviewed in refs *40,49*) and more recently by protein crystal structures of the extracellular domains of γ, δ, and ε *(50–52,53)*. The extracellular
FIGURE 10.2 Structural features of the CD3 molecules. As in Figure 10.1, transmembrane regions (TM), carbohydrate addition sites (CHO), and cysteine residues (C) are indicated. In addition, negatively charged transmembrane residues (D for aspartic acid and E for glutamic acid) and putative phosphorylation sites are shown.

domains of the γ-, δ-, and ε-chains show a significant degree of similarity to one another. These domains retain the cysteines that have been shown to form intrachain disulfide bonds, and each consists of a single Ig superfamily domain. The spacing of the cysteines in these domains produces a compact Ig-fold, similar to a constant region domain. The γ and δ subunits form distinct heterodimers with ε via highly conserved residues at the dimerizing interface (50–52,*53*). The connecting peptides of the CD3 γ-, δ-, and ε-chains all contain highly conserved, closely spaced cysteines just before the membrane-spanning regions. These residues are likely candidates for the formation of intrachain disulfide bonds and appear to play a role in the assembly of the CD3 and TCR polypeptides *(50,54)*. The extracellular domain of the ζ-chain consists of only nine amino acids and contains the only cysteine, which is responsible for the disulfide linkage of the $\zeta\zeta$ homodimer or the $\zeta F_c\varepsilon RI\gamma$ heterodimer. Each of the γ-, δ-, ε-, and ζ-polypeptides contain a conserved, negatively charged amino acids in their transmembrane region complementary to the positive charges seen in the TCR TM regions (55,*56,57,58*).

The cytoplasmic regions of the γ-, δ-, ε-, and ζ-chains are the intracellular signaling "domains" of the TCR heterodimer. Each of these molecules contains one or more amino acid sequence motifs that can mediate cellular activation *(59)*. The intracellular sequences responsible for this activation are contained within an 18 amino acid conserved ITAM motif (60) with the sequence $X_2YX_2L/IX_7YX_2L/I$. Both of the tyrosines in this motif are absolutely required to mediate signal transduction because mutation of either completely prevents the mobilization of free Ca^{++} or cytolytic activity *(61)*. This sequence occurs three times in the ζ-chain, and once in each of the CD3 γ-, δ-, ε-, and $F_c\varepsilon RI$ γ-chains. There are also pairs of tyrosines present in the cytoplasmic domains of the γ-, δ-, ε-, and ζ-chains. This sequence motif is also present in the mβ-1 and B29 chains associated with the (Ig) β-cell receptor and in the $F_c\varepsilon RI$ β-chain, but there are many more *(9)* in TCR/CD3 than in any other receptors that use ITAMS. The tyrosines in these cytoplasmic sequences are substrates for the tyrosine phosphorylation that is one of earliest steps in T cell signaling *(59)* and is thought to occur aberrantly in nonproductive T cell responses (e.g., antagonism, discussed later). Serine phosphorylation of the CD3γ also occurs upon antigen or mitogenic stimulation of T cells *(62)* and may play a role in T cell activation as well.

Assembly and Organization of the TCR/CD3 Complex

The assembly of newly formed TCR α- and β-chains with the CD3 γ-, δ-, ε-, and ζ-chains and their intracellular fate have been studied in detail (39,*40,*41,*61*,63). Early

studies have focused on mutant hybridoma lines, which fail to express TCR on their cell surface and on transfection studies using cDNA for the different chains in the receptor; but recently, Wucherpfennig and colleagues have developed an elegant *in vitro* translation and assembly system that has clarified a number of important issues (55,54).

Experiments in a nonlymphoid cell system *(64)* have shown that TCRα can assemble with CD3 δ and ε but not CD3 γ and ζ. In contrast, the TCR β-chain can assemble with any of the CD3 chains except the ζ-chain. When the ζ-chain was transfected with either α- or β-chain genes, or any of the three CD3 chains, no pairwise interaction occurred. Only when all six cDNA's were cotransfected was it shown that the ζ-chain could be coprecipitated with the other chains *(64)*. Based on these data, a model has been proposed that suggests that TCRα- pairs with CD3 δ- and ε-chains and that TCRβ-pairs with the CD3 γ- and ε-chains in the completed molecule. The ζ-chain is thought to join the TCR and other CD3 polypeptides in that last stage of assembly.

Pulse-chase experiments have shown that all six chains are assembled in the ER, transported to the Golgi apparatus, and then transferred to the plasma membrane. It also appears that the amount of ζ-chain is rate limiting, as it is synthesized at only 10% the level of the other chains. This results in the vast majority of newly synthesized α-, β-, or CD3 components being degraded within four hours of their synthesis. The remaining nondegraded chains are long lived due to the formation of complete TCR/CD3 complexes with the limiting ζ-chain *(65)*. TCR/CD3 lacking CD3 ζ-chains migrate through the ER and Golgi intact but then are transported to and degraded in the lysosomes and degraded. The immunological significance of this pre-Golgi degradation pathway is most evident in $CD4^+CD8^+$ thymocytes, where, despite high levels of synthesis of both mRNA and protein for all the TCR, CD3, and ζ-chains, surface expression is relatively low. The TCR chains in immature thymocytes seem to be selectively degraded *(65)*. Thus posttranslation regulation appears to be an important means of controlling the cell surface expression of TCR heterodimers.

The TCR and CD3 γ-, δ-, and ε-chains contain ER retention signals *(65,66)*. If the γ and δ signals are removed, then the chains are transported through the Golgi and rapidly degraded in the lysosomes. In contrast, removal of the CD3 ε ER retention signal allows this chain and any associated chains to be transported to the cell surface. Thus, association of the TCR and other CD3 chains with ε renders their ER retention signals inoperative. However, the ε ER retention signal remains functional. This prevents the surface expression of partial complex intermediaries until CD3 ζ is incorporated into the complex, which then masks the ε ER retention signal and allows the transport of mature complexes to the cell surface.
FIGURE 10.3 A model of the $\alpha\beta$ T cell receptor (TCR)–CD3 complex. This shows the approximate positions of the $\alpha\beta$ TCR chains and the CD3α, δ, ε, and ζ chains based on the membrane reconstitution and mutagenesis experiments of Call and Wucherpfennig (55). More recent experiments suggest that the CD3 polypeptides may be somewhat more clustered on the side of the TCR heterodimer (299).

The overall stoichiometry of the $\alpha\beta$ TCR/CD3 complex is controversial. The work of Call and Wucherpfennig (55) has shown the relationships between different CD3 dimers ($\gamma\varepsilon$, $\delta\varepsilon$, and $\zeta\zeta$) and a single TCR $\alpha\beta$ heterodimer (as shown in Figure 10.3). Using mutagenesis, they found very specific interactions based on the positive charges in each TCR transmembrane domain with complementary negative charges in the transmembrane domains of the different CD3 components. The two positively charged residues of TCRα mediate interactions with the negatively charged residues of the of CD3$\delta\varepsilon$ and CD3$\zeta\zeta$ dimers, while the single positively charged residue of TCRβ mediate interactions with the negatively charged resiues of CD3$\gamma\varepsilon$. In addition, their data suggest a highly ordered assembly process as they found that the TCR/CD3$\delta\varepsilon$ association facilitates the assembly of CD3$\gamma\varepsilon$ into the complex and that the association of the TCR and CD3 heterodimers was a prerequisite for incorporation of CD3$\zeta\zeta$ into the complex. Importantly, the data show that there is only one TCR heterodimer per nascent TCR/CD3 complex in their in vitro expression system.

In contrast, a number of groups have found evidence that there can be two TCR heterodimers in a given TCR/CD3 cluster on T cell surfaces. In particular, Ter-horst and colleagues (as reviewed in ref. *[40]*) showed that in a T–T hybridoma, a monoclonal antibody against one TCR$\alpha\beta$ pair could comodulate a second $\alpha\beta$ heterodimer. In addition, sucrose gradient centrifugation of TCR/CD3 showed a predicted molecular weight of 300 kDa, more than 100 kDa larger than expected from a minimal δ subunit complex (α,β,γ,δ,ε_2,ζ_2) *(67)*. Another study suggesting that there are least two TCRs in a given CD3 complex is Scatchard analysis indicating that the number of CD3ε molecules on a T cell surface equals the number of $\alpha\beta$ TCRs *(68,69)*. Finally, there is the work of Fernandez-Miguel et al. (70), who showed that in T cells that have two transgenic TCRβ chains, antibodies to one Vβ can immunoprecipitate the other. It was also found that they are often close enough to allow fluorescence energy transfer, meaning that the two TCRβs in a cluster are within approximately 50 Angstroms of each other (70). Interestingly, it appears that the TCR complexes with CD3 either have CD3 γ or CD3δ, but not both, and these two receptor types are expressed in different ratios in different cells. These data may not be irreconcilable; because while the initial TCR/CD3 assembly may involve only one TCR, these may dimerize or multimerize later on the cell surface (50,71).

The composition of TCR/CD3 complexes on $\gamma\delta$ T cells is distinct from that of $\alpha\beta$ T cells and changes with the activation state of the cell. Biochemical analysis showed that most murine $\gamma\delta$ TCRs contain only CD3$\gamma\varepsilon$ dimers. Interestingly, a differentially glycosylated form of CD3γ was found to associate with $\gamma\delta$ TCRs dependent on the activation state of the cells (72). In addition, while C3$\zeta\zeta$ is incorporated into the complexes of naïve cells, activation results in the expression and incorporation of F$_c$$\varepsilon$R1 γ into the $\gamma\delta$TCR complex (72). Using quantitative immunofluorescence, Hayes and Love have suggested a model of murine $\gamma\delta$TCR stoichiometry in which there are two CD3$\gamma\varepsilon$ dimers, as well as one CD3ζ dimer in each TCR complex (73). This strongly suggests that signal transduction through the TCR will occur differently in $\gamma\delta$ versus $\alpha\beta$ T cells.

TCR GENES

As shown in Figure 10.4, TCR gene segments are organized similarly to those of Igs, and the same recombination machinery is responsible for joining separate V and D segments to a particular J and C. This was initially indicated by the fact that the characteristic seven and nine nucleotide conserved sequences adjacent to the V, D, and J regions with the 12 or 23 nucleotide spacing between them, first described for Ig genes, are also present in TCRs (74). The most conclusive evidence of this common rearrangement mechanism is that both a naturally occurring recombination-deficient mouse strain (severe combined immune deficiency, SCID; ref. 75) and mice engineered to
FIGURE 10.4 T cell receptor gene organization in mice and humans. Schematic of V, D, J, and C elements of the T cell receptor genes. Transcriptional orientation is from left to right, except where noted. The overall size of each locus is as indicated to the right. **E** designates enhancer elements, and **S** are silencer elements.

lack recombinase activating genes (RAG) 1 *(76)* or 2 *(77)* are unable to rearrange either TCR or Ig gene segments properly. Many of the other molecules involved in Ig gene rearrangement serve the same function in TCRs as well *(78)*. As with Igs, if the V region and J region gene segments are in the same transcriptional orientation, the intervening DNA is deleted during recombination. DNA circles of such material can be observed in the thymus *(79,80)*, the principal site of TCR recombination (see below). In the case of TCRβ and TCRδ, there is a single V region 3′ to the C in the opposite transcriptional orientation to J and C. Thus rearrangement to these gene segments occurs via an inversion. Variable points of joining are seen along the V, D, and J gene segments as well as random nucleotide addition (N regions) in postnatal TCRs. The addition of several nucleotides in an inverted repeat pattern, referred to a P element insertion, at the V–J junction of the TCRγ chains has also been observed *(81)*.

Organization of the TCR α/δ Locus

In humans and in mice there is a single α-chain C-region gene that is composed of four exons encoding: 1) the constant region domain, 2) 16 amino acids, including the cysteine that forms the interchain disulfide bond, 3) the transmembrane and intracytoplasmic domains, and 4) the 3′ untranslated region (Figure 10.4). The entire α/δ locus spans about 1.1 MB in both mice and humans. There are 50 different J-region gene segments upstream of the C-region in the murine locus. At least eight of these J-regions are nonfunctional because of in-frame stop codons or rearrangement and splicing signals that are likely to be de-

fective. A similar number of α-chain J-regions are present in the human locus. This very large number of J-regions compared to the Ig loci may indicate that the functional diversity contributed by the J segment of the TCR (which constitutes a major portion of the CDR3 loop) makes an important contribution to antigen recognition (discussed later).

Both the murine and human Cδ, Jδ, and two Dδ gene segments are located between the Vα and Jα gene segments. In the murine system there are two Jδ and two Dδ gene segments on the 5′ side of Cδ, and the Cδ gene is approximately 75 kb upstream of the Cα gene, but only approximately 8 kb upstream of the most 5′ known Jα gene segments. The human organization is similar, with three Dα gene segments and two Jδ. Surprisingly, in both species, all of the D elements can be used in one rearranged gene rather than alternating as is the case with TCRβ or IgH. That is, in mice one frequently finds Vδ D$_1$, D$_2$, Jδ rearrangements *(82)*, and in humans Vδ, D$_1$, D$_2$, D$_3$, Jδ *(83)*. This greatly increases the junctional or CDR3 diversity that is available, especially because of the potential for N-region addition in between each gene segment. This property makes TCRδ the most diverse of any of the antigens receptors known, with approximately 10^{12} to 10^{13} different amino acid sequences in a relatively small (10 to 15aa) region *(82)*. The implications for this and comparisons with other antigen receptor genes are discussed later.

The location of Dδ, Jδ, and Cδ genes between Vα and Jα gene segments suggests that TCR δ and α could share the same pool of V gene segments. Although there is some overlap in V gene usage, in the murine system, four of the commonly used Vδ genes (Vδ1, Vδ2, Vδ4, Vδ5) are very

different than known Vα sequences, and they have not been found to associate with Cα (84). The other four Vδ gene families overlap with or are identical to Vα subfamilies (Vδ3, Vδ6, Vδ7, Vδ8 with Vα6, Vα7, Vα4, Vα11, respectively).

The mechanisms that account for the preferential usage of certain gene segments to produce δ versus α chain are not known. While some Vδ genes are located closer to the Dδ and Jδ fragments than Vα genes (e.g., Vδ1), other Vδs (e.g., Vδ6) are rarely deleted by Vα Jα rearrangements and thus seem likely to be located 5′ of many Vα gene segments.

One of the Vδ gene segments, Vδ5, is located approximately 2.5 kb to the 3′ of Cδ in the opposite transcriptional orientation and rearranges by inversion. Despite its close proximity to Dδ Jδ gene segments, Vδ5 is not frequently found in fetal $\gamma\delta$ T cells. Instead, the Vδ5→DJδ rearrangement predominates in adult $\gamma\delta$ T cells.

An implicit characteristic of the α/δ gene locus is that a rearrangement of Vα to Jα deletes the entire D-J-C core of the δ-chain locus. In many $\alpha\beta$ T cells, the α-chain locus is rearranged on both chromosomes and thus no TCR δ could be made. In most cases this is due to Vα →Jα rearrangement, but evidence suggesting an intermediate step in the deletion of TCRδ has been reported (85). This involves rearrangements of an element termed T early alpha (*TEA*) to a pseudo-Jα 3′ of Cδ. The rearrangement of TEA to this psuedo Jα would eliminate the δ-chain locus in $\alpha\beta$ T cells. Gene targeting of the TEA element resulted in normal levels of $\alpha\beta$ and $\gamma\delta$ T cells but usage of the most Jαs was severely restricted (86), suggesting that its function is to govern the accessibility of the most proximal 5′ Jαs for recombination.

Organization of the TCR β Locus

The entire human 685 kb β-chain gene locus was originally sequenced by Hood and coworkers *(87)* (Figure 10.5). One interesting feature is the tandem nature of J_β-C_β in the TCRβ locus. This arrangement is preserved in all higher vertebrate species that have been characterized thus far (mouse, human, chicken, frog). The two C_β coding sequences are identical in the mouse and nearly so in humans and other species. Thus it is unlikely that they represent two functionally distinct forms of C_β. However, the J_β clusters have relatively unique sequences, and thus this may be a mechanism for increasing the number of J_β gene segments. Together with the large number of Jα gene segments, there is far more combinatorial diversity (Jα × Jβ = 50 × 12 = 600) provided by J regions in $\alpha\beta$ TCR's than in Igs.

Most of the V-regions are located upstream of the joining and constant regions, and in the same transcriptional orientation as the D and J gene element and rearrange to DβJβ gene via deletion. Similar to the case of Vδ5, a single Vβ gene, Vβ14 is located 3′ to C-regions and in the

opposite transcriptional orientation, thus rearrangements involving Vβ14 occur via inversion.

In the NZW strain of mouse, there is a deletion in the β chain locus that spans from Cβ1, up to and including the Jβ 2 cluster *(88)*. In SJL, C57BR, and C57L mice, there is a large deletion (89) in the V-region locus from Vδ5-Vβ9. These mice also express a V gene, Vβ17, that is not expressed in other strains of mice. Deletion of about half of the V genes (in SJL, C57BR, and C57L mice) does not seem to have any particular effect on the ability of these mice to mount immune responses, whereas mice which have deleted the J_β2 cluster show impaired responses (90).

Organization of the TCR γ Locus

The organization of the mouse and human γ-chain loci are shown in Figure 10.4. The human γ genes span about 150 kb (81) and are organized in a fashion similar to that of the β chain locus with two JγCγ regions. The mouse locus is much smaller, encompassing only about 36 κb (91). There is more than one commonly used nomenclature used to describe the γ chain genes (81,92,93,*94*). Here, we use that of Lefranc and Rabbitts (95) and Tonegawa and colleagues (81)—for the human and mouse γ chains respectively. An array of Vγs, in which at least six of the V-regions are pseudogenes, is located 5′ to these JγCγ clusters, and each of the V genes is potentially capable of rearranging to any of the five J-regions. The sequences of the two human Cγ regions are very similar overall and only differ significantly in the second exon. In Cγ2, this exon is duplicated two to three times, and the cysteine that forms the interchain disulfide bond is absent. Thus, Cγ2 bearing human T cells have an extra large γ-chain (55,000 MW) that is not disulfide bonded to its δ-chain partner.

The organization of the murine γ chain genes is very different than that of the human genes in that there are three separate rearranging loci that span about 205kb (96,97). Of four murine Cγ genes, Cγ3 is apparently a pseudogene in BALB/c mice, and the Jγ3 Cγ3 region is deleted in several mouse strains including C57 Bl/10. Cγ1 and Cγ2 are very similar in coding sequences. The major differences between these two genes is in the 5 amino acid deletion in the Cγ2 gene that is located in the C II exon at the amino acid terminal of the cysteine residue used for the disulfide formation with the δ chain. The Cγ4 gene differs significantly in sequences from the other Cγ genes (in 66% overall amino acid identity). In addition, the Cγ4 sequences contain a 17 amino acid insertion (compared to Cγ1) in the C II exon located at similar position to the 5 amino acid deletions in the Cγ2 gene (G. Kershard, S.M. Hedrick, unpublished results). Each Cγ gene is associated with a single Jγ gene segment. The sequences of Jγ1 and Jγ2 are identical at the amino acid level, whereas Jγ4 differs from Jγ1 and Jγ2 at 9 out of 19 amino acid residues.

The murine Vγ genes usually rearrange to the Jγ Cγ gene that is most proximal and in the same transcription orientation. Thus Vγ1 rearranges to Jγ4, Vγ1 to Jγ2 and Vγ4, Vγ5, Vγ6, and Vγ7 to Jγ1. Interestingly, some Vγ genes are rearranged and expressed preferentially during $\gamma\delta$ T cell ontogeny and in different adult tissues as well (97). The reasons for this are not understood at this time.

Control of Transcription and Rearrangement

It has become increasingly apparent that transcriptional accessibility and rearrangement of TCR and Ig loci are closely linked, following the early work of Alt and colleagues (98). Factors governing accessibility and rearrangement include histone methylation (*99,100,*101,102), DNA methylation, and the presence of enhancer and specific promoter elements (103). Even specific variations in the recombination signal sequence (RSS) have been shown to elicit specific biases in V (D)- J joining (78). With respect to enhancer elements in the TCR loci, these were first identified in the TCRβ locus, 3' of Cβ2 (104,105) and subsequently for the other TCR loci as well (103), as indicated in Figure 10.4. These TCR enhancers all share sequence similarities with each other. Some of the transcriptional factors that bind to the TCR genes are also found to regulate Ig gene expressions. It has been shown that TCRα enhancer (Eα) is not only important for normal rearrangement and expression for the α chain locus, but is also required for the normal expression level of mature TCRδ transcripts *(106)*. Also interesting is the work of Lauzurica and Krangel *(107,108)*, who have shown that a human TCR δ enhancer-containing minilocus in transgenic mice is able to rearrange equally well in $\alpha\beta$ T cells as in $\alpha\delta$ T cells, but that an Eα-containing construct was only active in $\alpha\beta$ lineage T cells. Similar to Ig genes, promoter sequences are located 5' to the V gene segments. Although, D$\rightarrow$J$_\beta$ rearrangement and transcription occur fairly often in B cells, and in B cell tumors *(109)*, V$_\beta$ rearrangement and transcription appears highly specific to T cells. In addition to enhancers, there also appear to be "silencer" sequences 3' of Cα (110,111) and in the Cγ1 locus (112). It has been suggested that these "repressor sites" could turn off the expression of either of these genes, influencing T cell differentiation toward either the $\alpha\beta$ or the $\gamma\delta$ T cell lineage.

The murine TCR Cγ1 gene cluster comprises four closely linked Vγ gene segments, in the order Vγ7, 4, 6, and 5, which rearrange to a single common downstream J gene segment, Jγ1 (Figure 10.4). In early fetal thymocytes, rearrangements of Vγ5 and Vγ6 genes predominate, and the resulting Vγ3$^+$ and Vg4$^+$ cells migrate to the skin or reproductive tissue, respectively. Later in ontogeny, Vγ4 and Vγ7 rearrangements predominate, and cells expressing these V regions migrate from the adult thymus to the secondary lymphoid organs (96,97). At least two *cis*-acting,

enhancer/LCR elements are present in the Cγ1 cluster. One is a T cell–specific transcriptional enhancer, 3γEγ, located 3 kb downstream of the Cγ1 gene segment (113). A second element, has, was found between the Vγ7 and Vγ4 genes, based on Dnase I hypersensitivity (114). Similar enhancers have also been found to be associated with the Cγ2 and Cγ3 genes (91). Experiments suggest that simultaneous deletion of has and 3γEγ in Cγ1 cluster severely diminishes TCRγ transcription, selectively impairs development of $\gamma\delta$ thymocyte subsets, but only modestly reduces TCRγ gene rearrangement, while deletion of each element separately has little effect (115). In contrast to these results in thymocytes, deletion of has alone reduces transcription of one Vγ gene, specifically in peripheral $\gamma\delta$ T cells. Thus, the two elements not only exhibit functional redundancy in thymocytes but also have unique functions in other settings.

Allelic Exclusion

In Igs, normally only one allele of the heavy chain locus and one of the light chain alleles is productively rearranged and expressed, a phenomenon termed *allelic exclusion*. With respect to $\alpha\beta$ TCR expression, while TCRβ exhibits allelic exclusion (116), TCRα seems much less constrained (*117,*118), and many mature T cells express two functional TCRα chains. As the chances of forming an in-frame joint with any antigen receptor is only one in three, the probability that a T cell would have two productively rearranged TCRαs is only $1/3 \times 1/3 = 1/9$ or 11%. However, even when this happens, the two TCRα chains may not form heterodimers equally well with the single TCRβ that is expressed; and, thus, only one heterodimer may be expressed.

There also appears to be an important role for the pre-TCR heterodimer (e.g., pre–Tα:TCRβ) in blocking further TCRβ rearrangement and thus ensuring allelic exclusion at that locus (119,120). In particular, pre–Tα deficient mice had a significant increase in the number of cells with two productive TCRβ rearrangements, compared with wild-type mice (119).

TCR Diversity

Although the basic organization and V(D)J recombination machinery are shared between TCR loci and Igs, there are a number of striking differences. One of these is somatic hypermutation. In antibodies, this form of mutation typically raises the affinities of antigen-specific Igs several order of magnitude, typically from the micromolar (10^{-6}M) to the nanomolar (10^{-9}M) range (121,122). We now know that most cell surface receptors that bind ligands on other cell surfaces, including TCRs, typically have affinities in the micromolar range (see later section), but that they compensate for this relatively low affinity by engaging multiple

receptors simultaneously (e.g., increasing the valency) and by functioning in a confined, largely two-dimensional volume (e.g., between two cells). Cells employing such receptors require weak but highly specific interactions so that they can disengage quickly (123,*124*). The rapid off-rates seen with TCRs (see later section) may even amplify the effects of small numbers of ligands (125,126).

There has also been no enduring evidence for a naturally secreted form of either an $\alpha\beta$ or $\gamma\delta$ TCR. Here again, it can be argued that such a molecule would have no obvious use, as the affinities are too low to be very useful in solution. Thus, for most TCRs, the concentration of protein would have to be extremely high in order to achieve an effect similar to soluble antibodies (in the milligram/mL range).

A third mechanism seen in antibodies but not TCRs is C_H switching, which allows different Ig isotypes to maintain a given V region specificity and associate it with different constant regions that have different properties in solution (e.g., complement fixation, basophil binding, etc.). As there is no secreted form of the TCR, this feature would also lack any obvious utility.

Where TCRs are equal—and in fact generally superior—to Igs is in the sheer number of possible receptors that can be generated through recombination alone. Table 10.1 summarizes the potential V region diversity that TCRs are capable of when the number of V region gene segments is multiplied by D, J, and N region diversity. It can be seen from this table that while the V region number is generally lower in murine TCRs, particularly TCR δ and TCR γ, this is more than compensated for by the degree of junctional diversity (where V and J or V, D, and J come together)

and chain combinations, such that overall TCRs have orders of magnitude greater potential diversity than Igs. This junctional region corresponds to complementarity-determining region 3 (CDR3) as originally defined by Kabat and Wu for Igs *(127)*. With respect to $\alpha\beta$ TCRs, the concentration of diversity in this region (in both chains) can be explained by the key role that these sequences play in recognizing diverse peptides in MHC molecules (see later section), as supported by mutagenesis and structural studies. For $\gamma\delta$ TCRs and Igs, however, the diversity is almost all in just one chain (TCRδ and IgH, respectively) and the implications of this are discussed later.

The CDR3 Length Distributions of $\gamma\delta$ TCRs Are More Similar to Those of Ig than to Those of $\alpha\beta$ TCRs

Because CDR regions are loops between different β strands of an Ig or TCR V region (see later section), the configurations they adopt are generally very sensitive to their length, such that a difference of even one amino acid may produce a significant change in the overall structure *(3,128)*. A comparison of CDR3 length distributions between the different TCRs and Igs (Figure 10.5) (129,*130*) showed that those of TCR α and β have a very constrained distribution of lengths and that these are nearly identical in size. These length constraints may reflect a requirement for both the α and β chains of TCRs to contact both the MHC molecules and bound peptides on the same plane, as borne out by structural studies (see later section). In contrast, the CDR3s of Ig heavy chains are long and variable,

▶ **TABLE 10.1 Sequence Diversity in T-cell Receptor and Immunoglobulin Genes**

	Immunoglobulin		**TCR α/β**		**TCR γ/δ**	
	H	**κ**	**α**	**β**	**γ**	**δ**
Variable segments	250–1,000	250	100	25	7	10

Joining segments	4	4	50	12	2	2
Variable region combinations	62,500–250,000		2,500		70	
Junctional combinations	$\sim 10^{11}$		$\sim 10^{15}$		$\sim 10^{18}$	

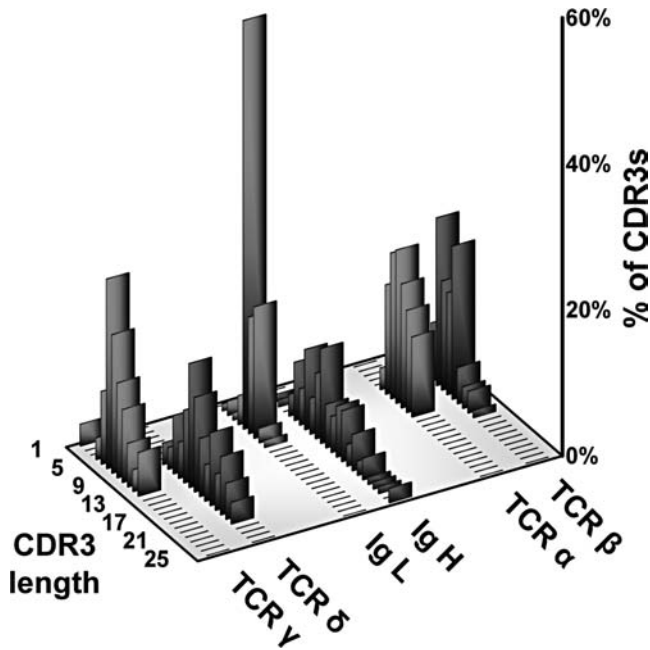
Calculated potential amino acid sequence diversity in TCR and immunoglobulin genes without allowance for somatic mutation. The approximate number of V gene segments are listed for the four TCR polypeptides and contrasted with immunoglobulin heavy and light chains. CDR1 and CDR2 are encoded within the V gene segments. The pairing of random V regions generates the combinatorial diversity listed as "variable region combinations." Because there are fewer TCR V gene segments than immunoglobulin V gene segments, the combinatorial diversity is lower in TCRs than in immunoglobulins. Estimates for the number of unique sequences possible within the junctional region are contrasted for TCRs and immunoglobulins. Amino acids within CDR3 are encoded almost entirely within the D and/or J region gene segments. (The last few amino acids encoded by a TCR V gene segment can contribute to diversity within the TCR CDR3-equivalent region, but the effects of these residues on junctional diversity are not included in these calculations.) The mechanisms for generation of diversity within the junctional region that are used for this calculation include usage of different D and J gene segments. N region addition up to six nucleotides at each junction, variability in the 3′ joining position in V and J gene segments, and translation of D region in different reading frames. Numbers are corrected for out-of-frame joining codon redundancy and N-region mimicry of germ-line sequences. Modified from Elliott JF, Rock EP, Patten PA, et al. The adult T-cell receptor delta-chain is diverse and distinct from that of fetal thymocytes. *Nature*. 1988;331(6157):627–631.


FIGURE 10.5 CDR3 length analysis of T cell receptor (TCR) polypeptides versus immunoglobulin (Ig) heavy and light chains. These data, modified from Rock et al. (129), show that whereas TCR α and β CDR3 regions are relatively uniform with respect to each other, the other antigen receptor pairs show a marked asymmetry. Specifically, both Ig light chains (κ and λ) show very short CDR3s, as do TCR γ chains. In contrast, both IgH and TCR δ TCRs are quite heterogeneous and tend to be longer. These data suggests that $\gamma\delta$ TCRs have a more antibodylike structure and binding properties. This has been borne out by subsequent analysis (see text).

while those of Ig light chains are short and constrained. This may reflect the fact that Igs recognize both very small molecules (e.g., haptens) as well as very large ones (e.g., proteins). Surprisingly, $\gamma\delta$ TCR CDR3 length distributions are similar to those of Igs in that the CDR3 lengths of TCR δ chains are long and variable, while those of the TCR γ chains are short and constrained. Thus, on the basis of this measure of ligand recognition, one might expect $\gamma\delta$ TCRs to be more similar to Igs than to $\alpha\beta$ TCRs. This has been validated in subsequent biochemical and structural studies (see later sections).

Chromosomal Translocations and Disease

The chromosomal locations of the different TCR loci have been delineated in both mouse and humans, and the results are summarized in Table 10.2. One significant factor in cancers of hematopoietic cells are chromosomal translocations that result in the activation of genes normally turned off or the inactivation of genes that are normally turned on. Thus, B or T lymphocyte neoplasia is frequently associated with inter- or intra-chromosomal rearrangements of Ig or TCR loci, and in some cases both *(131,132).*

TABLE 10.2 Chromosomal Locations of T-cell Receptor, Immunoglobulin, and Related Loci in Mouse and Human		
	Mouse Chromosome	*Human Chromosome*
TCR-α	14	14(q11–q12)
TCR-δ	14	14(q11–q12)
IgH	12	14(qter)
TCR-β	6	7(q35)

Ig-λ	16	22(q11.2)
MHC	17	6(p21)
Pre-Tα	17	6

Ig, immunoglobulin; IgH, heavy chain immunoglobulin; MHC, major histocompatibility complex; TCR, T-cell receptor.

These translocations seemed to be mediated by the V(D)J recombinase machinery, indicating the inherent danger and need for tight regulation of this pathway. Such rearrangements are particularly common in the α/δ locus, perhaps because this locus spans the longest developmental window in terms of gene expression, with TCRδ being the first and TCRα the last gene to rearrange during T cell ontogeny (as discussed in more detail later). In addition, the α/δ locus is in excess of 1 Mb in size, and this provides a larger target for rearrangement than either TCRβ or TCRγ. Interestingly, in humans, TCRα/δ is on the same chromosome as the IgH locus, and $V_H \rightarrow J_\alpha$ rearrangements (by inversion) have been observed in some human tumor material *(133,134)*. The functional significance of this is not known.

Particularly frequent is the chromosome 8–14 translocation (t(8;14) (q24;q11)) that joins the α/δ locus to the c-myc gene, analogous to the c-myc$\rightarrow$IgH translocation in many mouse myeloma tumors and in Burkitt's lymphomas in humans. In one cell line, a rearrangement occurred between the Jα-region coding sequences, and a region 3' of c-myc *(135)*. In both B and T cell malignancies, the translocation of c-myc into IgH or TCR α/β appears to increase the expression of c-myc and may be a major factor in the unregulated cell growth that characterizes cancerous cells. Other putative protooncogenes that have been found translocated into the TCR α/β locus are the LIM domain containing transcription factors Ttg-1 *(136)*, and Ttg-2 *(137,138)* which are involved in neural development; the helix-loop-helix proteins Lyl-1 *(139)* and Scl *(140)*, which are involved in early hematopoietic

development; and the homeobox gene Hox 11 *(141)*, which is normally active in the liver. How these particular translocations contribute to malignancy is unknown, but they presumably causes aberrations in gene expression that contribute to cell growth or escape from normal regulation. In T cell leukemia patients infected with the HTLV-I virus, there are large numbers of similar translocations, and here it is thought that HTLV-I itself is not directly leukemogenic, but acts by causing aberrant rearrangements in the T cells that it infects, some of which become malignant.

Another disorder that frequently associates with TCR and Ig locus translocation is ataxia telangiectasia (AT), an autosomal recessive disorder characterized by ataxia, vascular telangiectasis, immunodeficiency, increased incidence of neoplasia, and an increased sensitivity to ionizing radiation. Peripheral blood lymphocytes (PBL) from patients with AT have an especially high frequency of translocations involving chromosomes 7 and 14 *(142)*. These sites correspond to the TCR γ, β, and α loci, and the Ig heavy chain locus. Thus, it appears as though one of the characteristics of Ataxia Telangiectasia patients is a relatively error-prone rearrangement process that indiscriminately recombines genes that have the TCR and Ig rearrangement signals *(143)*.

THE STRUCTURE OF $\alpha\beta$ AND $\gamma\delta$ TCRs

As discussed earlier, the sequences of TCR polypeptides show many similarities to Igs, and thus it has long been suggested that both $\alpha\beta$ and $\gamma\delta$ heterodimers would be antibody-like in structure (23,24,*144*). The similarities between TCRs and Igs include the number and spacing of specific cysteine residues within domains, which in antibodies form intrachain disulfide bonds. Also conserved are many of the inter-and intra-domain contact residues, and, in addition, secondary structure predictions are largely consistent with an Ig-like "β barrel" structure. This consists of three to four antiparallel β strands on one side of the "barrel" facing a similar number on the other side, with a disulfide bridge (usually) connecting the two β "sheets" (sets of β strands in the same plane). All Ig variable and constant region domains have this structure, with slight variations in the number of β strands in variable region domains (by convention including V, D, and J sequences) compared with constant domains.

$\alpha\beta$ TCR Structure

Efforts to derive x-ray crystal structures of TCR heterodimers and fragments of heterodimers presented many technical hurdles (as summarized in [145]). One difficulty is that structure determination required engineering the molecules into a soluble form. A second problem is that many of the TCRs are heavily glycosylated, and it was nec-
FIGURE 10.6 Ribbon diagrams of the T cell receptor (TCR) structures. This shows the structures of the 2C$\alpha\beta$TCR (150) versus the G8$\gamma\delta$ TCR (153). The TCRβ and the TCRγ chains are in cyan, and the TCRα and γ chains are in vermillion. The CDRs of both are in yellow. The very long TCRδCDR3 in G8, which binds the T10/T22 ligands, is very apparent here but is shorter in most other $\gamma\delta$ TCRs. Note the different C region interactions with these TCRs and the deviations from the classic "β barrel" structure in both Cα and Cδ. The prominent Cβ loop to the left is also unusual and may mediate interactions with CD3 or other molecules on the T cell surface. (Figure courtesy of Dr. K. C. Garcia) (See color insert.)

essary to eliminate most or all of the carbohydrates on each chain to achieve high-quality crystals. An alternative is to express soluble TCRs in insect cells, where they have compact N-linked sugars, or in E. coli, where they are unglycosylated. The first successes in TCR crystallization come from the laboratory of Mariuzza and collaborators who solved the structure of first a Vβ Cβ polypeptide (146), and then a Vα fragment (147). In the following year, the first complete $\alpha\beta$ TCR structures were solved (*148*,149). The structure of the 2C TCR by Garcia and colleagues is shown in Figure 10.6 (from *[148]*). In general, as predicted from sequence homologies, these domains are all Ig-like, with the classical β-barrel structure in evidence in all three domains. At each end of the barrel in each V region-domain there are four loops between the β sheets, three of which form the CDRs of Igs, which are numbered in Figure 10.6. The fourth loop, between the D and E strands has been implicated in superantigen binding. The six CDR loops from the two variable domains form the antigen-binding surface in both Igs and TCRs. The major anomaly in terms of similarity of TCRs to Igs is the structure of the Cα (150). Cα consists of one half of the classical β-barrel—that is, one set (or "sheet") of β strands—while the rest of the partially truncated domain exhibits random coils. This type of structure is unprecedented in the Ig gene family. The functional significance of such a variant structure is unknown, but it has been suggested that this incompletely formed Ig-like domain may be responsible for the observed

lability of TCR α, and this may allow greater flexibility in the regulation of its expression. Another possible explanation is that this configuration is designed to accommodate one or more of the CD3 molecules.

The now large number of solved $\alpha\beta$ TCR structures can be compared to the two $\gamma\delta$ heterodimers (discussed in more detail later), and although these also resemble the Fab fragment of an antibody, there are several features that are unique to the $\alpha\beta$ molecules, which may be significant. These include: 1) In one structure (150), four out of seven N-linked sugars diffracted to high resolution, indicating that they are not free to move very much and thus are likely to play a structural role, particularly in Cα:Cβ interactions. This correlates with mutagenesis data indicating that certain Cα sugars cannot be eliminated without abolishing protein expression *(151)* and the disordered state of a Cα domain in the structure of a TCR lacking glycosylation (149). 2) There is significantly more contact between Vβ and Cβ and between Vα and Cα than in the equivalent regions of antibodies. 3) The geometry of the interaction of Vα and Vβ more closely resembles that of the C$_H$3 domains of antibodies than V$_H$V$_L$. 4) Between the CDR3 loops of Vα and Vβ, there is a pocket that can (and does in at least one case [150]) accommodate a large side chain from the peptide bound to an MHC.

$\gamma\delta$ TCR Structure

There are now two $\gamma\delta$ heterodimer structures: a $\gamma\delta$ TCR from a human T cell clone G115 (152), which can be activated by natural or synthetic pyrophosphomonoesters, and a $\gamma\delta$ TCR from the murine T cell clone G8 together with its ligand, the nonclassical MHC class I molecule T22 (153). The G8 structure is shown in Figure 10.6, alongside the 2C $\alpha\beta$ TCR. The structure of a single human Vδ3 domain also has been determined (154). The Vδ2 domain of the G115 structure is similar to the isolated Vδ3 domain, and the quaternary structure of G8 is similar to that of G115 (153).

The most distinctive feature of both the G115 and the G8 TCR, when compared with $\alpha\beta$ TCRs and Igs, is that the C domains "swing out" from under the V domains. This unusual shape is highlighted by both a small elbow angle of 110°, defined as the angle between the pseudo two-fold symmetry axes that relate V to V and C to C, and a small V-C inter-domain angle. This contrasts with an average of 149° for $\alpha\beta$ TCR structures (Adams and Garcia, unpublished communication). The small angle between the Vγ and Cγ domains shifts both Cδ and Cγ to one side. Moreover, the molecular surfaces of the constant domains are different than those of $\alpha\beta$TCRs with no clear similarities either in the shape or the nature of the CαCβ and CγCδ surfaces; there are only a few solvent-exposed residues that are conserved in both Cβ and Cγ domains as well. Thus, it is unclear where or how the extracellular domains of the

CD3 subunits interact with the extracellular portions of $\gamma\delta$ TCRs compared with $\alpha\beta$ TCRs. This may explain why the CD3 components of $\alpha\beta$TCRs are so different from those of $\gamma\delta$TCRs.

In terms of ligand binding surfaces, we note that although the CDR3 lengths of the G8 and G115 TCR are similar to those of $\alpha\beta$ TCRs, the Vδ CD3 of G8 protrudes significantly away from the other CDRs, as shown in Figure 10.6. This has significance in that this is the major region of contact with the T10 ligand (see later section). In the case of G115, both Vδ and Vγ CDR3 loops protrude from the rest of the putative binding surface and create a cleft between them. Portions of the CDR1γ and δ and CDR2γ combine with the clefts between the CDR3 loops to form a pocket, which is surrounded by positively charged amino acid residues contributed by CDR2γ, δ, and CDR3γ. The jagged surface of this TCR resembles the surface of an antibody that binds a small-molecule antigen. Although this would be consistent with the supposition that this TCR binds the negatively charged phosphate compounds (155), direct binding between the TCR and phospho-antigen-binding experiments including crystal-soaking and co-crystallization experiments have not been successful. Instead, a soluble G115 was found to bind a soluble form of ATP synthase F1 and Apolipoprotein A-1 *(156)*.

$\alpha\beta$ TCR-LIGAND RECOGNITION

Binding Characteristics

Although it has long been established that T cells recognize a peptide in association with an MHC molecule, a formal biochemical demonstration showing that this was due to TCR binding to a peptide/MHC complex took many years to establish. Part of the difficulty in obtaining measurements of this type has been the intrinsically membrane-bound nature of MHC and TCR molecules. Another major problem is that the affinities are relatively low, in the micromolar range, which is too unstable to measure by conventional means.

The problem of membrane-bound molecules can be circumvented by expressing soluble forms of TCR and MHC, which is also essential for structural studies (discussed earlier). For TCRs, many successful strategies have been described, including replacing the transmembrane regions with signal sequences for glycolipid linkage (157), expressing chains without transmembrane regions in either insect or mammalian cells *(158)*, or a combination of cysteine mutagenesis and E. coli expression (149). Unfortunately, no one method seems to work for all TCR heterodimers, although the combination of insect cell expression and leucine zippers at the c-terminus to stabilize heterodimer expression has been successful in many cases *(159)*. The production of soluble forms of MHC molecule has a much

longer history, starting with the enzymatic cleavage of detergent solubilized native molecules *(160)* as well as some of the same methods employed for TCR such as GPI-linkage *(161)*, E. coli expression and refolding *(162,163)*, and insect cell expression of truncated (or leucine-zippered) molecules *(164)*. One interesting variant that seems necessary for the stable expression of some class II MHC molecules in insect cells has been the addition of a covalent peptide to the N-terminus of the β chain (165).

The first measurements of TCR affinities binding to peptide/MHC complexes were performed by Matsui et al. (166) and Weber et al. (167). Matsui and colleagues used a high concentration of soluble peptide/MHC complexes to block the binding of a labeled anti-TCR Fab fragment to T cells specific for those complexes, obtaining an equilibrium binding affinity (K_d) value of ~50μM for several different T cells and two different cytochrome peptide/I-E^k complexes (as shown in Table 10.3). Weber and colleagues (167) used a soluble TCR to inhibit the recognition of a flu peptide/I-E^d complex by a T cell and obtained a K_D value of ~10μM. While these measurements were an important start in TCR biochemistry, they gave no direct information about the kinetics of TCR-ligand interactions. Fortunately the development of surface plasmon resonance instruments, particularly the BIAcore™ (Pharmacia Biosensor), with its remarkable sensitivity to weak macromolecular interactions *(168)*, has allowed rapid progress in this area. In this technique, one component is covalently cross-linked to a surface, and then buffer containing the ligand is passed in solution over it. The binding of even ~5% of the surface-bound material is sufficient to cause a detectable change in the resonance state of gold electrons on the surface. This method allows the direct measurement of association and dissociation rates—that is, kinetic parameters—and has the advantage of requiring neither cells nor radioactive labels. Recently, microcalorimetry has also been used to measure some TCR ligand affinities, and these analyses have confirmed the SPR values (169) but do not allow kinetic measurements. These and other data (reviewed in [*124*,145]) showed definitively that TCR and peptide-loaded MHC molecules alone are able to interact and that expression in a soluble form has not altered their ability to bind to each other. As shown in Table 10.3, SPR measurements show that while the on-rates of TCRs binding to peptide/MHC molecules vary from very slow (1,000 M sec) to moderately fast (200,000 M sec) their off-rates fall in a relatively narrow range (0.5 to .01 sec^{-1}) or a t$_{1/2}$ of 12 to 30 seconds at 25°C. This is in the general range of other membrane-bound receptors that recognize membrane molecules on other cells (123), but it has been noted that most TCRs have very slow on-rates *(124)*, which reflects a flexibility in the binding site that might help to foster cross-reactivity (discussed later). In the case of a class I MHC-restricted TCR, 2C, this relatively fast off-rate may be stabilized (10-fold) if soluble CD8 is introduced (150), but this result is

controversial *(170)*. CD8 stabilization of TCR binding has been seen by Luescher et al. in cell-based TCR labeling assay *(171)*; however, no enhancement of TCR binding has been seen using soluble CD4 *(172)*. Although most of the SPR measurements cited earlier were performed at 25°C due to instrument limitations, the actual dissociation rates are likely to be much faster (10 to 20×) at 37°C (173). One major caveat is that thus far all of these measurements have been made in solution, and it remains to be seen how the peculiar conditions of binding in between two cell membranes will influence the actual values in situ.

To what extent are we now able to predict a T cell response based on the binding characteristic of its TCR to a ligand? One of the most intriguing discoveries concerning T cell reactivity has been the phenomenon of altered peptide ligands. These are single amino acid variants of antigenic peptides that either change the nature or degree of the T cell response (partial agonists) or prevent a response to a normally stimulating ligand (antagonists) *(174,175)*. Discussions concerning the mechanism of these "altered peptide" responses have centered on whether they are due to some conformational phenomenon involving TCRs and/or CD3 molecules or to affinity or kinetic characteristics. With the data now available, we can say that most, but not all, T cell responses correlate well with the binding characteristics of their T cell receptors. In particular, Sykulev et al. *(176)* first noted that higher affinity peptide variants elicited more robust T cell responses. Subsequently Matsui et al. (177) found that in a series of three agonist peptides, increasing dissociation rates correlated with decreasing agonist activity. Lyons et al. (178) found that this correlation extended to antagonist peptides in the same antigen system (moth cytochrome c/I-E^k). They also showed that while an antagonist peptide might differ only slightly in affinity compared with the weakest agonist, its dissociation rate differed by 10-fold or more. This data in a class II MHC-restricted system is largely supported by the studies of Alam et al. in a class I MHC system (179), which also saw a drop-off in affinities and an increase in off-rates (with one exception as noted in Table 10.2) with antagonist versus agonist ligands. In the cell-based TCR labeling system of Luescher, a survey of related peptide ligands of varying potency also found a general, but not absolute, correlation between receptor occupancy and stimulatory ability (180). Thus, while there is a general trend toward weaker T cell responses and faster off rates and lower affinities, this does not seem to be an absolute rule, and thus other factors may be important in some cases. Alternatively, Holler et al. (181) have suggested that some or all of the discrepancies may derive from differences in peptide stability (in the MHC) between the relatively short (minutes) time scale of BIAcore analysis at 25°C compared with the much longer (days) cellular assays at 37°C. But this explanation probably only applies to a fraction of the anomalous cases in which TCR ligands fail to adhere to the "$t_{1/2}$ rule." In particular, Krogsgaard et al. *(182)* performed
FIGURE 10.7 Dissociation rate and heat capacity with peptide–major histocompatibility complex (MHC) ligands both influence T cell activation. Data from Krogsgaard et al. show that where deviations from the general dependence of T cell activation on dissociation rate occur, they may be compensated for by another factor, namely the heat capacity (ΔC_p) of the T cell receptor (TCR)–pMHC interaction (169). This is a measure of changes in mobility or conformation during the binding interaction and suggests that other binding parameters can influence TCR-mediated activation besides half-life (184). **A:** The relationship between the half-maximal peptide concentration needed for T cell activation (EC_{50}) and the half-life ($t_{1/2}$) of the TCR binding to that particular ligand. In this series, three of the seven peptides tested (K2, K3, and PPC) do not seem as dependent on $t_{1/2}$ as the others (PCC* represents a correction for a lack of stability when bound to the MHC at 37°C). **B:** When ΔC_p is factored in, all of the peptides can be plotted on a line.

a very comprehensive survey of both known and newly derived cytochromic peptide antigens and found that almost half of the peptide-MHC ligands analyzed failed to exhibit a linear relationship between $t_{1/2}$ and T cell stimulatory ability (Figure 10.7). Extensive thermodynamic analyses of these ligands showed that one particular parameter, the change in heat capacity ($-\Delta C_p$), which reflects changes in conformation or flexibility upon binding, seems to be synergistic with $t_{1/2}$ in enhancing a ligand's stimulatory capacity. In fact, as shown in Figure 10.7, when ΔC_p values are combined with $t_{1/2}$ the x axis, values for the range of ligands correlate much better with T cell stimulation. This suggests that ΔC_p may be the "missing" variable in correlating ligand binding to stimulation.

How could a negative change in heat capacity synergize with the stability of binding? One possibility is that large conformational changes at the binding surface of a TCR

that can occur when it engages pMHC ligands (as shown by structural studies; see later discussion) can translocate the TCR deeper into the membrane—as suggested by the "piston (50,183) and twist cap"(169) models—and trigger conformational changes in the CD3 signaling domains. Chakraborty and colleagues recently suggested another possibility for how conformational changes at the binding surface might exert their effect (184). They found that in the context of membrane–membrane interactions, conformational changes in the surfaces of relatively rigid proteins (e.g., as TCRs are thought to be) would act to increase the effective half-life of TCR–pMHC interactions. Thus $t_{1/2}$ and ΔCp may be equivalent in the unique environment in between two cell surfaces.

How might the relatively small differences in the binding characteristics of the ligands cause such different T cell signaling outcomes as agonism or antagonism? As McKeithan (185) and Rabinowitz (186) have noted, a multistep system such as T cell recognition has an inherent ability to amplify small differences in signals that are received on the cell surface to much larger differences at the end of the pathway, in this case gene transcription in the nucleus. Thus antagonism may occur at one threshold and an agonist response at another. Alternatively, an antagonist ligand may traverse the activation pathway just far enough to use up some critical substrate, as proposed by Lyons et al. (178). Yet another possibility that has also been suggested is that some antagonists may act even earlier, by blocking TCR clustering at the cell surface *(187)*. Lastly, Germain and colleagues have found evidence that a feedback loop involving the phosphatase SHP-1 may act as an alternative pathway to inactivate TCR signaling of insufficient strength (188,189).

Another controversy that relates to TCR binding characteristics is the "serial engagement" model of Lanzavecchia and colleagues (190), which proposed that one way that a small number of peptide/MHC complexes can initiate T cell activation is by transiently binding many TCRs in a sequential fashion. While the dissociation rates reviewed here show that TCR binding is likely to be very transient, they do not in fact, support the statement that more interactions are better. This is because, in most cases, improvements in TCR-peptide/MHC stability within any one system result in a more robust T cell response. This has been shown most eloquently in the work of Kranz and colleagues (191), who selected a nanomolar affinity TCR from a mutagenized library expressed in yeast. With a ~100-fold slower off-rate than the original, this TCR should have been only poorly stimulatory based on the serial engagement model. Instead, T cells bearing it are considerably more sensitive to antigen, which casts considerable doubt on this model. But the concept that the rapid dissociation rates of TCRs for peptide-MHC liquids could serve to amplify signaling has reemerged in the context of the "pseudodimer" model (126,192), as discussed later.

Topology and Cross-reactivity

As discussed earlier, TCR sequence diversity resides largely in the region between the V and J region gene segments, which corresponds to the CDR3 regions of antibodies (193). This has led to models in which the CDR3 loops of Vα and Vβ make the principal contacts with the antigenic peptide bound to the MHC (193). Support for this model has come from many studies that have shown that the CDR3 sequences of TCRs are important predictors of specificity (as reviewed in ref. [193]), as well as elegant mutagenesis studies that have shown that a single CDR3 point mutation could alter the specificity of a TCR (194), and a CDR3 "transplant" could confer the specificity of the donor TCR onto the recipient (195). In addition, a novel approach to TCR–ligand interactions was developed by Jorgensen et al. (196), who made single amino acid changes in an antigenic peptide at positions that affect T cell recognition but not MHC binding. These variant peptides are then used to immunize mice that express either α or β chain of a TCR that recognizes the original peptide, and the responding T cells are analyzed. Using these "hemi-transgenic" mice allows the resulting T cells to keep one half of the receptor constant, while allowing considerable variation in the chain that pairs with it. The results from this study and work in another system by Sant'Angelo et al. (197) are very similar in that every mutation at a TCR sensitive residue triggered a change in the CDR3 sequence of Vα, Vβ, or both, and in some cases, changed the Vα or Vβ gene segment as well (as summarized in Figure 10.8). One of the more striking examples of a CDR3-peptide interaction occurred in the cytochrome c system, where a Lys→Glu change in the central TCR determinant on the peptide triggered a Glu→Lys charge reversal in the Vα
FIGURE 10.8 Sensitivity of T cell receptor (TCR) complementarity-determining region 3 (CDR3) sequences and Vα/Vβ usage to changes in the antigen peptide. This figure summarizes the data of Jorgensen et al. (196,198) and Sant'Angelo et al. (197), who immunized single-chain transgenic mice (TCRα or TCRβ) with antigenic peptides (MCC or CVA) altered at residues that influence T cell recognition but not major histocompatibility complex binding. These data show that such changes invariably affect the CDR3 sequences of Vα or Vβ or both and that there appears to be a definite topology in which Vα governs the N-terminal region and Vβ seems more responsible for the C-terminal portion of the peptide.

CDR3 loop, arguing for a direct Lys→Glu contact between the two molecules (196).

Another interesting finding was the order of Vα→Vβ preference going from the N-terminal to the C-terminal residues of the peptides. This led Jorgensen to a proposed "linear" topology of TCR-peptide/MHC interaction in which the CDR3 loops of Vα and Vβ line up directly over the peptide (196,198). Sant'Angelo et al. (197) proposed an orientation of the TCR in which the CDR3 loops are perpendicular to the peptide. This was partially based on intriguing data they found suggesting an interaction between the CDR1 of Vα and an N-terminal residue of the peptide. A third orientation was proposed by Sun et al. (188) based on the analysis of a large number of class I MHC mutants and their effect on TCR reactivity. This produced a roughly, diagonal footprint of TCRs over the MHC compared to the two previous models. On the other hand, an extensive class II MHC mutagenesis study failed to reveal a consistent "footprint" of TCR interaction and, furthermore, found the pattern of TCR sensitivity was remarkably labile and highly dependent on sequences in the TCR CDR3 region or the peptide (199).

This controversy regarding orientation has been largely resolved by the numerous crystal structures of TCR-pMHC complexes (145). These studies show that TCRs bind in roughly diagonal to 90° configurations, ranging over 30°.
FIGURE 10.9 T cell receptor (TCR)-peptide/major histocompatibility complex (MHC) crystal structure of a TCR-peptide/MHC complex. Peptide and complementary-determining regions are portrayed in different colors (150). (See color insert.)

In these structures, one of which is shown in Figure 10.9 (150), the CDR3 loops are centrally located over the peptide, but the Vα CDR1 and the Vβ CDR1 are also in a position to contact the N-terminal and C-terminal peptide residues, respectively. Such a contact between Vα CDR1 and an N-terminal residue has now been seen in other structures as well *(200)*. The confined nature of TCR recognition constitutes a major departure from antibody–antigen interactions and may reflect a need to accommodate other molecules into a particular configuration that is optimal for signaling, such as CD4, CD8, or CD3 components.

As αβ T cell receptor heterodimers are first selected in the thymus for reactivity to self-peptides bound to MHC molecules, all foreign-peptide reactive TCRs could be considered to be inherently cross-reactive. Indeed a number of T cells have reactivity to very different peptide sequences, as shown by Nanda and Sercarz (201). It has also been argued by Mason (202) that the universe of peptides is so large that each T cell must on average be cross-reactive to $\sim 10^6$ different peptides (although many of the differences in peptide sequence in this calculation would not be accessible to the TCR, being buried in the MHC binding groove). Several large-scale screens of a random 9-mer peptide library with different T cells did turn up a great many stimulatory peptides, but very few have changes in the 2-4 key TCR sensitive residues (203,204). This lead Garcia and colleagues to conclude that cross-reactivity to different agonist peptides may not be a general feature of T cell specificity (203). Instead, the major requirement for cross-reactivity may be in thymic selection (205) or in the use of endogenous peptide-MHC's to augment T cell sensitivity to agonist ligands (192,206). Analyses of a T cell hybridoma that could recognize either a lysine or a glutamic acid residue in the center of a cytochrome c peptide on a panel of MHC mutants revealed that a different MHC "footprint" was evident, depending on which peptide was recognized (199,207). This suggests a plasticity of TCR binding to particular pMHC complexes. More direct evidence of TCR plasticity was first obtained by Garcia et al. (208), who in comparing the x-ray crystal structures of the same TCR bound to two different peptide-MHC ligands found a large conformational change in the CDR3 loop and a smaller one in the CDR1α loop. An even larger conformational change (15 Å) has been found in the CDR3β residue of another TCR as it binds to a pMHC complex (209), as shown in Figure 10.10. That each TCR may have many different conformations of its CDR3 loops is suggested by the 2D NMR studies of Reinherz and Wagner and colleagues, who found that the CDR3 regions of a TCR in solution were significantly more mobile than the rest of the structure (210). That this may be a general feature of most TCRs is supported by thermodynamic analyses of various TCRs binding to their peptide/MHC ligands, both class I and class II. Here the binding is often
FIGURE 10.10 CDR3 movement in $\alpha\beta$ T cell receptor (TCR) binding. In most cases where there is a structure for an $\alpha\beta$ TCR as well as for one (or more) for that TCR in complex with a peptide-MHC, there is a marked movement of one or the other of the Vα or Vβ CDR3s. This example from Mallissen et al. (209) shows a particularly large (14 Å) movement of CDR3β with binding. This meshes well with thermodynamic data showing an "induced fit" binding mechanism for most TCRs (173,211). (See color insert.)

accompanied by a substantial loss of entropy (Table 10.4) and, in most cases, an "induced fit" mechanism (169,173,211). This seems to be a situation where an inherently flexible binding site achieves greater order upon binding. This is a mechanism that is also employed by DNA recognition proteins, and Boniface et al. (173) have suggested that it might represent a common mechanism of "scanning" an array of very similar molecular structures (MHCs or DNA) rapidly for those few that "fit" properly. We have seen previously that the association rates are often remarkably slow, with K_as ranging from 1,000 to 10,000 $M^{-1}s^{-1}$ (Table 10.3). This indicates that either a multistep process is occurring before stable binding can be achieved or that only a fraction of the TCRs in solution have the correct conformation. Just how such a scanning mechanism might work for TCRs is seen in the analysis of Wu and colleagues (212), who found that a cytochrome c/MHC II–specific TCR derived most of its stability of binding from antigenic peptide residues, but very little of its initial activation energy from these residues. In contrast, MHC residues contributed by far the most of the initial binding, but had relatively modest effects on stability. This indicates that "scanning" may be a process (as shown in Figure 10.11) that first involves contact with (and orientation by) the α-helices of the MHC, and then a "fitting" process with and stabilization by peptide residues that involves a substantial loss of entropy. This model of TCR binding might help to explain the striking efficiency and sensitivity of T cell recognition with the MHC helices guiding the TCR into the correct orientation. It might also be the structural basis for cross reactivity in which structurally different peptides bind to the same TCR, as the CDR3 regions of TCR could "fold" into the peptide in many possible configurations. While attractive, there remain caveats about this

"two-step binding" model; one is the existence of some important human class I MHC antigens that "bulge" out of the binding groove, creating a barrier to "scanning" as a mechanism of binding to those antigens (213). A second issue is that one would expect a reproducible "footprint" for MHC binding of particular TCR V regions, which until recently has been elusive. But recently, Garcia and colleagues have documented such specific footprints that correlate to particular Vβ usage, although it does seem that there are multiple ways way in which a particular V region can contact a particular MHC (203).

Role of CD4 and CD8

What is the role of CD4 and CD8 with respect to the T cell response to agonist and antagonist peptides? In the case of a T helper cell response, the presence of CD4 greatly augments the amount of cytokine produced and, in some cases, determines whether there is a response at all (as reviewed in [214]). Much of the effect of CD4 seems to come from the recruitment of lck to the TCR/CD3 complexes. In addition, there is also a significant positive effect even with CD4 molecules that are unable to bind lck, and thus there appears to be an effect on TCR–ligand interaction as well. Nonetheless, while a weak binding of CD4 to class II MHC has been observed *(172)*, there is no apparent cooperativity with respect to TCR binding to peptide-MHC, unlike the case of CD8 and class I–specific TCRs (discussed later). Together with the recent low-resolution structure of CD4-class II MHC *(215)*, the classical model of CD4 binding to the same MHC as a TCR that it is associated with (104) seems untenable. And yet there is abundant evidence that CD4 molecules do associate with TCRs, especially on previously activated T cells *(216)*. Thus models in which CD4 cross-linking to MHC II indirectly supports TCR binding to peptide-MHCs and potentiates signaling through the delivery of lck seem more likely (discussed later).

In addition, the results of Irvine et al. (217) and Purbhoo et al. (218) using a single-peptide labeling technique, found appreciable T cell responses to even one agonist peptide in all four T cells analyzed, resulting in a "stop" signal for the T cell and a small but detectable rise in intracellular calcium. In CD4$^+$ T cells, these effects are attenuated by antibody blockade of CD4, such that many more (25 to 30) peptides are required to elicit a stop signal and a calcium flux (217). How could CD4 be facilitating the recognition of small numbers of peptides? Irvine et al. (217) have proposed a "psuedodimer" model, which suggests that a CD4 molecule associated with a TCR binding to an agonist peptide-MHC could bind laterally to an endogenous peptide-MHC complex that is also being bound by an adjacent TCR. This takes advantage of the apparent abundance of endogenous pMHCs that can be bound by a given TCR (219) and uses two weak interactions (CD4 $\rightarrow$ MHC

II and TCR → endogenous peptide-MHC) to help create a dimeric "trigger" for activation. CD8 also greatly augments the response of class I MHC–specific T cells (214) and binds to class I MHC in much the same fashion as CD4 *(220)*. CD8$^+$ T cells have the same sensitivity to antigen as CD4$^+$ T cells (219), but the data of Gascoigne and colleagues suggests that they are not sensitive to particular endogenous pMHCs (206). Overall, it seems likely that each of these coreceptor molecules has two roles: to stabilize TCR–ligand interactions physically and to aid in signaling by recruiting lck. Consistent with this is data showing CD4 can convert an antagonist peptide into a weak agonist *(221,222)*, although CD4 has no apparent effect on antagonism (223,224). This situation with CD8 is less clear, but there are clearly some differences in how it synergizes with TCR versus CD4, some of which may relate to its much higher affinity for its MHC (∼10μM for CD8-MHC1 *[148,170]* versus >250μM for CD4-MHCII *[172]*).

Superantigens

One of the most interesting and unexpected areas to emerge from the study of $\alpha\beta$ T cell reactivities is the discovery of "superantigens." Whereas a particular anti-genic peptide might only be recognized by one in 100,000 or fewer T cells in a naïve organism, a given superantigen might stimulate 1% to 20% of the T cells (as reviewed in [225,226]). As will be discussed in more detail later, the physical basis for this is that the superantigen binds to a Vβ domain of the TCR on T cells while simultaneously binding to an MHC class II molecule on an antigen presenting cell (although not in the peptide-binding groove). This allows a single superantigen, such as SEA in Table 10.5, to stimulate virtually every murine T cell bearing Vβ 1, 3, 10, 11, 12, or 17 (about ∼15% of all $\alpha\beta$ T cells), in most cases regardless of what Vα it is paired with or what CDR3 sequence is expressed. Clearly this is a very unique class of T cell stimulatory molecule.

The first indication of a superantigen effect was the discovery of minor lymphocyte stimulating (MIS) determinants by Festenstein in the early 1970s (227). Many years later, Kappler and Marrack and their colleagues characterized a mouse strain-specific deletion of T cells expressing specific TCR Vβs that were attributable to these loci (228). It emerged that these effects were due to endogenous retroviruses of the mouse mammary tumor virus family (229–233). Different family members bind different TCR Vβ domains (as shown in Table 10.5) and
FIGURE 10.11 As shown by Wu et al. (212), mutational analysis of T cell receptor (TCR)-peptide/major histocompatibility complex (MHC) binding indicates that the TCR first contacts MHC residues (in the transition state), and the peptide has very little influence. Subsequently, however, the peptide residues contribute greatly to the stability of the complex. Thus, we have proposed that the transition state largely involves TCR–MHC contact followed by stabilization of mobile complementarity-determining region 3 residues into a stable state, usually involving significant conformational change and loss of entropy.

stimulate T cells expressing them. Meanwhile, Janeway and colleagues (234) had shown earlier that staphylococcus enterotoxins could polyclonally active naïve T cells in a Vβ-specific manner without a requirement for antigen processing. Many of these enterotoxins have been characterized extensively (225,226,235,236). Unlike the MMTV proteins, which are type II membrane proteins, the enterotoxins are secreted. Subsequently, proteins having similar properties have been isolated from other bacteria specifically (Yersinia pseudotuberculosis *[237,238])*, streptococcus *(239)*, and from mycoplasma *(240,241)*. There is also evidence of superantigen-like activities in other mammalian viruses such as rabies *(242)*, cytomeglovirus *(243)*, herpes virus *(244)*, Epstein-Barr virus *(245)*, and also in the toxoplasma gondii *(246)*. Because so many pathogenic or parasitic organisms possess these molecules, apparently by convergent evolution, there must be some selective advantage, but in most cases there is no conclusive evidence as to what this might be. The one exception is the case of the MMTV superantigens, where it has been shown that polyclonal T cell stimulation allows the virus to more efficiently infect the B lymphocytes that are activated by the T cells (247,248). This may be a special case, however, and most authors have

suggested that superantigens primarily serve to confuse and occupy the immune system while the pathogen escapes specific targeting and elimination. Large doses of superantigens have also been implicated in various "shock" syndromes, such as food poisoning or "toxic shock" (225), but this is probably not their everyday purpose, as it would violate the general rule that the host and parasite should coexist.

It has also been suggested that superantigens might be involved in triggering autoimmune diseases (249). Here the hypothesis is that a large number of T cells bearing a particular Vβ are activated by a pathogenic superantigen and that subsequently self-reactive T cells within those activated cells are more easily stimulated by a particular tissue antigen. That this may occur in some cases is supported by the work of Stauffer et al. on a human endogenous retrovirus that specifically stimulates Vβ7 T cells and is implicated in the initiation of type I diabetes *(220)*. Another report implicates a superantigen in Crohn's disease, another autoimmune disorder (250).

Although the biochemistry of superantigen binding to TCR and MHC is similar to that of TCR peptide/MHC interactions (251), mutagenesis, and particularly x-ray structural data, has shown that the topology is both quite

different and variable (226). In particular, it has been found that Mls-la presentation to T cells is most affected by mutations on the "outside" surface of the Vβ domain, which do not affect peptide/MHC recognition (147). In contrast, the CDR1 and CDR2 of regions of Vβs are involved in bacterial superantigen reactivity (252).

An example of the structural data is shown in Figure 10.12, which shows how a model TCR-SAg-MHC complex (derived from separate structures) would displace the TCR somewhat (but not entirely) away from the MHC binding groove (253), thus making the interaction largely insensitive to the TCR/peptide specificity. Other TCR-SAg-MHC complexes have very different geometries (254–256).

Why do all the many independently derived superantigens interact only with the TCR β-chain? One possibility is that the β-chain offers the only accessible "face" of the TCR, perhaps because the CD4 molecules hinders access to the Vα side (as suggested by the antibody blocking studies of Janeway and colleagues *[257]*).
FIGURE 10.12 Crystal structure of a T cell receptor (TCR) β/superantigen (SAg) complex. Fields et al. (253) crystallized TCR-SAg complexes and from the structure of the same superantigens with a class II major histocompatibility complex (MHC) molecule and were able to deduce the relative spatial arrangement of the three molecules. This model suggests that TCR does not contact the MHC very strongly, which is consistent with the relative peptide insensitivity of SAg activation. (See color insert.)

ANTIGEN RECOGNITION BY $\gamma\delta$ T CELLS

Antigen Recognition Requirements

Because the study of $\gamma\delta$ T cells is relatively recent and does not stem from any knowledge of their biological function, experiments designed to characterize their specificity and function had drawn heavily on our knowledge of $\alpha\beta$ T cells. Because $\alpha\beta$ T cell recognition requires antigen presentation by MHC and related molecules, it was assumed that $\gamma\delta$ T cell recognition would also follow the same rules. Even in cases where classical MHCs are clearly not involved, it has been suggested that nonclassical MHC molecules or some yet-to-be-identified surface molecules might play a similar role. These possibilities are difficult to

test experimentally. Thus, analysis of $\gamma\delta$ T cells specific for MHC molecules were carried out to determine the antigen recognition requirement of $\gamma\delta$ TCRs. This approach asks the following questions: When $\gamma\delta$ T cells recognize MHC molecules, what kind of antigen processing is required? Is any of the specificity conferred by bound peptide? Which part of the MHC molecule is recognized? This approach takes advantage of the detailed knowledge of the molecular structure of MHC class I (258,259) and MHC class II molecules (260), thus making T cell epitope mapping feasible and interpretable. In addition, and more important, the biosynthetic pathways and antigen processing requirements for both MHC class I and MHC class II molecules had been extensively studied. Mutant cell lines defective in either pathway were readily available and could be transfected with various MHC class I and MHC class II genes. Therefore, potential antigen processing and presentation requirements for alloreactive $\gamma\delta$ T cells could be studied with precision and compared with those of $\alpha\beta$ T cells.

The $\gamma\delta$ T cell LBK5 *(261,262)* recognizes I-E[b,k,s], but not I-E[d]. An analysis of the fine specificities of LBK5 showed that the peptide bound to the I-E molecules does not confer specificity and that no known antigen processing pathways were required in the recognition of I-E by LBK5. All variations in the ability of different stimulator cells to activate LBK5 can be attributed solely to their level of surface I-E expression and are independent of their species origin (mouse, hamster, human) and cell type (B cells, T cells, fibroblasts). Modifications of the repertoire of peptides loaded onto MHC molecules also showed no effect because native I-E[k], GPI-linked I-E[k], I-E[k] expressed with or without invariant chains, and the presence or absence of functional MHC class I or class II antigen processing pathways all stimulated LBK5 similarly (263). Thus, LBK5 recognizes native I-E[k] molecules with a variety of different bound peptides or in the case of GPI-linked I-E[k], which most likely does not complex with a peptide. In addition, LBK5 recognizes *E. coli*-produced I-E[k] α and β chains folded with a single peptide *(264)*.

The functional epitope on IE for LBK5 recognition maps to the $\beta67$ and $\beta70$ residues *(264)*. This explains why LBK5 recognizes I-E[b,k,s] but not I-E[d] and why peptide bound to IEk does not confer the specificity. Surprisingly, IEk mutants with an altered carbohydrate structure on the $\alpha84$ position are not recognized by LBK5 *(264)*. Although the binding interface of the LBK5 $\gamma\delta$ TCR and I-E has yet to be determined, it is reasonable to assume that it will not deviate much from those reported for antibodies, $\alpha\beta$ TCRs and the G8 $\gamma\delta$ TCR. From the coordinates of a published crystal structure of I-E[k] *(265)*, the distance between $\beta67$ to 70 (the LBK5 epitope) and the carbohydrate attachment site at position $\alpha82$ was estimated to be around 28 to 33Å. Hence, it is likely that the carbohydrate structure is peripheral to the core of the LBK5/I-E interaction.

This type of interaction may be similar to that described for human growth hormone and the extracellular domain of its receptor *(266)*, where a central hydrophobic region at the contact site, which is dominated by two tryptophan residues, accounts for more than three quarters of the binding free energy and where peripheral electrostatic contacts contribute substantially to the specificity of binding but not to the net binding energy. This type of protein–protein interaction has been postulated to ensure the specificity of an interaction without requiring a high affinity *(267)*.

Two independently derived $\gamma\delta$ T cell clones, KN6 *(268)* and G8 *(269)*, are found to recognize T10 and T22, two closely-related, nonclassical MHC class I molecules that have 94% amino acid identity. T22 appears to be expressed constitutively on a variety different cell types, while the expression of T10 is inducible on cells of the immune system. Among strains of mice tested so far, all express T10. However, mice of the H-2^d or H-2^k MHC haplotypes (e.g., BALB/c and C3H, respectively) lack functional T22 molecules *([268]* and MP Crowley, thesis) (Figure 10.13). T10 and T22 have also been identified as natural ligands for murine $\gamma\delta$ T cells and ~0.2 to 1% of the $\gamma\delta$. T cells in normal, unimmunized mice are T10/T22 specific *(269)*.

The primary sequences of T10 and T22 suggest that the necessary structural features that enable classical MHC

FIGURE 10.13 T10/T22-specific $\gamma\delta$ T cells can be detected in normal mice through use of a tetrameric T22 staining reagent. As shown by Crowley et al. (274), a T22 reagent that was generated by similar methods as tetrameric peptide/major histocompatibility complex reagents stained approximately 0.6% of splenic $\gamma\delta$ T cells in normal animals. More than 90% of these cells are CD4$^-$CD8$^-$; the rest are either CD4 or CD8 single positive (about 3% to 4% each). A similar frequency of tetramer-positive $\gamma\delta$ T cells was also found in the intestinal intraepithelial lymphocyte (IEL) population (data not shown).

class I molecules to bind peptides are absent. Indeed, X-ray crystallography has shown that T10 and T22 adopt a severely modified MHC-like fold that lacks a classical peptide-binding groove and exposes part of the β sheet "floor" of the $\alpha1/\alpha2$ platform (270,271). Consistent with the structural data, no endogenous peptides can be eluted from chimeric T10/L^d molecules that are expressed by transfected cells *([272]* and H. Schild, Y-h. Chien, and H. Rammensee, unpublished results). This indicates that these molecules can reach the cell surface devoid of peptide. Importantly, the *E. coli*–produced, *in vitro*–folded T10/β_2m and T22/β_2m molecules can stimulate the G8 $\gamma\delta$ T cell *(273)*, which provides unequivocal evidence that these peptide-free molecules retain their immunological function.

Direct binding between soluble G8 $\gamma\delta$ TCRs and T10/β_2m and T22/β_2m complexes has been measured (274). Surface plasmon resonance showed that the dissociation rates for the interaction between G8 and T10^b and T22^b were similar (k$_d$ = 8.1 $\pm$ 2.3 $\times$ 10^{-3} s^{-1}) and slower than those that had been observed for most interactions between $\alpha\beta$ TCRs and peptide/MHC complexes. The association rates (k$_a$ = 6.53 $\pm$ 1.73 $\times$ 10^4 M^{-1}s^{-1}) are among the fastest that had been reported for $\alpha\beta$ TCRs and their ligands. Therefore, compared to $\alpha\beta$ TCRs, the affinity between G8 $\gamma\delta$ TCRs and their ligand is rather high (K$_D$ = 0.13 $\pm$ 0.05 μM). A Scatchard analysis of equilibrium binding generated a similar affinity of 0.11 $\pm$ 0.07 μM for this interaction (274).

As summarized in Table 10.6, the recognition of I-E, T10/T22 (263,275), herpes simplex virus glycoprotein gI (276), MICA and MICB (277), and the recently described recognition of the F1-ATPase and the apoliprotein A-I complex specific $\gamma\delta$ T cells *(156)* indicates that the molecular nature of $\gamma\delta$ T cell antigen recognition is fundamentally different than that of $\alpha\beta$ T cells. In all cases, the antigens are recognized directly. This suggests that many (and perhaps all) $\gamma\delta$ T cells can function without a requirement for antigen processing. While MHC and MHC-related molecules are recognized by $\gamma\delta$ T cells, $\gamma\delta$ T cell antigens need not be MHC or MHC-related molecules. Thus, pathogens and damaged tissues can be recognized directly, and cellular immune responses can be initiated by $\gamma\delta$ T cells without a requirement for antigen degradation and specialized antigen presenting cells, such as B cells, macrophages, and dendritic cells. This would allow for greater flexibility than is present in classical $\alpha\beta$ T cell responses. T10, I-E, as well as MICA and MICB expression can be induced under certain physiological/pathological conditions *(278)*. ATP synthase F1 is normally localized in the membranes of mitochondria, but it has also been found on the surfaces of tumors, hepatocytes, and endothelial cells *(279–281)*. Thus, $\gamma\delta$ T cell activation may be regulated through the level of protein expression. In addition, the recognition of I-E by LBK5 is acutely sensitive

▌ TABLE 10.6 Partial List of $\gamma\delta$ T Cell Reactivities

Name (referred to as)	Source	Reported Reactivities	Comments	Reference
Murine				
DGT3	Lymph node cells from DBA2 mouse primed with poly(Glu^{50}Tyr^{50})	Qa-1/(Glu^{50}Tyr^{50})		317
KN6	Double-negative thymocytes from C57Bl/6	T10/T22*b,k* not *d*		318
TgI4.4	Lymph node of HSV-infected C3H mouse and restimulated with L cells transfected with HSV-gI	HSV-gI	Can be stimulated by gI protein alone	319,320
G8	BALB/c nu/nu immunized with B10.BR APCs	T10/T22*b,k* not *d*	Direct binding and co-crystal structure have been shown	153,274,323
LBK5	C57Bl/10 nu/nu immunized with B10.BR splenocytes	I-E*k,s,r* not *d*	Can be stimulated by I-E proteins alone; reactivity is not peptide-specific	322,323
LKD1	B10.BR immunized with B10.D2 splenocytes	I-A*d*		322
69BAS-122	C57Bl/10, adult splenocyte	HSP-60 peptide, cardiolipin, b2-glycoprotein 1	Transferring TCR transfers reactivity	324,325
BNT-19.8.12	C57Bl/10, newborn thymocyte	Mycobacterium PPD, cardiolipin, b2-glycoprotein 1	Transferring TCR transfers reactivity	325,326
7–17 and other dendritic epidermal T cells	$\gamma\delta$ T cells from murine epidermis	Keratinocytes	Transferring TCR transfers reactivity	33
Human				
Panels of T cell clones expressing Vγ9Vδ2	PBMC stimulated with irradiated PBMCs and PHA	Tumor cells (e.g., Molt-4), M. tuberculosis extracts (MT), metabolites in the mevalonate pathway	20% of Vg9Vd2 clones do not react to MT; only slightly more than 50% of MT- or Molt-4-specific clones recognize the other specificities	327,328
Panels of T cell clones expressing Vγ9Vδ2 including G42 and G115	$\gamma\delta$ T cells from PBM cultured with irradiated PBLs and lymphoblastoid cells	phosphoAg, tumor cells (e.g., Daudi), AS/ApoA-I (G115 TCR)	Close correlation between Daudi and mycobacterial reactivity; direct binding between AS/ApoA-I; heterogenous reactivity to ApoA-I	156,329,330
DG.SF13 (Vγ9Vδ2)	$\gamma\delta$ T cells isolated from RA synovial fluid stimulated with sonicate of M. tuberculosis	Daudi cells, M. tuberculosis, MEP	Transferring TCR transfers reactivity	331
Panels of T cell clones expressing Vγ9Vδ2 including CP1.15 and DG.SF68	PBMC $\gamma\delta$ T cells stimulated with M. tuberculosis extract	phosphoAg, alkylamines, aminobisphosphonates	Reactivities require cell-cell contact	332,333
Clones 1, 2, 3, 4, 5 (Vδ1)	Lymphocytes extracted from human intestinal epithelial tumors cultured with irradiated CIR-MICA and CIR-MICB cells	MICA, MICB	Transferring TCR transfers reactivity; Vδ1-Jδ1 with diverse CDR3 are used; not all Vδ1-Jδ1 cells are MIC-specific	334,335
JR.2 and XV.1 (Vδ1)	PBL stimulated with autologous CD1$^+$ DC and M. tuberculosis extract	CD1c expressing cells	Transferring TCR transfers reactivity; many Vd1 positive gd T cells are not CD1c-reactive	335
Vγ1.3Vδ2 expressing BW5147	gd TCR chains PCR'd from muscle-infiltrating T cells of a polymyositis patient and transfected into TCR-deficient BW5147	Muscle cell extract and E. coli extract		336,337
4-29 and 5-3 (Vδ2 negative)	PBMC from CMV-infected transplant recipients stimulated with irradiated PBMC and PHA	CMV-infected fibroblasts, Hela, HT-29, Caco-2		338

The names of the T cells, the way they are generated and their reported reactivities.

to changes in the glycosylation of the I-E molecule. This suggests a novel way by which antigen recognition by $\gamma\delta$ T cells can be regulated. Changes in the posttranslational modifications of surface glycoproteins often indicate that tissues have become infected, have undergone neoplastic transformations, or have experienced other types of cellular stress. For example, it has been shown that the infection of mice with *Listeria monocytogenes* impairs the addition of sialic acid to host cell glycoproteins that include MHC molecules (282). Additionally, whereas the surface glycoprotein mucin is heavily glycosylated in normal cells, it is under-glycosylated in breast, ovarian, and pancreatic carcinomas, such that the peptide backbone is unmasked *(283)*. Thus, both the quantity and the quality of the ligand could contribute significantly to the specificity of $\gamma\delta$ TCR recognition.

$\gamma\delta$ *TCR Ligands*

Despite intense efforts, the identification of $\gamma\delta$ TCR ligands has been difficult and confusing. Few "agents" are known to activate $\gamma\delta$ T cells (Table 10.6). Even fewer are known to be both necessary and sufficient to trigger T cell responses through the $\gamma\delta$ TCR and are therefore $\gamma\delta$ TCR antigens. These include the murine MHC class Ib molecules T10 and T22 that are the ligands for 0.2 to 1% of $\gamma\delta$ T cells (274), the human MHC class I–like molecules MICA and MICB (277), and an ATP synthase F1/apolipoprotein A-I (AS/ApoA-I) complex *(156)*.

Significantly, the same human $\gamma\delta$ T cell clones that recognize AS/ApoA-I complexes are activated by a set of nonpeptidic pyrophosphomonoesters that are collectively referred to as *phosphoantigens* (phosphoAgs) (reviewed in [155]). It has been observed for well over a decade that human peripheral blood Vγ9Vδ2 cells can be stimulated by phosphoAgs such as isopentenyl pyrophosphate (IPP) and dimethylallyl pyrophosphate (DMAPP). These cells show *in vitro* responses to tumors, phosphoAgs produced by eukaryotes and prokaryotes, natural and synthetic alkylamines, and aminobisphosphonates. However, repeated attempts to show interactions between phosphoAgs and Vγ9Vδ2 TCRs have failed. The identification of AS/ApoA-I complexes as antigens of some of these T cells further challenges this notion.

As indicated in Table 10.6 *(130)*, other than phosphoAgs, the reactivities of Vγ9Vδ2-expressing T cells to other challenges such as tumors and AS/ApoA-I are far from homogeneous. Further, these cells mount a much more robust response to phosphoAgs than to CD3 crosslinking. Thus, it is possible that IPP and other isoprenoid intermediates enhance antigen-specific responses of Vγ9Vδ2 cells without being TCR antigens themselves. IPP and DMAPP are metabolites of the mevalonate pathway that regulates the biosynthesis of cholesterol, as well as of isoprenoids that mediate the membrane association of certain GTPases.

The addition of isoprenoid intermediates has been shown to augment antigen-specific $\alpha\beta$ T cell responses and to alter their cytokine profiles *(284)*.

Antigen Recognition Determinants of $\gamma\delta$ TCRs: V Genes Versus CDR3 Regions in $\gamma\delta$ TCR Ligand Recognition

In part because $\gamma\delta$ T cells from different anatomical sites show preferential V gene expression, $\gamma\delta$ T cells are commonly divided into subsets based on V gene usage *(285,286)*. Numerous studies have also reported that $\gamma\delta$ T cell functions segregate with Vγ, or VγVδ usage *(285–288)*. These observations have led to suggestions that the bias in V gene usage enables $\gamma\delta$ T cells to respond to antigens that are specific to their resident tissues (10,*286*,289). If this were the case, then $\gamma\delta$ TCRs would function like innate immune receptors even though VDJ recombination of the TCR δ chain leads to orders of magnitude higher potential junctional (CDR3 region) diversity than is found in Ig and $\alpha\beta$ TCRs (as discussed previously).

To resolve this issue, it is essential to understand the basis of $\gamma\delta$ TCR antigen recognition. Based on the analysis of T22 specific $\gamma\delta$ T cells isolated from normal mice, the majority of T22-specific $\gamma\delta$ TCRs use Vγ1 and Vγ4 in the spleen and a sizeable number use Vγ7 in the IEL compartment (290). Thus, at least for T22 specificity, Vγ usage reflects tissue origin and not antigen specificity. Consistent with this, it has been demonstrated that the preferential usage of Vγ7 by $\gamma\delta$ T cells that can migrate into the IEL compartment primarily results from IL15-driven control of Vγ7 accessibility during thymic VJ rearrangement (291).

While different Vγs and Vδs were associated with T22-specific TCR sequences, there is one defining feature that is common among them (290). This is a prominent CDR3δ motif shown in Figure 10.14 that consists of a Vδ or Dδ1-encoded Trp (W), a Dδ2-encoded sequence of Ser, Glu, Gly, Tyr, and Glu (SEGYE) and a P-nucleotide-encoded Leu (L). Gene transfer experiments established that TCRs with the W-(S)EGYEL motif bound T22, while those lacking the motif did not ([290] and Table 10.6).

Proof that the W-(S)EGYEL motif is the antigen contact site came from the crystal structure of the G8 $\gamma\delta$ TCR bound to T22 (153). As discussed in the previous section, T22 has an MHC class I–like fold, but one side of what would normally be a peptide-binding groove is severely truncated and exposes the β-sheet "floor" (270). G8 binds T22 at a tilted angle that contrasts with the essentially parallel alignments of the long axes of the $\alpha\beta$ TCR and the peptide/MHC when in complex (Figure 10.15). The majority of the contact residues are contributed by the β-sheet floor and the α1 helix of T22 and the fully-extended CDR3d loop with Trp anchoring at the N-terminal end and residues Gly,
FIGURE 10.14 The T22 structure and the interaction with the G8 $\gamma\delta$ TCR. **A:** The structure of a T22 molecule, a nonclassical class I MHC that is missing half of an alpha helix and does not bind peptides (270). **B, C:** The intersection with the G8 TCR, where the long TCR δ CDR3 accounts for almost all of the contact residues (153). (See color insert.)

FIGURE 10.15 Conserved TCRδCDR3 sequences correlate with T10/T22 specificity in $\gamma\delta$ T cells. Sequence data from Shin et al. (290) showing that both established cell lines (G8 and KNG) and $\gamma\delta$ T cells from clonal cultures that are specific for the T10/T22 share highly conserved TCRδCDR3 sequences. These are largely derived from the Dδ2 gene segment and from the structural data (Adams et al., color plate 4, 153). These conserved sequences constitute the main interaction between these $\gamma\delta$ T cell receptors and their ligand. (See color insert.)

Tyr, Glu, and Leu together with a Thr residue encoded in the J region anchoring the loop at its C-terminal end. This is similar to Ig, where antigen specificity in nonsomatically mutated antibodies resides predominantly in the CDR3 of the heavy chain (292). This mode of antigen recognition also fits well with analyses of CDR3 length distributions of all immune receptor chains that first suggested that $\gamma\delta$ TCRs bind antigens more similar to Igs than to $\alpha\beta$ TCRs (129).

There are two G8/T22 complexes in the asymmetric unit (153). While the contact residues are similar at the interface of the CDR3/T22 β sheet, the two complexes differ by a relative rotation between the G8 TCRs. This shift alters the contacts formed between the CDR1, CDR2, HV4, and CDR3 loops and T22 in each TCR, suggesting that the CDR3 loop acts as a pivot point for G8 binding, with some flexibility in the interaction between the other CDR loops and T22. The hinge-like flexibility around this pivot point stands in stark contrast to interactions seen in antibody/antigen and $\alpha\beta$ TCR/pMHC complexes. In those cases, the relatively straight-on docking mode results in multipoint (i.e., multi-CDR) attachment of the receptor to the ligand, essentially rigidifying the intermolecular orientations between the two binding partners. In most cases, the $\alpha\beta$ TCR CDR1 and CDR2 loops provide a perimeter of contacts with the MHC helices surrounding the CDR3 loops, and so far, no variation has been seen in the docking angle of TCR to MHC in cases where multiple complexes exist in the asymmetric unit. Thus, the CDR3 motif of G8 and other $\gamma\delta$ TCRs may be thought of as a somewhat autonomous binding entity that is presented by a variety of germline-encoded variable domain scaffolds without strong preference for particular CDR1 and 2 sequences. It would be interesting to see whether these features are present in other examples of $\gamma\delta$ TCR/ligand binding.

CDR3 regions were found to be important for $\gamma\delta$ T cell recognition of MICA/MICB. In this case, the reactivity correlates only with a junction between Vδ1 and Jδ1. Aside from the W-(S)EGYEL motif, the T22-specific CDR3$\gamma\delta$ sequences were diverse and were encoded by various Vδs, N- and P-nucleotides and Dδ1 of different lengths and reading frames. Importantly, it was shown that sequence variations in the CDR3 regions around this motif modulated the affinity and the kinetics of T22 binding (290). In fact, the T22-specific repertoire in normal mice covers a range of affinities, as is evident by the large range of T22 tetramer staining intensities (274,290). This allows for the selection of T cells with the "most optimal" antigen binding capabilities during an immune response, which is a hallmark of the adaptive immune response.

Nonetheless, such a repertoire that is created mainly by V, D, and J region–derived germline-encoded nucleotides, despite requiring VDJ recombination, would be "innate" in character, because the antigen specificities would be predetermined and the repertoire would be much less variable among individuals of the same species.

Analysis of the formation of T10/T22-reactive repertoire indicates that biases linked to the recombination machinery influence the generation of a $\gamma\delta$ T cell repertoire toward certain specificities. A repertoire that is generated by recombination but conferred by a limited set of germline or germline-like residues at the CDR3 region will be created at a much higher frequency than one whose specificity is conferred primarily by N-nucleotide additions, as is the case with that of $\alpha\beta$ TCRs. Indeed, the one in 100 frequency of T22-specific $\gamma\delta$ T cells in normal mice is much higher than the estimated one in 10^5 to 10^6 frequency of naïve peptide/MHC-specific $\alpha\beta$ T cells (293,294,295). This could provide a solution to the apparent paucity of $\gamma\delta$T cells and could allow for a significant response without an initial need for clonal expansion as is required for most $\alpha\beta$ T cell responses. It was shown that rearrangements at the TCR δ locus are biased toward full-length Dδ2 sequences rather than extensive D region nucleotide deletion, as is the case for the TCRβ locus (290). Thus, different reading frames of Dδ2 may contribute to the recognition of other ligands by $\gamma\delta$ TCRs in a manner similar to that of T22-specific $\gamma\delta$ TCRs and would lead to a repertoire that is biased toward a relatively small number of ligands, more on the order of hundreds to thousands versus millions as estimated for $\alpha\beta$ T cells, but with highly variable antigen binding affinities. A repertoire of this type would allow more flexible and efficient responses to changes in ligand expression. These are testable hypotheses, especially once more $\gamma\delta$TCR ligands have been identified.

GENERAL FEATURES OF TCR AND Ig DIVERSITY

A Dominant Role for Diverse CDR3 Regions in Antigen Specificity

One interesting observation that emerges from a detailed analysis of the gene rearrangements that create both T cell receptor and Igs is how the diversity of the CDR3 loop region in one or both of the chains in a given TCR is so much greater than that available to the other CDRs. A schematic of this skewing of diversity is shown in Figure 10.16 for human Igs and for $\alpha\beta$ and $\gamma\delta$ TCR heterodimers. In the case of $\alpha\beta$ TCRs, this concentration of diversity occurs in both Vα and Vβ CDR3 loops, and numerous TCR-pMHC structures (145) have confirmed that these loops sit largely over the center of the antigenic peptide (see previous section). While this concentration of diversity in $\alpha\beta$ TCRs in the regions of principal contact with the many possible antigenic peptides seems reasonable, it is much harder to explain for Ig or $\gamma\delta$ TCRs. Clearly, there must be some chemical or structural "logic" behind this phenomenon. A clue as to what this might be comes from the elegant
FIGURE 10.16 Diversity "map" of immunoglobulins and T cell receptors; calculated potential for sequence diversity in human antigen receptor molecules (Adams et al., 153). The N region addition is assumed to contribute zero to six nucleotides to the junction of each gene segment, except for immunoglobulin K chains, in which this form of diversity is seldom used.

work of Shin et al. (290) in the demonstration that for at least one $\gamma\delta$ T cell specificity, the antigen recognition determinants are encoded by germline V or D region residues, with remaining sequence diversity modulating the affinity (Figure 10.15). While this may be a feature of some or many $\gamma\delta$ TCRs, it could not explain the much broader repertoire of Igs. Instead, one possible explanation comes from the studies of Wells and colleagues (266), who systematically mutated all of the amino acids (to alanine) at the interface of human growth hormone and its receptor as determined by x-ray crystallography. Interestingly, only a quarter of the 30 or so mutations on either side had any effect on the binding affinity, even in cases where the x-ray structural analysis showed that the amino acid side chains of most of the residues were "buried" in the other. This study illustrates an important caveat to the interpretation of protein crystal structures, which is that although they are invaluable for identifying which amino acids could be important in a given interaction, they rarely show which ones are the most important. This is presumably because the "fit" at that many positions is not "exact" enough to add significant binding energy to the interaction. In this context, we have proposed a new model (296,297) in which the principle antigen specificity of an Ig or TCR is derived from its most diverse CDR3 loops. In the case of antibodies, we imagine that most of the specific contacts (and hence the free energy) with antigen are made by the V_H CDR3

and that the other CDR's provide "opportunistic" contacts that make generally only minor contributions to the energy of binding and specificity. Once antigen has been encountered and clonal selection activates a particular cell, somatic mutation would then "improve" the binding of the CDR1s and 2s to convert the typically low-affinity antibodies to the higher affinity models as observed by Berek and Milstein (121) and also by Patten et al. (122,298). As a test of this model, Xu et al. (292) analyzed mice, which have a severely limited Ig V region repertoire, consisting of one V_H and effectively two V_LS ($V\lambda_1$ and $V\lambda_2$). These mice are able to respond to a wide variety of protein and haptenic antigens, even with this very limited complement of V regions. In several cases, hybridomas specific for very different antigens (e.g., ovalbumin versus DNP) differ only in the V_H CDR3. A limited V region repertoire also seemed no barrier to deriving high-affinity antibodies with somatic mutation, as repeated immunizations produced IgG monoclonals with very high affinities (10^9 to 10^{-10}M). The major immune deficit in these mice was in their inability to produce antibodies to carbohydrates, which may require a special type of binding site or specific V region. Thus, while these experiments only involved one V_H, the results are highly suggestive about the inherent malleability of $V_H V_L$ in general, at least with respect to protein and haptenic epitopes. With respect to $\alpha\beta$ TCRs we expect that most of the energy of the interaction with a typical ligand will reside in

the CDR3-peptide contacts, and here again the CDR1 and 2 regions will make less energetically important contacts. For $\gamma\delta$ TCRs, it is not yet clear whether the T10/T22 specificity (290) is an isolated case or the general rule. From the hypothesis discussed here, if there are $\gamma\delta$ TCRs that use the very large inherent diversity in the Vδ CDR3 directly for antigen recognition, it may be that the lack of somatic mutation forces it to provide more diversity in the initial repertoire (versus Igs).

CONCLUSION

Since T cell receptor genes were first identified in the early 1980s, information about their genetics, biochemistry, structure, and function has accumulated to become a field unto itself. Despite this very real progress, many issues still remain unsolved, such as: What do $\gamma\delta$ T cells normally "see" and what function do they serve? What do superantigens actually do during the course of a normal response and how is this of benefit to the pathogen/parasite? What is the structural/chemical basis of TCR specificity? What rearrangements or conformational charges occur in the TCR/CD3 molecular ensemble upon ligand engagement? These and other questions will require many more years of effort.

T Lymphocyte Signaling Mechanisms and Activation

Gary A. Koretzky

INTRODUCTION

Protection of the host from the universe of potential pathogens requires a rapid, dynamic, and flexible immune system capable of responding to organisms that are evolving to escape immune detection. The most rapid responders are cells of the innate immune system that recognize patterns commonly present on pathogens but absent on host cells. Cells of the adaptive immune system (T and B lymphocytes) are generally slower to respond but are equally essential for host protection, as lymphocytes are uniquely able to recognize subtle differences between self and non-self. This chapter focuses on how T cells sense their environment and mount the appropriate

response when challenges are detected. Several essential tenets of T cell biology are discussed, including how T cells recognize antigen, the biochemical consequences of this recognition event, what signals beyond antigen recognition are required for T cells to be stimulated to respond, how the T cell response is terminated once the pathogenic challenge has been met, how an appropriate T cell response might go awry, and how knowledge regarding these critical processes has led to therapeutic modalities to treat immune-mediated disorders.

THE ANTIGEN-BINDING COMPONENT OF THE T CELL ANTIGEN RECEPTOR COMPLEX

Similar to immunoglobulin (Ig) (see Chapters 4 and 6), the antigen-binding component of the receptor expressed on T cells (T cell antigen receptor, or TCR) is composed of the products of rearranging gene segments (1). In most T cells, these proteins are present as an $\alpha\beta$ disulphide-linked heterodimer; however, a minority of T cells express instead a related dimer that is the product of rearranged γ and δ genes (see Chapter 10). The combinatorial rearrangement of multiple gene segments, the error-prone process of joining these different DNA segments, and the various combinations of α with β or γ with δ lead to tremendous diversity of the TCRs, enabling these receptors to respond to the universe of antigens that pathogens present.

Much more is understood about the biology of $\alpha\beta$ T cells compared to their $\gamma\delta$ T cell counterparts; however, it is clear that there are major differences in where these cell types reside in the body and in the antigens that stimulate their activation. As described more fully in Chapter 10, $\gamma\delta$ T cells respond most often to lipid antigens presented by CD1 (a major histocompatibility complex [MHC]–like molecule), while classical $\alpha\beta$ T cells respond to peptide antigens presented within MHC. $\gamma\delta$ T cells are found largely in epithelial and mucosal barriers and to a lesser extent in secondary lymphoid organs, where $\alpha\beta$ T cells reside. The remainder of this chapter focuses on $\alpha\beta$ T cells. For a fuller description of the biology of $\gamma\delta$ T cells, see Chapters 12 and 13 and reference (2).

T cell precursors arise in the bone marrow and then home to and mature in the thymus (3). Early in T cell ontogeny (at the double-negative three [DN3] stage in the thymus; see Chapter 12), the gene segments of the β chain of the TCR rearrange. Because this is a stochastic event and will often lead to a nonfunctional protein, the cell must pass a checkpoint (β selection) to move forward through development. β selection requires that the newly rearranged gene product indicate that it is correctly assembled by stimulating a biochemical change in the cell. It is not known precisely what this biochemical signal is; however, many of the key signaling proteins discussed later in this chapter have been demonstrated to be required for β

selection to occur. It appears that at this stage in T cell development, the β chain is only signaling its appropriate formation and conformation and is not tested for antigen reactivity, as the ligand-binding region of the receptor is not essential for β selection to proceed (4). Successful β selection leads to silencing of the other TCR β allele (allelic exclusion), protection of the cell from apoptosis, cell division, and differentiation into CD4/CD8 double-positive thymocytes. Failed signaling results in rearrangement of the other allele, testing of that β chain, and either developmental progression, if productively rearranged, or cell death.

THE CD3 CHAINS ARE CRITICAL FOR SURFACE EXPRESSION OF THE TCR

Cells that move beyond the DN3 stage in the thymus rearrange their TCR α chains as they become double-positive thymocytes preparing for positive and negative selection. For development beyond this checkpoint, appropriate antigen recognition is required; therefore, the $\alpha\beta$ heterodimers must be transported to the cell surface. This surface expression cannot occur without coexpression of the CD3 chains (5), a collection of protein dimers ($\gamma\varepsilon$, $\delta\varepsilon$, and $\zeta\zeta$) that associate with α and β. Neither the CD3 nor $\alpha\beta$ dimers can be expressed on the cell surface in isolation, because the partner proteins are needed to mask charged residues or sequences that target the isolated proteins for degradation (6). It is this same $\alpha\beta$-CD3 complex (henceforth referred to as the *TCR complex*) that is essential for antigen recognition and signal transduction by mature T cells in the periphery (Figure 11.1A).

Once the components of the TCR complex were discovered, a great deal of work was undertaken to determine the roles of the α and β chains versus the CD3 molecules. Given that α and β arise from Ig-like rearranging gene segments, it seemed plausible that these components of the TCR complex were responsible for antigen recognition. This role was proven formally by the transfection of cDNAs encoding α and β chains from one T cell clone into another, resulting in transfer of reactivity to both peptide antigen and MHC sequences (7). Not only did this experiment demonstrate the role of the $\alpha\beta$ heterodimer, but it also cemented the notion that there is a single receptor for antigen plus MHC, ending a long controversy in the field of T cell biology.

Understanding the role of the CD3 molecules was more difficult. It seemed likely that these proteins were responsible for signal transduction—that is, informing the inside of the cell that an antigen recognition event (mediated by the α and β chains) had taken place. This notion was suggested by the observation that antibodies directed against CD3 proteins elicited the same T cell activation events as did stimulation of T cells with peptide antigen plus MHC. Additionally, it was known that the $\alpha\beta$ proteins

A

B
FIGURE 11.1 Structure of the T cell antigen receptor/CD3 complex and the immunoreceptor tyrosine-based activation motifs. **A:** The T cell antigen receptor (TCR) is a complex of proteins that includes a disulfide-linked dimer ($\alpha\beta$) that binds peptide antigen and MHC. There is an obligatory, noncovalent association of $\alpha\beta$ with a series of protein dimers ($\gamma\varepsilon$, $\delta\varepsilon$, and $\zeta\zeta$) collectively known as CD3. The association between $\alpha\beta$ and CD3 is mediated in part by charged residues within the transmembrane domains of each receptor component. Adapted from Janeway CA, et al. *Immunobiology*. 6th ed. New York: Garland Science, 2005. **B:** Within the cytoplasmic domains of the CD3 molecules are stretches of amino acids known as ITAMs (immunoreceptor tyrosine-based activated motifs) that are critical for signal transduction. In resting cells, the tyrosines within the ITAMs are nonphosphorylated; however, following TCR engagement, these residues become phosphorylated and then are able to bind to other proteins.

possess very short cytoplasmic tails, making it difficult to imagine how signals could be initiated by ligation of these molecules, whereas the CD3 proteins each possess a large number of cytoplasmic amino acids. However, it was difficult to prove the role for CD3, given that these molecules could not be expressed in isolation, without α and β. Investigators turned to cell line model systems (in particular the Jurkat T cell leukemic and BW5147 mouse T cell lymphoma lines) as an initial approach to unravel the biochemical events that occurred when the TCR complex was engaged. These cell lines were particularly useful, because they can be grown in large numbers and are genetically stable (eliminating donor to donor variation), yet can be genetically manipulated for both loss and gain of function experiments. Although the precise antigen specificity of the TCRs expressed on these cell lines was not known, it was possible to stimulate T cell responses using agonistic monoclonal antibodies, directed against the TCR complex. Importantly, the lessons learned about the molecular and biochemical signals critical for receptor ligation to be translated into downstream biologic functions from these cell line studies (with rare but notable exceptions) have been confirmed using primary cells from murine or human sources (8).

Critical tools for the earliest studies that deciphered the role of the CD3 chains were variants of the Jurkat and BW5147 cell lines that lacked surface expression of the TCR complex. Once it became clear that the impediment for cell surface expression of the CD3 molecules in the absence of $\alpha\beta$ was due to sequences that targeted the incomplete complexes for degradation, it was possible to engineer CD3 mutants that could be transported to the membrane without other TCR components. Several groups created artificial receptors that were constructed by fusing irrelevant extracellular domains and transmem-

brane domains (e.g., from the CD8 protein) to the cytoplasmic domain of one of the CD3 molecules, enabling stable expression without other elements of the TCR. When such chimeric receptors were expressed on T cells lacking the TCR, it was shown that binding the extracellular domains of these molecules was sufficient to activate the same biochemical second messengers that are stimulated when the intact TCR binds antigen (9,10). These model systems led to a subsequent series of structure/function studies, demonstrating conclusively that the signal transduction capacity of the TCR rests within specialized domains within the cytoplasmic domains of the CD3 molecules, the immunoreceptor tyrosine-based activation motifs, or ITAMs (Figure 11.1B).

ITAMS AND PROXIMAL SIGNALS MEDIATED BY THE TCR

ITAMs were first discovered as signature sequences that appeared in cell surface molecules on immune cells (11). ITAM-containing proteins that regulate immune responses include the CD3 chains and similar proteins associated with the B cell antigen receptor (the Ig-α [CD79α] and Ig-β [CD79β] molecules), different classes of Fc receptors, and adapter proteins (e.g., DAP10 or DAP12) associated with MHC recognition molecules on natural killer (NK) cells. ITAMs are defined by the presence of a tyrosine residue followed by two amino acids, then a leucine or isoleucine, followed again by a spacer of 6 to 8 unspecified amino acids, then another tyrosine, a 2 amino acid spacer, followed by a leucine or isoleucine (YXXL/IX_{6-8}YXXL/I) (12). Each of the CD3 γ, δ, and ε molecules contain a single ITAM, while each ζ chain possesses three ITAMs in tandem. Mutagenesis of the CD3 molecules prior to transfection

into the TCR-deficient cell lines revealed that the most critical features of the ITAMs are the two tyrosines and the spacing between them (13).

As the CD3 complex is composed of two ζ chains (each with three ITAMS), two ε chains, one γ chain, and one δ chain (each with a single ITAM), there are 10 ITAMs associated with each TCR complex. The reason for this large collection of signaling modules associated with the receptor is unclear. It has been proposed that the various ITAMs couple differentially to unique biochemical pathways or that the multiple ITAMs are necessary for signal amplification. To date, however, there is no definitive evidence to support these or other models for the role of the large number of signaling modules associated with the TCR. Although ITAMs are found in all hematopoietic cell types, this strategy for coupling receptors to signaling pathways is not widespread in other nonhematopoietic lineages. Although ITAMs are found in ERM (ezrin, radixin, moesin) proteins, which are expressed not only in immune cells but also in most other tissues, the role of the motif in the function of this family of proteins has not yet been established (14). Additionally, ITAMs have been reported to be expressed in neuronal tamalin, a cytoplasmic protein that is recruited to the membrane in activated cells (15). ITAMs also appear in proteins of pathogenic viruses that infect cells of the immune system, allowing these viruses to coopt the signaling machinery of their target cells (16).

Concurrent with the studies that identified the different roles of the various components of the TCR complex were other experiments designed to uncover the biochemical signals elicited by TCR engagement that are critical for T cell activation. Biochemical, genetic, and pharmacologic approaches established that the most proximal event associated with TCR ligation is the activation of protein tyrosine kinases (PTKs), including the following: fyn and lck, two members of the src PTK family (17); ZAP-70 (ζ chain-associated protein of 70 kDa), a syk (spleen tyrosine kinase) family PTK (18); and at least two members of the tec family, ITK (interleukin [IL]-2-induced tyrosine kinase) and RLK (receptor-like kinase) (19). As the importance of PTKs for T cell activation became clear, attention refocused on the CD3 ITAMs and their essential tyrosines. Studies revealed that upon TCR engagement, the CD3 ITAM tyrosines rapidly become phosphorylated. It was shown further that once phosphorylated, these tyrosines become docking sites for proteins that possess src homology 2 (SH2) domains (canonical sequences found in a wide spectrum of proteins that allow for phosphotyrosine binding) and that the critical binder to the phospho-ITAMs is ZAP-70, a PTK critical for T cell activation. These studies and others led to a model (20) suggesting that upon binding of antigen/MHC to the TCR, a conformational change occurs making the CD3 ITAMs susceptible to phosphorylation by lck and/or fyn, allowing for recruitment of activated ZAP-70 to the complex (Figure 11.2). Exactly how ligand binding induces such a conformational change and

the precise character of this change have not yet been established, but it is clear that an essential event in initiating a T cell response is for the TCR complex to be converted from an enzymatically inactive structure to one that is associated with active PTK function.

Ample evidence now exists for the essential role played by src, syk, and tec family PTKs in signal transduction mediated via the TCR complex and in subsequent T cell development and/or activation. This evidence has come from experiments making use of cell lines (in particular, variants of the Jurkat line) that have been selected for TCR signaling abnormalities (21,22), mice in which genes for these PTKs have been targeted for deletion or mutation (23,24), and naturally arising mutations in humans that lead to severe immune disorders (25). Loss of fyn has a more minor phenotype than loss of lck in both cell line models and in deficient mice, as lck loss results in a severe block in thymocyte development *in vivo*, whereas peripheral T cells appear in nearly normal numbers in fyn-deficient animals, suggesting that T cell development can occur in the absence of this PTK. Inducible lck deletion in peripheral T cells leads to T cells that fail to be activated upon TCR engagement, similar to what is seen in an lck-deficient Jurkat variant (26). In contrast, fyn-deficient T cells can transduce signals via their TCR, and early reports suggested that only minor functional defects were present (23). More recently, though, rigorous studies of fyn-deficient mice have revealed abnormalities in effector T cell functions, including skewing of T helper (Th) subsets and cytokine production (27,28). Double deficiency of both lck and fyn leads to a complete block of T cell development in mice, with the absence of any cells beyond the DN3 stage in the thymus (29,30), indicating that Fyn can compensate, albeit suboptimally, for the absence of Lck.

ZAP-70 deficiency also results in a severe TCR signaling block in cell lines (nearly all second messenger cascades normally stimulated by the TCR are absent [22]), and ZAP-70–deficient mice demonstrate a block in T cell development at the CD4/CD8 double-positive stage in the thymus (31). Interestingly, the defect in ZAP-70–deficient mice is not as pronounced as that in the fyn/lck double-deficient animals, suggesting that another PTK can compensate, at least partially, in the absence of ZAP-70 prior to the DP stage. Follow-up studies suggest that syk, the other member of this PTK family, is present in developing thymocytes and that mice lacking both syk and ZAP-70 phenocopy the lck/fyn double-deficient animals (32).

The importance of these PTKs for development and function of human T cells has been documented with the description of patients with mutations in lck or ZAP-70. One individual with virtually no T cell function has been identified as having a mutation in lck (33). A number of individuals deficient in ZAP-70 have also been described. These patients have no peripheral CD8$^+$ T cells. Although CD4$^+$ T cells are present, they fail to respond to TCR engagement (34). It is intriguing that the same genetic
FIGURE 11.2 TCR complex stimulation induces tyrosine phosphorylation of the CD3 ITAMs and recruitment of effector molecules. In unstimulated T cells, the ITAMs within the CD3 chains are not phosphorylated, and ZAP-70 is present in the cytosol. The CD4 coreceptor (bound to lck) is present at the membrane, but not in close proximity to the CD3 ITAMs. Upon engagement of the TCR with peptide/MHC, CD4/lck is brought into the vicinity of the bound TCR due to the interaction of CD4 with nonpolymorphic residues of MHC. This results in the tyrosine phosphorylation of the CD3 ITAMs by lck and recruitment of ZAP-70 to the engaged receptor via the ZAP-70 SH2 domains. The enzymatically inactive receptor on the resting T cell is thus converted to an active PTK (protein tyrosine kinase).

alteration (ZAP-70 deficiency) in mice and humans does not result in the exact same T cell phenotype, underscoring the idea that, although often excellent model systems, studies of mice can only suggest but not conclusively prove mechanisms by which human T cells function. The importance of ZAP-70 expression in human disease has recently been demonstrated further with studies profiling gene expression in malignant cells from patients with chronic lymphocytic leukemia (CLL). The expression of ZAP-70 is a marker of a more aggressive form of the disease (35,36). Experiments are currently underway to determine the molecular basis for why ZAP-70 expression in these B cell leukemias leads to more severe disease.

As both src and syk family PTKs function in the most proximal step of the TCR signaling pathway (i.e., phosphorylation of and recruitment of ZAP-70 to the CD3 ITAMs), it is not surprising that deficiency of these proteins has a marked effect on TCR complex function. In contrast, the tec family PTKs (ITK and RLK) function later in the TCR complex signaling cascade (discussed later) and therefore have a more subtle effect on T cell development. As such, in

the absence of ITK or RLK, secondary lymphoid organs are populated with nearly normal numbers of T cells, and assays of T cell activation, while showing mild impairment, are much closer to normal than what is seen in the absence of lck or ZAP-70 (37,38). However, when ITK- or RLK-deficient (and even more so when ITK/RLK double-deficient) mice are challenged with pathogens *in vivo,* the T cell response is markedly abnormal, most obviously in responses that require differentiation of CD4[+] T cells into Th1 versus Th2 subsets (19). It is virtually certain that as mice deficient in tec kinases are examined with greater scrutiny, additional defects in T cell function will be revealed.

THE REGULATION OF TCR-STIMULATED PTK ACTIVITY

The simplest model for how the TCR makes use of src, syk, and tec family PTKs for T cell activation is that upon TCR engagement, lck or fyn are activated and phosphorylate

the CD3 ITAMs. Both lck and fyn are positioned strategically to enable them to act upon the CD3 molecules. Fyn co-immunoprecipitates with CD3, suggesting a close association even in resting cells (39), and lck is associated with the cytoplasmic domains of both CD4 and CD8 (40). CD4 binds to conserved residues of MHC class II, and CD8 binds similarly to MHC class I (see Chapter 20). Thus, as the TCR comes into contact with an antigen/MHC complex, both fyn and lck are available to catalyze ITAM phosphorylation. This phosphorylation allows for the recruitment of ZAP-70, which in turn phosphorylates multiple substrates, eventually recruiting a number of key signaling molecules, including ITK and RLK, into a larger activation complex.

While there is a great deal of experimental evidence to support this model of sequential activation of PTKs, additional data suggest that while this general scheme is correct, there is also considerable cross-talk between the PTKs that makes their regulation more complex. Hence, it appears that the PTKs are substrates of each other and that kinases originally thought to act only downstream of particular activation events may also influence their upstream activators. There is a great deal of current work examining the tyrosines of the src, syk, and tec PTKs that are phosphorylated, as mounting evidence points to phosphorylation of specific residues having significant effects (positive or negative) on PTK function and the ultimate T cell response (41,42). Ongoing studies, again using cell lines with mutations in the PTKs and mice in which specific residues have been altered within the genome, will certainly shed light into the intricate regulation of each of these critical signaling molecules.

As the importance of tyrosine phosphorylation for TCR-induced T cell activation was becoming appreciated, additional work was focusing on other T cell proteins. One of the most abundant surface antigens present on all immune cells is CD45, a transmembrane molecule that was shown to have potent protein tyrosine phosphatase activity

(43). With this discovery, the notion developed that CD45 most likely functioned as a negative regulator of TCR signaling, as it was reasoned that CD45 would reverse the TCR-stimulated tyrosine phosphorylation events. CD45-deficient cell lines were established, with the expectation that these cells would exhibit uninhibited TCR function. The CD45-deficient cells were examined, and the result of these experiments was exactly the opposite of the predictions: T cells without CD45 failed to signal via their TCR (44,45). These studies indicated that CD45 was, in fact, a required positive regulator of T cell activation. An explanation for this surprising result came from studies demonstrating that a key substrate for CD45 is a tyrosine residue in the carboxyl-terminal region of src family kinases (46), a tyrosine that, when phosphorylated, diminishes the ability for the PTK to function. Thus, the model arose for CD45 being permissive for TCR-stimulated lck or fyn activation by dephosphorylating a tyrosine that would otherwise impede src family PTK function (Figure 11.3).

Although there is a single gene for CD45, there are multiple isoforms expressed on the surface of immune cells, due to alternative splicing of exons that comprise the extracellular domain of this transmembrane phosphatase (47). The importance of these alternative forms of CD45 is suggested by the fact that their expression is highly regulated and that different forms of CD45 predominate in cells with different functions (e.g., resting versus activated or memory T cells). The appreciation of the regulated expression of the different isoforms led to an intensive search for ligands that are specific for the different CD45 splice variants, the results of which remain elusive. It was suggested that the extracellular domains of CD45 contain signals important for dimerization of the phosphatase, an event that is speculated to alter the ability of CD45 to dephosphorylate substrates (either through changing enzymatic activity or substrate availability) (48). Support for this notion comes from a study of mice with a mutation of CD45 knocked into the locus that is predicted to interrupt CD45
FIGURE 11.3 Dynamic regulation of src family PTKs by a kinase and a phosphatase. Src family PTKs possess a carboxyl-terminal tyrosine that, when phosphorylated, mediates an intramolecular interaction that diminishes enzymatic activity. Phosphorylation of this tyrosine is highly regulated, being mediated by the kinase csk (carboxy-terminal Src kinase) and its dephosphorylation by the phosphatase CD45. When dephosphorylated, src PTKs adopt a more open conformation that is permissive for their activation. This feature of src PTK control makes CD45 an essential positive regulator of T cell activation and csk an effective inhibitor.

dimerization (49). Mice expressing this CD45 mutant exhibit autoimmunity, suggesting unimpeded activation of immune cells. This idea has been extended to human immune-mediated diseases with the recent description of polymorphisms of the CD45 gene being correlated with multiple sclerosis, autoimmune hepatitis, and other autoimmune disorders (50). Exactly how these alterations in the gene translate into abnormal CD45 function remains to be determined.

Given the importance of the carboxyl-terminal tyrosine of src family PTKs as a controller of kinase activity, it is not surprising that phosphorylation (in addition to dephosphorylation) of this residue is a regulated event. Csk (carboxyl-terminal src kinase) opposes the action of CD45 by catalyzing the phosphorylation of this inhibitory tyrosine (51) (Figure 11.3). Thus, one means to control the likelihood that engagement of the TCR will result in T cell activation is how csk versus CD45 action is balanced. Exactly how this balance is accomplished appears to rest in large part on where in the cell CD45 and csk reside and which enzyme is found in proximity to the src PTKs. This subcellular localization of the src PTK regulators is a complex process that involves a chaperone protein for csk (discussed later) and regulated movement of CD45 before and during TCR engagement.

SIGNALS DOWNSTREAM OF THE PTKs

The discovery of the essential role played by PTKs for T cell activation was followed by a search for substrates of these PTKs in an effort to understand how activation of these kinases leads ultimately to T cell effector function. Among these substrates are key components of several signal transduction pathways known to be essential for activation of multiple cellular lineages. One of the critical second messenger cascades is initiated when the TCR-stimulated PTKs phosphorylate and activate phospholipase C $\gamma 1$ (PLC$\gamma 1$), an enzyme that hydrolyzes the membrane phospholipid phosphatidylinositol-1,4-bisphosphate (PIP$_2$) into a soluble sugar, inositol-1,4,5-trisphosphate (IP$_3$), and the lipid diacylglycerol (DAG) (52) (Figure 11.4). IP$_3$
FIGURE 11.4 Binding of the TCR initiates the phosphatidyl inositol second messenger cascade. One of the most important signaling pathways initiated by engagement of the TCR begins by activation of phospholipase c $\gamma 1$ (PLC$\gamma 1$). This enzyme catalyzes the hydrolysis of the membrane phospholipid phosphatidylinositol-1,4-bisphosphate (PIP2) into two products, the soluble sugar inositol-1,4,5-triphosphate (IP3) and the lipid diacylglycerol (DAG). IP3 interacts with its receptor on the endoplasmic reticulum causing a release of intracellular calcium. Increased cellular calcium activates a calcium-regulated calcium channel (CRAC) and calcium-dependent enzymes such as calcineurin, a phosphatase that dephosphorylates nuclear factor of activated T cells (NFAT), allowing this transcription factor to enter the nucleus. DAG activates members of the protein kinase C (PKC) family and the Ras signaling pathway via the Ras exchange factor, RasGRP1. PKCs activate the NFκB transcription factor, and a Ras-stimulated kinase cascade including Raf and members of the mitogen-activated protein kinase (MAPK) family activates activator protein-1 (AP-1).

binds to its receptor on the endoplasmic reticulum (ER), causing a release of calcium from this organelle.

The increase in cytosolic free calcium in TCR-stimulated cells occurs in two phases. The initial burst in calcium release from the ER (mediated by the interaction between IP_3 and its receptor) is followed by a more sustained increase in calcium that is mediated by activation of a calcium-regulated membrane channel designated *CRAC* (calcium release-activated calcium channel) (53). While it was clear that such a channel existed and that its function was essential for T cell activation to occur and be sustained, the identity of this channel until recently was a mystery. Studies of a patient with severe combined immunodeficiency coupled with a novel genetic screen demonstrated that at least one CRAC component critical for T cell activation is the product of the *orai1* gene, a transmembrane protein found in multiple cell lineages (54). This discovery is one of many examples of how investigators, studying human immune disorders, have added to our fundamental knowledge of the mechanisms by which immune cells translate antigen receptor occupancy to an effector immune response. Experiments are now underway to determine the molecular nature of the entire channel and its mode of regulation.

TCR-mediated increases in cellular calcium activate several calcium-dependent enzymes, including the serine phosphatase calcineurin (55). When activated, calcineurin dephosphorylates nuclear factor of activated T cells (NFAT), allowing NFAT to leave the cytosol and enter the nucleus, where it cooperates with other transcription factors to stimulate expression of key T cell activation-associated genes (56). NFAT activation is terminated by kinases in the nucleus that phosphorylate the transcription factor, leading to its nuclear export back to the cytosol (57,58). In the cytosol, it can again be dephosphorylated by calcineurin and transported back to the nucleus, if the appropriate activation conditions are still in place. The key role that calcineurin and the NFAT pathway play in T cell activation is underscored by the efficacy of cyclosporine, a pharmacologic inhibitor of this pathway, as a clinically important immunosuppressive agent (59).

The other hydrolysis product of PIP_2, DAG, is also critical for T cell activation (Figure 11.4). DAG functions by binding to specialized motifs on several other proteins, including members of the protein kinase C (PKC) family and RasGRP1, a guanine nucleotide exchange factor (GEF) for the small molecular weight GTP-binding protein Ras (60). DAG binding activates the PKCs and promotes the ability of RasGRP1 to allow Ras to release GDP and bind GTP (61). PKCs phosphorylate several key substrates (discussed later), while activated Ras stimulates yet another series of kinases. These kinases include Raf and different members of the mitogen-activated protein kinase (MAPK) family (62). Collectively these signals are integrated, leading to the activation of other transcription factors criti-

cal for initiating the genetic program for T cell activation. Among these key transcription factors are the AP-1 (activator protein-1) complex (that cooperates with NFAT) and members of the NFκB family (63).

Although much has been learned about TCR signal transduction, many of the details regarding the molecular events critical for its activation remain unknown. For example, although it has been shown that the src family PTK fyn associates directly with CD3 components and that the src PTK lck is brought into the activation complex via the association of lck with the important coreceptors CD4 and CD8, exactly how ligand binding to the TCR α and β chains is translated into increased enzymatic activity of the src PTKs is unclear. Additionally, it is not known if activation of the src PTKs is sufficient for CD3 ITAM phosphorylation or if other TCR-mediated events are required. For example, it has been argued that ligand binding to the TCR induces a conformational change in the entire TCR complex, making the CD3 ITAMs susceptible to phosphorylation by lck and/or fyn; however, a detailed explanation of this conformational change has not yet been provided and remains an important area for future discovery.

HEMATOPOIETIC-SPECIFIC ADAPTER PROTEINS ARE CRITICAL FOR T CELL ACTIVATION

Insights into how TCR-stimulated PTK activation initiates the PLC signaling cascade arose from the discovery of two adapter proteins: linker of activated T cells (LAT) (64) and SH2 domain-containing leukocyte-specific phosphoprotein of 76 kDa (SLP-76) (65) (Figure 11.5). Adapter proteins are molecules that possess no intrinsic catalytic activity but act as scaffolds to create multimolecular complexes, bridging receptors with their downstream effector molecules. LAT is a transmembrane protein that resides largely in lipid rafts, membrane microdomains enriched in cholesterol, due to palmitoylation of two cytoplasmic cysteines within the juxtamembrane region of LAT (66). Upon TCR ligation, LAT becomes tyrosine phosphorylated on multiple residues, providing docking sites for other proteins that possess SH2 domains. Among the proteins that bind to phosphorylated LAT are effector molecules (e.g., PLCγ1) and phosphatidylinositol 3-kinase (PI3K), a lipid kinase that activates a cascade of important second messengers. While TCR engagement appears to simulate the PI3K pathway, ligation of coreceptors on T cells, in particular CD28, is much more effective at initiating this signaling cascade and is discussed in more detail later in this chapter. Phosphorylated LAT also associates with the SH2 domain of growth factor receptor binding protein 2 (Grb2), an adapter molecule that binds constitutively to son of sevenless (SOS), a GEF that allows Ras to bind to GTP. Although Grb2/Sos appears less important than RasGRP1
FIGURE 11.5 Adapter molecules are proteins that contain modular domains that function by mediating interactions with other molecules in the cell. Shown here are several adapters (not drawn to scale) mentioned in the text, containing some but not all of the possible protein interaction domains. Src homology 2 (SH2) domains mediate interactions with other proteins phosphorylated on tyrosine residues, SH3 domains associate with other proteins that are rich in proline residues, proline-rich regions (Pro) bind to other proteins with SH3 domains, and residues that are themselves substrates of protein tyrosine kinases (P-Y) allow for interactions with other proteins that possess SH2 domains. Some adapters are cytosolic, while others possess transmembrane domains (TM), allowing their insertion into the plasma membrane. These adapters may also possess juxtamembrane cysteines (C) that are posttranslationally modified for targeting to lipid rafts within the membrane (see text for details). LAT, linker for activated T cells; PAG/Cbp, phosphoprotein associated with glycosphingolipid-enriched domains/csk-binding protein; SLP-76, SH2 domain-containing leukocyte-specific phosphoprotein of 76 kDa; SAP, SLAM-associated protein; GADS, Grb2-related adapter downstream of Shc.

for Ras activation in T cells, genetic studies indicate that this pathway is important for optimal T cell function (67). When phosphorylated, LAT inducibly associates with another member of the Grb2 family, Grb2-related adapter downstream of Shc (Gads) (68). The LAT/Gads interaction is critical, because Gads binds constitutively to SLP-76 (69).

Like LAT, SLP-76 is a hematopoietic-specific adapter molecule. SLP-76 possesses three functional domains: an amino-terminal region that becomes phosphorylated upon TCR engagement and inducibly binds to other proteins with SH2 domains, a central proline-rich region allowing it to bind to proteins with src homology 3 (SH3) domains constitutively, and a carboxyl-terminal SH2 domain allowing SLP-76 to bind to other proteins that are themselves phosphorylated on tyrosines (70). In resting cells, SLP-76 associates with Gads in the cytosol. Upon TCR engagement and LAT phosphorylation, the SLP-76/Gads complex is recruited to LAT (and lipid rafts). Because both SLP-76 and LAT bind independently to PLCγ1, the association between SLP-76 and LAT (mediated by Gads) stabilizes the recruitment of this critical enzyme, enhancing its ability to interact with PIP$_2$ within the membrane (71). PLCγ1 function is enhanced further, because SLP-76 associates also with ITK, a tec family PTK that phospho-

rylates PLCγ1. In addition to recruiting PLCγ1 and ITK to LAT and lipid rafts, SLP-76 binds to Vav, a GEF critical for TCR-induced changes in the cytoskeleton, Nck, an adapter that cooperates in this same pathway, and adhesion- and degranulation-promoting adapter protein (ADAP), an adapter that coordinates TCR signaling to integrins (72,73) (Figure 11.6).

In addition to stimulation of the PLCγ1-dependent pathway, TCR complex engagement results in numerous other downstream signals that are essential for full T cell activation. As alluded to earlier, TCR ligation results in an alteration of the cytoskeleton characterized by polymerization of actin and T cell shape change (74). This process requires Vav, a protein with adapter domains and a region that enhances the exchange of GDP for GTP on members of the Rac and Rho family of small molecular weight GTPases (75). Tyrosine phosphorylation of Vav leads to both enhancement of its GEF function as well as its binding to a number of other proteins in the T cell activation pathway. Vav is critical as a regulator of the T cell cytoskeleton and as a modulator of T cell migration and adhesion after activation. This requires the GEF activity of Vav acting on Rac proteins and another GTP-binding protein, Cdc42, to increase actin polymerization at the leading edge as T cells migrate. Vav also is necessary for the redistribution of
FIGURE 11.6 TCR binding results in the formation of a multimolecular signaling complex critical for initiating several signaling pathways. Following TCR engagement, inducible tyrosine phosphorylation of the two adapters linker of activated T cells (LAT) and SH2 domain-containing leukocyte-specific phosphoprotein of 76 kDa (SLP-76) results in a multimolecular complex that couples protein tyrosine kinase (PTK) activation to downstream signaling events. Activation of lck, fyn, and ζ-associated protein of 70 kDa (ZAP-70) leads to phosphorylation of LAT. SLP-76, which binds constitutively to Gads, is recruited to phospho-LAT, because the Gads SH2 domain has affinity for several of the LAT phosphorylation sites. Phospholipase Cγ1 (PLCγ1) binds to both SLP-76 and LAT, bringing this enzyme into the complex. PLCγ1 is activated when it is phosphorylated by a series of PTKs, including ITK, a tec family PTK that is also recruited by SLP-76. Activated PLCγ1 then initiates the calcium and DAG signaling pathways described for Figure 11.4. In addition to binding the effectors of this signaling pathway, SLP-76 also recruits adhesion- and degranulation-promoting adapter protein (ADAP) to the complex, enhancing integrin activation. The LAT/SLP-76 complex also promotes alterations in the cytoskeleton by recruiting Vav and Nck to the site of TCR engagement.

molecules on the surface of T cells, most notably integrins, during T cell activation (76). Analyses of mice deficient in Vav reveal that this protein has additional effects, including modulation of TCR-stimulated increases in calcium mobilization and activation of ERK (77). Expression of Vav mutants on the background of Vav-null T cells will provide insights into how the various domains of this molecule function, allowing it to have its multiplicity of effects on T cell activation.

Another important regulator of actin polymerization in activated T cells is the Wiskott-Aldrich syndrome protein (WASP), a protein that is either absent or mutated in an immunodeficiency syndrome that is characterized by defective B and T cell immunity and platelet function (78). WASP is brought into the TCR-stimulated activation complex by its association with Nck, but it is activated through its association with Vav (79,80). These two pathways are linked, as both Vav and Nck bind to phosphorylated SLP-76. Biochemical and genetic studies have shown that WASP functions as a regulator of the cytoskeleton by

activating the Arp2/3 complex that is critical for initiating actin polymerization, directed T cell migration, and T cell adhesion (81) (Figure 11.7). However, this mechanism is not the only one by which TCR engagement promotes alteration in the cytoskeleton, as T cells with mutations in these signaling components still manifest actin polymerization, albeit with less efficiency.

T CELL ACTIVATION OF SERINE/THREONINE KINASES

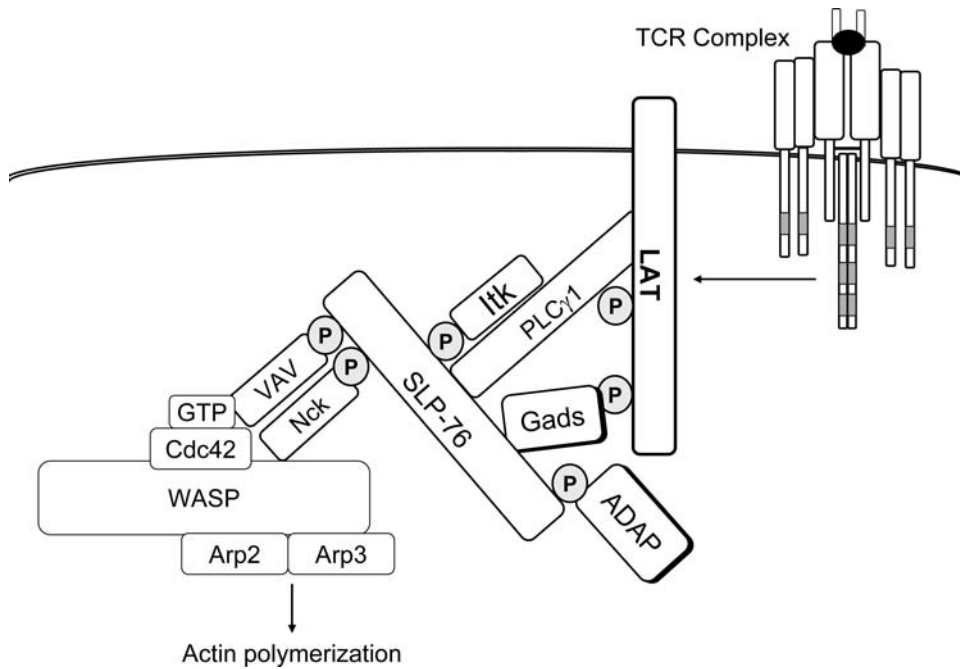
One of the earliest observations made in the study of signaling events that occur following TCR engagement was that treatment of T cells with phorbol esters (DAG-like molecules) plus calcium ionophores could recapitulate the activation events seen with receptor binding (82). This work led quickly to the notion that PKC (as the target of phorbol esters) was an important component of the TCR signaling cascade. As studies began to uncover the


FIGURE 11.7 The LAT/SLP-76 complex stimulates cytoskeletal changes by recruiting the WASP signaling complex. Recruitment of SH2 domain-containing leukocyte-specific phospho-protein of 76 kDa (SLP-76) to linker of activated T cells (LAT) via Grb2-related adapter downstream of Shc (GADS) (described in detail for Figure 11.6) initiates changes in the cytoskeleton by localizing active Vav, Cdc42, Wiskott-Aldrich syndrome protein (WASP), and the Arp2/3 complex, resulting in actin polymerization. This is one of several ways in which the TCR engagement causes alterations in the cytoskeleton, a key step for T cell migration and effector function.

importance of PTKs in T cell activation, experiments examining particular PKC family members and the potential role of other serine/threonine kinases lagged. Recently, however, there have been numerous reports of the importance of these second messengers for effective T cell responses.

Understanding the role of PKC in T cell activation is complicated by the fact that there are multiple members of the PKC family (83). The PKC isoform that has received the most attention as a regulator of T cell function is PKCθ, an enzyme that exhibits an intriguing subcellular localization pattern. In resting T cells, PKCθ is found in the cytosol; however, upon engagement of the TCR complex, it quickly translocates to the site of the en-

gaged receptor (84). Following this observation, investigators generated mice targeted for PKCθ deletion and discovered a requirement for this enzyme in TCR-induced activation of the NFκB pathway (85) (Figure 11.8). The signaling pathway downstream of PKCθ is becoming clear, as mounting evidence has shown that PKCθ phosphorylates CARMA1 (caspase-recruitment domain [CARD] membrane–associated guanylate kinase [MAGUK] protein 1), an adapter protein that when phosphorylated nucleates a molecular complex including two other signaling proteins, MALT1 (mucosa-associated-lymphoid-tissue lymphoma-translocation gene 1) and Bcl10 (B cell lymphoma 10) (86). The resultant complex recruits yet another serine kinase, IKK (inhibitor of NFκB [IκB] kinase) that,
FIGURE 11.8 Engagement of the TCR results in PKC-mediated activation of the NFκB pathway. Following TCR stimulation, protein kinase C θ (PKCθ) becomes activated, in part via the generation of diacylglycerol (DAG) (see Figure 11.4). PKCθ then phosphorylates caspase-recruitment domain (CARD) membrane–associated guanylate kinase (MAGUK) protein 1 (CARMA1), which forms a complex with two other proteins, B cell lymphoma 10 (Bcl10) and mucosa-associated-lymphoid-tissue lymphoma-translocation gene 1 (MALT1). Together, these proteins activate inhibitor of NFκB (IκB) kinase (IKK), which phosphorylates IκB, a negative regulator of NFκB. Upon its phosphorylation, IκB is degraded, allowing NFκB to escape the cytosol and enter the nucleus. Adapted from Matthews SA, Cantrell DA. *Current Opinion in Immunology.* 2006;18:314–320.

when activated, leads to the degradation of IκB, a negative regulator of the NFκB transcription factor (87). Loss of IκB allows NFκB to escape the cytosol and enter the nucleus, where it can transactivate genes critical for T cell activation, including the gene for IL2, a cytokine essential for T cell proliferation.

Recent studies have embarked on the difficult task of unraveling the roles of the other members of the PKC family in the regulation of T cell activation. Investigators have made use of mice with targeted deletion of genes for particular isoforms and pharmacologic inhibitors or activators that are relatively selective for different PKC enzymes. The collective results of these studies indicate that PKC enzymes other than PKCθ are also essential for T cell function, in particular to mediate T cell adhesion and migration, both critical steps to position T cells appropriately to respond to antigenic challenges (60). To add to the complexity of how PKC functions in T cells, it appears that members of the PKC family may serve as negative regulators of immune cell function, a finding that has important implications when one considers PKC as a potential therapeutic target (88).

One difficult but useful approach to decipher the role of PKC in T cell activation has been to search for substrates of the kinases. Antibodies have now been developed that are able to detect signature sequences of phosphorylated residues that are targets for PKC enzymes. These reagents have been used to identify protein kinase D (PKD) as a protein that is inducibly phosphorylated by PKC following TCR engagement (89). Multiple PKC isoforms have been shown to be capable of phosphorylating PKD. The consequences of PKC phosphorylation of PKD have been described best in nonlymphoid cells; however, there is considerable evidence that PKD plays a role regulating the activity of small molecular weight GTPases in T cells (90,91), which are critical for inside-out signaling from the TCR to integrins (see later discussion). Additional work has shown that subcellular localization of PKD is also a key determinant in its function and that PKD phosphorylation likely plays a role in its trafficking within the cell. Other serine/threonine kinases and their substrates have been identified recently as important for T cell function, including AMPK (5′AMP-activated protein kinase), a regulator of glucose metabolism and cellular bioenergetics (92). It is anticipated that with the advent of improved reagents, additional serine kinases will be identified that are critical for T cell development and function.

INSIDE-OUT SIGNALS FROM THE TCR TO INTEGRINS

In addition to activation of genes important for T cell effector function, TCR engagement primes the cell to respond to other activating stimuli. One mechanism for this priming is a TCR-inducible increase in avidity of integrins for their ligands. Integrins are cell surface receptors that mediate interactions between other cells or the extracellular matrix (93). Increased adhesion of T cells to antigen presenting cells (APCs) via integrins increases the stability of the association between the TCR and antigen/MHC (also present on the APCs), thus potentiating the ability of the TCR to transduce its activating signals. The process of TCR-induced changes in integrin avidity is known as "inside-out" signaling, as intracellular signals initiated by the TCR feed back onto the integrins to change their surface properties (Figure 11.9). The biochemical basis of inside-out signaling requires many of the same components as signals leading to transcriptional activation of cytokine genes, including the src PTKs, ZAP-70, LAT, SLP-76, and Vav. However, it appears that an additional set of adapter proteins is essential to translate TCR engagement into increased integrin avidity. These proteins include ADAP, src kinase–associated phosphoprotein of 55 kDa (SKAP55), and Rap1-GTP interacting adapter molecule (RIAM) (94,95). Recent data suggest that for maximal integrin function, it is necessary to form a complex of SLP-76/ADAP/SKAP55/RIAM to bring the Rap1 GTPase to the cell surface. Active Rap1, when expressed as a transgene in T cells, increases T cell adhesion by stimulating clustering of LFA-1 (leukocyte function-associated antigen 1), making it a better binder to its ligand, ICAM-1 (intercellular adhesion molecule-1) (96). A potential link between Rap1 and integrin function has been provided by the observation that for active Rap1 to function as an enhancer of integrin avidity, it must bind one additional protein, RAPL (regulator of adhesion and cell polarization enriched in lymphoid tissues), which has been shown to bind directly to LFA-1 (97). Collectively, these studies, making use of biochemical and imaging approaches in cell lines and genetically altered mice, have revealed an intricate pathway that at least partially explains how inside-out signaling couples the TCR complex to integrins.

The pathway described results in clustering of integrins on the T cell surface, thus increasing their avidity for ligands. It is known additionally that engagement of the TCR complex results in a change in the integrins themselves, so that their binding affinity for ligand is increased. The structural basis for the change in affinity has been described in a series of elegant experiments that have captured and visualized integrins in their resting state, in a transitional state, and in their most active conformation (98). It is not clear exactly what biochemical event is the most critical for inducing these conformational changes, but possibilities include posttranslational modifications of the integrin cytoplasmic domains (e.g., by PKC). The entire spectrum of the signals downstream of the TCR that are necessary for integrin clustering and avidity changes remain unknown, but considerable work has implicated Vav and other cytoskeletal regulators (76).
FIGURE 11.9 TCR engagement leads to increased avidity of integrins. The signaling complex described in Figure 11.4 recruits another series of adapter proteins including adhesion- and degranulation-promoting adapter protein (ADAP), src kinase-associated phosphoprotein of 55 kDa (SKAP-55), and Rap1-GTP interacting adapter molecule (RIAM). Together, these molecules allow the activated form of the GTPase Rap1 to be recruited to the membrane in the vicinity of integrins. Active Rap1 (likely via effector molecules such as regulator of adhesion and cell polarization enriched in lymphoid tissues [RAPL]) stimulates clustering of integrins, hence increasing their avidity for ligand. Genetic experiments have also implicated Vav in this process. In addition to increasing integrin clustering, TCR stimulation also activates a signaling pathway that causes alterations in integrin conformation resulting in increased affinity for ligand.

T CELL COSTIMULATION

One of the most striking features of T cell activation is that engagement of the TCR complex alone, while stimulating multiple second messenger cascades, is not sufficient to activate a mature peripheral T cell. In fact, such stimulation often results not only in failed activation but also in a long-lived state of T cell unresponsiveness known as anergy (see Chapter 30 and ref [99]). Effective T cell activation therefore requires two signals: signal 1 initiated by engagement of the TCR complex, and signal 2 initiated by binding of one of several costimulatory receptors that transduce independent signals or enhance the signaling cascades initiated by engagement of the TCR complex (Figure 11.10). Although there are no conclusive data to explain the need for two signals to drive full T cell activation, one attractive model is that such a system allows for an extremely sensitive antigen receptor that is "held in check" by the requirement for a second signal to ensure that activation occurs only at the right time and place. This model predicts that the second signal should require an interaction between the T cell and the appropriate APC, a prediction that has been born out by experimental data.

Although there are a number of costimulatory receptors on T cells that are able to provide the essential second signal in various experimental models, CD28 appears to be the most physiologically relevant. CD28, a cell surface homodimer, is present on virtually all CD4$^+$ T cells and

the majority of CD8$^+$ T cells (100). It is bound by members of the B7 family of ligands (predominantly B7-1 [also known as CD80] and B7-2 [now designated CD86]) that are present, as would be predicted, on APCs. In fact, members of the B7 family are only expressed at low levels on resting APCs (e.g., quiescent macrophages or immature dendritic cells [DCs]), but as innate immune cells begin to signal the presence of pathogens, one important response is the induction of both MHC class II and the CD28 ligands, making APCs better able to deliver both signals 1 and 2 (see Chapter 15 and ref [101]). The importance of CD28 has been established *in vivo* through analysis of mice made deficient in the gene. Although these animals are still able to mount immune responses, they occur much less efficiently than in wild type mice (102).

Since the identification of CD28 as a major inducer of signal 2, many studies have been performed to determine the critical biochemical event initiated by CD28 that prevents T cells from becoming anergic and instead initiates activation (100) (Figure 11.11). As is the case for other costimulatory receptors on T cells, one consequence of CD28 ligation is more efficient signal transduction by the TCR complex, resulting in enhanced as well as prolonged activation of downstream pathways (100). Exactly how CD28 engagement results in enhanced TCR signaling remains obscure, but mechanisms that have been hypothesized include stabilization of the TCR/APC interaction, decreased turnover of the receptor, or synergistic recruitment of effector molecules.
FIGURE 11.10 Two signals are required for productive T cell activation. Engagement of the TCR by peptide/MHC results in activation of multiple second messenger pathways. These signals by themselves, however, are not sufficient to stimulate T cell proliferation or differentiation into effector cells. In fact, delivery of signal 1 alone results in T cells becoming unresponsive to antigen encounter, in some model systems, exhibiting long term "anergy." When signal 1 is delivered concurrently with a costimulatory signal (signal 2), instead of being rendered anergic, T cells are stimulated to expand and develop effector function. There are many molecules that can deliver signal 2 to activate a T cell, the prototype being CD28 when bound by members of the B7 family of ligands present on APCs.

FIGURE 11.11 Costimulation of T cells by CD28 activates numerous signaling events. Stimulation of CD28 by its ligands on APCs results in enhanced signaling via the TCR as well as stimulation of additional second messengers. One such signaling pathway is activation of the phosphatidyl inositol-3 kinase (PI3K) pathway that leads to increased enzymatic activity of AKT, a serine kinase that promotes cellular survival and glucose metabolism. CD28 engagement potentiates cytokine production both by inducing mRNA stability and by stimulating transcription through unique promoter elements (e.g., the CD28 response element [CD28RE]). Additionally, CD28 stimulation results in activation of c-Jun kinase and several protein arginine methyltransferases. Adapted from Alegre ML, et al. *Nature Reviews Immunology.* 2001;1:220–228.

Although microarray analysis to date has not revealed qualitative changes in gene transcription during T cell costimulation (103,104), there is compelling evidence that in addition to augmenting TCR signals, CD28 engagement results in unique second messenger signaling events. The first demonstration of such a unique CD28 signal came from mutagenesis studies demonstrating that within the promoter for the IL2 gene is a specific sequence, designated the CD28 RE (response element), that when altered abrogates CD28-mediated transcriptional up-regulation of the IL2 promoter while leaving TCR-mediated activation largely intact (105). The CD28RE acts in conjunction with the adjacent AP-1 site to form a unique composite element, RE/AP, whose activation absolutely requires two signals for stimulation, in contrast to other transcriptional elements from the IL2 promoter, such as NFAT, which can be activated by TCR stimulation alone (106). In addition, CD28 clearly relies on signals that are different from those induced by the TCR, since CD28 signaling leading to the upregulation of RE/AP and IL2 is cyclosporine insensitive, in contrast to TCR-stimulated signals (106,107). However, it remains unclear exactly what biochemical signals are necessary to uniquely activate this region of the *Il2* promoter.

In addition to increasing the transcription of the *Il2* gene, CD28 has been shown to enhance IL2 production by stabilizing mRNA for this cytokine (108). This outcome of CD28 signaling is not unique to the *Il2* gene, as compelling data exist for the ability of CD28 to significantly enhance mRNA half-life of multiple other cytokine genes. The transcripts that respond to CD28 in this manner are alike, in that they have stretches with many adenosine and uracil bases (so-called *AU-enriched sequences*) 3′ to the translational stop codons. Again, the precise biochemical mechanism for the CD28-stimulated mRNA stability remains unclear; however, there is evidence to suggest that one important signal is activation of c-Jun kinase, a pathway stimulated strongly by CD28 engagement (ref [109]; discussed later).

Many laboratories have searched for the unique signal(s) initiated by CD28 engagement separate from those seen following stimulation of the TCR complex. One pathway critical for effective T cell responses that appears to

be relatively selectively stimulated by CD28 is activation of phosphatidyl inositol-3 kinase (PI3K), a lipid kinase that phosphorylates the membrane lipid $PI(4,5)P_2$ (110). CD28 appears to communicate with this signaling pathway via phosphorylation of a key residue within the CD28 cytoplasmic tail (the tyrosine within a YMNM motif), leading to recruitment of the p85 subunit of the PI3K complex. The result is an altered lipid composition of the membrane in the vicinity of engaged CD28 with subsequent recruitment of other molecules containing pleckstrin homology (PH) domains, such as the tec family kinases and a serine/threonine kinase, AKT (111). The concurrent recruitment of PDK1, PDK2, and AKT to the plasma membrane results in dual phosphorylation of AKT by PDK1 and PDK2 at two key regulatory sites, resulting in AKT activation, which in turn stimulates a cascade of signaling events leading to enhanced cell survival. Mounting evidence supports the notion that activation of this pathway is important for effective T cell costimulation and inhibition of an apoptosis program.

The finding that CD28 potentiates cell survival has led to the investigation of other signals stimulated by CD28 binding, but not by engagement of the TCR, that lead ultimately to protection from apoptosis. Experiments in other cellular systems have shown that the balance between various members of the MAPK family of enzymes, in particular the relative activation of the ERK (extracellular signal-regulated kinase) versus Jun kinase pathways, is a critical determinant of cell survival. These findings led to a series of studies in T cells demonstrating that engagement of CD28 is a potent activator of c-Jun kinase, whereas ERK activation appears to be driven mainly by TCR ligation (109). It remains unclear, however, whether this is the pivotal difference in the cell signaling program that dictates survival of stimulated cells. Regardless of whether ERK versus Jun kinase activation is the critical step, many experiments have now shown that CD28 engagement does up-regulate important anti-apoptotic genes, including Bcl2 family member proteins (112–114).

Several intriguing reports suggest other possible mechanisms for CD28 to deliver its unique signals. Like phosphorylation of serine, threonine, or tyrosine residues, protein methylation appears to be an important posttranslational modification that modulates function, although in most cases the mechanism for altered function is not known. With the advent of improved detection approaches and the cloning of genes encoding protein arginine methyltransferases, it has become apparent that arginine methylation of proteins is important in many biologic systems, most often to regulate activity of transcription factors. Recent work has shown that TCR engagement has only a minor effect on protein arginine methyltransferase activity in T cells; however, costimulation via the TCR with CD28 (and even CD28 engagement alone) results in potent activation of the methyltransferases (115). Substrates of these enzymes are being isolated. To date, molecules identified include several that are critical for T cell activation including Vav and an NFAT-associated protein known as NFAT-interacting protein 45 (NIP45) (116). Another recently described model for CD28 function is costimulation-dependent changes in cellular energy metabolism. This intriguing model has attracted a great deal of attention, as it suggests that glucose uptake and utilization is a cause not a consequence of enhanced T cell activation (117).

CD28 signals are major costimuli for T cells, and CD28 has many functions. It is likely that only through a combination of its many described effects on signaling pathways can the full impact of CD28 engagement be realized. Many investigators continue to work on CD28, anticipating that understanding the molecular basis for how CD28 contributes to T cell activation will provide new opportunities to modulate immune cell function for therapeutic purposes.

THE CD28-RELATED RECEPTOR ICOS COSTIMULATES ACTIVATED T CELLS

CD28 is expressed at high levels on resting T cells and plays a critical role in the initial activation of cells once they encounter antigen/MHC on an activated APC. More recent studies have identified another member of the CD28 family, inducible costimulator or ICOS (118). In contrast to CD28, ICOS expression is low on naïve cells but up-regulated on cells stimulated via their TCR (119). Although CD28 stimulation is not absolutely required for ICOS induction, engagement of CD28 promotes ICOS expression, further suggesting that these two related proteins function sequentially during T cell activation. ICOS does not bind to either B7-1 or B7-2, but instead it interacts with a novel member of the B7 family known as ICOS ligand (120). ICOS ligand is expressed more broadly than B7-1 or B7-2, as it is found on nonhematopoietic cells following stimulation with inflammatory cytokines. This expression provides one likely explanation for how activated, ICOS-bearing T cells can be stimulated in tissues that may be deficient in professional APCs but that have been induced to express ICOS ligand.

ICOS is a disulfide-linked homodimeric glycoprotein that, like CD28, contains a binding site for the p85 subunit of PI3K in its cytoplasmic domain. When engaged, ICOS stimulates greater PI3K activity than does CD28, but some of the other CD28 effectors (e.g., Ras and Jun kinase) are not activated upon the binding of ICOS to its ligand. As expected based on these differences, there are overlapping but also distinct consequences of stimulating T cells via ICOS versus CD28. Both enhance T cell–mediated cytokine production; however, ICOS does not up-regulate IL2. ICOS appears to be more important in regulating the ability of T cells to provide help to B cells, both for Ig class switching and for formation of mature germinal centers (121).

Because of its expression and role on activated T cells, many investigators have considered ICOS blockade as an attractive target to interfere with ongoing, unwanted immune responses. Interruption of the interaction between ICOS and its ligand has been shown to ameliorate immune-mediated disorders such as collagen-induced arthritis or experimental allergic encephalomyelitis, two well-studied models of autoimmunity in mice (122).

ADDITIONAL RECEPTORS THAT MODULATE T CELL RESPONSES

In addition to CD28 and ICOS, other cell surface receptors have been identified that, when engaged, either augment the efficiency of TCR signaling or provide additional signals that potentiate T cell activation. These receptors include integrins that when bound to ligands on APCs stabilize the contact between APCs and T cells, thus allowing for more effective interactions between the TCR complex and MHC/peptide. In addition to inside-out signaling that links TCR engagement to integrin function, integrins are also known to transduce signals when they are engaged by ligand, a process known as *outside-in signaling*. Many studies have shown that at least some integrin-mediated signaling occurs independently of the TCR but, interestingly, makes use of many of the same biochemical intermediates including src and syk PTKs and the adapter protein SLP-76 (but not LAT) (123). Among the major downstream effects of integrin stimulation are T cell spreading and adhesion, two events that require activation of Vav and alterations in the cytoskeleton. Integrin interactions with their ligands are also important for creation of the immunological synapse (see later discussion), a structure that is thought to correctly position the TCR and its effector machinery. Other cell surface receptors have also been shown to provide costimulatory signals for T cell activation. Most of these receptors have been identified in experiments where cross-linking that particular receptor together with the TCR significantly enhances the known signaling events, cytokine production, and T cell effector function. One important group of such receptors belongs to the tumor necrosis factor (TNF) family and includes CD137 (4-1BB), CD27, CD30, HVEM (herpes virus entry mediator), GITR (glucocorticoid-induced TNF receptor), and CD134 (OX40) (124). Some of these proteins are present on resting cells, while others in this group are found only on cells that have already been activated and function primarily downstream of initial T cell activation to sustain immune responses. These receptors transduce their signals in a way similar to other TNF receptors that are better known as inducers of apoptosis (see the discussion of CD95 [Fas] later in this chapter).

Another family of costimulatory receptors for T cells was identified that makes use of a novel signaling pathway.

This second messenger cascade appears to be particularly important, as mutations in one critical component lead to a rare but devastating immune disorder known as X-linked lymphoproliferative syndrome (XLP) (125). SLAM (signaling lymphocytic activating molecule) was the first identified member of a family of T cell costimulatory receptors that function by homotypic interactions, leading to signaling cascades that are also initiated by activation of src family PTKs (126). In studies designed to unravel how SLAM signals, experiments were performed to identify molecules that interact with the receptor. These experiments converged with studies by other groups attempting to identify the causal gene for XLP, leading to the identification of a novel adapter molecule known as SLAM-associated protein or SAP. SAP is a small cytosolic adapter that consists only of an SH2 domain and a short cytoplasmic tail. It appears to function by serving as a bridge between SLAM (and other SLAM family receptors) and fyn (127,128). Recent studies have suggested that the SAP/Fyn interaction is critical for optimal activation of PKCθ and NFκB during T cell activation (129) (Figure 11.12). Loss of SAP severely
FIGURE 11.12 The adapter protein SAP links the TCR to a fyn PTK signaling pathway important for directing T cell effector differentiation. SAP (SLAM [signaling lymphocytic activating molecule]–associated protein) is a small cytosolic molecule that associates with tyrosine (in some cases nonphosphorylated and in other cases phosphorylated) residues in the cytoplasmic domains of SLAM family receptors, T cell costimulatory molecules that are stimulated by homotypic interactions. SAP bridges SLAM family receptors to the fyn PTK via a unique interaction with the fyn SH3 domain. The SLAM/SAP/Fyn module has been shown to function in the PKC/NFκB pathway to direct cytokine production in activated T cells.

impacts multiple immune cell lineages (including T cells, NK cells, and NKT cells), suggesting that loss of this single adapter impairs normal function of multiple receptors (130). The consequence of SAP deficiency in the T cell compartment is severe perturbation of cytokine responses, in particular after Epstein-Barr virus infection, leading to an uncontrolled inflammatory response, ultimately causing death in many affected children (125). Studies in several laboratories are underway, using mice deficient in SAP as well as mice in which mutations have been introduced into the SAP gene, to investigate the molecular basis for SAP function in the various lineages in which this adapter protein is expressed.

In addition to SLAM (CD150), which is expressed on T cells, B cells, DCs, macrophages, platelets, and hematopoietic stem cells, other SLAM family members include 2B4 (CD244), NTBA (Ly108), Ly9 (CD229), CD84, and CRACC (CD319, CS1) (131). Studies performed thus far indicate that deletion of any particular SLAM family member impairs immune cell function but only to a moderate extent, indicating that the various family members may be able to at least partially compensate for each other. As more data accumulate, the unique importance of each of the individual members of this family of costimulatory receptors will become apparent.

THE IMMUNOLOGICAL SYNAPSE, CONCENTRATING SIGNALING MOLECULES, AND LIPID RAFTS

As the components most critical for TCR signaling became known, efforts were made to uncover where in the cell these molecules reside, both under resting and stimulating conditions. These studies have made use of biochemical approaches to fractionate the cell and then separate proteins using typical electrophoresis techniques, as well as imaging modalities to visualize molecules in either fixed samples or in real time in living cells. Early work in this area led to the interesting observation that molecules important for T cell activation appear to cluster as the TCR is engaged. One seminal series of experiments described several structures that appeared in a temporally defined fashion during T cell activation (132).

In model systems where T cells are engaged by an APC or are stimulated by antigen/MHC on a planar bilayer that also includes the integrin ligand ICAM-1, the first event that can be seen is the recruitment of LFA-1 (the integrin receptor for ICAM-1) to the point of contact between the T cell and stimulating surface. This engagement is followed closely by the migration of LFA-1 away from the central contact site to a more peripheral location and the replacement of LFA-1 at the center by the TCR complex (133). The larger structure has been designated the supramolecular activation cluster (SMAC), with a central region (cSMAC), enriched quickly for the TCR, and peripheral region (pSMAC), where LFA-1 resides. As these structures were first being described, additional imaging approaches making use of cytoplasmic staining techniques and expression of molecules tagged directly with fluorochromes followed by three-dimensional reconstruction indicated that as the cSMAC is formed, molecules known to be critical for transducing TCR-dependent signals (e.g., PKCθ) appeared at the site of the engaged TCR. These findings led to the notion of an "immunological synapse," reminiscent of the contact site between neurons or neurons and muscle cells, where a concentrated stimulus interacts with aggregated receptors to initiate a cellular response (Figure 11.13).

These early findings led to the hypothesis that formation of the immunological synapse was a necessary step in T cell activation, as signaling efficiency would be enhanced by localizing the receptor and its effector molecules to the point of contact of the TCR with antigen (134). Subsequent experiments have demonstrated that this simple model of creating the synapse to initiate TCR signaling is unlikely to be correct, as careful kinetic analyses have documented effective TCR signaling prior to synapse formation (135). Further, as reagents have been developed to detect molecules that are active in the TCR signaling pathway (e.g., phospho-site–specific antibodies that can distinguish active ZAP-70 molecules from ZAP-70 molecules that have not been stimulated to increase PTK function), a surprising observation has emerged that there is a relative paucity of active signaling molecules within the synapse. These observations have led to the suggestion that the role of the immunological synapse is not to initiate TCR signaling but instead to terminate activation events, perhaps by providing a site for collecting and degrading signaling molecules (136). Another model speculates that the immunological synapse is not critical for signaling but is necessary to direct activated T cells to secrete either cytotoxic materials, in the case of CD8$^+$ T cells, or cytokines, in the case of CD4$^+$ T cells, that will influence other cells of the immune system. It is likely that the immunological synapse plays multiple roles (almost certainly including some that have not yet been proposed) in the biology of T cell activation. A complete understanding of the importance of this structure will require additional experiments that make use of improved reagents for real time imaging of living cells.

The description of the immunological synapse instigated another controversy related to how receptors and their effector molecules position themselves within the plasma membrane. In contrast to the longstanding fluid mosaic model that described membranes as a sea of homogenous lipids in which proteins floated randomly, recent studies have demonstrated clearly that cell membranes are quite heterogeneous and that they contain large and small islands of proteins (137). The protein islands are not uniform; their constituents differ. Additionally, the lipid regions of the membrane are also heterogeneous, as
FIGURE 11.13 The immunological synapse appears at the site of the engaged TCR. The first intermolecular interaction to occur upon encounter between an APC and T cell is the binding of intercellular adhesion molecule-1 (ICAM-1) to its receptor leukocyte function-associated antigen-1 (LFA-1). If there is also recognition between the TCR and MHC/peptide present on the APC, LFA-1 moves from the center of the recognition domain to its periphery, while the TCR, bound to peptide/MHC, aggregates within the center of the complex. Other molecules—for example, the tyrosine phosphatase CD45—are excluded from the developing synapse. Although intracellular signaling molecules also appear at the synapse, the kinetics of their appearance and activation suggests that the synapse does not form to initiate T cell activation. Models for the biologic role of the synapse are presented in the text. pSMAC, peripheral supramolecular activation cluster; cSMAC, central supramolecular activation cluster. Adapted from Koretzky GA. T-cell activation and inactivation. In: Rich R, et al., eds. *Clinical Immunology*. London: Mosby, 2001.

there are discreet domains that differ greatly in lipid composition, with some regions rich in cholesterol and others where this lipid is less abundant. The cholesterol-rich regions are designated lipid (or membrane) rafts, as these domains float to the top of a sucrose gradient when disrupted and subjected to ultracentrifugation. These lipid rafts are also enriched in a subset of proteins that are posttranslationally modified to contain lipid species (e.g., palmitoyl groups) that insert preferentially into the cholesterol-rich domains.

The role of lipid rafts in receptor signaling and how these structures relate, if at all, to the immunological synapse is an area of intense investigation. There is compelling evidence demonstrating that in resting cells, the TCR is found either outside of lipid rafts or in rafts that are of very small size, whereas upon antigen encounter, the TCR is easily found within these domains (138). The potential importance of this localization was shown when disruption of lipid raft integrity by pharmacologic cholesterol depletion abrogated the ability of the TCR to signal (139). Other evidence for the importance of lipid rafts in TCR function is that some molecules essential for TCR-mediated signal transduction (e.g., LAT) are targeted to lipid rafts due to posttranslational palmitoylation. Mutation of the raft-targeting sequences abrogates the ability of

these proteins to support TCR-mediated signal transduction (140). In addition to certain proteins being restricted to lipid rafts, others seem to function normally only if they are excluded from these membrane domains. In these circumstances, forced expression of these molecules within rafts interferes with TCR signaling events.

It is recognized that the experiments described earlier, where molecules are artificially relocalized, while consistent with a role for lipid rafts in TCR function, do not prove causality. Similarly, the effect of pharmacologic disruption of lipid rafts is suggestive of their importance; however, the agents that are used may have other effects on the cell. A number of laboratories are now combining imaging and signaling assays at the single cell level to probe the importance of these membrane domains for T cell activation.

T CELL PROLIFERATION REQUIRES SIGNALING VIA THE HIGH AFFINITY RECEPTOR FOR IL2

In addition to the acquisition of effector function by T cells, combating pathogenic challenges also requires the number of antigen-specific T cells to expand so that a critical mass of responding cells is achieved. This proliferative

response requires the signaling pathways described earlier, both to stimulate production of IL2, an essential growth factor for T cell proliferation (via the TCR/CD28 signaling pathways detailed earlier) and to make the stimulated T cells responsive to this cytokine. Prior to stimulation, naïve T cells express a moderate affinity receptor for IL2 consisting of two components, the β and γ chains. One of the outcomes of TCR engagement is the inducible expression of a third IL2 receptor component, the α chain (CD25), that together with the β and γ chains results in a receptor with substantially higher affinity. Binding of IL2 secreted by activated T cells to the trimeric high-affinity receptor initiates a series of biochemical signals that drive the proliferative response to expand the number of antigen-reactive cells. The details of the signaling pathways stimulated by IL2 and other cytokines are detailed in Chapter 24.

PREVENTING T CELL ACTIVATION: THE BIOCHEMICAL BASIS FOR ANERGY

The material presented in this chapter thus far has focused on how T cells become activated when an antigenic challenge has been detected. As noted earlier, an effective T cell response only occurs when the TCR is engaged and costimulatory receptors are bound. This dual signaling allows for highly responsive TCRs but ensures that T cells only respond in the appropriate setting—that is, when the TCR stimulus is associated with an activated APC. Stimulation of the TCR alone, presumably indicating that the TCR has been engaged aberrantly, leads not to cellular activation but instead to a state of unresponsiveness or anergy. Even more striking is the observation that anergy may be maintained long after the TCR stimulus in the absence of a costimulatory receptor signal has occurred (see Chapter 30). This property of T cell biology has attracted a great deal of attention by investigators, as understanding the biochemical basis of anergy will likely provide insights into how it may be possible to disable T cell responses in an antigen-specific fashion. Such knowledge would be extremely useful in the design of novel therapeutics directed toward selectively turning off T cell responses to particular antigens—for example, antigens presented by an allograft in a transplant patient or self-antigens that are inappropriately stimulating a T cell response in an individual with autoimmunity. Studies examining the biochemistry of anergy have been informative but have also suggested that the biology of anergy versus activation is extremely complex. There are likely multiple mechanisms by which this decision is made.

Some of the earliest studies investigating the molecular basis of anergy were spawned by the finding that effective T cell stimulation correlates with activation of both the calcium pathway, leading to NFAT translocation to the nucleus, and the Ras pathway, leading to the MAPK cascade

and stimulation of the AP-1 family of transcription factors. When experiments were performed that selectively activated the calcium pathway without concomitant Ras stimulation (initially with the use of calcium ionophores as a pharmacologic means to stimulate only calcium increases), T cell anergy ensued (141). These studies suggested a model that T cell activation required a balance between Ras and calcium signals and that conditions that created an imbalance in these events would fail to activate T cells, leading to long-term unresponsiveness (142). A number of experimental systems have provided support for this model, including those that have used pharmacological approaches or genetically altered mice to manipulate one or the other of these two key signaling pathways.

A series of recent experiments using different approaches has converged on the idea that costimulation may be critical for determining whether a T cell will adopt an activated or anergic phenotype, at least in part by regulating the balance between calcium and Ras signaling. One consequence of costimulation of T cells via the TCR plus CD28 is enhanced DAG production, which is greater than that seen when cells are stimulated via the TCR alone (143). This increased DAG production presumably results in enhanced Ras activation via more potent stimulation of RasGRP1. Concordant with this finding was the observation that transcription of a member of the diacylglycerol kinase (DGK) family (DGKα) is markedly up-regulated in anergic cells. DGKs act by phosphorylating DAG, leading to the production of phosphatidic acid, thus terminating the ability of DAG to stimulate RasGRP1 (and hence Ras) or members of the PKC family (144). Thus, it was suggested that anergic cells display decreased signaling relative to calcium responses because of rapid loss of DAG. Subsequent studies revealed that in contrast to anergic cells, T cells that have been productively activated reveal marked decreases in DGK isoform gene expression, suggesting a means to maintain high levels of Ras signaling (143). Concordantly, overexpression of DGK in T cells leads to failed activation and enhanced anergy (145), while loss of expression due to targeted deletion of DGK isoform genes leads to failed anergy induction in both *in vitro* assays and *in vivo* (140).

Further studies have indicated that although modulation of DAG signaling is an effective means to alter anergy induction, there are other biochemical events (that may or may not converge on the Ras pathway) that can affect whether stimulation of the TCR without a costimulus will result in effector cell function or anergy. The T cell hyperactivity and failed anergy observed in DGK-deficient animals is phenocopied quite closely in mice in which the gene for the PTEN (phosphatase and tensin homolog deleted on chromosome 10) phosphatase is targeted for deletion (146). PTEN is a lipid phosphatase that dephosphorylates phosphatidylinositol 3,4,5-trisphosphate (PIP$_3$), the product of PI3K activity, the enzyme system that appears

critical for effective CD28-mediated costimulation. Several recent studies have shown that loss of PTEN in the T cell compartment results in enhanced TCR function (147). It has been reported further that loss of PTEN allows T cells to be effectively stimulated via signal 1 alone, presumably because the requirement for CD28 engagement is obviated, since the product of low levels of PI3K activity is maintained in the absence of the phosphatase (146).

Additional studies have focused on yet other mechanisms of anergy induction. A large series of experiments has implicated control of the half-life of particular signaling molecules as a major determinant of outcome following receptor engagement. Many of these studies have focused on the biology of E3 ubiquitin ligases in the control of T cell effector versus anergic fate. Ubiquitin ligases form part of the complex that targets proteins for degradation. Genetic studies have implicated several ubiquitin ligases as key controllers of T cell fate following receptor engagement; these include c-Cbl, Cbl-b, GRAIL, Itch, and Nedd4 (148). Each of these proteins appears to negatively regulate T cell activation, in most cases by targeting key activators (including the TCR itself, as well as important components of the TCR-stimulated signaling cascades) for degradation. Loss of these proteins results in unchecked TCR function that, in animal models, leads to failed central or peripheral tolerance and lymphoproliferation, frequently leading to overt autoimmunity. Further work to clarify precisely the substrates of the individual E3 ubiquitin ligases will provide additional insights into the mechanisms by which T cell anergy is induced to control undesired outcomes of T cell effector function.

There are many mechanisms that have evolved to hold T cell responses in check. While failure to adequately costimulate T cells results in the inability of the adaptive immune system to clear invading pathogens, defects in anergy induction lead to devastating, inappropriate immune responses. It is only by carefully titrating activating and inhibitory signals that the host can mount a vigorous immune response to combat pathogens yet protect itself from the potential danger of T cells that are allowed to respond in an uncontrolled fashion.

NEGATIVE REGULATION OF T CELL RESPONSES

The TCR complex has evolved to possess exquisite sensitivity to antigen/MHC, enabling the host to respond to subtle differences between self and foreign proteins. When stimulated to become effectors, T cells are extremely potent at perpetuating inflammatory responses and directly destroying host cells that have been infected by a pathogen. This is necessary to combat invading organisms; however, whenever T cells are stimulated, there is a risk that bystander host tissue (not affected by the pathogen) may be injured

as well. Further, to maintain the sensitivity of the TCR, it is also necessary to have mechanisms in place to thwart a T cell response that has been initiated inappropriately. The immune system has developed a number of critical, overlapping approaches to hold T cell responses in check and to eliminate stimulated T cells once a pathogenic challenge has been met.

IMMUNORECEPTOR TYROSINE-BASED INHIBITORY MOTIF–CONTAINING PROTEINS AND OTHER INHIBITORS OF T CELL ACTIVATION

One potent means to terminate T cell responses is to activate biochemical pathways that interdict the stimulatory events associated with a productive T cell response. This mechanism involves engagement of cell surface receptors that signal T cell inhibition. Among these receptors are those that contain immunoreceptor tyrosine-based inhibitory motifs (ITIMs) instead of ITAMs (Figure 11.14). ITIMs are recognized by their signature sequence (S/I/V/LXYXXI/V/L) (149). Like ITAMs, the tyrosines of ITIMs are inducibly phosphorylated (most often by src PTKs), but instead of recruiting activating molecules (e.g., ZAP-70), the inhibitory receptors recruit enzymes that counter the pathways required for T cell activation. Examples of such inhibitors are the tyrosine phosphatases SH2 domain-containing phosphatase 1 (SHP-1) and SHP-2 (150) and the lipid phosphatase SH2 domain-containing inositol phosphatase (SHIP) (151). Physiologically important ITIM-expressing receptors include killer inhibitory receptors (KIRs) that are best known for inhibiting the cytotoxicity of NK cells (see Chapter 16). KIRs are also present on activated cytotoxic T cells and appear to have this same inhibitory function.

SHP-1 and SHP-2 are cytosolic protein tyrosine phosphatases that possess a catalytic domain carboxyl-terminal to two tandem SH2 domains. Upon tyrosine phosphorylation of the ITIMs of the inhibitory receptors, the SH2 domains of SHP-1 or SHP-2 are recruited to the ITIMs and convert the receptor complex into an active tyrosine phosphatase. It is presumed that because the ITIM-bearing receptors are present in close proximity to the TCR-stimulated activation complex, SHP-1 and SHP-2 can then oppose the action of src and syk PTKs by dephosphorylating the kinases themselves (thus rendering them less active) or key proximal substrates of the PTKs. In this regard, a number of experiments have shown that SHP-1 and SHP-2 are able to dephosphorylate Vav, PLCγ1, and SLP-76. SHIP does not act on substrates of the TCR-stimulated PTKs but instead dephosphorylates key lipid second messengers that are critical for cellular activation.

One area of intense current investigation involves studies designed to unravel the circumstances that favor
FIGURE 11.14 CTLA4 inhibits T cell activation. **A:** Stimulation of T cells via the TCR (by peptide/MHC) and CD28 (by B7-1 and B7-2) results in numerous biochemical signaling events, leading ultimately to clonal expansion and effector cell function. **B:** CTLA4, present on activated T cells, competes for binding to B7-1 and B7-2 precluding CD28-mediated activating signals. Engagement of CTLA4 also induces inhibitory signals, including changes in the spectrum of MAPKs that are activated and recruitment of phosphatases that counteract the effects of the TCR-stimulated PTKs. Failed costimulation in the setting of continued TCR signals may lead to apoptosis or anergy.

inhibitory versus stimulatory responses when the TCR complex encounters antigen/MHC. One intriguing notion is that the quality of the antigen itself plays a large part in this determination, and a number of studies have revealed the existence of so-called *altered peptide ligands* (APLs). APLs are antigens that bind the TCR, but instead of activating a response (even in the presence of costimulation), APLs induce no response or even induce anergy (152). Some experiments indicate that whether a peptide induces full T cell activation or blocks T cell responses depends upon the affinity of interaction with the TCR complex. How this translates into altered signaling remains controversial. Some studies have provided evidence that APLs stimulate some but not all of the TCR signals required for activation (e.g., partial phosphorylation of the ζ chain and other CD3 ITAMs with failed recruitment of ZAP-70 [153]). Other proposed models for APL function are that the APLs may activate ITIM-bearing receptors out of proportion to what is seen when fully agonistic peptides encounter the TCR complex or that APLs stimulate a different spectrum of MAPKs than do agonistic peptides. Additional studies are required to evaluate these models further.

ADAPTER PROTEINS ARE ALSO NEGATIVE REGULATORS OF T CELL ACTIVATION

Adapter proteins, such as LAT and SLP-76, play critical roles in integrating signaling pathways that are essential for T cell activation. Adapter proteins have also been iden-

tified that function to regulate the inhibition of these signaling cascades. Examples of such molecules include the transmembrane adapter proteins LAX (linker for activation of X cells) and SIT (SHP-2–interacting transmembrane adapter protein) (154,155). Data from mice made deficient in these proteins suggest that these proteins do not play as central a role as LAT or SLP-76, but they do appear to modulate the ability of the TCR to become activated and potentially keep autoimmunity in check.

Another transmembrane adapter protein, PAG (phosphoprotein associated with glycosphingolipid-enriched domains) or Cbp (csk-binding protein), has attracted considerable attention by investigators studying signaling events important for T cell activation (156,157). PAG/Cbp was identified as a binder of csk. The adapter is present in lipid rafts due to posttranslational modifications and is basally phosphorylated on a key tyrosine residue that is an excellent docking site for the SH2 domain of csk. Thus, PAG/Cbp is thought to position csk in lipid rafts to maintain src family PTKs in their inactive state (by phosphorylating their regulatory carboxyl-terminal tyrosines). Upon TCR stimulation, PAG/Cbp becomes dephosphorylated (by an as yet unknown tyrosine phosphatase), thus losing its ability to bind csk. Csk leaves the lipid rafts, allowing lck and fyn to exert their positive effect on the TCR signaling machinery. While there are considerable data from cell lines and transgenic mice to support this model of PAG/Cbp action (158), mice engineered to be deficient in the adapter protein show no overt T cell phenotype (159). This result suggests that either there are additional

proteins that can compensate for PAG/Cbp function or that the notion for how these proteins function needs to be reconsidered.

INTERFERING WITH COSTIMULATION, THE ROLE OF CTLA4 IN INHIBITING T CELL RESPONSES

A critical tenet in T cell biology is that stimulation of the TCR without costimulation leads to failed T cell activation and in many cases to T cell anergy. Thus, interfering with the ability of CD28 to transduce its signals is a logical means to inhibit T cell responses. As might be predicted, interfering with CD28 signaling has been shown to be an extremely potent (and physiologically crucial) means to regulate T cell function.

One of the most effective ways to prevent CD28 signaling is the coexpression of CTLA4 (CD152), a cell surface receptor expressed once an initial T cell response has begun (160). Although CTLA4 is only one of a number of negative regulators of T cell activation, its physiologic importance sets it apart from the others. Mice in which the gene for CTLA4 has been eliminated suffer from a uniformly fatal lymphoproliferative syndrome characterized by massive enlargement of secondary lymphoid organs (161,162). Although these mice are born with an apparently normal repertoire of T cells (both in numbers and antigen reactivity), implying that CTLA4 is not critical for thymic development, within several weeks of birth, the animals demonstrate markedly enhanced T cell mass and severe autoimmunity. These observations led to tremendous interest in the mechanisms by which CTLA4 modulates T cell responses. Evidence has emerged indicating that CTLA4 engagement may lead to inactivation of T cell responses and, in some cases, death of effector T cells, both important ways in which this surface molecule terminates T cell function.

CTLA4 is in the CD28 family, but it has much greater affinity for B7 family members than does CD28 itself. Thus, expression of high levels of CTLA4 on an activated T cell provides a "sink" for CD28 ligands, thereby prohibiting the activating costimulatory receptor from stimulating a T cell effector response (163). Lack of CD28 costimulation prevents further T cell activation and terminates additional expansion of antigen-specific clones. This observation has been turned into a new and extremely effective therapeutic tool. A soluble fusion protein consisting of CTLA4 covalently linked to the Fc region of antibody (CTLA4-Ig) was administered first to mice and then to human patients suffering from transplant rejection or autoimmune diseases (164,165). CTLA4-Ig binds the B7 ligands with high affinity, thus depriving antigen-specific T cells from receiving a CD28 signal, abrogating the unwanted *in vivo* immune response.

CTLA4 does not function merely in a passive fashion by competing with CD28 for ligand binding. Instead, it appears that CTLA4 also transduces signals of its own to actively dampen T cell responses. This activity has been shown in two ways. First, studies show that CTLA4 expression is effective at blocking activation of T cells that lack CD28 (166). Second, other experiments show that a mutant of CTLA4 lacking the cytoplasmic tail but still able to bind with high affinity to B7 ligands only partially ameliorates the autoimmune phenotype of CTLA4-deficient mice (167). Although it is clear that the ability of CTLA4 to interfere with T cell activation directly requires the CTLA4 cytoplasmic domain, the precise molecular mechanism of this action is unclear. Several models, each of which is supported by experimental evidence, have been put forth.

In one scenario, CTLA4 has been shown to modulate signaling pathways downstream of the TCR that are critical for activation. In a number of these studies, engagement of CTLA4 affects various members of the MAPK family, most prominently ERK and c-Jun kinase (168). The relative effect on the various kinases is not consistent from study to study, underscoring the complexity of the system and the potential differences one may uncover when different model systems are studied. It is unclear also whether the effects of CTLA4 on MAPK activation are direct or whether these findings represent the ability of CTLA4 engagement to interfere with TCR-mediated events upstream of MAPK stimulation. One mechanism for how CTLA4 may manipulate membrane proximal events stimulated by the engaged TCR came from studies demonstrating that the complement of proteins that associate with the cytoplasmic domain of CTLA4 changes upon engagement of this receptor by B7 ligands. One such experiment suggested a regulated interaction between CTLA4, the protein tyrosine phosphatase SHP-2, and the ζ chain of the TCR (169); however, the molecular basis for these associations and whether they control CTLA4 function remain controversial. In fact, although there are several phosphorylated tyrosines within the CTLA4 cytoplasmic domain, a number of investigators have provided compelling evidence that phosphorylation of these residues is not critical for the inhibitory effects of CTLA4 on T cell activation (170,171).

Several groups have suggested another mechanism by which the CTLA4 cytoplasmic region may control its ability to regulate T cell activation. In this scenario, in productively activated cells, the cytoplasmic tail of CTLA4 associates with the clathrin adapter, AP50, leading to CTLA4 endocytoses and degradation (172). Stimulation of CTLA4 abrogates its association with AP50, retaining CTLA4 on the cell surface (173). Still other groups have provided complementary evidence suggesting that the function of CTLA4 is regulated most precisely by where in the cell CTLA4 is localized, being sequestered away from the TCR contact site as cells are stimulated and being directed toward the activation complex to terminate T cell responses.

Thus, while it is clear from genetic, biochemical, and molecular studies that CTLA4 is a major negative regulator of T cell activation, details regarding how it exerts its essential functions remain obscure.

OTHER INHIBITORY RECEPTORS THAT BIND TO B7 LIGANDS

PD-1 (programmed death-1) belongs to the same family as CD28 and CTLA4, but PD-1 exists as a monomer on the cell surface, as it lacks the cysteine required for dimerization (174,175). It contains two phosphorylatable tyrosines within its cytoplasmic domain, at least one of which forms a partial ITIM and therefore has negative regulatory functions. PD-1 binds to two members of the B7 family of ligands, PD-L1 and PD-L2. Evidence for a negative role of PD-1 in T cell function comes from mice made deficient in the gene for this molecule; these mice exhibit lymphoproliferation early in life and overt autoimmunity as they age (176). More recent studies have shown that the interaction between PD-L1 and PD-1 results in failed clearance of viral pathogens, providing one mechanism for the development of chronic viral infection, such as is seen after exposure to human immunodeficiency virus (HIV) (177). This finding has resulted in a great deal of excitement about the potential of blocking PD-1 in the setting of chronic infection as a means to generate a maximal effector T cell response. It is not yet clear how PD-1 interferes with T cell function, as preliminary studies have failed to reveal any defects in TCR-mediated signaling when PD-1 is engaged. It does appear that PD-1 interferes with expression of T cell survival genes, and the costimulatory receptor has been shown to associate with SHP-2 (but not SHP-1 or SHIP), suggesting a possible mechanism of action.

Additional members of the CD28 family have been identified as binders to other newly identified members of the B7 family of ligands (178). Biochemical and genetic studies suggest that these ligand/receptor pairs will also play important costimulatory roles for T cell activation, indicating that we do not yet appreciate the full complexity of this process. It is likely that each of these receptors will play its most essential role under particular circumstances (e.g., in naïve versus memory cells or in T cells that are fated to particular *in vivo* functions), but it is also likely that these molecules will have overlapping functions and compensate, at least partially, for each other during immune responses.

ELIMINATING THE EXPANDED T CELL POPULATION

Interfering with the activation of resting or antigen-stimulated T cells is not sufficient for homeostasis of the T cell compartment. The normal T cell response to a patho-

logic challenge is massive clonal expansion of antigen-specific cells, so that the number of effector cells is sufficient to eliminate the pathogen. As described earlier, it is essential that once the antigenic challenge has been met, the responding T cells stop dividing and discontinue their effector functions to prevent damage to tissue unaffected by the pathogen. Additionally, it is necessary to resolve the increased mass of T cells to prevent progressive enlargement of the secondary lymphoid organs and eliminate any T cells that may have been inadvertently stimulated (as bystanders) as the immune response developed. Thus, the vast majority of T cells that participated in the effector response must be removed, leaving only a small number of previously activated antigen-specific T cells that will be retained to provide a memory response, should that particular pathogen be encountered again in the future.

At the completion of an immune response, T cells are eliminated via apoptosis, otherwise known as programmed cell death. There are several mechanisms by which this death occurs (179). Some T cells die because factors necessary for their growth (e.g., IL2) are no longer being produced. This results in the failed production of anti-apoptotic proteins, such as members of the Bcl2 family. In addition to this passive means of apoptosis, T cell death following an effector immune response occurs actively in a process designated *AICD* (activation-induced cell death) that results from the orchestration of signaling events initiated by engagement of specific cell surface receptors (Figure 11.15).

An extremely important pathway for *in vivo* AICD was revealed by a confluence of observations made by different teams of investigators, some studying basic receptor biology *in vitro,* others investigating spontaneously arising mutations in mice, and yet another group interested in understanding the molecular basis of a rare but severe lymphoproliferative disorder. The receptor biologists were interested in the question of how T cell numbers are controlled, and they reasoned that if T cell loss is regulated, it was likely that this process is mediated by cell surface receptors. These investigators generated monoclonal antibodies directed against cell surface proteins present on activated T cells in the hope that some of these antibodies would serve as agonists that, when incubated with activated T cells, would lead to cell death. Such antibodies were identified that were potent inducers of apoptosis in activated but not resting T cells (180). As this work progressed and Fas (now known as CD95), the receptor that was recognized by the death-inducing antibodies, was being characterized, other investigators were examining mice that carried spontaneously occurring mutations that led to massive lymphoproliferation and autoimmune events. Careful examination of the mice revealed that two strains of animals existed with identical phenotypes but clearly different genotypes. Follow up

FIGURE 11.15 Stimulation of CD95 by its ligand results in AICD. One consequence of T cell activation is the up-regulation of the surface receptor CD95 (Fas) and its ligand. Engagement of CD95 leads to the recruitment of the adapter protein Fas-associated death domain (FADD) that nucleates the formation of a molecular complex, activating pro-caspase 8, leading to a cascade of cysteine-directed proteases that ultimately leads to DNA cleavage by Caspase-activatable DNAse (CAD). The resultant apoptosis eliminates the majority of activated T cells once an antigenic challenge has been cleared. CD95-mediated apoptosis is a highly regulated process and can be inhibited by endogenous inhibitors, such as c-FLIP (cellular FLICE [FADD-like interleukin-1β converting enzyme] inhibitory protein) that functions by preventing the activation of the proenzyme form of Caspase 8. Adapted from Koretzky GA. T-cell activation and inactivation. In: Rich R, et al., eds. *Clinical Immunology*. London: Mosby, 2001.
studies demonstrated that one of the strains (designated *lpr*) carried a mutation in a molecule that likely served as a receptor expressed on T cells, while the second strain (designated *gld*) was mutated in the ligand for that receptor (181). As these studies were being performed, clinical immunologists were identifying patients with immune system dysfunction that resembled that of the *lpr* and *gld* mice. Although these patients appeared normal at birth and had no difficulty with early childhood illnesses, as they aged they demonstrated significant lymphadenopathy, and their peripheral T cells lacked both CD4 and CD8. The constellation of these findings plus the propensity of these patients to develop autoimmune syndromes led to the description of autoimmune lymphoproliferative syndrome (ALPS) (182). Eventually, it became clear that all three investigations were examining the same phenomenon and that CD95 was the causal gene for the *lpr* strain (183), CD95 ligand was the causal gene for the *gld* strain (184), and that mutations in CD95, CD95 ligand, or the signaling pathway stimulated by this receptor ligand pair were responsible for ALPS (182).

Follow-up molecular experiments, further examination of the mice, and additional studies of the patient samples have led to considerable insight into the biochemistry of AICD. CD95 is present at low levels on the surface of resting T cells. One of the consequences of TCR stimulation is up-regulation of this key death receptor. Another consequence of the signaling pathways stimulated by engagement of the TCR is inducible expression of CD95 ligand. Thus, in addition to stimulating all of the steps necessary for cellular activation, TCR ligation also results in up-regulation of the

machinery critical for AICD (185). In fact, it appears that one other control point that prevents inappropriate T cell activation is that effective costimulation is required to interdict the AICD pathway.

CD95 exists as a trimer on the cell surface. When bound to CD95 ligand (also a trimer, either present on other activated T cells, other cell types, or secreted), a signaling pathway is initiated that involves the recruitment of an adapter protein named FADD (Fas-associated death domain protein), which in turn brings the proenzymatic form of Caspase 8 into the complex (186). This results in activation of Caspase 8, which initiates a sequence of enzymatic events leading to activation of a series of additional caspases that eventually stimulates a DNAse, designated CAD for Caspase-activatable DNAse. Active CAD enters the nucleus and cleaves cellular DNA into the nucleosome pattern characteristic of apoptosis. A critical step in the apoptotic process is loss of mitochondrial membrane integrity, leading to the leakage of cytochrome C from this organelle into the cytosol. In the cytosol, cytochrome C binds to Apaf-1 (apoptosis protease activating factor-1), forming a complex that participates in Caspase activation leading eventually to DNA cleavage within the nucleus (187).

AICD is a carefully regulated process. In addition to control of expression of both CD95 and CD95 ligand, there are cytoplasmic inhibitors of the apoptosis pathway. One such example is FLIP (FLICE [FADD-like IL-1β converting enzyme] inhibitory protein), a protein that inhibits formation of the FADD-mediated death-inducing complex (188). FLIP expression is modulated in T cells and has been found to be up-regulated in T cells that have received effective

costimulation in addition to engagement of the TCR. Other cytoplasmic regulators of AICD include members of the Bcl2 family (e.g., Bcl-XL and Bcl2), which preserve mitochondrial membrane integrity, as well as *in vivo* modulators of the Caspases (I-CADs or inhibitors of Caspase-activatable DNase), which are critical for prevention of cell death (189,190). To make matters even more complex, there are also members of the Bcl2 family (most notably Bax and Bak) that potentiate apoptosis by destabilizing the mitochondrial membrane (191).

Although CD95 and its ligand have attracted a great deal of attention as regulators of AICD, other TNF receptor family members are also important in the control homeostasis of the T cell compartment. These receptors work by similar mechanisms; however, the identities of the signal transducers are different. Thus, TNF receptors cooperate with other adapter proteins including TRADD (TNF receptor 1–associated death domain protein) and members of the TRAF (TNF receptor–associated factor) family, leading to activation of signaling pathways that overlap with those stimulated by CD95. In addition to TNF receptors that activate the apoptosis pathway, other so-called *decoy receptors* are present on the cell surface that appear to serve as a sink for death receptor ligands. Engagement of these receptors fails to initiate apoptosis and is thought to deprive the activating death-inducing receptors from interacting with ligands. Abnormalities in the signaling pathways initiated by engagement of CD95 and the other TNF family receptors have been described, not only in immune disorders, but also in other diseases associated with abnormalities in cell death, most notably in malignancy. Thus, understanding the basic mechanisms by which these receptors function normally has become an important goal of many laboratories with far-ranging interests.

SIGNALING MOLECULES ARE IMPORTANT TARGETS FOR IMMUNOMODULATORY THERAPY

There are a number of clinical circumstances during which it is important to dampen T cell responses. Among these are autoimmune disorders, which are spontaneously arising diseases characterized by inappropriate immune responses against self tissues, and latrogenic conditions, where it is necessary to abrogate an otherwise normal immune response—for example, protecting a transplant from rejection. Because T cells play a central role in mediating both autoimmunity and transplant rejection, molecules critical for T cell activation are important targets for therapeutic intervention. Initially, such drugs were identified empirically, by screening compounds in assays designed to detect inhibitors of T cell activation using a very distal event (e.g., cellular proliferation or cytokine production) as a readout. This strategy was required, because the molecular identity of the key signaling molecules was not yet known. Even so, extremely effective drugs were developed. Among these is cyclosporine, a natural (fungal) product that is one of the most important immunosuppressive agents in clinical use today (192). Cyclosporine acts by inhibition of the calcineurin pathway, thus preventing NFAT dephosphorylation and translocation to the nucleus. This drug was used for decades before its molecular mode of action was discovered. In fact, much of what we know about calcineurin and NFAT came from studies undertaken to explain why cyclosporine is such an effective immunosuppressant. Rapamycin is another clinically important immunosuppressive agent that was identified originally in a search for bacteria-derived products that could potentially serve as anti-fungal agents (193). Further testing of this drug revealed potent immunosuppressive effects (as well as antiproliferative effects that are now being exploited to combat various cancers [194]). Like cyclosporine, in addition to being a clinically useful immunosuppressant, studies of rapamycin have provided a great deal of basic knowledge about how immune cells transduce signals—in this case, the biochemical basis for IL2 receptor function.

As knowledge about particular signaling molecules was gained, drug discovery became directed toward validated biologic targets in the hope that more effective and specific therapies could be developed. OKT3, a monoclonal antibody directed against the CD3 proteins, is now a mainstay in the clinical armamentarium for therapy against transplant rejection (195). Similarly, monoclonal antibodies directed against the receptor for IL2 have found an important place in the clinic (196). As mentioned earlier, one very recent example of a novel therapeutic agent that has been introduced into the clinic based on our understanding of the biology of T cell activation is soluble CTLA4-Ig, an agent that was developed as an inhibitor of CD28 function (197). Although early in its clinical use, CTLA4-Ig has shown outstanding promise as an inhibitor of unwanted T cell activation. Numerous other agents are now being developed and tested based on what we have learned over the past few years. Intriguing candidates are drugs directed toward modifying functions of other receptors, such as ICOS, activity of enzymes, such as ZAP-70 and PKCθ, and key transcription factors, such as members of the NFκB family. The next decade is also likely to see yet another class of immunomodulatory agents, in this case drugs that will augment rather than inhibit T cell responses. One of the limitations of T cell immune responses in the setting of chronic viral infections is early termination of T cell responses, an event known as T cell exhaustion. Recent work has implicated key receptors (e.g., PD-1) and signaling molecules (e.g., SHP-1) in T cell exhaustion. Agents are now being developed that are designed to interfere with this inhibition of T cell responses in the hope that better therapies can be developed for chronic viral illnesses.

CONCLUSION

The past two decades have seen an explosion in our knowledge regarding the molecular and biochemical basis of T cell activation. Prior to the early 1980s, the identity of the TCR, the receptor that initiates the T cell response to antigen, was unknown. In fact, it was then unclear whether T cells responded to peptide antigen via one receptor and MHC proteins via a second cell surface protein or whether a single receptor was capable of binding to both antigen and MHC. Since the discovery of the TCR and its obligatory relationship with the CD3 molecules, an intricate cascade of signaling networks has been described. These pathways are now known to be critical for T cell activation as well as termination of T cell responses. We have learned how these signal transduction cascades intersect with others initiated by other receptors on T cells and what the biochemical consequences are of signaling via some receptors in isolation versus signaling via multiple receptors simultaneously. Studies of how T cells respond to activating and inhibitory stimuli have made great use of new knowledge gained by investigators in other fields but have also informed scientists studying other biologic systems about ways in which their work should proceed. Most importantly, however, investigations into how T cells are programmed to respond have provided crucial insights into the basic mechanisms of multiple human disorders and have given us important clues to help develop novel therapeutic modalities that promise to significantly diminish the morbidity and mortality of immune system diseases.

Initial insights into the molecular events associated with T cell activation utilized malignant cell lines that represent either developing thymocytes or mature T cells. While there are limitations to this approach (malignant cell lines are transformed and thus may not faithfully recapitulate the situation of a normal primary cell), results of studies using these reagents have been remarkably predictive of what is seen in more physiological settings. Especially during the early days of study, before the important molecules themselves were known, the availability of a stable source of cells that could be manipulated genetically provided outstanding experimental tools. Now, as may of the critical modulators of immune cell signaling have been identified, more physiologically relevant experiments are performed routinely using mice in which genes for these key regulators are modified within the genome.

The next generation of studies will continue to make use of such genetically altered mice. An important new direction for these investigations is generating mice in which mutations in signaling molecules can be selectively expressed in a temporal and lineage-specific manner. This control is particularly important, since mutations in signaling molecules often have dramatic effects on T cell development. It is often impossible to ascertain if abnormalities detected in peripheral T cell function are a result of altered development or because that particular molecule is also essential for transducing signals in mature T cells. The advent of mice in which wild type genes can be switched to genes with targeted mutations after T cell development is complete will soon allow studies to proceed that will selectively probe the importance of signaling pathways for thymocyte development versus mature T cell activation.

Advances in imaging will also markedly impact our ability to take studies of T cell activation to the next level of rigor and sophistication. A key advantage of modern image analysis approaches is that such studies make it possible to study individual cells, in contrast to most of our current methodologies that analyze thousands to millions of cells concurrently for any single data point. Clearly, much information is lost under these circumstances. To this end, techniques are also being developed to analyze posttranslational modifications of cytoplasmic molecules on a single cell basis. Reagents are now becoming available that can detect activation of particular signal transduction pathways using antibodies that can distinguish resting versus activated enzymes and substrates by flow cytometry.

Although most of the receptors and signaling molecules described in this chapter are designated as either positive or negative regulators, recent data have demonstrated that many of these proteins appear to function as activators under some circumstances and as inhibitors under others. For example, mice deficient in FADD, a key component of the pathway leading to AICD, demonstrate developing thymocytes and mature T cells that are resistant to activation, suggesting that FADD may be an essential positive regulator of T cell function. Similarly, PD-1, described initially as an inhibitor of T cell activation, appears essential for function in some model systems. Even the best-established negative regulators, such as CTLA4, have been shown to have positive regulatory function under some experimental conditions. Thus, similar to all other biologic systems, the more we learn about the biology of T cell activation, the more we realize we have yet to learn and that future experiments will continue to require an unbiased assessment of data as they emerge.

The importance of combining *in vitro* studies, experiments using model organisms, and learning from human patients cannot be underestimated. While valuable insights into the basic functioning of the human immune system have been elucidated in the laboratory utilizing cell lines and animal models, it has been shown time and again that these findings are not always recapitulated identically in humans. Additionally, many of the features of how T cells are stimulated to respond or to terminate their effector functions have been learned directly from careful analysis of patients afflicted with immune-mediated disorders. As new therapies based on our understanding of basic immune mechanisms are being brought into the clinic, it will be increasingly important for clinical and basic immunologists to work closely together so that these novel agents

can be used for optimal advantage. Without doubt, the use of these new drugs will yield some surprising results that will require an adjustment to our thinking of how T cell function is regulated *in vivo*. These new insights will then be translated into the next generation of agents that will hopefully have even greater efficacy.

Development of T Cells

Ellen V. Rothenberg and Mary A. Yui

INTRODUCTION

T cell development is a composite of overlapping processes in the domains of developmental biology, immunology, and cell biology. It starts with purely hematopoietic developmental mechanisms leading to T lymphoid lineage commitment; then gradually, the basis for subsequent developmental choices becomes dominated by the immunology of T cell receptor (TCR) repertoire selection. The underlying mechanisms by which these later choices are made can be understood only in terms of a richly complex cell biology of checkpoint enforcement, defining the two TCR-dependent fate-determination processes of β selection and positive/negative selection. Repertoire selection is crucial for establishing a functionally competent, mostly self-tolerant population of peripheral T cells, and

it has attracted a great deal of interest in isolation from other aspects of T cell development. In this chapter, we show how this cellular process occurs, on the basis of mechanisms that emerge from a unique and fascinating developmental program. A recurrent theme is how the signals from various TCR complexes come to intertwine with underlying developmental mechanisms to control cell fate at a succession of distinct checkpoints and lineage choices.

To begin, this chapter introduces the broad map of T cell developmental events. The subsequent sections focus in on the mechanisms involved in a few of its most interesting watersheds.

OVERVIEW OF T CELL DEVELOPMENT

In mammals, most circulating T cells develop in the thymus. Bone marrow precursors in small numbers enter the thymus from the blood and undertake a course of proliferation, differentiation, and selection, which converts them into T cells. In an adult mouse, this takes 3 to 4 weeks (faster in fetal animals). The mature cells then emigrate from the thymus and take up their surveillance roles in the body. Precursors seed the thymus and differentiate into T cells continuously from midgestation throughout adult life. An additional site of development may be the intestinal epithelium, in which certain T cells that mostly remain associated with the gut epithelium may also be generated. In either case, T cells distinguish themselves from most hematopoietic cell types by migrating away from the bone marrow to carry out their differentiation. It is in the thymus that most TCR gene rearrangement occurs and the cells first acquire their clonal recognition properties. The thymus not only promotes maturation but also rigorously screens each cohort of developing cells to eliminate those with either useless or dangerous TCRs in a process called *repertoire* selection.

Key Molecules: Cell Stage Markers and TCR Genes

At any one time after birth, the thymus contains cells in all stages of development, from the earliest precursors to cells that are virtually mature. Understanding of the process of T cell differentiation has been possible because cells in different stages can be distinguished, and cells of each type can be isolated preparatively without being killed. At least seven developmental stages can be distinguished on the basis of their expression of useful surface molecules. These are introduced in Figure 12.1. Key markers for subdividing the majority of thymocytes are TCR$\alpha\beta$, TCR$\gamma\delta$, and the coreceptors CD4 and CD8 (Figure 12.1A). These help to identify cells in the later half of intrathymic differentiation.

The majority of thymocytes, approximately 80%, express both CD4 and CD8 and low levels of surface TCR$\alpha\beta$ complexes, a constellation of markers that is not seen in general on peripheral T cells (Figure 12.1A). This distinctive population, called *double positive* (DP), is a key developmental intermediate that undergoes TCR repertoire selection, the complex process that eliminates cells with either useless or autoreactive TCR specificities. The unique properties of DP cells make TCR repertoire selection possible. Minorities of the cells are CD4$^+$CD8$^-$ TCR$\alpha\beta^{high}$ or CD4$^-$CD8$^+$ TCR$\alpha\beta^{high}$, and these single positive (SP) thymocytes are the most mature cells.

Cells in the earlier 2 weeks of differentiation in the thymus lack any TCR expression as well as any expression of CD4 or CD8. Nevertheless, different stages can be distinguished in this double negative (DN) or triple negative population. In mice, they can be subdivided, on the basis of expression of the interleukin (IL)–2 receptor α-chain CD25, the adhesion molecule CD44, and the stem cell growth factor receptor c-Kit (CD117), into progressive developmental stages termed DN1, DN2, DN3, and DN4 (or TN1, TN2, and so forth) (Figure 12.1B). Two other useful markers for these stages are up-regulated with CD25: the small phospholipid-linked heat-stable antigen (HSA, CD24), which remains on until the late stages of thymocyte maturation, and Thy-1, which once activated is expressed on all T cells. In the human system, different markers are useful for distinguishing corresponding stages, and they are described later. An outline of the progression of mouse precursor cells through these stages is shown in Figure 12.2 as a framework for this narrative.

TCR gene rearrangement plays a pivotal role in thymocyte fate. Ultimately, thymocytes can survive to maturity only if they successfully carry out combinations of gene rearrangements that will give them in-frame α and β chains or γ and δ chains, to be assembled into TCR$\alpha\beta$/CD3 or TCR$\gamma\delta$/CD3 complexes. The rules of the rearrangement process are, therefore, worth reviewing (see Chapters 6, 10). There are four TCR gene loci, each consisting of the constant region exons and multiple variable (V), joining (J), and sometimes diversity (D) segments of the TCRα, β, γ, and δ chain genes (see Chapter 10). The TCRβ and TCRδ loci have D segments as well as V and J segments to be rearranged, whereas the TCRα and TCRγ loci do not. Also note that the TCRδ locus is embedded in the middle of the TCRα locus in such a way that any V-Jα rearrangement automatically deletes the TCRδ locus entirely, regardless of whether it had undergone rearrangement before. These features are important for the regulation of rearrangement and, as described later, for understanding the choice between becoming a TCR$\alpha\beta$- or a TCR$\gamma\delta$-lineage thymocyte. The rearrangement process is ordered, with D-Jβ rearrangements occurring before V-D-Jβ and V-Dδ rearrangements occurring before V-D-Jδ.

FIGURE 12.1 Subsets of T cell precursors: normal development versus development without TCR gene rearrangement. The major subsets of cells discussed in this chapter are shown in a typical flow cytometric analysis. Top panels (**A** and **B**) show normal thymocytes, and bottom panels (**C** and **D**) show thymocytes from RAG-deficient mice, which cannot rearrange any TCR genes. Cells are stained with fluorescent antibodies against CD4 and CD8 (**A** and **C**), and the DN cells (boxed in **A**) are further analyzed with fluorescent antibodies against CD44 and CD25 (**B** and **D**). The axes show increasing levels of these surface molecules on a 4-decade logarithmic scale (10^4-fold range) of staining intensity. The main populations discussed in Figure 12.2 are indicated (DN, DP, CD4 SP, CD8 SP) (**A**), and the DN cells are subdivided into DN1, DN2, DN3, and DN4 (**B**). The recombinase-deficient thymocytes are developmentally arrested in the DN stages (**C**; cf. **A**), and these DN cells accumulate in the DN3 state and are blocked from progressing forward to the DN4 state (**D**; cf. **B**). RAG-deficient thymocytes also accumulate to only about 1/100 as many cells per thymus as wild-type ($\sim 4 \times 10^6$ versus $\sim 3 \times 10^8$). (See color insert.)
Narrative of T Cell Development

Figure 12.2 traces the progress of cells through the best-known stages of mouse T cell development.

The cells that enter the thymus are capable of giving rise to all subsets of T cells plus natural killer (NK) cells and dendritic cells. As discussed later, they may be able to give rise to macrophages and B cells, too. These cells are initially c-Kit$^+$, Thy-1^{low}, CD44^{high}, CD25$^-$, and CD24^{low}. At this stage, the TCR genes are not yet rearranged. These precursor cells form the key component of the subset called DN1 or TN1.

Once in the thymus, these cells undergo a major transition, losing much of their ability to give rise to anything but T cells, turning on the expression of multiple T cell genes, and starting to proliferate. They begin to express Thy-1, CD25, and CD24, and CD44 and c-Kit continue to be expressed on the cell surface, although at declining levels. The stage marked by this new phenotype is classified as DN2 (TN2) (Figures 12.1B, 12.2). This is the stage when TCR gene rearrangement begins. TCRγ, TCRδ, and the D-J segments of TCRβ all appear to become accessible to rearrangement during this initial period, but TCRα is not. Proliferative expansion in the DN1 and DN2 stages is considerable, approximately 6 to 10 rounds of division.

During the next stage, DN3, CD44 and c-Kit are fully down-regulated, most cell proliferation stops, and rearrangement of the TCRβ, γ, and δ genes occurs with maximum efficiency. The DN3 stage (Thy-1$^+$ c-Kit$^-$ CD44$^-$ CD25$^+$ CD24$^+$ cells) is a landmark because, in both adult and fetal thymocytes, it is the first stage at which the cells appear to have lost the ability to develop into anything but

T cells. It is also the first stage when the protein products of rearranged TCR genes are detected in the cytoplasm. Beyond this stage, the proliferation and survival of the cells depend essentially on interactions mediated by TCR proteins. If they rearrange their TCR genes correctly, they can proceed, often with a burst of proliferation. If they fail, they die.

The exact path that the cells follow from this point depends on whether the cells succeed in making D-Jβ and V-D-Jβ rearrangements to form a productive TCRβ open-reading frame before they have completed productive rearrangements of both the γ and δ loci. In the first case, they develop into $\alpha\beta$ T cells; in the second case, they develop into $\gamma\delta$ T cells. The $\gamma\delta$ cells mature with modest additional proliferation and with few known changes to their surface phenotype other than down-regulation of CD25 and CD24. Cells that rearrange β, on the other hand, undergo a complex succession of events known as β selection. These cells proliferate in a rapid burst; down-regulate the DN2/DN3 marker CD25; turn on expression of CD4 and CD8; stop TCRβ, TCRγ, and TCRδ rearrangements; begin rearranging TCRα; and undergo profound functional transformations. Through this cascade of events, the cells are converted from DN3 to DP cells, through proliferating intermediates called *DN4* and *immature single positive* (ISP) cells, usually CD8$^+$CD4$^-$CD3$^-$ (Figure 12.2). DP cells are physiologically peculiar, and their peculiarities make them uniquely poised for TCR-dependent repertoire selection. They are, therefore, key intermediates in the production of a self-tolerant T cell population. As a rule, the DP cell fate is part of the $\alpha\beta$ program and not part of the $\gamma\delta$ program. Thus, although the choice of $\alpha\beta$ versus $\gamma\delta$ fate
FIGURE 12.2 Outline of events in T cell development. Summary of the events occurring in normal mouse T cell development, including developmental branch points, changes in growth and survival requirements, CD4 and CD8 expression, other key changes in gene expression, and TCR gene rearrangement status. The approximate time taken in each set of transitions is also indicated. Developmental branch points taken rarely are indicated *by broken-line arrows.* The two major checkpoints discussed in the chapter, β selection and positive selection, are indicated. The alternative to positive selection, death, includes both negative selection and death by "neglect," as discussed in the text. Additional branch points, to NKT, CD8$\alpha\alpha$, and T$_{reg}$ cells, also exist but are not depicted. Stages of development in which a majority of cells are proliferating are indicated by *gray filled circles.* Cells expressing rearranged TCRγ and TCRδ genes (TCR$\gamma\delta$) and cells expressing rearranged TCRβ genes either alone or together with rearranged TCRα genes are indicated above the main diagram. Below the main diagram, *bars* show the extents of expression of major cell-surface markers and growth factor receptors. Periods of recombinase expression, specific gene rearrangement, and key developmental events are also indicated by *horizontal bars. Broken bars* show reduced levels of expression. Common abbreviations of cell stages are given in the text. ETP = early T cell precursor, c-Kit-high CD44$^+$ CD25$^-$ DN1 cells. ISP = immature single positive, a transitional stage between DN and DP.

is based at least partly on the stochastic success or failure of rearrangements, it results in a real choice between developmental programs.

Cells that fail to complete any productive TCRβ or TCRγ and δ gene rearrangements die within a few days.

In mutant mice that cannot make rearrangements at all, development cannot proceed beyond the DN3 stage (Figure 12.1C,D), and death of cells blocked at that point results in a thymus that is only about 1% of the normal cellularity. Besides the choice of TCR$\alpha\beta$ versus TCR$\gamma\delta$, the

DN3 stage, therefore, represents a rigorous developmental checkpoint. The "β selection checkpoint" is the first of two checkpoints at which survival is dependent on the TCR.

For cells taking the TCRβ^+ CD4$^+$CD8$^+$ path, rescue from death at the β selection checkpoint is only a temporary, conditional reprieve. In these DP cells, TCRβ rearrangement must be followed by a successful TCRα gene rearrangement within about 3 days after the proliferative burst subsides, or else the cells die of "neglect." The selection for cells that have made an acceptable TCR$\alpha\beta$ complex defines the second TCR-dependent checkpoint in T cell development: "positive selection." The criteria for rearrangement success here are more stringent than for β selection. Any TCRβ gene rearrangement that generates a translatable protein coding sequence is adequate for β selection, but the TCRα rearrangement is evaluated both on the basis of a translatable protein coding sequence and on the basis of the recognition specificity that emerges from the new combination of TCRα chain with the previously fixed TCRβ chain. The cells must be able to interact with major histocompatibility complex (MHC) molecules in the microenvironment, but not too well, or else the cells die. The criterion is set so that individual CD4$^+$CD8$^+$ TCRβ^+ cells have less than a 5% chance of satisfying it. As a result, about 30% of this population dies each day in the young mouse thymus (more than 90% die without maturing in the whole 3- to 4-day lifetime of each cell cohort) and must be replaced as a fresh cohort of CD4$^+$CD8$^+$ cells enters the selection pool.

DP cells are actually put through two tests. The first determines whether the newly expressed TCR$\alpha\beta$ can make sufficiently strong interactions with MHC molecules to be useful, and the second assesses whether the interactions of this TCR with self-antigens in the thymus are weak enough to reduce the danger of autoimmunity. These thresholds are tested in two separable processes: positive selection and negative selection. Cells exceeding the minimum affinity threshold are positively selected, initiating a new cascade of phenotypic changes and enhancing the viability and functional responsiveness of the cells. Cells that exceed the maximum affinity threshold can be stripped of their receptors or negatively selected by induced apoptosis. Key changes that help trace progress through positive selection are the transient up-regulation of the activation marker CD69, the stepwise increase in TCR$\alpha\beta$ surface expression from low to intermediate to high, a parallel up-regulation of CD5 and MHC class I molecules, and ultimately the down-regulation of the immature cell marker CD24. Cells remain susceptible to negative selection for several days after the initiation of positive selection, however. They may even encounter the most potent negative selection stimuli in the period after positive selection. Only cells escaping both death by neglect and death by negative selection can complete their maturation and emigrate to the peripheral lymphoid system.

Positive selection also appears to drive a choice of maturation fates. The molecular mechanisms activated in positive selection determine whether a cell will be a CD4$^+$ helper cell, a CD8$^+$ killer cell, or a specialist in other functions such as an NKT cell. As described further later, detailed aspects of the TCR–ligand receptor interactions during this process guide or select cells to develop into one type of effector or the other. Cells with TCRs that recognize MHC class II molecules tend to develop as CD4$^+$ cells, whereas those with TCRs that recognize MHC class I molecules develop as CD8$^+$ cells. The basis of this profound differentiation choice begins with subtle quantitative and kinetic aspects of TCR/coreceptor interaction with MHC, which trigger distinctive regulatory gene expression cascades. The exact maturation pathway followed also depends on the type of cell that interacts with the developing thymocyte for TCR/MHC interaction. Most dramatically, there is even an alternative maturation pathway that rescues some high-affinity interacting cells from negative selection, by converting them into tolerance-enforcing "regulatory T cells" (T$_{reg}$).

Regulated Proliferation in T Cell Development

TCR-dependent selection is draconian. To supply enough TCR$^+$ "input" cells to leave a diverse TCR repertoire among the survivors of selection, the T cell development program needs to include proliferation as an integral part. As a result, in steady state, the thymus always contains far fewer cells in the earliest stages than in the later stages. All the DN stages together, representing approximately 2 weeks of developmental change, contribute only approximately 2% to 4% of the cells in a typical young adult thymus. The earliest precursors in the DN population have been estimated to be less than 1 one-hundredth of that frequency. In other words, a thymus that turns over approximately 5×10^7 cells per day, through negative selection and death by neglect, may be resupplied continuously with an input averaging only 50 to 100 cells per day.

During T cell development, phases of intense proliferation alternate with phases of little or no cycling. The differences in cell cycle activity are dramatic. As shown in Figure 12.2, DN1 and DN2 cells are cycling, DN3 cells halt, and then, after β selection, cells appear to go through six to eight rounds of division in about 3 days (1,2). After positive selection, in contrast, maturing cells appear to reside in the medulla for almost a week with little if any significant proliferation (2a). Each phase of proliferation tends to be driven by a different mechanism (3). The growth controllers used at various stages include many genes that are essential for progression through the T cell developmental pathway (4).

In the first DN1 precursors, the initiation of cell division may be controlled by c-Kit signaling (5). In the DN1-DN2

states, proliferation is mostly driven by signals from the interaction of IL-7, a cytokine secreted by the thymic stroma, with IL-7 receptor complexes, composed of IL-7Rα (CD127) and γc chains (CD132) (Figure 12.2) (6–8). The cells also depend on interactions with stromal ligands that signal to them through the Notch receptor throughout these early stages. During β selection, population expansion is driven by signaling through the pre-TCR (TCRβ complex), which is discussed later in detail. The later events of positive selection and maturation do not involve significant proliferation; however, they completely depend on TCR$\alpha\beta$ for survival signaling. These sequential requirements for survival have overlapping critical periods, so that the mutant phenotypes are slightly leaky but still have powerful quantitative effects (9). After export from the thymus, mature T cell proliferation depends on TCR$\alpha\beta$ triggering and signals through the IL-2, IL-4, IL-7, or IL-15 receptors. The shift from one kind of proliferative stimulus to another is caused, at least in part, by intrinsic developmental changes in the cells. It is an important factor contributing to the one-way polarity of developmental change.

The proliferative bursts are vital for setting up the large excess of precursors that makes it possible to use stringent selection at the checkpoints in T cell development. The huge losses that occur in these selection processes seem shocking, except that the developmental program also provides for more than 10^5-fold clonal expansion from each precursor. Harsh selection against useless or autoreactive cells is a price the adaptive immune system pays for its somatic generation of diversity in recognition structures. This suggests that the mechanisms used by lymphoid precursors to drive developmental proliferation are evolutionarily old and likely to have coevolved with the mechanisms generating clonal diversity.

Anatomical Path of T Cell Development

The thymus is made up of lobes, each of which is divided into distinct zones with different stromal cells making up their microenvironments (10). The largest domain is the cortex, which is packed mostly with DP thymocytes. The cortex surrounds an inner domain called the medulla, where the more advanced, SP thymocytes are found. The outermost rim of the cortex (i.e., the subcapsular region) and the region defining the cortical/medullary junction are also specialized in some ways. The organization of the thymus is diagrammed schematically in Figure 12.3.

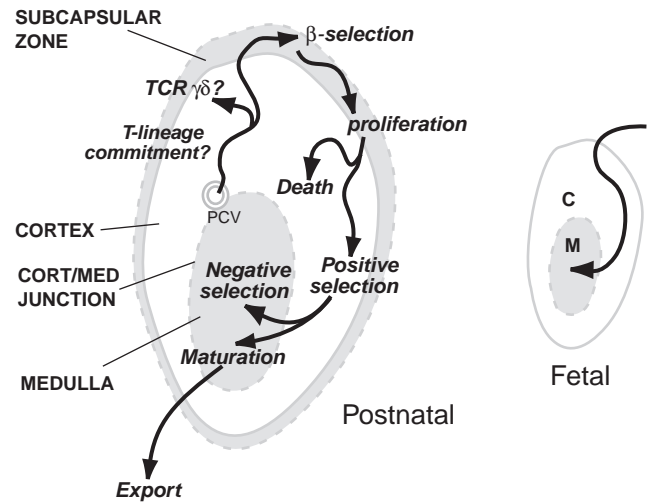
It is now clear that the cells migrate through this organ in a hairpinlike path as they differentiate (10a). Blood-borne precursors enter the parenchyma of the postnatal thymus from the medium-size blood vessels (postcapillary venules) at the cortical/medullary junction. These cells, in an early DN1 state, initially proliferate in the deep cortex. They then make their way outward toward the subcapsular zone over the next 2 weeks, differentiating through the


FIGURE 12.3 Summary of migration pathways of thymocytes through the postnatal and fetal thymic microenvironments. The pathway of migration of adult thymocytes from the postcapillary venule (PCV) through the cortex, subcapsular zone, cortex, and medulla is shown on the **left.** For comparison, the entry and migration through the fetal thymus is shown on the **right.**

DN2 and DN3 states as they go. The subcapsular zone is where the cells audition for β selection and where proliferation of the successful cells resumes. Numerous, rapidly cycling blasts can be seen in the outer cortex; they represent the DN4, ISP, and early DP cells that have just passed this test. As they gradually stop proliferating, the DP thymocytes in profusion fall back into the cortex, reversing direction from before. The cells continue to sink inward during their 3 days of postmitotic life, while new generations of precursors on their way to the subcapsular zone continue to work their way up through the crowd. Even if the DP cells fall back to the cortical/medullary junction, however, they are not allowed to enter the medulla unless they have passed positive selection. Those that do not succeed die in the cortex and are rapidly engulfed by resident macrophages. Those few that are positively selected, along with mature $\gamma\delta$ cells, cross over from the cortex to the medulla (Figure 12.3) (11).

Maturation of the surviving cells occurs in the medulla over the following week (2a), if they can avoid negative selection. The medullary epithelial cells are distinct from the cortical epithelial cells. One remarkable property of these cells is that they express a very wide range of self-antigens that are otherwise expressed only in some other particular organ of the body. In effect, they present an "immunological homunculus" in molecular terms, which is valuable in negative selection or the programming of T$_{reg}$ cells (12). Dendritic cells, which are also specifically located in the medulla, present self-antigen to the new SP cells in the most efficient way for the most stringent form of negative selection. It is only if they survive these encounters that

the SP cells complete their maturation, changing their response physiology so that high-affinity interactions with antigen can lead to activation instead of paralysis or death.

The compartmentalization of functions in the thymus probably helps guide certain developmental transitions (10). As the cells change in intrinsic responsiveness to different proliferative signals, their migration may carry them from a zone rich in early stimuli (e.g., IL-7) (13) to a zone that may be rich in a distinct set of stimuli. Certain transitions from proliferation to G_1 arrest, such as from DN2 to DN3 or from β selection to a resting DP state, could result from migration of the cells into a zone where the most recent proliferative stimulus is no longer present. Also, the change in direction of migration of precursors through the cortex, from outbound to inbound, is likely to be a result of a change in the expression of adhesion molecules and chemokine receptors in the DN3 state or during β selection (4). At least one adhesion molecule, CD44, is expressed very highly in the DN1 cells but then clearly turned off between the DN2 and DN3 state; this could be a participant in the early homing or guidance mechanisms or both. Later, at least one new chemokine receptor is turned on at β selection, and this may help attract DP cells back toward the interior (14,15). Migration between domains with different kinds of stromal cells allows a separation between positive and negative selection events in space and time.

Variations in Thymocyte Development in Ontogeny

The general outlines of thymocyte development are similar in postnatal and fetal mice, but there are many differences (16). The mouse fetal thymic stroma develops from the outpocketing of third pharyngeal pouch endoderm, between 10 and 12.5 days of gestation (E10 to E12.5) (reviewed in refs. 17,18). It may undergo some inductive interaction with the overlying ectoderm and neural crest cells of the third branchial arch. The thymic epithelium establishes a distinctive structure and gene expression pattern before any lymphoid precursors arrive. Starting at about E12, hematopoietic precursors migrate directly across the mesenchyme from the subclavian vessels to the tiny, non-vascularized epithelial rudiment; they collect around the thymus and then enter it directly from the outside (Figure 12.3, right panel).

Lymphoid precursors proliferate exponentially in the fetal murine thymus, increasing from about 10^4 cells at E14.5 to about 5×10^5 at E18. In contrast to the postnatal thymus, in the fetal thymus the first TCR$\alpha\beta$ DP cells are generated at about E16, the first SP CD4 cells about 2 days later, and CD8 cells a day after that, followed by birth at day 20. The first emigrants are exported to the periphery within 3 days after birth. Thus, the times spent in the

DN state and in the medulla are cut from approximately 14 days and 7 days in the postnatal ("adult") thymus to less than 3 days each in the fetal thymus.

The precursors that initially seed the fetal thymus from fetal liver are qualitatively different from any that enter it later. Radiation chimera experiments establish that they can generate the same types of T cells that are made from adult bone marrow–derived precursors, but they also have a capacity that adult precursors do not. The first thymic immigrants are uniquely capable of generating two classes of $\gamma\delta$ T cells that seed the skin, tongue, and reproductive organ epithelia in late fetal life but are not produced at all after birth (19). These "early-wave" $\gamma\delta$ cells express directed, predetermined V(D)J rearrangements without junctional diversification, so that their recognition specificities are completely invariant. They are, in fact, the first wave of TCR$^+$ thymocytes made in the mouse at all, maturing by E15.5 to E16.5, and they have a number of distinctive properties, including growth factor requirements and transcription factor profiles (20,21).

The thymus continues to be seeded by precursors in discrete waves, around birth and then throughout postnatal life (22). In the meantime, the properties of the major populations of hematopoietic precursors themselves continue to change not only in site of origin but also in molecular programming (23–25). Certain gene disruptions have sharply different effects on T cell development in fetal, postnatal, and adult mice, because of intrinsic differences in different precursor cohorts.

Thymocyte Development in Species Other than Mouse

The overall organization of thymic lobes is conserved from mammals to cartilaginous fish (26). The overall roles of cortex and medulla for T cell development seem to have been established early in vertebrate evolution. In chickens and *Xenopus,* there is also strong evidence for development of distinctive T cell populations in the tadpole or embryo, unlike those made after hatching. Chicken thymocyte developmental studies have actually provided some of the first evidence for the distinctiveness of early-wave $\gamma\delta$ cells (27). However, relatively few markers are available to distinguish developmental stages in these animals, and much remains to be learned about homology or lack of homology of their T cell developmental pathways with those in mice.

Thymocyte development has been studied in much more detail in rats and humans. Surprisingly, the detailed patterns of surface marker expression have not been well conserved, even over the short phylogenetic distances among mammals. The Thy-1 surface glycoprotein is not expressed in rat or human mature T cells, and CD25, which is distinctively up-regulated in murine DN2 and DN3 stages, is not up-regulated at a corresponding stage in human (28).

▶ **TABLE 12.1 Comparison of Markers in Human and Murine T-Cell Development**

Stage	Mouse Phenotype	Human Phenotype
Intrathymic T/DC/NK precursor	CD44+ c-kit+ CD25−	CD34+ CD38lo CD1a− CD44+
Intrathymic T/NK precursor	(Fetal only) NK1.1+ CD122+ CD44+ c-kit+ CD25−	CD34+ CD38+ CD1a−
Committed T precursor	CD44− c-kit− CD25+ CD24+	CD34+ CD38+ CD1a+
TCRδ, TCRγ, TCRβ rearrangement	CD44+/− c-kit+/− CD25+	CD34+ CD38+ CD1a+ CD4− (possibly earlier) to CD4+
β-selection*	CD25+ CD4− CD8− (DN3)	CD34+ CD38+ CD1a+ CD4+/− CD8− to CD4+ CD8α+β− (CD4 ISP, early DP)
TCRα rearrangement	CD25− CD4+/− CD8$\alpha\beta$+ (ISP, DP)	CD4+ CD8α+β− (possibly earlier) to CD4+ CD8α+β+ (early DP to DP)
Mature cells	TCR/CD3hi and CD4+ or CD8$\alpha\beta$+	CD1a− TCR/CD3hi and CD4+ or CD8$\alpha\beta$+

TCR, T-cell receptor; T/DC/NK, T cells/dendritic cells/natural killer cells.
Human data from Blom and Spits (262) and Dik et al. (31).
*The position of β-selection may not be as sharply defined by CD4 and CD8 phenotype in human as in the mouse, and
  data for pre-TCR deficient mutant human cells are not available for confirmation.

Rat and human differ from mouse also in their expression patterns of MHC class II molecules and CD2, and in the fine timing of CD4 and CD8 expression. Homologous surface markers cannot always be assumed to mark homologous developmental stages in these three mammalian species.

Against this background of evolutionary variation, however, the central framework of T cell development appears to be highly conserved between mouse and human, as listed stage by stage in Table 12.1 (28–30). The human pathway starts with an uncommitted precursor (CD34+CD38lo) that enters the thymus with a range of developmental potentials that is similar or identical to that of its mouse counterpart. Although the markers useful for distinguishing stages are different (Table 12.1), the basic sequence of lineage commitment, TCR gene rearrangements, CD4 and CD8 expression, selection, and postselection maturation is the same.

EARLY LINEAGE CHOICES: CLUES TO MOLECULAR MECHANISMS

Developmental Potential of Earliest Intrathymic Precursors

The cells that enter the thymus in either fetal or postnatal life are not committed to the T cell pathway yet (30a,30b). They can be removed from the thymus, purified, and reintroduced *in vivo* or in any of a variety of *in vitro* culture systems, and these experiments reveal that they are still multipotent. Not only the same populations, but even the same individual cells, when assayed under clonal conditions, can efficiently give rise to innate immune system cells, especially dendritic cells, NK cells, and macrophages, as well as T cells. Thus commitment to the T cell lineage

is an event that occurs only after the cells have entered the thymus and only under the influence of the thymic microenvironment.

A striking feature of the commitment process is that the precursor cells in the thymus with T cell potential demonstrate little or no B cell potential, even when they continue to show ability to generate nonlymphoid cell types. The data are particularly emphatic on this point for immigrants to the fetal thymus (31,32). This result is surprising because it is a natural expectation that B and T cells should be closely related in developmental lineage, as they are the two main cell types of the adaptive immune system and the only two cell types known to use recombination activating gene (RAG)–mediated recombination. There has been a great deal of experimental analysis and discussion about what this means (33–42), but a few general points emerge. First, the thymic cortex provides a microenvironment in which any B cell potential of sensitive precursors can rapidly be extinguished. Second, cells can enter the thymus from any of a range of developmental states, from stem cell through various kinds of partially restricted hematopoietic precursors, and still be sucked into the vortex of T cell development. There are some exceptions that escape the T cell fate—there are even some nests of B cells within the thymus, and both NK and dendritic cells are also generated by intrathymic precursors, but the thymus can make T cells out of a variety of starting materials. Third, commitment to the T cell fate occurs at a late stage in the thymus relative to most of the proliferation and early differentiation events (30b). The most clear evidence of this is the ability of some thymocytes to reverse course and differentiate into dendritic cells and macrophages, simply by being removed from the thymic microenvironment, even after they have undergone some TCR gene rearrangements (37,43). Actual commitment to

a T cell fate does not appear to become complete and irreversible until the cells reach the DN3 stage—that is, closely associated with the proliferation arrest at that point.

Dominant Role of Notch Ligands in the Thymic Environment

From the time of entry into the thymus through β selection, T cell development is guided by Notch signaling and totally dependent on interaction of thymocyte Notch molecules with Delta-family Notch ligands in the thymic microenvironment. This was first revealed to be a major control mechanism for blocking B cell development while enabling and promoting T cell development (44). The transcription factor that is the agent of many Notch signaling effects (called *RBP-Jκ* or *CSL*) is also indispensable for early T cell development and for the suppression of the B cell fate (45). Subsequent work has shown that Delta-type ligand expression is a unique requirement that defines a T lineage–promoting microenvironment (4). A stromal cell line expressing the DL1 or DL4 Notch ligand has now been shown to support early T cell development from stem cells all the way through the DP stage in monolayer culture, and this has opened the way to remarkably accelerated progress (46). In fact, until commitment, recurrent, high-dose Notch/Delta interactions are needed to keep cells within the T cell pathway and away from the NK and dendritic cell pathways, as well as away from the B cell pathway (30b,47–53). In addition to instructively activating and maintaining the T cell program (54–56), Notch signaling is needed to maintain viability, especially at the DN3 stage, as the cells become poised for β-selection (57). There is evidence that other receptor/ligand systems, such as the canonical Wnt pathway, also play a role in thymic epithelial effects on lymphoid precursors (58), but the role of Notch appears to be paramount through these early stages.

Successful β selection, though not $\gamma\delta$-selection, depends on continued Notch signaling (59–63). Interestingly, though, after β selection, Notch-dependent transcription appears to become dispensable for T cell maturation (59,64). Thus, the Notch-dependent phase of T cell development gives way to the TCR-dependent phase.

Transcription Factor Requirements for T Lineage Specification

The Notch signal impinges on a complex regulatory state in the developing thymocytes. Prethymic cells competent to respond to Notch/Delta interaction already express a large number of cell-intrinsic transcription factors, many of which continue to be required for T cell development. The Notch/Delta signal induces the expression of more of these factors, setting in motion a richly combinatorial regulatory cascade. The full progress to successful T lineage commitment and passage through β selection or $\gamma\delta$-selection depends on Ikaros, PU.1, c-Myb, GATA-3, Gfi1, Bcl11b, and factors of the T cell factor (TCF)/lymphoid enhancer factor (LEF) family, the Runx family, and the basic helix-loop-helix E protein family (65–67,78–80). The exact regulatory relationships between these factors and their target genes still need to be worked out in detail. But it is interesting that some of the key factors in T cell development appear to have important roles as repressors, suggesting that one necessary aspect of early T cell development is to silence previously active stem cell genes.

Ikaros, PU.1, c-Myb, and GATA-3 are critical for the earliest T cell precursor generation. An additional phase of transcription factor action is during the specification and expansion events in the DN2 and DN3 stage. The "E proteins" E2A and HEB are prominent here (66). Expressed in overlapping patterns and working as homo- or heterodimers, they collectively provide a vital regulatory input that combines with Notch-activated transcription factors to turn on many components of the T cell program (54,68). Also, E2A seems to be important for the proliferative arrest in the DN3 state that makes TCR gene rearrangement possible (66).

The high-mobility group (HMG) box transcription factors TCF-1 and LEF, have important roles in β selection and before. TCF-1 and LEF mediate Wnt signaling through the canonical β-catenin-dependent pathway, and they also can affect gene regulation in a Wnt-independent way through "architectural" roles in enhanceosome assembly (69,70). TCF-1 and LEF are not needed until β selection in fetal and young postnatal thymocytes, but the later cohorts of precursors that populate the adult thymus also need TCF-1 for the initial stages of T cell development, at the DN1-to-DN2 transition (58,71–75). In fact TCF-1 and GATA-3 are two of the earliest T lineage genes induced in hematopoietic precursors in response to Notch signaling (55).

These regulatory factors that are essential for T lineage differentiation are not themselves T cell specific. Ikaros, c-Myb, and Runx1 are all required for mature hematopoietic stem cell function, the E proteins are crucial for B cell development as well as for T cell development, and factors such as PU.1 have the potential to divert cells completely from the T lineage fate to various myeloid fates (reviewed in ref. 65). Even GATA-3 can have lineage-diversionary effects at high levels (65a). The two things that make T cell development emerge from this mixture of regulatory inputs seem to be, first, the quantitative balance among the levels of expression of different regulators at each stage, and, second, the dominant modulating influence of Notch signaling on the activities of individual transcription factors (48,65a,65b).

The regulatory factors involved in early T cell development do not act in a simple, sequential way limited to

particular stages. Although none of these factors appear to be "master regulators" of T cell identity, the regulatory genes that drive initial T lineage differentiation are used repeatedly throughout T cell development (65). Only PU.1 is an exception, playing a hit-and-run function confined to the earliest stage. Like the TCF family factors, GATA-3, Myb, and Runx1 are all required again at β selection as well as for initial specification. Notch family genes may participate in as many as three lineage choices within the T cell pathway. E2A family and Id genes act in β selection and positive selection (66). GATA-3 influences not only the CD4/CD8 choice but also the postthymic differentiation of T_H1 and T_H2 effector subsets of helper T cells (65,76). Even Ikaros recurs in specific roles in later T cell development. Thus, early T cell specification sets up an interplay of developmentally potent factors that becomes a permanent feature of the T cell regulatory apparatus. Shifting combinations of these factors may help to give mature T cells some of their richly nuanced repertoire of responses to their environment.

β SELECTION AND $\gamma\delta$-SELECTION

A Regulatory Upheaval: Transition from TCR–Independent to TCR–Dependent T Cell Development

The β selection checkpoint is a watershed in T cell development that marks the change from events dominated by hematopoietic-like mechanisms to events dominated by TCR interactions with the microenvironment. After 2 weeks of TCR-independent growth, this checkpoint suddenly polarizes the fates of cells that have succeeded or failed at TCR gene rearrangement. A novel criterion of viability is imposed on the cells: The successful ones are rewarded with proliferation and differentiation, and the failures die. In mice that can assemble neither TCR$\gamma\delta$ complexes nor TCRβ-containing "pre-TCR" complexes, such as RAG-1 or RAG-2 knockout animals, all the cells die at this point. There are two related but divergent pathways through this checkpoint, β selection and $\gamma\delta$-selection. Both β selection and $\gamma\delta$-selection trigger distinct programs of sweeping regulatory change.

The β selection checkpoint is encountered by developing DN3 cells as they reach the subcapsular cortex. More than a differentiation arrest, this is a survival and growth arrest (77). Inappropriate passage through the checkpoint appears to be a hotspot for T lineage leukemias and lymphomas. Functions known to be required for checkpoint enforcement also act as T lineage tumor suppressors, including p53, E2A, Ikaros, and correctly regulated Notch signaling (78–86). There are sharp discontinuities in regulatory gene expression when the cells first enter the resting DN3 stage, including a transient burst of Notch response gene expression, which may reflect checkpoint functions.

Gene expression dramatically shifts again during β selection itself (61,87,88). This suggests that specific regulatory changes in the DN3 stage are needed to separate the cells from their uncommitted, "hematopoietic" past, before they can safely pass through β selection.

β selection, the escape from checkpoint arrest, is important both because of the special form of TCR complex signaling that it involves and because of its dramatic impact on cell physiology (62,89–93). In murine DN3 cells, β selection causes the cells to shut off CD25 gene expression and to turn on CD4 and CD8 for transition to the DP stage. DN3 cells just beginning selection rapidly enlarge and increase their expression of the cell-surface receptor CD27 (61,94). TCR gene rearrangement temporarily halts as the cells surge into proliferation, and the TCRβ, γ, and δ loci convert to a conformation that is inaccessible to future rearrangement, causing allelic exclusion of TCRβ. The ability of a pre-rearranged TCRβ transgene to cause precocious β selection explains why it blocks endogenous TCRβ gene rearrangement. Under normal circumstances, though, the particularly intense proliferation triggered by β selection expands each cell into a large clone so that each successful TCRβ rearrangement can be tested later for the recognition specificity it confers in association with multiple different TCRα rearrangements. This mitotic burst may also include some of the last cell cycles that T cell precursors undergo, in adults, before they finish development and emerge to the periphery. The transition to the DP stage through β selection confers unusual properties on the cells that optimize them for TCR repertoire selection, described later.

Triggering Requirements for β Selection

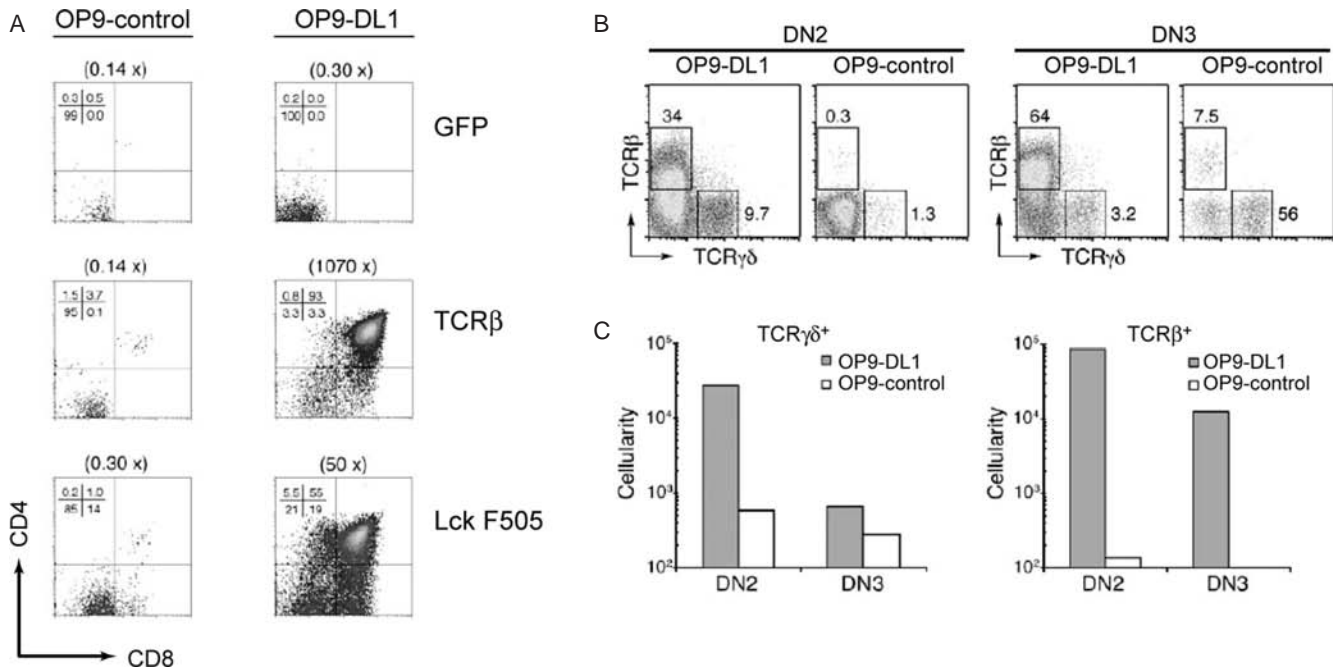
β selection is triggered when a TCRβ gene rearrangement generates a sequence that can be translated into a β chain protein. For example, Figure 12.4A (middle right) shows that RAG-deficient thymocytes can be triggered to undergo β selection *in vitro* if they are transfected with a productively rearranged β chain gene. The β chain assembles into a pre-TCR complex with the surrogate α chain pTα, the CD3 components γ, δ, and ε, and TCRζ_2, which are already being expressed in DN2 and DN3 cells, and the complex enters the traffic to the plasma membrane. pTα, a key component of this complex, is an invariant transmembrane glycoprotein that is encoded by a nonrearranging immunoglobulin superfamily gene and expressed very specifically in DN and DP thymocytes (90). The TCRβ/pTα/CD3/TCRζ_2 complexes associate very efficiently into cholesterol-rich lipid microdomains (lipid rafts) on the cell membrane, and they oligomerize with each other and spontaneously initiate signaling (90,95,96). Artificial crosslinking of CD3 complexes on the DN3 thymocytes of RAG-knockout mice is also sufficient to drive the full β selection response. The DN3 thymocytes


FIGURE 12.4 Triggering requirements for β selection and $\gamma\delta$ selection. **A:** DN to DP transition induced in RAG-deficient thymocytes by introduction of a rearranged TCRβ transgene or activated Lck (LckF505): proliferation and differentiation depend on Notch/DL1 interaction. Left panels show RAG-knockout thymocytes cultured on OP9 stromal cells that do not express the Notch ligand DL1 (OP9-control); right panels show the same populations of cells cultured on OP9 stromal cells that do express DL1 (OP9-DL1). Numbers in parentheses above panels show the change in cell number recovered from each culture relative to input. Note that DN to DP transition and proliferation require both an Lck-activating stimulus (pre-TCR assembly or LckF505) and an interaction between cellular Notch and its DL1 ligand. From ref. (253), with permission. **B:** Wild-type DN3 thymocytes can generate $\gamma\delta$ cells, but not TCRβ^+ cells, in the absence of Notch/DL1 interaction. Here cells were pre-fractionated into DN2 and DN3 subsets and only then cultured on OP9-control or OP9-DL1. DL1 is needed for both kinds of TCR$^+$ cells to be generated from DN2 cells, but once the cells reach DN3 stage, DL1 is no longer needed for $\gamma\delta$ cell development. **C:** Cell counts for cultures shown in panel **B**. Panels **B, C** from ref. (62), with permission.

themselves may be particularly responsive to any kind of CD3 complex signaling.

The pre-TCR signaling cascade launches the complex β selection response by activating the kinase Lck, engaging the adaptors SLP-76 and linker of activated T cells (LAT), and thus activating protein kinase C, Ras, and MAP kinases. All these mediators are essential, and protein kinase C is particularly important for TCRβ allelic exclusion (97,98). Artificial activation of Lck or the Ras/Raf, PI3-kinase, or protein kinase C pathways is sufficient to cause a burst of DP cells to be generated even in RAG-knockout mutants, which cannot rearrange their TCR genes and so cannot undergo β selection legitimately (99) (reviewed in 91–93). Figure 12.4A (lower right) shows the dramatic effect of constitutively activated Lck, comparable to a rearranged TCRβ itself. Similarly, Lck can be activated constitutively by mutation of the *csk* gene, and this also enables cells without pre-TCR to differentiate spontaneously to DP cells (100).

These details imply that β selection is activated by a signaling cascade that is strikingly similar to the one that is triggered by the mature $\alpha\beta$ TCR in later stages of T cell development, during positive selection, as well as in mature T cell responses to antigen. Indeed, β selection serves as the "maiden voyage" in development for the multicomponent TCR signaling apparatus that will govern all future interactions of the T cell with its environment.

The TCRα locus under normal conditions is neither rearranged nor transcribed appreciably until β selection. However, already-rearranged TCRα transgenes can be expressed in DN cells to make TCR$\alpha\beta$ complexes as well as pTα:TCRβ pre-TCR complexes. To a limited extent, rearranged TCRα can replace pTα to mediate β selection. However, TCR$\alpha\beta$ complexes are less effective than pre-TCR complexes in triggering the major proliferative expansion that normally occurs at β selection, due to intrinsic differences in signaling capability (101,102).

Constituent Events in the β Selection Cascade

Gene disruption and overexpression experiments show that once triggered, successful β selection consists of components under partially separable control: (a) early proliferation, with short-term protection from apoptosis (DN→ISP); (b) later proliferation (ISP→DP); (c) CD4, CD8, TCRα transcriptional activation; (d) transcriptional repression of CD25 and a variety of Notch response genes; (e) transient down-regulation of RAG1, RAG2, and pTα; (f) allelic exclusion (i.e., long-term shutoff of Vβ and Vγ rearrangement); (g) antiapoptotic functions for ISP→DP cells; and (h) transcriptional silencing of the TCRγ genes, whether or not they are rearranged, once the cells reach the DP stage. These phases are regulated discontinuously by a variety of factors with dynamically shifting roles. E protein (E2A/HEB) function is required for TCR rearrangement but must be counteracted to allow the initial burst of proliferation. This occurs through a transient increase in expression of the E protein inhibitor, Id3, which then subsides to allow differentiation (66,103). Factors of the Egr family are sharply induced by pre-TCR signaling and important for many of the initial transcriptional responses, but become antagonistic if their expression is not subsequently shut off (104–107). The HMG box transcription factors TCF-1 and LEF have a substantial role, later in making β selection effective overall, at least by promoting proliferation in the ISP to DP stage and viability of emergent DP cells (30,71,108). Transitions in viability support functions are particularly complex, involving shifts in Bcl-2 family member expression (87,94,109), NF-κB activation (94,110), induction of the DP-specific orphan nuclear receptor RORγt (111–113). The roles of death-domain containing signaling adaptors such as FADD also shift between pro-apoptotic and pro-proliferative effects (82,114).

Perhaps surprisingly, the phenotypic differentiation from CD4$^-$ CD8$^-$ DN to CD4$^+$ CD8$^+$ DP may be the aspect of β selection that is closest to a default program. RAG-knockout DN3 thymocytes can begin to differentiate spontaneously if the mice are recovering from irradiation, if the p53 checkpoint control function is absent, or if they are expressing a dominant-negative allele of FADD (82,84,86), in spite of their lack of pre-TCR. These are manipulations that are unlikely to "instruct" the DP developmental program. Instead, they presumably remove a barrier to it. Further, in RAG-knockout mice with a diabetes-prone NOD genetic background, although the thymocytes cannot express any form of TCR, an age-dependent breakthrough of the checkpoint occurs that generates DP cells at a high penetrance (87). DN3 cells thus appear to be developmentally primed for DP cell differentiation, but restrained by the β selection checkpoint machinery. One major thing that the pre-TCR and Lck signaling cascade appears to do is to lift this barrier.

In these violations of the β selection checkpoint, however, what fails is the normal level of proliferation. Also correlated with the poor proliferation in these cases is a failure to complete the down-regulation of DN3-specific genes such as CD25. In the NOD case, which has been analyzed most closely, the breakthrough cells demonstrably fail to extinguish expression of the IL-7Rα (CD127) and c-Kit (CD117) genes as well as a series of DN3-specific transcription factors including the Notch-response transcription factor HES1 (87). Proliferation is also required to terminate expression of the TCRγ genes in the DP cells emerging from β selection (115). These results suggest that the extensive proliferation normally triggered during β selection is functionally linked with the ability to "clear the decks" developmentally and to relinquish the gene expression patterns of the pre-selection state.

Choices of Fate within the T Cell Lineage: Differences between $\alpha\beta$ and $\gamma\delta$ T Cells

At every point in T cell development at which TCR complex signaling affects cell fate, the outcome is affected by quantitative details of the strength and duration of signaling. The choice at these checkpoints is not just whether the cells will be allowed to survive, but also a choice between at least two developmental programs to follow by the cells that succeed. This is true of positive and negative selection based on TCR$\alpha\beta$ interactions with MHC and self-peptide, and somewhat surprisingly, it also appears to be true of the generation of $\alpha\beta$ or $\gamma\delta$ T cells by DN3 thymocytes.

Mature TCR$\gamma\delta$ cells differ in many respects from TCR$\alpha\beta$ cells. Their program of gene expression generally does not include expression of CD4 or CD8β, in contrast to TCR$\alpha\beta$ cells. Because the cytoplasmic tails of CD4 and CD8 are the major known docking sites for Lck, their absence probably alters the way mature TCR$\gamma\delta$ cells can recruit Lck to lipid rafts with the TCR during antigen recognition. TCR$\gamma\delta$ cells can express conventional immune cytokines such as IL-2, but with distinctive features of their regulation (116). In the periphery, TCR$\gamma\delta$ cells home to different sites and carry out different surveillance assignments from those of TCR$\alpha\beta$ cells, including wound healing and epithelial maintenance (117). These functions reflect TCR$\gamma\delta$-specific programming for expression of insulinlike growth factor I and keratinocyte growth factor (FGF-7), which act on the epithelial cells.

Intracellular expression of TCRγ and δ proteins is first detectable in a subset of DN3 cells (118), and a variety of staining and reporter gene knock-in techniques visualize TCR$\gamma\delta$ cells emerging from the DN3 population (61,62,119). $\gamma\delta$-selection causes the cells to shift to a CD25$^-$ CD44$^{+/-}$ phenotype, with relatively high CD5 expression. Emerging $\gamma\delta$-selected cells diverge from β-selected cells immediately in their expression levels of survival and regulatory genes, including Bcl2, Runx3, Aiolos,

Egr family, and HEB genes (61,120). Direct comparisons between β selection and $\gamma\delta$ selection show that $\gamma\delta$ selection triggers fewer rounds of proliferation (61,63). The question has been how developing thymocytes can tell the difference.

TCR$\gamma\delta$ cells are usually defined by their success in making both V-Jγ and V-D-Jδ gene rearrangements productively before they either die or undergo complete β selection. The TCR$\gamma\delta$ receptor is both their main distinguishing feature and their most apparent cause of divergence from the TCR$\alpha\beta$ path. TCRγ and nondeleted δ genes may also be rearranged in TCR$\alpha\beta$ cells, but these are usually out of frame for protein translation. On the other hand, the correlation between TCR rearrangement and fate is imperfect. There are some in-frame TCRβ rearrangements in $\gamma\delta$ cells, so the commitment to the $\gamma\delta$ fate can occur sometimes in spite of TCRβ expression (121,122). In some circumstances, a TCR$\gamma\delta$ receptor can even promote development to a DP fate, or a TCR$\alpha\beta$ complex can drive differentiation toward a $\gamma\delta$-lineage-like fate (123–125), Therefore, the unique structural properties of the $\gamma\delta$ and pTα:TCRβ complexes cannot be the only things that determine developmental fate.

Factors Influencing Commitment to the $\alpha\beta$ or $\gamma\delta$ Lineage

Tantalizing evidence has shown that the generation of TCR$\gamma\delta$ lineage cells depends on different balances of regulatory inputs than the generation of TCR$\alpha\beta$ cells via β selection. For example, IL-7 signaling is crucial for the development of almost all subtypes of $\gamma\delta$ cells, and this is due to direct effects of the IL-7R–activated transcription factor STAT5 on TCRγ locus rearrangement and expression (126–132). IL-7 also influences generation of $\alpha\beta$-lineage cells, mostly in the degree of proliferative expansion before β selection, but for $\gamma\delta$ cell generation the effect is all or nothing. Accordingly, at stages before TCR rearrangement is complete and before any TCRγ or δ protein is detectable in the cells (133), subsets of DN2 cells with the highest levels of IL-7R expression show more competence to develop into TCR$\gamma\delta$ cells than those with lower IL-7R surface expression (134). Conversely, there are genetic circumstances under which TCR$\gamma\delta$ cells can develop and $\alpha\beta$-lineage cells cannot. For example, loss of function of various genes, ranging from E proteins to the Notch transcription factor RBP-Jκ (CSL) to a DNA methyltransferase, can each block generation of DP cells while leaving TCR$\gamma\delta$ cell numbers unchanged (59,135–137). Conceivably, then, the precursors of $\alpha\beta$ and $\gamma\delta$ cells could diverge at a regulatory gene level before reaching the first TCR-dependent selection point. But even if such differences exist before TCR rearrangement, it turns out that differential strength of signaling through the $\gamma\delta$ TCR and pre-TCR is sufficient

to control which developmental program the cells actually choose (reviewed by 138,139).

The strength of the signal transduced by a fully assembled $\gamma\delta$ complex appears normally to be stronger than that transduced by the TCRβ:pTα pre-TCR complex (96). Remarkably, in elegant transgenic systems, the same TCR$\gamma\delta$ complex can promote either β-selection or $\gamma\delta$-selection with high efficiency, depending on the strength of the signal that it is allowed to deliver (120,140). A great deal of ingenuity was used to determine this, because in general the ligands for TCR$\gamma\delta$ and their roles in $\gamma\delta$-selection are not known. One study took advantage of a rare TCR$\gamma\delta$ transgene that is known to be positively selected by interaction with a nonclassical class I MHC protein. In this transgenic, the availability of the ligand could be controlled separately by mutation of the essential MHC class I component β_2-microglobulin (120). Where the ligand was present, the TCR$\gamma\delta$ transgene-expressing cells developed into $\gamma\delta$ lineage cells; where it was not, they proliferated more and developed into DP cells instead. In another study, a different TCR$\gamma\delta$ transgene with an unknown ligand was used, but signaling through this receptor was manipulated by separate mutations that affected the intrinsic signaling efficiency of the TCRζ chains that transduce signals from the TCR complex. Here any TCR$\gamma\delta$–ligand interaction would be exactly the same as in the normal case. However, as the competence of the TCR$\gamma\delta$ signaling complex was reduced, the cells again generated increasing numbers of thymocytes in steady state and increasingly developed into DP cells instead of TCR$\gamma\delta$ cells (140). Thus, not only the presence or absence of an assembled TCR complex but also the quantitative details of its signaling determine the future differentiation of cells confronting the β-selection checkpoint.

Differential Notch Requirements for TCR$\alpha\beta$ vs. TCR$\gamma\delta$ Cell Production

As signal strength appears to favor the TCR$\gamma\delta$ lineage, one of the most important factors favoring TCR$\alpha\beta$ lineage development now appears to be Notch signaling. The first TCR-dependent checkpoint is the stage when developing T lineage cells graduate from Notch dependence to TCR dependence. Once selection has begun, Notch signaling is not strictly needed for either β or $\gamma\delta$ selection to finish successfully (59,64). The down-regulation of Notch target gene HES1 (49,141) and many others including Notch1 and Notch3 themselves, is an early feature of both types of selection (61). However, Notch/Delta signaling remains vital for cells beginning to undergo β selection even as it becomes dispensable for $\gamma\delta$ selection.

The clearest demonstration of this specific requirement has been revealed by *in vitro* culture of sorted DN3 cells with stromal cells that do or do not express the Notch ligand DL1 (46). As shown in Figure 12.4A, ongoing

Notch/Delta signaling (OP9-DL1 stromal culture) is absolutely required for DN3 cells to start β selection; this is true no matter what kind of TCR they have (61–63,89,142). In contrast, eligible DN3 cells can undergo $\gamma\delta$ selection without these signals (Figure 12.4B,C: OP9-DL1 versus OP9-control samples). There is even evidence that the strength of the pre-TCR signal may need to be offset by the intensity of Notch signaling in order to generate DP thymocytes (63,89). These results imply that Notch signaling is an integral part of a balance of signals that determines the choice between $\alpha\beta$ and $\gamma\delta$ developmental programs.

The essential role of Notch pathway regulation in β selection illuminates a grim side of its role. Hyperactivity of the Notch pathway at β selection, or a failure to turn it off once β selection begins, appears to be a key precipitating factor for T lineage acute lymphoblastic leukemia, with or without other predisposing mutations in Ikaros, E2A, or other genes (78–80,143–145). The explosive proliferation that β selection entails mobilizes other proto-oncogenes, such as c-Myb and Pim-1 (146–149), and the cells can be imagined to come close to the brink of oncogenic transformation in every generation. The mechanism leading to down-regulation of the Notch pathway during β selection is not well understood yet, but if it allows DP cells to come to a resting state, it may be critical for the health of the organism.

CD4+ CD8+ DOUBLE-POSITIVE THYMOCYTES AND THYMIC HOMEOSTASIS

Impacts of β Selection on Later T Cell Differentiation

As a developmental event, β selection is momentous. The approximately 10^2-fold proliferation at β selection effectively erases the developmental alternatives for TCR$\alpha\beta$ cells, consummating not only T lineage commitment but the separation of $\alpha\beta$ and $\gamma\delta$ cell fates. In adult mammals, this is the last significant proliferation that T cell precursors undergo before being exported to the periphery. Thus, the form in which cells emerge from the various stages of β selection dictates the defaults for their responses to positive and negative selection signals for most of the rest of their residence in the thymus.

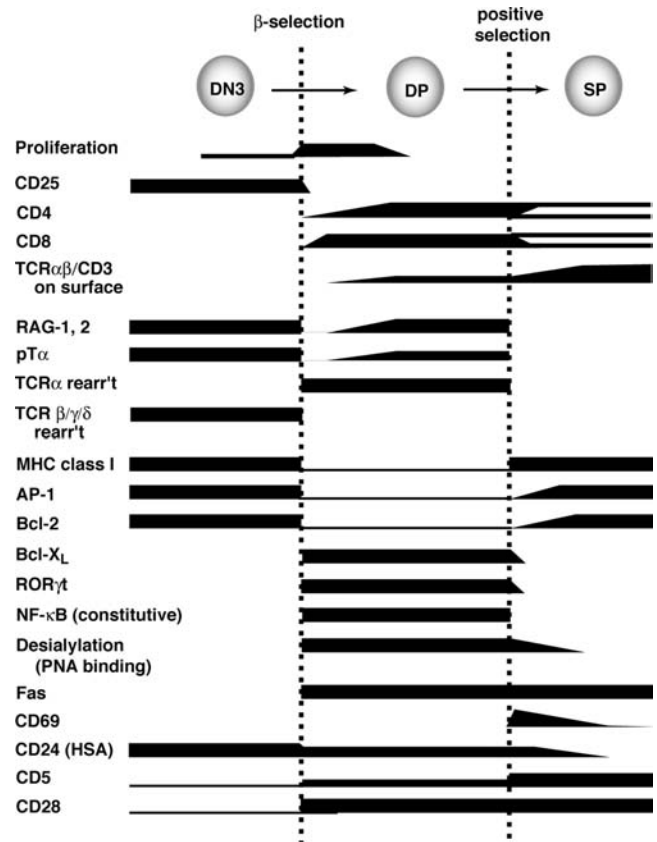
β selection causes an immediate impact on the cells that in certain ways is the reverse of the impact of positive selection (see later discussion). In particular, there are changes in Bcl-2, Bcl-X$_L$, NF-κB, and AP-1 activation, RORγt expression, glycoprotein sialylation, and signaling thresholds that will all be reversed when the cells are positively selected, as summarized in Figure 12.5. Nevertheless, many of the triggering functions used in β selection are the same as those used in positive selection. The signals


FIGURE 12.5 Transformations of cell phenotype during β selection in mouse thymocytes: comparison with later transformations during positive selection. The changes in gene expression, rearrangement accessibility, and cell-surface phenotype at the transition from DN3 cells to DP are shown, compared with changes that occur later during positive selection. Changes in cell-surface phenotype where several distinct levels of marker expression are useful to distinguish among developmental states are depicted by sloping or stepped forms, whereas others are simplified as all-or-none changes. For discussion, see text. CD4 and CD8 expression patterns are shown bifurcating at positive selection to represent the CD4/CD8 SP lineage split. Proliferation between the DN3 and DP stages extends through the DN4 and immature SP stages (not marked here) and into the beginning of the DP stage. RAG1 and RAG2 and pTα are transiently shut off during proliferation after β selection and then expressed again in DP thymocytes. Expression of RORγt in DP cells correlates with alterations in functional responsiveness. AP-1 loss of function in DP thymocytes is a loss of inducibility of deoxyribonucleic acid (DNA) binding and transactivation activity, leading to broad defects in effector gene inducibility. The up-regulation shown for NF-κB in the DP stage refers only to constitutive nuclearization of DNA-binding activity: NF-κB is also inducible by stimulation at other stages of development. The expression of surface glycoproteins deficient in sialic acid is detected by a sharp increase in binding to the lectin peanut agglutinin (PNA). Fas is a TNF receptor family death receptor. CD69, CD24 (HSA), CD5, and CD28 are cell-surface receptors with potential roles in modulating or costimulating TCR signaling activity.

may not be instructive in themselves, therefore, but more like a toggle between alternative physiological states.
