The herpesvirus entry mediator (HVEM, TNFRSF14) provides an example of a TNFR system that binds an alternate ligand. Although HVEM binds two TNF-related ligands—LIGHT and LTα—it also engages a member of immunoglobulin superfamily—B and T lymphocyte attenuator (BTLA) (31). BTLA binding to HVEM occurs in CRD1, on the opposite face of where LIGHT/LTα binds CRD2 and 3. The BTLA-binding site in CRD1 of HVEM is a region also targeted by herpesviruses (32–34). The engagement of ligands distinct from TNFSF members implicates a higher level of integration with other signaling pathways.

Viral Orthologs

The TNFR-like proteins are found in several viral pathogens representing captured cellular genes imprisoned in the viral genome that evolved as part of that pathogen's immune evasion strategy (Table 25.3) (35). Poxvirus was the first pathogen identified harboring a version of a cellular TNFR (36). Poxvirus TNFR displays significant sequence conservation to TNFR2 and binds TNF and LTα. The rabbit poxvirus protein T2 is secreted by virally infected cells and contributes to the virulence of infection (37,38). Smallpoxvirus, the former scourge of mankind, also harbored viral versions of TNFR2 *(39)*.

SIGNALING PATHWAYS AND CELLULAR RESPONSES

Regulation

The cellular response activated by a TNF-related cytokine depends on several factors, including the temporal patterns of expression of the ligands and receptors in the interacting cells and the cellular context (the state of differentiation of the responding cell). Regulation is achieved at the level of transcriptional and translational controls and by modulating the availability of the ligand or receptors (Figure 25.4). For some ligands, transcriptional activation is a critical feature controlling the duration of mRNA expression. Some ligands exhibit inducible, transient

▌**TABLE 25.3** Viral Orthologs and Modulators of the Tumor Necrosis Factor (TNF) Superfamily

Virus	Name/ORF	Ortholog[a]	Mechanism
Poxvirus:			
Myxoma	T2	Soluble TNFR2	TNF and LTα decoy
Virola	crm B (G2R)	Soluble TNFR2	TNF and LTα decoy
Coxpox	vCD30	Soluble CD30	CD30 ligand inhibitor
Herpesvirus:			
HSV1, 2	Glycoprotein D	BTLA	Entry; HVEM blockade
HCMV	UL144	HVEM	BTLA activation
EBV	LMP1	CD40 intracellular	TRAF activation
γHV	vFLIP	FLIP	Caspase 8 blockade
Adenovirus	E3-10.4,14.5,6.7	?	Fas and TRAILR downmodulation
Retrovirus:			
EIAV	Envelope gp90	?	HVEM entry factor
FIV	Envelope gp95	?	Ox40 entry factor
ASLV	Envelope gp85	?	TRAILR entry factor
Rabies virus	Envelope RVG	?	NTRp75 entry factor

ASLV, avian sarcosis and leucosis virus; BTLA, B and T lymphocyte attenuator; EBV, Epstein-Barr virus; EIAV, equine infectious anemia virus; FIV, feline immunodeficiency virus; FLIP, FLICE-inhibitory protein; γHV, equine gamma herpesvirus; HCMV, human cytomegalovirus; HEVM, herpesvirus entry mediator; HSV, herpes simplex virus; RVG, rabies virus glycoprotein, TRAF, TNF receptor–associated factor.
[a]Relationship determined by sequence or structural homology to the indicated TNF superfamily member; a question mark indicates that no homology is recognized.
FIGURE 25.4 Regulation of tumor necrosis factor (TNF) bioavailability. The expression of TNF is regulated at the transcriptional and translational levels, and its bioavailability is affected by altering its physical location and cellular receptors. TNF transcription is regulated by the action of multiple transcription factors, including NFAT (nuclear factors of activated T cells), AP-1 (activated protein-1), and NF-κB (nuclear factor of the immunoglobulin κB locus). NFAT is a predominant transcription factor regulating TNF transcription in T and B lymphocytes, and NF-κB and AP-1 are important in myeloid lineage cells after activation via innate pattern recognition receptors, such as the Toll-like receptors. TNF mRNA stability is controlled by an AU-rich element (ARE) in the 3′ untranslated region present in many transiently expressed inflammatory genes (297). Stability of TNF mRNA is decreased by the action of tristetraprolin (TTP), and T cell intracellular antigen (TIA1) silences translation of TNF mRNA through the ARE (298). TACE proteolytically controls the TNF at the membrane, generating a soluble form of TNF. TACE also cleaves TNFR1 and 2 (299), downregulating cell surface receptors and releasing soluble receptors that retain TNF-binding activity. Soluble TNFRs can stabilize the TNF trimer at subsaturating concentrations, and at higher, saturating concentrations they act as decoys, competing for TNF binding to cellular receptors *(300)*.

expression of mRNA after antigen recognition or through innate receptor recognition systems. The half-life of mRNA levels may be controlled by an AU-rich element in the 3′ region (40), a feature very important in regulating TNF mRNA levels. Deletion of the AU-rich element in TNF mRNA in mice leads to a profound inflammatory disease (40,*41*). TNF mRNA is inducible in macrophages by multiple pathways, particularly innate activation pathways such as Toll-like receptor signaling, whereas other ligands, like 41BBL and Ox40L, are constitutively expressed in differentiated antigen-presenting dendritic cells. T and B lymphocytes require activation prior to expression of TNF. Signals via the antigen receptor using the NFAT transcription factor are needed for TNF inducibility. The inducible or constitutive patterns of expression are observed with the receptors as well.

Posttranslational regulation of signaling is achieved by proteolytic cleavage of the ligand or receptor from the cell's surface, which places the protein into the soluble phase, where its half-life may be dramatically shortened. TNF and Fas ligand, for example, are shed from the surface by membrane proteases. The enzyme processing TNF, ADAM17 (also known as TNFα converting enzyme [TACE]), into a soluble form is involved in cleaving multiple cell surface proteins, including transforming growth factor-α (TGFα), L-selectin, and TNFR1 and 2; the latter substrates may be important in regulating TNF bioavailability as decoy receptors (Figure 25.4).

Most of the TNF-related ligands are expressed by dendritic cells, activated lymphocytes, and myeloid cells, particularly macrophages, but they can also be produced by nonlymphoid cells. TNF is an example of a ligand expressed by many cell types, depending on the stimulus. In contrast, expression of TNFR is widespread. TNFR1 is expressed on most cells, although TNFR2 is limited to cells of hematopoietic origin and is expressed after activation of B or T cells. Macrophages are a primary source of TNF in response to TLR signaling, and T cells when activated by antigenic stimuli, but fibroblasts also produce TNF in response to virus infection, and nonlymphoid tumor cells may ectopically express TNF. FasL is another example of a ligand with varied cellular expression pattern. FasL is expressed by effector T cells and NK cells as a component of their cell lytic activity, yet FasL mRNA is detected in reproductive organs and epithelium of the eye, which may use this ligand to kill organ-infiltrating inflammatory cells, providing a mechanism to dampen inflammation.

Signal Transduction Pathways

TNF receptors initiate signaling pathways that alter gene expression patterns as well as apoptotic pathways terminating cellular life. The propagation of signals to enzymatically active proteins is mediated by two distinct types of signaling motifs in the cytosolic domain of the various TNFR: death domain (DD) receptors, such as Fas, TNFR1, and TRAILR1 and 2, and those that have a TRAF recruitment motif, including LTβR, CD40, and CD27, among others. Three basic schemes are used by TNF receptors to connect to enzymatically driven signaling pathways (Figure 25.5A). Adaptor molecules are required to establish the signaling connection. The DD connects TNFR to death effector domain (DED)–containing proteins, which in turn link to proteolytic active caspases (cysteine-based, aspartic acid–specific proteinases). Alternatively, the TRAF proteins connect to the cytosolic domain of the TNFR, linking to pathways that activate NF-κB and AP1 transcription factors. The third scheme involves an indirect link to TRAF adaptors via a DD adaptor, TRADD.

The apoptotic and NF-κB pathways activated by the TNFR family help to regulate cellular homeostasis by controlling cell death and survival. In the immune system, apoptosis is key to controlling homeostasis and eliminating antigen-bearing cells from the host. Many TNFRs can induce activation of survival or death pathways depending in part on the differentiated state of that cell. In all nucleated cells, the apoptotic pathway is the default, that is, all of the constituents are expressed and ready to be activated (Figure 25.6), whereas cellular survival requires transcriptional induction of genes that encode regulatory proteins that suppress progression of the apoptotic pathway. Ligation of TNFR promotes assembly of the death-inducing signaling complex (DISC), which promotes dimerization of pro-caspase 8, forming an active enzyme (42). Activated caspase 8 acts directly to cleave pro-caspase 3 and 7, which are known as the executioner caspases because they directly cleave critical cellular substrates leading to apoptotic death. Caspase 8 also cleaves BID, a crucial connection to the mitochondria-associated death mechanism, which greatly amplifies the apoptotic process. The inhibitors of apoptosis (IAP) are direct caspase inhibitors regulated at gene expression level by NF-κB. FLIP (FLICE/Fas-associated death domain [FADD] inhibitory protein) is an NF-κB–regulated gene, with a DED and pseudo caspase domain that attenuates the apoptotic pathway by blocking conversion of pro-caspase 8. As expected, many viruses have evolved different strategies to alter the proapoptotic pathways, and some use viral orthologs of IAP and FLIP (Figure 25.6).

Transcriptional activation by TNFR uses TRAF adaptors. After ligand binding, TRAFs are recruited to the activated receptor, but through different mechanisms. TRAF2, 3, and 5 bind directly to the receptor's cytosolic domain, whereas TRAF2 can also uses TRADD to couple to TNFR1. TRAF3 and TRAF6 appear to be preassociated with different protein kinases involved in multiple signaling pathways, including the pathogen recognition and interferon (IFN) pathways (43). TRAF adaptors link TNFR directly to protein kinase cascades, which in turn lead to activation of transcription factors, including NF-κB and AP1.
FIGURE 25.5 Signaling pathways and NF-κB. **A:** Adaptors link TNFR to proteinases and kinases. Three basic schemes link activated tumor necrosis factor receptors (TNFRs) to signaling pathways: The death-inducing signaling complex (DISC) formed with Fas is initiated by ligand clustering of Fas, promoting death domain (DD) interactions, which recruits FADD (heterotypic interaction). The death effector domain (DED) of Fas-associated death domain (FADD) links to the DED of pro-caspase (Casp) 8. The proximity of multiple pro-caspase 8 domains forms an active enzyme, which can process other caspase 8 molecules. By contrast, TNFRs bind TRAF adaptors (TNFR-associated factors) via short peptide motifs that release TRAF from associated kinases, such as NF-κB–inducing kinase (NIK). The third scheme is a combination of DD and TRAF recruitment. TNFR1 uses the DD protein TRADD to recruit RIP and TRAF2, promoting the activation of NF-κB. There are six TRAF members with distinct interaction patterns with the TNFR family. TRAF proteins may function as regulators of key kinases. TRAF3 and TRAF6 function as modulators of several different kinases involved in Toll-like receptor signaling, induction of type 1 interferon responses, and signaling by some TNFR family members. TRAF proteins contain an N-terminal RING finger motif, a coiled-coil domain (isoleucine zipper), and the receptor association (TRAF) domain. The TRAFs are trimers formed through their TRAF and coiled-coil domains. The TRAF domain can bind to several different TNFRs through a relatively short proline-anchored sequence that is responsible for binding directly to the mushroom head of various TRAF molecules (301). The zinc RING of TRAF6 functions together with Ubc13 and Uev1A as a ubiquitin ligase targeting proteins for proteasome degradation. (Modified from Ware CF. Tumor necrosis factors. In: Bertino JR, ed. *Encyclopedia of Cancer*, Vol. IV. San Diego, CA: Academic Press, 2002:475, with permission.) **B:** NF-κB activation. TNFR1 and LTβR induce distinct forms of the NF-κB family of transcription factors. TNFR1 signaling is a potent activator of RelA/p50 but does not activate the RelB pathway, whereas LTβR can activate both. The RelA and RelB forms of the κB family control transcription of distinct sets of genes; however, the two pathways are interrelated through the control of p100 expression by the RelA/p50 complex. (Modified from Dejardin E, Droin NM, Delhase M, et al. The lymphotoxin-beta receptor induces different patterns of gene expression via two NF-kappaB pathways. *Immunity*. 2002;17(4):525, with permission.)
FIGURE 25.6 Apoptosis and survival signaling. **Top:** Ligation of TNFR1, Fas, or TRAILR1 and 2 activates apoptosis pathways. The nascent death-inducing signaling complex (DISC) can directly cleave the executioner caspases 3, 6, and 7. Caspase 8 also cleaves BID to truncated BID (tBID), activating the mitochondrial-regulated apoptotic pathway, dramatically accelerating cellular death. A number of viral proteins interfere with apoptosis induced through the tumor necrosis factor pathway, including human papilloma virus (HPV), hepatitis C virus (HCV), and herpesvirus FLICE-inhibitory proteins (vFLIPs) and virus orthologs of Bcl2 and vMIA that act on the mitochondria. (Adapted from Benedict CA, Banks TA, Ware CF. Death and survival: viral regulation of TNF signaling pathways. *Curr Opin Immunol.* 2003;15(1):59, with permission.) **Bottom:** The components of the apoptotic pathway are preformed in the cytosol, enabling the cell to respond rapidly to death signaling. In contrast, the key regulators of the apoptotic pathway, including Bcl2 and IAP (inhibitor of apoptosis) require new gene expression controlled by NF-κB. An important NF-κB–induced gene is cellular FLIP, which contains a pseudo caspase domain. The cFLIP protein interferes with caspase 8 activation, blocking the pro-death pathway. If the cell is transcriptionally inactive or unable to activate NF-κB, which often occurs in a pathogen-infected cell, then the proapoptotic pathway dominates the signals emanating from the TNFR1 signaling complex, leading to apoptosis and curtailing parasitism of the cell.

The NF-κB family of transcription factors controls expression of genes critical for cell survival, inflammatory, and immune responses. In mammalian cells, the NF-κB family consists of five members: RelA, RelB, c-Rel, p50/NF-κB B1, and p52/ NF-κB B2 (proteolytic processing of p105 and p100 yields the active forms p50 and p52, respectively) (44,45). Homo- and heterodimers of NF-κB family members are held inactive in the cytosol by inhibitors of κB (IκB), such as IκBα, masking nuclear localization motifs.

The inhibitor of κB-kinase (IKK) complex is the common target of a variety of signals that control the activation of the RelA NF-κB transcription factor, which in turn regulates expression of several hundred genes within a signal-responsive cell. A distinct pathway regulates the activation of RelB NF-κB through a distinct complex comprised of NF-κB–inducing kinase (NIK)-IKKα kinases. Receptor ligation releases the active form of NIK that phosphorylates IKKα, which induces the proteasome-dependent

processing of p100 to p52, allowing the RelB/p52 complex to activate gene transcription.

TNFR1 and LTβR activate separate yet related pathways that lead to distinct forms of NF-κB, the RelA/p50 and RelB/p52 complexes (46). Each form of NF-κB activates a large number of genes with distinct roles in physiology (Figure 25.5B). TNFR1 signaling rapidly mobilizes (within minutes) the RelA/p50 complex, which controls expression of many proinflammatory genes. By contrast, the processing of p100 and accumulation of nuclear RelB/p52 take several hours after the initial stimulus. Rel B–dependent genes are often involved in lymphoid tissue organogenesis and homeostasis. The NF-κB–inducing kinase (NIK) is also required for NF-κB RelB and RelA activation by CD27, CD40, and BAFF-R but not by TNFRI, which is restricted to activating RelA/p50 complex (47,48).

THE IMMEDIATE LT AND TNF FAMILY

Tumor necrosis factor (TNF, formerly TNFα, TNFSF2) and LTα (formerly TNFβ, TNFSF1) were originally pursued and characterized as inducers of tumor cell death, holding promise as antitumor therapeutics; however, the potent inflammatory action of TNF, particularly in the cardiovasculature, was quickly realized by observing the response of cancer patients injected with recombinant protein. We now recognize that TNF and LTα are two components of an interconnected network of "signaling circuits" that include LTβ and LIGHT (TNFSF14) and their specific receptors and regulatory proteins (Figure 25.2). Each individual pathway has unique and cooperative signaling activities with other members of this immediate family. The immunologic processes controlled by this cytokine network are extensive, ranging from the development and homeostasis of lymphoid organs to the mobilization of innate defense systems to cosignaling activity promoting adaptive immune responses (49,50,51).

TNF, LTα, LTβ, and LIGHT define the immediate group of TNF-related ligands that bind four cognate cell surface receptors with distinct but shared specificities. TNF and LTα both bind two distinct receptors, TNFR1 (p55-60, TNFR1A) and TNFR2 (p75-80, TNFR1B). The heteromeric LT$\alpha\beta$2 complex binds the LTβR, which also binds LIGHT (TNFSF14). LIGHT also engages the herpesvirus entry mediator (HVEM, TNFRSF14), which acts as a ligand for BTLA (31), an immunoglobulin (Ig) superfamily member. Two distinct human herpesviruses—herpes simplex virus and cytomegalovirus—target the HVEM-BTLA pathway using different mechanisms (34) (Figure 25.7).

TNF mediates a diverse range of cellular and physiologic responses linked to acute and chronic inflammatory processes. The diversity of responses is due in part to the broad expression of TNFR1 and the release of TNF as a soluble mediator, where it can act in a systemic fashion.

TNF production is triggered by many of the innate recognition systems, such as the Toll-like receptors, and by T and B cells, whereby in chronic inflammation, TNF production can lead to tissue damage and organ failure. Genes expressed in response to TNF signaling coordinate the physiologic responses during inflammation (Table 25.4). The responses reflect the characteristic of the inflamed organ and the local or systemic source of TNF and the duration of TNF signaling. Acute inflammatory responses involve rapid changes in hemodynamics (plasma leakage and edema) and leukocyte adherence, extravasation, and organ infiltration induced by TNF. TNF production during chronic inflammation may contribute to systemic metabolic derangements and wasting (cachexia) or loss of organ structure and function (bone erosion in joints of patients with rheumatoid arthritis). In some models, TNF can promote an inflammatory environment that promotes tumor formation (52,53,*54*).

Elucidation of the functions associated with this TNF/LT signaling network has been aided by studies with genetically modified mice engineered with null or transgene expression of the cytokine or receptor (Table 25.5). Deficiency in TNF or TNFR1 but not TNFR2 leads to similar phenotypes with alterations in host defense to intracellular bacterial pathogens, like *Listeria monocytogenes* and *Mycobacterium tuberculosis*, but surprisingly modest susceptibility to some viral pathogens. These results demonstrated a role for TNF in acute-phase response of the host defense system. In contrast, LTα-deficient mice showed a failure in formation of peripheral lymphoid organs, a phenotype not observed in mice deficient in either TNFR or TNF, which implicated the LT$\alpha\beta$ complex signaling through the LTβR as a key developmental pathway for lymphoid organogenesis.

LT$\alpha\beta$-LTβR, a Mammalian Organ Development Pathway

Gene-deficient mice sharing a common phenotype of no lymph nodes revealed the framework of a signaling pathway involved in mammalian organ development. LTα-, LTβ-, or LTβR-deficient mice fail to develop secondary lymphoid tissues (55,*56*). Several other knockout mice, including transcriptional regulators Ikaros, ID2, and RORγt, also lack lymph nodes *(57–61)*, as do mice deficient in components of the NF-κB activation pathway, including TRAF6, NIK, IKKα, and Rel B and their gene targets. Deficiencies in target genes including CXCR5, the receptor for CXCL13, show defective lymphoid organ structure, as do CCR7$^{-/-}$ mice (receptor for CCL19/CCL21). The developmental program of secondary lymphoid organ formation initiates at 13 days postcoitus, progressing in an organized fashion from dorsal to lateral movement, with intestinal Peyer's patches forming during the first postnatal week *(62)*. The defect is irreversible, in that transferring
FIGURE 25.7 The herpesvirus entry mediator (HVEM)–B and T lymphocyte attenuator (BTLA) switch. The cartoon depicts the interactions involving HVEM that initiate positive cosignaling through LIGHT–HVEM interaction or inhibitory signaling through HVEM binding to BTLA. LIGHT bound to HVEM activates tumor necrosis factor receptor (TNFR)–associated factor–dependent activation of NF-κB, whereas HVEM-BTLA acts through an immuno tyrosine–based inhibitory motif (ITIM) of BTLA to recruit the phosphatase SHP2, attenuating kinases activated by TCR signaling. The herpes simplex virus (HSV) virion envelope protein gD attaches to HVEM, acting as an entry step for infection. The binding of glycoprotein D (gD) to HVEM can also competitively block BTLA binding and noncompetitively block the binding of LIGHT, inhibiting both intercellular communication pathways. UL144 of human cytomegalovirus binds BTLA but not LIGHT, selectively mimicking the inhibitory pathway of HVEM–BTLA. (From Kinkade A, Ware CF. The DARC conspiracy—virus invasion tactics. *Trends Immunol.* 2006;27:362, with permission.)

LT$\alpha\beta$-sufficient bone marrow into an adult LT-mutant mouse failed to induce lymph node formation. Accumulating studies indicate that the formation of lymphoid organs involves two distinct cell types: an embryonic, LTβR-expressing mesenchymal stromal cell that responds to LT$\alpha\beta$ expressed in a hematopoietically derived lineage,

TABLE 25.4 Physiologic Correlates of Tumor Necrosis Factor–Mediated Gene Induction

Induced Gene	Response
iNOS	Vasodilation, edema
VCAM-1	Leukocyte margination and extravasation
IL-8	Leukocyte chemotaxis
MHC-1	Antigen presentation
Caspase 8 activation	Apoptosis
LPL	Cachexia

Caspase 8, cysteine-dependent aspartic acid specific proteinase-8; iNOS, inducible nitric oxide synthetase; IL-8, interleukin-8 (CXC chemokine); LPL, lipoprotein lipase; MHC-1, major histocompatibility complex-1; VCAM-1, vascular cell adhesion molecule-1.

termed the lymphoid tissue inducer (LTi) cell. The LTi cell develops separately from lymphocytes and myeloid cells in a pathway dependent on ID2 and RORγt and different cytokines, including interleukin-7 (IL-7), RANK ligand (TRANCE, TNFSF11), and TNF. These cytokines induce surface LT$\alpha\beta$ in LTi cells that differentially engender formation of lymph nodes and Peyer's patches (63). Cells of the LTi lineage are maintained in the adult tissues at low levels (0.5%), presumably aiding in the homeostasis of lymphoid organs (64,65).

The microarchitecture of the white pulp in the spleen (66) is disrupted in LT- and TNF-deficient mice *(67)*. Multiple features of the architecture, including missing macrophages in the marginal sinus and the loss of positional segregation of T and B cells into discrete zones, are observed in LT- and TNF-deficient mice. The segregation of T and B cells into discrete compartments depends on expression of the tissue-organizing chemokines, with CCL19 and CCL21 attracting T cells and CXC13L for B cells. CCL19 and CCL21 act through the chemokine receptor CCR7 expressed on T cells, and CXCR5 acting on B cells promotes localization in the follicles. An LT-chemokine

circuit is formed by migration of B cells to LTβR$^+$ stromal cells expressing CXCL13, which in turn induces expression of LT$\alpha\beta$ on B cells (*68,69,70*). Circulating B cells lack surface LT$\alpha\beta$, but expression is regained on reentry into the CXCL13-rich microenvironment *(70)*. The formation of the splenic microarchitecture depends on B cell expression of LT$\alpha\beta$, which induces differentiation of specialized stromal cells (e.g., secretion of CCL20 and CXCL13 chemokines) in the spleen during postnatal maturation. Remodeling of the microarchitecture of the secondary lymphoid organs occurs during immune responses, which requires both TNF and LT pathways signaling on fibroblastic reticular cells (71). The viral pathogen cytomegalovirus can induce specific changes in the splenic microenvironment through modulation of CCL21 expression (72).

The LTβR and TNFR pathways facilitate lymphocyte entry into lymphoid tissues in part by modulating expression of adhesion molecules, such as peripheral node and mucosal addressins on high endothelial venules (73). LTβR signaling is necessary to maintain networks of follicular dendritic cells involved in capturing antigen and immune complexes that aid in activating B cells. These cellular interactions are further enhanced by LTβR signals that provides growth signal for some conventional myeloid dendritic cells (DCs) (CD8$^-$ subsets) within the lymphoid organ, whereas TNF plays a role in differentiation of DC progenitors in bone marrow (74).

T and B cells can communicate with stromal and myeloid cells via the LT$\alpha\beta$-LTβR pathway and thus dur-

ing the course of an immune response modify their immediate microenvironment. Nonlymphoid tissues suffering from chronic inflammation associated with autoimmune disease, graft rejection, or microbial infection often contain organized accumulations of lymphocytes reminiscent of secondary lymphoid organs, called tertiary lymphoid organs. Activated T and B cells provide the source of LT$\alpha\beta$ that helps to drive the process of forming these structures, but as antigen is cleared, immune responsiveness subsides and these structures resolve. A gradation of features may be found in the tertiary lymphoid organs, including presence of dendritic cells, expression of chemokines, high endothelial venules, segregated regions of T and B cells, and germinal centers, but they typically lack the permanence of a lymph node. TNF also contributes to formation of granuloma that assists in walling off bacteria (75). Thus, the LT$\alpha\beta$ and TNF pathways operative in embryonic life also play critical roles in the adult in the formation of tertiary lymphoid structures.

Influence of the LT$\alpha\beta$ Pathway on Lymphocyte Development

Mounting evidence indicates the LT$\alpha\beta$-LTβR pathway contributes to the ontogeny of unconventional T cells, including $\gamma\delta$ T cells and invariant NK T cells, whereas conventional T cell subsets are normal in mice deficient in the TNF and LTβR pathways. The LTβR pathway seems to operate at distinct levels during thymic development (76).

Double-positive (DP) thymocytes regulate the differentiation of early thymocyte progenitors and $\gamma\delta$ T cells via the LTβR pathway *(77)*, yet the LTβR is not expressed in thymocytes, suggesting an indirect mechanism. In this regard, LTβR signaling is required for the proper formation and function of the thymic stroma, which influences T cell development *(78)*. The thymic medulla appears to control the export of iNKT cells from the thymus *(79,80)*. In addition, LTβR signaling in thymic stroma affects central tolerance to peripherally restricted antigens, which may be either dependent on or independent of the autoimmune regulator Aire *(81)*. Thymic differentiation depends on the LTβR pathway to mediate the cellular communication between lymphoid and stromal compartments.

Autoimmunity

Dysregulated expression of several members of the TNFSF leads to autoimmune-like diseases in humans and animal models. For example, enforced expression of TNF or LIGHT, which overrides the normal transient expression, causes severe autoimmune and inflammatory processes in mice (82–84). LTα or LT$\alpha\beta$ transgenic expression in the pancreas leads to insulitis and formation of tertiary lymphoid structures (85). These types of results have implicated members of the TNF superfamily as immune regulators and support the notion that LT$\alpha\beta$ and LIGHT pathways contribute to inflammation and tissue destructive processes.

Infectious Diseases

TNF is a major inflammatory cytokine required for the acute-phase response to bacterial infection. For instance, lipopolysaccharide (LPS) in gram-negative bacteria is a potent inducer of TNF secretion through the TLR4 innate recognition system, as are all the other TLRs. In mice, LPS induces a shock syndrome that is rapidly lethal owing to profound changes in blood circulation; however, mice survive LPS in the genetic absence of TNFR1 or if treated with a TNF-neutralizing antibody, indicating that host-derived TNF mediates pathogenesis (86,87,*88*). On the other hand, TNFR1 is essential for resistance to infection with a live organism, such as *L. monocytogenes*, through multiple processes including enhancement of phagocytosis and bacteriocidal destruction by macrophages. By contrast, T cell immunity is not overtly impaired in TNFR1$^{-/-}$ mice. Humans treated with TNF inhibitors show some increase in susceptibility to selective pathogens, particularly *M. tuberculosis*, reinforcing the role of TNF as a critical host defense system (89).

In contrast, LT-deficient mice showed significant variability in susceptibility to individual pathogens (Table 25.6). Increased susceptibility resulted from either

developmentally controlled aspects of lymphoid organ structure (e.g., lymphocytic choriomenigitis virus, leishmania) or a requirement for LT$\alpha\beta$-LTβR pathway as an effector system in innate and adaptive immune systems (e.g., mouse cytomegalovirus). Viewed from an evolutionary perspective, this variation in the requirement for LT signaling may reflect specific contributions from the pathogen used to evade the broader TNF- and LT-dependent pathways (34,90).

TNF SUPERFAMILY AND T CELL COSIGNALING

Antigen recognition together with cooperative signaling or "cosignaling" systems determines the quality of the adaptive immune responses. Lymphocyte responses to antigen are dynamic processes that start with the activation of naive cells and transition through effector and memory phases. Cosignaling systems assist these phases by promoting more efficient engagement of antigen-binding T cell receptor (TCR) molecules to enhance initial cell activation and cell division (clonal expansion), augment cell survival (clonal contraction or memory cell differentiation), or induce effector functions such as cytokine secretion or killer function. Negative signals (inhibitory cosignaling) may also be delivered to T cells depending upon the particular system, which may prevent initial cellular activation or eliminate excess activated cells to dampen inflammation. Cosignaling can be quantitative, modifying thresholds of common signaling intermediates, or qualitative, involving signals distinct from other cosignaling systems or the TCR. Cosignaling receptors and ligands can be up- or downregulated at the transcriptional and protein levels depending on the stage of the T cell response and the inflammatory milieu. In the absence of cosignaling, T cells may become unresponsive (anergic) or die.

The TNF receptor superfamily is one of two major families of cosignaling regulators that modulate T cells. The other cosignaling systems belong to the immunoglobulin superfamily, such as CD28 *(91)*, CTLA-4 *(92)*, ICOS (93), PD1 (94), and BTLA (B-T lymphocyte attenuator) *(95,*96). TNF receptor superfamily members involved in cosignaling include Ox40, 41BB, DR3, CD27, CD30, and HVEM (97–99,*100,*101), whereas CD40 and BAFFR are more involved in cosignaling in B lymphocytes (102,103); however, considerable crossover of activities in both lymphocyte populations can be demonstrated. Death receptors such as Fas and TNFR1 are thought to be involved clonal contraction through apoptosis of activated effector cells, although TNF via TNFR2 also shows costimulatory action in naive T cells. In tissue culture models several of the TNF-related signaling pathways show costimulatory activities for T cells, which probably reflects the common induction

of NF-κB–dependent survival genes, a common trait of TN-FRSF members. However, analyses of physiologic models often reveal distinct roles for these molecules in the life of T cells. Cosignaling systems are emerging as important targets that enhance immune responses to tumors or attenuate autoimmune diseases (93,104,*105–107,*108).

Expression and Function of TNFRSF Cosignaling Molecules During Primary T Cell Responses

The TNFRs encoded on chromosome 1p36 share a common function as cosignaling systems for T cells (99,101). This region (human 1p36.33-1p36.21; syntenic with mouse 4E2-D3) contains the genes encoding GITR, Ox40, HVEM, DR3, 4-1BB, CD30, and TNFR2, representing an expansion of the region on chromosome12p13 where genes for TNFR1, LTβR, and CD27 reside. The TNF-related ligands for these receptors are linked in the MHC paralogs on chromosomes 1, 6, 9, and 19, reflecting a common functional link as costimulatory molecules modulating T cell differentiation (Figure 25.2).

Expression of TNFRSF members by T cells follows several distinct patterns during T cell activation: Expression on naive T cells in peripheral lymphoid tissues (e.g., CD27 and HVEM) that follow activation are upregulated or downregulated, respectively. Ox40, 4-1BB, TNFR2, and CD30 are only expressed by T cells after activation (99); TNFR2 is rapidly downmodulated after cleavage by TNFα-converting enzyme, generating soluble receptors that modulate TNF availability. The differing time course of expression of these molecules determines the phase at which they act in T cell differentiation.

Experimental activation of TNFRSF members can be achieved with agonist monoclonal antibodies. Antibodies specific for Ox40, 4-1BB, CD30, or CD27 all augment T cell clonal expansion and TCR-induced cytokine expression in tissue culture and mouse models. For example, CD27, which is expressed at very early stages of T cell activation, mediates initial cytokine production, cell division, and/or survival (*109,*110), whereas Ox40 and 4-1BB, which are expressed after cellular activation, promote T cell survival and proliferation during the later stages of the primary response (111,*112,*113). Although less is known regarding the exact timing and function of CD30 in T cell activation, CD30–CD30L interactions promote primary CD8$^+$ T cell expansion (114), suggesting functional parallels with other TNFRSF molecules. Coxpox virus encodes a specific CD30 mimic to block the action of CD30L as part of its immune evasion strategy (Table 25.3).

Death receptor-3 engages TL1A, promoting IFNγ expression by proinflammatory TH1 cells in mice (115) and humans (116), especially in intestinal tissues. The LIGHT-HVEM-LTβR pathway is also associated with T cell inflammatory processes in mucosal tissues (83,117). Similar

cosignaling activities are reported for the glucocorticoid-induced TNF-related receptor (GITR) (118), with the potential of these systems to affect different subsets of T cells, such as GITR expression on T regulatory subsets. The role of these TNFRSFs in regulating different subsets is an active area of research. Deletion of genes for these members did not affect developmental pathways; however, immune deficiency is often revealed in response to infections.

By contrast, HVEM appears to play a role as an inhibitor of naive T cell activation though engagement of the Ig superfamily member BTLA (119). In this situation, HVEM acts as a ligand for BTLA, which, through a phosphatase recruitment domain (immuno tyrosine–based inhibitory motif [ITIM]) in its cytosolic tail limits signaling by antigen receptor–associated kinases (120). The BTLA-binding site on HVEM is distinct from the position occupied by LIGHT, yet membrane LIGHT can disrupt HVEM–BTLA binding, which suggests that HVEM acts as a regulatory switch between inhibitory and stimulatory cosignaling. The HVEM-BTLA pathway likely functions in maintaining inhibitory control over naive T cells. This pathway appears particularly effective in controlling CD4 T cell activation (121), but it is also important in regulating differentiating memory CD8 T cells (122). Together with the programmed death-1 cosignaling system (PD1), BTLA is needed to curtail antigen-induced lung inflammation (123).

T Cell Memory

Cosignaling through several TNFRSF members promotes the differentiation of memory T cells. Mice deficient in Ox40-Ox40L, CD27-CD70, or CD30-CD30L pathways all display defective memory responses to antigen (110,114,124–126). The Ox40 system is illustrative of the costimulatory signals provided to T cells by these TNFRs. Pharmacologic stimulation of Ox40 with an agonist antibody or ligand during a primary antigen-specific response in mice enhances the generation of memory CD4 T cells (*127*,128). The enhanced response of T cells includes increased accumulation of antigen-specific effector T cells at the site of inflammation producing effector cytokines such as IFNγ *(129)*. Moreover, blockade of Ox40-Ox40L interactions with monoclonal antibody specific to Ox40L during recall responses in models of collagen-induced arthritis (130) and experimental allergic lung inflammation (131) ameliorates inflammation. In Ox40-deficient mice, CD8 T cells expand normally; however, their accumulation and survival at later times in the primary response were significantly impaired, but the T cells also failed to fully differentiate as measured by loss of expression of effector cell surface markers, the synthesis of cytokines, and cytotoxic activity. In contrast, the formation of extrafollicular plasma cells, germinal centers, and antibody responses was independent of Ox40. Ox40 signaling induces tran-

scription of survival genes such as Bcl2 and survivin in T cells, which may serve as the key targets that allow memory cell differentiation (*132*,133).

The discovery that HVEM can elicit inhibitory signaling in T cells through engagement of the Ig family member BTLA highlights the possibility that in certain situations TNFRSF molecules can counterregulate the stimulatory actions during T cell responses. Indeed, 4-1BB–deficient CD4+ T cells in some models are hyperresponsive (134), and stimulation of 4-1BB can suppress immune responses in several models of autoimmune disease (*135–137*,138). Although activation of 4-1BB enhances the expansion of human antiviral memory CD8+ T cells *in vitro* (139), several studies demonstrate that the absence of 4-1BB in mice leads to enhanced T cell responses (134,140), reminiscent of the phenotype associated with HVEM-deficient mice (141,142). Moreover, CD30 signals can, in some circumstances, suppress cytotoxic T lymphocyte activity (143). That TNFRSF molecules such as GITR or Ox40 are expressed on T regulatory cells suggests that costimulatory pathways may enhance the suppressive function of these cells during immune responses.

Mouse models of autoimmune diseases such as experimentally induced encephalomyelitis (EAE) and diabetes uncover critical roles for Ox40-Ox40L (*144*,145). Blockade of the CD27-CD70 pathway also ameliorates EAE through the suppression of TNF induction but not T cell priming (146). Furthermore, blockade of Ox40, 4-1BB, CD27, or CD30 costimulation can reduce transplant rejection and/or graft-versus-host disease (*147*,148,*149*,150).

Stimulation of these pathways may also be applicable for the treatment of diseases in which antigen-specific T cell responses are ineffective such as in cancer and infectious diseases. Stimulation of Ox40, 4-1BB, CD30, and CD27 with agonist antibodies augments T cell–mediated killing of a variety of tumors (reviewed in refs. 99,151). The critical roles of the cosignaling TNF-TNFRSF members are distinguished in immune responses to infectious pathogens. Similar to the immediate TNF family, the role of a specific cosignaling pathway in mediating protective T cell responses during infection depends on the pathogen (Table 25.7).

CD40L and the BAFF Systems

The CD40 and BAFF systems plays a major role in coordinating a range of costimulatory signals, including those important to B cell function, such as affinity maturation, isotype switching, immunoglobulin production, and clonal expansion (102,*152*,153–155). As are other TNF superfamily members, the CD40 system (Figure 25.3) is a key communication mechanism in host defense, autoimmunity, and cancer. Often these pathogenic processes are centered on the function of B cells. CD40 ligand maps to the X chromosome. Inducible CD40 ligand expression by

T helper cells promotes humoral immunity and is regulated by transcription factors NFAT, TFE3, and TFEB. CD40 ligand is also expressed on a variety of other cells, including activated B cells, endothelial cells, basophils, mast cells, and platelets. CD40 is expressed in many cells, prominently on B cells, using both TRAF3 and 6 to activate NF-κB and AP1 transcription factors, among other signaling pathways (156). Epstein-Barr virus, a B cell–transforming herpesvirus, mimics the CD40 pathway though its LMP1 protein, driving naive B cells into a memory state (*157*,158,*159*).

CD40 signaling is necessary for induction of activation-induced cytidine deaminase (AID), a key enzyme in class switching and somatic mutation of Ig genes. This process occurs in B cells in contact with T helper cells, which express CD40 ligand. The importance of the CD40 system in the activity of B cells was revealed in patients with hyper-IgM syndrome (HIGM). Several mutated genes underlie this syndrome, including CD40 ligand and CD40 (*160,161*), the RelA NF-κB activating kinase subunit IKKγ (NEMO), and AID, among others (162). HIGM patients with mutated CD40L have elevated levels of IgM, often with no serum IgG, IgE, or IgA, and display increased susceptibility to bacterial and opportunistic infections. However, treatment of these patients with passive transfer of human immune IgG corrects infection by bacteria but not opportunistic pathogens such as *Pneumocystis carinii*. This latter result reflects the importance of CD40 system in T cell macrophage activation, which controls these opportunistic pathogens. In addition, the CD40 system can supplant T helper cell signals that allow DC and CD8 T cells to generate effector cells in the absence of CD4 T cells (*163*,164). In some patients, significant amounts of IgA and IgE are present in serum, even in the complete absence of CD40 ligand, a result indicating that another mechanism(s) can induce Ig class switching. Evidence has emerged for the BAFF/APRIL system in inducing Ig class switch independent of the CD40 system (165).

Since the discovery of B cell–activating factor of the TNF superfamily (BAFF, TNFSF13B, BLyS) and a proliferation-inducing ligand (APRIL, TNFSF13), much has been elucidated with regard to CD40 ligand-independent isotype switching and B cell development and survival in the periphery, as well as implications of BAFF-APRIL dysregulation in autoimmune disease and lymphomas (103,166). Although human BAFF maps to chromosome 13q34 and APRIL to 17p13.1, the proteins are strikingly more conserved (approximately 50% homology) than other TNF ligands. TWEAK (TNF-related ligand with weak apoptosis activity) maps adjacent to APRIL, part of a clade of genetically similar members that also includes ectodermal dysplasin (EDA1/EDA2). BAFF and APRIL form homo- and heterotrimers that interact with multiple receptors to form a complex signaling circuit (Figure 25.3). Membrane BAFF is shed via a furin protease at the cell surface, whereas APRIL is processed in the Golgi and secreted only in soluble form (167), although the receptor-binding domain of APRIL can be membrane anchored via an unusual splice variant with the TWEAK cytosolic and transmembrane domain (TWE-PRIL) (168). The significance of membrane-restricted local BAFF expression to systemic availability of soluble BAFF and APRIL remains to be established, although BAFF-APRIL heterotrimers are detected in serum from patients with systemic rheumatic diseases (7). BAFF and APRIL are inducibly expressed in monocytes, macrophages, dendritic cells, and T cells in the spleen and lymph nodes in response to certain cytokines such as type I and II IFN and IL-10; other TNF family members like CD40 and LTβR signaling also induce BAFF and APRIL. BAFF can be expressed in some B cell–derived chronic lymphocytic leukemia cells, and some epithelial-derived cancer cell lines and primary tumor tissues express APRIL. Stromal cell expression of BAFF maintains the major mature B cell pool, whereas inducible BAFF expression in myeloid cells aids in local B cell survival at sites of inflammation.

Three cognate receptors mediate the biological actions of BAFF. BAFFR (TNFRSF13C), TACI (transmembrane activator and calcium signal modulating cyclophilin ligand interactor, TNFRSF13B), and BCMA (B cell maturation antigen, TNFRSF17) are expressed on B cells and on other cell types. APRIL also engages matrix proteoglycans with weak binding, which may serve to enhance access to TACI and BCMA, or function as a distinct receptor–ligand interaction *(169)*. Signaling through BAFFR and BCMA are required for B cell survival and differentiation at different stages of B cell–mediated humoral response. BAFFR$^{-/-}$ mice display an almost complete loss of mature and marginal zone B cells acting at the late transitional phase of B cell maturation, whereas BCMA deficiency impaired the survival of long-lived bone marrow plasma cells (170,171).

By contrast, APRIL$^{-/-}$ mice develop normally but have altered class switching to IgA (172,*173*). TACI signaling may antagonize BAFFR and BCMA, because TACI$^{-/-}$ mice have elevated numbers of mature B cells (174). Both classical and alternative NF-κB pathways have been implicated in BAFFR and BCMA survival signals, with Bcl2 rescuing the B cell defect in BAFFR$^{-/-}$ mice. BAFFR and TACI engagement has also been shown to provide the necessary signals for CD40L-independent class switch recombination to IgG and IgE for BAFFR and IgG, IgE, and IgA for TACI in knockout mice, although IgA production seems specifically dependent on APRIL–TACI interaction (175). BAFFR is also connected to promoting the B cell coreceptor complex CD19/CD21/CD81, which binds to C3b-opsonized antigens to enhance rapid T-independent antibody response; however, overall impairment of T-independent antibody response appears to be greatest in TACI$^{-/-}$ mice and depends on APRIL–TACI interactions in B1 B cells. BAFFR, and not TACI, has also been proven to be important in T cell costimulation in *in vitro* and *in vivo* mouse models of allograft rejection response, where BAFFR$^{-/-}$ and BAFF$^{-/-}$ but not TACI$^{-/-}$ or BCMA$^{-/-}$ mouse recipients prolong graft survival due to weakened alloproliferative response (176).

Elevated levels of BAFF and APRIL have been detected in the serum, and especially the synovial fluid, of patients suffering from inflammatory autoimmune disorders such as systemic lupus erythematosus, rheumatoid arthritis, Sjörgen's syndrome, and multiple sclerosis (177). These levels tend to correlate with increasing amounts of autoreactive antibodies in serum, but soluble TACI-Ig treatment can lessen the severity of disease symptoms and progression in mouse models of lupus and collagen-induced arthritis (178). It is hypothesized that these excess quantities of BAFF and APRIL may contribute to the formation of autoreactive B lymphocytes and loss of tolerance during development and perpetuate their survival as plasmablasts. Emerging evidence connects the BAFF and APRIL systems to the pathology of B cell–derived cancers

like B cell chronic lymphocytic leukemia, non-Hodgkin's lymphoma, and multiple myeloma. Malignant myeloma cells express high levels of BAFF and APRIL and receive ligand-induced survival signals, with upregulation of antiapoptotic Bcl-2 and Mcl-1 molecules (179). Therefore, BAFF and APRIL may bolster tumor survival via autocrine and paracrine signaling mechanisms.

TWEAK binds Fn14, a fibroblast growth factor (FGF)-2–inducible gene, limited to a monogamous interaction compared to its siblings (Figure 25.3). Fn14, a type I transmembrane protein with one CRD, binds TWEAK homotrimers in a manner similar to BAFF, APRIL, and their receptors (180,181). The biological functions of TWEAK-Fn14 system are broad, and perhaps paradoxical, promoting survival or inducing death; they are proinflammatory or immunorepressive. Due to these seemingly disparate observations, there is speculation that another, uncharacterized TWEAK receptor is involved, or that TWEAK acts in conjunction with other cosignaling systems that elicit different effects specific to its immunologic environment or context. TWEAK, like BAFF and APRIL, may be cleaved at its furin site to produce an active soluble form (180). Human and mouse TWEAK share 90% or greater sequence identity in the receptor-binding domain and manifest high-affinity cross-species interaction to respective Fn14 homologs (167). TWEAK has relatively wide organ mRNA expression, including heart, brain, spleen, lymph nodes, and human fibroblasts, although in some cells protein levels do not correlate with mRNA expression; it has also been detected in established cancer cell lines and primary tissue samples. TWEAK/Fn14 signaling induces apoptosis in some cancer lines (HT29, HSC3) and primary neurons (182,183,*184*). Other potential described capacities and proposed biological roles include induction of survival and growth in endothelial cells, migration and wound closure in endothelial monolayers, enhancement of proinflammatory cytokines (IL-6, IL-8), and angiogenesis (180,181). Very recent data connect TWEAK to regulation of the shift from innate to adaptive immune responsiveness by repressing innate inflammatory cytokines (IL-12, IFNγ) important in promoting TH1 immunity—a potential counterbalance to the proinflammatory actions of TNF (182). TWEAK may also have a potentiating influence in chronic tissue inflammation when dysregulated, such as its role in excessive demyelination and ultimate progression to excessive autoimmune encephalomyelitis *(185)*. In a mouse collagen-induced arthritis model, elevated levels of TWEAK in serum correspond to severe disease progression and enhanced arthritogenic mediator molecules (186). In obese patients with type 2 diabetes, TWEAK-Fn14 signaling augments proinflammatory cytokine release by adipocytes (187). TWEAK may prevent excessive luteinization after gonadotrophin-induced ovulation by controlling progesterone production in rats (188). This evidence suggests that the TWEAK-Fn14 system may provide

important homeostatic functions to counteract inflammation in various tissues.

DEATH RECEPTORS AND LIGANDS

Fas Ligand and Fas System

The Fas (CD95, TNFRSF6)-Fas ligand (FasL, TNFSF6) system is an example of a direct signaling pathway to apoptotic cell death. The importance of the Fas-FasL system in immune regulation was revealed by the recognition that mice and humans with the autoimmune-like disorders lymphoproliferative (*lpr*) and generalized lymphoproliferative disorder (*gld*) harbored mutations in Fas and Fas ligand (*189*,*190*,191). Mice with the *lpr* or *gld* mutation display autoimmune phenotypes with high accumulation of activated T cells in the periphery and CD4⁻CD8⁻ T cells in the lymph nodes (lymphoadenopathy) and autoantibody production. The Fas-FasL system is involved in proinflammatory responses, tumor survival, and non–immune tissue homeostasis in osteoclastogenesis and angiogenesis (192). Activated lymphocytes are particularly sensitive to Fas-induced apoptosis, suggesting a role for Fas in the clonal contraction phase of the immune response. The finding that epithelial cells in the eye express FasL, suggest FasL may limit inflammation in organs sensitive to immune damage. FasL is believed to be one of several proapoptotic systems used as a killing mechanism by cytotoxic T cells and NK cells. Fas ligand binds Fas and, in primates, decoy receptor3 (DcR3), which also binds LIGHT and TL1A (193).

FasL can undergo cleavage by matrix metalloproteases to produce soluble FasL, which may induce markedly different events when it engages Fas compared to the membrane-bound form, such as loss in cytotoxicity (194). Other findings suggest that soluble FasL may counteract the proinflammatory properties of membrane-associated FasL as an immunosuppressive, particularly in the eye and tumor environments (195,196). Conversely, Fas has also been linked to lymphoproliferation and activation via NF-κB signaling pathways.

Essential biological roles of FasL-Fas include regulating lymphocyte homeostasis (via contraction of clonally expanded effector T and NK cells), directing cytotoxic T lymphocyte (CTL)–mediated apoptosis and lysis (immune surveillance), and establishing immune-privileged organs and sites. Fas is expressed in a wide variety of tissues such as the thymus, spleen, heart, and liver, whereas FasL can be found on activated T cells, NK cells tumor cells, immune-privileged sites, lung, and other tissues (192,197,198). In mature activated T and NK cells, Fas-FasL signaling plays a critical role in the induction of apoptosis during the latter stages of inflammation or activation-induced cell death and in shifting lymphocyte population numbers back to baseline (199). In certain organs like the liver, lung, and small intestines, FasL on stromal cells can be upregulated to control the overabundance of activated T cells after an inflammatory response and ultimately reduce tissue damage. Alternatively, dysregulation during hepatitis C infections can lead to death of hepatocytes and acute liver damage (200). The Fas system has also been implicated in curtailing autoantibody production by damping T cell helper–induced B cell activation and direct elimination of activated B cells, in which CD40 stimulation also upregulates Fas expression (192).

The Fas-FasL system, together with preforin and granzymes, is vital to CTL-mediated destruction and clearance of tumor and virally infected cells. Viruses have evolved multiple mechanisms of suppressing Fas signaling (90), including downmodulation of Fas (201) and blockade of caspase 8 activation (202). Tumor genome instability may lead to mutations that aid in escaping or resisting death pathways conducive to developing the metastatic phenotype (203). Uterine and breast cancer patients may have elevated levels of soluble FasL and Fas, which may aid in neutralizing CTL- and NK cell–induced lysis, or even killing Fas-expressing effector cells. HSV-1 infection *in vitro* of human neonatal neutrophils—critical effectors in innate and humoral immunity—upregulates Fas and FasL surface expression, leading to apoptosis, exemplifying a theme of pathogenic modulation of apoptotic signaling events to evade or attenuate immune responses (204). FasL is constitutively expressed in the eye, central nervous system (CNS), testis, fetal trophoblast, and placenta, where any lymphocyte infiltration could lead to unrestricted, irreversible bystander damage to these tissues (205). The implications of immune privilege have been applied to tissue transplantation rejection therapies; however, conflicting results on whether FasL expression reduces the likelihood of allograft rejection (*206*,207) or potentates effector responses (208,*209*) emphasize that induction of immune privilege by the Fas-FasL system is not that simple and is rather more complex. Fas-FasL interactions are at the core of graft-versus-host disease (GVHD), where contaminating donor effector T cells in an allograft expand to damage the recipient's tissues. In a mouse model for acute GVHD, p53-dependent upregulation of Fas on host stem cells leads to subsequent bone marrow depletion through FasL-mediated apoptosis (210). With regard to tissue homeostasis, FasL has been reported to enhance RANKL-mediated osteoclastogenesis and differentiation in mouse bone marrow–derived macrophages (211). Fas is also implicated in pulmonary inflammatory diseases resulting in fibrosis after acute lung injury (197).

TRAIL AND TRAIL-RECEPTOR SYSTEM

TRAIL (TNF-related apoptosis-inducing ligand, TNFSF10) is closely related based on sequence homology to FasL and TNF. Interest in TRAIL was spurred by its ability to selectively induce apoptosis in tumor cells (212).

TRAIL binds five different receptors: TRAILR1 (DR4, TNFRSF10A), TRAILR2 (DR5, TNFRSF10B), TRAILR3 (DcR1, TNFRSF10C), TRAILR4 (DcR2, TNFRSF10D), and osteoprotegerin (OPG, OCIF, TNFRSF11B) (Figure 25.3). TRAILR1, 2, and 4 are type I transmembrane proteins; all are membrane associated, with the exception of the more distantly related OPG, a dimeric, soluble decoy receptor, and the type III transmembrane protein TRAILR3 (213). TRAILR1 and 2 contain highly homologous DDs in their cytoplasmic tails that form the death-inducing signaling complex (214,215) responsible for apoptosis. TRAILR3 is anchored to the membrane via a glycophosphatidyl inositol tail, whereas TRAILR4 has a truncated, nonfunctional DD (193,216,*217*). How TRAILR3 and 4 antagonize TRAIL-induced apoptosis may not fully be explained by the "receptor decoy" paradigm of ligand competition. Nevertheless this does not preclude a "competition"-based mechanism for TRAILR3, especially if there is differential surface expression of death versus decoy receptors. Alternative splicing is a common feature among TRAIL and its receptors and is believed to regulate programmed cell death *(218)*. Two variants of human TRAIL, TRAILβ and TRAILγ, exhibit total loss of their proapoptotic potential due to incomplete receptor-binding domains. TRAILR2 has two forms, DR5A (short) and DR5B (long) *(219)*, and the TRAILR4-β variant lacks the first complete CRD1 of the ligand-binding site (220). The genetic organization of the TRAIL receptor loci in the mouse differs from that in humans. The mouse genome has TRAILR2, 3, and 4 homologs, but the TRAILR4 homolog does not bind TRAIL.

A major function of TRAIL-TRAILR signaling system is to induce apoptosis and to a lesser degree NF-κB activation. For example, the apoptotic function of TRAIL system is necessary for regulating the response of memory CD8$^+$ T cells to rechallenge with antigen. In the absence of CD4 T cell help, CD8 T cells undergo apoptosis mediated by TRAIL (221,222). In much the same way as Fas, TRAILR death domains are thought to recruit FADD and initiator caspases 8 and/or 10 into the DISC to activate downstream effector caspases in apoptosis. Caspase 8 contribution to this process is well defined, but caspase 10 involvement was less so until recent studies in autoimmune lymphoproliferative syndrome II patients and some carcinoma cell lines found that mutant caspase 10 ablates TRAIL-induced apoptosis (216). In some cell types, the extrinsic mitochondrial pathway is important in amplifying DISC signals in TRAIL-induced apoptosis, which is analogous to certain mechanisms for Fas-FasL signaling *(223)*. TRAIL is being intensely pursued as an anticancer therapeutic, and it has been found to be particularly potent in combination with chemotherapy because TRAILR2 expression can be increased in response to DNA damage (224).

TRAIL seems most involved in regulating immune homeostasis and immune surveillance and in clearing virally infected and cancerous cells. IFNγ treatment of tumor cells increases sensitization to TRAIL-induced death.

This has been observed in melanoma and ovarian carcinoma cells (216) and is analogous to Fas-FasL apoptotic signaling in human colorectal carcinoma line HT-29. IFNα possesses powerful antiviral and antitumor properties as well and has been shown to upregulate TRAIL via JAK-STAT pathways in stimulated human multiple myeloma *in vitro*. TRAIL is also upregulated on NK cells in response to IFNγ, enhancing antitumor effector function (225).

TL1A-DR3 SYSTEM

TL1A (VEGI, TNFSF15) is a paralog of FasL, LIGHT, and LTβ, and its receptor, DR3, is a homolog of TNFR1 (APO3, TNFRSF25). TL1A also binds decoy receptor-3DcR3, potentially limiting any TL1A signaling mediated by DR3. Genetic deletion of TL1A or DR3 in mice revealed poor T cell responses to cosignaling but no overt developmental abnormalities (115,226,*227,228*). Specific mutations in the ligand-binding domain of DR3 are linked to rheumatoid arthritis, and, of interest, appear to be paralleled in other TNFRSF members and associated autoimmune pathologies (229).

ORPHAN RECEPTORS

The orphan death receptor-6 (DR6) has no known ligand related to the TNF superfamily. However, emerging evidence suggests that DR6 has a role in immune function. In a mouse EAE model, DR6 deficiency was shown to protect against CNS demyelination and leukocyte infiltration but also enhance overall CD4$^+$ T cell proliferation and Th2 differentiation, underscoring a role for DR6 in mediating Th1-specific immune responses in EAE progression (230).

Taj/TROY and RELT also do not bind any of the known TNF ligands; however, recent evidence indicates that Taj/TROY functions more like p75NTR, capable of binding myelin inhibitory factors (29,30). The role of Taj/TROY and RELT in immune function is unclear.

RANK LIGAND, RANK, AND OPG SYSTEM

Osteoprotegerin (OPG, TNFRSF11B) was initially identified as a key factor in the mechanism regulating bone density (231) (Figure 25.3). As a soluble receptor, OPG is a regulator of the RANK (receptor activator of NF-κB, TNFRSF11A) and RANK ligand (also known as TRANCE) signaling pathway involved in the differentiation of bone-resorptive osteoclasts from hematopoietic progenitors (osteoclastogenesis) (232–234). However, this system is also crucial for development of mammary glands *(235)*, lymph nodes, and DC–T cell interactions (*236*,237). Bone remodeling needed to sustain skeletal integrity and calcium homeostasis is regulated by a dynamic equilibrium

between osteoblasts (bone forming) and osteoclasts (bone resorbing), which is regulated by the RANKL-RANK-OPG system. Dysregulation of the RANKL-RANK-OPG system has consequences in inflammatory, osteologic, and cancer pathophysiology, such as bone loss in inflammatory autoimmune diseases, preferential breast and prostate tumor metastasis to the bone, and gender bias in osteoporosis.

OPG functions as a decoy receptor that binds RANKL with high affinity, and it also binds TRAIL, albeit at low affinity in comparison to RANKL (238,239). Despite such a weak binding, *in vitro* studies show that OPG can block TRAIL-mediated apoptosis, which suggests that the OPG-TRAIL system contributes to osteoclastogenesis. RANK interacts with TRAF2, 5, and 6. The membrane-proximal TRAF site is highly specific for TRAF6, and several studies have shown TRAF6 to be essential in RANKL-RANK signaling in osteoclastogenesis and lymph node genesis (240,241). Several "osteotropic" factors have been reported to regulate RANKL and OPG expression in osteoblast and osteoclast lineages, such as TGFβ, IL-1, TNF, estrogen, prostaglandin E_2, glucocorticoids, and vitamin D_3 (240,242). In a few cases, OPG and RANKL are differentially modulated by the same factor; parathyroid-related protein increases RANKL while decreasing OPG mRNA expression in osteoclast-like odontoclasts (243). The components in the RANK signaling triad are widely expressed. RANK is upregulated on CD40L-stimulated maturing DCs, whereas RANKL is upregulated during T cell activation and is constitutively expressed in some tumors and mammary gland epithelial cells.

TRAF6$^{-/-}$ and RANK$^{-/-}$ mice lack NF-κB activation in osteoclasts in response to RANKL and exhibit abnormally high bone density (osteopetrosis) (244,245). Osteoblasts and stromal cells stimulate differentiation via direct cell contact with osteoclast precursors. Macrophage colony stimulating factor (M-CSF) cooperates with RANKL-expressing osteoblasts to transmit positive signals through c-Fms and RANK expressed on precursors, promoting their differentiation (234), whereas OPG is a negative regulator by competitively binding RANKL, thus ablating all signals through RANK. RANK$^{-/-}$ and RANKL$^{-/-}$ mice phenocopy each other, displaying severe osteopetrosis due to absolute lack of osteoclasts (246). Complementing the observations in RANKL and RANK deficiencies is the finding that OPG blocks osteoclast differentiation in a dose-dependent manner. OPG overexpression in transgenic mice causes acute osteopetrosis, and OPG-deficient mice suffer from osteoporosis due to excessive osteoclastogenesis. In humans OPG and RANK mutations are linked to juvenile Paget's disease, familial expansile osteolysis, and other osteolytic disorders (233,240).

The RANKL-RANK system is proving to be an important enhancer of cell-mediated immune responses by promoting DC survival and naive T cell proliferation. RANKL stimulates DCs to produce proinflammatory cytokines such as IL-12 (247,*248*). The RANK pathway may serve to bolster CD40-CD40L interaction between DCs and T cells after TCR stimulation or prolong survival of activated DCs to ensure the establishment of T cell memory. For instance, in CD40L$^{-/-}$ mice, RANKL-RANK costimulation is protective against *Leishmania* infection by inducing IL-12 secretion and consequent Th1 immune response (249).

Bone loss in autoimmune and infectious models of inflammatory disease is mediated through slightly different mechanisms. In recent studies, activated, CD4$^+$RANKL$^+$ T cells have been shown to support osteoclastogenesis and mediate bone loss in humanized mouse models of *Actinobacillus*-specific periodontal disease, suggesting a role for Th1 immunity in inflammatory bone destruction (250,251). In HIV-positive patients, the virion envelope protein gp120 induces disease-related osteoporosis via induction of RANKL on CD4$^+$ T cells and augmentation of osteoclastogenesis (252).

In mouse models of tumor metastasis, high OPG and RANK levels are risk factors for metastasis to the bone and subsequent osteolysis, especially in breast tumors (253). OPG from human bone marrow stroma can protect prostate tumors from TRAIL-mediated apoptosis (254), and treatment with anti-TRAIL neutralizing antibodies reduces osteoclastogenesis in mixed lymphocyte–bone marrow cultures from patients with multiple myeloma, presumably by interfering with OPG-TRAIL complexes formed by activated T cells expressing TRAIL, OPG, and RANKL (255). The RANKL-RANK-OPG system has also been implicated in diabetes-associated osteopenia because serum levels of OPG are higher in patients with types 1 and 2 diabetes (256). Of interest, these patients are at greater risk for developing atherosclerotic plaques, perhaps reflected in the OPG-deficient mice, which suffer from arterial calcification (257), presumably from unrestricted bone resorption and Ca^{2+} release. Although elevated endogenous OPG levels are considered a risk factor in certain disease manifestations, the complexity of the cytokine networks that regulate RANKL-RANK-OPG interactions and vice versa render the clinical relevance difficult to interpret. Use of human anti-RANKL monoclonal antibody (denosumab) to disrupt RANKL-RANK signaling is being considered to reduce bone resorption in postmenopausal osteoporotic women and patients with multiple myeloma and osseous metastatic breast tumors (258).

TNF AND TNF INHIBITION IN THE THERAPY OF HUMAN DISEASE

TNF Inhibitors

The TNF superfamily is associated with a wide range of human diseases, as evidenced by genetic deficiencies or mutations in individual components of the TNF

▶ **TABLE 25.8** **Human Genetic Diseases Associated with the Tumor Necrosis Factor (TNF) Superfamily**

System	Disease	Mutation
TNFR1	Familial periodic fever	Mutation in first cysteine-rich domain
CD40 Ligand	Hyper–immunoglobulin syndrome	Multiple mutations affecting receptor binding and processing
EDA	X-linked hypohidrotic ectodermal dysplasia	Multiple mutations affecting receptor binding, trimerization, and secretion
RANK	Familial expansile osteolysis	Mutation in the signal peptide
Fas	Autoimmune lymphoproliferative syndrome	Multiple mutations/deletion in Fas

superfamily and in the therapeutic efficacy of TNF inhibitors in autoimmune diseases (Table 25.8). Although cancer therapy was the original motivation in developing TNF, the success of TNF inhibitors in autoimmune diseases such as rheumatoid arthritis, ankylosing spondilitis, psoriasis, and Crohn's disease provides significant motivation to explore therapeutics targeting other members of the TNF superfamily, and this is an active area of research.

In general, TNF inhibitors are designed along the properties of specific antibodies or soluble receptors (Figure 25.8). Both antibody- and receptor-based reagents block the capacity of the ligand to bind receptor, functioning as competitive antagonists. A partially humanized mouse monoclonal antibody to human TNF (infliximab) and fully human anti-TNF (adalimumab) are approved for use in humans. The ectodomain of the TNF receptor-2 genetically linked to the Fc region of human IgG1 (etanercept) was used to create a bivalent molecule that has higher avidity for TNF than naturally occurring soluble receptors. Soluble decoy receptors retain their ability to bind their native ligands, which in the case of TNFR2-Fc are TNF and LTα, whereas anti-TNF antibodies are specific for TNF and do not cross-react with LTα.

Bivalent antibodies directed to TNF receptors can function as agonists and mimic the ligand, but they are specific for a single receptor, a feature that may distinguish an antibody from a ligand, such as TRAIL, which has multiple receptors. Moreover, antibodies are inherently more stable than the native ligand and provide better pharmacodynamics (serum half-life and bioavailability). Agonist receptor antibodies (e.g., anti-TRAILR, anti-Ox40) are in preclinical studies and clinical trials. Although these drugs are classified as biologics (protein-based drugs) and are inherently safe, side effects like lymphoma and increased infections accompany TNF inhibition, as perhaps should be expected based on understanding the roles TNF plays in innate and adaptive immune responses.

Effect of TNF Blockade in Inflammatory Diseases

TNF inhibitors are approved for use in the treatment of rheumatoid arthritis (RA), psoriatic arthritis, ankylosing spondylitis, juvenile rheumatoid arthritis, Crohn's disease, and ulcerative colitis. Rheumatoid arthritis is a chronic autoimmune joint disease that occurs in genetically predisposed individuals. Treatment of RA is usually initiated with disease-modifying antirheumatic drugs (DMARDs), such as methotrexate or corticosteroids, to improve
Inhibitor	Ligand	Disease
TNFR2-Fc (etanercept)	TNF, LTα	RA, psoriasis
IgG1κ (infliximab) (adalimumab)	TNF	RA, IBD

FIGURE 25.8 Tumor necrosis factor (TNF) inhibitors. The main structural features of TNF decoy receptor (etanercept) created as a genetic fusion protein of the ectodomain of TNFR2 with the Fc region of human immunoglobulin (Ig) G1, which forms a disulfide-linked dimer. Monoclonal antibody (mAb) specific for human TNF derived from mice and partially humanized (infliximab) or a fully human antibody (adalimumab) contain both H and L immunoglobulin chains. Both types of inhibitors are approved for use in treating autoimmune diseases: rheumatoid arthritis (RA), psoriasis, and inflammatory bowel diseases (IBD).

symptoms and reduce joint damage. The American College of Rheumatology uses clinical and laboratory measures to assess improvement in response to therapy in RA. A patient with a 70% or greater improvement according to these parameters is designated as having an ACR-70 response. TNF inhibitors in combination with methotrexate (the most widely used DMARD) produce ACR-70 responses in 33% to 40% of patients with early RA and in 10% to 27% percent of patients with established RA. In comparison to patients receiving methotrexate alone, the ACR-70 responses occurred in 19% to 21% of early RA patients and fewer than 5% of patients with established disease (259). In RA, joint damage begins early in the disease course as articular erosions when visualized by radiographic techniques in 40% of patients in the first year of disease and in 90% by the second year (260). TNF inhibitors slow radiographic progression in RA (261). Of interest, in a randomized, controlled trial of 428 patients with active RA, the combination of infliximab and methotrexate reduced the radiographic progression in patients that achieved ACR-20 responses as well as in those who did not meet these clinical criteria (262).

Inflammatory bowel disease, ulcerative colitis (limited to colon and bowel), and Crohn's disease (entire intestine) are chronic inflammatory conditions in which TNF is disproportionately expressed when the disease is active. Lamina propria mononuclear cells from patients with inflammatory bowel disease produce significantly higher levels of TNF after stimulation by lipopolysaccharide (263). The formation of fistulating inflammatory granulomas is a pathologic feature of Crohn's disease. Clinical trials demonstrated an initial response in 59% to 69% of patients and a dose-dependent clinical remission that ranged between 28% and 38% in nonfistulating Crohn's disease and between 64% and 97% of patients with complete fistula disease when categorized by location (264,265). In ulcerative colitis (UC), controlled trials (800 patients with active UC) showed an initial response at week 8 in 65% in patients treated with anti-TNF (infliximab) versus 35% in the placebo group, with remission achieved in 35% and 15% in infliximab- and placebo-treated patients, respectively (266). Anti-TNF of human origin (adalimumab) was efficacious in controlled trials in patients with moderate to severe Crohn's disease (264). By contrast, soluble TNFR2-Fc (etanercept) at doses known to be effective in rheumatoid arthritis failed to produce benefit in a controlled trial for Crohn's disease (267).

Erythrosquamous lesions containing infiltrating leukocytes and epidermal hypertrophy characterize psoriasis, a chronic inflammatory skin disease. Skin lesions of psoriatic patients contain elevated levels of TNF, and after treatment with TNF inhibitors, serum and skin levels of TNF decrease with clinical response (268,269). A significant subset of patients with psoriasis develops inflammatory, erosive arthritis (270). In clinical trials, both etaner-

cept and infliximab significantly inhibited disease activity and improved the quality of life in patients with psoriatic arthritis (271–273,*274,275*).

Serious Adverse Effects

Side effects with the use of TNF inhibitors include lupus-like syndromes, aplastic anemia, hepatotoxicity, interstitial lung disease, optic neuritis, and exacerbations of quiescent multiple sclerosis. The rate of serious skin and soft tissue infections is also higher in treated patients, and there is also an increased risk of bacterial intracellular infections, primary tuberculosis and reactivation of latent *Mycobacterium tuberculosis* among patients treated with TNF inhibitors (276,277). Risk due to infection can be minimized and controlled (e.g., a tuberculosis skin test prior to treatment for patients that have not been previously vaccinated for *Mycobacterium*).

The contribution of anti-TNF therapy to increased risk of cancer is unclear. A systematic review of randomized clinical trials using infliximab and adalimumab found a dose-related increase of malignancies in RA patients (278). Some of the increased risk of malignancy (i.e., lymphoma) is difficult to dissect due to the increased association with RA (277).

TNF has been implicated in the pathogenesis of cardiac dysfunction, in part due to its negative ionotropic activities *in vitro* and *in vivo*; however, TNF blockade significantly increased the incidence of cardiac death. This observation led to the recommendation that TNF inhibitors be discontinued in patients with cardiac dysfunction (279,*280,281*).

Anti-CD40L

The interaction between CD40 and CD40L is involved in the pathogenesis of inflammatory diseases (102), and interference with this pathway induces amelioration of autoimmune disease and allograft rejection in animal models (282,283,*284–286*). Humanized anti-CD40L was tested in clinical trials of transplantation and autoimmunity including idiopathic thrombocytopenic purpura, psoriasis, Crohn's disease, and multiple sclerosis (287–289). However, controlled clinical trials using anti-CD40L for the treatment of proliferative lupus nephritis was halted because of thromboembolic events. A partial evaluation of the trial demonstrated decreased anti-dsDNA antibodies, increased serum complement levels, and reduced hematuria in some of the treated patients, consistent with the expected immunologic outcome (288). A phase II, double-blinded, placebo-controlled clinical trial in patients with mild to moderately active systemic lupus erythematosus using another anti-CD40L antibody was found to be safe but did not demonstrate efficacy when compared to placebo (287).

TNF in Cancer Chemotherapy

Tumor angiogenesis—the formation of vessels to support cancer growth—is a process essential for tumor growth. The ability of TNF to induce apoptosis of tumor-associated endothelial cells can result in the impairment of the tumor vasculature, leading to necrosis of the tumor. This mechanism involves perturbation of cell–cell adhesive junctions and inhibition of $\alpha v \beta 3$ integrin signaling in tumor-associated vessels (290). However, clinical phase I and II studies in cancer patients receiving recombinant TNF reported "septic shock–like syndrome," a dose-limiting toxicity, in quantities 10 times lower than the calculated antitumor dose extrapolated from animal studies (291,292). Animal studies also revealed the strong hemodynamic effects of TNF in the mediation of septic shock (293). Although anecdotal, reports of tumor regression after TNF administration *(294)* due to the induction of vasoplegia. TNF's use as an antitumor agent has been limited to treatment of locally advanced tumors by isolated limb perfusion, which limits systemic toxicity of TNF (295).

Preclinical and early clinical trials are in progress for many other members of the TNF superfamily. For example, antibodies to BAFF and LTβR-Fc decoy are in clinical trials for suppressing inflammation in autoimmune diseases and agonist antibodies to TRAILR for induction of cancer cell apoptosis. Modulation of immunity through the cosignaling members of the TNFR family such as Ox40, 41BB, LIGHT, and others is being considered for targeting to modify malignant diseases (108,151). Well-controlled studies are anticipated to help evaluate the efficacy of targeting these members of the TNF superfamily.

Chemokines

Philip M. Murphy

INTRODUCTION

Chemokines (or <u>chemo</u>tactic cyto<u>kines</u>) are members of a family of extracellular immunoregulatory proteins defined by sequence homology and a common structural fold (1). Differentially expressed by most cell types, chemokines can be loosely divided into two main immunologic groups: homeostatic chemokines, which are expressed constitutively; and inflammatory chemokines, which are induced by infection and injury or in the setting of inappropriate inflammation (2–15). At the biochemical level, both types act by binding to one or more members of a large subfamily of seven-transmembrane-domain G-protein–coupled receptors, signaling mainly through G_{i2} (16,17). At the cellular level, chemokine action in the immune system is determined by differential expression of chemokine receptors on both lymphoid and myeloid cells, and classically results in directed cell migration (chemotaxis), although effects on activation, specific effector function, memory, proliferation, and apoptosis may also occur. At the biologic level, chemokines play critical roles in immunity and inflammation, acting at multiple levels, including immune system development (18), transendothelial migration (19,20), leukocyte positioning within microenvironments (21,22), and both phagocyte and

lymphocyte activation (23–25). As a result, chemokines may function both beneficially, for example, in the setting of antimicrobial host defense and tissue repair, or harmfully, for example, in the setting of cancer, chronic inflammation, autoimmunity, and infectious disease. The discovery of pathogens that encode multispecific chemokine-binding proteins and chemokine receptor antagonists able to subvert chemokine action provides compelling evidence for the importance of chemokines in host defense and for the significance of their redundant functions (26–28). Some pathogens, most notably HIV and *Plasmodium vivax*, go further and actually co-opt and exploit parts of the host chemokine system as essential virulence factors (16,29,30). Some chemokines also have nonimmunologic functions, including regulation of organ development (31,32), angiogenesis (33), and cancer (34–36). Together these physiologic and pathologic properties have suggested potential chemokine-based therapeutic opportunities, both as drug targets (37,38) and as immunologic response modifiers, for example, as adjuvants in DNA vaccines (39,40). To date, >100 chemokines, chemokine receptors, and viral chemokine mimics have been discovered, each having its own interesting place in immunology. The goal of this chapter is to delineate the basic principles of how chemokines are organized as a system, and to illustrate classic and more recently discovered immunologic roles using well-established examples.

MOLECULAR ORGANIZATION OF THE CHEMOKINE SYSTEM

Chemokines

Chemokines are defined by structure, not by function, although almost all chemokines have strong chemotactic activity for at least one subtype of leukocyte. Most mature chemokines are 66 to 111 amino acids long, and all occupy a common sector of sequence space bounded loosely by ~20% identity for any pairwise comparison; tertiary structure is highly conserved, in part because of conservatively spaced disulfide-bonded cysteines (Figure 26.1) (41). Chemokines are subclassified based on variation in cysteine number and location; all have at least two cysteines, and all but two have at least four (Tables 26.1, 26.2). In the four-cysteine group, the first two are either adjacent (CC motif, $n = 24$) or separated by either one (CXC motif, $n = 16$) or three (CX3C motif, $n = 1$) nonconserved amino acids. The C chemokines ($n = 2$) have only two cysteines, corresponding to C-2 and C-4 in the other subgroups. Disulfide bonds link C-1 to C-3 and C-2 to C-4. The conserved chemokine fold contains three β sheets arranged in the shape of a Greek key, overlaid by a *C*-terminal α-helical domain and flanked by an N-terminal domain that lacks order. Sequence identity is <30% between members of different groups, but ranges from ~30% to 99% among members of the same group. The group motifs are used as roots, followed by the letter L for ligand and a number (e.g., CXCL1), in a systematic nomenclature that was established to resolve competing aliases (42).

CC and CXC chemokines can be subclassified by additional motifs that may have functional significance. The seven human CXC chemokines with Glu-Leu-Arg (ELR) N-terminal to C-1 are >40% identical, attract neutrophils, bind the same receptor CXCR2, and are angiogenic (Table 26.1) (43). Among CXC chemokines that lack ELR, only CXCL12 is angiogenic and attracts neutrophils, but by using a distinct receptor, CXCR4 (44); CXCL9–11 also are >40% identical and share a receptor (CXCR3), but are angiostatic, not angiogenic (45). The CC group has two large subgroups, the MCPs (monocyte chemoattractant protein) and the MIPs (macrophage inflammatory protein), whose members typically chemoattract monocytes/macrophages but not neutrophils, in addition to having differential cell targets (46). CXCL16 and CX3CL1 cross groups to form a unique multimodular subgroup (47,48). Each has a chemokine domain, a mucinlike stalk, a transmembrane domain, and a *C*-terminal cytoplasmic module and can exist as a membrane-bound or shed form, mediating direct

Structural Signature

FIGURE 26.1 Chemokine classification and nomenclature. Chemokine classes are defined by the number and arrangement of conserved cysteines, as shown. Brackets link cysteines that form disulfide bonds. ELR, Glu-Leu-Arg; X, an amino acid other than cysteine. The underscore is a spacer used to optimize the alignment. The N and C termini can vary considerably in length (not illustrated). For the molecules with four cysteines, there are approximately 24 amino acids between Cys-2 and Cys-3 and 15 amino acids between Cys-3 and Cys-4. At right are listed the nomenclature system and the number of human chemokines known in each class (*n*).

▌ TABLE 26.1 The Human CXC, CX3C, and C Chemokine Families

ELR Motif	Chemokine	Common Aliases	Main Source	Main Immunologic Roles	Chromosomal Location
ELR+	CXCL1	GROα MGSA	Many tumors	Neutrophil trafficking	4q21.1
	CXCL2	GROβ			
	CXCL3	GROγ			
ELR−	CXCL4	PF-4	Preformed in platelets	Procoagulant	
	CXCL4L1		Preformed in platelets	ND	
ELR+	CXCL5	ENA-78	Induced in epithelial cells of gut & lung; N, Mo, Plts, EC	Neutrophil trafficking	
	CXCL6	GCP-2	Induced in lung microvascular EC; Mo; alveolar epithelial cells, mesothelial cells, EC & MΦ		
	CXCL7	NAP-2	Preformed in platelets		
	CXCL8	IL-8	Induced in most cell types		
ELR−	CXCL9	Mig	Induced in PMN, MΦ, T cells, astrocytes, microglial cells, hepatocytes, EC, fibroblasts, keratinocytes, thymic stromal cells	Th1 response	
	CXCL10	IP-10	Induced in ECs, Mo, keratinocytes, respiratory & intestinal epithelial cells, astrocytes, microglia, mesangial cells, smooth muscle cells		
	CXCL11	I-TAC	ECs, Mo,		
	CXCL12	SDF-1, PBSF	Constitutive in bone marrow stromal cells; most tissues	Myelopoiesis HPC, neutrophil homing to BM B lymphopoiesis	10q11.21
	CXCL13	BCA-1	Constitutive in follicular HEV of secondary lymphoid tissue	Naïve B- & T-cell homing to follicles B1-cell homing to peritoneum Natural Ab production	4q21.1
	CXCL14	BRAK	Constitutive in most tissues, breast and kidney tumors	Macrophage migration	5q31.1
ELR+	(CXCL15)	(mouse only)	Constitutive in lung epithelial cells	Neutrophil trafficking	NA
ELR−	CXCL16	Sexckine	Constitutive in spleen; DCs of the T zone	T-cell and DC homing to spleen	17p13
NA	CX3CL1	Fractalkine	EC, neurons, Mo, DC	NK, monocyte, MΦ, and Th1 cell migration; neuroprotection	16q13
	XCL1	Lymphotactin α	γδ epidermal T cells, NK, NK-T, activated CD8+ and Th1 CD4+ T cells	CD62L^{low} T-effector cell migration	1q24.2
	XCL2	Lymphotactin β			

NA, not applicable; ND, not determined; Mo, monocyte; PMN, neutrophil; DC, dendritic cell; EC, endothelial cell; HEV, high-endothelial venule; MPC, myeloid progenitor cell; plt, platelet; MΦ, macrophage; GRO, growth-related oncogene; PF-4, platelet factor-4; GCP, granulocyte chemoattactant protein; ENA-78, 78-amino acid epithelial cell-derived neutrophil activator; NAP, neutrophil-activating protein; IL-8, interleukin-8; Mig, monokine induced by IFNγ; I-TAC; interferon-inducible T-cell α chemoattractant; SDF, stromal cell–derived factor; BCA, B-cell–activating chemokine; BRAK, breast- and kidney-associated chemokine.

cell–cell adhesion and chemotaxis, respectively. The discovery of "chemokine" DMC (human dendritic cell- and monocyte-attracting chemokinelike protein) by sequence threading techniques, not primary sequence homology (49), provides proof of principle that the boundaries of chemokine sequence space can expand substantially as protein structures are determined or modeled.

Chemokine monomer, dimer, and tetramer structures may occur, and complex quaternary structures bound to glycosaminoglycans (GAGs) on the surface of cells may be important for function in vivo (50). Location of the GAG-binding domains is variable and depends on the highly basic nature of these proteins. Chemokine heterodimers have been described, both CC/CC and CC/CXC (51,52),

▶ **TABLE 26.2 The Human CC Chemokine Family**

Chromosomal Location	Chemokine	Common Aliases	Sources	Main Immunologic Roles
17q11-12	**CCL1**	I-309	Inducible in Mo & CD4$^+$ and CD8$^+$ $\alpha\beta$ and CD4$^-$CD8$^-$ $\gamma\delta$ T cells	Th2 response
	CCL2	MCP-1	Inducible in Mo, fibroblasts, keratinocytes, EC, PMN, synoviocytes, mesangial cells, astrocytes, lung epithelial cells & MΦ Constitutively made in splenic arteriolar lymphatic sheath and medullary region of lymph node, many tumors, & arterial plaque EC	Innate immunity Th2 response CD4$^+$ T-cell differentiation
	CCL3	MIP-1α LD78α MIP-1αS	Inducible in Mo/MΦ, CD8$^+$ T cells, B cells, plts, PMN, Eo, Ba, DC, NK, mast cells, keratinocytes, fibroblasts, mesangial cells, astrocytes, microglial cells, epith cells	Innate immunity Th1 response CD4 T-cell differentiation
	CCL3L1	LD78β MIP-1αP	Similar to CCL3	Probably similar to CCL3
	CCL4	MIP-1β	Similar to CCL3	Innate immunity Th1 response
	CCL5	RANTES	Inducible in EC, T cells, epithelial cells, Mo, fibroblasts, mesangial cells, NK cells Constitutively expressed and stored in plt and Eo granules	Innate immunity Th1 and Th2 response
NA	**(CCL6)**	Mouse only	Inducible in bone marrow and peritoneal-derived MΦ	ND
17q11-12	**CCL7**	MCP-3	Inducible in Mo, plts, fibroblasts, EC, skin, bronchial epithelial cells, astrocytes	Th2 response
	CCL8	MCP-2	Inducible in fibroblasts, PMN, astrocytes Constitutively expressed in colon, small intest, heart, lung, thymus, pancreas, spinal cord, ovary, placenta	Th2 response
NA	**(CCL9/10)**	Mouse only	Constitutively expressed in all mouse organs except brain; highest in lung, liver, & thymus Induced in heart & lung	ND
17q11	**CCL11**	Eotaxin	Epithelial cells, EC, smooth muscle, cardiac muscle, Eo, dermal fibroblasts, mast cells, MI, Reed–Sternberg cells	Th2 response Eosinophil trafficking Mast cell trafficking Basophil trafficking, degranulation
NA	**(CCL12)**	Mouse only	Inducible in lung alveolar MΦ & smooth muscle cells; spinal cord Constitutive expression in lymph node and thymic stromal cells	Allergic inflammation
17q11-12	**CCL13**	MCP-4	Inducible in nasal and bronchial epithelial cells; dermal fibroblasts; PBMCs; atherosclerotic plaque EC & MΦ Constitutively expressed in small intestine, colon, thymus, heart, & placenta	Th2 response
	CCL14a	HCC-1	Constitutively expressed in most organs; high plasma levels	ND
	CCL14b	HCC-3	Same as CCL14b except absent from skeletal muscle and pancreas	ND
	CCL15	HCC-2 Lkn-1	Inducible in Mo and DC Constitutive RNA expression in liver, gut, heart, & skeletal muscle, adrenal gland & lung leukocytes.	ND
	CCL16	HCC-4 LEC	Constitutively expressed in liver, possibly many other organs. Also, Mo, T cells, & NK cells express mRNA	DC maturation factor
16q13	**CCL17**	TARC	Constitutive in normal DC and Reed–Sternberg cells of Hodgkin's disease	Th2 response

▌**TABLE 26.2 The Human CC Chemokine Family** (Continued)

Chromosomal Location	Chemokine	Common Aliases	Sources	Main Immunologic Roles
17q11.2	**CCL18**	DC-CK1 PARC	Constitutive in Mo/MΦ, germinal-center DC	DC attraction of naïve T cells Hematopoiesis
9p13.3	**CCL19**	ELC, MIP-3β	Constitutive on interdigitating DC in secondary lymphoid tissue	Naïve and memory T cell & DC homing to lymph node
2q36.3	**CCL20**	LARC MIP-3α	Constitutive in follicle-associated epithelium overlying GALT inductive sites (Peyer patches & isolated lymphoid follicles) Inducible in GALT, Th17 cells	GALT development B and DC homing to GALT IgA humoral response in gut Th17 response
9p13.3	**CCL21**	SLC 6Ckine	Constitutive in lymphatic EC, HEV, & interdigitating DC in T areas of 2° lymphoid tissue, thymic medullary epith cells, & EC	Naïve and memory T cell & DC homing to lymph node
16q13	**CCL22**	MDC	Constitutive in DC and MΦ Inducible in Mo, T & B cells	Th2 response
17q12	**CCL23**	MPIF-1	Constitutive in pancreas & skeletal muscle	ND
7q11.23	**CCL24**	Eotaxin-2	Inducible in Mo	Eosinophil migration
19p13.3	**CCL25**	TECK	Constitutive in thymic stromal cells & small intest	Thymocyte migration Homing of memory T cells to gut
7q11.23	**CCL26**	Eotaxin-3	Constitutive in heart & ovary Inducible on dermal fibroblasts & EC	Th2 response
9p13.3	**CCL27**	CTACK Eskine	Constitutive in placenta, keratinocytes, testis, & brain	Homing of memory and effector T cells to skin
5p12	**CCL28**	MEC	Constitutive in epith cells of gut, airway	Homing of T cells to mucosal surfaces

NA, not applicable. Mo, monocyte; PMN, neutrophil; DC, dendritic cell; EC, endothelial cell; HEV, high-endothelial venule; MPC, myeloid progenitor cell; plt, platelet; MΦ, macrophage MCP, monocyte chemoattractant protein; MIP, macrophage inflammatory protein; RANTES, regulated upon activation normal T cell expressed and secreted; MRP, MIP-related protein; HCC, hemofiltrate CC chemokine; TARC, thymus and activation-related chemokine; PARC, pulmonary and activation-related chemokine; ELC, Epstein–Barr virus–induced receptor ligand chemokine; LARC, liver and activation-related chemokine; SLC, secondary lymphoid tissue chemokine; MDC, macrophage-derived chemokine; MPIF, myeloid progenitor inhibitory factor; TECK, thymus-expressed chemokine; CTACK, cutaneous T-cell–associated chemokine; mucosal epithelium chemokine; MEC, mucosa-associated epithelial cell chemokine.

and some may form preferentially over homodimers in a GAG-dependent manner (53); native heterodimers have also been identified (54). It will be important to define the functional significance of this so-called interactome (55).

Chemokine Receptors

Chemokine receptors are defined as mediators that activate cellular responses upon binding chemokines. All 19 known human subtypes, together with receptors for the classical lipid and peptide chemoattractant receptors (16), are members of the rhodopsinlike 7TM superfamily of G-protein–coupled receptors (see www.gpcr.org/7tm for a Web site devoted to this superfamily). Apart from odorant receptors, this is the largest known subfamily of GPCRs, itself the largest protein family from *Caenorhabditis elegans* to human (16,17,56). Chemokine-binding, membrane-anchoring, and signaling domains are formed from a single polypeptide chain. Although homo- and heterodimers have been reported, the precise physiologic form has not been clearly delineated (57–59).

Usually the chemokine ligand–receptor relationship is promiscuous but chemokine subgroup–restricted (Table 26.3). A systematic nomenclature formula exploits this as follows: receptor name = ligand subgroup root + R (for "receptor") + number, in order of discovery. An exception is the C-chemokine receptor XCR1, where "X" distinguishes it from CR1, the previously assigned name for complement receptor 1. For consistency, the XCR1 ligands are named XCL1 and XCL2. Each chemokine has a unique receptor-specificity profile, and each receptor has a unique chemokine-specificity profile. Promiscuous ligands of a given receptor interact with the same receptor chain, which contrasts with other types of cytokines that share receptors. Almost all chemokines are chemotactic agonists, and a few are both agonists at one receptor and antagonists at another.

Atypical Chemokine System Components

Atypical chemokine system components have been known since 1993 and continue to be discovered in large numbers. Some have been shown to play important functional

roles. Perhaps most intriguing are the functional chemokines and 7TM chemokine receptors encoded by poxviruses and herpesviruses, a clear result of "molecular piracy" of their hosts, and presumably of great importance in pathogenesis, although precise roles have not yet been well defined. A second category includes three human 7TM proteins (Duffy, D6, and CCX CKR) that bind chemokines promiscuously but do not signal (60,61). Several herpesviruses and poxviruses (26), as well as *Schistosoma mansoni* (62) and ectoparasitic ticks, also encode promiscuous chemokine-binding proteins, but they have unique non-7TM structures and are secreted. Duffy, also known as DARC (Duffy antigen receptor for chemokines), is expressed mainly on red cells and is an extreme exception to the ligand rule because it binds with high affinity many, but not all, CC and CXC chemokines. Expressed in placenta and on lymphatic endothelium, D6 is catalytic and not stoichiometrically restricted in its ability to scavenge inflammatory CC chemokines by a process of rapid internalization and recycling to plasma membrane. CCX CKR binds multiple CC chemokines (63). One theory is that nonsignaling chemokine-binding proteins function as anti-inflammatory chemokine buffers. Accordingly, they have been referred to as chemokine scavengers, interceptors, and silent or decoy receptors. Evidence from knockout mouse experiments with D6 and Duffy suggest that this may be the case in some but not all contexts.

Several endogenous nonchemokine ligands bind chemokine receptors, including aminoacyl tRNA synthetases, some of which function as autoantigens in autoimmune disorders (64); *β* defensin 2, which activates CCR6, possibly linking innate to adaptive immunity (65); chemokine-like factor 1, an agonist at CCR4 (66); and CD82 (KAI1), a tetraspanin expressed on leukocytes and cancer cells that binds to endothelial cell–expressed DARC, triggering senescence in tumor cells and suppression of metastasis (67). CCR5 acts as a dendritic cell pattern-recognition receptor for myHsp70, a heat-shock protein produced by *Mycobacterium tuberculosis*, promoting T-DC synapse formation and effector immune responses (68). Numerous chemokines bind scavenger-receptor ligands, such as oxidized LDL, through their receptor-binding domains (69). The prototype is CXCL16, which was originally called SR-PSOX (scavenger receptor for phosphatidyl serine and oxidized LDL). CXCL16 has also been shown to function as a transporter for CpG oligonucleotides across the plasma membrane for action at TLR9 (70), as well as to mediate bacterial phagocytosis by antigen-presenting cells (APCs) (71).

In contrast, a truncated form of CCL23, unlike full-length CCL23, has not been shown to activate any chemokine receptors yet is an agonist at FPRL1, a member of the classical chemoattractant fMet-Leu-Phe receptor subfamily (72). Perhaps the most surprising example of an alternative chemokine receptor agonist is the tripeptide Pro-Gly-Pro, a breakdown product of collagen from extracellular matrix that is found in bronchoalveolar lavage samples from patients with chronic obstructive pulmonary disease. This peptide shares structural homology with a domain in CXC chemokines (73), is a chemotactic agonist at CXCR2, and has been shown to recruit neutrophils via CXCR2 activation in a mouse model of lung inflammation. Examples of non-chemokine chemokine receptor ligands (agonists or antagonists) have been identified in numerous pathogens. For example, HIV Tat is an antagonist at CXCR4 (74), and *M. tuberculosis* heat-shock protein Hsp70, *Toxoplasma gondii* cyclophilin, and HIV gp120 are all agonists at CCR5.

Immunologic Classification of the Chemokine System

Chemokines and chemokine receptors have differential leukocyte specificities but together regulate the full spectrum of leukocytes. As such, they can be loosely divided into two main functional subsystems, *homeostatic* and *inflammatory* (Table 26.4). Homeostatic chemokines are differentially and constitutively expressed primarily in specific microenvironments of primary and secondary immune organs, and recruit hematopoietic precursor cells, mature dendritic cells (DCs), and naïve and central memory lymphocyte subsets via constitutively expressed receptors. Inflammatory chemokines are induced by noxious stimuli in diverse tissue cells and leukocytes. Inflammatory chemokine receptors are constitutively expressed on myeloid cells, natural killer (NK) cells, and effector but not naïve lymphocytes. Dynamic shifts in receptor expression occur during DC and NK cell maturation and during lymphocyte maturation, activation, and differentiation (75–78). This is not an absolute classification, because constitutive chemokines may be further induced, and chemokines that are highly inducible in some cell types may be constitutively expressed in others.

Evolution of the Chemokine System

Comparative whole-genome analysis has identified chemokine genes and chemokine receptor homologs in all vertebrates examined so far, including jawless fish, but not in any invertebrates including sea squirt and sea urchin, placing the system's origins between 564 and 650 million years ago. Forty-two human, 23 chicken (*Gallus galli*), 25 frog (*Xenopus tropicalis*), and, surprisingly, 63 zebrafish (*Danio rerio*) chemokine genes have been identified in the draft sequences for these organisms (79,80). Several human chemokines (e.g., CXCL8, CCL18) lack mouse counterparts and vice versa. CXCL12 and its receptors CXCR4 and RDC1/CXCR7 are all exceptionally highly conserved, and all three genes regulate both development and immunity and, at least in mouse, are essential for life (81). contrast, mice that lack CXCL14, the only other highly conserved chemokine, appear healthy and immunologically intact, and its putative receptor has not yet been identified (82). Orthologs for other chemokines among different vertebrate classes are difficult or impossible to assign. A model of chemokine system evolution has been proposed involving lineage-specific *en bloc* and tandem duplications. It has been speculated that the diverse roles of the chemokines were established early in their ontogeny, and that expansion accompanied the origin of recombination-activation gene (RAG)-based adaptive immunity (79).

Genes encoding inflammatory chemokines are found in two main clusters on human chromosomes 4q12-q21 (CXC) and 17q11-q21 (CC); CXCL16 is an exception, being located on chromosome 17 but on the other side of the centromere from the CC gene cluster. Genes for homeostatic chemokines are scattered alone or in small clusters on chromosomes 1, 2, 5, 7, 9, 10, and 16. Chemokine genes typically are ~4 kb long and usually have four exons in the case of CXC chemokines and three exons in the case of CC chemokines.

The 19 human chemokine receptor genes and three chemokine-binding-protein genes can be divided by chromosomal location into three groups: a large cluster on chromosome 3p21-23 including multiple CCRs, CX3CR1, XCR1, and CXCR6, plus D6 and CCX CKR ($n = 12$); CXCR1, CXCR2, and one receptor pseudogene clustered on 2q34-q35; and the rest unclustered. With the exception of CCR9, genes in the two clustered groups lack introns in the open reading frame (ORF) but have at least one and as many as 10 introns separating the promoter from the ORF. In contrast, an intron divides the N terminus of the majority of unclustered receptor genes (*CXCR3, 4,* and *5*; *CCR6,* and *10*). Several of these undergo alternative splicing creating isoforms with distinct N termini, and in the case of *CXCR3* this is functionally significant. CXCR3A and B both bind CXCL9, 10, and 11 with similar affinity, whereas only CXCR3B also binds the distantly related CXCL4. CXCR3A is selectively expressed on Th1 cells and mediates chemotactic responses in a G_i-dependent manner, whereas CXCR3B is expressed on microvascular endothelial cells and mediates the angiostatic effects of all four of its ligands through a distinct signaling mechanism (83).

With regard to horizontal evolution, variation in gene dosage among individuals has been observed for only a few chemokines. *CCL3* is an example in humans, and the *plt* locus (*p*aucity of *l*ymph node *T* cells) is an immunologically important example in mouse. In contrast, gene polymorphism is common among individuals for most chemokine and chemokine receptors, although the degree of polymorphism varies greatly among different genes. The most extreme and important example is the *CCR2-CCR5* locus, in which combinations of common dimorphic single-nucleotide polymorphisms (SNPs) in the CCR5 promoter with a SNP in the ORF of *CCR2* named *CCR2 V64I* and a 32-base pair (bp) deletion in the ORF of CCR5 named *CCR5Δ32* together form at least eight distinct haplotypes that may modulate susceptibility to and progression of various diseases, including HIV (84,85).

The Issue of Chemokine Redundancy

Two chemokines that bind to the same receptor may still have highly specific biologic roles, as a result of differential expression in time and space; activation of the same receptor via different signal transduction pathways or the same pathway with differential efficacy; or activation of additional differentially expressed receptors. A good example of differential expression is CXCL7 (NAP-2, neutrophil-activating protein-2) and CXCL8. Both are agonists for neutrophil CXCR2, but CXCL7 is stored in platelet α granules and released upon platelet activation, whereas CXCL8 is made by virtually all cell types upon gene induction by proinflammatory stimuli. There are few inflammatory processes in which only one chemokine is involved. They typically act cooperatively, on the same or separate cell types, but in a hierarchical manner through promiscuous receptors. The net result is that there may be enough functional redundancy in the whole system such that loss of a single inflammatory chemokine or chemokine receptor, for example, in a knockout mouse, does not cause altered susceptibility to naturally acquired infections or other diseases, yet there may not be sufficient redundancy to handle a stronger stress when one particularly important component is missing. In contrast, homeostatic chemokines act much less redundantly, with typically only one or two ligands per receptor, and their loss has been associated with major defects in development and basal leukocyte homing.

Chemokine Presentation Mechanisms

Chemokines typically act locally, and are thought to be concentrated for cell activation by tethering to endothelial cells via GAGs or transmembrane domains, or to matrix (22). GAG-dependent oligomerization has been shown to be important for in vivo activity of CCL5 and CXCL10 (86,87). The tethering cell may have produced the chemokine or else imported it by transcytosis from neighbors (88). The ligand-binding site includes the receptor N terminus and one or more extracellular loops, depending on the specific chemokine, which allow docking of the chemokine N-loop domain, and 7TM domains, which then accept the chemokine's N terminus and are critical for triggering. Tyrosine sulfation on the receptor N terminus has been shown to facilitate chemokine receptor binding to both chemokine and nonchemokine ligands (e.g., HIV gp120) (89).

LEUKOCYTE RESPONSES TO CHEMOKINES

Both homeostatic and inflammatory leukocyte trafficking require transendothelial migration, a multistep process involving an endothelium- and leukocyte-specific molecular code, in which chemokines regulate at least two steps (19,90). In an initial chemokine-independent step, leukocytes roll on inflamed endothelium in a selectin-dependent manner. Next, chemokines posted on endothelium stimulate rolling leukocytes to express activated $\beta2$ integrins, which mediate shear-resistant adhesion via endothelial ICAMs. Leukocytes respond to chemokine gradients by changing their shape to produce a front and a back and by crawling toward the front (91,92). Motion is based on shear-dependent coordinated cytoskeletal remodeling, involving expansion of the front (lamellipodium), myosin-based contraction at the back (uropod), release of the uropod from substrate, and membrane lipid movement. Navigation through tissue may require relays of chemokines and adhesion molecules. Fine navigation within tissue microenvironments has also been shown to be directed by specific chemokines up to the point of immunologic synapse formation (93,94), and there is now evidence that CCR5 and CXCR4 may accumulate in the immunologic synapse formed by CD4$^+$ T cells and dendritic cells *in vitro*, and that this may provide chemokine-dependent costimulatory signals (95,96).

Chemokines and their receptors have been increasingly implicated in other cell functions, including regulation of apoptosis (97–100), regulation of antigen sampling by immature DCs (e.g., CCR7 and CX3CR1), maturation of DCs (CCR7), and inhibition of mature DC endocytosis (CCR7) (101). Inflammatory chemokines may induce mediator release (e.g., defensins, proteases, perforins, histamine, eicosanoids), resulting in cytotoxic or vasomotor responses. Some chemokines even have direct antibacterial activity (102), which could explain why they may be found constitutively at high concentrations in body fluids such as sweat.

CHEMOKINE SIGNALING PATHWAYS

G$_i$-Dependent Effectors

Chemokines trigger chemokine receptors to act as guanine nucleotide exchange factors (GEFs), especially for G$_{i2}$ (103). G-protein activation involves exchange of GDP for GTP by the α subunit, leading to dissociation of the trimer into α and $\beta\gamma$ subunits. The duration of G-protein signaling is regulated in part by intrinsic GTPase activity possessed by the α subunit, which can be markedly increased by GTPase-activating proteins (GAPs) known specifically as RGS proteins (<u>r</u>egulators of <u>G</u>-protein <u>s</u>ignaling). Signaling appears to be mainly me-

diated by $\beta\gamma$, which activates diverse effectors, including phospholipases A2, C (subtypes $\beta2$ and $\beta3$) and D, phosphatidylinositol-3-kinase γ (PI3Kγ), protein tyrosine kinases (PTK) and phosphatases, low–molecular-weight GTPases, and mitogen-activated protein kinases (Figure 26.2). The requirements of these enzymes for chemotaxis are both chemoattractant- and cell-type dependent, and the complex mechanistic details underlying specificity remain to be elucidated.

PLC hydrolyzes PI(4,5) bisphosphate (PIP$_2$) to form 1,2-diacylglycerol (DAG) and inositol-1,4,5-trisphosphate (IP$_3$). IP$_3$ induces Ca^{2+} release from intracellular stores, which acts with DAG to activate protein kinase C (PKC). PI3Kγ phosphorylates PIP$_2$ to form PIP$_3$, which recruits proteins containing pleckstrin homology (PH) or Phox (PX) domains to lamellipodium, thereby converting shallow extracellular chemokine gradients to steep intracellular effector gradients (104,105). Four PH-domain–containing targets—Akt, and GEFs for Rac, Rho, and cdc42—modulate distinct phases of cell movement in various model systems. Rho regulates cell adhesion and chemotaxis, and myosin contraction. Rac and cdc42 control lamellipodia and filipodia formation, respectively. Downstream targets of Rac include PAK1, which also regulates myosin contraction. In neutrophils, signal amplification, gradient sensing, and cell orientation have been shown to be further amplified and reinforced by ATP release at the leading edge, which provides autocrine feedback signaling through P2Y2 nucleotide receptors. This is further amplified by conversion of ATP to extracellular adenosine, which signals through A3 receptors mobilized to the leading edge (106). Motility, phagocytosis, and immunologic synapse formation are all critically dependent on local polymerization of actin, coordinated by a large number of actin-binding proteins.

G$_i$-Independent Effectors

Many chemokine receptors couple to G proteins other than G$_i$ *in vitro*; however, the role of these proteins *in vivo* is not well defined. There is *in vitro* evidence from studies of the fMet-Leu-Phe receptor that G12/13, through activation of Rho, may be important in formation of the uropod (107). Mice that lack both G12 and G13 selectively in B cells have reduced numbers of splenic marginal-zone B cells, resulting in a delay of antibody production in response to thymus-independent antigens. However, responsiveness of these cells to chemokines is normal. Instead, the phenotype may be a result of impaired sphingosine-1-phosphate signaling (108).

Chemokines may activate effectors such as MAP kinases and nonreceptor PTKs by a variety of G$_i$-independent mechanisms. A recent example is CXCR4, which has been shown to associate physically with TCR in a CXCL12-dependent manner, resulting in activation of ZAP-70 and
FIGURE 26.2 Chemokine signal transduction in chemotaxis. Depicted are key steps in two of the main pathways induced by most chemokines. The PI3Kγ pathway is particularly important for cell migration. Chemokines are able to activate other pathways as well, including non–G_i-type G proteins, protein tyrosine kinases, and MAP kinases, resulting in effects on cell proliferation and activation. Model is modified from the Alliance for Cell Signaling www.signaling-gateway.org). PLC, phospholipase C; PI3K, phosphatidylinositol 3-kinase; RGS, regulator of G-protein signaling; DAG, diacylglycerol; IP3, inositol trisphosphate; PIP, phosphatidylinsol phosphate; GAG, glycosaminoglycan; CK, chemokine; PKC, protein kinase C; GRK, G-protein–coupled receptor kinase; GEF, guanine nucleotide-exchange factor.

downstream effectors, including ERK, calcium flux, AP-1, and costimulation of cytokine secretion (96).

REGULATION OF CHEMOKINE ACTION

Chemokine and chemokine receptor expression may be positively or negatively regulated at the transcriptional level by diverse factors, including proinflammatory cytokines, hypoxia, viruses, bacterial products, cell adhesion, shear stress, antigen uptake, T-cell costimulation, and diverse transcription factors. Proinflammatory cytokines such as IL-1, TNF, and IL-15 induce expression of many of the inflammatory chemokines involved in innate immunity such as CXCL8, whereas immunoregulatory cytokines such as IFN-γ and IL-4 are more tightly focused on Th1 (e.g., CXCL9-11)- and Th2 (e.g., CCL11)-selective chemokines, respectively. Interferons, glucocorticoids, and anti-inflammatory cytokines (e.g., IL-10) may inhibit inflammatory chemokine gene expression. Chemokines may also be regulated at the level of mRNA stability and cell type–specific polyubiquitinylation and proteasomal degradation (109,110).

A chemokine gene may generate families of proteins that vary dramatically in activity and potency by alternative splicing and posttranslational modification, especially

N- and C-terminal proteolytic trimming. Proteases may target many chemokines (e.g., CD26 [dipeptidyl peptidase IV] and matrix metalloproteinases [MMP]) (111,112), or few or only one (e.g., TACE [the TNFα-converting enzyme], plasmin, urokinase plasminogen activator, and cathepsin G), and the cleaved forms may be the dominant forms in biologic fluids, as shown for several CCR1 ligands (113). Chemokine action may be blocked by chemokine-binding proteins (e.g., Duffy), endogenous receptor antagonists, receptor decoys, and autoantibodies. In addition, cytokines may convert a signaling receptor into a decoy (e.g., IL-10 inactivates CCR2 and other receptors on monocytes/macrophages) (114). Also, a receptor may have different functions on different cell types. In addition to RGS proteins, chemokine receptor signaling may be regulated by homologous and heterologous desensitization, which involves phosphorylation by G-protein–coupled receptor kinases or PKC and PKA, respectively, and internalization by clathrin-dependent and -independent mechanisms (115). Release mechanisms may vary dramatically for different chemokines. CXCL4 is stored in platelet α granules, whereas the highly related CXCL4L1 is continuously produced and released (116). CCL5 is released from T-cell granules that are preassociated with GAGs (117). CCL3 is released multidirectionally from activated T cells, presumably to create chemotactic gradients, unlike IL-2 and IFN-γ, which are secreted directly into the immunologic synapse (118).

CHEMOKINE REGULATION OF HEMATOPOIESIS

CXCL12 and CXCR4

Originally identified as a pre–B-cell-stimulatory factor from stromal cells that also enhanced HPC colony formation ex vivo, CXCL12 is the most abundant chemokine in bone marrow. Its production is under the control of G-CSF and adrenergic neurotransmission, among other factors (119). Mice that lack CXCL12 or its receptor CXCR4 have severe defects in bone marrow myelopoiesis and B-cell lymphopoiesis (81). The CXCL12/CXCR4 axis is also critical for mobilization of human peripheral blood progenitor cells and neutrophils from bone marrow in patients and for engraftment of human hematopoietic stem cells in SCID mice (120). Consistent with this, myelokathexis, or neutropenia without maturation arrest, is a defining phenotype of WHIM syndrome, a rare autosomal-dominant immunodeficiency disorder characterized by underline{w}arts, underline{h}ypogammaglobulinemia, underline{i}nfection, and underline{m}yelokathexis, which has been linked to truncating mutations in the C tail of CXCR4 that prolong receptor signaling by delaying desensitization and blocking internalization (121). GM-CSF treatment overcomes this defect; moreover,

patients can appropriately mobilize neutrophils in the setting of bacterial infection, so that the condition is usually not life-threatening. The exact mechanism underlying the selective predisposition to papillomavirus infection in this syndrome is unknown. AMD3100, a selective full CXCR4 antagonist, is able to mobilize HPCs and is under development for that indication in the setting of transplantation (122,123), but it has not been tested in WHIM patients. Other chemokines such as CXCR2 agonists may also regulate marrow egress and homing of neutrophils and stem cells (124,125), and this may be relevant for patients with WHIM who lack CXCR4 mutations.

CXCR4 is also expressed on platelets, megakaryocytes, and most mature peripheral blood leukocytes, as well as on some normal and malignant epithelial cells. CXCL12 and CXCR4 knockout mice die in the perinatal period with multiple developmental abnormalities, including a ventricular septal defect, defective gastric vascularization, and defects in cerebellar development (81,126,127). A developmental role for CXCR4 has also been found in zebrafish, in which the ortholog *cxcr4b* mediates gonadal germ-cell migration and self-organizing tissue migration in the lateral line during morphogenesis (128). CXCL12 also binds to a second highly conserved and highly selective GPCR, formerly known as the orphan RDC1, a close relative of the adrenomedullin receptor (129,130). Provisionally designated CXCR7, it appears to play a limited role in immunology (it affects positioning of marginal-zone B cells), but an essential role in development of the heart, particularly for all four cardiac valves. Curiously, mice that are deficient in CXCL12 do not exhibit this developmental defect, suggesting that CXCR7 may have other, more relevant ligands. Moreover, although CXCL12 binds to CXCR7 with high affinity, persuasive evidence of receptor triggering is lacking, thus the designation CXCR7 is provisional.

Consistent with a more general role in vascular biology, CXCR4 is expressed on vascular and cancer stem cells under the control of oxygen tension. These cells home to vascular niches under hypoxic conditions that occur during wound healing and in tumors. Hypoxia induces reduction of pVHL, which derepresses transcription factor HIF-1, a strong inducer of *CXCR4* expression (131–133).

Myelosuppressive Chemokines

When added to bone marrow culture systems ex vivo, many chemokines are able to suppress growth factor–dependent colony formation, apparently by acting directly on stem cells and early progenitors. The biologic significance of this remains unclear except for CXCR2. CXCR2$^{-/-}$ mice develop massive neutrophilia, splenomegaly, myeloid hyperplasia, and expansion of HPCs. CXCR2-dependent myelosuppression may be important for opposing overstimulation of hematopoiesis induced by environmental flora, because this phenotype is absent in mice derived in

germ-free conditions. These mice also develop lymph node B-cell hyperplasia, which may occur by an indirect mechanism.

T Lymphopoiesis

During development, T cells must migrate from thymic cortex to medulla. Chemokines and chemokine receptors are differentially expressed in thymus and could coordinate migration, but precise roles have not been clearly delineated by phenotypes of gene-targeted mice or by other approaches. This is more likely to be a result of functional redundancy than lack of active chemokines in the thymus.

CCR9 and its ligand CCL25 may be important because competitive transplantation of CCR9$^{-/-}$ bone marrow is less efficient than normal marrow at repopulating the thymus of lethally irradiated Rag-1$^{-/-}$ mice (134). CCL25 is expressed by medullary dendritic cells and both cortical and medullary epithelial cells, and CCR9 is expressed on the majority of immature CD4$^+$CD8$^+$ thymocytes, but is downregulated during transition to the CD4$^+$ or CD8$^+$ single-positive stage. Just before thymic egress, thymocytes become CCR9-negative and upregulate L-selectin. Transition from CD4$^+$CD8$^+$ thymocytes in the cortex to CD4 or CD8 single-positive thymocytes in the medulla is also associated with upregulation of CCR4 and CCR7, receptors for CCL22, and CCL19 and CCL21, respectively, which are expressed on endothelial cells of medullary venules. Studies with knockout mice have suggested that CCR7-dependent cortex-to-medulla migration of positively selected thymocytes may be essential for establishing central tolerance but not for maturation or export of thymocytes in vivo (135).

Hematopoietic Cell Positioning in Peripheral Tissue

Recent work has begun to clarify chemokine-dependent mechanisms that control homeostatic positioning of leukocytes in peripheral tissues. The gut has been particularly well studied. CCL11 and its receptor CCR3 are important for migration of eosinophils to the gastrointestinal tract (and spleen) (136). CCL20 and its receptor CCR6 regulate positioning of immature myeloid CD11c$^+$CD11b$^+$ DC in the subepithelial dome of Peyers patches (137,138), which may explain in part why humoral immune responses within the gut mucosa and defense against enteroinvasive pathogens are abnormal in CCR6$^{-/-}$ mice. CCR6 is also expressed on gut-homing B and T cells, which may become rapidly activated by CCR6$^+$ DCs. CX3CR1 also regulates location of myeloid DCs in Peyers patches and may promote dendrite protrusion into the lumen as a method of antigen sampling. Consistent with this, CX3CR1 is important for controlling *Salmonella* infection after oral challenge (139). CCL25/CCR9 signaling regulates gut cryp-

topatch formation and subsequent positioning of intraepithelial lymphocytes (138).

CHEMOKINE REGULATION OF THE IMMUNE RESPONSE

Innate Immunity

Platelet-Derived Chemokines

Made primarily during platelet development, stored in platelet α granules, and rapidly released during platelet degranulation, CXCL4, CXCL4L1, and CXCL7 may be among the first chemokines to appear at sites of tissue injury and infection, particularly when there is hemorrhage and vascular damage, and may reach high concentrations (140). CXCL4 aggregates to form tetramers that are critical for binding to chondroitinsulfate proteoglycans and to CXCR3B on endothelial cells. In contrast, CXCL7 is activated by sequential proteolysis of its N terminus. The prepropeptide form, named platelet basic protein (92 amino acids [aa]), is trimmed during platelet maturation to produce the 85-aa major stored form, named connective tissue activating peptide-III (CTAP-III), which is inactive on neutrophils. CTAP-III is further processed during degranulation to 81-aa β-thromboglobulin, also inactive. This is then cleaved by a cell surface–bound, cathepsin G–like enzyme on neutrophils to form 70-aa CXCL7, which has high homology to CXCL4 (70% aa identity). Thus CXCL7 may function as an immediate-early mediator of neutrophil recruitment released from platelets at sites of inflammation. Although it is not a prominent leukocyte chemoattractant and does not induce degranulation of neutrophil lysosomal enzymes, CXCL4 is able to induce secondary granule exocytosis and release matrix-degrading enzymes, which may facilitate neutrophil penetration of infected or injured tissues. Both CXCL4 and CXCL4L1, the product of the highly homologous nonallelic variant gene of CXCL4, PF-4var1/PF-4alt, are strong angiostatic factors (141). In contrast, another platelet-derived chemokine, CXCL12, may be a major determinant of revascularization, as suggested by an ischemic hindlimb mouse model, in which its release could be regulated by Kit ligand and thrombopoietin and it functions to recruit CXCR4$^+$ VEGFR$^+$ hemangiocytes to the site of injury (142). The ultimate response in inflammation and revascularization may depend on the relative concentration and activities of these counterregulatory chemokines.

Neutrophil-Targeted Chemokines

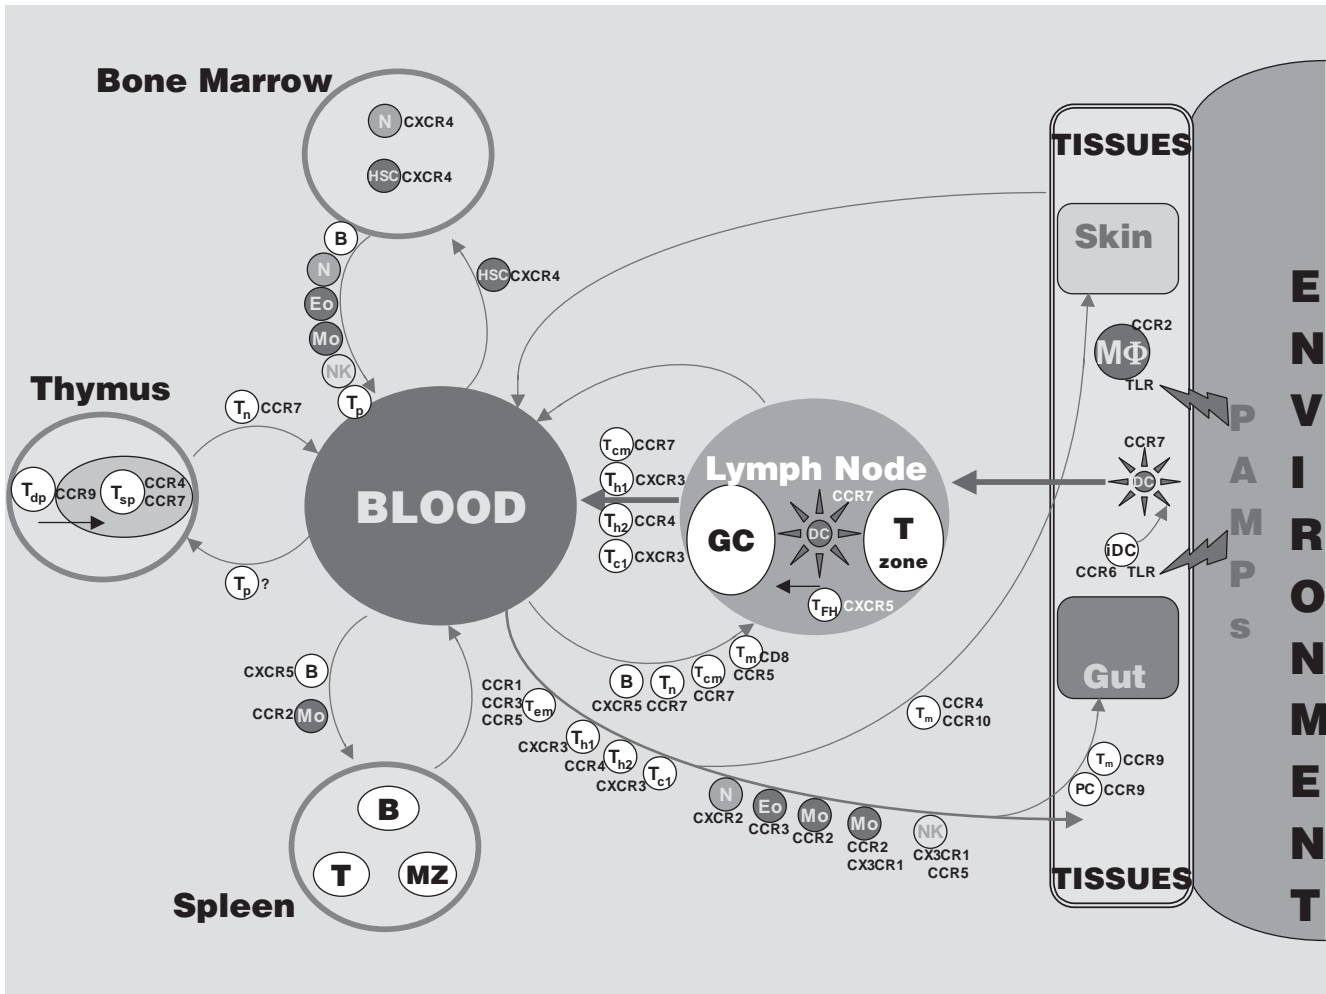
All seven ELR$^+$ CXC chemokines preferentially recruit neutrophils in vitro by binding to CXCR2. One of these, CXCL8, is also a potent agonist at CXCR1, which is coexpressed at similar levels on neutrophils (Figure 26.3) (143).


FIGURE 26.3 Chemokine receptor control of leukocyte trafficking. Shown are routes among primary and secondary immune organs and the periphery, leukocyte subtypes trafficking on those routes, and some of the chemokine receptors that appear to be most important in regulating each route. Tn, naïve T cells; Tp, precursor T cells; Tm, memory T cells; Tem, effector memory T cells; Tcm, central memory T cells; T_{FH}, follicular help T cells; iDC, immature dendritic cells; N, neutrophil; Eo, eosinophil; Mϕ, macrophage; Mo, monocyte; NK, natural-killer cell; PC, plasma cell; HSC, hematopoietic stem cell; GC, germinal center; Tdp, double positive T cells; Tsp, single positive T cells; MZ, marginal zone; TLR, Toll-like receptor; PAMP, pathogen-associated molecular patterns. Model is based primarily on studies in knockout mice.

These seven chemokines are rapidly inducible but may differ biologically as a result of temporal and spatial differences in expression, which may provide a mechanism for graded navigation of neutrophils through tissue. Blocking studies in multiple animal models have demonstrated the importance of CXCL8 and CXCR2 in neutrophil accumulation in response to infectious and noninfectious stimuli. The role of CXCR1 in vivo has not yet been defined and is difficult to analyze, because its major human agonist, CXCL8, is not found in the mouse; instead, the sole specific agonist identified for mouse CXCR1 is CXCL6 (GCP-2), which has relatively low potency in chemotactic assays in vitro. In a human blister model, endogenous CXCL8 peaks at ~24 hours, whereas C5a and leukotriene B4, which also recruit neutrophils, appear earlier. Thus the primary role of CXCL8 may be to amplify recruitment of neutrophils initiated by other chemoattractants.

Intradermal injection of CXCL8 in man causes rapid (<30 minutes) and selective accumulation of large numbers of neutrophils in perivascular regions of the skin without causing edema. Tissue-specific transgenic overexpression of the mouse CXCL8 paralogs KC and MIP-2 results in a similar picture, suggesting that in vivo these factors may recruit cells but not independently activate cytotoxic mechanisms. In vitro, the ability of CXC chemokines to activate neutrophil cytotoxic responses is modest. Instead, they may prolong survival of neutrophils in the setting of bacterial infection and paradoxically provide an

intracellular niche in which at least some bacterial species such as *Staphylococcus aureus* may persist (144). Studies in mice have revealed that $\alpha\beta$ CD4$^+$ T cells are critical in providing CXC chemokines that foster abscess formation in several models of experimental *S. aureus* infection, and that the absence of these cells results paradoxically in smaller/fewer abscesses with reduced bacterial burden. In addition, pathogens such as *Streptococci* may actively interfere with the action of CXC chemokines by degrading them with specific proteases (145). Thus, although there is no question that neutrophils are critical in defense against bacterial and fungal pathogens and that CXCR2 agonists are critical for neutrophil trafficking in the setting of infectious disease, the ultimate outcome of infection may be determined by a balance between CXCR2-dependent neutrophil recruitment, niche development, and negative regulatory mechanisms.

CXCL1, -2, -3, -7, and -8 have also been reported to induce basophil chemotaxis and histamine release in vitro, which together with other factors such as complement-derived anaphylatoxins may promote vasodilatation during early stages of the innate immune response. CC chemokines can also activate human neutrophils, but this typically requires prestimulation of the cells with IFN-γ and other factors able to induce expression of appropriate receptors. Conversely, late apoptotic neutrophils can actively promote the resolution phase of acute inflammation by terminating chemokine signaling through scavenging by CCR5, which is expressed in a manner that depends on caspases and anti-inflammatory lipid mediators (146).

Monocyte/Macrophage-Targeted Chemokines

Circulating blood monocytes can be divided into two principal subsets with distinct migratory properties based on chemokine receptor expression (147). *Inflammatory* monocytes are short-lived CX3CR1^{low}CCR2$^+$Gr1$^+$ cells that are actively recruited to inflamed tissues in the mouse. These cells correspond to human CD14$^+$CD16$^-$ monocytes, which are CX3CR1^{low}. *Resident* monocytes are long-lived CX3CR1^{high}CCR2$^-$Gr1$^-$ cells in the mouse, characterized by CX3CR1-dependent engraftment and recruitment to noninflamed tissues. These cells correspond to human CD16$^+$ monocytes that are CX3CR1^{high} but do not express inflammatory chemokine receptors. Both subsets can differentiate in vivo into DCs that stimulate naïve T cells. There are numerous examples of the functional importance of these receptors in the monocyte/macrophage lineage in vivo. CX3CR1 is particularly important in microglial cell migration and function in the inflamed central nervous system (148), and has been linked to macular degeneration in aged mice and in human disease. Both receptors play a role in macrophage accumulation in atherosclerotic plaque (149). In a *Listeria* model, CCR2 was shown to be important for release of monocytes from the bone marrow to the circulation, but not for migration of circulating cells to the spleen (150).

Monocytes express additional inflammatory chemokine receptors including CCR1, CCR5, CXCR1, and CXCR2. Differentiation in vitro to macrophages is associated with downregulation of CCR2 and induction of CCR5 and CX3CR1. Polarized M1 and M2 subsets of macrophages have been described in keeping with the Th1/Th2 polarization paradigm for T cells. In this regard, the classic anti-inflammatory Th2 cytokine Il-10 is able to downregulate signaling by inflammatory chemokine receptors on macrophages (24). CCR4, which is a key receptor in Th2-mediated immune responses, has also been reported to play a dominant role in innate immunity in mouse models, including endotoxic shock and bacterial peritonitis, through effects on macrophage differentiation (151).

NK Cell–Targeted Chemokines

Human NK cell subsets express unique repertoires of chemokine receptors (77). The CD56^{dim}CD16$^+$ subset, which is associated with high cytotoxic capacity and low cytokine production, expresses primarily CXCR1 and CX3CR1, whereas the minor subset of CD56^{bright}CD16^{dim} cells, which produce large amounts of cytokines but have low killing capacity, preferentially express CCR7. The exact profile of chemokine receptor expression can be modulated by adherence and stimulation ex vivo with IL-2. Cognate chemokines chemoattract NK cells, and promote degranulation and killing. The importance of chemokines in NK cell function in vivo is well illustrated by mouse cytomegalovirus (MCMV) infection, a cause of hepatitis. MCMV induces CCL3 production in the liver that is required for recruitment of NK cells. NK cells are the major source of IFN-γ in this model, and IFN-γ induces CXCL9, which is required for protection. Thus a cytokine-to-chemokine-to-cytokine cascade is required for NK cell–mediated host defense against this pathogen (152).

Dendritic Cells and Transition to the Adaptive Immune Response

Transition from innate to adaptive phases of the immune response involves antigen uptake by antigen-presenting cells, especially dendritic cells, mediated by Fc and complement phagocytic receptors, as well as pattern-recognition receptors (PRRs), including DC-SIGN and Toll-like receptors (TLRs). Through specific PRR ligands, pathogens may shape the nature and magnitude of the immune response in a specific direction, in part by inducing production of specific sets of chemokines with distinct leukocyte specificities (153).

Chemokine receptor expression and function also depends on the nature of the inflammatory stimulus, but also

on the type of DC. For example, blood-derived plasmacytoid and myeloid DCs express a similar repertoire of inflammatory chemoattractant receptors, but they are functional only on myeloid DCs. CCL3, CCL4, and CCL5 may be particularly important for recruiting additional mononuclear phagocytes and DCs to sites of infection. This can amplify the late stage of the innate immune response, and in the extreme may devolve into endotoxic shock. Consistent with this idea, genetic disruption of the CCL3/CCL4/CCL5 receptor CCR5 renders mice relatively resistant to LPS-induced endotoxemia. CCR4$^{-/-}$ mice are also resistant to endotoxic shock, and this is associated with reduced macrophage extravasation to the peritoneum and production of the CCR4 ligand CCL17, which can be produced by DCs (151).

Adaptive Immunity

Afferent Trafficking to Secondary Lymphoid Tissue

The homeostatic receptors CXCR4, CXCR5, and CCR7 and their ligands are major regulators of lymphoid development and the adaptive immune response (21,78,154–158). DC maturation in peripheral tissues is associated with downregulation of inflammatory receptors, which may be important for recruitment, migration, and retention in the periphery, and reciprocal upregulation of CCR7, which mediates mature DC migration via afferent lymphatics to draining lymph nodes in response to CCL21 expressed on lymphatic endothelial cells. Inflammatory receptors may also contribute, as demonstrated for CCR2 on Langerhans cells in a mouse model of *Leishmania* infection (159).

With regard to lymphocytes, CCR7, and to a lesser extent CXCR4, mediate both B- and T-cell entry from blood into lymph node. In lymph node and Peyers patch T zone, CCL21 is produced by HEV endothelial cells, whereas CCL19 (the second CCR7 ligand) and the CXCR4 ligand CXCL12 are produced by adjacent stromal cells. All three chemokines are displayed on the luminal and abluminal sides of the HEV, appropriately positioned to mediate transendothelial migration from the blood of naïve B and T lymphocytes, which both coexpress CCR7 and CXCR4 (160). CCR7 plays a dominant role in mediating B- and T-cell adhesion, but CXCR4 also contributes. CCR7$^{-/-}$ mice and the *plt* mouse, which is naturally deficient in CCL19 and the CCL21 isoform expressed in secondary lymphoid organs, have similar phenotypes: atrophic T-cell zones populated by a paucity of naïve T cells. This, plus the failure of activated DC to migrate to lymph node from the skin of these mice, explains why contact sensitivity, delayed-type hypersensitivity, and antibody production are severely impaired.

CXCR5 is expressed on all peripheral blood and tonsillar B cells, but on only a fraction of bone marrow B cells. Its ligand CXCL13, produced selectively by HEV endothelial cells and follicular stromal cells, is constitutively displayed on follicular HEV. CXCL13/CXCR5 supports ~50% of the signaling required for B-cell entry from blood to Peyers patch, although CXCR4 may also contribute (160,161). In CXCR5$^{-/-}$ mice, B cells do not migrate to lymph nodes, Peyers patches are abnormal, and inguinal lymph nodes are absent. CXCL13 is also required for B1-cell homing, natural antibody production, body cavity immunity, and lymphoneogenesis in the setting of autoimmunity. CXCR5$^{-/-}$ mice still can produce antibody, perhaps in part because B cells and follicular DC, by an unknown mechanism, are able to form ectopic germinal centers within T zones of the periarteriolar lymphocyte sheath of spleen. In Peyers patches, B-cell entry is also dependent on CCR7 and CXCR4.

CXCR5 and CCR7 are probably not the only chemokine receptors responsible for afferent trafficking of leukocytes to lymph node. CCL9 has been reported to mediate monocyte homing. In addition, inflamed peripheral tissues may exert "remote control" for monocyte homing to draining lymph nodes from the blood by "projecting" their local chemokine profile to HEVs of the draining lymph node (162). Migration of T cells to splenic red pulp may involve local production of CXCL16. NK-T cells and activated CD4$^+$ and CD8$^+$ T cells are found in this area and express the CXCL16 receptor CXCR6. CXCL16 is also made by DCs in the T zone, and CXCR6 is also found on intraepithelial lymphocytes. Thus, CXCL16 may function in T cell–DC interactions and in regulating movements of activated T cells in the splenic red pulp, and in peripheral tissues.

Migration within Lymph Node Microenvironments

CXCR5 and CCR7 also appear to be important for lymphocyte movement within the lymphoid microenvironment. So-called follicular helper T cells (T$_{FH}$), a CD57$^+$ subset, lack CCR7 but express CXCR5, which appears to facilitate migration from the T zone following activation to the follicles in response to CXCL13, where they provide help for B-cell maturation and antibody production. They do not produce Th1 or Th2 cytokines upon activation (163). Reciprocally, B cells activated by antigen in the follicles upregulate CCR7 and move toward the T zone in response to CCL21 (164). Thus B–T interaction may be facilitated by reciprocal movement of these cells, which may be determined in part by the balance of chemokines made in adjacent lymphoid zones.

CXCR4 signaling may also be important in naïve and memory B-cell trafficking to germinal centers. An active chemokine-dependent process has also been identified for CD4$^+$ T-cell–dependent activation of rare antigen-specific naïve CD8$^+$ T cells (94). After immunization in a TCR-transgenic mouse model, but before antigen recognition, naïve CD8$^+$ T cells in immunogen-draining lymph

nodes upregulate CCR5, permitting the cells to home to sites of CD4$^+$ T cell–dendritic cell interaction in lymph nodes, where CCL3 and CCL4 are produced. Interference with this process inhibits antigen-specific memory CD8$^+$ T cell generation. There is also evidence that T-cell zone chemokines such as CCL21 are bound to the surface of lymph node DCs in vivo and function to capture and prime naïve T cells for activation by peptide-MHC. Thus T cells are costimulated "in trans" and sequentially after initial engagement with their chemokine-rich environment (165).

Efferent Trafficking

Critical determinants of lymphocyte egress from lymph node are sphingosine 1-phosphate and its receptor S1P (21). Naïve lymphocytes that do not encounter antigen continue to recirculate between the blood and secondary lymphoid tissue without acquiring any tissue-specific homing properties. In contrast, most antigen-stimulated T cells die by apoptosis. The survivors may be divided into functionally distinct subsets that preferentially express certain chemokine receptors. Within the CD4$^+$ subpopulation, three memory subsets and three primary effector subsets have been proposed. The memory subsets include T_{FH} cells, described previously, and effector memory (T_{EM}) and central memory cells (T_{CM}) (166). Memory cells classically express CD45RO. In addition to this, classic T_{CM} cells also express L-selectin (CD62L) and CCR7, which are thought to mediate homing of the cells from blood to secondary lymphoid organs across HEV; these cells are not polarized and lack immediate effector function. Instead, they are thought to interact with DCs in lymph node and differentiate into T_{EM} upon secondary stimulation. T_{EM} cells express L-selectin but lack CCR7, and were originally proposed to differentiate from T_{CM} and to traffic through peripheral tissues as immune surveillance cells, rapidly releasing cytokines in response to activation by recall antigens.

It is increasingly clear that the original T_{CM}/T_{EM} paradigm requires revision, in part because CCR7$^+$ effector memory cells have been detected in inflamed tissues and CCR7 facilitates their exit into lymphatics (167,168). Rather than a dualism with a single precursor–product relationship, analysis of freshly isolated human peripheral blood CD4$^+$ T cells has suggested that memory-cell differentiation may be a continuum with multiple branch points arising probabilistically, giving rise to many subpopulations that preferentially express certain chemokine receptors (169).

Upon activation, the classic polarized effector subsets, Th1 and Th2, downregulate CXCR5 and CCR7 and upregulate inflammatory chemokine receptors (170). This switch facilitates exit from lymph node via efferent lymphatics and homing to inflamed sites. In vivo, Th1 cells, which by the simplest definition secrete IFN-γ but not IL-4 and which control cellular and humoral immunity to intracellular pathogens, more frequently express CXCR3, CXCR6, CCR2, CCR5, and CX3CR1 than Th2 cells. The most highly differentiated CD4$^+$ memory T cells, so-called 'first responders,' express CCR2 and CCR5. In contrast, Th2 cells, which express IL-4 but not IFN-γ, and are associated with cellular and humoral immunity to extracellular pathogens and allergic inflammation, more frequently express CCR3, CCR4, and CCR8 than Th1 cells. CXCR3 expression is dependent on T-bet expression and has been most consistently associated with Th1 immune responses and Th1-associated disease. Consistent with this, its agonists CXCL9-11 are highly induced by IFN-γ but not by IL-4. Thus, in Th1 immunity there is the potential for a positive feedback loop in which IFN-γ induces production of CXCL9-11, which then recruit CXCR3$^+$ Th1 cells that produce IFN-γ. The "Th1 chemokines" may also help maintain Th1 dominance in part through their ability to block CCR3. Specific cytokines, microenvironments, and inflammatory stresses may differentially regulate CXCL9-11 expression, which may account for specialized biologic roles. For example, though all three chemokines are inducible by IFN-γ, CXCL10 and CXCL11 but not CXCL9 are also inducible by type I interferon. There is evidence that Th1 and Th2 cell recruitment into tissue is differentially regulated by Stat1 and Stat6, respectively, and that Stat1 controls recruitment of Th1 cells through the induction of CXCR3 ligands and CXCL16 (171).

Conversely, research on chemokine expression and targets has led to a model of Th2 immunity in which IL-4 and IL-13 made at inflamed sites in the periphery may induce production of CCL7, CCL11 and other CCR3 ligands, the CCR4 ligands CCL17 and CCL22, and the CCR8 ligand CCL1. CCR3 is expressed on a subset of Th2 T lymphocytes as well as on eosinophils and basophils, the three major cell types associated with Th2-type allergic inflammation, and Th2 cells are associated with CCR4 expression. Arrival of Th2 cells amplifies a positive feedback loop through secretion of additional IL-4. Moreover, CCL7 and CCL11 may block Th1 responses by antagonizing CCR2, CXCR3, and CCR5. Many chemokine receptors have been identified on CD4$^+$ regulatory T cells, including CCR4, CCR5, and CCR8. CCR5 has been shown to play an important role in homing of these cells to skin during *Leishmania major* infection, favoring pathogen persistence (172).

Recently, IL-17 producing T cells or Th17 cells, have emerged as an important third subset of CD4$^+$ effector cells, involved in autoimmunity and host defense. All Th17 cells express CCR6 (172a).

T-Cell Differentiation

Some chemokines appear to regulate not just trafficking but also T-cell polarization, at least in certain contexts. CCL2 and its receptor CCR2 have been most extensively studied in this regard, but the results are complex and

appear at first glance contradictory because in vivo CCR2 is strongly associated with Th1 immune responses and CCL2 is associated with Th2 responses (173). CCL2 appears to promote Th2 polarization directly, by inhibiting IL-12 production in monocytes, and by enhancing IL-4 but not IFN-γ production in memory and activated T cells. Thus, CCL2 influences both innate immunity, through effects on monocyte trafficking, and adaptive immunity, through control of T-helper cell trafficking and potentially T-cell polarization. In the case of aerosol challenge with *M. tuberculosis* in CCR2$^{-/-}$- mice, DC migration to draining lymph node is markedly impaired, which preempts any direct effects of CCL2 on T cells. Why CCL2 and CCR2 have opposite effects on Th polarization is unclear but is most likely a result of ligand-receptor promiscuity.

Tissue-specific Lymphocyte Homing

CLA$^+$ T lymphocytes, which home to skin, preferentially express CCR4 and CCR10. The CCR4 ligand CCL22 is made by resident dermal macrophages and DCs, whereas the CCR10 ligand CCL27 is made by keratinocytes. Blocking both of these pathways, but not either one alone, has been reported to inhibit lymphocyte recruitment to the skin in a DTH model, implying that in this model these two molecules act redundantly and independently of inflammatory chemokines (174).

Homing to small intestine is determined in part by T-lymphocyte expression of the integrin $\alpha_4\beta_7$ and CCR9. The $\alpha_4\beta_7$ ligand MAdCAM-1 and the CCR9 ligand CCL25 colocalize on normal and inflamed small intestinal endothelium, and most T cells in the intraepithelial and lamina propria zones of the small intestine express CCR9. These cells, which are mainly $\gamma\delta$ TCR (+) or CD8$\alpha\beta$(+)$\alpha\beta$TCR(+), are reduced in small intestine from CCR9$^{-/-}$ mice. CCL20 and its receptor CCR6 are also important in gut mucosal immune responses. CCL20 is constitutively expressed in follicle-associated epithelial cells (FAE) overlying GALT-inductive sites (Peyer patches and isolated lymphoid follicles), but can also be induced in GALT under inflammatory conditions. It is important for GALT development and for B and DC homing to GALT. CCR6$^+$ DC recruited to the dome region of Peyer patches upon invasion of FAE by an enteric pathogen has been shown to mediate rapid activation of pathogen-specific T cells (175).

As B cells differentiate into plasma cells, they also downregulate CXCR5 and CCR7 and exit the lymph node. B immunoblasts expressing IgG coordinately upregulate CXCR4, which promotes homing to the bone marrow, whereas B immunoblasts expressing IgA migrate specifically to mucosal sites. Like gut-homing T cells, gut homing IgA-secreting B immunoblasts express $\alpha_4\beta_7$ integrin and CCR9 and respond to CCL25. Intestinal dendritic cells may help shape mucosal immunity by generating gut-homing IgA-secreting B cells through the synergistic ac-

tion of several mediators, including retinoic acid, IL-5, and IL-6 (176–178). The chemokine requirements for trafficking to the colon and other mucosal sites have not been worked out yet.

CHEMOKINES AND DISEASE

There is a vast literature correlating the presence of chemokines with diverse human diseases, but strong evidence that they are actually involved in pathogenesis is available for only a small subset of these (Tables 26.5, 26.6). Many pathogenetic mechanisms have been proposed, including activation of innate immunity, activation of adaptive immunity, and cell trafficking. These mechanisms may cooperate so that, for example, nonspecific activation of innate immunity may markedly enhance susceptibility to destruction of a solid organ by adaptive immune mechanisms (179).

HIV

HIV infection requires fusion of the viral envelope to a target cell membrane, a process that is initiated by direct binding of the HIV envelope glycoprotein gp120 to both CD4 and a coreceptor on the target cell (30,180). Although many chemokine receptors and related GPCRs can function as coreceptors in vitro, CCR5 and CXCR4 appear to be the most relevant on primary cells. Their interaction with CD4 may be constitutive and stabilized by gp120. The usage of these receptors is so important that HIV strains are now functionally classified and named according to their specificity for CXCR4 (X4 strains), CCR5 (R5 strains), or both (R5X4 strains).

The importance of CCR5 in clinical HIV/AIDS was established by the seminal discovery that *CCR5Δ32*, a nonfunctional allele founded more than 5,000 years ago in Caucasians and now present in ~20% of North American Caucasians, is a strong AIDS-restriction factor, protecting homozygotes from initial infection and slowing the rate of progression to AIDS in infected heterozygotes (181). Additional genetic risk factors affecting the rate of HIV disease progression have been identified in the CCR5 signaling system, including SNPs in the promoters for *CCR5* and its ligand *CCL5*, and variation in the gene copy number of the CCR5 ligand CCL3L1, which cumulatively may account for ~9% of the risk of slow progression to AIDS (182–185). Genetic restriction factors have also been identified in some but not all studies for the CXCR4 ligand CXCL12 (*SDF1-3'A*) and the minor HIV coreceptors CCR2 (*CCR2-64I*) and CX3CR1 (*CX3CR1-M280*), but their biologic significance and mechanisms remain undefined. The pattern of genetic variation at *CCR5Δ32* is most consistent with neutral evolution (186). *CCR5Δ32* homozygotes appear healthy, as do unstressed CCR5 knockout mice. Drug development programs by several pharmaceutical companies targeting

▌ TABLE 26.5 Some Phenotypes of Chemokine-Receptor Knockout Mice

	Phenotype		
Receptor	*Infectious Disease*	*Inflammation*	*Development*

CXCR2	*Increased susceptibility to:*
	  T. gondii
	  Brain abscess
	  Onchocerca volvulus
	  E. coli pyelonephritis
		Reduced:
		  Wound healing
		  A. fumigatus AHR
		  Urate crystal-induced synovitis
			Expansion of neutrophils & B cells in blood, marrow, & lymphoid organs (not seen when derived in germ-free environment)

CXCR3	Increased susceptibility to MTb	Delayed cardiac allograft rejection	

CXCR4			Perinatal lethality
			Defective:
			  Ventricular septum
			  Bone marrow myelopoiesis
			  B-cell lymphopoiesis
			  Gastric vascularization
			  Cerebellar granule cell migration

CXCR5			Few Peyer patches, no inguinal LN Defective germinal centers & B-cell homing to LN
CXCR7			Defective cardiac development

CCR1	*Increased susceptibility to:*
	  T gondii
	  Pneumonia virus of mice
	  A. fumigatus
		Increased:
		  Th1 response and glomerular injury in nephrotoxic nephritis model
		  Th2 response to SEA
		Reduced:
		  Neutrophilic alveolitis in pancreatitis–ARDS model
		  Airway remodeling and Th2 response in A. fumigatus model
		  Th1 response & resistance to EAE
		  Th1 response to PPD
		  Delayed cardiac allograft rejection
			NR

CCR2	*Increased susceptibility to:*
	  C. neoformans
	  L. monocytogenes
	  L. major
	  M. tuberculosis
	Resistance to:
	  L. donovani
	  Influenza A
		Decreased:
		  EAE
		  DVT resolution
		  Response to PPD
		  Atherosclerosis
		  Cardiac allograft rejection
		  AHR to CRA
		  Dextran sulfate–mediated colitis
		  Thioglycollate-induced peritonitis
		  FITC and bleomycin-induced pulmonary fibrosis
		  MΦ recruited to injured nerve
		  DTH
		  Monocyte extravasation
		Increased:
		  AHR to OVA
		  AHR to A. fumigatus
		  Glomerulonephritis in antiglomerular basement membrane antibody model
			Enhanced myeloid progenitor cell cycling and apoptosis

(*continued*)

▶ **TABLE 26.5 Some Phenotypes of Chemokine-Receptor Knockout Mice** (Continued)

	Phenotype		
Receptor	*Infectious Disease*	*Inflammation*	*Development*

CCR3		*ip OVA sensitization → OVA challenge:*
		  Increased AHR & airway mast cells; decreased airway eos, trapped between elastic lamina and endothelial cells
		Epicutaneous OVA sensitization → OVA challenge:
		  Protection from allergic skin inflammation & AHR. Eos and mast cells not recruited to skin or lung
		  Decreased IL-13–induced pulmonary eosinophilia & remodeling	

CCR4		Increased susceptibility to lps	

CCR5	*Increased susceptibility to:*
	  L. monocytogenes
	  C. neoformans
	  T. gondii
	  Influenza A
	  L. major
	  West Nile Virus
	Resistance to:
	  L. donovani
		Decreased:
		  Dextran sulfate-mediated colitis
		  Lps toxicity
		  Mouse hepatitis virus-induced demyelination due to decreased MΦ recruitment to CNS
		  Cardiac allograft rejection
		
		Increased:
		  DTH
		  Humoral response to T-dependent Ag	

CCR6	Impaired humoral immune response to orally administered antigen and to rotavirus	Defective CRA-induced allergic airway inflammation Increased contact hypersensitivity to 2,4-dinitrofluorobenzene Resistance to DTH to allogeneic splenocytes Decreased arthritis	Absent myeloid CD11b$^+$ CD11c$^+$ dendritic-cells in subepithelial dome of Peyer patches Increased T cells in intestinal mucosa
CCR7		Delayed humoral response Defective contact sensitivity Defective DTH Defective renal fibrosis & fibrocyte accumulation in unilateral ureteral obstruction	Defective lymphocyte and DC migration to LN Undeveloped T-cell zones Impaired trafficking of T cells and DC to LN
CCR8		Defective SEA-induced granuloma formation; decreased OVA- and CRA-induced allergic airway inflammation Decreased inflammation in IBD models	
CCR9			Decreased preproB cells, but nl T and B cells Decreased ratio of gut intraepithelial T-cell-to-epithelial cell ratio due to decreased $\gamma\delta$ T cells
CX3CR1	Increased susceptibility to *Salmonella* infection	Resistance to cardiac allograft rejection in cyclosporin A–treated animals	
Duffy		Increased or decreased neutrophil mobilization, depending on the model	
D6		Increased CFA- or TPA-induced psoriasiform dermatitis Reduced EAE	fetal loss

SEA, *Schistosoma mansoni*–soluble egg antigen; OVA, ovalbumin; CRA, cockroach antigen; AHR, airway hyperreactivity; LN, lymph node; DC, dendritic cell; DTH, delayed-type hypersensitivity; NR, not reported.

WHIM syndrome (<u>w</u>arts, <u>h</u>ypogammaglobulinemia, <u>i</u>nfection, <u>m</u>yelokathexis) and CXCR4
Plasmodium vivax malaria and Duffy
HIV/AIDS and CCR5
West Nile virus disease and CCR5
Kaposi sarcoma and human herpesvirus 8 vGPCR
Atherosclerotic cardiovascular disease and CX3CR1
Autoimmune heparin-induced thrombocytopenia and CXCL4
Chronic renal allograft rejection and CCR5
Rheumatoid arthritis and CCR5
Eosinophilic esophagitis and CCL26

[a]The list includes diseases for which there is consistent evidence for chemokine regulation of pathogenesis in humans. Chemokines have been implicated in many other human diseases by physical expression in disease sites, or by studies in animal models, but clear and consistent evidence for a functional role in human disease pathogenesis is not yet available, for example, from genetic studies or drug trials.

CCR5 have succeeded in identifying small-molecule antagonists, and Pfizer's Maraviroc has been approved by the FDA for the treatment of HIV/AIDS—the first approved drug targeting the chemokine system. Resistance to CCR5 antagonism has been documented for R5 HIV, but the mechanism involves usage of alternative drug-insensitive domains of CCR5, not conversion to CXCR4 tropism.

CCR5 is also important in the neuropathogenesis of West Nile virus (WNV) infection, in both humans and in a mouse model of disease, but unlike HIV, here it plays a protective role by facilitating antiviral leukocyte trafficking to the brain (187). CCR5-blocking agents could theoretically increase the risk of symptomatic WNV disease in infected patients, particularly in the setting of HIV/AIDS, in which the immune system is already compromised. Pathogenesis in the mouse model of WNV is also regulated by neuronal CXCL10 through recruitment of CD8+ T cells to the brain (188). CXCL10 also controls pathogenesis in a mouse model of the related flavivirus Dengue virus, both by regulating T-cell recruitment through CXCR3 and by competitively inhibiting viral binding to cell-surface heparan sulfate (189).

X4 HIV strains typically do not transmit disease, but instead appear to evolve from R5 quasispecies in a minority of patients late in infection during the transition to clinical disease. Consistent with this, these strains appear more virulent than R5 strains in vitro. The reason is not fully defined, but it is important to note that the percentage of CD4+ T cells expressing CXCR4 greatly exceeds that expressing CCR5. Moreover, the X4 envelope protein expressed on CD4+ T cells has been shown to induce autophagic programmed cell death of uninfected bystander cells by binding to CXCR4 on the cell membrane, signaling in a non–G_i-, non–caspase 3-dependent manner (190). An unresolved question is why X4 strains do not readily transmit disease, given the broad expression of CXCR4 on macrophages and CD4+ T cells.

Malaria

Analagous to CCR5 and HIV, Duffy, the 7TM promiscuous chemokine-binding protein, is required for infection of erythrocytes by *Plasmodium vivax*, a major cause of malaria. The parasite ligand, which is named the *Plasmodium vivax* Duffy-binding protein (PvDBP), is expressed in micronemes of merozoites and binds to the N-terminal domain of Duffy via a cysteine-rich domain (191). This interaction is required for junction formation during invasion, but not for initial binding or parasite orientation. Duffy deficiency, which is due mainly to an inherited single-nucleotide substitution named −46C at an erythroid-specific GATA-1 site in the Duffy promoter, is fixed in sub-Saharan Africa but not in other malaria-endemic regions of the world. Accordingly, *P. vivax* malaria is rare in sub-Saharan Africa but common in Central and South America, India, and Southeast Asia. Fixation of the mutation in Africa presumably occurred because of positive selective pressure from malaria. Together with *CCR5Δ32*, Duffy −46C is the strongest genetic resistance factor known for any infectious disease in humans. Duffy deficiency in humans and knockout mice is not associated with any known health problems under unstressed conditions. Chemokine control of *P. falciparum* malaria is less well studied, although in an intriguing development endothelial cell CX3CL1 was reported to bind parasite-infected erythrocytes in vitro (192), suggesting that the parasite expresses a mimic for the CX3CL1 receptor CX3CR1. Conversely, the G glycoprotein of respiratory syncytial virus has been reported to function as a CX3CL1 mimic, binding to CX3CR1 to induce chemotaxis and possibly promote viral entry (193), and human cytomegalovirus encodes US28, a chemokine receptor that is able to bind CX3CL1, possibly to mediate viral attachment to target cells. Together, these examples show the rich dialogue between hosts and pathogens using the chemokine system as a preferred method of communication.

Kaposi's Sarcoma

A full discussion of the many virally encoded chemokines and chemokine receptors is beyond the scope of this chapter (Table 26.7) but can be found in recent reviews (26,27). HHV8 ORF74 deserves special mention, however (194). HHV8 encodes three CC chemokines, vMIP-I, -II, and -III, as well as a constitutively active CC/CXC chemokine receptor named vGPCR, encoded by ORF74. All of these factors are angiogenic and may contribute to the pathogenesis of Kaposis sarcoma (KS), a highly vascular, multicentric, nonclonal tumor caused by HHV8, typically in a setting of immunosuppression such as in HIV/AIDS. Consistent

▌ **TABLE 26.7 The Viral Chemokine System**[a]

Structural classification

Chemokines (e.g., HHV8 vMIP-I, -II, and -III; Molluscum
  contagiosum virus MC148-R)

7TM chemokine receptors: ligand-regulated and/or constitutively
  active (e.g., HCMV US28, HHV8 vGPCR)

Unique structure

Chemokine-binding proteins (e.g., γHV68 vCKBP-III)

Chemokine mimics (e.g., HIV gp120)

Functional classification

Cell entry factors (e.g., HIV gp120)

Leukocyte chemoattractants (e.g., HHV8 vMIP-II)

Immune evasion

Chemokine scavengers (e.g., γHV68 vCKBP-III)

Chemokine-receptor antagonists (e.g., Molluscum contagiosum
  virus MC148-R)

Angiogenic factors (e.g., HHV8 vGPCR)

Growth factors (e.g., HHV8 vGPCR)

[a]The role of chemokines in immunoregulation may be revealed by studying
the viral chemokine system. Viral chemokine elements may also have
applications as therapeutic agents.

with this, vGPCR induces KS-like tumors when expressed constitutively or inducibly in transgenic mice on endothelial cells. The mechanism may involve signaling through diverse pathways, including the nonconventional G protein Gq, and phosphorylation of tuberin, which promotes activation of mTOR, a rapamycin-sensitive target, through direct and paracrine mechanisms (195). The latter may include activation of NFκB and induction of angiogenic factors such as VEGF and proinflammatory chemokines and cytokines. Thus, this virus appears to have converted a hijacked receptor, probably CXCR2, into a regulator of gene expression. The model identifies rapamycin as a candidate therapeutic in Kaposi's sarcoma.

Atherosclerosis

There is now compelling genetic evidence from knockout mice and human disease cohorts that CX3CR1 is a significant proatherogenic factor. The mechanism remains unclear but may involve induction of CX3CL1 on vascular smooth muscle cells, and recruitment and retention of CX3CR1-positive monocytes to plaque through the dual chemotactic and adhesive functions of this ligand–receptor pair (196). The evidence in humans is based in part on consistent association of a defective receptor variant named CX3CR1 M280, with reduced risk of cardiovascular disease endpoints in multiple cohort studies (197). There is also extensive evidence in mouse models for a proatherogenic role for CCL2 and its receptor CCR2 (5).

Adoptive transfer studies of bone marrow from knockout mice have also revealed a role for CCR5 and CXCR2 in mouse models of atherosclerosis. CXCR2 may work by promoting monocyte adhesion to early atherosclerotic endothelium, through interaction with its mouse ligand KC and activation of the VLA-4/VCAM-1 adhesion system (198). Immunoneutralization experiments have revealed a role for CCR7 on foam cells in a mouse model of atheroregression (199). Surprisingly, CCR1 and CXCL16 deficiency appeared to increase inflammation in atherosclerosis models (200). CXCL10 has also been implicated in atherogenesis in a mouse model, possibly acting by recruitment of CXCR3$^+$ Th1 cells. Lack of CXCL10 was also associated with a relative increase of regulatory T cells in plaque (201). Additional work will be needed to integrate these findings into a mechanistic model of how chemokines regulate atherosclerosis.

Autoimmunity

Two human diseases have been identified in which chemokines act as autoantigens for autoantibodies. The first, heparin-induced thrombocytopenia (HIT), is the only human autoimmune disease directly linked mechanistically to chemokines (202). An established risk factor for thromboembolic complications of heparin therapy, HIT occurs in 1% to 5% of patients treated with heparin and is the result of autoantibodies that bind specifically to CXCL4/heparin complexes in plasma. The second, autoimmune myositis, is associated with autoantibodies to histidyl tRNA synthetase, a protein synthesis factor that is also able to induce DC chemotaxis, apparently by acting as an agonist at CCR5 (64). Its exact importance in promoting inflammation in myositis has not been established. Several other autoantigens have also been shown to activate chemokine receptors in vitro.

In general, T-cell–dependent autoimmune diseases in humans such as psoriasis, multiple sclerosis (MS), rheumatoid arthritis (RA), and type 1 diabetes mellitus are associated with inflammatory chemokines and tissue infiltration by T lymphocytes and monocytes expressing inflammatory chemokine receptors. Rheumatoid arthritis has been consistently negatively associated with homozygous *CCR5Δ32*, suggesting that CCR5 is important in pathogenesis in humans (203). Consistent with this, Met-RANTES, a chemically modified variant of CCL5 that blocks CCR1, CCR3, and CCR5, was beneficial in a collagen-induced arthritis model in DBA/I mice.

Numerous chemokine receptors affect immunopathogenesis in mouse experimental allergic encephalomyelitis (EAE), a model of MS. In most cases, for example, CCL2, CCL3, and CCR2, gene disruption results in attenuation of disease. Neutralization of CCL3 and CCL2 with MAbs markedly reduced the early and relapsing phases of EAE, respectively. In contrast, CX3CR1$^{-/-}$ mice have increased mortality, nonremitting spastic paraplegia, and hemorrhagic inflammatory lesions in EAE. The phenotype is associated with a selective defect in migration of NK cells, which strongly express this receptor, to the central

nervous system, suggesting that NK cells are negative immunoregulators in this context (204). Mice that lack D6, the chemokine scavenger, have decreased severity of EAE, because of decreased T-cell infiltration, which is opposite to prediction for a negative regulator, and opposite to what was observed for D6 knockouts in a psoriasis model (205). *CCR5Δ32* homozygotes have been reported who have MS, indicating that this receptor is not required for disease.

Paradoxically, in some cases, blocking chemokine receptors may lead to increased inflammation, as has been shown for CCR1 and CCR2 in nephrotoxic nephritis and glomerulonephritis mouse models. This is associated with increased renal recruitment of $CD4^+$ and $CD8^+$ T cells and macrophages and enhanced Th1 immune responses; however, the exact mechanism is not defined.

Acute Neutrophil-mediated Inflammatory Disorders

Many neutrophil-mediated human diseases have been associated with the presence of CXCL8, including psoriasis, gout, acute glomerulonephritis, acute respiratory distress syndrome (ARDS), rheumatoid arthritis, and ischemia-reperfusion injury. Systemic administration of neutralizing anti-CXCL8 antibodies is protective in diverse models of neutrophil-mediated acute inflammation in the rabbit (skin, airway, pleura, glomeruli), providing proof-of-concept that CXCL8 is a nonredundant mediator of innate immunity and acute pathologic inflammation in these settings. Moreover, CXCR2 knockout mice are less susceptible to acute urate crystal-induced gouty synovitis, and SB-265610, a nonpeptide small-molecule antagonist with exquisite selectivity for CXCR2, prevents neutrophil accumulation in the lungs of hyperoxia-exposed newborn rats. Together the results identify CXCL8 and its receptors as candidate drug targets for diseases mediated by acute neutrophilic inflammation. CXCR2 knockout mice also have delayed wound healing.

Transplant Rejection

An advantage of transplant rejection over other animal models of human disease is that in both the human and animal situations, the time of antigenic challenge is known precisely. The most extensive analysis of the role of chemokines in transplant rejection has been carried out in an MHC class I/II-mismatched cardiac allograft rejection model in the mouse, which is mediated by a Th1 immune response (206). Similar sets of inflammatory chemokines are found in the mouse model as in the human disease. ELR^+ CXC chemokines and CCL2 appear early, and are probably made by engrafted blood vessel endothelial cells. These are associated with neutrophil and mononuclear cell accumulation. On day 3 after engraftment, CCL2 is still present, and the three CXCR3 ligands CXCL9–11 and the

CCR5 ligands CCL4 and CCL5 appear. Of the CXCR3 ligands, CXCL10 appears earliest and in largest amounts, probably in response to IFN-γ coming from NK cells. This phase is associated with transition to an adaptive immune response with accumulation of trafficking of recipient T cells, macrophages, and DCs to the graft, followed by acute and chronic rejection. Graft arteriosclerosis, which is distinct from the lipid-driven disease, may be driven in part by CXCL10 and IFN-γ. Analysis of knockout mice has demonstrated that while multiple chemokine receptors contribute to rejection in this model, there is a marked rank order: CXCR3 >> CCR5 > CCR1 = CX3CR1 = CCR2. Most impressively, rejection and graft arteriosclerosis do not occur if the recipient mouse, treated with a brief, subtherapeutic course of cyclosporin A, is $CXCR3^{-/-}$ or if the donor heart is $CXCL10^{-/-}$, identifying this axis as a potential drug target. Neutralization of CXCL9, a CXCR3 ligand that appears later than CXCL10, can also prolong cardiac allograft survival, and delay T-cell infiltration and acute rejection in class II MHC–disparate skin allografts. In rats, BX-471, a nonpeptide small-molecule antagonist of CCR1, was reported to be effective in heart transplant rejection. In humans, CCR5 may be important in chronic kidney allograft rejection, because individuals who are homozygous for *CCR5Δ32* are underrepresented among patients with this outcome in a large German kidney transplantation cohort (207).

Allergic Airway Disease

Chemokine receptors associated with asthma include CXCR2, CXCR4, CCR3, CCR4, and CCR8. CCR3 is present on eosinophils, basophils, mast cells, and some Th2 T cells, and CCR4 and CCR8 identify airway T cells of allergen-challenged atopic asthmatics. CCR8 knockout mice have reduced allergic airway inflammation in response to three different Th2-polarizing antigens: *Schistosoma mansoni*–soluble egg antigen, ovalbumin, and cockroach antigen (208). The situation with the CCR4 axis is unsettled, because neutralization of the CCR4 ligand CCL22 was protective in a mouse model of airway hyperreactivity and eosinophilic inflammation, but CCR4 gene knockout was not. Because CCR4 is expressed on both Th2 effector cells and $CD4^+CD25^{high}Foxp3^+$ regulatory T cells, the relative functionality of other chemokine receptors on these cells would be expected to determine the overall effect of blocking CCR4 on allergic disease. A role for the CCR3 axis in asthma has been supported by CCL11 neutralization in guinea pig, and CCR3 gene knockout in mouse. Only one of three studies of CCL11 knockout mice found protection, ∼40% reduction in airway eosinophils in ovalbumin-sensitized/challenged mice, possibly as a result of compensation by other CCR3 ligands. The net effect of CCR3 knockout was expected to be more profound, but the exact phenotype depends dramatically on the specific method of

sensitization and challenge, because of complex and opposite effects on eosinophil and mast cell trafficking. Thus CCR3$^{-/-}$ mice sensitized IP have reduced eosinophil extravasation into the lung but an increase in mast cell homing to the trachea, with the net result being a paradoxical increase in airway responsiveness to cholinergic stimulation. Mast cell mobilization is not seen after epicutaneous sensitization, and these animals therefore have reduced airway eosinophilia on challenge and no increase in airway hyperresponsiveness (209,210). CCR3 and its ligands have also been clearly shown to play a critical role in an *Aspergillus*-induced chronic allergic airway disease mouse model, in part because of failure of eosinophils to traffic to the lung (211). CCR6 also appears to play a role, because CCR6$^{-/-}$ mice have decreased allergic airway inflammation in response to sensitization and challenge with cockroach antigen, which is consistent with the induction of its ligand CCL20 in this model. CXCL12/CXCR4 may be more than a homeostatic regulator, because neutralization of either ligand or receptor resulted in decreased lung eosinophilia and airway hyperreactivity in a mouse model of allergic airway disease (212).

Cancer

Many chemokines have been detected in situ in tumors, and cancer cells have been shown to produce chemokines and express chemokine receptors (34). However, the exact role played by endogenous tumor-associated chemokines in recruiting tumor-infiltrating lymphocytes and tumor-associated macrophages and in promoting an antitumor immune response has not been delineated. On the contrary, there are data from mouse models suggesting that the overall effect may be to promote tumorigenesis through additional effects on cell growth, angiogenesis, apoptosis, immune evasion, and metastasis (213). Controlling the balance of angiogenic and angiostatic chemokines may be particularly important (214). This has been shown in several instances, including human non-small-cell lung carcinoma (NSCLC), in which the ratio of ELR to non-ELR CXC chemokine expression is high, and where in a Scid mouse model neutralization of endogenous tumor-derived CXCL8 (angiogenic) could inhibit tumor growth and metastasis by about 50% through a decrease in tumor-derived vessel density, without directly affecting tumor-cell proliferation. Chemokine receptors on tumor cells have been shown to mediate chemokine-dependent proliferation directly, for example in the case of CXCL1 in melanoma, and metastasis, in the case of CXCR4 in a mouse model of breast cancer and glioblastoma. Moreover, chemokines may function in cancer by reprogramming cancer-associated stromal fibroblasts to a senescent pro-tumorigenic state, as shown recently in ovarian cancer for CXCL1 (215). It remains to be seen how general these effects are in other cancers.

THERAPEUTIC APPLICATIONS

Chemokines and Chemokine Receptors as Targets for Drug Development

Although chemokine-targeted drug development is still in the early stages and there are no approved drugs, there are already two accomplishments that deserve special mention: first, chemokine receptors are the first cytokine receptors for which potent, selective nonpeptide small-molecule antagonists have been identified that work in vivo, and second, targeting host determinants, as in the case of CCR5 and CXCR4 in HIV/AIDS, is a new approach in the development of antimicrobial agents. Other reasonable disease indications are Duffy in *P. vivax* malaria; CXCR2 in neutrophil-mediated inflammation such as chronic obstructive pulmonary disease; CXCR3 and CCR2 in Th1-driven disease; CCR2 and CX3CR1 in atherosclerosis; CCR3 and possibly CCR4 and CCR8 in Th2 diseases such as asthma; and CCR9 in inflammatory bowel disease.

As of early 2007, potent and selective nonpeptide small-molecule antagonists had been discovered for CXCR1-4 and CCR1-5, reported in ∼250 patent applications, and tested in nine clinical trials (37). A nitrogen-rich core is a common structural feature for many of these molecules, which typically block ligand binding by acting at a conserved allosteric site analogous to the retinal-binding site in the transmembrane region of rhodopsin.

To date, Maraviroc is the only FDA-approved drug targeting the chemokine system, blocking CCCR5 in HIV/AIDS. AMD 3100 targeting CXCR4 has been shown to be as effective as GCSF in Phase 3 clinical trials for hematopoietic stem cell mobilization. Although small molecules taken as pills are the main goal, other blocking strategies are being actively pursued, including ribozymes, modified chemokines (e.g., amino-terminally modified versions of CCL5) and intrakines, which are modified forms of chemokines delivered by gene therapy that remain in the endoplasmic reticulum and block surface expression of newly synthesized receptors. Strategies to block chemokine/GAG binding are also under investigation (216).

Success in therapeutically targeting the chemokine system must overcome numerous potential and actual obstacles, including chemokine redundancy, the inability to treat in advance of most clinical illnesses, and the unreliability of many preclinical disease models.

Chemokines as Biologic Response Modifiers

Both inflammatory and homeostatic chemokines are being evaluated for therapeutic potential as biologic response modifiers, acting mainly as immunomodulators or as regulators of angiogenesis. Studies to date have not revealed major problems with toxicity, and efficacy has been observed in animal models of cancer, inflammation, and

infection. To date, clinical trials in cancer and stem-cell protection have been disappointing. Chemokines are also being developed as vaccine adjuvants, delivered either as pure protein, as immunomodulatory plasmid, or as recombinant protein within antigen-pulsed DC. Chemokine gene administration has also been shown to induce neutralizing antibody against the encoded chemokine, and has successfully blocked immune responses and improved EAE and arthritis scores in rodent models.

Many chemokines, when delivered pharmacologically as recombinant proteins or by plasmid DNA or in transfected tumor cells, are able to induce immunologically mediated antitumor effects in mouse models and could be clinically useful. Mechanisms may differ depending on the model but may involve recruitment of monocytes, NK cells, and CD8+ cytotoxic T cells to tumor. Chemokines may also function as adjuvants in tumor antigen vaccines. Chemokine–tumor antigen fusion proteins represent a novel twist on this approach that facilitate uptake of tumor antigens by APCs via the normal process of ligand-receptor internalization. Non-ELR CXC chemokines such as CXCL4 also exert antitumor effects through angiostatic mechanisms. Despite impressive antitumor effects in animal models, translating chemokines to patient therapy remains a major challenge.

CONCLUSION

The immune system, unlike all others, is a system in motion, and the study of chemokines has provided major new insights into how order is maintained as cells enter a tissue, traffic to a target, and in some cases leave and recirculate. In addition, chemokines are increasingly appreciated as multifunctional cytokines, playing large roles in some cases such as CXCL12 in development, and perhaps smaller or less well-appreciated ones in immune-activation processes. Most impressive is the degree to which pathogens and cancer cells have co-opted the chemokine system for harmful purposes. A major challenge for future research will be to attempt to target this misuse therapeutically, and great progress has been made in HIV toward this end.

Programmed Cell Death

Nicolas Bidère, Helen C. Su, and Michael J. Lenardo

INTRODUCTION

Nontransformed cells have a finite lifespan. After a characteristic number of divisions, cells can undergo senescence, stop dividing, and subsequently die. Most of our cells will die long before we do, and evidence suggests that this is important for our health. However, adult vertebrates, as well as their internal organs, generally stay a constant size, so a form of homeostasis is implied (1). In certain organs, this involves a constantly fluctuating dynamic equilibrium. A prime example is the immune system, which employs cell renewal, expansion, and elimination in carrying out its function *(2,3,4,5)*. These changes can be systemic or localized to anatomic sites proximate to an antigen stimulus and may affect specific subsets of immune cells as dictated by the stimulus.

Programmed cell death (PCD) denotes a set of internal biochemical mechanisms that cause specific cells to die

under defined conditions that are typically advantageous to the organism (6). Reasons for cell elimination include cell excess, improper cell differentiation, cell transformation, genetic damage to cells, and infection. In addition to this operational definition, considering a death event "programmed" usually means that one or more genes are required. This chapter has been organized so that we start with a broad overview of general immunoregulatory principles and then provide details on the molecules involved in PCD in specific sections at the end. Although there are conceptual antecedents from the 19th century, the selection of cells for survival or death by specific external stimuli was introduced by Levi-Montalcini for neural cells in the 1940s and later by Burnet for lymphocytes. Investigation into the molecular mechanism of PCD began in the mid-1980s and accelerated rapidly. DNA sequence databases permitted the rapid identification molecules involved in PCD *(7)*. Although PCD is a large and contentious area of cell biology

research, molecular advances have established a firm and tractable theoretical foundation. Remarkably, much of what we will discuss was almost completely unknown two decades ago. Yet these pathways are at work every day in our bodies to control responses to infectious agents, establish cellular homeostasis, prevent autoimmunity, and avert lymphoid malignancies.

OVERVIEW: CELLULAR HOMEOSTASIS AND PCD IN MULTICELLULAR ORGANISMS

Internal programs of death are likely to exist in all mammalian cells. Martin Raff has suggested that these internal programs must be constantly and actively suppressed (8). For experimental investigation, it is thus important to discriminate between accidental cell death and that initiated or "programmed" by an internal biochemical mechanism. The term *apoptosis,* a Greek word meaning "falling off" as in leaves from a tree, was introduced in 1972 by Andrew Wyllie and coworkers to describe the normal, presumably programmed, attrition of cells (9). It was defined microscopically as cell shrinkage with nuclear and cytoplasmic condensation within an intact, but blebbed, cell membrane (10) (Figure 27.1B, C). This cell phenotype has long been associated with cell death *(11)*. Apoptosis is now mainly identified by the biochemical effects of the caspase family of proteases *(12)*. Caspases are important in two respects. First, they are a feature of most, if not all, apoptosis pathways. Second, once highly activated, they usually represent a commitment to apoptosis that is not reversible, although there are suggestions that low-level caspase activation may occur during lymphocyte activation *(13,14)*. For these reasons, caspases have been regarded as a final common pathway of apoptosis. In fact, the concept of PCD was significantly strengthened by the identification of caspases and other molecules that comprise dedicated internal biochemical death pathways. In general, the molecular components of the death mechanism are preassembled and available without new gene transcription or protein synthesis (6). For example, caspases are constitutively expressed in the cytoplasm of the cell as zymogens. Once proteolytically activated, caspases carry out specific protein cleavages leading to the morphological changes of apoptosis. The proteolytic substrates of caspases are highly selective because most proteins remain uncleaved. A panoply of molecular events entrained to caspases includes cleavage of chromosomal DNA, nuclear chromatin condensation, exposure of phosphatidylserine on the exterior of the cell membrane, proteolysis of specific proteins including other caspases, and mitochondrial changes. These processes are detectable by simple assays in tissue culture cells *in vitro* or, in some cases, *in vivo*. Protocols for these assays have been well described *(15,16)*.

Cells that die without the characteristics of apoptosis typically undergo what is usually called *necrosis*. While necrosis is often associated with accidental cell death, it may also result from programmed mechanisms. In certain cases, nonapoptotic mechanisms of cell death can be promoted by caspase inhibition (17). The appearance of a necrotic cell differs dramatically from apoptosis. Necrotic cells swell and lose the integrity of internal organelles and the cell membrane, giving an enlarged, "fractured" appearance under the microscope (Figure 27.1D). Recently, various research groups have begun to define molecular programs resulting in necrotic death (18). Several varieties of "programmed" necrosis that share the hallmarks of early loss of plasma membrane integrity and excessive reactive oxygen species (ROS) have been described. Programmed necrosis that involves the RIP serine/threonine kinase has been well documented in lymphocytes, especially under conditions of caspase inhibition (17,18). A closely related variant of this cell death program has been defined as necroptosis (19). Finally, the induction of autophagy has been genetically linked to a necrotic program of death (20). Autophagy is induced by starvation or other stimuli and involves internal membrane rearrangement leading to engulfment of portions of the cytoplasm, which are then degraded by fusion with lysosomes. Under death conditions, this mechanism leads to membrane damage and necrosis by ROS, which overaccumulate because of accelerated catalase degradation (21). The precise role of these necrosis programs, especially autophagic cell death, in immune function has not yet been worked out. However they are often provoked by the inhibition of caspase-dependent apoptosis.

Thus, it is important to distinguish between "programmed" necrosis and necrosis due to accidental causes, because these involve very different molecular events. It has been generally argued that apoptosis, which preserves membrane integrity, prevents inflammation from released cellular contents, whereas necrosis results in total cellular breakdown and content release which causes an inflammatory response *(22)*. There are contrasting views on whether remnants of apoptotic or necrotic cells are more immunogenic when engulfed by antigen presenting cells (APCs), though exposure to necrotic cells can cause dendritic cell (DC) maturation (*23,24,*25). The distinct immunological effects due to apoptosis and necrosis remain the subject of substantial experimental exploration.

As we will argue later in this chapter, the necessity of cellular homeostasis as well as the acute need to eliminate cells that are harmful or nonfunctional led to the early emergence of conserved cell death mechanisms during evolution *(11)*. Work by Horvitz and colleagues genetically identified several molecules essential for the death of specific cells during the development of the roundworm *C. elegans* that have subsequently been found to be homologues for mammalian PCD genes (26). It is clear from this
FIGURE 27.1 Electron microscopy elucidates the morphology of different forms of PCD. **A:** A normal, unstimulated Jurkat leukemia cell. **B:** Jurkat cell undergoing apoptosis in response to Fas receptor stimulation. Notice the condensed chromatin and the blebbing, but maintenance of plasma membrane integrity. **C:** Jurkat cell undergoing apoptosis in response to staurosporine treatment. Note the prominent nuclear condensation. **D:** Necrosis of human peripheral blood T lymphocyte infected with the human immunodeficiency virus. Notice the general loss of cellular integrity as well as the lack of chromatin condensation in the dying cell. (Figure courtesy of Diane Bolton and Jan Orenstein)

simplified system that the molecular logic of one form of cell death was likely established early in evolving multicellular organisms *(27)*. PCD mechanisms are now evident in most contemporary multicellular organisms from plants to humans, although it is not clear whether convergent evolution or conservation of function is responsible. However, the molecular pathways in worms and other simple organisms are rudimentary compared with the complexity found in mammalian PCD systems. To understand how these mechanisms contribute to immunity, we focus on

mice and humans, which are the subjects of most immunological research.

PCD AND IMMUNE REGULATION

The fundamental unit of immune responsiveness is the cell. Lymphocytes, the major immune cells, are distinguished by expressing a unique clonotypic antigen receptor. A large number of lymphocytes with different

receptor specificities are generated during ontogeny (e.g., the "immune repertoire"), and these cells can be programmed to expand or die throughout the life of the organism. Somatic hypermutation during B cell expansion in the germinal center can expand the repertoire. Although the level of antigen presentation, the degree of lymphocyte responsiveness (versus nonresponsiveness or anergy), and other factors also play important roles, the presence or absence of cells with specific recognition properties at any given time is a primary determinant of the quantitative response to any antigenic stimulus. The homeostasis of major lymphocyte populations is independently regulated such that deficits in B cells, T cells, or even major T cell subpopulations ($\alpha\beta$ versus $\gamma\delta$-, or CD4 versus CD8) may qualitatively alter but do not prevent the normal homeostasis of the remaining populations. During development, lymphocytes respond to the antigenic environment with either survival or death (28). Developmental PCD eliminates lymphocytes that cannot recognize antigen appropriately or have potentially dangerous self-reactivity (28,29). In the mature immune system, death is principally a negative feedback response that counterbalances proliferative responses to antigen (30). Although the clonal selection theory of F. M. Burnet encompassed clonal elimination during ontogeny, in the mature immune system, it allowed only selective expansion of antigen-stimulated lymphocytes. However, antigen-specific regulation of mature lymphocyte survival also powerfully controls immune responses and tolerance (4,30,31). Since the organism encounters an unpredictable universe of antigens in a lifetime, it is essential that there is feedback regulation of adaptive immune responses. Feedback is an essential element of any dynamic system in which final outcomes cannot be predicted from the starting conditions *(32)*. To achieve measured immune responses, proliferation and death are coordinated by feedback regulation to control the number of immunologically responsive cells. Moreover, during immune reactions, potentially harmful self-reactive cells may unexpectedly increase; because they continue to signal, these self-reactive cells are preferentially eliminated by feedback death mechanisms. Hence, homeostasis of both lymphocyte numbers and reactivities can be continuously maintained.

Thymic Deletion: Positive and Negative Selection

Thymic selection represents an intriguing example of apoptosis in which the same receptor—the clonotypic T cell receptor (TCR)—can lead to diametrically opposite outcomes depending on the level of stimulation (28,29). During development, when thymocytes express the TCR and both the CD4 and CD8 coreceptors (the "double-positive" stage), thymocytes will undergo apoptosis if they receive no TCR stimulation. This has been called *death by neglect (33)*. This process will eliminate thymocytes that have not productively rearranged the TCR genes or have no capacity to recognize antigen in the context of self–major histocompatibility complex (MHC). "Low-level" stimulation of the TCR antagonizes death by neglect. This protective event insures MHC-specific antigen recognition by T cells and is called *positive selection (34)*. While weak TCR signals can deliver an anti-apoptotic stimulus, strong TCR engagement of double-positive thymocytes delivers a pro-apoptotic signal. This event, termed *negative selection,* prevents the emergence of strongly autoreactive lymphocytes from the thymus *(33)*. This deletion step is a major mechanism of central tolerance and the prevention of autoimmunity *(35)*. These processes of selection employ caspase-dependent apoptosis and rapid phagocytosis of the dead thymocytes (*36*,37). Hence, thymocytes travel a narrow bridge of TCR avidity during development and will die if they deviate from it.

The differences between the neglect (or null), weak, and strong signals that result in life or death appear to be determined at early stages of TCR signaling (38,39). Death receptors (discussed later) appear not to be crucial; instead, there is a direct connection of the TCR signaling apparatus to mitochondrial death pathways (40,41,42,43). Although there is not complete certainty about how the TCR dictates life or death at specific antigen levels, the answer to this puzzle will almost certainly reside in the complex signal pathways emanating from this receptor. TCR engagement that causes transient induction of the Erk kinase is associated with positive selection, whereas slow but constant Erk activity is associated with negative selection (44–46). Other distinctions in TCR signaling have been identified. Signaling through phosphotidylinositol-3 kinase, the anti-apoptotic Akt kinase, and the retinoid orphan receptor (ROR)–gamma may promote thymocyte survival (reviewed in [38,47]). Gene knockouts in mice have revealed that several transcription factors, such as E2A, Id3, and IRF-1, can affect thymic cellularity, indicating that differential signaling may trigger transcriptional events that regulate cell survival (*48–50*,51). Finally, Andreas Strasser has emphasized that various forms of physiological cell death are likely to involve the subset of BH3-only proteins in the Bcl-2 family (52,53). The activation of proapoptotic BH3-only proteins, such as Bak, Bid, and especially Bim, by TCR signals initiates mitochondrial apoptosis during thymic selection processes. Thus, early TCR-induced signaling differences directly entrain transcriptional events that modulate BH3-only regulators of mitochondrial apoptosis. These distinct signals are tied to specific microenvironments within the thymus in which positive and negative selection occur (54). Hence, by intracellular communication with distinct apoptosis regulatory molecules, the TCR has a remarkable ability to signal life or death by the apparent strength of stimulus it receives.

PCD and the Homeostasis of Peripheral T Cells

Death of peripheral T cells differs markedly from thymocyte selection in that PCD of mature lymphocytes occurs mainly in cells that have proven usefulness (i.e., they have been already activated by antigen). This is because PCD of mature T cells is employed primarily to counter antigen-driven proliferation of activated T cells. In general, most naïve lymphocytes survive and circulate in the body in a resting state (G_0). The survival of such resting T cells is constitutively maintained by the presence of contact with MHC, the cytokine IL-7, and expression of the anti-apoptotic protein Bcl-2 (35,55,56,57). During an active immune response, T lymphocyte proliferation can involve as much as a 1,000-fold expansion within days. Such explosive proliferation is necessary to counter the extraordinarily rapid propagation of microbial pathogens. However, these activated and cycling T cells are potentially damaging due to toxic effector functions and potential cross-reactivity with self-antigens. Activated T cell expansion does not go unchecked and is subject to negative feedback

in the form of cell death. However, because immune responses are directed at specific antigens, they must be independently regulated since some responses might expand while others contract. The immune system has developed propriocidal mechanisms to control independent populations of activated T cells. *Propriocidal regulation* refers to the various negative feedback death mechanisms that maintain homeostasis of mature peripheral T cells in an antigen-specific manner. These potently restrain antigen-activated T cells and tightly control lymphocyte numbers during and at the conclusion of immune responses.

Propriocidal regulation of T cells is triggered by remarkably simple attributes of T cell activation—the level of cell cycling and the level of antigen restimulation (30,55). These two features are ideally suited for triggering negative feedback death because they provide both a "sensing" mechanism for the level of active T cell proliferation and a negative response mechanism sensitive to the level of antigen stimulation. There are essentially two different mechanisms: 1) active or antigen-stimulated PCD, and 2) passive or lymphokine withdrawal PCD (Figure 27.2) (4,58,59,60). These have different roles and occur at
FIGURE 27.2 Propriocidal regulation of immune cells. Shown are the apoptosis pathways that govern T lymphocyte homeostasis by the antigen-restimulated (extrinsic death) and no antigen (cytokine withdrawal [intrinsic death]) pathways of apoptosis. Also shown are the regulation of B cells by FasL expressed by T cells, and DCs by TRAIL expressed by T cells.

different times, as will be described in detail later. In some respects, it is paradoxical that lymphocytes that respond well to foreign antigen and presumably could have protective value are actively eliminated. However, it is vital to constrain the number of activated T cells to prevent unhealthy effector or autoimmune reactions. During a strong immune response, lymphocytes that cross-react with self-antigens may proliferate. The propriocidal mechanisms that cause these cells to die upon encountering self-antigens could be an important mechanism of preserving self-tolerance. By this formulation, tolerance is a quantitative effect that is due to the low number of significantly self-reactive lymphocytes in the naïve organism. Clonal expansion during immune responses can unleash dormant or infrequent self-reactive clones, called *forbidden clones* by Burnet, creating an autoimmune diathesis. Propriocidal death reduces these clones and thereby promotes tolerance. Active antigen-induced propriocidal death, which is induced by high or repeated doses of antigen, is especially well suited for the elimination of self-reactive clones since self antigen is likely to be present in continuously high amounts (30,55).

Extrinsic or Antigen-stimulated T Lymphocyte Death

The extrinsic death mechanism involves apoptosis of mature T cells in response to antigen stimulation. This requires the T cells to be activated and cycling at the time that they undergo strong antigenic restimulation (30,55). The death is indirect in the sense that it requires the antigen-induced secretion of death ligands that engage specific apoptosis-inducing death receptors (DRs) in the tumor necrosis factor receptor (TNFR) and ligand superfamilies (Figure 27.2) (61,62). Current evidence suggests that Fas ligand (FasL) as well as TNF are the key death ligands that mediate this process in mature CD4$^+$ and CD8$^+$ T cells (4,5,63). Th2-differentiated CD4 cells are less sensitive than their Th1-differentiated counterparts to Fas-mediated killing (64). Instead, they preferentially die through a suicidal pathway that triggers internal release of granzyme B (65,66). Nagata originally observed that the lymphoproliferative and autoimmune phenotype of *lpr* mice was due to genetic alterations of Fas, and a similar disease in *gld* mice was due to a mutation in FasL (67,68). Defects in Fas (CD95) or FasL cause severe derangements of lymphocyte homeostasis and tolerance that will be detailed later in this chapter. In humans, defects in Fas and FasL cause the autoimmune lymphoproliferative syndrome (ALPS) types Ia and Ib, respectively (69). An alternative mechanism of propriocidal regulation is via perforin, which is a chief mediator of cytolytic T cell killing of target cells. Perforin defects in both mice and humans cause impaired clearance of activated CD8$^+$ T cells (70,71,72,73). Often these forms of death are called

"activation-induced cell death" (AICD), but this is a misnomer *(74)*. AICD has been used to describe any form of death of activated T cells, thus causing confusion among investigators working on molecularly distinct death pathways (4,75). Activation *per se* does not directly cause cell death; instead, extrinsic death induction requires antigenic restimulation of activated T cells (i.e., TCR reengagement after the initial activation). For resting T cells, antigen encounter under costimulatory conditions leads to activation with very little cell death. Obviously, if the initial activation directly induced death, this would preclude immune responses. On the contrary, activated, cycling T cells do not spontaneously die by FasL or TNF unless they are strongly restimulated by antigen in the activated state, which causes up-regulation of the genes for these death cytokines and responsiveness to them (76).

Extrinsic death is a negative feedback mechanism, which explains why it is triggered by lymphokine-induced cell cycling (usually caused by IL-2) and reengagement of the TCR. IL-2-induced cell cycling indicates that there has been a productive antigen response and the T cells are multiplying. Because T cells can expand rapidly to great numbers, a large fraction of cycling T cells dictates a need to down-regulate the response to any further antigen exposure. The presence of repeated or continuously high amounts of antigen would be a powerful stimulus to greater proliferation. Under these conditions, the system programs a fraction of the restimulated cells to undergo apoptosis by death ligand production or perforin. Unchecked exponential T cell expansion is thereby prevented by a simple and specific feedback loop. Like most negative feedback systems, the propriocidal response directly reverses the ongoing process of proliferation by eliminating activated T cells. Antigen-induced death provides an explanation for many historical observations in the literature that show that reapplication or continuous presence of high concentrations of antigen can lead to suppression rather than augmentation of an immune response (reviewed in [55]).

Sensitivity to the extrinsic death mechanism is chiefly due to the effect of IL-2 in inducing cell cycle progression into late G1 or S phase, which confers susceptibility to death (77–79). The requirement for cell cycle progression has not been fully explained but appears to be necessary for apoptosis induced by TCR engagement or with direct Fas stimulation. Other cytokines that augment T cell cycling such as IL-4, IL-7, and IL-15 can also promote cell death to some degree but none with the potency of IL-2 (76). Hence, the theory of propriocidal regulation advanced the concept that IL-2 would have an important regulatory role in the elimination of activated T cells in addition to its previously known role in lymphocyte proliferation (55). This concept was later validated when genetic deficiencies of IL-2 and IL-2 receptor in mice were found to have defective apoptosis of activated T cells and autoimmunity

(80,*81,82*). Although the immunopathology in these animals has been also recently attributed to T regulatory cells, the latter may constitute another form of clonal deletion by cytokine competition. This surprising property of IL-2 is important to consider in the use of IL-2 as a therapeutic agent or vaccine adjuvant. It also underscores an important feature of feedback regulation—that to achieve a maximal response for, say, a vaccine, more stimulation is not necessarily better. In a variety of test situations, extrinsic antigen-induced death decreases the number of T cells, but does not completely eliminate the T cell immune response (30,31). In certain extraordinary conditions, such as high levels of a noncytopathic or chronic virus, essentially all responding T cells can be eliminated (83). FasL expressed on T cells also causes the death of B cells, which do not themselves express FasL (84). This causes a parallel regulation of B cell proliferation by Fas-induced death that can be antagonized by B cell receptor (BCR) engagement (Figure 27.2). Antigen-induced death therefore provides a mechanism to eliminate specific antigen-reactive lymphocytes under chronic stimulatory conditions when they might cause the host more harm than good.

Antigen-induced expression of death receptors and their ligands shunts a proportionate fraction of the antigen-specific activated cells, but not bystander cells, into the death pathway. The activated T cells still carry out their effector function when restimulated by antigen, but their ultimate fate is death instead of proliferation (76,83). Since the agents of cell death—Fas and other TNFRs—have no inherent antigen specificity, it is important to consider how the clonal specificity of antigen-induced apoptosis is achieved (30). For the death of activated T cells, the simple engagement of Fas by its ligand is insufficient (85,86). Efficient death induction also requires a "competency" signal from the TCR delivered at the same time FasL binds Fas (85,87). However, these signals do not require new protein synthesis and are delivered rapidly in a few hours or less (85,86). The requirement for simultaneous engagement of Fas and TCR plays a critical role in establishing the antigen-specificity of death. For example, it was shown that TCR stimulation of a specific subpopulation within a pool of Fas-expressing T cell blasts, such as with agonistic anti-Vβ8 antibody, leads only to the death of that subpopulation despite the apparent exposure of other subtypes of T cells to the Vβ8-expressing cells that have been induced to express FasL (30,85). Also, deletion *in vivo* is antigen-specific (88). The molecular nature of the competency signal is presently unknown.

Intrinsic Growth Factor Withdrawal T Cell Death

As important as it is to avert over-reaction during an immune response through extrinsic, TCR-induced death, it is equally important for the immune system to down-modulate the immune reaction after successful elimination of the pathogen. Lymphokine withdrawal death is a form of T cell apoptosis that occurs naturally at the end of an immune response when the accumulation of effector cells becomes unnecessary and potentially damaging *(89)*. When the trophic cytokine for activated T cells, typically IL-2, decreases because of reduced antigen stimulation, the excess T cells undergo apoptosis *(90)*. This form of negative feedback death may affect specific classes of T cells, for example, "effector" versus "memory" cells, though this distinction may be difficult to discern experimentally. Because most T cells in the expanded population are antigen-specific, this represents clonotype-specific T cell propriocidal regulation controlled by antigen and cell cycle progression. The activated cells can "sense" decreased antigen drive and decreased trophic cytokine, which programs them for apoptosis. The elimination of the expanded pool of activated cells, except for a small amount of memory cells, reestablishes homeostasis in T cell numbers. It has been shown that if IL-2 is exogenously delivered during a proliferative response to superantigen, the reactive T cells persist as long as lymphokine is provided (91). Therefore, the lack of IL-2 is a key element in the feedback regulation of the cellular response. Antigen and IL-2 therefore mediated propriocidal regulation in the midst of an immune response and at its conclusion downregulate T cell numbers.

Genetic studies reveal that the molecular mechanism of lymphokine withdrawal death is different than antigen-induced apoptosis (*58*,59). Although this event is often confused with extrinsic cell death mediated by Fas, DRs are not involved. Rather, cytokine withdrawal for 2 hours–4 hours commits the cell to a death pathway requiring new protein synthesis (92). Apoptosis is initiated through the mitochondrial pathway and is orchestrated by the Bcl-2 family of proteins. In fact, the ratio between the pro- and the anti-apoptotic Bcl-2 family members is believed to determine the fate of the cells. In the presence of growth factors, the anti-apoptotic Bcl-2, Bcl-X_L, and Mcl-1 proteins sequester the BH3-only activators Bim and Bid, thereby preventing the executioners Bax and Bak from permeabilizing the mitochondrial outer membrane (MOM) (see later discussion) *(93)*. Bim is an essential up-stream regulator of Bax and Bak during cytokine withdrawal-induced apoptosis in lymphocytes (for review, see [94]). Cytokine deprivation rapidly upregulates Bim mRNA levels through activation of the forkhead-like transcription factor FOXO3A. CD4$^+$ and CD8$^+$ T cells from mice homozygously deficient for Bim survived much longer than their wild-type counterparts following *in vitro* and *in vivo* activation with the superantigen *Staphylococcus aureus* enterotoxin B (95). Moreover, Bim is critical for both IL-2- and IL-7-withdrawal-induced cell death of T cells (52,95,96). PUMA, another BH3-only protein, functions synergistically with Bim downstream of FOXO3A in lymphoid

cells and accounts for the Bim-independent death (97,98). When the trophic cytokine is present, the Ser/Thr kinase Akt phosphorylates key substrates and prevents mitochondrial collapse. For example, Akt suppresses FOXO3A activity. Akt also phosphorylates the pro-apoptotic Bad protein, which is then sequestered by the 14-3-3 scaffold protein (99,100). Another target inactivated by Akt is glycogen synthase kinase-3 (GSK-3), which phosphorylates Mcl-1 on residue S159 when cytokines are removed. The rapid degradation of phosphorylated Mcl-1 by the ubiquitin-proteasome pathway disrupts the fragile equilibrium between the pro- and the anti-apoptotic Bcl-2 family members and promotes cell death (101). Thus, Akt can preserve viability by targeting appropriate Bcl-2 family members.

T Regulatory Cells

An intriguing area of immune tolerance research is the emerging understanding of a subset of CD4 T cells, termed *T regulatory* or *Treg*. These cells express the forkhead box P3 (FoxP3) transcription factor and suppress the expression of many TCR-induced genes, including cytokines and cytokine receptors (*102*,103). Similar to other subsets of T cells in their "activated" state, Tregs require common gamma chain cytokines for survival. In particular, they characteristically express the IL-2 alpha chain receptor (CD25) and require IL-2 to persist in the periphery (104). IL-7 can also act as a survival factor for Treg cells (105). A postulated function of Treg cells has been an ability to "suppress" immune responses, although the mechanism by which this is achieved has been obscure (106). One line of evidence suggests that they may have the ability to cause death by a perforin or granzyme B mediated mechanism (107,108). Tregs have been proposed to use this mechanism to kill APCs, B cells, and T cells as a means to suppress immune responses (*109*,110). This possible death mechanism is still controversial but could involve clonal deletion *(110a)*.

T Cell Memory

T cells, once activated, can persist as "memory" cells. One view is that the process involves an escape from apoptosis (37,*111–113*). Hence, such cells would have to avoid elimination by the propriocidal mechanisms. Increasing evidence supports the concept that memory is due to the long-term survival of antigen-specific T cells even without further antigen exposure. Several means to achieve such survival are possible. To escape killing by Fas and other death receptors, T cells could express c-FLIP (<u>c</u>ellular <u>FLICE</u> <u>I</u>nhibitory <u>P</u>rotein), which is a homologue of caspase-8 and -10 that has no enzymatic function but can interpose itself into the death receptor complex and block caspase activation (114). This type of inhibition has been demonstrated in B cells by the ability of Ig stimu-

lation, which upregulates c-FLIP (*115*,116), to block Fas killing *(117)*. Various "inhibitor of apoptosis proteins" (IAPs) might also interfere with DR killing (118,*119*). Further, the mitochondrial death pathway could be attenuated by upregulation of Bcl-2 and Bcl-X_L. These anti-apoptotic molecules, which are upregulated in CD8 and CD4 memory cells (*113*,120), have been shown to block lymphokine withdrawal apoptosis *(93)*. The necessity of these inhibitory molecules for the persistence of a memory population of T cells is unknown.

Another view is that long-term survival, in a nonproliferative "resting" state characteristic of "virgin" T cells, is never reestablished by memory cells. Recent work by Phillipa Marrack, Rafi Ahmed, and others reveal a surprisingly dynamic T cell memory pool. Their study proposes a constant, low-level proliferation of memory CD8$^+$ T cells that is antigen-dependent and maintained by IL-15 and to a lesser extent by IL-7 *(121,122)* (reviewed in [123]). Also, the fraction of memory cells remains constant over time, indicating that death is continuously maintaining a balance. Hence, the balance of slow proliferation and slow death ensures memory cell maintenance. As the molecular mechanism of the memory state is further elucidated, the differing views of "memory" are likely to be reconciled.

The mitochondrial pathway of death is likely to play a prominent role in the generation of memory cells. In addition to their proliferative effects, the cytokines IL-15 and IL-7 appear to promote survival of memory cells through their induction of anti-apoptotic molecules such as Bcl-2 *(124–126)*. This countervailing effect is consistent with a recently demonstrated Bim-dependent mechanism for limiting memory CD8 T cells (127). In addition, a Bim-independent mechanism for expunging memory T cells was shown (127), and this is likely to involve death receptors. For instance, CD4 T cell help is required for CD8 T cell memory. In the absence of CD4 help, TRAIL is expressed on and mediates apoptosis of CD8 cells upon antigen restimulation (128). TRAIL deficiency, however, only delayed the loss of CD8 memory cells, revealing that non-TRAIL mechanisms also contribute to the homeostasis of CD8 memory cells (129). Further studies are needed to dissect the PCD mechanisms contributing to T memory cell generation and homeostasis.

B Cell Homeostasis

We have focused most of our attention on T lymphocyte apoptosis thus far because it has received the greatest experimental examination and more details are known. However, PCD also governs B cell homeostasis and is regulated in ways that have similarities and differences with T cells. Both DR triggering and withdrawal of trophic stimuli contribute to B cell elimination. Similar to T cells, B cells developing in the bone marrow undergo a series of proliferative expansion and apoptotic contraction events to

shape the final B cell repertoire *(130)*. Immunoglobulin (Ig) gene rearrangement starting at the pro-B stage generates the BCR. The cytokine IL-7, which promotes the survival of developing thymocytes (131,132), is crucial for sustaining survival at the pro-B/pre-B juncture (133,134). IL-7 induces transcription of the anti-apoptotic molecule Mcl-1, which selectively binds to and antagonizes the pro-apoptotic Bcl-2 family member Bim (*135,*136). Then selection for B cells occurs in two developmental steps with successive gene rearrangements at the heavy- and light-chain Ig loci. B cells that fail to generate a productive BCR, due to abortive Ig gene rearrangements, are eliminated by PCD. At the other end of the spectrum, B cells that express BCRs directed against self-antigens are eliminated by apoptosis or undergo receptor editing to acquire new antigen specificity (137). The survival and antigen responsiveness of immature B cells can also be increased by lipopolysaccharide (LPS) exposure, presumably to enhance B cell production during infections *(138)*. Fas, TNFR-1 or perforin are not involved in the death of developing B cells (reviewed in [139]). Rather, death appears to be a consequence of a direct signaling event generated by the BCR (140).

In contrast to B cells in development, mature B cells rely heavily on TNFR family receptors such as CD40, Fas, and BAFF for regulating their survival and death. It is also clear that T cells control PCD of mature B cells. Christopher Goodnow and colleagues have illustrated the importance of CD40 and Fas in the balance of life and death in B cells using the hen egg lysozyme (HEL)–transgenic and HEL-specific TCR transgenic mice (141,142). Naïve, HEL-specific B cells undergo proliferation in the presence of HEL and HEL-specific CD4 T cell help. Hence, proper B cell activation requires triggering of the BCR as well as "help" in the form of CD40L expressed on activated T cells. The primary function of CD40L is to prevent death of the activated B cells. Survival allows further differentiation and function *(143)*. However, anergic HEL-specific B cells from HEL transgenic animals undergo apoptosis in the presence of the same HEL-specific CD4 T cell help. This antigen-specific B cell death is absent in Fas-deficient B cells (141), thus suggesting a role for Fas in causing the death of anergic antigen-specific B cells. Fas killing of mature B cells can also be abrogated by BCR engagement and IL-4, which promote antibody responses (144,*145*). An imbalance of CD40 and Fas signals might contribute to autoantibody production consequent to Fas and FasL mutations in both human and mouse. More recent studies using similar transgenic systems suggest that whereas Fas can mediate apoptosis of activated B cells by CD4 T cells, BCR-induced death of immature or resting mature B cells is primarily Fas-independent. Central to this Fas-independent pathway is up-regulation of the pro-apoptotic molecule Bim (*146*,147,148). Moreover, the recently discovered B cell survival and maturation factor BAFF serves as a survival factor for mature B cells by sustaining the

MAPK Erk signals that in turn inhibit Bim accumulation (149).

The attenuation of B cell responses at the end of an immune reaction is likely to involve cytokine withdrawal death similar to that of T cells, but this phenomenon is less well characterized. Cytokines such as IL-7 and IL-15, which enhance cellular survival through the up-regulation of Bcl-2, Bcl-X_L, or Mcl-1, may be responsible (136,*150*). Lymphokine withdrawal death in B cells, like T cells, requires de novo RNA/protein synthesis *(151)*. An interesting observation is that a secreted lipocalin, identified through microarray analysis of an IL-3 dependent pro-B cell line, was implicated as a potential mediator for IL-3 withdrawal death (152). This protein appears to regulate intracellular iron levels, which may modulate Bim levels for apoptosis induction (153). However, it remains to be seen whether lipocalins or other similar molecules are involved in lymphokine withdrawal death in primary mature B or T cells. As we will discuss later in this chapter, survival genes such as Bcl-2 can protect cells against lymphokine withdrawal death and therefore play an important role in mature B cell homeostasis. Moreover, Bcl-2 can contribute to the survival of B lymphoma cells as revealed by the t(14:18) translocation of Bcl-2 to the Ig locus in follicular B cell lymphomas (154).

DC Homeostasis

Understanding the cell fate regulation of DCs is still in its infancy. However, emerging evidence suggests that these highly efficient APCs are also subject to homeostatic regulation by PCD. The natural turnover of DCs was demonstrated in the mouse by Jenkins and coworkers (155). Using elegant cell-labeling experiments, they showed that antigen-laden DCs stimulate the formation of a cluster of activated antigen-specific T cells and then disappear. This process was antigen- and T cell–dependent. Later, it was shown that the TNF homologue TRAIL (TNF-related apoptosis-inducing ligand), which is produced by activated T cells, could induce apoptosis in DCs and that this mechanism could be defective in patients harboring mutations in caspase-10 (156). Together these data introduced the concept that there is homeostatic regulation of DCs involving recruitment and differentiation followed by their active elimination by stimulated T cells. Early removal of DCs has the benefit of allowing the activation of T cells but avoiding T cell restimulation and propriocidal death too soon in the response to antigen. Recent work in mice genetically engineered to selectively express the p35 apoptosis inhibitory protein in DCs reveals that apoptotic removal of DCs is essential to preserve tolerance and prevent autoimmunity (157). Moreover, autoimmunity was accelerated when such mice were backcrossed onto the autoimmune-prone *MRL* strain. A similar acceleration in autoimmunity is observed when mice with T and B cell apoptosis defects

are on an *MRL* genetic background. Thus, impaired DC apoptosis can collaborate with other genetic and environmental factors to powerfully predispose to autoimmunity.

PCD as an Immune Effector Mechanism

Although this topic will be covered authoritatively elsewhere in the book, it is important to recognize that the same pathways that participate in homeostatic cell death also are used as immune effector mechanisms. The Fas pathway is now recognized as the principal Ca^{2+}-independent pathway of cytotoxic T cell (CTL) killing (71). Fas ligand displayed by either $CD4^+$ or $CD8^+$ T cells can eliminate Fas-bearing cells that may be infected or malignant by inducing caspase-mediated apoptosis. Similarly, the Ca^{2+}-dependent CTL mechanism involving perforin and granzymes also can induce PCD in target cells. The two main proteases are granzyme A and granzyme B; this latter is the only serine protease capable of processing caspases *(158–162)*. When perforin breaches the target cell membrane, granzyme B gains access to the cytoplasm and proteolytically activates caspases leading to apoptosis. Although this cytoplasmic pathway of death does not emanate from the mitochondria, the latter may amplify the death signal by Bid cleavage *(163,*164,*165,*166,*167*). These parallels may provide an insight into why lymphocytes have evolved an indirect mechanism, involving the surface interaction of FasL and Fas or perforin/granzyme releases to homeostatically control their numbers by apoptosis. This mechanism permits the T cell to regulate itself, other immune cells, and expunge nonlymphoid cells that require immune elimination, such as those that are infected or malignant. Natural killer cells may also use PCD mechanisms for self-regulation and expunging infected or malignant cells (168,*169*). Hence, for mature T cells, the same molecules can subserve several death functions, perhaps even simultaneously. By contrast, a more direct connection of the TCR or BCR to death pathways is present in developing lymphocytes, which have no use for effector mechanisms or propriocidal regulation.

CELLULAR AND MOLECULAR MECHANISMS OF PCD

Apoptosis Initiation Mediated by Caspase Complexes: Two Principal Pathways

Caspases must be highly active within the cell cytoplasm to cause apoptosis. Like all proteases, these potentially destructive proteins are first produced as zymogens that are then proteolytically activated. In mammalian cells, the molecules and pathways regulating caspase activation are complex (Figure 27.3). Elucidating these complex pathways provides a window into the myriad of molecular ab-

normalities of apoptosis that contribute to immunological diseases and cancer. Fortunately, mammalian apoptosis can be understood with a few key concepts. Most importantly, the processing enzymes that activate caspases are caspases themselves. As explained later, activation and autoprocessing occur when caspase zymogens are brought into specific signaling complexes. In general there are two main forms of caspases. Those with long prodomains that have protein interaction domains capable of bringing them into activating platforms for autoprocessing are called *initiators,* upstream, or *apical caspases.* Those with short prodomains that must be cleaved by other proteases (caspases or granzyme B) are called *effectors,* downstream, or *executioner caspases.* This is achieved by various adapter molecules with domains that specifically recruit and assemble caspases into complexes: the death effector domains (DEDs) or the caspase recruitment domains (CARD) *(170,171).* The DED and CARD are protein–protein interaction domains found in the caspase prodomains and other adapter molecules that generate the specific intermolecular assemblies. In contrast to executioner caspases, which require processing to become active, dimerization of initiator caspases drives their activation (172,*173*). When juxtaposed at the receptor complex, initiator caspases become proteolytically active and will cleave one another. This leads to the maturation of the enzyme through separation of the large and small enzymatic subunits. Autoprocessing also cleaves the enzymatic units from the prodomain, thereby liberating the highly active enzyme from the receptor complex. As discussed later in the chapter, structural studies suggest that active caspases are tetrameric species composed of two small and two large subunits. Hence, it is likely that activation and autoprocessing of caspases involves the cross-cleavage of at least two units of the unprocessed zymogen.

To initiate the caspase cascade, the enzyme must dock onto the appropriate adapter molecules. The adapter/caspase complex presumably provides a conformation that facilitates the initial autoprocessing step of the caspase zymogen. Adapter/caspase complexes originate from two principal sites in the cell: 1) the plasma membrane (through DRs), also known as extrinsic pathway, or 2) the mitochondrion, or intrinsic pathway (Figure 27.3). We will employ this primary dichotomy of intrinsic and extrinsic pathways since it recapitulates the two major forms of propriocidal apoptosis: antigen-induced and lymphokine withdrawal, respectively.

DR engagement by cognate ligand causes the formation of the death-inducing signaling complex (DISC), which comprises the cytoplasmic tail of the receptor, the FADD adapter protein, and caspase-8 or -10 (*174,*175). The recruitment of caspase-8 or -10 into the DISC triggers the processing of these proteases into their active form. An 80-amino acid death domain (DD) present in the Fas cytoplasmic tail and FADD causes their interaction. The DD
FIGURE 27.3 Signal transduction pathways of death receptors. Shown are the two principal apoptosis pathways associated with death receptors (Fas and TNFR-1) and that associated with the mitochondrial pathway of caspase-9 activation. The solid arrows indicate direct association of the steps involved, whereas the dashed arrows indicate that multiple steps are involved. Inhibitory interactions are shown by a barred line.

contains a "hexahelical bundle" that nucleates this complex, as described in greater detail later. There is an obligatory 3: 3 stoichiometry of the FADD adapter protein and the Fas receptor. FADD recruits caspase-8 or -10 by homotypic interaction between DEDs present in each of these molecules. The DED has a hexahelical bundle homologous but not identical to DDs. Sensitive energy transfer techniques showed that both caspases can enter the same receptor complex (176). FADD self-association at the receptor level also triggers the formation of microscopically visible clusters of Fas, termed *SPOTS* (signaling protein oligomerization transduction structures). These structures enhance caspase-8 recruitment and activation (177). Fas receptor capping and internalization in endosomal vesicles follow SPOTS formation and may promote the killing process *(178)*. The signal complex for TNFR-1 is different from Fas since it includes the DD-containing adapter TRADD in addition to FADD and caspase-8 and -10 (discussed later). Similar signaling complexes are likely formed with other DD-containing members of the TNFR superfamily includ-

ing DR 3, TRAIL receptors (TR)-1 and -2 (also called DR-4 and -5, respectively), and DR 6 *(179–181)*. The physiological significance of apoptosis mediated by any of these receptors besides Fas and TNFR-1 in immune regulation is unknown, although DR6 has been implicated in Th2 cell differentiation *(182,183)*. It has been proposed that TR-1 and TR-2 may mediate the preferential killing of tumor cells (including lymphoid tumors) (184).

Activation of the mitochondrial pathway of apoptosis during lymphokine withdrawal or in response to developmental cues achieves the same end as DRs caspase activation. However, signal complex formation occurs in a different way. Intrinsic signals converge on the mitochondria, resulting in outer membrane permeabilization (MOMP) and the release of the pro-apoptotic molecules from the intermembrane space (IMS) into the cytosol. One key factor released is cytochrome c, a molecule also involved in the electron transport chain. Once liberated into the cytosol, cytochrome c binds and triggers the oligomerization of apoptotic protease-activating factor 1 (Apaf-1) in

the presence of ATP/dATP, to form a heptameric complex often referred to as the *apoptosome* (185,186). The complex nucleates caspase-9 recruitment and activation (reviewed in [187,*188,189*]). There are specialized regulatory proteins for caspase-9 that provide additional levels of control: X-linked IAP (XIAP), which inhibits caspase-9, and Smac/Diablo, which counteracts XIAP (190,191). These mitochondrial events are tightly regulated since caspase-9 activation commits the cell to die.

The Central Role of the Mitochondrion

A special role for the mitochondrion in apoptosis was first suggested by the finding that Bcl-2 and related molecules were anchored predominantly in the outer mitochondrial membrane (OMM). The inner mitochondrial membrane (IMM) is devoted to energy conversion and ATP generation, but the OMM has emerged as a primary regulator of cell viability. A diversity of death inducers, including trophic factor withdrawal, drugs such as staurosporine or steroids, or DNA damage, can all generate signals that converge on the mitochondrion. Their principle effect is to increase OMM permeability to large proteins, leading to the release of apoptogenic factors into the cytosol. As described earlier, cytochrome c coalesces with Apaf-1 and caspase-9 into a lethal proteolytic complex soon after its release into the cytosol. The essential role of cytochrome c in apoptosis was elegantly demonstrated by generating "knock in" mice expressing a mutant cytochrome c (K72A) (192). This mutant version of cytochrome c retains its electron transfer function but lacks its ability to activate Apaf-1. The mutant mice display developmental abnormalities similar to Apaf-1 or caspase-9–deficient animals, and the surviving mice exhibit impaired lymphocyte homeostasis. In contrast to Apaf-1$^{-/-}$ cells, thymocytes from these mice were normally sensitive to intrinsic stimuli such as γ-irradiation, dexamethasone, and etoposide. This implies the existence of a cytochrome c- and apoptosome-independent but Apaf-1–dependent mechanism of caspase activation and cell death (192).

Interestingly, 85% of cytochrome c is sequestered inside the intra-cristae region formed by the convoluted folds of IMM, with a limited access to the IMS *(193)*. Therefore, the sudden "all-or-nothing" release of cytochrome c requires two steps: 1) a BH3-only–dependent (typically Bid) remodeling of the cristae structure allowing cytochrome c to access the IMS, and 2) the Bax- and Bak-dependent permeabilization of the OMM. The cristae structure was recently shown to be controlled by the IMM Presenilin-associated rhomboid-like protein (PARL) and by the IMS resident dynamin-related Optic Atrophy 1 (OPA1) (194,195). In yeast, homologues of these proteins, Rbd1 and Mgm1 respectively, regulate mitochondrial fusion, a process of mitochondrial metabolism. Mice deficient for PARL die between 8 weeks and 12 weeks of pro-

gressive cachexia, and their lymphocytes undergo massive apoptosis. Moreover, MEFs derived from these animals were significantly more sensitive to intrinsic stimuli, demonstrating the anti-apoptotic function of PARL. Normally, PARL cleaves OPA1, and both cleaved and uncleaved OPA1 form hetero-oligomers that maintain a tight bottleneck configuration of the cristae, keeping cytochrome c sequestered.

How the OMM releases its mortal poison is still unclear, and two models have been proposed. In one, the pro-apoptotic Bcl-2 family proteins Bax and Bak selectively permeabilize the OMM, without affecting the IMM. In the second model, a pore in the IMM known as the mitochondrial permeability transition complex (mPTC) opens and allows water and solutes up to 1.5 kDa to accumulate into the matrix. The matrix swells as water enters, and the OMM bursts *(196,197)*. Cells from mice lacking cyclophilin D, a critical component of the mPTC, remain sensitive to intrinsic death insults, favoring the first model. However, the mPTC appears to be essential for stimuli promoting necrosis such as calcium overload and ROS. Perhaps this accounts for the fact that the knockout mice were resistant to ischemia/reperfusion-induced cardiac injury (198,199). As detailed later in this chapter, MOMP appears to be regulated and coordinated by the large family of proteins related to Bcl-2.

In addition to cytochrome c, several other pro-apoptotic proteins from the IMS are released outside the mitochondria during apoptosis. The flavoprotein "apoptosis-inducing factor" (AIF) translocates from the mitochondria to the nucleus, causing DNA fragmentation and chromatin condensation in response to apoptotic stimuli (200,*201*). Genetic deficiency of this protein in mice inhibits the death of embryonic cells in response to serum starvation and leads to defects in embryonic morphogenesis and cavitation of the embryonic cell mass. The observation that these processes did not depend on caspase-3, caspase-9, or Apaf-1, suggests that unlike *C. elegans,* not all programmed death in mammalian cells is dependent on caspases (202). Further work with conditional genetic deficiencies of AIF in immune cell lineages will be needed to determine whether this mechanism has any role in immunity. Another mitochondrial protein important in apoptosis is endonuclease G (EndoG). EndoG is a resident mitochondrial nuclease that is released and translocates to the nucleus upon apoptotic stimulation. Once situated in the nucleus, EndoG cleaves DNA into nucleosomal sizes independent of caspases, thus distinguishing itself from the caspase-dependent activation of another apoptotic nuclease CAD (203) (see later discussion). Thus, the mitochondrion may participate in nuclear chromatin fragmentation, which is one of the chief effects of apoptosis. When released in the cytosol, Smac/DIABLO and Omi/HtrA2 neutralize the inhibitors of apoptosis proteins (IAPs), and thus promote caspase activation.

Studies on the mitochondrion have also focused on caspase-independent apoptosis. AIF, EndoG, and Omi/HtrA2 were proposed to mediate such a pathway. In general, this concept stemmed from examples of apoptosis that could not be blocked by small peptide caspase inhibitors such as zVAD (204,*205*). However, conclusions drawn from such experiments are limited by the short half-life of such inhibitors and the fact that they do not block all caspases. Also, kinetic experiments show that AIF release occurs slowly secondary to the fast simultaneous redistribution of cytochrome c, Smac/DIABLO, and Omi/HtrA2 (*206,*207). Finally, cells from double-knockout mice for the executioner caspases-3 and -7 exhibit a delayed translocation of cytochrome c and AIF, indicating that caspases act as an amplification loop necessary to fully permeabilize the mitochondria (208). Thus, it is uncertain if there is a truly caspase-independent form of apoptosis, although the possibility remains.

Programmed Necrosis

While PCD has generally been equated with apoptosis, recent evidence suggests that necrotic or alternative forms of death may also result from internal death programs (204,*205,209,*210). This is different from secondary necrosis that occurs in the late phase of apoptosis when membrane integrity is lost. Rather, PCD leading to a necrotic morphology without any intermediate stage of apoptosis or caspase activation is now well documented (18,202). For example, it has been found that DRs can trigger necrotic death rather than apoptotic death under certain circumstances (204,*205,209*). Although TNF stimulation through TNFR-1 can trigger caspase-dependent, classical apoptosis, necrosis may well be the dominant pathway for TNFR-1, at least in certain cell types (204,*209*). By contrast, Fas predominantly triggers apoptosis but can also induce necrosis (18). A shift from apoptosis to necrosis can be induced by tetrapeptide caspase inhibitors suggesting that a necrotic pathway may exist for cell elimination when apoptosis fails or is blocked (*205*). Moreover, the recent identification and characterization of a small molecule that specifically inhibits necrosis but not apoptosis points to a distinct biochemical pathway for programmed necrosis (19). These observations have physiological relevance since propriocidal death of mature T cells is partly refractory to inhibition by caspase blockers and can manifest features of necrosis (18). For these reasons, we have chosen to introduce the name *programmed necrosis* to describe death by necrosis (or at least a clearly nonapoptotic phenotype) that results from a specific molecular pathway and appears to be advantageous to the host.

An interesting example of programmed necrosis has been investigated by Tschopp and coworkers. They have shown that necrosis can occur through strong Fas stimulation in a process that requires the receptor interacting protein (RIP) (18). Originally identified by a yeast two-hybrid interaction screen using the DD of Fas as bait (*211*), RIP was later found to be an essential component of the TNFR-1 signaling complex that could induce the anti-apoptotic transcription factor NF-κB (211–213, *214*). Besides a carboxyl terminal DD that is required for homotypic binding to the receptor-signaling complex, RIP also contains an amino-terminal serine/threonine kinase domain that is dispensable to its apoptosis-inducing activity but is essential for its necrotic function. Both direct Fas engagement or TCR stimulation (which presumably indirectly triggers Fas by FasL induction) can stimulate necrosis *in vitro* (18). A similar form of RIP-dependent, caspase-independent necrosis has also been observed for TNFR-1 (17,215). Thus, RIP appears to be a bifunctional signaling molecule with stimulatory and necrosis-inducing effects. Paradoxically, RIP-deficient mice are severely runted and die shortly after birth, apparently due to increased TNF-induced death due impaired NF-κB induction (216). Because Fas-induced PCD has not been investigated extensively in the RIP-deficient animals, it remains to be seen whether RIP-dependent programmed necrosis has any role in normal physiology. Nevertheless, RIP appears to be the clearest talisman of a molecular pathway of programmed necrosis. The downstream signals in this pathway remain obscure, but in the case of TNF are distinct from the TRADD-dependent, caspase-dependent apoptotic pathway (215) and may partially involve oxidative stress (215,*217*). Cyclophilin D can regulate some forms of necrotic death induced by ROS and calcium but its role has not yet been studied in lymphocytes (198,199).

What is the potential role of DR-induced necrosis in immunity? Many viruses, particularly the poxviruses, encode inhibitors of caspases (17,*218*). Infection by poxviruses leads to blockade of caspase-dependent apoptosis. This sensitizes cells to TNF-induced necrosis (*219*). Therefore, programmed necrosis may serve to counteract the effects of viral anti-apoptotic mechanisms by eliminating virally infected cells. From an immunological standpoint, necrotic cells may have a superior stimulatory activity than apoptotic cells for DC maturation (*23,24*). During viral infection, TNF-induced necrosis may indirectly enhance the CTL response to the virus by promoting the maturation of DCs. Programmed necrosis may therefore have an immunostimulatory role in addition to directly eliminating virus-infected cells. Programmed necrosis could thereby serve as a "bridge" between the innate arm of immunity and the adaptive immune response.

Another important reason to further understand necrosis in the context of the immune system is that it may be responsible for the pathogenesis of viruses such as human immunodeficiency virus (HIV). Although many claims have been made that HIV causes apoptosis—of either directly infected or bystander T cells—most dying infected cells do not manifest hallmarks of apoptosis. Further,

these cells actually appear necrotic when examined by electron microscopy (Figure 27.1) (220). Hence, apoptosis does not appear to be the major mode of death. HIV-induced necrosis is not impaired by the absence of RIP, thus distinguishing it from DR-induced necrosis. Further studies on identifying the molecules involved in virally induced necrosis are needed to determine whether it involves a specific molecular program or simply lethal cell injury.

FAMILIES OF MOLECULES PROVIDE PRECISE REGULATION OF PCD

Caspases

A key concept in understanding PCD is that it was apparently so vital to the successful evolution of multicellular organisms that a specific set of genes was dedicated to the task. Chief among these genes were those encoding caspases. Junying Yuan and H. Robert Horvitz in 1993 first observed that a gene crucial for PCD in *C. elegans,* ced-3, was related to a mammalian caspase, IL-1ß-converting enzyme (ICE), thus implicating specific proteolytic events in the death program (221). The "caspase" moniker is a rubric indicating that these enzymes contain an active site **C**ysteine, cleave substrates on the carboxyl side of **ASP**artate residues, and are prote**ASES**. Caspases have been called the "executioners" of apoptosis. Once activated, their cleavage of various cellular substrates, including other caspases, results in the morphological features of apoptotic cell death. Earnshaw et al. (222) authoritatively discuss the detailed biochemical features of caspases and their substrates, which are beyond the scope of this chapter. There are 15 caspases in mammals *(223)*. All appear to be involved in apoptosis except human caspase-1 (ICE) and caspase-4 (caspase-11 in the mouse), which serve to proteolytically process the precursors of cytokines such as IL-1ß into their mature forms. In addition to its pro-apoptotic role, caspase-12 was recently proposed to inhibit the pro-inflammatory functions of caspase-1. Indeed, caspase-12 functions as a FLIP and directly binds to caspase-1 to suppress its activity. Functionally, mice deficient in caspase-12 are resistant to sepsis and clear bacterial infection more efficiently. Further, humans with a caspase-12 polymorphism that results in an inactive truncated protein have increased LPS-stimulated cytokine production, as well as a correspondingly decreased risk for developing and dying from sepsis (224,225).

Much early work equated caspase enzymatic activity with processing. Although true for the so-called downstream "effector" caspases, recent studies have established that cleavage is neither necessary nor sufficient for activation of initiator caspases (172). Rather, oligomerization of procaspases-8 or -10 within the DISC, procaspase-9 within the apoptosome, or procaspase-2 within an Apaf-1–

independent complex, is sufficient for activity *(226–229)*. The proximity-induced dimerization of the initiator caspases is due to their long N-terminal prodomains, which allow the caspases to enter into large activating multimeric complexes (as described later). Further processing of active procaspases may stabilize activity or allow for diffusion of active caspases intracellularly where they can access other protein substrates.

Because of the thermodynamic irreversibility of proteolysis, downstream caspase activation is a commitment to death that cannot be undone. Hence, caspases are tightly regulated. This regulation is achieved by three principle means: 1) Caspases are zymogens requiring proteolytic processing; 2) Certain caspases have long "prodomains" that allow them to enter complexes with adaptor molecules that promote autoprocessing; and 3) Specific inhibitors exist (6). How these mechanisms work is clear from the structures of caspases (Figure 27.4). Caspases have an NH$_2$-terminal "prodomain" that is removed in the active enzyme. The COOH-terminal protease domain comprises two catalytic subunits of the mature enzyme that are denoted by their processed molecular weights—for example, p20 and p10. The processing sites between these parts occur at short specific tetrapeptide sequences ending in aspartate residues that dictate that the major processing enzymes are caspases themselves (222). For caspases with short prodomains, namely caspases 3, 6, and 7, this event is believed to be the primary mode of regulation. Those with long prodomains harbor protein-interaction domains that allow them to enter activating complexes for specific death pathways as described earlier. Caspase-8 and -10 have DEDs and caspases-1, -2, -4/-11, -5, -9, -12, and -13 have CARD domains. How complex formation stimulates autoprocessing is not understood, but likely involves a stoichiometry in which multiple proenzymes come into close contact. Within such a complex, the proenzyme chains adopt a more active structure that may or may not resemble the final processed active structure. The liberated subunits form a heterotetramer of two large and two small enzyme subunits as reflected in the crystal structures of processed caspases (230,231,*232–234*). The consequences of subunit cleavage are dramatic: There is a 180° shift of the NH$_2$-terminus of the small subunit to bring it into apposition with the catalytic cleft (235). To begin autoprocessing, an active intermediate pseudoconformation could be stabilized by internal hydrophobic interactions or by the action of chaperones. After caspase zymogens are recruited to a trimeric DR complex, an enzyme pseudostructure formed by two precursors could process a third proenzyme molecule. Subsequent subunit rearrangements could then lead to processing of additional unprocessed chains. Once a processed heterotetramer is formed, it will be thermodynamically stable and move away from the activating complex. If the stoichiometry of the activating complexes requires three proenzymes, this would match the
FIGURE 27.4 Mammalian caspases. **A:** The structures of the 15 known mammalian caspases are shown. Many of the caspases contain at their NH$_2$-terminal the CARD domain. Caspase-8 and caspase-10 contain a tandem copy of the DED at the NH$_2$-terminal end of the pro-enzyme, which is essential for recruitment to the DISC. Caspase-15 contains a pyrin (PYD) domain at the NH$_2$-terminus. The large (p18/p20) and small (p10/p12) subunits near the COOH-terminals are also shown. The optimal tetrapeptide substrate specificity of each caspase is shown on the right-hand column. Notice that the caspase-4 and caspase-11 are human and mouse homologues, respectively (asterisks). **B:** Proximity-induced oligomerization is cruicial in activating initiator pro-enzymes, which also undergo autoproteolytic cleavage. Shown in the diagram by the arrows are the proteolytic cleavage sites of caspase-8 at aspartate residues 210, 216, 374, and 384, as well as the active site cysteine (C360) indicated by a bar. Two of each of the large and small subunits of the enzyme form the active enzyme in a head-to-tail conformation, resulting in a tetramer that contains two catalytic sites at the two ends of the molecule. The active sites of the enzyme, which are made up of residues from both the large and small subunits, are designated by the circles at the ends of the processed enzyme.

symmetry of DRs (see later discussion). Proteolytic activation is regulated by a variety of proteins. These inhibitors interact with the fully formed enzyme and remain bound as competitive inhibitors. Examples of such inhibitors are the CrmA protein, its homologs found in other viruses,

and the IAP proteins *(218,236)*. Other viral proteins that harbor DEDs can enter the DR signaling complexes and inhibit cleavage of caspases-8 and -10 (114,*237*). Initially, it was thought that these inhibitors, termed *v-FLIPs* for *viral FLICE (caspase-8) inhibitory proteins,* inhibit apoptosis by competing with caspase-8 and -10 for entry into the DR complex. However, it is now clear that the inhibitor and the caspase enter the complex together. Resolution of the crystal structure of MC159, a v-FLIP from the pox virus Molluscum contagiosum virus, reveals that it cooperatively assembles with FADD and Fas through an extensive charge surface encompassing a conserved charge triad. This prevents FADD self-aggregation and disrupts higher order oligomerization necessary for activation of caspases-8 and -10 (238). Cellular FLIP, or *c-FLIP,* is structurally homologous to caspase-8 and -10 (indeed, it is encoded in the same locus on human chromosome 2 as these caspases) but has multiple mutations in the caspase domain that inactivate its protease function (116). It can also enter the Fas signaling complexes and prevent caspase recruitment and activation (238,*239*). However, c-FLIP can also induce apoptosis under certain conditions, which may be due to its ability to heterodimerize with and thus activate procaspase-8 *(240)*. The ability of antigen receptor stimulation to block Fas-induced death in B cells is regulated in part by c-FLIP *(117)*.

Another class of caspase regulators is the cellular IAPs (c-IAPs) that can directly inactivate mature caspases to avert the deleterious effects of inadvertent caspase activation (118,*119*). IAPs are characterized by the presence of up to three baculovirus IAP repeats (BIRs). Originally identified in baculovirus, the BIR domains are characterized by the presence of cysteine and histidine residues in defined spacing arrangements ($Cx_2Cx_6Wx_3Dx_5Hx_6C$) (for review, see [118]). The mechanisms of inhibition by IAPs on different caspases are quite distinct. For caspase-9, inhibition by XIAP depends on binding of the BIR3 domain with the tetrapeptide sequence ATPF at the NH$_2$-terminal of the p12 subunit that is exposed only in the mature enzyme. Hence, XIAP specifically inhibits active caspase-9, but not pro-caspase-9 (190). By contrast, XIAP inhibits caspase-7 and -3 by forming contacts in the catalytic groove with little involvement of the BIR domains (241). Interestingly, this mechanism of XIAP association is adopted by Smac/Diablo to inhibit the anti-apoptotic function of XIAP during the onset of mitochondrial PCD pathways (191). Smac/Diablo is a protein that resides in the intermembrane space of the mitochondria. It functions as an elongated dimer of α helices that adopts the shape of an arch. The NH$_2$-terminal amino acids AVPI generated from cleavage of the mitochondria targeting sequence are not well organized in the crystal structure. Nevertheless, they are critical for the inhibitory function of the protein. Mutation of alanine to methionine abolished the inhibitory activity of Smac/Diablo on XIAP (190,191).

This IAP-binding motif (IBM) is also shared by other IAP antagonists (Omi/HtrA2, and GSPT1/eRF3), and by caspase-9, suggesting that IAP antagonists and caspase-9 compete for binding to XIAP (190). The action of XIAP is flexible in order to carry out diverse functions. Instead of the BIR3 domain, XIAP uses the linker region between BIR1 and BIR2 to interact with and inhibit the function of caspases-3 and -7. In this case, the linker inserts into the catalytic groove of the caspase in reverse orientation to that of the tetrapeptide inhibitor DEVD-CHO. While BIR2 does not directly participate in the inhibitory activity, it may contribute to the stability of the association by making other contacts with caspase-3 (231,242,243).

The death-inducing effect of caspases is highly specific in that most proteins in the dying cell remain uncleaved. Lethality is therefore due to cleavage of a limited set of targets. Caspases have an absolute requirement for aspartate at the amino side of its cleavage sites (P1 site). Further specificity is dictated in part by the three amino acids preceding the obligatory aspartate in the substrate (P2-P4 positions) (222). Preferred tetrapeptides have been identified for each of the mammalian caspases so that, for example, caspase-3 is known to preferentially cleave at the sequence DEVD, whereas caspase-8 prefers IETD (*12,*244,245). Nicholson and coworkers have developed valuable tetrapeptide substrates and inhibitors based on these preferences, but they emphasize that these are not absolutely specific (*12,*222). In addition to primary amino acid sequence, additional secondary structural features of target proteins may be recognized. For example, many proteins harboring a DVED sequence may not be cleaved at that sequence by caspase-3 *(119)*. Thus, the tetrapeptide recognition sequences are required but not sufficient for apoptotic protein cleavage. Nevertheless, model caspase substrates and inhibitors based on short recognition peptides, such as zVAD- or DVED-fmk (<u>f</u>luoro<u>m</u>ethyl <u>k</u>etone), have been useful in assessing caspase function *in vitro* and *in vivo*.

Proteins known to be cleaved by caspases in the dying cells have been grouped according to apparent functional importance: a) cytoskeletal proteins such as actin, gelsolin, and α-fodrin, among others; b) nuclear structure proteins, especially lamins A and B; c) DNA metabolism and repair proteins such as poly (ADP-ribose) polymerase (PARP); d) protein kinases, such as various isoforms of PKC; e) signal transduction proteins such as STAT1, SREBP-1 and phospholipase C-γ1. A more extensive discussion of identified caspase substrates has been published (222). Since PCD typically involves the elimination of somatic cells, there may be little evolutionary constraint on random cleavage sites. Hence, it has been difficult to distinguish functional versus adventitious sites. Key caspase substrates that have unequivocal roles in apoptosis include caspases themselves, Bcl-2 and Bcl-X$_L$, the ICAD inhibitor (<u>i</u>nhibitor of <u>c</u>aspase <u>a</u>ctivated <u>d</u>eoxyribonuclease) of the DNase CAD,

which is one enzyme causing apoptotic nuclear fragmentation, and the nuclear lamins *(246,247)*. Cleavage of the nuclear lamins was shown by Eileen White to be responsible for certain nuclear changes in apoptosis by experiments in which the aspartate cleavage sites were modified and the apoptotic changes were abrogated (248). This stringent test has been applied to very few proteins cleaved during apoptosis. In fact, evidence weighs against the role of many caspase substrates in apoptosis. The knockout of the PARP gene in mice revealed no abnormality of development, immunity, or apoptosis (249). Hence, further work is necessary to determine the importance of proteins cleaved during apoptosis.

Genetic analyses of human caspases have provided important information about their function. By contrast, homozygous deficiencies in mice have been associated with embryonic lethality or neurological defects but have not yielded specific immunological phenotypes (222). Inherited mutations of two caspases in humans cause prominent effects in the immune system. The first, an inherited mutation in caspase-10, was detected in the human disease ALPS, type II (156,250). Individuals with caspase-10 mutations exhibited defects in apoptosis triggered by multiple DRs affecting the homeostasis of T cells, B cells, and DCs. The abnormal accumulation of immune cells leads to the formation of a variety of autoantibodies that cause autoimmune conditions including hemolytic anemia, thrombocytopenia, and others. Individuals harboring mutations in caspase-8 have also been identified (251). These individuals also exhibit abnormal lymphocyte apoptosis and the accumulation of lymphocytes in secondary lymphoid tissues. However, unlike a caspase-10 mutant individual, the lack of caspase-8 leads to minimal autoimmunity. Rather, the affected individuals exhibit immunodeficiency manifested as recurrent sinopulmonary and viral infections. Biochemical analysis shows that caspase-8 is required for NF-κB induction by the TCR, BCR, and Fc receptor, which accounts for this T, B, and NK lymphocyte activation defects. These patients represent a novel clinical entity, termed *caspase-8 deficiency state* (CEDS) (252). The clinical differences between humans having caspase-10 or caspase-8 mutations may reflect differences in substrate specificities of these two closely related caspases (176,*253*).

TNF/TNFR Superfamily Members

The TNF/TNFR superfamily contains many key regulators of immunity (Figure 27.5). These receptors and their cognate ligands facilitate communication between immune cells in the orchestration of immune responses. They also comprise a major class of cellular sensors to external physiological cues that regulate PCD (254). The hallmark of these receptors is the presence of "cysteine-rich domains" (CRDs) in the extracellular region, which are required for receptor assembly and ligand binding. Each receptor
FIGURE 27.5 Interacting proteins of the TNF/TNFR superfamily. TNFR- and TNF-related proteins are shown at the left and right of the figure, respectively, with arrows connecting ligand-receptor pairs. CRDs are shown as small ovals. The NH$_2$-terminal CRDs (CRD1a,1b,1c,1d) are grouped on the basis of sequence similarity as indicated by the use of colors in the figure. Small vertical lines denote the locations of intron excision sites from the RNAs that encode the proteins (this information was not available for RANK, DcR1 and DcR2). Red boxes mark the locations of DD-related sequences in the cytoplasmic regions of the TNFR-related proteins. Numbers to the immediate left of the TNFR cytoplasmic regions denote known or inferred interactions with the indicated TRAFs. The locations of the human genes that encode the proteins are provided at the extreme left and right of the figure; the mouse cluster on chromosome 17 is also noted. (Figure adapted from [61] with permission from Cell Press by Nigel Killeen)

contains between one (BCMA and TWEAK-R) *(255,256)* to six (CD30) CRDs. The receptors can be further subdivided into two classes based on sequence homology within the cytoplasmic signaling domain. The DRs contain an 80-residue-long DD that is essential for death signaling

*(174,*257). The majority of the receptors lack a DD, and therefore are not called DRs, but have a region that interacts with the TRAF (TNF receptor associated factors) proteins *(258)*. Interestingly, some of the DRs, including TNFR-1, can indirectly recruit TRAF proteins, which may

explain cross-talk between certain DD-containing and DD-lacking receptors (259,260,*261*). Signals transduced by the non-DD-containing receptors are frequently pro-survival, while that of the DRs are typically pro-apoptotic. In all, more than 20 members of the TNF receptor family in humans have been identified (61). With a few exceptions (EDAR and XEDAR), essentially all TNFRs play important regulatory roles in the immune system.

Signaling by the TNFRs is initiated when the cognate ligands, which are obligate trimers, contacts the pre-formed receptor complex (reviewed in [*259,262*]). Downstream signaling of DRs requires the recruitment of DD- or DED-containing proteins. For Fas, receptor engagement results in rapid recruitment of FADD and caspases-8 or -10 within the DISC, as detailed earlier (175). Other DRs such as TNFR-1 may require recruitment of an additional adaptor molecule like TRADD prior to the docking of FADD (263). These events rapidly culminate in caspase activation. The non-DD-containing receptors mediate NF-κB induction and the activation of c-Jun kinases through the recruitment of TRAF proteins, a property that is shared by some DRs such as TNFR-1. Recruitment of TRAF proteins by DRs may counter the pro-apoptotic response through their interactions with c-IAPs. "Knockout" analyses in mice reveal that many of these signaling intermediates, including TRAF2 (264), RIP (213), and components of the NF-κB activation pathway *(265–269)*, are essential for conferring protection against apoptosis induced by DR ligands. Deficiency of NF-κB tends to sensitize cells to TNF-induced death (270–272). Both TRAF2 and NF-κB induction through RIP may act in concert to promote survival in response to TNF (273). Interestingly, unlike the TNFR-1 and Fas-deficient mice, which are viable, knockout of the signaling components such as FADD or TRADD often results in embryonic lethality. The discordant results in knockout animals imply that TNFR signaling intermediates are involved in ontogenetic processes other than PCD. Alternatively, other TNFRs may mediate critical PCD events during development using the same set of signaling molecules. However, many other TNFR-deficient animals, including Fas-, DR6-, or multiply-deficient animals (TNFR1$^{-/-}$, TNFR2$^{-/-}$, and Fas$^{lpr/lpr}$ together) are viable, thus arguing against the latter hypothesis (*182,183,*274).

Bcl-2 Gene Family

Bcl-2 and Bcl-X$_L$ are the prototypes of a diverse family of apoptosis-regulatory proteins whose filial relationships are conferred by four impressively short homology regions, termed BH-1 to BH-4 (Figure 27.6) (275,*276*). Proteins in this family can be classified into three groups: 1) the "multidomain" anti-apoptotic proteins (Bcl-2, Bcl-X$_L$, Mcl-1, Bcl-w, A1, and BOO), which contain the four BH domains; 2) the "multidomain" pro-apoptotic Bax, Bak, and Bok that possess BH1–3 domains; and
FIGURE 27.6 Schematic diagram of members of the Bcl-2 family. The dark blue, green, red, and orange boxes represent the different Bcl-2 homology (BH) domains and the gray boxes designate the hydrophobic transmembrane (TM) region that is required for insertion into the mitochondrial membrane.

3) the "BH3-only" proteins (Bid, Bad, Bim, Bik, Noxa, and Puma). Bcl-2 was identified at the chromosomal breakpoint of t(14;18)-bearing follicular B cell lymphomas. Vaux and Cory demonstrated that the oncogenic effect of Bcl-2 could be attributed to enhanced cell survival rather than proliferation (154,*277*). Consequently, Bcl-2 represented a new class of death-preventing oncogenes that collaborates with growth-promoting oncogenes, such as Myc (278). It is not uncommon to find abnormal overexpression of Bcl-2 in lymphoid and nonlymphoid malignancies *(279)*. Bcl-2 and Bcl-X$_L$ regulate various types of immune cell death caused by lymphokine withdrawal, γ-irradiation, and chemical death inducers such as glucocorticoids, phorbol esters, DNA-damaging agents, and ionomycin—all of which provoke mitochondrial apoptosis (reviewed in [280]). Apoptosis induction is one means by which cancer chemotherapeutics exert an anti-tumor effect. Thus, since apoptosis antagonism may be as important in transformation as mitogenesis, new therapeutic strategies aimed at

antagonizing Bcl-2 may be effective in cancer therapy (see later discussion).

How Bcl-2 family proteins regulate cell death remains unsolved, but several regulatory principles have been delineated (275). Key family members, including Bcl-2, Bcl-X_L, and Bax, associate with intracellular membranes, especially the OMM, via a carboxy-terminal hydrophobic domain *(281–284)*. Death regulation by the Bcl-2 family involves controlling the permeability and integrity of the OMM. Structural features suggest that Bcl-X_L may form pores or channels in membranes, which could govern this process *(171)*. Bcl-2 family members form homotypic and heterotypic dimer complexes. The balance between pro- and anti-apoptotic members determines cell fate probably through direct interactions with each other (*285–289*, 290). The precise stoichiometry of these associations that lead to survival or death have not been defined. Regulation by these proteins appears to be "upstream" of caspase activation, but they may also control caspase-independent forms of cell death, including autophagic cell death (202). These proteins have their most important effects on mitochondrial death pathways and comparatively less effect on DR-initiated pathways. In particular, the pro-apoptotic family members such as Bax and Bak can cause mitochondrial release of cytochrome c and activation of cytosolic caspases (291). Diverse pathways, such as transcriptional induction (Bim, Puma, Noxa, and Bcl-X_L), phosphorylation (Bad), processing (Bid), conformational changes (Bax and Bak), or organelle translocation (Bim, Bid, Bax), control the presence and biological activity of Bcl-2 family members (100,*292*). Each of these principles has reported exceptions, but they constitute the current basis for our understanding of the Bcl-2 family of proteins.

The biological function of Bcl-2 family members has been examined in genetically engineered mice and tissue culture cells (for a review see [94]). Bcl-X_L–deficient mice die around embryonic day 13 due to massive neuronal apoptosis (293). By contrast, Bcl-2–deficient mice survive a few weeks postnatally but then develop polycystic kidney disease, hypopigmentation due to decreased melanocyte survival, and, most important, massive apoptotic loss of all B and T lymphocytes (294). Thus, while Bcl-2 is not necessary for lymphocyte maturation, it is indispensable for the maintenance of mature lymphocytes. However, expression of Bcl-X_L is required for the survival of DP (CD4$^+$CD8$^+$) thymocytes, B220$^+$ bone marrow cells, and mature B cells (275). Mcl-1 deficiency results in peri-implantation lethality (295). A conditional knockout in the T cell compartment increases apoptosis at the double-negative 2 stage and arrests the development of both B and T lymphocytes. Mcl-1 is also essential for mature lymphocyte survival, and experimental elimination of this molecule triggers their rapid loss (136). Transgenic experiments in which Bcl-2 or Bcl-X_L were overexpressed suggest, however, that the two proteins can functionally substitute for one another

and govern a final common death pathway (275). Selective transgenic overexpression of Bcl-2 in B or T cells leads to increased numbers of those cells and the late onset of lymphomas (296,297). Bcl-2 overexpression also blocks Apaf-1– and caspase-9–independent pathways of apoptosis, demonstrating the broad inhibitory effect of Bcl-2 (298). Further, Bcl-2 was recently shown to suppress Beclin 1 autophagic cell death, a novel form of nonapoptotic cell death (20,299). Deficiency of the pro-apoptotic Bax protein has a surprisingly mild phenotype in mice, causing only abnormalities in testis development and sterility (300). Deficiency of the pro-apoptotic Bak protein also causes very little effect in mice. However, a combined deficiency of Bax and Bak causes multiple organ abnormalities and perinatal death due to failed apoptosis (301). This includes an accumulation of lymphocytes and other hematopoietic cells, underscoring the importance of the Bax and Bak proteins for normal immune homeostasis.

Recent work has focused on the BH-3–only subset (Figure 27.6). Structural analysis has revealed that Bcl-2 family members interact through a hydrophobic pocket formed by the confluence of the BH-1, BH-2, and BH-3 helices. The interactions between Bcl-2 family members have a characteristic selectivity and hierarchy that may depend principally on binding to the BH-3 helix *(302)*. The BH-3–only proteins may selectively regulate the other family members through interactions at the hydrophobic pocket. Genetic ablation experiments have demonstrated the critical role of this family during developmentally programmed cell death as well as stress-induced death (94). So far, only one BH-3–only protein, called EGL-1 (egg laying defective 1), has been characterized in *C. elegans*. In mammals, the BH-3–only subset includes Bad, Bik, Bid, HRK, Bim, Noxa, Puma, Bmf, and perhaps others because the BH-3 motif is only a 9–16 amino acid long of alpha helix. Induction of cell death by BH-3–only proteins requires Bax and Bak, indicating that BH-3 proteins act upon or upstream of pro-apoptotic relatives *(303,304)*. The activity of BH-3–only proteins is governed transcriptionally and posttranscriptionally in a highly regulated fashion according to their function. Bid is cleaved by caspase-8, yielding a 15 kDa fragment that is myristoylated, which can insert into the mitochondrial membrane. This triggers the oligomerization of Bax and Bak thereby connecting the DRs to the mitochondrial pathway of death (*163,167*,291,305,*306*,307). Phosphorylation of Bad and Bim can control their association with 14-3-3 proteins or the microtubule-associated dynein motor complex, respectively (100). When released, Bad and Bim can induce apoptosis through the mitochondrial pathway. Interestingly, most of Bim is bound to Bcl-2 and Bcl-X_L at the mitochondria in both resting and activated T lymphocytes (308). Genetic deficiency of Bim protects against a variety of death inducers, such as cytokine deprivation, γ-radiation, glucocorticoids, ionomycin, DNA damage,

etoposide, and Taxol but not FasL (52). Deficiency of Bim also significantly impairs TCR-induced thymocyte selection. These diverse forms of regulation provide a mechanism for a variety of different apoptosis inducers to converge on the mitochondrial pathway of death.

The mechanism by which the BH-3–only proteins control cell death is still an intense field of research. Studies carried out with peptides corresponding to the α-helical BH-3 domains distinguish two different subgroups of BH3–only proteins (*309,310,*311,*312*). The "activating BH-3" proteins (including Bim and Bid) can directly trigger death by Bax and Bak besides counteracting Bcl-2 and Bcl-X_L. The second group includes Bad and Bik and is called *derepressor BH3* or *sensitizing BH-3*. These molecules suppress the anti-apoptotic activity of Bcl-2 and Bcl-X_L but fail to activate the executioners Bax and Bak. They thus sensitize the mitochondria by increasing OMM permeability but require the intervention of an additional activator of Bax to induce apoptosis. The development of drugs mimicking sensitizing BH-3 protein associations represent an appealing therapeutic approach to modulate the anti-apoptotic Bcl-2 proteins during cancer treatment *(279)*. A small organic molecule (ABT-737) with mechanistic similarity to Bad was recently characterized as a potent inhibitor of the anti-apoptotic molecules Bcl-2, Bcl-X_L, and Bcl-w. Resembling a Bad-derived peptide, ABT-737 inhibits anti-apoptotic Bcl-2 proteins, but does not directly activate Bax and Bak. ABT-737 exhibits synergistic cytotoxicity with chemotherapeutics and radiation *in vitro* and *in vivo*. It displays single-agent activity against lymphoma, small-cell lung carcinoma, primary patient-derived cells, and promotes the regression of solid tumors (313).

Apaf Proteins

Mammalian Apaf-1 constitutes another class of proteins that is critical for the mitochondrial pathway of apoptosis. Apaf-1 is structurally and functionally homologous to the *C. elegans* Ced-4 protein (314). Both Apaf-1 and Ced-4 contain an NH$_2$-terminal CARD domain followed by a nucleotide-binding oligomerization domain (NOD). Ced-4 can complex with caspase-9 via CARD domains present in both molecules. The NOD domain is essential for binding ATP and homo-oligomerization. In addition, Apaf-1 also contains WD-40 repeats at the carboxy-terminal, which bind cytochrome c released from damaged mitochondria. Interestingly, *C. elegans* Ced-4 contains no carboxy-terminal WD-40 repeats and does not respond to mitochondrial insults *(315)*. Apaf-1, cytochrome c and ATP are all required to properly activate pro-caspase-9 (186,316). Genetic evidence from knockout animals revealed that Apaf-1 and caspase-9 are obligatory components of the apoptosis response through p53 to DNA damage and other mitochondrial death events (*317,318,*319).

Other proteins similar to Apaf-1/Ced-4 have been identified, most of which contain regions of homology to the NOD domain. Overexpression studies suggest that several of these (NOD1, NOD2, IPAF, and cryopyrin) may modulate apoptosis, but most evidence indicates they chiefly mediate proinflammatory responses. These proteins initiate intracellular responses to peptidoglycan or other bacterial antigens, through NF-κB induction or maturation of caspase-1 (320). One of these proteins, NOD2, has been mapped as a susceptibility gene for Crohn's disease (321,322). The CARD domain of NOD2 may allow it to be involved in apoptosis as well as inflammatory responses. Many members of the TNFR superfamily such as TNFR-1 and Fas have divergent effects (e.g., cellular activation versus apoptosis) that are apparent at different times and depend on the context of the immune response. Hence, combinations of protein interaction motifs like the CARD, NOD, and other signaling domains in single adapter proteins may allow bifurcation of biological responses from the same receptor.

STRUCTURAL REGULATION OF PCD

TNF/TNFR Structure

The recent determination of structures of components of the PCD pathways has led to a better physical sense of how these death programs work (Figure 27.7). In almost all cases, the formation of specific stoichiometric protein complexes is crucial for apoptosis signaling. Receptor-mediated apoptosis by DRs within the TNFR superfamily is triggered by receptor-specific ligands within the TNF superfamily (61). The defining structural motif of the TNFR superfamily, the CRD, is a 40 amino acid cluster of β strands folded back on themselves and pinned in place by three disulphide bonds formed by six cysteines in highly conserved positions (Figure 27.7A). Most of the TNFRs have multiple CRDs, which serve two primary functions depending on location. The membrane proximal or central CRDs mediate ligand binding. For example, in TNFR-1, the two central CRDs, CRD2 and 3, provide the key ligand-binding contacts. The membrane distal CRD mediates receptor pre-assembly on the cell surface (323,324). This membrane distal CRD along with adjacent amino-terminal sequences is called the *pre-ligand assembly domain* or PLAD. It promotes the oligomerization of like receptor chains prior to ligand engagement. Pre-assembly of receptor chains into trimers or perhaps other oligomeric complexes is obligatory for both ligand binding and signal transduction. The PLAD has been identified in both DRs such as Fas, TNFR-1, and TRAIL receptors, as well as in non-DD receptors, such as TNFR-2 (323,324). The orientation of the receptor chains is likely to change drastically between the unliganded and liganded complexes as reflected
FIGURE 27.7 Structural biology of apoptosis. **A:** Structure of the unliganded TNFR-1. **B:** Side view of the TNFβ-bound TNFR-1 looking from plane of the membrane. Conserved disulphide bonds that are structurally essential are shown in red. **C:** Bird's eye view of the TNF/TNFR-1 structure looking down at the plane of the membrane. **D:** NMR structure of Bcl-X$_L$. The BH-3 (α2) domain runs perpendicularly across the molecule and the two central hydrophobic helices (α5 and α6) are buried in the middle portion of the molecule. **E:** Structure of the Fas DD, a prototypical hexahelical bundle. The bundle is composed of six helices, a structural scaffold that is also conserved in the DED and the CARD domain. The position of each of the helices is indicated. **F, G:** Structures of caspase-7 before (F) and after (G) proteolytic autoprocessing. Notice that the catalytic site (box) in the pro-enzyme is relatively "loose" (F). Processing of the pro-enzyme results in substantial "tightening" of the catalytic loops. The red-colored strand inside the boxed area in (G) denotes the position of the pseudosubstrate tetrapeptide DEVD.

in the extant crystal structures for unliganded and liganded TNFR-1 (see Figure 27.7A, B). The receptor chains are initially attached at the membrane distal CRD and then these interactions fall apart as the receptor admits the ligand between three receptor chains to interact with the CRDs closer to the membrane. The discovery of the PLAD overturned the prevailing model that TNFR family members signal by the ligand "cross-linking" solitary receptor chains

into a trimeric complex. Instead, the ligand will bind to and change the configuration of pre-assembled receptor complexes. Hence, CRDs can regulate both intra- or intermolecular associations critical to receptor function.

The ligands for TNFRs are typically obligate homotrimers that adopt a compact "jelly-roll" conformation with a hydrophobic face where the individual subunits stably interact with each other (61,*325*). Certain exceptions, such as LTα and LTβ, can form heterotrimers. The ligand subunits are usually synthesized as type II transmembrane proteins and, following trimerization, may remain membrane bound or undergo metalloproteinase cleavage to a soluble form (326). Binding of the pre-assembled receptor complex with the trimeric ligand forms a symmetric three-to-three ligand-receptor complex that is evident in the crystal structures of the liganded TNFR1 and TRAIL receptors (241,327,328,*329,330*). Functionally, the ligand interaction appears to re-orient the receptor chains so that the intracellular domains adopt a specific juxtaposition favoring the binding of appropriate intracellular signaling proteins. The recently solved structure of the TRAIL trimer differs from the TNF structure in that it contains a loop insertion in the first β-strand that is critical for receptor association (241,327,328,*329,330*). In both the TNFR-1 and TRAIL-R2 crystals, ligand contacts appear to be restricted to the second and third CRDs. The extensive receptor–receptor interaction in the PLAD region found in the unliganded TNFR-1 receptor structure is absent in the ligand-bound receptor crystal structures (*331–333*,334). How the ligand initially contacts the pre-formed receptor complex and initiates chain rearrangement are important unresolved questions.

The fundamental three-fold symmetry of the TNF superfamily ligands and receptors appears to be conserved among the proximal signaling complexes. This includes the receptor–TRAF2 interaction (335,*336*), TRADD–TRAF2 interaction (337,*338*), and Fas–FADD interaction. The importance of the trifold symmetry in the receptor and signaling apparatus is highlighted by genetic mutations found in both human and mouse. For instance, heterozygous mutations in the cytoplasmic DD of Fas found in the *lpr^{cg}* (mouse) or Fas-defective form of ALPS resulted in a greater than 50% reduction in receptor signaling (339,*340*,341). This is likely due to the fact that inclusion of at least one bad subunit in the receptor trimer prevents the formation of a 3:3 Fas:FADD complex and thereby abrogates signaling (341).

The genetic effect by which a mutant allele encodes a protein that interferes with the same protein encoded by a wild-type allele is called *dominant interference*. Dominant interference is usually observed in proteins that function by forming multiprotein complexes, which is now known to be a common feature in PCD pathways. In the case of the trimeric Fas receptor, dominant interference may be potent due to the fact that with equal expression of a

wild-type and mutant allele, $(1/2)^3$ or 1/8 would be expected to have solely *wild-type* subunits and 7/8 of the complexes would have at least one bad subunit by random reassortment of receptor chains (339,*340*,341). More generally, a dominant-interfering disease mechanism may be especially important in PCD disorders in outbred human populations, where most gene loci are heterozygous rather than homozygous. Thus, our understanding of the Fas receptor reveals that although higher order symmetric signaling complexes may provide rapid and selective signaling in immune regulation, they also create a vulnerability to genetic disease.

Bcl-2 Homology Structures

Bcl-X_L has the best-characterized structure, and it suggests interesting hypotheses regarding the function of Bcl-2 family members *(171)*. It contains a conserved nest of alpha helices including a backbone of two hydrophobic helices that are encircled by several amphipathic helices, including the BH4 helix, which is a key interaction site for members of the Bcl-2 family (Figure 27.7D). The structure has revealed a tantalizing similarity to pore-forming domains of bacterial toxins. This has stimulated a wealth of research into whether membrane pore formation is a key element of apoptosis modulation by Bcl-2 family proteins (342,*343*). It is interesting to consider that pore-forming toxins of bacteria have homology to regulatory proteins whose primary site of action is the mitochondria (which is believed to have evolved as a bacteria-like organism subsumed into eukaryotic cells). Structurally, Bcl-2 homology regions, BH1, BH2, and BH3 are widely spaced in the primary sequence but closely apposed in a hydrophobic pocket. Through this pocket, the pro- and anti-apoptotic members of the Bcl-2 family interact and cross-regulate one another. Proteins with only an amphipathic BH-3 helix can also interact with this pocket in the anti-apoptotic Bcl-2 family members and potentially nullify their protective function *(171)*. The specific amino acids contained in this pocket dictate a select hierarchy of interactions between various members of the Bcl-2 family. Hence, the structure reveals a possible functional interaction with the mitochondrial membrane and explains associations between members of the Bcl-2 family that determine survival or death.

The Hexahelical Bundle

The DD, DED, and CARD domains are critical protein–protein interaction motifs in DR-mediated PCD. Interestingly, all three domains adopt a similar structural scaffold of a compact bundle of six anti-parallel α-helices, which we will refer to as the "hexahelical bundle" (HHB) (Figure 27.7E). This structure is an ancient one that is related to the "ankyrin repeat," a protein interaction motif occuring in a

plethora of proteins and conserved throughout phylogeny (61,*171*). Despite remarkable overall similarity, significant differences exist among the DD, DED, and CARD, which likely account for their binding specificities. They usually form homotypic associations. For example, the surfaces of Fas DD is made up of mostly charged residues (344), whereas the FADD DED contains hydrophobic patches that are important for binding to caspase-8 *(170)*. The six helices in CARD domain of RAIDD form an acidic surface on one side of the molecule and a basic region on the other side of the molecule, which may be important for binding of the corresponding CARD domain in caspase-2 (345). Structural and mutagenesis data corroborate the notion that helices 2 and 3 are critical contact regions for homophilic DD and DED interactions. In addition to $\alpha2$ and $\alpha3$, homophilic CARD–CARD interactions appear to involve electric dipole interactions between $\alpha2$, $\alpha3$, $\alpha5$ on one molecule and $\alpha1$, $\alpha4$ on the partner. Examination of the CARD domain from Apaf-1 yields similar observations (346,*347*). Thus, specific molecular pathways are determined by defining residues in DD, DED, or CARDs presented on a common scaffold. It is also important to recognize that DDs, DEDs, and CARDs are primarily protein–protein interaction domains, and although they were initially discovered in apoptosis pathways, homologs of these motifs may be utilized by nature to associate proteins in pathways unrelated to apoptosis. In fact, a class of proteins containing the Pyrin domain also appears to use a HHB structural scaffold (*348,349*,350). The pyrin domain was originally identified in a protein mutated in patients with familial Mediterranean fever, thus providing a molecular link between apoptosis and inflammatory diseases.

An intriguing feature of HHBs is that they often occur in two tandem copies in proteins that promote or inhibit apoptosis. For example, the tandem DEDs in caspase-8 or -10 can augment apoptosis, whereas those in viral or cellular FLIPs inhibit apoptosis. The recent solution of the crystal structure of a viral FLIP, MC159, at 1.2 Angstroms resolution revealed a noncanonical fold of DEDs with a rigid dumbbell-shaped structure. Each DED played a unique role in the overall structure to generate an asymmetric interaction with DD proteins over an extensive surface (238). MC159 assembles into the DISC with Fas and FADD via a surface topology that differs from proapoptotic molecules. This blocks FADD self-association, which disrupts the higher-order oligomerization of the Fas receptors on the cell surface that is required for caspase activation.

Caspase Structure

The recruitment of DD-, DED-, or CARD-containing proteins eventually leads to the complex formation and activation of caspases. The structures of caspase-1, -3, -7, -8, and -9 have been determined (191,230,231,*233,234*,

235,242,243). Each caspase is composed of small and large subunits of approximately 10 kDa and 20 kDa (generally referred as p10 and -20, respectively). The catalytic subunits of all caspases are similarly composed of two p10/p20 heterodimers. Each p10/p20 heterodimer is folded into a compact cylindrical structure of six β strands and five α helices. The active site of the enzyme is formed by loops contributed by both the p10 and p20 subunits that come together at the top of the cylinder of β strands. The two heterodimers are aligned in an anti-parallel fashion where the β sheet forms the vertical axis of the tetrameric complex (Figures 27.6, 27.7F, G). Despite the overall structural similarity, distinct differences, especially in loops surrounding the catalytic active site, can explain the respective substrate preferences between different caspases.

Regulation of caspases by viral inhibitors has also been elucidated by structural studies. The baculovirus p35 is a potent inhibitor of many caspases that requires cleavage at its caspase recognition residue D87 to manifest inhibitory activity. Crystallographic studies reveal the formation of a thioester bond between the active site cysteine of caspase-8 (C360) and the aspartate of the amino-terminal cleavage product of p35 (351). Lu et al. showed that following caspase-8 processing, the buried p35 NH_2-terminus portion is liberated and undergoes a native chemical ligation reaction between residues D87 and C2. This mechanism, also used by self-splicing proteins, leads to the formation of a circular NH2-terminal p35 peptide, which is kept bound to the caspase-8 active site to ensure its long-lasting inhibitory effect (352).

PCD as Immune Therapy

Because of its exquisite antigen specificity, the possibility of using antigen-induced death, particularly of T lymphocytes, for the treatment of immunological diseases has been suggested *(353,354)*. In particular, the T cell components of graft rejection, autoimmune diseases, and allergic reactions could potentially be suppressed by antigen-induced elimination. This concept has been tested in both mice and monkeys with clearly beneficial effects on disease outcome. For example, it was found that the repetitive administration of a myelin basic protein antigen could suppress experimental allergic encephalomyelitis in mice by deleting the disease-causing T cells (88). This suggests that antigen-specific therapy is achievable if antigens relevant to the disease process are sufficiently well-defined and death of the culpable T cells can be triggered without exacerbation of symptoms (31).

Because these requirements have limited further evaluation of antigen-specific therapy in human clinical trials, other ways of triggering death have been explored. Fas or TNF agonist administration results in systemic toxicities limiting their potential utility (355,356). However, TRAIL agonists potentially induce death of neoplastic cells preferentially (184,357). Intracellular apoptosis signaling molecules targeted in preclinical or clinical trials include caspases, IAPs, Smac, and pro- or anti-apoptotic BCL2 family members (*253,313,358,359*). Many of these are rationally designed small molecules or peptidomimetics, which have demonstrated promising results, particularly against lymphoid and other malignancies.

PCD and Development of Lymphoid Malignancy

In this last section, we return to the question of why the mature immune system assiduously eliminates lymphocytes that have been activated by antigen and therefore have proven usefulness. Why can't the immune system adopt a laissez-faire economy of previously activated cells, which might have great value if the same pathogen is reencountered? Several lines of evidence strongly suggest that in addition to potential loss of tolerance and autoimmunity, lymphoid malignancy is also promoted by defective apoptosis. Hence, the accumulation of immune cells that have a propensity to proliferate and can undergo additional genetic changes may be deleterious to the organism. The association of translocations of the Bcl-2 gene with diffuse large cell lymphoma suggested that somatic aberrations in apoptosis pathways might be important in the transformation process. Since then, somatic changes in a variety of apoptosis molecules including Fas, caspases, and Bcl-2 family members have been documented in lymphoid tumors *(360)*. By contrast, the well-known inheritable apoptosis defect in p53 in the Li-Fraumeni syndrome seems to cause predominantly solid tumors but not lymphomas. Examination of large kindreds of patients with ALPS has revealed a 15-fold greater incidence of lymphomas. It is striking that these families have several different classes of lymphoma, suggesting that Fas protects against transformation not for a single cell type but generally for B and T lymphocytes (361). Moreover, Fas stimulation not only results in death induction, but also induction of signals for survival and proliferation such as NF-κB and MAPK activation; these dichotomous signals may have different thresholds, which can contribute to lymphomagenesis *(362)*. Thus, besides autoimmune manifestations, we can infer that protection against lymphoid malignancy demands strict control over the accumulation of activated lymphocytes.

CONCLUSION

The study of PCD has provided insights into many aspects of immune function, particularly in the establishment of central and peripheral tolerance and the numerical homeostasis of immune cells. PCD plays a vital part in the clonal composition, both qualitatively and quantitatively, of the

immune repertoire. Immune cells utilize conserved mechanisms of apoptosis and necrosis that are common to perhaps all mammalian cells. Indeed, the immune system has been one of the most instructive model systems for understanding how these networks function. Finally, death is regulated by cues from the environment. For developing lymphocytes, the antigen environment determines cell survival and elimination. For mature cells, antigen and growth cytokines determine life or death. In this manner, the immune system can develop a wide repertoire of reactive cells, select the most useful members of the repertoire, and then expand and contract specific clonotypes as needed for specific immune responses. Such homeostatic control allows rapid cell proliferation in protective responses while preserving tolerance and avoiding autoimmunity and immune cell malignancies. There are still important challenges in this area of investigation. The molecular mechanisms of antigen receptor–induced apoptosis and necrosis are still not fully understood. In fact, fundamental questions such as what the crucial proteolytic substrates of caspases are for apoptosis remain unanswered. Also, the genetic or environmental influences that cause autoimmunity in certain individuals with Fas defects but not others await definition. Also, the death effects by various lymphocytes subsets, particularly FoxP3$^+$ CD4$^+$ T cells, have not been fully explored. Finally, harnessing our understanding of PCD in the immune system for the diagnosis, prevention, and treatment of immunological diseases is an exciting frontier for the future.

Immunologic Memory

Stephen P. Schoenberger and Shane Crotty

MEMORY AS A BIOLOGICAL CONCEPT

The Protected State

Yet it was with those who had recovered from the disease that the sick and the dying found most compassion. These knew what it was from experience, and had now no fear for themselves; for the same man was never attacked twice—never at least fatally. And such persons not only received the congratulations of others, but themselves also, in the elation of the moment, half entertained the vain hope that they were for the future safe from any disease whatsoever (1).

The preceding quote comes from the Greek historian Thucydides (ca. 460 BCE to ca. 395 BCE) and describes his first-hand account of a plague that struck Athens during a protracted war with Sparta. Although the identity of the causative agent continues to be a matter of speculation (2), these words transcend the ages to vividly illustrate the concept of immune memory—the phenomenon in which prior exposure to an infectious pathogen endows an individual with immunity, a durable state of protection against reinfection with the same organism. Unknown to Thucydides and his fellow Greeks, the immunity observed in the survivors of this plague reflected changes in the operational status of their immune systems as a result of

the first (primary) response to the infecting pathogen. In the act of responding to the initial infection, the immune system expands a diverse population of antigen-specific B and T lymphocyte clones possessing a range of affinities and effector capacities. Through a process that is just now beginning to be understood at the molecular level, a portion of this repertoire is retained within the memory pool in the form of cells that are able to persist for long periods of time at relatively stable numbers by maintaining a slow but steady rate of division that is roughly equivalent to their rate of loss (death). When faced with a renewed challenge from the same (or antigenically related) infectious agents, memory cells mount a strong and rapid effector response that is capable of stopping reinfection at its earliest stages. The functional units of immune memory, therefore, are the long-lived B and T cells that mount rapid secondary (recall) responses on reencounter with their cognate antigen. In the broader teleologic concept of memory, however, it is the antigen receptors that were shown to be "useful" in combating the initial infection that are selected and preserved at an increased frequency on clonal progeny that possess enhanced response kinetics and specialized functions. Whether generated through infection or vaccination, the value of the protected state that they confer to the individual is self-evident because preexisting immunity can prevent or limit the potential damage of

an otherwise unrestrained infection. This can be of benefit from the earliest days of life, as seen in the example of maternal antibodies transmitted to the neonate in milk and serum that may serve to limit infections and transform them into "natural vaccinations" and thereby diminish the severity of childhood infections that will be encountered during the next 1 to 2 years (3,3a).

This chapter examines the phenomena and mechanisms of long-lasting protection that can develop following infection or vaccination and focuses on the factors that govern the establishment and maintenance of specialized subsets of lymphocytes generated from the naïve repertoire during the primary response to a given antigen. This concept stands in contrast to the "memory" associated with immune tolerance, through which the adaptive arm of the immune system can prevent inappropriate responses against ubiquitous self-antigens. Immune memory involves a stable increase in the number of antigen-experienced B and T lymphocytes that have acquired specialized functional properties allowing them to generate secondary responses that are more rapid and effective than those made by their clonal antecedents during the primary response. It is in the establishment, maintenance, and execution of memory responses that the adaptive immune system finds its greatest purpose for the preservation of both the individual and population. As shown in this chapter, immune memory depends on a remarkable degree of interaction and cooperation among many different cell types in an elegant division of labor aimed at preserving those T and B cell specificities that have proved useful in the battles fought and won against previously encountered pathogens. It is important in considering the concept of immune memory, however, that distinctions be drawn between the protected state, an operational definition that can vary with the nature and magnitude of the antigenic challenge used to test its integrity, and memory cells, the clonal elements of memory whose contribution to the protected state can only be inferred from their phenotypic and functional properties.

Lifelong Memory Can Be Induced Through Infection or Vaccination

Observations of acquired resistance to recurring diseases are recorded throughout the history of human epidemics. The careful observations of the Danish physician Ludwig Panum were among the first clearly to illustrate just how durable the protected state can be in an individual. Working on the remote Faroe Islands in the North Sea, Panum studied two separate measles epidemics that took place 65 years apart between the 18th and 19th centuries. In the apparent absence of outbreaks in the intervening period, he found that people who had contracted measles in the first epidemic were not affected during the second, whereas those of appropriate age who were infected dur-

ing the second outbreak had not been affected during the first (4). Thus, Panum observed, a single infection was capable of endowing an individual with lifelong immunity through a process that did not require reexposure to the pathogen. Although immune reactivity can be boosted by repeated exposure to a given organism, the extent to which this determines the maintenance of immune memory remains a source of some controversy (5,507). A source of uncertainty in applying this concept to human immunology is the difficulty in determining whether a single exposure or multiple exposures have taken place before the memory state is assessed. With infrequently encountered life-threatening infections such measles, yellow fever, or polio it is relatively straightforward to infer that a single exposure can establish a state of protection for up to 75 years that appears to be mediated by antibodies (4,6,7). With less threatening ubiquitous agents such as those causing the childhood infections chicken pox (varicella zoster) and whooping cough (*Bordatella pertussis*), it is unclear whether immune memory may depend on occasional subclinical reinfection (8,507).

Given the long history of immunity in survivors of infectious disease, it is notable that even the most rudimentary understanding of how the protected state could be achieved was realized long after methods for its induction had been devised. Among the earliest practices was that of variolation, which had long been in practice in China and India as a means for enhancing protection against the deadly smallpox virus, which had been a major source of mortality in humans since recorded history (9). Variolation involves the intentional inoculation with dessicated material obtained from the open pustules of smallpox victims in the hope that exposed individual would develop a milder form of the disease and, on recovery, be immune to smallpox (variola virus). Although effective in many cases, the procedure was not without risk to the recipient, who risked contracting a more serious life-threatening form of the disease that could be spread to others. In 1796, Edward Jenner famously (and dramatically) overcame these obstacles by using material obtained from the pustules of milkmaids infected with cowpox (vaccinia virus), an antigenically related but less virulent type of poxvirus, to inoculate young James Phipps, who subsequently survived his exposure to infectious smallpox patients (10). In the 19th century, Louis Pasteur further developed the concept of using less-virulent or intentionally disabled forms of infectious organisms to confer immunity to bacterial diseases such as chicken cholera and anthrax and viral diseases such as rabies. Pasteur used the word "vaccine" as a generic term to describe antigenic preparations administered to produce immunity, in reference to Jenner's earlier work with cowpox (vaccinia) virus (*vacca* is Latin for "cow"). As described in more detail in the chapter on vaccines, current vaccines can be generated from organisms that are antigenically related to the one against which immunity is desired,

from inactivated forms of the entire disease-causing organism, or from specific constituent portions of the infectious organism such as proteins, polysaccharides, or nucleic acids.

Despite their various compositions, all effective vaccines recapitulate several important aspects of the immune response leading to memory formation: they mimic the threat of an infectious pathogen through stimulation of innate immunity via Toll-like receptors (TLRs), and they contain distinct antigens that can become recognizable by cells of the adaptive immune system (11,12). The power of vaccination to induce long-lasting immune memory is best illustrated by the example of the smallpox vaccine (vaccinia). This once-devastating organism has been virtually eradicated since the late 1970s through a worldwide mass vaccination program that stands as one of the crowning achievements of the 20th century (13). The immunity induced by the smallpox vaccine is of remarkable durability, with both antibody and CD4$^+$ and CD8$^+$ T cell responses detectable 50 years after initial priming (14–16), and effectiveness, with a lifelong protection rate of 90% to 95% in vaccinated individuals and a fatality rate of only 2% in those vaccinated within a decade before exposure (17,18). With the advent of modern immunologic tools such as enzyme-linked immunosorbent assay (ELISA), intracellular cytokine staining (ICCS), and enzyme-linked immunospot (ELISPOT) assays for the detection of rare vaccinia-specific T and B cells, a more detailed longitudinal picture of the response to the smallpox vaccine has emerged. These studies suggest that humoral immunity is more durable than cellular immunity: Increased numbers of vaccinia-specific memory B cells remain stable for more than 50 years after vaccination, whereas CD4$^+$ and CD8$^+$ T cell responses continue to decline over time, with a half-life of 8 to 15 years (14,16). This indicates that memory B cell responses, and to a lesser extent memory T cell responses, are maintained by robust mechanisms. The reason for the apparent discrepancy between the longevity of memory B versus T cell responses is unknown, but it may involve the selective ability of mature B cells to perform more extensive DNA repair than T cells through their recombination and somatic hypermutation machinery (19).

Given the remarkable longevity of the immunity induced through either infection or vaccination, it is clear that the cells mediating the protected state must possess several key properties to preserve useful specificities generated in previous antigenic experiences; the study of memory T cells has revealed insights into a number of these features. First among these is that antigen-specific memory cells must be present in the immune repertoire in greater numbers than in the naïve repertoire as a result of their initial proliferation (20–25). Second, they must have undergone a program of differentiation involving alterations in chromatin structure and activation of specific transcription factors to allow the expression of key effector

molecules such as perforin, granzyme B, and interferon-γ (IFNγ) to be constitutively expressed and to be available immediately on recognition of antigen-expressing target cells (26–32). Memory cells must be able to survive as a clonal population over time; that is, they must be able to replace cells lost to normal homeostatic turnover (reviewed in refs. 33, 34). Memory cells also must perform a sentinel function by occupying specific physiologic niches where naïve cells are not usually found and where antigen exposure will either occur or be detected such as the mucosa of the lung or gastrointestinal tract (reviewed in refs. 35, 36). Consistent with this sentinel function, memory cells are found to be capable of responding to lower concentrations of antigen than naïve cells through the selective expansion of high-affinity clones and the upregulation of adhesion molecules and reorganization of their T cell receptor (TCR) (37–40). Lastly, memory cells should be able to respond quickly to reencounter with their cognate antigen with the induction of rapid effector functions and renewed rounds of clonal expansion (41). Memory cells have developed a variety of mechanisms to achieve each of these specialized properties. In the following section, we examine how memory cells are generated during immune responses and how these key features are imparted during priming, maintained over long periods of time, and expressed when needed to confer rapid protection from reinfection.

THE GENERATION OF MEMORY T CELLS

Antigen-driven T cell responses can be broadly categorized as having two main components: a comparatively short-lived effector arm that comprises large numbers of cells that mediate direct functional response against target cells, and a smaller but longer-lived memory population that ensures the potential of rapid and potent recall responses against the inducing antigen. The memory component can be distinguished into two separate activities: one that resides mainly within lymph nodes, where it can respond to antigenic challenge by renewed clonal expansion and production of secondary effectors ("central memory" phenotype T cells [T$_{CM}$s]), and one that is largely disseminated throughout peripheral tissues, where the first contact with infectious pathogens is likely to occur ("effector memory" phenotype T cells [T$_{EM}$s]), and is capable of mediating immediate effector functions on antigen recognition (35,42). These subsets were first distinguished in humans based on their expression of the lymph node homing receptor CD62L and CCR7 and by their effector functions and proliferative capacity (41,43). The specific roles in immunity and the signals that may govern the development of these subsets are discussed in subsequent sections in this chapter. Although the effector and memory responses typically display notable quantitative, qualitative, and temporal

differences in their function, it is generally accepted that both originate from the same primary response to antigen, with memory population being endowed with an enhanced capacity for self-renewal and recall responsiveness. It is the precise relationship between the effector and memory populations that has been the focus of intense experimental interest over the last 10 to 15 years, with distinct and often contradictory results emerging from different experimental systems. This is due in part to kinetic and functional differences in which effector and memory populations are detected, their shared expression of many surface markers, and the paucity of methods for reliably tracking both their emergence from naïve precursors and determining their lineage relationships over time.

There are several models for how both effector and memory populations could be concomitantly generated, either in parallel or sequentially (Figure 28.1). The first model suggests that memory cells are the clonal progeny of a distinct precursor population that follows a separate differentiation fate from that of the primary effectors and instead survive to execute these effector functions during the recall phase (separate precursor model). The second model posits that memory cells derive from the same precursor pool as the effectors but are descended from cells that have received qualitatively and/or quantitatively distinct signals at the time of their the initial priming or subsequent development (instructive model) (44). The inductive signals that can influence memory versus effector fates in this view include a range of antigen-specific and nonspecific stimuli, such as the strength and duration of TCR signals, the nature of costimulatory molecules and cytokines produced, or the type of antigen-presenting cell(s) (APCs) involved. An alternative model supports the notion that memory cells are generated in a stochastic manner via asymmetric cell division that occurs at a preprogrammed stage of antigen-driven clonal expansion (stochastic model) (45,46). This model envisions memory as a cellular fate governed by the same common biological strategy used during ontogeny and development to specify distinct functional properties in selected cells and their clonal progeny (47). Finally, memory T cells may constitute a functionally distinct population generated through progressive differentiation of the same precursors that give rise to short-lived effectors (progressive differentiation model) (48). Two mutually nonexclusive pathways have been suggested through which this can occur: linear and nonlinear differentiation. In the linear pathway, T cells proceed sequentially through distinct functional states, first as effectors, with a subset of these developing into the memory population (reviewed in refs. 49, 50). Alternatively, memory development may follow a nonlinear pathway in which environmental signals and an individual cell's stimulation history influence whether primary effectors develop into T_{EM} or T_{CM} subsets. Variations applicable to the latter three models have been proposed in which

sequential encounters with antigen can decrease the potential of a given cell to differentiate fully into a memory cell (51,52). In each of these models, the initiating event leading to memory cell development is the primary activation of a naïve T cell in response to immunization or infection. We therefore begin our consideration of memory T cell generation with the illustrative example of the CD8$^+$ T cell response. Many of the concepts relevant for CD8$^+$ T cell priming are also applicable to the generation of CD4$^+$ T cell memory, whose unique characteristics are discussed in the following section.

The Generation of Memory CD8$^+$ T Cells

CD8$^+$ T cells are critical for the control of acute and chronic infections by a range of pathogens, including viruses, intracellular bacteria, and single- and multicellular parasites, and can mediate the destruction of tumor cells (53–60). Most of our understanding of how memory CD8$^+$ T cells are formed has emerged from studies on the response to acute infection in mice. This is partly due to the nature of the immunogens used to generate robust T cell responses in these models, such as lymphochoriomeningitis virus (LCMV), influenza A (flu), or *Listeria monocytogenes* (LM), which produce significant numbers of effector CD8$^+$ T cells specific for a subset of immunodominant class I major histocompatibility complex (MHC)–restricted antigens on infection of inbred mice (61–63). Another reason is the availability of superior tools for the detection and longitudinal tracking of antigen-specific CD8$^+$ T cells such as intracellular cytokine staining (ICS), which allows enumeration of cells secreting cytokines in response to their cognate peptide antigen, and the use of peptide/MHC tetramers, which are soluble forms of the ligand structure recognized by T cells and which allow the detection of cells recognizing a specific antigenic determinant (64,65). When combined with more traditional antibody-based immunophenotyping approaches used in flow cytometry, these techniques have revealed important features of the specificity, kinetics, magnitude, and functional differentiation of antigen-specific CD8$^+$ T cells following infection and have allowed new insights into the process of memory T cell development (66,67). Finally, the use of TCR-transgenic T cells in adoptive transfer experiments has allowed the fate of a monoclonal population of antigen-specific CD8$^+$ T cells to be followed throughout their development from naïve to memory cells. Such studies have established that the CD8$^+$ T cell response to infection can be divided into four main phases: priming, contraction, memory maintenance, and recall (Figure 28.2). As explained in this section, the first two phases involve a complex and carefully orchestrated series of cellular interactions to transport antigen from the site of inflammation or infection to the secondary lymphoid organs where the events leading to memory formation can take place. next phases (maintenance and recall) of the CD8$^+$ T cell response are considered in a subsequent section.

Phase I: Priming and Clonal Expansion

The process of generating T cell memory begins at priming, which is the initial activation of mature postthymic precursors by peripheral antigens. Before the priming phase can be initiated, however, antigen-specific naïve precursors must sample a network of professional antigen-presenting cells, usually dendritic cells (DCs), within the spleen and lymph nodes (LNs) and locate the rare few that present the specific surface class I MHC/peptide complex recognized by their TCR. This is not a simple task because CD8$^+$ T cells recognizing any one single antigen are rare in the naïve repertoire, occurring with a frequency of perhaps 1 in 10^5 to 10^6 among the total population (68). The antigen-bearing APCs are also likely to be infrequent among the (tens of) millions of cells within a given LN or in the spleen because in most cases they must first obtain their antigenic cargo at peripheral sites of infection and then migrate via the lymphatics to LNs or via the bloodstream to the spleen (69). As will be described, the complex interaction of rare and migrating cell types necessary for the generation of immune responses is facilitated by highly regulated patterns of migration and by the structural features of the secondary lymphoid organs themselves.

Naïve T cells are produced at a modest rate by the thymus, with approximately 1–2×10^6 cells per day emerging into the bloodstream in young mice (70,71). These recent thymic emigrants (RTEs) are preferentially incorporated into the periphery regardless of the size of the existing pool (72). The homeostatic survival of naïve cells/RTE requires at least two types of extrinsic signals: (a) MHC molecules that are presumably occupied with low-affinity ligands (self or environmental peptides) and provide tonic TCR stimulation, and (b) a critical cytokine, interleukin-7 (IL-7) (73–79). IL-7 is a nonredundant member of the type I cytokine family that signals through a heterodimer comprised of the common cytokine signaling γ-chain (γc) and IL-7Rα (reviewed in ref. 80). Neither of these components is unique to IL-7; γc is shared with IL-2, IL-4, IL9, IL-15, and IL-21, and IL-7Rα is shared with thymic stromal lymphopoetin (TSLP). IL-7 is produced by nonhematopoietic stromal cells in multiple organs, including the thymus, where it promotes survival of developing T cells, and within peripheral lymphoid organs, intestine, and liver, among other sites. IL-7 has many roles in lymphopoiesis, promoting the survival, proliferation, and development of B cells, thymocytes, and mature T cells (81). Because γc is expressed widely among lymphocytes, IL-7 responsiveness is governed by surface levels of IL-Rα that are tightly regulated through thymopoiesis (high on double negative cells, absent on double positive cells, and high once again on thymocytes undergoing positive selection) and, as will be discussed, on naïve and memory T cells (82,83). Consequently, mice deficient in either IL-7 or IL-Rα have severely reduced numbers of peripheral T cells, and excess IL-7 provided exogenously or through transgenic expression leads to cycling and expansion of the naïve T cell pool (84–88).

Once released from the thymus, naïve T cells circulate continuously between blood and lymph, entering into LNs via the high endothelial venules (HEVs) before returning to the blood through the thoracic duct lymph (89–93). Naïve T cells express high levels of two receptors that are critical for this pattern of recirculation: (a) CD62L, which allows T cells to arrest at the site of expression of specific ligands expressed on HEV and initiate the process of translocation into the LN cortex, and (b) CCR7, a chemokine receptor that allows T cells to follow a gradient of the chemokines CCL19 (ELC) and CCL21 (SLC) produced by LN endothelial cells at the point of entry (94,95). Once inside the LN environment, naïve T cells are guided by a network of collagen fibers ensheathed in specialized stromal cells (called fibroblast reticular cells [FRCs]) toward specialized T cell compartments, where they encounter APCs that have arrived from peripheral sites via afferent lymph drainage and transport through pores in the subcapsular sinus (96–100). Thus the entry of naïve T cells into the LN is a highly regulated process that is facilitated by specific homing receptors, chemokines, and the structural features of the LN environment. Entry of naïve T cells into the spleen, by contrast, is nonspecific, with blood-borne precursors carried in by the splenic artery and deposited in the marginal zone between the red and white pulp before moving selectively to the white pulp, where they accumulate around central arterioles called periarteriolar lymphocyte sheaths (PALS). The movement of naïve T cells from the marginal zone to the PALS is guided by CCR7-mediated recognition of ligands expressed on stromal cells; activated CD8$^+$ T cells lacking this receptor are excluded from the white pulp and effector cells, with enforced expression of CCR7 localized almost exclusively to this compartment (101,102). Continuous migration of naïve T cells through the secondary lymphoid organs ensures their rapid exposure to antigens derived from pathogens. In the absence of antigenic stimulation, the blood-to-lymph process takes about 12 to 18 hours for circulation through LNs, whereas the average residence time of a naïve T cell in the spleen is 12 hours (103). To become stimulated (primed), naïve T cells must recognize antigens in the form of peptide fragments bound to MHC molecules on professional antigen-presenting cells such as DCs. Within the T cell areas of LN and spleen, DCs form a dense cellular network that is continuously sampled by recirculating T cells for the presence of antigenic peptides, that is, those peptides for which a TCR repertoire exists and which are presented in an immunogenic context by an activated APC.

In their response to microbial pathogens, immature DCs migrate to sites of infection and inflammation in response to a range of CC and CXC chemokines. For example, immature DCs respond to CCL3, CCL4, CCL5, and CCL20, which are inducible on inflammatory stimuli (104–107). Of note, each immature DC population displays a unique spectrum of chemokine responsiveness. Langer-hans cells migrate selectively to CCL20 (via CCR6) and blood CD11c$^+$ DCs to MCP chemokines (via CCR2), and monocyte-derived DCs respond to CCL3 and CCL4 (via CCR1 and CCR5), whereas blood CD11c$^-$ DC precursors do not respond to any of these chemokines. Each of these chemokines is inducible on inflammatory stimuli, such as CCL20, which is only detected within inflamed epithelium, a site of antigen entry known to be infiltrated by immature DCs. Once at the site of infection, DCs acquire both soluble and particulate antigens through various phagocytic (pinocytosis, phagocytosis) and endocytic pathways (receptor-mediated endocytosis) that are highly active when DCs are in the immature state (reviewed in refs. 69, 108). As a consequence of antigen uptake at the site of an infection, these DCs will be exposed to a range of immunostimulatory adjuvants derived from the infectious microorganisms themselves, such as lipopolysaccharide (LPS), double-stranded RNA, or unmethylated CpG DNA that can be recognized by a family of highly conserved germline-encoded sensor molecules called Toll-like receptors (109–111). These receptors, expressed on the plasma membrane and within cells, signal through a set of intracellular adaptor molecules called TIR adaptor proteins because they share a common Toll-like/IL-1 receptor domain used for homophilic association with the TLRs (112). Four 4TIR proteins are identified that transduce TLR-mediated signals (MyD88, MAL/Tirap, TRIF/Ticam-1/Lps2, TRAM), and a fifth (SARM) appears to negatively regulate TRIF (113–120). Each of the TIR adaptor proteins associates with a specific set of TLRs (MyD88 with all TLRs, TRIF with TLR-3 and TLR4, etc.), and it is believed that differential use of these TIR domain–containing adaptors provides specificity to individual TLR-mediated signaling pathways (121,122). Ligation of different TLRs induces gene programs in DCs that lead not only to the robust production of general proinflammatory mediators and upregulation of costimulatory molecules, but also to the production of unique effectors, which provide pathogen-tailored immune responses. In addition to directly sensing the presence of infectious microbes, DCs can also react to the tissue damage caused by these microorganisms via endogenous "danger" signals such as heat-shock proteins, nucleotides, reactive oxygen intermediates, extracellular-matrix breakdown products, neuromediators that are released by stressed or damaged tissues, or those undergoing abnormal death (123). Damaged or infected cells can also produce alarm signals through the production of interferons, such as type I interferons (IFNα, IFNβ) that can lead to complex signaling events within DCs that synergize with those emanating from TLRs to promote a range of gene expression and functional changes in DCs (reviewed in refs. 124, 125).

After exposure to either endogenous or exogenous alarm signals, DCs undergo a transition from an immature to a mature state and begin to express new chemokine

receptors that facilitate their migration away from sites of inflammation and toward the T cell areas of secondary lymphoid organs (126). The most important among these is CCR7, the same receptor used by naïve T cells for LN chemokinesis (reviewed in ref. 127). The CCL19-CCL21-CCR7 chemokine system, therefore, plays a critical role in orchestrating immune responses by guiding both naïve T cells and migrating DCs to high-traffic areas within the deep cortex of LNs, where they can interact and T cell priming can occur. Consistent with this, mice lacking either CCR7 or CCL19/CCL21 have profound defects in T cell and DC motility and mount substantially depressed antiviral T cell responses (128–132). In addition to altered migration characteristics, DCs undergoing maturation initiate a variety of other changes that enhance their capacity to present antigen in an immunogenic form. These include a marked cellular redistribution of major histocompatibility complex class II molecules (MHC II) from late endosomal and lysosomal compartments to the plasma membrane that is accompanied by downregulation of some forms of endocytosis (133–137). The result of this is the surface presentation of MHC class II molecules with a substantially increased half-life, thus preserving the "antigenic fingerprint" of the material (in the form of peptides bound to MHC molecules) ingested at the site of infection for subsequent presentation to T cells in the secondary lymphoid organs (138).

Another critical consequence of DC activation is the upregulated expression of numerous costimulatory molecules and cytokines that contribute to T cell priming by promoting cell division, survival, and differentiation (69,139–141). The primary activation of naïve T cells has traditionally been believed to require at least two signals: an antigen-specific "signal 1" that is transmitted on TCR-mediated recognition of its cognate peptide/MHC complex and an antigen nonspecific "signal 2" costimulus (142,143). This "two-signal" model predicted that engagement of the TCR in the absence of costimulation is insufficient for sustained clonal expansion and cytokine production, and cells instead become anergic and unresponsive to further stimulation (144). Although this outcome has been demonstrated in a number of studies, the number of ligand/receptor pairs capable of functioning as "signal(s) two" has grown considerably in the last decade. CD80 and CD86 are considered to be the prototypical costimulatory molecules expressed on APC capable of transmitting "signal 2" through their interaction with CD28 expressed on T cells. CD80/86-mediated ligation of CD28 produces signals in T cells that are distinct from that of the TCR and enhances clonal expansion, effector functions, and memory development (145–148). Although many CD4$^+$ and CD8$^+$ T cell responses depend on CD28, the requirement is not absolute because many types of T cell responses can occur in its absence *in vivo*, including allograft rejection, induction of allogeneic graft-versus-host and delayed-type hypersen-

sitivity responses, and the generation of cytotoxic CD8$^+$ T cells (149–153). These observations suggest that additional pathways exist for costimulation of T cells other than CD28 (154). A number of these have emerged from the tumor necrosis factor receptor (TNFR) family [CD27/CD70, 4-1BB (CD137)/4-1BBL, OX40 (CD134)/OX40-L, HVEM-LIGHT, CD30/CD30-L, and GITR], each of which can provide costimulatory stimuli that synergize with TCR signals to sustain T cell activation after priming and have been shown to be important for the magnitude and longevity of CD8$^+$ T cell responses *in vivo* in studies of knockout mice lacking either ligand or receptor (reviewed in refs. 154–156). It should be pointed out that the influence of costimulatory interactions on the regulation of CD8$^+$ T cells responses is by no means limited to the priming event: Several receptor–ligand pairs, notably 4-1BB/4-1BBL, OX4O/OX40L, BTLA/HVEM, and PD-1/PDL1/PDL1, can act on the expanded population with either positive or negative effects on T cell function and survival (156–158).

In addition to contact-dependent costimulation, a number of inflammatory cytokines including IL-12, IFN$\alpha\beta$, and IFNγ, have been implicated in the transmission of a "signal 3" that is required for optimal development of CD8$^+$ T cells (reviewed in ref. 159). One of these is IL-12, produced by DCs after some infections and by CD40 stimulation; it helps to drive the development of Th1-polarized CD4$^+$ responses (reviewed in ref. 160). Addition of IL-12 to CD8$^+$ T cells primed by peptide/MHC and B7 or IL-2 substantially promotes their proliferation, survival, and cytotoxic potential (161–163). The effect appears to be directly on the CD8$^+$ T cells because IL-12 can support wild-type CD8$^+$ T cell responses in IL-12Rβ_1-deficient hosts (164). The evidence for IFN$\alpha\beta$ as a signal 3 for CD8$^+$ T cells is less clear and may be influenced by the nature of the immunogen. Studies on CD8$^+$ T cells primed *in vitro* with peptide/MHC and CD80 showed that optimal expansion and development of lytic functions required addition of IFNα (165). *In vivo* studies with IFN$\alpha\beta$R-deficient LCMV GP-specific CD8$^+$ T cells transferred to wild-type mice showed dramatic reductions in their ability to undergo clonal expansion and to generate a memory pool following infection with LCMV (166,167). When the LCMV GP was expressed from a recombinant vaccinia virus, however, only a modest defect in CD8$^+$ T cell expansion and survival was observed, suggesting that the IFN$\alpha\beta$ dependence of CD8$^+$ T cell memory is influenced not by the target antigen but rather by the immunogen (166). This idea has found support in a recent study showing that the response of IFN$\alpha\beta$R-deficient transgenic CD8$^+$ T cells to the same peptide-pulsed DC vaccine offered in the context of four different infections (LCMV, vaccinia virus, vesicular stomatitis virus, and *Listeria monocytogenes*) were most severely inhibited for LCMV infection (166a). IFNγ has also been shown to support optimal CD8$^+$ T cell expansion
FIGURE 28.3 Models of CD4$^+$ T cell help for CD8$^+$ memory formation.

after LCMV infection or peptide vaccination, and transgenic CD8$^+$ T cells lacking the IFNγR1 display reduced expansion compared to wild-type cells in the same host (168–170). It is unclear why a range of factors can serve as signal 3, but the answer may have something to do with pathogen-specific innate responses and the range of inflammatory cytokines (i.e., IFN$\alpha\beta$ versus IL-12, etc.) that each produces (159). Alternatively, the kinetics with which the various signal 3 cytokines are produced could ensure that CD8$^+$ T cell responses are exposed to at least one during the course of their priming.

Although DCs increase their immunogenicity in response to inflammatory stimuli delivered at peripheral sites of antigen uptake, their stimulatory capacity can be further enhanced within the LNs through the action of CD4$^+$ "helper" cells (Th) that recognize peptide antigens bound to MHC class II molecules at the surface of the same APC presenting to the CD8$^+$ T cell (171–173) (Figure 28.3). The contribution of Th cells to CD8$^+$ priming had initially been thought to be conditional, that is, required for response to some immunogens but not others, and limited in mechanism to the production of paracrine IL-2 for the benefit of CD8$^+$ T cells present in a "three-cell cluster" together with APCs (174–176). More recent evidence, however, has shown that CD4$^+$ T cells make important contributions to the generation and maintenance of CD8$^+$ T cell responses at a number of discrete steps (reviewed in refs. 172, 177). Several studies have shown that a key function of Th cells involves the engagement of CD40 on DCs, which leads to a number of immunostimulatory alterations, including high-level expression of costimulatory and adhesion molecules, including CD80, CD86, 4-1BB, OX40, and CD70, as well as high-level production of IL-12 (156,178–182). CD4$^+$ T cells can also help to guide naïve CCR5-expressing CD8$^+$ T cell precursors to relevant APCs within secondary lymph nodes by enhancing production of the chemokines CCL3 and CCL4

at the CD4$^+$ T cell/DC interface (183,184). NKT cells are also able to provide CD40-dependent "help" for CD8$^+$ T cell responses, likely through recognition of glycolipid ligands such as α-galactosyl ceramide that are presented by CD1 molecules at the surface of DCs (185–187). Finally, CD4$^+$ T cells have been shown to be important for the maintenance of CD8$^+$ T cells whether they were primed in the presence or absence of Th cells (188). The "help" under these conditions apparently need not be cognate (antigen specific) as it is in the case of help for priming, suggesting that its role may involve the direct or indirect provision of homeostatic survival factors (discussed in the next section) (34). The absence of Th cells can have different effects on the CD8$^+$ T cell response depending on the immunogen and the functional parameter measured. In most cases, the primary response to immunization or acute infection is only modestly decreased. In acute infections using higher challenge doses and in chronic viral infections, however, CD8$^+$ T cells responses wane over time, leading to either deletion or exhaustion, a state of persistence without effector function (189–195). An explanation for these findings may be based in the "helpless" or "lethargic" phenotype displayed by CD8$^+$ T cells primed in the absence of Th cells in which they proliferate less, produce fewer cytokines during primary responses, and are defective in their ability to mount secondary proliferative responses, a hallmark of immune memory (196–200). In the case of recall responses to a cellular vaccine, the mechanism responsible involves the Th-mediated modification of the CD8$^+$ T cell developmental program to avoid apoptosis on secondary stimulation by TRAIL (TNF-related apoptosis-inducing ligand) *(201)*. The role of TRAIL in this process may be limited in its duration because, although TRAIL appears to regulate the secondary expansion defect of "helpless" CD8$^+$ T cells for at least 4 weeks after priming in the absence of Th cells, additional factors conferred by CD4$^+$ T cells are required for their homeostatic survival in the months afterward *(202)*.

Once a naïve CD8$^+$ T cell recognizes its cognate peptide/MHC ligand on an activated DC within the secondary lymphoid organs, the interactions of priming (i.e., the 'antigenic signal') can take place. The molecular details of this process involves the formation of immune synapses at the T/APC contact site that are composed of rapidly clustering TCR molecules binding peptide/MHC complexes on APCs plus the local accumulation of intracellular signaling molecules such PKC-θ, LAT, and LCK. The signaling events and downstream consequences for T cell activation are discussed in Chapters 11 and 13. To elucidate the cellular details of CD8$^+$ T cell priming, several groups have used multiphoton and confocal microscopy to visualize the process within intact LNs. These studies have revealed that the lymph node environment is dynamic, with T cell migration at a velocity of approximately 12 mm/min in their search for antigen and DCs able to sample 500 T cells per hour and make contacts with 10 T cells at any given moment *(203–206)*. By applying these visualization techniques to LNs within living animals (intravital microscopy), the priming of naïve CD8$^+$ T cells by DC was observed to occur in three distinct phases *(207)*. The first lasts several hours and is characterized by short interactions between T cells and DCs, with upregulation of activation markers such as CD44 and CD69.

Phase 2 of priming lasts for approximately 12 hours and features sustained (1 hour or longer) contacts between T cells and DCs as well as initiation of cytokine production. In the third phase, the T cells disengage from the DCs, proliferate, and return to their pattern of high motility. The rate of CD8$^+$ T cell clonal expansion can be remarkable, with cells undergoing sequential divisions approximately every 6 to 8 hours during their initial rounds *(32,208–211)*. The extent of CD8$^+$ T cell division and magnitude of their numerical increase can be equally impressive, with cells undergoing 15 to 20 rounds of division and number of effector cells increasing more than 10^4-fold over their initial frequency in the naïve repertoire in the setting of acute infection with LCMV or *Listeria (212–215)*. The factors that govern the extent of CD8$^+$ T cell division *in vivo* are unclear but may relate to the availability of antigen, as demonstrated in studies that have revealed a relationship between antigen load and the number of effector cells generated *(209,210,216–218)*. Coincident with their clonal expansion, the growing population of CD8$^+$ T cells develop the key effector capacities that are important to their function as cytotoxic cells. The full differentiation of CD8$^+$ T cells into cytotoxic effectors appears to be tightly linked to proliferation because the same stimulus provided to clonal precursors to induce their clonal expansion also results in the development of effector functions such as secretion of IFNγ and TNF and to kill target cells *(209–211)*. These observations suggest that at least for CD8$^+$ T cells, the commitment to division and effector differentiation are elements of an instructional program

of development that is established in clonal precursors by inductive signals transmitted during their primary activation. Because memory CD8$^+$ T cells appear to originate from this same event, their development can also be seen as a resulting from instructional programs established during priming (44,*219*). Although many details remain to be elucidated, programming appears to involve the acquisition of specific functional capacities in response to discrete signals received during the priming phase. For example, the presence of CD4$^+$ T cells during the priming of CD8$^+$ T cell precursors endows their clonal progeny with the ability to undergo secondary proliferative responses on reencounter with antigen (198). More recently, a role for IL-2–mediated signals transmitted via CD25, the high-affinity subunit of the IL-2 receptor, to CD8$^+$ T cells has been demonstrated in programming their capacity for secondary expansion *(220)*. These experiments used radiation bone marrow chimeras to control the expression of CD25 on CD8$^+$ T cells and IL-2/anti–IL-2 immune complexes to provide IL-2 signals. They revealed that secondary expansion of memory CD8$^+$ T cells detected at day 60 required that IL-2 signals were provided during the first week of priming by infection *(220)*. The IL-2 signal was not required for the primary expansion of the CD8$^+$ T cells, and its source in this scenario is unknown, being either autocrine, from the CD8$^+$ T cells themselves, or paracrine, from either CD4$^+$ Th cells or activated DCs that have been shown to produce IL-2 in response to microbial stimuli *(221–224)*.

After commitment to clonal expansion and acquisition of effector functions, CD8$^+$ T cells begin to express new surface patterns of chemokine, homing, and adhesion receptors that mediate their egress from LNs and facilitate their migration to peripheral sites. An initial event in this process is the downregulation of CD62L and CCR7, the receptors used by naïve precursors to enter the lymph node, and restoration of the chemotactic response to the lysophospholipid sphingosine-1-phosphate (S1P) through reexpression of its receptor (S1P-receptor-1), which promotes migration to blood and lymph by distinct sources of its ligand (35,*225–227*). After this, the migration of effector CD8$^+$ T cells to nonlymphoid tissues is largely determined by homing receptors and chemokines *(228)*. These include chemokine receptors such as CCR2 and CCR5 that guide cells to inflammatory sites through recognition of a variety of ligands, as well as α1- and β1-integrins such as LFA-1 that allow activated T cells to bind to and penetrate the walls of small blood vessels and thereby gain access to extravascular spaces throughout the body. In some cases, and for reasons that are poorly understood, a subset of these cells reexpress CD62L and CCR7, thereby allowing their reentry into the LN, where they can function as central memory cells (T$_{CMS}$), the functional properties of which are described in the following section *(229)*. Others migrate to the spleen via the blood and take up residence in

the red pulp and are largely excluded from the white pulp (101). The ultimate "address" to which the cell will migrate, however, can be influenced by the conditions under which it was activated. In response to systemic infection, for example, the migration of effector CD8$^+$ T cells can be relatively nonspecific and promiscuous, with cells able to access all nonlymphoid compartments (35,230,231). This has been confirmed in parabiosis studies (involving surgically conjoined animals) showing that effector cells primed in the infected parabiont equilibrate in essentially all tissues of its noninfected partner within 2 weeks *(232)*. In other cases, however, the migration of T cells can be tissue specific, reflecting the particular homing receptors they expressed. The homing of activated T cells to inflamed skin, for example, depends on binding to E- and P-selectins and tissue-specific chemokines, such as CCL17, expressed by skin vascular epithelium, and TACK, expressed on keratinocytes that are recognized by complimentary receptors on T cells, that is, E- and P-selectin ligands, CCR4, and CCR10 (for CCL17 and TACK, respectively) *(233,234)*.

In some instances, the pattern of homing receptors expressed by CD8$^+$ T cells can result from imprinting by the DCs responsible for their priming or reactivation. DCs from Peyer's patches—specialized secondary lymphoid organs within the intestine—have been shown to induce the selective expression of the integrin $\alpha 4\beta 7$ and the CCR9 chemokine receptor, both of which are essential for gut homing, in CD8$^+$ T cells *(235–238)*. The migration pattern of gut versus skin homing appears to be "reprogrammable," however, because restimulation of gut-tropic T cells by peripheral LN DCs can restore a skin-homing phenotype *(235–238)*. Thus, DCs not only can transmit information to naïve T cells regarding the presence of an infectious pathogen encountered at the site of inflammation through exogenous and endogenous danger signals, but they also can instruct T cells to express the appropriate homing receptors needed to enable their migration to the specific anatomic site where they are needed, that is, where ligands for these receptors are produced (36).

Contraction

After clonal expansion and effector differentiation, CD8$^+$ T cells migrate to the periphery, where they can engage the pathogen through direct killing of infected cells through use of death receptors (Fas, TNF, etc.), secretion of lytic granules (containing perforin, granzymes, etc.), or production of effector cytokines such as TNF or IFNγ that can act either directly or through activation of accessory cells such as macrophages and DCs *(239–241)*. Coincident with pathogen clearance at the end of the primary response, the majority of effector CD8$^+$ T cells within secondary lymphoid organs will be eliminated through a complex and poorly understood process that involves their orderly apoptosis (programmed cell death [PCD]) via inter-

actions among various member of the TNF family of cell surface receptors and well as elements of the mitochondrial pathway of apoptosis (reviewed in refs. *242, 243*). Effector molecules such as perforin and IFNγ can play a role in contraction, in that mice deficient in either of these have increased numbers of CD8$^+$ T cells in both the expansion and contraction phases (168). The contraction phase leaves a small population of cells, perhaps 5% to 10% of the numbers present at the peak of the response, to survive as the memory subset at levels that remain stable for the life of the animal (reviewed in refs. *244, 245*). Although the disappearance of CD8$^+$ T cells has traditionally been considered as causally related to the elimination of the infectious pathogen and the disappearance of antigen, recent evidence suggests that contraction, like many other aspects of the CD8$^+$ T cell response, can be "programmed," that is, independent of the extent of clonal expansion, the dose and duration of infection, or the amount of antigen displayed *(246,247)*. The removal of effector cells achieves two important goals for the immune system, in that it prevents the T cell repertoire from being skewed to a focused population of cells that have outlived their usefulness, and it restores homeostasis to the available environmental niches for support of T cells so that new antigenic challenges can be met. The loss of CD8$^+$ T cells from secondary lymphoid organs at the end of immune responses is largely attributable to apoptotic death, although some portion of this is also due to the irreversible migration of cells into peripheral tissues such as the lung, intestine, and bone marrow, where activated cells are maintained more stably over long periods of time *(248–253)*.

The apoptotic death of T cells during the contraction phase can occur by two main pathways: (a) activation-induced cell death (AICD), also called antigen (Ag)-driven ("active") apoptosis, and (b) cell autonomous or activated T cell autonomous cell death (ACAD). AICD is believed to operate toward the end of the expansion phase following priming and can be triggered by TCR stimulation and signals transmitted via various surface-expressed members of the TNF receptor family such as Fas, Fas ligand, and TNF and the p55 and p75 TNF receptors (reviewed in ref. *254*). The degree to which CD8$^+$ T cells are eradicated through AICD *in vivo* depends on their subsequent encounter with antigen and death receptor ligands such as CD95-L (FasL), TNF, and TRAIL during or near the end of their clonal expansion phase and on the balance of proapoptotic (FADD, FLICE, etc.) and antiapoptotic (c-FLIP, Bcl-2, Bcl-XL, etc.) proteins they express *(255,256)*. The anatomic location of the T cell also plays a role, in that T cells in peripheral nonlymphoid tissues such as the lungs, fat pad, and peritoneal cavity are more resistant to apoptosis than those in secondary lymphoid organs *(253)*. It is not known whether this reflects intrinsic properties of the effector memory subset that occupy these nonlymphoid niches, or whether the local cellular environment (through cells

and/or cytokines) controls T cell turnover in the periphery (33–35).

In contrast to the Ag-driven pathway, ACAD does not depend on death cytokines, receptors, or antigen but appears to involve the proapoptotic activities of the Bcl-2–related protein Bim and PUMA (p53-upregulated modulator of apoptosis), which are induced by a variety of cellular stressors, including the withdrawal of key survival cytokines such as IL-2, IL-7, and IL-15 *(243,257–263)*. BIM or PUMA can bind Bcl-2 or BCL-XL on the mitochondrial membrane and promote the release of cytochrome c and the induction of cell death *(264,265)*. During their expansion phase, T cells also decrease their expression levels of Bcl-XL and thereby allow for activation of the intrinsic ACAD pathway *(266)*. Both AICD and ACAD are believed to work through a final common pathway involving cysteinyl aspartate–specific proteases (caspases) that activate the apoptotic cascade *(245,267)*. ACAD, rather than AICD, is believed to be responsible for the contraction of CD8$^+$ T cells that follows the expansion phase. The extent of contraction within a given CD8$^+$ T cell response can be variable, with decreases of 95% of peak numbers observed in cases of acute systemic infections with virus or bacteria and more modest decreases seen when the infection is limited, for example, with antibiotics in the case of *Listeria* infection, although this may also limit the size of the memory pool generated (32,213–215,268,269).

Generation of CD4$^+$ T Cell Memory

Although a number of unique features characterize the generation of CD4$^+$ memory T cells, many of the basic processes described in the preceding section on CD8$^+$ memory T generation are also relevant for the initiation of CD4$^+$ T cell responses. Common features include the factors governing the ontogeny of naïve T cells, the role of extrinsic signals in their survival, and the range of homing receptors and migration patterns that guide them to the secondary lymphoid organs where priming occurs. In addition, the role APCs in the acquisition and transport of Ag and the role of inflammatory signals in determining the (co)stimulatory context in which it will ultimately be presented are also shared between CD4$^+$ and CD8$^+$ T cells. Other aspects of their biology related to priming and memory development are distinct from CD8$^+$ T cells and will be discussed in this section. These include their capacity develop into long-lived memory cells, key aspects of their functional specialization, and the extent of their clonal expansion and contraction. CD4$^+$ T cells contribute to immunity in a number of ways, including through activation of DC via CD40–CD40L interactions, the secretion of inflammatory cytokines such as IFNγ that activate the antimicrobial response of macrophages, and by providing help to both B cells for antibody responses and to CD8$^+$ T cells for their optimal development into memory cells

(141,179,*270–273*). In addition, regulatory CD4$^+$ T cells (Treg) identified by expression of the transcription factor FoxP3 can profoundly suppress the development of immune responses directed against self and non-self antigens (reviewed in refs. *274–276*).

Less is known about memory development in CD4$^+$ than in CD8$^+$ T cells. This is due in part to the apparent reduced capacity of CD4$^+$ T cells to develop into long-term resting memory cells compared to CD8$^+$ T cells in the widely used murine models of infection such as vaccinia, LCMV, Sendai virus, and *L. monocytogenes (208,277–279)*. Likewise, adoptive transfer studies with CD44^{high} memory phenotype CD4$^+$ T cells have shown that a nondividing subset disappears with a half-life similar to that of naïve cells *(280)*. A comparatively smaller number of studies have been undertaken using sensitive tools such as peptide/MHC tetramers and transgenic T cells that have facilitated memory CD8$^+$ T cells studies through the detection and phenotyping of responding populations at the single-cell level *(281,282)*. As with CD8$^+$ T cell responses, the generation of CD4$^+$ memory T cells is believed to occur during the same priming event that produces the effector cells. Once primed, however, CD4$^+$ and CD8$^+$ T cells display intrinsic differences in both their kinetics of activation and proliferative potential. For example, it has been observed that CD8$^+$ T cells require a comparatively shorter period of stimulation (2 to 4 hours) for commitment to clonal expansion and effector development than do CD4$^+$ T cells (approximately 20 hours) *(209,211,283,284)*. CD8$^+$ T cells also begin dividing earlier after priming than CD4$^+$ T cells and have a faster rate of division *(284–287)*. In addition, and in contrast to CD8$^+$ T cells, it has been observed that CD4$^+$ T cells require continued antigenic stimulation throughout their period of expansion to achieve full proliferative and effector potential *(288,289)*. Based on these and other findings, Lanzavecchia and Sallusto suggested that the optimal development of memory T cells will occur in cells that receive a specific level of antigenic stimulation during their priming and subsequent expansion that enables them to use and access survival signals in a process termed progressive differentiation (48,*283,290,291*).

Naïve CD4$^+$ T cells constitute a multipotent precursor population in which clonal precursors expressing a single antigenic specificity can be directed toward distinct differentiation fates by the actions of both the innate and adaptive arms of the immune system. A surprising variety of functional subsets of CD4$^+$ T cells can be generated through a complex process of differentiation involving the interactions of specific cytokines, cell-signaling proteins, and transcription factors that lead to stable and heritable changes in gene expression patterns that are established and maintained by chromatin remodeling (26,160,*292*). Th1 cells, for example, are generated by priming of CD4$^+$ T cells in the presence of IL-12 produced by APCs that are stimulated in response to TLR

signals or CD40 signals (from activated CD4[+] T cells or NKT cells) *(293,294)*. TCRs and cytokine signals then act together through signaling and transcription factors such as signal transducer and activator of transcription factor 4 (STAT4) and T-bet to induce functional differentiation into IFNγ-producing effector cells that promote development of cellular immune responses *(295,296)*. Similarly, Th2 cells are generated by priming of CD4[+] T cells in the presence of IL-4, thereby activating STAT4 and GATA-3 to induce differentiation into effector cells that produce IL-4, IL-5, and IL-13 as "signature cytokines" and favor the development of humoral responses and those against certain parasites *(297–299)*. There is considerable evidence for cross-regulation of these two subsets through the cytokines they produce, with the development of Th1 cells being inhibited by Th2-produced IL-4 and the development of Th2 subset being inhibited by IFNγ-produced Th1 cells. Thus as each subset becomes polarized, its development into Th1 versus Th2 cells will be reinforced by its specific pattern of autocrine cytokine production. More recently, a new cytokine-polarized subset of the CD4[+] T cell subset has been described that produces the cytokine IL-17 and is suspected of playing a central role in inflammatory responses and autoimmunity *(300–303)*. Although the exact details of Th17 development remain to be elucidated, the cytokines IL-6 and transforming growth factor-β (TGFβ) appear to play an instructive role in their differentiation through engagement of the IL-21 and IL-23 pathways, as well as the transcription factor STAT-3 and the nuclear orphan receptor RORg *(304–307)*. The development of Th17 cells may be a reciprocal fate to that of Tregs for naïve CD4[+] T cells primed in the presence of a TGFβ cytokine milieu, with the vitamin A metabolite retinoic acid functioning as a key regulator of inflammatory signals that determine the developmental path chosen under these conditions *(308–310)*.

Once activated, the magnitude of clonal expansion is more modest for CD4[+] T cells than for CD8[+] T cells, although unusually vigorous clonal bursts have been reported for responses against the bacterium *Salmonella* (50,*208,311*). The activation of naïve CD4[+] has been shown to involve distinct costimulatory requirements from those of CD8[+] T cell priming. These studies have mostly been carried out through infection experiments performed in knockout mice lacking specific ligand or receptors for these pathways. Whereas LCMV-specific CD8[+] T cells can efficiently be generated in mice lacking CD28, CD40L, or OX40, virus-specific CD4[+] T cell responses are substantially reduced. The opposite situation is seen in mice lacking 4-1BB, which mount normal CD4[+] but diminished CD8[+] T cell responses to LCMV infection (reviewed in ref. *312*). CD4[+] T cells also display quantitative and kinetic differences in their contraction compared to CD8[+] T cells. For example, after initial viral clearance, LCMV-specific CD4[+] T cells initially contract rapidly but then substantially reduce their rate of disappearance and take a full 6 months to reach stable numbers of memory cells, whereas the CD8[+] T response in this study achieved a stable "setpoint" of memory after approximately 30 days *(279)*. Similarly, the numbers of CD4[+] Sendai virus–specific T cells in the lung declined during the first 3 months after pulmonary infection, whereas the CD8[+] T cell response remained stable during this period *(277)*. These observations of decreased longevity and diminished secondary responsiveness in Th1 T cells may relate to their production of IFNγ gas an effector cytokine. IFNγ-deficient mice generate 30% to 50% more activated CD4[+] T cells in murine models of mycobacterial infection and experimental autoimmune encephalitis *(313,314)*. The regulatory capacity of IFNγ in CD4[+] T cells is further supported by the observation that their longevity within homogeneous populations can be extended if this cytokine is inhibited during activation *(315,316)*. The mechanism underlying the selective susceptibility of IFNγ-producing Th1 cells appears to involve the induction of apoptosis via a caspase 8–dependent pathway and is selective for this CD4[+] T cell subset because Th2 cells display a greater propensity for memory formation *(317,318)*. There is little information on the ability of the Treg and Th17 subsets to form memory, although this will certainly change in the near future due to active experimentation in these fields. Finally, in contrast to CD8[+] memory T cells, the majority of CD4[+] memory T cells do not reexpress CD62L: Only 30% of polyclonal CD4[+] T cells express this marker as compared with 90% of memory CD8[+] T cells in some systems *(319,320)*. The absence of CD62L expression does not preclude access into lymph nodes, however, because these CD4[+] T cells can access lymph nodes via the afferent lymph, as shown by the presence of memory phenotype CD4[+] T cells found in the lymph nodes of CD62L$^{-/-}$ mice *(321)*.

Generation of Memory B Cells and Plasma Cells

Immunologic memory in the B cell compartment consists of two very different cell types: memory B cells and long-lived plasma cells. These two cell types perform two different functions. Long-lived plasma cells can be considered "active memory" because they continuously secrete voluminous quantities of antibodies that circulate in the blood. Memory B cells can be considered "quiescent memory" because these cells are resting, waiting for a second infection or reexposure to antigen to reactivate them. The proposed basic lineage relationship among naïve mature B cells, memory B cells, and plasma cells is shown in Figure 28.4. Different stages of B cell differentiation occur in histologically defined locations, as illustrated in Figure 28.5. In this basic model (Figures 28.4, 28.5), naïve mature B cells are activated by antigen (protein in adjuvant, viral infection, or autoantigen), and CD4 T cell help.
FIGURE 28.4 Development of B lineage immune response and memory. After antigenic stimulation, naïve B cells undergo clonal expansion and form clusters of activated B cells known as extrafollicular foci. These activated B cells can either differentiate into short-lived plasma cells or migrate back into the follicle and initiate a germinal center reaction. After proliferation and affinity maturation, germinal center B cells produce both long-lived plasma cells that produce high-affinity antibodies and memory B cells that have high-affinity B cell receptors. Memory B cells can self-renew by homeostatic proliferation. Memory B cells may also periodically differentiate, in an antigen-dependent or antigen-independent manner, into long-lived plasma cells to maintain long-term antibody production.

These initial interactions occur at the border between the T and B cell areas of the lymphoid organ (spleen or lymph node) *(322,323)*. The activated B cells undergo clonal expansion. During this initial phase of activation, B cells can class switch from immunoglobulin M (IgM) to IgG or other isotypes if stimulated strongly. B cells can initiate germi-

nal centers in the follicle, or they can proliferate and differentiate into plasmablasts (intermediately differentiated antibody-secreting plasma cells) and plasma cells and migrate to the red pulp *(322)*, where they can be observed as extrafollicular foci, frequently residing adjacent to blood vessels *(322,324,325)*. Given the complexity of the biology involved, it is perhaps not surprising that there are clear examples of exceptions to the basic model of B cell memory generation outlined in Figures 28.4 and 28.5 where steps are bypassed or significantly altered *(326–329)*. Nevertheless, the model appears to hold true for most conditions *(273,330,331)*.

A second phase of clonal expansion and differentiation of activated B cells occurs within the specialized microenvironment of a germinal center (GC) *(325,332,333)*. Because antigen-specific memory B cells and long-lived plasma cells come from germinal centers, germinal centers are the critical sites for the development of long-term humoral immunity. The detailed mechanics of the germinal center reaction are unclear, but extensive research has been done into the processes of germinal center B cell selection and differentiation *(332)*. It is normally within the germinal centers that affinity maturation occurs. Affinity maturation is the process by which a B cell clone improves the affinity of its B cell receptor (BCR) for the cognate antigen through multiple rounds of somatic hypermutation and selection. It is known that germinal center B cells are the only mature cells in the body that undergo somatic hypermutation. This reflects both the importance of germinal centers in immunity and the difficulties inherent in trying to produce high-affinity antibodies to the universe of possible antigens. In the germinal center, an antigen-specific B cell will undergo somatic hypermutation in its BCR gene via the enzymatic activities of AID and other factors *(334)* (also see other chapters in this volume). The mutated BCR is then expressed on the surface of
FIGURE 28.5 Anatomic features of effector and memory B cell differentiation. See text for details.

the B cell. If the mutant BCR is of higher affinity, the new clone more efficiently binds cognate antigen in the germinal center [tethered to follicular dendritic cells or otherwise present as an antigen depot *(328,335,336)*], processes and then presents peptides derived from the protein antigen in class II, and receives appropriate stimulatory signals from antigen-specific germinal center–resident CD4 T cells *(273,337)*. Germinal centers contain antigen-specific CD4$^+$ T cells, and both the generation and maintenance of germinal centers normally depend on antigen-specific CD4 T cells *(338–341)*. The germinal center CD4 T cells, often referred to as follicular helper CD4 T cells (T$_{FH}$s), provide stimulatory signals to germinal center B cells believed to consist of both T–B cell surface receptor–ligand interactions [e.g., CD40–CD40L *(338)*] and cytokines secreted by the CD4 T cells and bound by cytokine receptors expressed on the surface of the germinal center B cells [e.g., IL-21–IL21R *(342)*]. On receiving the appropriate stimulatory signals, the newly mutated, higher-affinity B cell proliferates and then repeats the cycle of somatic hypermutation, selection, and proliferation in the germinal center. Trafficking of B cells in germinal centers has recently been intensively examined *(343–346)*. Failure to bind cognate antigen and subsequently receive appropriate stimulatory signals from CD4 T cells or follicular dendritic cells (FDCs) results in apoptotic death. Given that these processes are acting on a population of antigen-specific B cells simultaneously, those B cells with the highest-affinity BCRs are expected to rapidly outcompete lower-affinity clones for

antigen and subsequent costimulation from CD4 T cells. Because random mutation of the BCR is more likely to result in a nonfunctional or lower-affinity receptor instead of a higher-affinity receptor, apoptotic death is rampant in germinal centers. B cells positively selected within the germinal center exit and mature into memory B cells or plasma cells *(347–349)*. It is unclear how B cells are triggered to exit the germinal center and become memory B cells or plasma cells. It is known that CD40 ligation inhibits plasma cell differentiation and IL-10 and IL-21 enhance plasma cell differentiation of human germinal center B cells *(350)*. It is reasonable to propose that once B cell has undergone sufficient BCR affinity maturation to reach a certain affinity/avidity threshold, it will exit the germinal center and will differentiate into a memory B cell or plasma cell based on the combination of signals it receives from CD4 T cells immediately prior to exiting the germinal center. However, this is mostly a speculative model. Alternatively, both the exit from a germinal center and the memory B cell/plasma cell differentiation decision may be stochastic. On exit from a germinal center, memory B cells primarily reside in the marginal zones of the spleen, whereas the plasma cells exit into the blood.

A subset of plasma cells produced in the germinal centers migrates from blood to bone marrow, where they reside as long-lived plasma cells *(351–357)*. The kinetics and anatomic location of antibody production after an immunization (in this case an acute viral infection) in mice is shown in Figure 28.6. There are two phases of antibody
FIGURE 28.6 Kinetics of B cell responses after acute viral infection of mice. The plasma cell response in secondary lymphoid tissues peaks during the first 2 weeks and then declines within 2 to 4 weeks after infection (14,354). As splenic plasma cell populations decline, antigen-specific plasma cells begin to migrate to and/or accumulate in the bone marrow compartment (344,351,355,359). After the germinal center reaction subsides, the bone marrow becomes the predominant site of antibody production, with up to 90% of the host's plasma cells located in this compartment (14,354).

production: acute and long term. Because preexisting antibody provides the first line of defense against repeat infection by microbial pathogens, the importance of long-term antibody production by plasma cells in protective immunity cannot be overstated. There are at least two populations of plasma cells: the early antibody-secreting cells forming extrafollicular foci, which produce antibody only for a short period after antigen exposure, and long-lived plasma cells, which survive for extended periods (the half-life is 3 to 4 months in mice) (Figure 28.6) (14,*353,356,358*). Data indicate that plasmablasts and plasma cells generated from B cells in extrafollicular foci are short lived, with a half-life of less than 3 days *(359–361)*. The acute responding, extrafollicular population of antibody-secreting cells has various names in the literature—plasmablast, antibody-secreting cell, plasma cell, short-lived plasma cell—due to the different assays used to identify the cells and the uncertainty surrounding plasma cell differentiation states. Plasmablasts are antibody-secreting B cells that still have the ability to proliferate. Plasma cells are terminally differentiated nonproliferating cells with greater capacity for antibody secretion. Plasmablasts can develop from naïve B cells, germinal center B cells, or memory B cells, but it is unclear whether all plasmablasts have the capacity for complete differentiation into plasma cells and whether all plasma cells are competent to become long-lived plasma cells (Figures 28.1, 28.5). Naïve B cells specific for any given antigen are rare (10^{-5}-10^{-6}), and therefore only a small number of B cells are recruited into the initial response. Within this small set of B cells, it is likely that there exists a range of B cell receptor affinities for the antigen. The recruited B cells with the highest affinity for the target antigen appear preferentially to differentiate into plasmablasts/plasma cells and form extrafollicular foci. The recruited B cells with intermediate to lower affinities appear preferentially to initiate germinal centers *(362,363)*. At the molecular level, this indicates that stronger BCR signals drive proliferation and then plasma cell differentiation, and weaker BCR signals drive proliferation without plasma cell differentiation. This suggests that the B cell differentiation program has evolved under selective pressure to produce an early wave of high-affinity, antigen-specific secreted antibody as rapidly as possible, presumably reflecting the importance of rapid antibody responses in blunting viral or bacterial replication after infection; it is also important, however, to evolve high-affinity antibodies that are much more efficient at controlling and eliminating the pathogen, which is done by the antigen-specific B cells that initiate germinal centers. Long-lived plasma cells predominantly (or possibly exclusively) come from post–germinal center B cells, as evidenced by defects in long-lived plasma cell generation in mice with germinal center defects *(364)* and the observation that bone marrow plasma cells exhibit DNA and antibody affinity signatures of affinity maturation *(349,365)*.

MAINTENANCE AND FUNCTION OF MEMORY CELLS

Maintenance and Function of T Cell Memory

The small fraction of effector T cells that survive contraction initiates the memory pool that confers lifelong protection to the individual. Despite their extensive culling from peak numbers, antigen-specific cells in the postcontraction population are found at a far higher precursor frequency than in the naïve repertoire, a fact that undoubtedly affects the increased speed and intensity that is characteristic of secondary responses. Although they possess some features associated with memory, having arisen in response to an antigenic challenge and being able to persist after the majority of their fellow effectors have been eliminated, the postcontraction T cells nonetheless comprise a heterogeneous population whose maintenance in the memory pool is a dynamic process involving phenotypic changes that determine their function, distribution, and protective capacity over time (35,41,*366*). A central theme governing this process involves adaptation to the homeostatic control mechanisms that regulate the equilibrium of naïve versus memory T cells. These pathways appear to be distinct and under independent control because the mechanism regulating naïve T cell homeostasis that prevents overcrowding of the available niches by thymic emigrants cannot compensate for cell loss when production falls below a critical threshold, whereas the mechanism regulating the memory pool can both reequilibrate memory cell numbers after the increased input that results from normal immune responses and promote reexpansion to match the set threshold after physiologic loss of T cells, as often occurs during viral infections *(367–369)*. As will be described, the homeostatic mechanisms that regulate the naïve and memory T cell pools also differ in their requirement for extrinsic factors such as TCR stimulation by self-MHC molecules (presumably occupied with peptide derived from self or environmental antigens) and signals provided by the γ-chain (γc) cytokines IL-7 and IL-15.

Before discussing the factors responsible for the survival of memory T cells, it is important to understand the types of experimental approaches that have been used in their study and how these influence the various conclusions that can be drawn from the experimental data. In general, there have been two main experimental settings through which memory T cells have been studied *in vivo*. One involves enumeration of cells that express markers associated with prior antigen experience such as CD44[high] or CD62L[low] for activated cells in either immunized or unmanipulated normal mice. In the latter case, the cells in question are the spontaneously arising "memory phenotype" (MP) T cells of unknown derivation and specificity, which increase in frequency with age *(370,371)*. In the case of antigen (Ag)-specific T cells, these can be generated

from either the endogenous polyclonal repertoire or adoptive transferred monoclonal transgenic T cells. A concern about immunization/infection studies is that antigens can persist for long periods of time in host animals, so that one may be studying continuous activation and not true memory. For this reason, a number of studies have monitored T cells that either arise spontaneously in normal mice (ostensibly in response to environmental antigens or self-MHC) or are specifically primed in one host and are transferred to a new, antigen-free host. This method has been used extensively for CD8$^+$ T cells, although the comparably modest expansion of activated CD4$^+$ T cells after priming has made their recovery in numbers sufficient for adoptive transfer a technical challenge. An additional concern for transfer of MP cells is that their antigenic specificity is unknown, precluding transfer to an antigen-free host. Lastly, many studies have involved transfer of naïve versus memory T cells to lymphopenic environments (irradiated or recombination activating gene [rag]–deficient mice). Under these conditions, the transferred T cells will expand to fill the available "space" (i.e., environmental niches), with the cell and molecular requirements for this type of proliferation termed "homeostatic expansion" to reflect the substantial increase in cell numbers it involves, being a topic of great interest in recent years *(372–376)*. This type of proliferation is clearly different in magnitude and, when applied to the various types of memory T cells described previously, perhaps in mechanism from the slower "basal" proliferation of T cells that maintains their numbers within intact mice *(377)*. Adding to the potential for confusion in the literature is the fact that different studies have used the term "homeostatic proliferation" to refer to the division of cells transferred to lymphopenic hosts as well as in normal T cell–replete hosts. For the purposes of this section, we refer to the slow turnover of T cells in a normal immunocompetent host as "basal homeostatic proliferation" and the faster, more extensive division of T cells within lymphopenic hosts as "homeostatic expansion."

As discussed earlier in this chapter, adoptive transfer studies have shown that the long-term survival of naïve T cells in lymphopenic hosts requires contact with self-MHC (73–78). Whereas initial studies in the 1990s suggested that both types of memory cells were maintained by occasional TCR contact with undetectable amounts of sequestered foreign or cross-reactive environmental antigens, more recent studies have shown that CD8$^+$ memory T cells can survive and remain functionally competent in the absence of either antigen or MHC molecules, arguing against any obligatory role for TCR stimulation in their maintenance (32,78,*378–381*). The situation for CD4$^+$ memory T cells is less clear, with studies on both antigen-specific and MP CD4$^+$ T cells revealing that maintenance of the pool size does not strictly depend on MHC or TCR (73,*382*). The rate of both basal homeostasis and homeostatic expansion of MP CD4$^+$ T cells, however, does appear to depend on the TCR–MHC interactions and declines significantly

when these signals are extinguished, leaving the cells in one study critically dependent on IL-7 (73,*382–385*). These findings suggest a more prominent role for TCR than cytokines for the homeostatic survival of MP CD4$^+$ T cells. Supporting data for this notion comes from a study of Ag-specific transgenic CD4$^+$ memory T cells, which, on transfer to MHC-deficient hosts, display impaired responses to antigen reencounter *in vitro* and *in vivo (386)*. These observations indicate that CD4$^+$ and CD8$^+$ memory T cells differ in their requirement for TCR signals for maintenance and further suggest the non–mutually exclusive ideas that different mechanisms regulate the maintenance versus functional responsiveness of MP and antigen-specific memory CD4$^+$ T cells and that significant heterogeneity exists in the rates of homeostatic proliferation within the Ag-specific memory versus MP CD4$^+$ T cell populations, as demonstrated in several systems (71,*280,387,388*).

These findings of MHC-independent survival of memory T cells have brought cytokines into focus as the main extrinsic factors responsible for their maintenance, with particular emphasis on the common γc family members IL-7 and IL-15. One of the important initial observations linking cytokines with memory T cell survival came from studies in which agents capable of stimulating interferon production by cells of the innate immune system, such as LPS and Poly I:C, caused a transient burst of TCR-independent proliferation from the major CD122^{high} CD44^{high} subset of antigen-experienced CD8$^+$ T cells through the IFN-α/β-induced production of IL-15 *(389–394)*. Of note, the IFN-α/β-induced proliferative burst of CD122^{high} CD44^{high} CD8$^+$ T cells was not observed in IL-15$^{-/-}$ mice, and the *in vivo* administration of exogenous IL-15 was found to mimic the effect of IFNs in stimulating the bystander proliferation of the MP CD8$^+$ T cell subset *(390,395,396)*. The receptor for IL-15 is composed of three subunits: a unique α chain, a β chain (CD122) that is shared with the IL-2 receptor, and the common γc that is shared with IL-2, IL-4, IL-7, IL9, and IL-21 *(397–399)*. Although a soluble cytokine under *in vivo* conditions, IL-15 is presented in *trans* via cell-associated complexes bound to IL-15Rα that are preassembled in the cytoplasm of the (non-T) cells that make both molecules *(400–402)*. Paradoxically, CD8$^+$ T cells also express IL-15Rα, and although this is not essential for them to respond to IL-15 (which requires expression of only the β and γ chains), it may enable them to activate other cells types such as T cells or APC via *trans* presentation *(400,401,403,404)*. The expression of CD122 is selectively elevated on the MP (CD44^{high}) subset of CD8$^+$ T cells that undergo bystander proliferation in response to IL-15, whereas it is expressed at low but detectable levels on naïve CD8$^+$ cells *(394)*. IL-15 is nonetheless important for the survival for both subsets because IL-15$^{-/-}$ mice show a 50% reduction in the number of naïve CD8$^+$ T cells, and both IL-15$^{-/-}$ and IL-15R$\alpha^{-/-}$ mice contain significantly reduced numbers of CD44^{high} CD122^{high} MP CD8$^+$ T cells *(390,405–407)*. The

effect of IL-15 on MP CD8$^+$ T cells may reflect its role in cell survival rather than development because these fail to proliferate and disappear rapidly on transfer to IL-15$^{-/-}$ recipients *(390)*. Consistent with this view, IL-15 transgenic mice were found to contain elevated numbers of MP CD8$^+$ T cells *(396,408)*. Taken together, these findings have led to the current view that the generation, survival, and basal homeostatic proliferation of MP CD8$^+$ T cells is mediated through contact with ambient IL-15 that is most likely produced by dendritic cells in the steady state, because these make both IL-15 and IL-15Rα, and by a variety of other cell types including skeletal muscle, kidney, placenta, and hematopoietic stromal cells under conditions of innate immune activation via the IFN pathway *(393,409,410)*. Studies of Ag-specific CD8$^+$ T cell responses have used MHC class I tetramers to follow the response to viral infection (LCMV or vesicular stomatitis virus) in IL-15$^{-/-}$ or IL-15R$\alpha^{-/-}$ mice, and have shown that, similar to MP CD8$^+$ T cells, IL-15 is also important for the maintenance of Ag-specific memory CD8$^+$ T cells *(377,411,412)*. These studies found that, although Ag-specific CD8$^+$ T cells were generated in the absence of IL-15 signals, they did not proliferate, and their numbers declined over time *(411,412)*. Taken together, these observations show that IL-15 mediates the homeostatic turnover of both MP and Ag-specific memory CD8$^+$ T cells. Although important for memory CD8$^+$ T cell homeostasis, IL-15 does not appear to be required for their function because LCMV-specific memory CD8$^+$ T cells are able to produce the effector cytokines IFNγ and TNF and are capable of responding to secondary infection *(411,412)*. The main effect of IL-15 on the homeostatic survival of CD8$^+$ T cells is likely mediated through upregulation of antiapoptotic factors such as BCL-2 and BCL-XL and avoidance of death via the mitochondrial pathway of apoptosis, a common mechanism of γc cytokines (79,*413–415*). The bone marrow may be the preferred site for homeostatic survival of memory CD8$^+$ T cells, as it contains a major pool of dividing memory cells and those that migrate there undergo division *(392)*.

In contrast to its clear role in the homeostatic survival of CD8$^+$ T cells, the requirement for IL-15 in memory CD4$^+$ T cell survival has been more difficult to define. This may have to do with the different survival requirements for the various types of memory cells used to study this phenomenon (MP, Ag-specific, and transgenic) and with the compensatory mechanisms that lymphocytes can develop in the absence of physiologic stimuli involved in their growth and development. For example, IL-15 has been considered to be irrelevant for the development and homeostasis of MP CD4$^+$ T cells because these express low levels of CD122 and can be found in normal numbers in IL-15$^{-/-}$ mice *(394,406)*. Given that the homeostasis of MP CD4$^+$ T cells appears to be governed more by TCR stimulation than by cytokines, as discussed previously, and that they are a homogeneous population containing a subset that undergoes a significantly faster rate of homeostatic

expansion, it is possible that the MP CD4$^+$ T cells undergoing homeostatic proliferation in IL-15–deficient environment do so because they are chronically stimulated by foreign antigens, perhaps derived from commensal bacteria. In contrast to MP cells, the homeostasis of Ag-specific CD4$^+$ T cells appears to be exclusively under the control of cytokines because these cells can survive and undergo homeostatic expansion in lymphopenic hosts lacking MHC II molecules *(382,416)*. Studies with Ag-specific memory CD4$^+$ T cells generated in IL-15$^{-/-}$ hosts indicate that they too are independent of IL-15 for their maintenance *(387,406)*. It has been suggested, however, that the CD4$^+$ T cells arising in IL-15$^{-/-}$ environment can become permanently conditioned to cope with IL-15 deficiency and may not represent the requirement of normal CD4$^+$ memory T cells formed in a T cell–replete environment (34,*417*). Similarly, the lymphopenic environment may also represent a nonphysiologic condition because the ambient levels of homeostatic cytokines can significantly increase in the absence of other T cells and NK cells that would normally compete for these resources *(418)*. In support of this idea, recent studies using transgenic and endogenous LCMV-specific CD4$^+$ memory T cells generated in normal mice and then transferred to lymphopenic versus normal nonlymphopenic hosts have shown that memory CD4$^+$ T cells depend on IL-15 for their basal homeostatic proliferation and long-term survival *(419)*. Consistent with this view, it has been shown that human and mouse CD4$^+$ T cells respond to exogenous IL-15, and IL-15-transgenic mice display enhanced CD4$^+$ T cell responses to infectious pathogens *(408,420)*. Taken together, these data indicate that both CD4$^+$ and CD8$^+$ memory T cells depend on IL-15 for their homeostatic survival.

The other cytokine known to affect the homeostatic survival of memory T cells is IL. As discussed previously, IL-7 is constitutively produced by nonhematopoietic cells, and perhaps some DC subsets, and is recognized by a heterodimeric receptor consisting of an α chain (shared with the receptor for TSLP) and γc *(421,422)*. Although memory CD8$^+$ T cells show a strong bias for IL-15, increasing the level of IL-7 *in vivo* through transgenic expression can overcome the requirement for IL-15 in promoting survival and homeostatic expansion of CD122^{high} memory CD8$^+$ T cells *(423)*. This finding is reminiscent of the apparent redundancy of IL-7 and IL-15 in promoting the homeostatic expansion of memory CD8$^+$ T cells, which has been shown to occur at a similar rate and magnitude in IL-15$^{-/-}$ hosts as in normal irradiated hosts *(377,388)*. Given the well-documented role of IL-15 as necessary for the survival of memory CD8$^+$ T cells, it would seem paradoxical that the lymphopenia, such as exists in both IL-15$^{-/-}$ and irradiated wild-type recipients, could alleviate this requirement. The reason turned out to be that IL-7, which in the absence of "consumers" such as naïve T cells and NK cells that normally compete for this key cytokine, is able to reach ambient higher levels in lymphopenic hosts that can

compensate for the lack of IL-15. When both IL-7 and IL-15 are removed through gene knockouts and use of antireceptor antibodies, homeostatic static expansion ceases. These results indicate a degree of functional overlap between IL-7 and IL-15 in promoting the homeostatic expansion of memory T cells, but they suggest that this pathway is operates only when IL-7 reaches higher levels than normally exist in immunocompetent animals. Both naïve and memory CD8$^+$ T cells express high levels of IL-7Rα, with most effector cells sustaining the downregulation that occurs on activated cells during their primary expansion phase (75,85,377,424,425). The presence of elevated IL-7Rα expression on a subset of CD8$^+$ T cells detected early in the response to acute LCMV infection has been suggested specifically to identify precursors that are destined to develop into memory CD8$^+$ T cells (424). This conclusion emerged from adoptive transfer experiments in which IL-7Rα^{high} and IL-7Rα^{low} populations of LCMV-specific CD8$^+$ effector T cells were transferred from infected mice into antigennegative recipients, with the latter population displaying better long-term survival and recall responsiveness (424). Subsequent experiments have indicated that this is more likely due to a survival advantage mediated by IL-7Rα expression in conferring enhanced sensitivity to ambient IL-7, and that CD8$^+$ memory T cells are not selected solely on the basis of IL-7/IL-7Rα interactions but result from a more complex series of differentiative events (426–429).

The role of IL-7 in the maintenance of CD4$^+$ memory T cells has been a question of continuing interest, with conflicting results coming from different systems. Despite numerous reports that IL-7 is essential for the thymic development and homeostasis of naïve CD4$^+$ T cells, one study found that transgenic CD4$^+$ T cells from mice lacking γc expression, and therefore lacking the ability to transmit signals from either IL-7 or IL-15, display a short lifespan as naïve cells but survived efficiently after developing into memory cells (417). Another study found that neither IL-7 nor IL-15 was required for the homeostatic expansion of MP CD4$^+$ T cells in lymphopenic hosts, despite the fact that memory CD4$^+$ T cells express high levels of IL-7Rα (388). Although these results would appear to support the idea that IL-7 is unimportant for the homeostasis of CD4$^+$ T cells, the development of the γc-independent CD4$^+$ T cells in the former case may have proceeded via an abnormal alternative pathway that obviates the normal role of IL-7, and the MP cells in the latter example were found to be the fast-dividing subset discussed previously that is thought to be under chronic TCR stimulation by endogenous ligands (77,430). Thus, these experimental systems may not accurately reflect the physiologic requirement for IL-7 in maintaining CD4$^+$ memory T cells, which itself is related to TCR signals and can apparently be masked by chronic TCR stimulation. In support of this, it has been found that when TCR signals are extinguished in MP CD4$^+$ T cells, they become acutely dependent on IL-7 for sur-

vival and homeostatic expansion in lymphopenic hosts (385). Similarly, Ag-specific transgenic CD4$^+$ T cells that do not undergo homeostatic proliferation were found to depend on IL-7 for their survival under lymphopenic conditions (431). More recently, it has been found that the survival and basal homeostatic proliferation of newly formed Ag-specific polyclonal memory CD4$^+$ T cells was substantially reduced after treatment with antibodies against IL-7R (387,432). In addition, both MP and Ag-specific memory CD4$^+$ T cells lacking IL-7Rα were unable to survive in intact and lymphopenic hosts (432). Together, these observations support the idea that IL-7 is essential to the maintenance and survival of CD4$^+$ memory T cells. The molecular mechanism through which this occurs is not entirely clear, although, as with IL-15, regulation of the balance of pro- and antiapoptotic members of the Bcl-2 family represents one potential explanation (433). IL-7 protects T cells from death by inducing the antiapoptotic factors Bcl-2 and Mcl-1 and inhibiting the proapoptotic factors Bax, Bad, and Bim (434–439). Furthermore, the T cell developmental defect in IL-7– or IL-Rα–deficient mice can be rescued by a bcl-2 transgene or deletion of Bax, and addition of anti-IL-7/anti-IL-7Rαa to memory cell cultures was found to reduce Bcl-2 expression (431,434,440,441).

Function of T Cell Memory: The Secondary Response

From an operational perspective, it can be argued that the ultimate purpose for the long-term maintenance of memory T cells is found in the secondary response to previously encountered antigens, which comprises both direct effector functions and renewed proliferation. Although both aspects of the recall response can be readily demonstrated *in vitro*, under physiologic conditions this task requires that memory cells be present wherever invading pathogens enter the body and where they are first detected by the APC system. Accordingly, T$_{EM}$ cells can be found in the blood and in a variety of peripheral tissues such as bone marrow, liver, gastrointestinal tract, lung parenchyma and fat pads, where they can mediate immediate effector functions, and T$_{CM}$ cells are found mostly within the lymph nodes, where they are able to produce IL-2 (in addition to IFNγ) and mount proliferative responses to restimulation (249–251,320). Although initial studies supported a clear division of labor between these subsets, it has become clear that some degree of overlap exists in their location, function, and phenotype. In the CD8$^+$ lineage, T$_{EM}$s can undergo substantial secondary expansion, and, conversely, T$_{CM}$s have been shown to migrate to and accumulate in the bone marrow and can display cytotoxic potential and production of effector cytokines equivalent to that of T$_{EM}$ (131,320,442,443). The relative contribution of T$_{EM}$ versus T$_{CM}$ subsets to recall responses and effective immunity can depend on the nature of the antigenic

challenge. For example, T_{CM} generated by immunization with virus-like particles (VLPs) are better able to protect from challenge with LCMV, a pathogen that replicates within lymphoid organs and is controlled perforin rather than $CD8^+$ T cell cytokines, whereas T_{EM} can be superior in mediating protection from vaccinia virus, which replicates in peripheral solid organs and is controlled by cytokines rather than by direct cytotoxicity *(444–448)*. Other studies, in contrast, have shown that T_{EM} are superior in mediating protection from viral challenge *(320)*. The timing of the challenge can also play a role because T_{EM} in the lung have been shown to be more effective at mediating protection against Sendai virus at early time points, whereas T_{CM} are superior at later time points *(449)*.

In addition to the increased frequencies of Ag-specific cells, the T cells that comprise the secondary response display a higher functional avidity and lower signaling thresholds than primary responders, and consequently they can mount faster and more effective responses to infection that the naïve repertoire (27,*450–453*). This "faster and better" response of memory T cells involves alterations in TCR signal transduction components that result in enhanced sensitivity to antigen, as well as epigenetic modification of key cytokine gene targets for TCR-mediated transcriptional activation, such as IFNγ and IL-2, resulting in more efficient and higher-level production (23,*451,452*). In the case of some effector molecules, including IL-4, and RANTES, memory T cells contain stored mRNA that is rapidly translated on TCR stimulation *(454–457)*. The enhanced functionality of the memory cells at the population level may reflect a mechanism in which Ag-driven clonal selection is controlled by affinity-based thresholds (40,*453,458*). In addition, a number of studies have shown that the secondary T cell response is prolonged compared to the primary response, with emerging evidence suggesting that renewed exposure to antigen can further improve the function of the available repertoire because secondary memory $CD8^+$ T cells have been shown to provide better per-cell protective immunity while retaining the capacity to undergo expansion in numbers similar to primary memory cells after reinfection (32,*246,249,268, 459–462*).

The structures and signals required to elaborate the secondary responses differ somewhat from those involved in the priming of naïve T cells. For many infections, the secondary response to antigenic challenge can proceed in the absence of encapsulated lymph nodes or spleen *(463,464)*. Mice deficient in lymphotoxin-α, which lack all secondary lymphoid organs, revealed the *de novo* generation of lymphoid organ–like structures within the airways called inducible bronchus-associated lymphoid tissue (iBALT) after pulmonary infection that were able to assume many of the T cell–activating functions of normal lymphoid organs *(463–465)*. The optimal secondary response to infection nonetheless appears to require DCs and, depending on

the model, can require costimulation by molecules such as CD28 and 4-1BB *(466–468)*.

Maintenance and Function of B Cell Memory

How does B cell memory persist? The mechanisms involved in sustaining memory B cells can be divided into two categories: antigen dependent and antigen independent. There are three antigen-dependent mechanisms for maintaining B lineage memory: reinfection/immunization, latent infection, and antigen depot. Periodic reexposure to the pathogen is an effective way to maintain high levels of immunity and serves as a natural "booster" to the immune system. Frequently, such reinfections are mild or asymptomatic due to the preexisting immunity. When using vaccines, booster immunizations serve the same purpose of recalling preexisting memory. Latent or very low grade persistent infections can also serve as efficient antigen-dependent mechanisms for maintaining memory. It is believed that this occurs extensively for reactivating herpes virus infections and possibly other infectious diseases. A third antigen-dependent mechanism for maintaining B lineage memory is the presence of persisting nonreplicating antigen. This antigen can be present as an antigen depot or bound to the surface of follicular dendritic cells or possibly other professional antigen-presenting cells *(328,335,336,469)*. Distinguishing antigen-dependent from antigen-independent maintenance of B lineage memory and understanding their biological relevance and contributions are central problems in examining memory B cells and long-lived plasma cells because antigen-dependent and antigen-independent mechanisms may affect these memory cell types in different ways. These issues are a constant challenge for experimentalists studying B lineage memory. It is equally important to understand immune memory in the absence of reexposure to antigen to know how long immunity intrinsically lasts, particularly in the context of understanding human vaccines to understand how to maximize their success.

There are several classic examples that have clearly documented long-term protective immunity lasting up to 75 years in humans in the absence of reexposure to the pathogen (Table 28.1) (64,70,*471*). These observations have been crucial in shaping our ideas about immunologic memory because they showed that the immune system could remember an encounter that occurred many years ago. Because antibodies are the main protective mechanism for poliovirus, the case of measles immunity on the Faroe Islands mentioned at the beginning of this chapter suggested that B cell memory lasts at least 65 years after measles infection in the absence of reexposure to the virus. A similar situation was observed with polio outbreaks in a remote Eskimo village. Three serotypes of poliovirus exist, and antibodies against one serotype were observed only

▌**TABLE 28.1** Long-Term Human Immunity in the Absence of Reexposure to the Pathogen

Infection	Duration of Immunity (yr)
Measles on the Faroe Islands (470)	65
Yellow fever virus in Norfolk, Virginia (471)	75
Polio in remote Eskimo villages (6)	40
Inactivated poliovirus vaccine in Sweden (472)	30+
Smallpox vaccine in United States, Israel, Italy (14–16,513,626)	30–60+

in Eskimos older than 40 years, and antibodies against a second serotype were observed only in individuals older than 20 years. Therefore, this epidemiologic observation indicated that production of antipoliovirus antibodies is long lived even in the absence of reexposure to the virus. A third example of long-term human immunity was an experiment. Yellow fever was an uncommon epidemic disease in the southeast United States during the 19th century. Seventy-five years after the last known outbreak in Norfolk, Virginia, serum samples were taken from individuals known to have been infected 75 years prior. The serum was transferred to primates, which were then challenged with yellow fever virus. Primates receiving the serum from immune humans were protected from disease, showing that individuals make anti–yellow fever virus antibodies for greater than 75 years after an infection. All of these examples are observations related to immunologic memory after acute viral infections. More recent studies have examined long-term immunologic memory in humans by quantifying antigen-specific serum antibody or memory B cell levels (14,16,*472,473*), as discussed later in the context of maintenance of memory.

Maintenance and Value of Memory B Cells: Quiescent Memory

The longevity of memory B cells in mice in the absence of antigen was controversial. Adoptive transfer studies of B cells into irradiated animals indicated that memory B cells have an extremely short lifespan in the absence of antigen (approximately 3 days) *(474)*. However, experiments done in intact animals suggested that the memory B cell numbers were stable, and a slow rate of memory B cell proliferation was observed (less than one division per month), indicating that the proliferation was homeostatic and not antigen driven *(475)*. Two additional studies observed a similar antigen-independent long lifespan of memory B cells with slow proliferation consistent with homeostatic cycling *(330,476)*. Studying antigen-independent maintenance of memory B cells in mice is extremely challenging because it has been shown that antigen can persist in

mice at low levels for more than 18 months in some conditions *(477)*, which is effectively the full life of a mouse. A transgenic switch approach has largely settled the matter by circumventing the issue of possible antigen persistence *(478)*. Mice were engineered with a genetic switch, such that memory B cells expressing an NP-specific B cell receptor (BCR) could be changed *in vivo* to instead express a PE-specific BCR. By inducing the switch in memory B cells, PE-specific memory B cells that had never seen cognate antigen (PE) could be examined. The cells persisted in an antigen-independent manner just as well as other memory B cells *(478)*. These results were consistent with results obtained in intact mice *(330,475,476)*. It should be noted that naïve mature B cells, and presumably memory B cells, must constantly maintain BCR expression for survival *(479)*, and therefore it is possible that constant very low affinity self cross-reactive binding is an intrinsic component of B cell survival.

Immunologic memory is not necessarily maintained in the same way in mice and humans. There are classic reports of long-term immunity in humans in the absence of reexposure to a pathogen, as mentioned earlier (Table 28.1) (64,70,*471*). However, those studies have left many important questions unanswered. How stable is long-term immune memory in humans? Is the stability similar or different in the multiple compartments of the adaptive immune system (circulating antibodies, memory CD8$^+$ T cells, memory CD4$^+$ T cells, and memory B cells)? If immune memory is not stable, what is the kinetics of decline? What are the cellular and molecular processes involved in memory cell maintenance? These questions are generally difficult to answer in humans, both because the time frame of interest is decades and it is difficult to find situations in which reexposure to antigen/vaccine/pathogen can be excluded as a source of intermittent "booster immunizations" maintaining the immune memory. Many vaccines induce serum antibody responses that persist for decades *(480)*, but most reports of durable antibody responses in humans are plagued by questions about the potential of intermittent reexposure to the antigen (live measles/mumps/poliovirus vaccines given to nearby children, tetanus in the soil, etc.). Furthermore, memory B cell levels have only been directly examined in a few studies, and it is unclear what the relationship is between serum antibody titers and memory B cell levels. Immune memory after smallpox vaccination is a valuable benchmark for understanding the kinetics and longevity of memory B cells in the absence of reexposure to antigen because immunization against smallpox was standard in the United States and throughout the Western world but was stopped in the mid 1970s, and smallpox disease was declared eradicated worldwide in 1980 after the last known case was observed in eastern Africa in 1977 *(481)*. Because the smallpox vaccine is a live virus vaccine, it is also an excellent model of a well-defined acute infection. Smallpox vaccine–specific

memory B cells can be detected for 60 years or more after vaccination (14). Of note, memory B cell levels appeared to be stable from 10 to 60 years postvaccination, indicating that antigen-specific memory B cells are maintained by robust mechanisms.

There are four models for how human memory B cells are maintained: (a) antigen dependent, (b) intermittent stimulation by cross-reactive antigens, (c) bystander activation, and (d) programmed homeostatic maintenance. These models are not mutually exclusive, and all are topics of active research to determine their importance in memory maintenance. The first model, antigen-dependent maintenance, was introduced earlier in the chapter. Reinfection or reimmunization is one clear mechanism for maintaining memory via recall. Microbial persistence is another clear mechanism for maintaining memory. A number of microbes (herpesviruses being the best-known examples) can persist at low levels in healthy individuals, and this chronicity can provide either a continuous or an intermittent antigenic stimulus to the immune system. This can be an effective mechanism of maintaining a higher frequency of antigen-specific T and B cells but requires a careful balance between pathogen levels and immune responses. This critical balance is necessary to avoid excessive immunopathology and also to avoid overstimulation of the antigen-specific T cells to such an extent that these cells get deleted or functionally exhausted (193,*482*). Antigen depots are an antigen-dependent mechanism for memory maintenance that does not depend on reinfection/exposure or microbial replication. The antigen depot model of memory maintenance relies on the ability of FDCs to trap antigen–antibody complexes on their cell surface and retain them for extended periods of time *(483,484)*. FDCs express Fc receptors on their cell surface, and antigen–antibody complexes can bind to these Fc receptors. It appears that FDCs do not internalize these antigen–antibody complexes but instead display them on their cell surface for long periods, thus promoting maintenance of germinal centers and continued affinity maturation of B cells *(335)*. It is well described that follicular dendritic cells bind antigen and present antigen to B cells in germinal centers. This antigen presentation is generally agreed to be a key component of the affinity maturation and selection process within the germinal center *(332,333,335,476,485)*, although this is debated *(328,336)*. It is generally agreed that antigen is required to maintain germinal center reactions to provide a substrate for positive selection and prevent apoptosis. Some studies have suggested that antigen can persist on FDCs for greater than 1 year, and it has been proposed that after the generation of memory B cells, the memory cells are maintained by periodic reencounter with antigen presented long term by follicular dendritic cells *(483)*. Data from the only study directly tracking antigen in germinal centers after a viral infection, using a mouse model, indicated that germinal cen-

ters are sustained by antigen on FDCs for approximately 30 days after clearance of the virus, after which there is a drop of greater than 90% in the number of germinal centers and a drop of greater than 90% in the amount of viral antigen bound by the FDCs *(484)*. This was corroborated by a second study with a nonreplicating antigen, indicating that FDCs were critical for maintenance of the germinal center reaction but were not involved in the maintenance of memory B cells after the subsidence of the germinal center reaction *(476)*. It is unlikely that viral particles or protein antigens *in vivo* can survive the wear and tear of antibody binding for long before being broken into pieces or destroyed. Essentially all proteins have a finite lifespan, with a half-life in the range of hours to weeks. Proteins and protein structures are damaged by environmental conditions, proteases, and interactions with other proteins, and presumably they would be consumed during memory B cell activation, antigen uptake, and presentation to CD4 T cells. Therefore, retention of biologically relevant levels of antigen by follicular dendritic cells may only be expected to occur for a period of weeks to months before exhaustion of the antigen depot *(476,484)*. Therefore, nonreplicating antigen is unlikely to maintain human memory B cells for greater than 50 years (14). Furthermore, murine memory B cells are maintained in the absence of antigen (discussed in detail previously), suggesting that human memory B cells are also likely to be maintained long term in the absence of antigen.

A second proposal is that memory is maintained by stimulation of memory B cells by cross-reactive environmental or self-antigens. B cells are stimulated by direct interaction of the B cell receptor with antigen, and the specificity of a B cell receptor is not absolute; cross-reactivity is observed. Therefore, it is possible that memory B cells are maintained long term by intermittent interaction with environmental antigens (i.e., allergens, food products, unrelated pathogens) or self-antigens. This hypothesis is exceptionally difficult to test. On a related topic, Rajewsky and colleagues showed that mature naïve B cells must constantly maintain BCR expression for survival *(479)*, presumably due to a need for tonic signaling through the BCR. Tonic signaling may or may not be dependent on low-affinity binding of the BCR to self-antigens. If the signaling is dependent on self-reactivity, memory B cell BCRs may also have a requirement for low-grade self cross-reactivity. On the other hand, memory B cells may have different requirements for BCR stimulation and may no longer require antigen for their survival or homeostatic proliferation. This would be similar to the differential requirements observed between naïve T cells and memory T cells for stimulation through the TCR *(486)*.

A third potential mechanism for the maintenance of memory B cells is bystander polyclonal activation. This model is based on the observation that memory B cells stimulated *in vitro* with TLR ligands or select polyclonal

activators will undergo several rounds of proliferation and differentiate into plasma cells, whereas naïve B cells will not *(473,487)*. If this same process occurs *in vivo*, memory B cells would be likely to proliferate in response to irrelevant microbes containing TLR ligands or proliferate due to production of cytokines secreted by responding cells of the immune system *(473,488)*. Intermittent bystander activation in this manner would result in small-scale expansion of memory B cells, thereby maintaining the population by replacing any memory B cells dying over time. This model is mechanistically plausible but seems unlikely. Although one study observed bystander activation of human memory B cells *in vivo*, as measured by increased antigen-specific serum antibody titers *(473)*, two others human studies observed no bystander activation *in vivo (489,490)*. Bystander activation was not observed in a mouse model system *(491)*. Adoptive transfer experiments involving co-transfer of human cytomegalovirus (HCMV)– and tick-borne encephalitis virus (TBEV)–specific memory B cells into T cell–deficient hosts showed that a memory B cell recall response only occurred when the mice were challenged with the correct cognate antigen *(491)*. Like each of the memory B cell maintenance models discussed in this chapter, this bystander activation hypothesis requires further examination, particularly by directly measurement of antigen-specific memory B cell proliferation and maintenance *in vivo* before, during, and after a number of heterologous infections and/or immunizations.

A fourth potential mechanism for the maintenance of memory B cells is programmed homeostatic proliferation. This hypothesis draws from the known mechanisms of CD8 T cell memory maintenance in mice *(52,411)*. As discussed elsewhere in the chapter, murine memory CD8 T cells accomplish prolonged maintenance by proliferation primarily via IL-15 signals. Memory CD8 T cells are believed to undergo homeostatic proliferation when they migrate through the bone marrow, where there are high concentrations of IL-15 and other proliferation and survival signals *(492,493)*. Therefore, antigen-specific memory B cells may maintain themselves by a similar programmed homeostatic maintenance involving intermittent proliferation triggered by certain autocrine/paracrine cytokines or other as-yet-unknown factors. Data from both mice and humans indicate that memory B cells undergo a slow rate of proliferation in the absence of rechallenge *(330,475, 476,494,495)*. This is consistent with slow homeostatic proliferation and does not require CD4 T cells *(496)*.

What is the value of long-term maintenance of memory B cells? Memory B cells have several features that indicate they are valuable for protection against infections. First, memory B cells are present in much greater numbers than naïve mature B cells of a given antigen specificity *(14,473,475,497,498)*. Second, memory B cells respond to reactivation faster than naïve B cells *(473,499)*, differentiate into plasma cells faster *(499)*, and have a larger burst size, indicative of resistance to apoptosis *(500)*. Third, memory B cells have undergone affinity maturation and therefore produce antibodies after reactivation that have substantially higher affinity and/or avidity than antibody produced from naïve B cells. Each of these properties likely makes memory B cells highly valuable for protection against reinfection because the memory B cells are able to make a rapid recall response and produce high levels of high-affinity antibodies quickly to limit the spread of the infecting microbe and quell the infection. In situations in which antibodies are known to be protective but are not present at high enough levels for sterilizing immunity (i.e., able completely to block infection by the microbial exposure or inoculation), memory B cells are likely to contribute to the observed protection against disease. The hepatitis B virus (HBV) vaccine is a well-characterized example known for antibody titers that drop over several years *(501–503)*. Antibodies against HBsAg are the defined correlate of protection for the HBV vaccine, and the minimum protective level has been established as 10 mIU/mL *(480)*. When serum anti-HBsAg antibody levels drop below that level, booster immunization is recommended. However, many individuals with low or undetectable levels of HBsAg fail to obtain booster immunizations, and some fraction of that population subsequently becomes exposed to HBV. Of interest, nearly of those individuals are still protected from HBV infection *(504)*. Why? Memory B cells are an appealing explanation because HBV surface antigen–specific antibodies are the correlate of protection for the vaccines, and memory B cells will rapidly differentiate into anti-HBsAg antibody-secreting cells within 3 to 5 days of virus exposure *(501,504,505)*. This may also be observed with the anthrax vaccine *(506,507)* and other vaccines or infections when the levels of circulating antibody do not result in sterilizing immunity. In any situation in which antibodies contribute to protective immunity, reactivation of memory B cells is likely to contribute to protection as long as the infectious agent is not so virulent as to cause disease before the memory B cells have time to proliferate and differentiate into plasma cells.

Maintenance of Long-lived Plasma Cells: Active Memory

There are at least two populations of plasma cells: long-lived and short-lived. Long-lived plasma cells are a central part of immune memory because these cells are largely responsible for the long-term continuous secretion of antibody. In contrast to memory B cells, plasma cells are terminally differentiated and cannot be stimulated by antigen to either divide or increase their rate of antibody production. Because preexisting antibody provides the first line of defense against infection by microbial pathogens, the importance of plasma cells in protective immunity cannot be overstated.

The traditional view was that all plasma cells are short-lived cells with a half-life of approximately 3 to 14 days *(359)*, and therefore continuous antigenic stimulation of memory B cells was necessary to replenish the pool of rapidly dying plasma cells and thereby maintain antibody production. This view has been replaced by a model describing two major populations of plasma cells: short-lived plasma cells that produce antibody soon after antigen exposure, and long-lived plasma cells that survive for extended periods (the half-life is 3 to 4 months in mice) (Figure 28.1) (14,*353,357,476,508*). The majority of serum antibodies are produced by plasma cells residing in bone marrow *(354,509–511)*. The secondary lymphoid tissue plasma cell response to an immunization or acute infection peaks within 1 to 2 weeks and then declines within 2 to 4 weeks after infection *(349,354,361,364)*. As splenic plasma cell populations decline, antigen-specific plasma cells begin to migrate to and/or accumulate in the bone marrow compartment *(349,351,355,361)*. After the germinal center reaction subsides, the bone marrow becomes the predominant site of antibody production, with bone marrow plasma cells responsible for 80% to 95% of the host's antibody production (14,*354,509,512*).

Many human vaccines induce serum antibody responses that persist for decades *(480)*, but it is usually unclear whether there is a long-term decline in the antibody levels, and there are usually questions about the potential of intermittent reexposure to the antigen, as stated earlier. An impressive study of long-term antibody levels that avoided the reexposure issue was the large cross-sectional study of poliovirus immunity done in Sweden (Table 28.1) *(472)*. The Swedish population was almost ideal for such a study, for several reasons: (a) poliomyelitis had been eliminated in Sweden since 1962; (b) only inactivated poliovirus vaccine (IPV, the Salk vaccine) provided by a single supplier has ever been used in the Swedish population; (c) the final booster immunization was given at the young age of 5 years; (d) the enterovirus infection burden in Sweden has been extremely low, and there were very few opportunities for introduction of poliovirus from foreign sources; and (e) Sweden has excellent health care records and public health surveillance. Given those factors, it was striking to see that when the Swedish population was surveyed for poliovirus immunity in 1991, substantial antipoliovirus antibody titers were detected in all age groups *(472)*. Of interest, there was virtually no difference in serum antibody titers among the different age groups (all at greater than 10 years postvaccination), indicating that antipoliovirus antibody titers are stably maintained in the absence of additional immunizations or exposure to live virus *(472)*. Of interest, declining levels of antitetanus and antidiptheria antibody titers were observed in that same study, suggesting that not all immune memory is created equal *(472)*. In other human studies, antibody responses after smallpox immunization can be maintained for greater than 60 to 75 years (14,16,*513*). It is impressive that the serum levels of anti–vaccinia virus (VV) antibodies were stable from 1 to more than 60 years postimmunization (14,16). Immune memory after smallpox vaccination is a valuable benchmark for memory in the absence of antigen reexposure because immunization against smallpox was stopped in the mid-1970s and neither smallpox nor the smallpox vaccine virus exists in the wild. Total anti-VV antibody levels in vaccines correlated reasonably well with neutralizing anti-VV antibody levels, providing some indication that antibody responses of different specificities were maintained equally well (14,16). Data from yet another group of studies examining immunity to HBV in humans showed that anti-HBV serum antibody levels decline over time in vaccinated individuals *(501–503)*. Altogether these studies show than human antibodies can be maintained for greater than 60 years in the absence of reexposure to antigen, but long-term maintenance of antibody levels does not occur in all cases, indicating that not all memory is created or maintained equally.

How is the antibody production maintained for 60 or more years? Long-lived plasma cells are crucial for the maintenance of antibody levels. There are two main theories for how numbers of antigen-specific long-lived plasma cells are sustained for years after vaccination (Figure 28.7): (a) competitive/conditional longevity of long-lived plasma cells, and (b) replenishment of long-lived plasma cells from differentiating memory B cells. The first model proposes that long-lived plasma cells are long lived because of the survival niche they occupy in bone marrow or spleen (358). Once a long-lived plasma cell is produced and homes to specific sites such as the bone marrow, the plasma cell may survive for decades without requiring replenishment from the memory B cell pool. Plasma cells generated *in vitro* or isolated *ex vivo* die rapidly, but their survival *in vitro* can be extended somewhat by providing stimuli found in bone marrow *(514)*. The conditional survival model proposes that a plasma cell will survive for as long as it physically stays in a survival niche *(358)*. If the plasma cell leaves the survival niche or is dislodged from the survival niche, it will die. Because the number of bone marrow plasma cells in mice and humans is relatively stable over a lifetime, old plasma cells must somehow be eliminated to make room for new plasma cells. This model proposes that the generation of a new immune response somehow induces the loss of longer-lived plasma cells *(358)*. There is human data indicating that bone marrow plasma cells can be mobilized into the blood after an irrelevant immunization *(515)*. At least one murine model study has detected a loss of plasma cells after a new immunization with a second antigen, and the survival of the long-lived plasma cells was correlated with lack of FcγRII expression *(516)*. A caveat to this model is that long-lived plasma cells in mice have a measured half-life of 3 to 4 months *(353,476)*, suggesting that plasma cells may have an intrinsic lifespan.
Model 1

Model 2

FIGURE 28.7 Two hypothetical models of antigen-independent long-term maintenance of antibody levels. Hypothetical model 1: Independent memory B cell and plasma cell populations are generated. If a plasma cell migrates to a survival niche (such as those present in bone marrow), the plasma cell becomes a long-lived plasma cell and will live indefinitely as long as it remains in the survival niche. New long-lived plasma cells can survive by occupying a survival niche vacated by an old, long-lived plasma cell. Hypothetical model 2: Memory B cell and long-lived plasma cell populations are generated. Plasma cells have a certain half-life, and die over time. Both memory B cell and long-lived plasma cell numbers are maintained or replenished by intermittent divisions by memory B cells coupled to differentiation of a plasma cell at the same time, such that one memory B cell effectively gives rise to one daughter memory B cell and one daughter plasma to maintain both the antigen-specific memory B cell and plasma cell compartments.

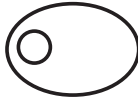
However, in a third study an indefinite half-life was observed *(512)*.

The second model is replenishment of long-lived plasma cells from memory B cells. Plasma cells are terminally differentiated and unable to proliferate. Therefore, repopulation of their numbers can be accomplished by proliferation and differentiation of memory B cells into antibody-secreting plasma cells. This replenishment is known to occur in an antigen-dependent manner after a booster immunization or reexposure to infection. It is proposed that there can be antigen-independent differentiation of memory B cells to long-lived plasma cells (Figure 28.2) *(488,507)*. There are models of long-term memory B cell maintenance that propose that antigen-specific memory B cells maintain themselves within the pool of total mem-

ory B cells either by intermittent bystander activation or by a programmed homeostatic maintenance proliferation, as described in the previous section. A corollary to those memory B cell maintenance models is that the antigen-independent proliferation of memory B cells to maintain their numbers may be coupled to differentiation of a plasma cell at the same time, such that one memory B cell effectively gives rise to one daughter memory B cell and one daughter plasma cell to maintain both the antigen-specific memory B cell and plasma cell compartments. If this model is accurate, there should be a correlation between memory B cell numbers and plasma cell numbers (or serum antibody levels). Two human studies have shown a positive correlation between antigen-specific memory B cell frequencies and serum antibody levels (14,473). In

both cases the correlation was moderate, indicating that there may be multiple factors controlling the relationship between circulating memory B cell levels and circulating antibody levels. Two other human studies observed no correlation looking at other antigens *(498,505)*, again indicating that multiple factors may control the relationship between memory B cells and serum antibody levels.

Neither of these models fully accounts for the observation that some antibody responses appear to be more stable and long-lived than others, as discussed earlier. Resolution of these disparate models of memory B cell and antibody maintenance requires further study, particularly in humans, in whom the issues of longevity are amplified due to interest in understanding immunologic memory that lasts for a decade or longer. In addition, understanding the detailed physiologies of memory B cells and plasma cells in both mice and humans will help to illuminate the functions of these cell types and the relationships among memory B cells, long-lived plasma cells, and the maintenance of humoral immunity.

THE PHENOTYPIC HETEROGENEITY OF THE CELLS CLASSIFIED AS MEMORY CELLS


Identification of T Cell Memory

A number of key questions regarding the origin, maintenance, and function of immune memory would be informed by a marker or set of markers through which memory cells could be identified and distinguished from the naïve and effector subsets. Unfortunately, this goal has been difficult to realize for a number of reasons, including the fact that the many of the phenotypic changes that occur in activated lymphocytes are often transient and can revert back to their status as naïve cells over time and that many of the surface proteins expressed by long-lived Ag-experienced cells that would otherwise qualify them as memory markers are also expressed on recently activated effectors. Furthermore, T cells can be found to express markers of prior activation without having responded to antigen in the conventional sense, such as occurs in lymphopenic hosts or in the rapidly dividing subset of CD4$^+$ T cells described previously in this chapter that appears to be under chronic antigenic stimulation. Finally, there is substantial heterogeneity within the memory population with regard to phenotype, function, and anatomic location, both in CD4$^+$ and CD8$^+$ compartments. Immunologists have nonetheless tried to define the features that distinguish populations of T cells that are presumed never to have previously encountered antigens (i.e., those from umbilical cord blood or germ-free mice) with those that are known to have recently undergone primary or secondary stimulation, with most studies focusing on surface molecules expressed in the different populations. Such studies have revealed a surprising degree of heterogeneity in putative memory markers with respect to both temporal and anatomic aspects of the expression.

It has long been appreciated that memory T cells express surface markers that distinguish them from naïve cells *(517,518)* (Figure 28.8). Much early work was focused on the high– and low–molecular weight isoforms of the surface-expressed tyrosine phosphatase CD45, which can be generated through differential splicing of three extracellular exons, called A, B, and C, which are differentially expressed on naïve versus memory T cells *(519)*. In the human system, naïve T cells express the high–molecular weight form called CD45RA that contains all three of the spliced exons, whereas memory cells tend to more often express the low–molecular weight form called CD45RO, with the different phenotypes assigned based on reactivity with isoform-specific monoclonal antibodies *(520,521)*. There is significant heterogeneity in CD45 expression, however, with variation in surface levels of the low–molecular weight isoforms on memory T cells as a result of reexpression of CD45RA after its initial downregulation, which itself occurs at different rates on CD4$^+$ versus CD8$^+$ T cells (reviewed in ref. *522*). Furthermore, although murine T cells also express variant isoforms of CD45, this has also proven to be a less reliable marker of naïve versus memory cells *(523–525)*. A number of studies have attempted to correlate the upregulation of adhesion molecules on memory cells, including members of the β1 (CD49d, CD40e, CD29) and β2 (CD11a, CD11b, CD18) family of integrins, as well as CD2, CD44, CD54, and CD58 (reviewed in ref. *371*). Among these, however, most appear to reflect recent activation status of the T cells; only CD44 appears to be a stably expressed marker of memory cells that is expressed at high levels when T cells are transferred to antigen-free recipient mice *(379,486,526–528)*. However, high-level CD44 expression is also found on the memory phenotype T cells discussed in a previous section that are believed to be subject to chronic stimulation by ubiquitous environmental antigens, so that CD44 expression alone cannot serve as an informative marker for memory cells. When used in conjunction with other markers, however, CD44 can be used more specifically to distinguish memory from naïve T cells.

A number of other molecules can differentiate between naïve and antigen-experienced cells. These include both CD122, a component of both the IL-2 and IL-15 receptors, and Ly-6c, a small GPI-linked surface protein, although this involves increased rather than *de novo* expression on memory cells, and this only on CD8$^+$ and not CD4$^+$ T cells *(394,529–531)*. CD8$^+$ T cells have also been shown to undergo changes in their cell-surface glycosylation that can help to distinguish effectors from resting memory cells (reviewed in ref. *532*). After activation, CD8$^+$ T cells undergo an elimination of sialic acid from core 1 O-glycans and an induction of core 2 O-glycans

until they differentiate into memory cells *(533)*. This difference allows selective binding of the 1B11 antibody, which binds to CD43 only when modified by core 2 O-glycans *(534)*. Of interest, although core 2 O-glycan expression decreases after conversion of CD8$^+$ effectors into memory cells, peanut agglutinin staining (which reflects the expression of unsialylated core 1 O-glycans) is slightly higher on memory than on naïve T cells, and it has been proposed that this influences their reduced TCR signaling threshold *(534–536)*.

In addition to these phenotypic markers of memory T cells, efforts have been made to identify these cells based on their function, usually defined by the parameters of protection, proliferation, and persistence. The unambiguous assignment of a unique set of functional markers through which they can be identified has also been difficult because many of the capacities they possess are simply not unique to the memory subset. For example, naïve T cells, like memory T cells, are capable of self-renewal in response to homeostatic cytokines and can proliferate extensively in response to antigen. Similarly, effector cells, which differ from effector-competent memory cells only in their longevity, can mediate potent functional responses and, if present in sufficient numbers, protective immunity, depending on the nature of the challenge. The physiologic location of memory cells has been held to represent a defining feature because naïve T cells are not normally believed to occupy extralymphoid environments (90). Recent studies using S1P-receptor antagonists, however, have revealed that naïve cells may pass through peripheral tissues as part of their normal recirculation pattern (90,537,538).

Chemokine receptors represent another class of molecules used to functionally define different subsets of memory T cells, in this case based on their specific homing behavior *(539–541)*. Skin-homing memory T cells, for example, express high levels of β1 and β2 integrins and cutaneous lymphocyte antigen (CLA), a molecule involved in lymphocyte homing to the dermis, as well as a number of receptors for inflammatory chemokines, including CCR1, CCR3, and CCR5, but neither of the lymph node–homing receptors CCR7 or CD62L (41). CCR7$^+$ memory T cells, in contrast, express lower integrin levels and no CLA, but express chemokine receptors that will guide them to lymphoid tissues such as CCR4, CCR6, and CXCR3, as well as CD62L. Based on the distinct homing potential of these two subsets (e.g., CCR7$^+$ CD62L$^+$ and CCR7$^-$ CD62L$^-$), it was proposed that they represent two specialized types of memory T cells, each charged with a specific task in host defense (reviewed in ref. *542*). The CCR7$^-$ CD62L$^-$ effector memory subset (T$_{EM}$) resides in peripheral tissues, where pathogens are likely to first gain access to the body, and can mediate direct effector functions against infected cells. The CCR7$^+$ CD62L$^+$ central memory subset (T$_{CM}$) is found mostly within lymph nodes, where it responds to antigenic stimulation by renewed proliferation and the generation of secondary effectors. It should be pointed out that expression of both CD62L and CCR7 also defines naïve T cells, so that additional markers are required to distinguish T$_{CM}$ such as high-level expression of CD44 in the mouse or the absence of CD45RA in the human. Although CD62L and CCR7 do not represent perfect sets of phenotypic markers with which to define memory subsets because significant heterogeneity exists in their respective expression patterns among memory T cells, the concept of a functional division of labor between T$_{EM}$ and T$_{CM}$ has been remarkably in-

fluential, with numerous studies dedicated to elucidating their lineage relationship and relative role in maintaining the protected state. Some of these have concluded that T$_{EM}$ and T$_{CM}$ arise sequentially through a linear pathway of differentiation, whereas others support the idea that they are separate populations that arise independently *(320,543–549)*. More recently, it has been suggested that the initial precursor frequency of antigen-specific T cells may influence the commitment of T cells to one or the other lineage, or that changing the anatomic location (e.g., from lymphoid to peripheral tissues) can cause the conversion from T$_{CM}$ to T$_{EM}$ phenotype *(546,550)*. Numerous laboratories are working on the elucidation of the origins and lineage relationships of T$_{EM}$ and T$_{CM}$ phenotypes, their relative roles in protective immunity, and their potential for interconversion.

Although much remains to be revealed about the phenotypic and functional characteristics by which memory T cells can be identified, a sufficient body of knowledge has been acquired so that an initial framework can be used to distinguish them from naïve and short-lived effector cells (Figure 28.8). As might be expected from the information discussed previously, memory T cells constitute a heterogeneous population with respect to surface phenotype, anatomic location, and functional capacity. Still, using a combination of markers for these parameters together with an understanding of the time that has elapsed since their initial priming, it is often possible positively to identify memory T cells.

Identification of B Cell Memory

Memory B cell and plasma cells markers differ in mice and humans. There is no widely accepted memory B cell marker in mice. CD27 expression does not selectively distinguish mouse memory B cells, in contrast to what is observed for human memory B cells (see later discussion). Mouse memory B cells are usually identified by flow cytometry as isotype-switched B cells (e.g., IgG$^+$ IgD$^-$) that are neither germinal center B cells (e.g., not PNA$^+$ FashiCD38loGL7$^+$) nor plasma cells (not CD138$^+$) *(363,551)*. This is problematic for the identification of IgM memory B cells, limiting our current understand of that compartment *(552,553)*. Antigen-specific memory B cells can be identified by their ability to bind fluorescently labeled antigen *(475,478,497,554)*, which is a rich source for experimental study, although it can be technically challenging *(331,555)*. Antigen-specific memory B cells can also be identified by *ex vivo* functional assays (14,556) or adoptive transfers *(557)*, although *ex vivo* reactivation assays are limited in their ability to provide single-cell-level analysis, and adoptive transfers can have unexpected complications *(491)*. Although some surface phenotypic markers have been proposed to be differentially expressed by mouse memory B cells (CD38^{high}, CD11b$^+$, Fasint) or
FIGURE 28.9 Plasma cell differentiation and markers. **A:** Known and/or postulated plasma cell populations and precursors (337, 349,352,361). subsets of memory cells (B220$^-$), there is debate about their utility, and none is widely adopted *(330,331,485,558)*. This suggests that memory B cells are either phenotypically heterogeneous or similar to naïve B cells in their cell surface protein expression profile *(330,331,485)*.

Plasma cells are identified histologically by their large size, eccentric nucleus, and high concentration of intracellular immunoglobulin. Plasma cells are identified functionally by their ability to secrete immunoglobulin *(477,559)*. Plasma cells are also identified by the surface phenotypic marker CD138 *(560)*. Fully differentiated murine plasma cells do not express CD19, B220, or MHC II *(512,561,562)*. Plasmablasts are larger than resting B cells and also have high concentrations of intracellular immunoglobulin *(562,563)*. Plasmablasts express CD138, but they still express intermediate levels of B220, CD19, and

MHC II *(352,561,562)*. It is unclear whether there are multiple distinct plasma cell differentiation pathways *in vivo* distinguishing short-lived from long-lived plasma cells and their precursors or there is one plasma cell differentiation pathway and the percentage of plasma cells with access to a long-term survival niche acquire a distinct phenotype based on their location (Fig. 28.9) *(352)*.

Humans

Human memory B cells selective express CD27 *(564–566)*, a member of the TNF receptor superfamily *(567)*. Surface expression of CD27 is now widely used as a specific marker, in conjunction with lack of IgD expression, to discriminate human memory B cells from naïve B cells. CD27 was initially determined as a marker of human memory B cells in both peripheral blood and spleen by demonstrating that CD27$^+$ B cells express somatically mutated Ig V genes, whereas CD27$^-$ B cells do not *(565,566)*. This was also consistent with the observation that nearly all isotype-switched B cells in peripheral blood are CD27$^+$, and the majority of IgD$^+$ B cells are not *(564,565)*. Memory B cells in tonsillar tissue can be identified as IgD$^-$ CD38$^-$ B cells as well as IgD$^-$ CD38$^-$ CD27$^+$ *(568,569)*. Vaccine induced antigen-specific memory B cells have also been shown to be predominantly CD27$^+$ *(473,570)*. Human CD27$^+$ memory B cells in the spleen localize to the marginal zone *(566)*, comparable to what has been observed in rats and mice. There does exist a small population of CD27$^-$ human memory B cells, and it has been proposed that differential expression of ABC transporter B1 (ABCB1) can be used to distinguish those memory B cells from naïve B cells *(495)*. There has also been debate as to whether somatically mutated IgM$^+$ IgD$^-$ CD27$^+$ B cells represent a true memory compartment, discussed in two recent reviews *(552,571)*.

Antigen-specific human memory B cells can be identified by fluorescent antigen binding and flow cytometry *(572,573)* or functional identification by *in vitro* reactivation *(473,570)*. Antigen-specific memory B cells are present at low frequencies [approximately 0.005% to 0.2% of total peripheral blood B cells (14,498)]. Using either approach, antigen-specific human memory B cells have been identified to the smallpox vaccine (14), the anthrax vaccine *(507)*, the tetanus vaccine *(473,489,498)*, measles *(473)*, malaria *(574)*, influenza (flu) *(575,576)*, rotavirus *(573,577)*, severe acute respiratory syndrome *(578)*, and wasp venom allergen *(498)*.

Human plasma cells express higher levels of CD27 than memory B cells and are conventionally distinguished in flow cytometry by their high level of CD38 expression and downregulation of CD20 expression *(515, 579,580)*. Human bone marrow plasma cells are similar to murine plasma cells, in that they express CD138, but this marker is not observed on tonsillar or splenic human plasma cells *(499,579)* or on *in vitro*–generated plasmablasts. Our understanding of human plasma cells is limited in large part due to the low frequency of plasma cells in peripheral blood (100 to 1,000 per million cells) and the very brief presence of antigen-specific cells in peripheral blood, making detailed analysis difficult. For studies of human antigen-specific plasma cells, serum antibody levels are classically used as a surrogate indicator.

THE MOLECULAR BASIS OF IMMUNE MEMORY

The Genetic Program of T Cell Memory

Although memory T cells share many features with short-lived effectors, their capacity for self-renewal and recall response suggests that they are guided by a distinct program of gene expression. The phenotypic distinction and functional specialization inherent within the T_{CM} and T_{EM} subsets give further evidence of this notion. Investigations into the molecular events that guide the generation and maintenance of memory T cells are at a relatively early stage in comparison to the phenotypic studies through which these phenomena have been defined. Nonetheless, a framework for understanding the genetic program of memory is beginning to emerge through the identification of genes and regulatory elements that control key functional parameters of T cell memory (30,*581*). Initial studies focused on performing genome-scale gene expression analysis in T cells using gene array hybridization techniques, first to resting versus-activated T cells and subsequently to T cells undergoing homeostatic proliferation (31,*582–584*). These studies revealed that the gene expression in T cells is a dynamic process that undergoes substantial alterations in response to TCR-mediated and environmental stimuli during the transition from resting to activated status. The phenotypic features of this process (e.g., proliferation, effector differentiation, survival) are matched in the global patterns of genes expressed (e.g., cyclins, effector molecules, anti-apoptotic factors, etc).

A key study on the transcriptional profile of memory T cells comes from Kaech et al., who performed genome-wide analyses of gene expression on naïve, effector, and memory transgenic CD8$^+$ T cells activated *in vivo* by LCMV (30). Among the findings emerging from a comparative analysis was that each phase of development was characterized by specific patterns of gene expression directly related to the development or function of the cells at that stage of differentiation; approximately 30% of the genes expressed by effector cells were also maintained in the memory cells, supporting the direct lineage relationship between these cell types (30). In some cases, the expression level of the genes was set at the peak of the effector response (d8), but in others the level of expression

decreased as the gradual conversion to memory occurred, perhaps reflecting a global reduction in transcriptional activity in these cells. Whereas the distinction of T_{EM} and T_{CM} subsets has traditionally been defined by phenotypic markers, Willinger at al. used transcriptional profiling to analyze the molecular signature of these subsets in human CD8$^+$ T cells and found that the T_{CM} subset had a pattern of gene expression that was intermediate between naïve and T_{EM} and effector/T_{EM} phenotype cells *(585)*. It has long been appreciated that memory T cells share several notable features related to self-renewal with long-term hematopoietic stem cells (Lt-HSCs). Consistent with this, Hyatt et al. found that both memory T and B cells appear to share many elements of their transcriptional program with Lt-HSCs, with notable increases in the expression of prosurvival and antiapoptosis genes *(581)*.

In parallel with the genome-wide studies of gene expression at the population level in T cells, efforts have been made to define the genetic program of memory in single cells or with respect to specific transcription factors. The recent study of Peixoto et al. is notable in its study of gene expression patterns at the level of single cells at various stages during an immune response *(586)*. This study revealed surprisingly heterogeneous and dynamic patterns of gene expression from the earliest point in the response, with both proinflammatory and effector functionality revealed in discrete cells, followed by a more uniform pattern in secondary responders. It is unclear whether the reduction in heterogeneity at later time points reflects a selection process or a progressive development of the entire memory populations. A number of studies have analyzed the contribution of specific transcription factors to the enhanced longevity and function of memory T cells. These include T-bet and eomesodermin (Eomes), the transcription factors that coordinately regulate a number of genes related to lineage commitment and effector differentiation in both CD4$^+$ and CD8$^+$ T cells *(295,296,587–589)*. T-bet$^{-/-}$ Eomes$^{+/-}$ mice have a near-total loss of effector and memory T cells through a mechanism that is believed to involve their role in regulating the expression of CD122 and thereby responsiveness to IL-15 *(590)*. The roles of T-bet and Eomes in determining whether effector cells are selected for memory development may involve their reciprocal regulation in response to inflammatory signals via IL-12. In response to pathogen-induced IL-12, Eomes is repressed and T-bet levels are increased, which can lead to inhibition of IL-7Rα expression and decreased survival in short-lived effectors *(591,592)*. When IL-12 signals are reduced, Eomes levels rise, whereas T-bet levels decrease, favoring the development of long-lived memory cells *(592,593)*. Another transcription factor that is relevant for memory formation is inhibitor of DNA binding-2 (Id2), an antagonist of E protein transcription factors that is upregulated in CD8$^+$ T cells during infection and maintained on their conversion to memory cells. Although Id2-deficient naïve CD8$^+$ T cells recognized antigen and proliferate normally early after infection, the effector cells become highly susceptible to apoptosis and fail to accumulate. Id2-deficient CD8$^+$ T cells responding to infection show defective memory formation and have altered patterns of expression in genes that influence survival *(594)*.

In addition to the transcription factors described previously, several transcriptional repressors have emerged as regulators of T cell memory. Bcl-6, first described as a transcriptional repressor with pleiotropic functions in B cell differentiation, appears to play a role the generation of both CD4$^+$ and CD8$^+$ T cell memory because the survival of Bcl-6 deficient CD4$^+$ effector T cells was greatly diminished compared to wild-type controls after priming, and Bcl-6–deficient mice were found to lack memory phenotype CD8$^+$ T cells after immunization *(595,596)*. The Bcl-6 homolog Bcl-6b, known to repress IL-2–induced B cell differentiation, is expressed by a small subset of CD8$^+$ T cells and regulates their capacity for secondary expansion in response to antigenic challenge *(597)*. Another transcriptional repressor first described in B cells that influences T cell homeostasis is Blimp-1, which is required for terminal differentiation of B cells through coordinate regulation of hundreds of genes (reviewed in refs. *598,599*). Mice lacking Blimp-1 suffer from a variety of immune-mediated pathologies including colitis and multiorgan inflammatory diseases that are characterized by accumulation of effector and memory T cells *(600,601)*.

It is worth noting that in the case of both the transcriptional activators and repressors that have been implicated in T cell memory, very little is known about the downstream genes they control or the effect these have on the phenotypic and functional parameters through which memory T cells have traditionally been defined. An especially exciting prospect for the near future is that meaningful connections can be made among these transcriptional regulators, the myriad of genes that the array-based approaches have identified at each stage of memory T cell development, and the variety of phenotypic and functions displayed by memory T cells in the generation and maintenance of the protected state.

The Genetic Program of B Cell Memory

The genetic program of B cell memory can be considered to be made up of different genetic programs regulating four cell types: genes regulating germinal center B cells, genes regulating CD4 T cells, genes regulating memory B cells, and genes regulating plasma cells. For example, mice and humans with defects in SAP (SLAM-associated protein, the product of the *sh2d1a* gene) have severe memory B cell deficiencies *(364,602)*. This defect is due to the requirement for SAP expression in CD4 T cells to provide B cell help and generate germinal centers *(340,364,603)*. Genes that regulate CD4 T cell help to B cells affect memory

B cell generation. Additional prominent examples include CD40L, ICOS, CD28, and CXCR5 *(273)*. Human genetic deficiencies in CD40L and ICOS have been identified and are associated with severe germinal center B cell defects and overall reductions in memory B cell numbers *(604,605)*.

Memory B cells are generated in germinal centers, and therefore genes necessarily expressed in B cells for germinal center B cell differentiation and function control memory B cell development. Prominent examples of genes expressed in B cells that are important for differentiation into germinal center B cells or function (class switching and hypermutation) of germinal center B cells include BCL6, AID, CD40, ICOSL, and IL21R *(342,606–609)*. An exhaustive list is available elsewhere *(332)*, with several notable recent additions *(610–612)*. Human genetic deficiencies in CD40 and AID have been identified and are associated with severe B cell defects, including overall reductions in memory B cell numbers *(605)*. Genes that are required for fully functional mature peripheral B cells also generally affect subsequent germinal center formation after infection/immunization. Genes in this category include B cell development and/or survival regulators including CD19, OBF, and BAFF-R *(613–616)*. All of these genes are important in germinal center development and are therefore directly or indirectly important for the differentiation of memory B cells. Genes have not been identified that are specifically required for the maintenance of memory B cells in a cell-intrinsic manner. Because memory B cells are believed to maintain themselves via slow homeostatic proliferation *(475,494,495)*, comparable to what is observed for CD8 T cells (34,52,*411*), it is likely that genes involved in cell survival, homeostatic proliferation, and the stem cell–like property of self-renewal (which may include quiescence factors) are important for memory B cell maintenance.

Genes necessary for plasma cell differentiation in a cell-intrinsic manner are necessary for the development of long-lived plasma cells and the long-term maintenance of serum antibody levels. Blimp-1 and XBP-1 are two prominent examples of important regulators of plasma cell differentiation *(617–620)*. The selective effects of Blimp-1 on plasma cell differentiation are highly informative. Blimp-1 expression in B cells is tightly correlated with plasma cell differentiation *(361)*, and Blimp-1 deficiency in mice leads to normal (or enlarged) germinal center development and memory B cell development but results in a complete lack of plasma cells after immunization *(621)*. These observations demonstrate that the memory B cell and plasma cell lineages are distinct and are controlled by different genetic programs. Regarding long-lived plasma cell survival, CXCR4 is a chemokine receptor important for homing of long-lived plasma cells to the bone marrow and other locations of survival niches *(358)*, and constitutive expression of Blimp-1 is required for maintenance of long-lived plasma cells *(622)*.

A fourth category of genes that affect B cell memory comprises genes important for lymphoid organ architecture and organization. Genes encoding cytokines in the TNF superfamily, including LTα, LTβ, the LTβ receptor, and TNF and TNFR1, and are crucial for the development of appropriate lymphoid architecture *(623,624)*. In the absence of these genes, germinal center formation is severely disrupted. It is believed that this disruption of germinal center development is due to the combined factors of defective lymphoid architecture and defective follicular dendritic cell differentiation. B cell expression of LT$\alpha\beta$ is key for establishing gradients of chemokines, which are important molecules affecting germinal center development (and therefore B cell memory generation) by organizing the cellular compartments of lymphoid organs *(625)*.

CONCLUSION

The salient features related to the phenomenon of immune memory have been recognized for decades and can be easily replicated in both *in vitro* and *in vivo* experimental systems. Despite this, a detailed molecular understanding of just how memory cells are able to persist and protect has yet to be realized. Key steps towards this goal have been the development of standard definitions for what memory cells are and can do and an appreciation of the remarkable phenotypic and functional heterogeneity they possess. The next advances in our understanding of immune memory will come from the application of more holistic molecular approaches to the study of physiologic immune responses *in vivo*, which will allow activities of the immune system, as opposed to a specific immune cell, to be studied. Although this might seem a daunting task in terms of its complexity and sheer volume of information to be obtained, the results will be transformative in terms of our fundamental understanding of the immune system and our ability to manipulate it for the prevention of disease.

Immunologic Tolerance

Ronald H. Schwartz

In 1905, Ehrlich and Morgenroth *(1)* observed that goats injected with red blood cells (RBCs) from another goat always made hemolytic antibodies directed against the immunizing cells, but these antisera never reacted against the recipient's own RBCs. Furthermore, they deliberately immunized a goat with its own RBCs and also observed that no antibody response was elicited. They coined the Latin phrase *horror autotoxicus* to describe this situation. To them, the term meant that the animals avoided self-destructive responses, although it was often interpreted by others to mean a failure to make any immune responses against self-components. In fact, in a footnote in their article *(1)*, they made clear the distinction between autoreactivity and autoimmune disease when they discussed the experiments of Metalinikoff *(2)*, who found that guinea pigs injected with homologous sperm made cytotoxic antibodies against these cells. Because the antibodies did not kill the sperm *in vivo*, they deemed the antibodies not to be autotoxic.

In this chapter I retain the perspective of Ehrlich and Morgenroth. Hence, I define tolerance as a physiologic state in which the immune system does not react destructively against the components of the organism that harbors it or against antigens that are introduced into it.

Destructive responses are prevented by a variety of mechanisms that operate during development of the immune system *and* during the course of each immune response. Pharmacologic manipulations are not included. This broad view allows one to consider immunoregulation as part of the tolerance process. Finally, I will focus on the adaptive immune system only and not discuss the tolerance processes for either natural killer (NK) cells or the innate like NK T (NKT) cells, B-1 cells, and TCR$\gamma\delta$ cells.

TOLERANCE IS AN ADAPTIVE PROCESS

Why did the goats not make antibodies against their own RBCs? The first observations that shed light on this issue were made by Owen (3) on dizygotic bovine twins and Owen et al. *(4)* on quintuplets. They analyzed the surface antigens of RBCs from these cattle using alloantisera of the type raised by Ehrlich and Morgenroth *(1)* in goats, and showed that each offspring possessed all of the antigens found in the parents, even though some of these determinants were not expressed by both parents. In the quintuplets this seemed unlikely to result from codominant heterozygosity as the outbred parents would have had to be homozygous at multiple genetic loci. Instead, Owen and colleagues were able to show in cytotoxicity assays that the offspring were chimeric, that is, their blood contained a mixture of cells with different phenotypes. Based on the earlier work of Lillie *(5)*, who had suggested that dizygotic cattle could exchange products through anastomoses of the blood vessels in their two placentas, Owen and colleagues postulated that hemopoietic stem cells from each sibling migrated to the bone marrow of the other sibs to create a stable chimeric state that persisted after the sibs were separated at birth. Because the chimerism of the antigenically disparate cells was not disturbed by an immune response, Owen and colleagues described this state of peaceful coexistence as one of tolerance. The observations suggested that a foreign substance could be either reacted against or tolerated by an immune system depending on when the antigen was presented to it. The observations also suggested that there was no fundamental distinction between self-molecules (encoded by the host's genome) and foreign molecules (coming from the sibling's hematopoietic cells) in their ability to induce a tolerant state.

Burnet and Fenner *(6)* were strongly influenced by Owen's observations, as well as by those of Traub *(7)*, who demonstrated that a carrier state for the lymphocytic choriomeningitis virus (LCMV) could be induced in mice by natural exposure to this virus *in utero* or during the neonatal period. Their interpretation of both sets of results was that the developing immune system was malleable and that if a foreign substance were introduced early enough, it would induce tolerance rather than immunity. The first experimental data to support this hypothesis were generated by Billingham et al. (8,9). They injected cell suspensions from mixed tissues of mouse strain A into neonatal or fetal mice of strain B and showed that as adults, the strain B mice could accept skin grafts from a strain A mouse, although they would rapidly reject skin grafts from a third-party strain C mouse. The concept derived from this work, that tolerance was an acquired state, was confirmed by Hašek *(10)*, who experimentally reproduced the observations of Owen *(3,4)* by parabiosis of chick embryos. After separation at birth, the adult birds could not make an antibody response against their partner's RBCs (Ehrlich's experiment *(1)*) and could not reject each other's skin grafts (Medawar's experiment *(8,9)*). Burnet subsequently gave a theoretical framework to all of these results in his clonal selection theory, in which he postulated that clones of lymphocytes with receptors on their surface specific for molecules present during the development of the immune system would be selectively eliminated by a deletion process (11). Similar ideas were put forth by Talmage *(12)*.

Consistent with the idea that the immune system learns to be tolerant during its development was the subsequent experiment of Triplett (13). He removed the pituitary anlage from tree frog larvae and let them differentiate under the skin of other larvae. When the tadpoles went through metamorphosis, he gave back to the adult frogs their own pituitaries and found that the animals rejected the autografts. Partial hypophysectomized animals did not reject the grafts, arguing that the rejection was not caused by the acquisition of new antigens, through either abnormal differentiation or carryover of the temporary host's tissues. Thus, even for self-antigens, tolerance appeared to be an acquired state requiring the presence of the antigen to induce it.

The adaptive nature of tolerance is a fundamental property of the vertebrate immune system. Given the task of the system, which is to recognize and respond to unexpected molecules using the random structural diversity generated from rearranging T- and B-cell antigen-receptor genes, there is no way to genetically program it to know what molecules will lead to self-destructive responses. Instead, a series of steps must be undertaken somatically during which the environment is sampled and the system fine-tuned to avoid its own destruction. The nature of these steps in both the mature and developing immune system will be the principal focus of this chapter.

NEGATIVE SELECTION DURING B-CELL DEVELOPMENT

Receptor Editing and Clonal Deletion

Tolerance that occurs in the primary organs in which lymphocytes develop (bone marrow and thymus) is called *central tolerance* and the process for B cells is referred to

as *negative selection*. The first direct demonstration of negative selection at the B-cell level was made by Nemazee and Bürki (14). They constructed a transgenic mouse expressing an IgM B-cell receptor (BCR) reactive with major histocompatibility complex (MHC^k) class I molecules. On a neutral MHC^d background, 25% to 50% of splenic B cells (B220$^+$, IgM$^+$) expressed this receptor and IgM antibodies with this specificity were found at significant levels in the serum. When crossed to an MHC^k mouse, however, both the splenic B cells and the antibody did not emerge. The site of tolerance induction appeared to be the bone marrow because IgM and transgene receptor levels on the cells there were low to undetectable, but B220^{low} expression (indicative of Pro- and Pre-B cell development) was normal (see Chapter 7 for a review of B cell development). This suggested that the tolerance process involved the down-modulation (cross-linking, capping, and internalization) of the BCR following antigen encounter immediately after the receptor was expressed at the cell surface of the immature B cell. This idea was consistent with much earlier studies, which showed that treatment of bone marrow or fetal liver B cells with high concentrations of anti-IgM antibody for 48 hours caused the permanent disappearance of immunoglobulin from the surface of the B cell (15,*16*).

There is now uniform agreement that sufficient engagement of the BCR on immature B cells can lead to a state of maturational arrest (17,18,*19*). BCR transgenic bone marrow cells placed in culture with membrane bound antigen or anti-kappa antibody down-regulate their receptors. If the cells come from double transgenic animals expressing both the BCR and the relevant antigen, the arrested cells persist in culture in the presence of antigen for up to 3 days, but do not make an antibody response (17). Interestingly, the cells can come out of this unresponsive state if the antigen is removed; the cells then differentiate into more mature B cells (B220^{high}, IgM^{high} IgD^{low}) and can proliferate and secrete antibody in response to lipopolysaccharide (LPS). Thus, the maturational arrest is a reversible process. More recent studies suggest that if one purifies the immature B cells away from other cell types in the bone marrow, then treatment with anti-BCR leads rapidly to apoptosis *(20)*. The death can be prevented by adding back a special bone marrow cell (Thy1^{low}, DX5$^+$), which in bone sections was seen to be interacting with immature B cells in the marrow, presumably facilitating maturational arrest over BCR-induced apoptosis *(21)*.

What is the function of the maturational arrest? Early experiments using BCR transgenics uncovered evidence that the B cells could undergo a qualitative change in their IgM receptors during this period, a process termed *receptor editing* (18,*22*). BCR transgenic bone marrow cells arrested at the immature B-cell stage increased the level of their recombinant activating gene (RAG) enzymes and underwent further light chain gene rearrangements when stimulated with an anti-kappa chain antibody *(19)*. Sec-

ondary rearrangements at the kappa locus can occur by deletion or inversion of the intervening DNA (see Chapter 6). New kappa light chains that emerge (referred to as "editors") allow escape from negative selection (23). Some cells switch to the use of the lambda chain locus when deletion of both kappa constant region genes occurs following recombination to a conserved downstream element referred to as the recombination sequence (see Chapter 6). Immature B cells from normal mice also showed an increased percentage of lambda-bearing cells (without undergoing cell division) following stimulation with an anti-kappa antibody *(19)*. Similar results were observed in hybridomas derived from BCR transgenic mice specific for dsDNA *(24)*. The editing process requires the activity of the *RAG* genes as it is not observed in mice in which at least one of these genes have been disrupted. Thus, the immature B cell can modify its receptor by light chain exchange in order to escape silencing when it encounters self-antigens in the bone marrow.

What happens to the B cell if the light chain replacement fails to shift the cell's specificity sufficiently away from autoreactivity? There is a mechanism for heavy chain editing involving V$_H$ gene and/or D element replacement by recombination with cryptic heptamer sequences embedded in the 3′ end of many (70%) V$_H$ genes *(24,25)*. However, under inescapable conditions, such as stimulating immature B cells with anti-Cμ, the maturational arrest is eventually followed by cell death (15,*16*). Early *in vivo* experiments, in which anti-μ antibodies were given *in utero* to chickens or mice, led to the elimination of IgG antibody production by what appeared to be an apoptotic mechanism (26). In the BCR transgenic mice, exposure to the membrane-bound antigens during development also resulted in a depleted peripheral B-cell pool (17,18). Thus, the bone marrow compartment has two mechanisms for dealing with autoreactive cells: one is a receptor selection process that allows cell survival following encounter with self-antigens at an immature stage of development by exchange of light chains and/or V$_H$ replacement; the second is a clonal deletion process by apoptosis, which ensues if the receptor is repeatedly occupied over a sufficient period of time without relief by receptor editing. Note that the latter is not really a simple direct clonal deletion process following receptor stimulation as originally envisioned by Burnet (11). It is instead a programmed bailout mechanism when all else fails, although it can be delayed experimentally by transgenic overexpression of the *Bcl-2* survival gene (17). Normal B-cell development, in contrast, involves a low level of basal (ligand independent) signaling from the assembled, unoccupied BCR. This positively selects the B cell for further maturation *(27)*.

Which of these two processes is the dominant mechanism for B-cell–negative selection? Early on it was thought that receptor editing was a rare rescue event, because membrane-antigen and BCR double-transgenic

mice showed mostly a loss of BCR$^+$ cells in the peripheral spleen and lymph nodes. However, this outcome is mainly a consequence of integration of the transgene outside the immunoglobulin locus. In this case, secondary light chain rearrangements and V_H replacement cannot alter the original transgene. This allows for the continued expression of an autoreactive receptor, unless a breakdown in allelic exclusion leads to the production of a second heavy and/or light chain, which decreases the density of the autoreactive receptor on the cell membrane or physically interferes with the transgene protein expression (e.g., by preferential chain pairing). In contrast, when the transgenic technology advanced to the point of allowing the construction of knockin mice, wherein the rearranged BCR transgene could be inserted directly into the immunoglobulin locus (referred to as *site-directed transgenics*), then the results were completely the opposite (*24,28,29,*30). With this new model, receptor editing could now rescue 85% to 98% of the B cells in as little as a 2- to 6-hour period (*29,*31). Multiple rearrangements were often required, and if this was impaired, for example, by eliminating downstream J-kappa segments, then a component of deletion was also observed (23,31). The same conclusion was reached for normal B cells, in a transgenic mouse that produced a membrane-bound, single-chain antibody reactive against the kappa constant region *(28)*. Here, the numbers of B220$^+$ cells in the spleen were reduced by 40% and the 60% of edited cells expressed exclusively lambda light chains (at three-to fourfold increased number compared with controls). In other studies, the total extent of receptor editing in the mouse B-cell repertoire was estimated to be around 25% of the repertoire *(32)*. This is in line with estimates of more than 50% for the prevalence of self-reactive antibodies in the germ line repertoire *(33)*. Thus, the current consensus in the field is that receptor editing is the major central tolerance mechanism during B-cell development and that clonal deletion is only undertaken as a last resort after several days of trying to replace the receptor.

In the process of receptor editing, the up-regulation of the *RAG* genes that follows BCR engagement also allows for a primary rearrangement to occur at the light chain locus on the other chromosome. This process is known as *allelic inclusion* and produces B cells with two receptors, one of which is still autoreactive. It had been predicted on theoretical grounds that such cells would be deleted by signaling through the autoreactive receptor *(34)*. However, in one well-studied BCR transgenic case, it was discovered that a large fraction of the escape variants of this type were not deleted, but rather survived by chronically down-regulating the autoreactive receptor and degrading it in lysosomes *(35)*. These receptors could be re-expressed on the cell surface if the cell was removed from the antigen in its extracellular environment. The cells also could be signaled *in vitro* through their other receptor using anti-BCR antibodies, and in the mouse, after many months, auto-antibodies secreted by these cells could be detected in the serum. Estimates on the percentage of such double cells in the normal mouse B cell population are as high as 10% *(32,36,37)*; but how many of them can go on to produce autoantibodies is currently unknown.

Signaling Aspects of B-Cell Negative Selection

Insights into what characteristics of self-reactive B cells and their autoantigens determine whether they will be negatively selected have been inferred from the early studies on B-cell tolerance induction to foreign antigens (38). With an *in vivo* limiting dilution splenic focus assay, it was demonstrated that if immunoglobulin-negative bone marrow cells were exposed for 24 hours to a hapten in the absence of T-cell help, they became unresponsive to subsequent stimulation by the hapten in the presence of T-cell help. In order to induce tolerance in this system, the antigen had to be multivalent. DNP$_4$-ovalbumin was tolerogenic for DNP-specific B cells, but DNP$_1$-papain was not. This observation suggests that signaling through the immunoglobulin receptor requires cross-linking in order to induce tolerance. In the BCR transgenic experiments of Nemazee and colleagues used to directly study B-cell central tolerance, the MHC^k class I antigen made an excellent tolerogen, presumably because it is a transmembrane glycoprotein and therefore displayed on cell surfaces in the bone marrow in a multimeric array *(39)*. In contrast, when the BCR transgenic mouse was crossed to a mouse strain expressing a soluble form of the MHCK^k molecule, no deletion of the B cells was observed (40). A similar difference in outcome was noted in the hen egg lysozyme (HEL) transgenic model depending on whether the antigen was expressed as a membrane bound (maturational arrest and deletion) or a soluble form (nondeletional, peripheral tolerance) (17). The latter can become deletional, however, if the BCR transgenic is made deficient in signaling molecules, such as CD22, Lyn, or SHP-1, that normally negatively regulate B-cell activation *(41–43)*. In these cases the enhanced strength of signaling converts a low-avidity BCR occupancy event into a high-avidity outcome. In a third BCR transgenic, B cells specific for a RBC surface antigen were eliminated from the conventional (B-2) splenic follicular pool (although the receptor was expressed in B-1 cells in the peritoneal cavity) *(44)*. Interestingly, when the cytoplasmic domain of the membrane bound HEL molecule was altered to retain it in the endoplasmic reticulum, it no longer induced deletion of HEL-specific B cells *(45)*. Instead, the cells differentiated into B-1 cells capable of secreting IgM autoantibody.

Also consistent with the idea that surface-displayed antigens are good tolerogens while intracellular molecules are not, is the general finding that many of the natural autoreactive antibodies are specific for intracellular

molecules (46,47,48); only a few have been identified that react with cell surface proteins (49,50), and these also arise (as in the anti-RBC and anti-HEL transgenics) from the B-1 subset of B cells, which may have different signaling properties. Finally, immature B cells with receptors specific for ds-DNA are heavily negatively selected against in both normal mice (51–53) and BCR transgenics (54–56). The structural reason for this is not fully clear, but may result from the stability of oligonucleosomes released from dying cells (57), which could allow for multimeric display of the antigen.

The affinity of the BCR for antigen is another important variable. In the anti-MHC[k] BCR transgenics, the receptor cross-reacts with several different MHC alleles, allowing an analysis of the tolerance process in the same model under different affinity conditions. The MHC K[bm3] allele has a binding constant of only 2×10^4 M^{-1} and yet the phenotype of the negative selection was the same as that for other allelic MHC proteins with 10- or 100-fold higher affinity; this was observed with both conventional and site-directed BCR transgenics (31,39). This suggests a high degree of sensitivity for the immature BCR. Indeed, when compared with mature B cells in their ability to mobilize intracellular calcium using a K[k] mimetic peptide, the immature B cells were found to respond at lower antigen concentrations, even though they had less surface IgM (58). This increased sensitivity was associated with enhanced tyrosine phosphorylation of Igα and Lyn and increased levels of the signaling intermediates SLP-65, Btk, and PLCγ2 (see Chapter 8). The activity of PLCγ2 was also prolonged, resulting in enhanced calcium mobilization, even though the size of the intracellular store of calcium was smaller. One suggested mechanism for this increased sensitivity has been a diminished content of free cholesterol in the plasma membrane resulting in predominant BCR signaling from outside of lipid rafts (59,60).

In addition to an increase in sensitivity, the immature B cell also has a different program of response to BCR stimulation than the mature B cell. Although it will up-regulate transcription of the *RAG* genes at low receptor occupancy, the immature B cell fails to up-regulate CD69, CD86 (B7-2), or MHC class II molecules, even when stimulated with high concentrations of antigen (61). In contrast, at high antigen concentrations, mature naive B cells up-regulate CD69, CD86, and MHC class II molecules, but not the *RAG* genes. Mature cells also enter the cell cycle and proliferate, whereas immature cells make cyclin D2, activate CDK4, and enter the G1 phase of the cell cycle, but do not go on to make cyclin E, activate CDK2, or enter S phase (62). Instead, the cells undergo growth arrest or apoptosis, depending on their immediate environment (as discussed earlier). This difference from mature B cells may be mediated by the level of c-myc expression, which is only transiently up-regulated in immature B cells, but shows sustained elevation in mature B cells

(59). This is again related to the levels of cholesterol in the plasma membrane and can be reversed in immature B cells by the introduction of exogenous cholesterol into their membranes. Finally, mobilization to the nucleus of the transcription factor NFκB is thought to play a key role in the signaling of mature B cells to proliferate (63) as well as in the reactivation of receptor editing in immature B cells (64). A contribution from the costimulatory receptor BAFF-R3 augments NFκB p52 levels in mature cells and facilitates cell survival by up-regulating the antiapoptotic kinase Pim2 (65,66). Differences in the activation of particular NFκB family members may contribute to unique phenotypic outcomes.

The increased signaling sensitivity of immature B cells, which can range more than 10,000-fold, is thought to provide a margin of safety in assuring that central tolerance eliminates as many potentially autoreactive B-cell clones as possible from the mature peripheral repertoire. In addition, by raising the threshold for activation during maturation of the remaining B cells, the chance of their being activated in the periphery by self-antigens should remain quite low. It is important to keep in mind, however, that even with this purging process, there will be B cells with receptors that can recognize self-antigens with low affinity (67), which may become activated to secrete antibody if provided with adequate T-cell help and a sufficient quantity of antigen (68,69–71). These types of observations in the past led investigators to question whether central tolerance occurred at all in the B-cell repertoire. But careful studies of affinity measurements in such systems have generally shown that clones with high-affinity receptors for the antigen have been purged, leaving mostly clones that produce only low-affinity antibodies (72). Nonetheless, such clones, once activated, may undergo somatic hypermutation and potentially generate autoantibodies of higher affinity (73).

NEGATIVE SELECTION DURING T-CELL DEVELOPMENT

Clonal Deletion

The first demonstration of negative selection as a central tolerance mechanism operating during T-cell development was made by Kappler et al. (74). They used a monoclonal antibody against the variable region of a T-cell receptor (TCR) beta chain (anti-Vβ17a) to follow the fate of T cells expressing this receptor. In mice that did not express an I-E molecule encoded by MHC class II genes, Vβ17a-bearing cells in the T-cell population were present at a frequency of 10%. In contrast, mice expressing I-E molecules did not possess Vβ17a$^+$ cells in the spleen. When I-E$^+$ and I-E$^-$ strains were crossed, the F$_1$ offspring contained no Vβ17a$^+$ cells in the periphery. A dominant elimination process was then shown to take place in the thymus.

Cells expressing Vβ17a were found in only slightly reduced numbers in the immature CD4$^+$8$^+$ TCR-low population, but these cells were greatly depleted in the more mature, single positive (CD4$^+$8$^-$ and CD4$^-$8$^+$) thymocyte subset. The possibility that the cells had simply down-regulated their receptors was subsequently ruled out by showing that Vβ17a mRNA was also absent in mature T-cell populations (P. Marrack and J. Kappler, unpublished data). Similar observations were made by others for Vβ6$^+$ T cells *(75)*. In this model the deletion process was exactly pinpointed to the late double-positive stage when TCR expression becomes elevated and CD4 and CD8 coreceptors have begun to down-modulate *(76,77)*. Physical evidence that the process is in fact clonal deletion by an apoptotic mechanism was subsequently published *(78,79)*.

The antigens involved in these Vβ-specific deletion processes are endogenous superantigens encoded by open reading frames (ORF) in the 3$'$ Long Terminal Repeats of mouse mammary tumor viruses (Mtvs) *(80)*. These proteins are capable of activating the T cell by interacting with both the Vβ and the I-E molecule at the same time. However, this activation mechanism is slightly different from that of peptide/MHC stimulation as it bypasses the need for the Src-family kinase, Lck *(81)*. Hence, it was important that Kisielow et al. (82) were able to extend the observations on clonal deletion to a more conventional antigen system, the male-specific antigen H-Y. They took advantage of the first alpha/beta T-cell receptor (TCR$\alpha\beta^+$) transgenic mouse—developed by Blüthmann et al. *(83)*—to follow the fate of a large cohort of T cells expressing the same anti-H-Y receptor, either in females, which do not express the antigen (controls), or in males, that do. The male mice had a thymus of greatly reduced size (less than 10% of normal) and a tremendous reduction in the percentage of double-positive thymocytes. Similar observations were made by others with TCR transgenic mice specific for an alloantigen (L^d) *(84)*. These mice deleted T cells bearing the receptor at the early double-positive (DP) stage when they were crossed to mice expressing the alloantigen. Thus, the basic model postulated by Burnet appears to be correct for the standard CD4$^+$ and CD8$^+$ TCR$\alpha\beta^+$ cells, that is, immature T cells encountering their antigen during development are clonally deleted instead of activated to make an immune response (11). This process is referred to as *negative selection*. An exception to this process involving the selection of regulatory T cells will be discussed later.

Stages of T-Cell Development at which Negative Selection Occurs

The experiments involving tolerance to the H-Y and L^d antigens suggested that clonal deletion takes place at the early DP stage, whereas the experiments involving tolerance to superantigens suggested that clonal deletion takes place at the transition from the DP to the SP stage. This dichotomy has been observed in a single transgenic mouse that carried a receptor specific for both a viral antigen and an Mtv-7 encoded superantigen (85). The T cells were deleted at the early DP stage if the mice were carriers of the virus, but deleted closer to the SP stage when the mice did not harbor virus, and instead were mated to animals expressing the Mtv-7 superantigen. Thus, it seemed likely that the nature of the recognition event—where and how the antigen and the receptor were expressed at the time of antigen presentation—would determine the stage at which the cells were deleted.

In the case of superantigens, the major cell type found to express these proteins is the B cell *(86)*. In the adult mouse thymus, these cells are mainly CD5$^+$ B1 cells located in the medulla, near the corticomedullary junction *(87,88)*. Interestingly, these B1 cells are not present in neonatal thymus, and Vβ6$^+$ T cells are not deleted by the Mtv-7 superantigen in the neonate *(88,89)*. In the case of the Mtv-6 superantigen, however, expression takes place in thymic dendritic cells (90) and deletion is completed earlier *(91)*. Vβ3$^+$ T cells are deleted in fetal thymic organ cultures (FTOCs), but not in reaggregated cultures that lack the dendritic cells. When compared with Mtv-1, which encodes an identical protein expressed in B cells, Mtv-6 mRNA expression is eightfold higher. This results in 50% deletion of DP thymocytes as well as all of the SP thymocytes, compared with one-half that effect in both compartments for Mtv-1. Thus, the amount and location of superantigen expression can determine the extent of clonal deletion that is observed.

In the case of the TCR transgenics, it now seems clear that the receptors are prematurely expressed at high levels at the double-negative (DN) stage of T-cell development when the TCR beta genes normally become active (DN2–DN3) *(92)*. If the antigen is sufficiently present in the environment at this time, then the TCR signaling induces a maturational arrest at the CD4$^-$,CD8$^-$ (DN) or CD4$^-$,CD8^{low} pre–T-cell stage, depending on the strength of signal and the exact timing of receptor expression *(92,93,94)*. In the case of the H-Y transgenic mouse, this must be at the CD4$^-$,CD8^{low} stage because CD8 interaction with the MHC class I molecule is required for deletion *(95)*. Some of the cells, however, do manage to survive, either by differentiating toward other lineages ($\gamma\delta$ T cells or CD8$\alpha\alpha$-intraepithelial lymphocytes) or by rearranging their endogenous alpha chain genes, which in some instances can interfere with signaling through the transgenic receptor by preferential chain pairing or by decreasing the cell surface density of the transgenic receptor *(96,97)*. As a consequence, the periphery is usually populated with these surviving, dual receptor T cells and T cells of other lineages. Under normal circumstances, of course, the T cells would not express their full surface $\alpha\beta$ receptor until the DP stage, after the alpha chain gene rearrangement has been completed. When the H-Y-specific TCR was engineered to separately express the alpha chain gene under the control of

a modified CD4 promotor, it emerged correctly at the DP stage and deletion in the male mice occurred later (98). In this case there was only a 50% decrease in the number of DP cells, while most of the SP cells were deleted.

But why did all the DP thymocytes not delete as soon as they expressed the H-Y–specific receptor? In contrast to the superantigens, whose expression is mostly restricted to the medulla, the H-Y antigens are ubiquitously expressed and in the thymic cortex could clearly produce substantial thymocyte deletion in the original TCR transgenic at the DN to DP transition. Indeed, a variety of experiments have demonstrated that if the antigen is introduced into the cortical environment at high concentrations, then all the DP thymocytes quickly die by apoptosis. This was first demonstrated by adding soluble superantigens or anti-CD3 antibody to FTOCs and observing apoptosis of DP cells in 18 hours (*78,99*). This was subsequently confirmed in TCR transgenic mice by administration of soluble peptide *(100–104)*. The *in vitro* culture experiments were critical because *in vivo* administration of peptides can lead to peripheral activation of mature T cells and release of cytokines such as tumor necrosis factor (TNF), which kill DP thymocytes independent of negative selection *(105,106)*. Yet even some FTOC gave outcomes different from *in vivo* results. Isolated cortical epithelial cells from mice expressing the circulating complement protein C5 were able to present this antigen in reaggregation FTOC as efficiently as isolated thymic dendritic cells for the deletion of TCR transgenic DP thymocytes, suggesting an adequate amount of antigen loading and effectiveness (107). However, *in vivo*, the deletion of the TCR+ cells did not occur until the DP to SP transition *(97)*. Thus, physiological levels of the processed C5 antigen on cortical epithelial cells were not adequate to induce clonal deletion of thymocytes *in vivo* at an early DP stage. However, this particular transgenic TCR may not delete early because it is expressed under the control of an hCD2 locus control region, which yields lower than normal TCR expression levels.

Recently it has been possible to examine clonal deletion in the thymus of normal B6 mice by two different methods. The first used a monoclonal antibody against a CD3ε conformational determinant that becomes exposed when the TCR receives a strong antigenic signal (108). By immunohistochemistry, this marker was greatly elevated in TCR transgenic mice undergoing negative selection and was associated with a marker of apoptosis occurring in the same cells. When this technique was applied to tissue sections of normal B6 thymus, only a small number of cells were positive, and these were mostly DP thymocytes located in the cortex and corticomedullary junction. The second approach looked at thymocytes that have up-regulated expression of the orphan steroid nuclear receptor Nur77 (109). This molecule is expressed within 1 hour after TCR stimulation, leading to cell death, and it is elevated in a small subset of thymocytes in both alloantigen-induced

and superantigen-induced clonal deletion. In B6 mice, the 0.5% Nur77+ cells were found in both the DP and CD4 SP subpopulations. All these cells expressed high levels of CD69 and the DP cells were TCR[int] and low for both CD4 and CD8, suggesting that they had just been positively selected. The CD4 SP cells were TCR[high] and CD24(HSA)[high], implying that they were semimature T cells normally found in the medulla (see later discussion). Thus, with this technique, normal negative selection appears to mainly occur at the late DP to SP transition.

Receptor Editing?

Why are the immature DP thymocytes not usually deleted *in vivo*? One possibility is that, similar to immature B cells (see previous discussion), the T cells undergo a receptor editing process instead. There are two intriguing experiments in the literature that suggest that this might be possible. A standard TCR transgenic mouse expressing its receptor under the control of an IgH enhancer assembled its receptor during the DN stage and deleted most of the TCR+ cells as they matured to the DP stage, when the mice were crossed to another transgenic mouse expressing the antigen *(110)*. In contrast, if the rearranged Vα-Jα gene was knocked into the TCRα locus and then crossed to a separate TCRβ chain-only transgenic mouse to reconstitute the original receptor, the DP thymocytes in this hybrid mouse were *not* deleted when crossed to the antigen transgenic. Instead, most of the knocked in TCRα chains disappeared and seemed to be replaced by other alpha chains. That this might be a receptor editing process was suggested by experiments with another TCR transgenic mouse, which, when its DP thymocytes were exposed to antigen in the cortex, up-regulated expression of the *RAG* genes, enhanced gene rearrangement at the TCRα locus, and increased expression of receptors bearing endogenous TCRα chains *(111)*. In neither set of experiments, however, was it proven that the loss of transgene expression was the direct result of receptor driven rearrangement of the knock-in allele.

In contrast to this work, a second major attempt to examine TCR editing by knocking in a rearranged anti–H-Y Vα-Jα gene and expressing it on both chromosomes failed to produce any evidence for receptor editing *(112)*. All that was observed was clonal deletion. Although these mice might not have shown editing because the transgenic receptor was expressed too early (at the DN stage), the conclusion of "no editing" was subsequently substantiated by studies with a β chain-only transgenic mouse in which pairing with the normal Vα repertoire generated a variety of anti-H-Y-specific T cells at the DP stage (113). Examination of the effect of the presence of the male antigen on a particular subset of anti–H-Y-specific receptors demonstrated no molecular evidence for receptor editing in the form of excess T-cell excision circles bearing the rearranged Vα-Jα gene. In fact, what was observed was

a decrease in the ratio of male-reactive T-cell excision circles, relative to out-of-frame sequences, in males compared with females. This result is more consistent with clonal deletion. Thus, in contrast to B cells, T cells mainly use clonal deletion as their mechanism for negative selection. The purpose of early receptor revision in T cells appears instead to be reserved for optimizing positive selection, in which the task is to generate as many receptors as possible that are capable of recognizing self MHC molecules *(114–116)*.

Antigen-presenting Cells for Negative Selection

If DP thymocytes do not undergo receptor editing in response to antigens presented by thymic epithelial cells, why do they not undergo clonal deletion more frequently? The dominant idea in the literature throughout the years has been that cortical epithelial cells are not very effective at presenting antigens for negative selection, either because they do not access and process the antigen adequately or because they are incapable of providing appropriate costimulatory signals. The earliest experiments giving rise to this concept involved various types of thymic and bone marrow MHC chimeras *(117)*. When (MHC-A × MHC-B)F_1 bone marrow cells were transferred into lethally irradiated strain B recipients, tolerance resulted for both strain A and strain B peptide MHC complexes as measured in a mixed leukocyte response (MLR) or a cytotoxic T lymphocyte (CTL) response (118). In superantigen models, this process involved deletion of thymocytes at the DP-to-SP transition stage, suggesting a role for hematopoietic cells, such as thymic dendritic and B cells, which repopulate an irradiated thymus quickly from bone marrow precursors *(119,120)*. In a more direct experiment (121), it was shown that allogeneic dendritic cells from the spleen introduced into a FTOC could induce tolerance to the alloantigens as measured in a CTL assay. Thus, a professional antigen-presenting cell (APC) capable of activating T cells in the periphery, tolerized thymocytes, again consistent with Burnet's original clonal deletion model (11). Other experiments with thymocyte suspensions from TCR transgenic mice showed directly that splenic APCs could induce deletion of $CD4^+CD8^+$ T cells *in vitro (122)*.

In contrast, the role of thymic stromal (nonhematopoietic) cells in negative selection has always been more controversial. Initial experiments with parental MHC-B bone marrow into (A × B)F_1 irradiated hosts revealed tolerance to strain B MHC molecules, but alloreactivity against strain A APC *(123)*. Similarly, deoxyguanosine-treated fetal thymuses (depleted of hematopoietic cells) when grafted into allogeneic nude mice, produced T cells that reacted in MLR *(124)* and CTL response *(125)* against the alloantigens of the thymus donor (126). The initial conclusion from these types of experiments was that thymic stromal

cells could not induce negative selection at all. A careful examination of the data, however, reveals that some negative effects do take place. For example, alloreactivity in the MLRs was often quantitatively diminished and the nude mice did not reject their thymus grafts *(127)*. How then does one account for the failure to completely induce tolerance by thymic stromal cell antigen presentation? One possibility is that the tolerance induced is tissue-specific (128). Although alloantigens have the virtue of directly presenting their peptides without cell transfer, they can only tolerize for the subset of bound peptides that are expressed in the stromal cells. Hence, MLR and CTL assays, in which splenic dendritic cells do the presenting, will still be capable of stimulating T cells specific for hematopoietic cell-derived peptides not expressed by the thymic stromal cells. When a second whole thymus graft is given, only the hematopoietic cells, not the stromal cells, are rejected (128). For example, when the MHC class II gene I-A$_\beta^b$ was targeted using a keratin-14 (K14) promoter for transgenic expression in the thymic cortical epithelium of MHC class II-deficient (I-A$_\beta^{b-/-}$) mice, the $CD4^+$ T cells from these animals were strongly responsive to "self" splenic dendritic cells in an MLR *(129)*. However, when given syngeneic thymus grafts, they accepted them because they were tolerant to peptide/MHC complexes expressed on the epithelial cells *(130)*. The MLR was due to dendritic cell peptide/MHC complexes that were not expressed on the thymic epithelium. The fate of other tissue grafts in this type of experiment depends on how much peptide overlap there is between the thymus and the grafts (128). Similar observations were made for $CD8^+$ T cells tolerized to MHC class I molecules that were targeted for expression in thymic cortical epithelial cells of a β2-microglobulin (β2m) knockout mouse with the K14 promoter driving expression of β2m *(131)*.

The second possibility to explain the presence of alloreactivity in parent into F_1 chimeras is that only T cells with high-avidity receptors are deleted, leaving low-avidity clones to respond to strong dendritic cell presentation *(127)*. This explanation has the virtue of being able to explain the absence of clonal deletion in chimera experiments involving viral superantigens. For the most part, these molecules stimulate regardless of what peptides are bound to the MHC class II molecule. Although in some cases the failure to delete *in vivo* may be the result of the inaccessibility of the superantigens to the MHC molecules on thymic cortical epithelium, an *in vitro* experiment with deoxyguanosine-treated FTOC reconstituted with fresh T cells plus or minus dendritic cells, showed that an exogenous superantigen could only rapidly induce clonal deletion in the presence of dendritic cells, even though the superantigen was shown to bind to the MHC class II molecules on the epithelial cells *(132)*. Cultures lacking dendritic cells, however, did demonstrate deletion on prolonged exposure to superantigen, suggesting that the

stromal cells are just inefficient at antigen presentation. For CD8+ T cells, targeting of an MHC class I molecule to the thymic medullary epithelium with either a keratin IV promoter or an aberrantly expressed Eμ promoter resulted in tolerance that was "spilt"; that is, the animals accepted skin grafts but manifested a CTL response *in vitro* in the presence of interleukin 2 (IL-2) *(133,134)*. Crossing this mouse to a CD8+ TCR transgenic mouse specific for the MHC class I molecule deleted only T cells expressing high densities of the TCR, and not those with lower densities (135). The latter exist because of endogenous TCRα chain expression and are probably of lower avidity and thus less readily activated.

In contrast to experiments involving alloantigens, negative selection experiments using peptides from non-MHC antigens were more straightforward to interpret. Chimera experiments with TCR transgenic animals revealed strong evidence for thymic stromal cell-mediated deletion. For example, transfer of TCR-transgenic bone marrow cells from a mouse expressing a nondeleting MHC allele, into a virus-infected irradiated host expressing on its stromal cells the MHC molecule capable of viral peptide-specific presentation and deletion, led to massive elimination of the cells in the thymus at the early DP stage (either because of premature TCR expression or high levels of antigen expression) (94). In experiments with the H-Y antigen, the early deletion was less dramatic if the bone marrow-derived cells expressed an allo-MHC molecule that could not present the peptide (136). In this case, thymocyte yields in the male were 25% of what was observed in the female, showing that partial deletion was occurring from stromal cell antigen presentation. However, the surviving DP cells all had high TCR expression and many made it to the CD8+ SP stage, suggesting that a significant fraction were not being deleted by the cortical epithelial cells. Similar results were observed in experiments using deoxyguanosine-treated, male thymic epithelial cell grafts into thymectomized females (136). In still other experiments, clonal deletion of the DP thymocytes was observed when the H-Y peptide was expressed as a transgene under the control of the K14 promoter, which limited expression to cortical thymic epithelial cells (93).

A particularly interesting result was obtained when a human papilloma virus protein (E7) was targeted to the cortical thymic epithelium with the K14 promoter *(137)*. This expression resulted in a reduction, following antigen priming, of the antiviral CTL response, but an enhanced T-cell proliferative response and normal B-cell help. This "split" result suggests that presentation by cortical epithelial cells of a particular peptide/MHC class I molecule can be more effective for tolerance induction than that of a particular peptide/MHC class II molecule derived from the same antigen. In another set of experiments with CD4+ T cells, a transgenic TCR specific for pigeon cytochrome c deleted only SP T cells when crossed to a transgenic mouse

expressing limited amounts of that antigen, but deleted at the DP stage when crossed to a second transgenic mouse that expressed three-to tenfold more antigen (138). Both antigen-transgenic mice expressed cytochrome mRNA in the cortex and medulla, but only the high antigen expressor induced observable apoptosis of thymocytes in the cortex. Interestingly, a second cytochrome c-specific TCR transgenic mouse expressing a receptor of lower affinity for the antigen, deleted only at the SP stage, even when crossed to the high antigen-expressing mouse. In contrast, cells with this same receptor were completely deleted at the DP stage when crossed to a strain very highly expressing an inducible form of the peptide embedded in an invariant chain transgene (108,*139*). Thus, the level of antigen expression and the affinity of the receptor for antigen determined whether deletion took place in the cortex at the DP stage of development.

What then are the differences that sometimes allow the same T cell to be deleted by thymic dendritic cells at the corticomedullary junction and not by epithelial cells in the cortex? One key factor on the T-cell side is that positive selection leads to a tenfold increase in TCR expression *(140,141)*. This allows TCR occupancy to be enhanced and could allow previously suboptimal signals to become adequate for negative selection. The second factor, on the APC side, is that thymic dendritic cells are in general more potent APCs. The ability of the two cell types to present antigens has been directly tested *in vitro*. Cortical epithelial cells were clearly inferior to thymic dendritic cells when asked to stimulate mature T cells to express CD69 or proliferate (107,*142*). Some of this inferiority may relate to a lack of expression of costimulatory molecules (such as B7), which have been shown in a number of different models to be required for clonal deletion in the thymus (*143*–*145*,146,*147*,148). Nonetheless, when tested in a direct assay for clonal deletion of thymocytes, cortical epithelial cells were found to be as potent as dendritic cells (107), perhaps because very few peptide/MHC complexes are required for clonal deletion *in vitro (149)*. *In vivo*, however, their weaker presentation capacity under nonsaturating conditions may normally hinder adequate stimulation of DP thymocytes for clonal deletion. Overall, the published results suggest that, although thymic epithelial cells are less efficient at antigen presentation, they can effectively induce DP T-cell clonal deletion in certain cases, depending on the affinity of the particular TCR, the density of the peptide/MHC complexes that are present, and the amount of costimulation available.

If one accepts that bone marrow-derived dendritic cells are the primary mediators of clonal deletion in the thymus, then it is possible to obtain a minimal estimate for the extent of clonal deletion that occurs during normal T-cell development by examining radiation chimeras in which the bone marrow is derived from MHC class II-deficient or MHC class I and II double-deficient mice. If the

irradiated host is normal for MHC expression, then positive selection will be unaffected. In contrast, negative selection by thymic dendritic cells would be completely eliminated. When this experiment was performed (150), the percentage of single-positive CD4$^+$ T cells in the chimeric thymus increased 1.7-fold over control chimeras, suggesting that about 40% of the positively selected cells normally undergo clonal deletion induced by bone marrow-derived cells. This result is consistent with studies on positive selection of CD4$^+$ T cells in the presence of a single peptide/MHC ligand wherein 65% of the repertoire sampled (by generating T-cell hybridomas) was autoreactive against the same MHC molecule plus other peptides (151). An experiment in which both approaches were combined, confirmed a steady-state 1.7-fold increase in CD4$^+$ T cells when bone marrow-derived dendritic cells expressed only a single peptide/MHC ligand, and conversely a deletion of two thirds of the repertoire positively selected on the single peptide/MHC ligand when the bone marrow-derived dendritic cells expressed a normal complement of multiple peptide complexes with the same MHC molecule *(152)*. Thus, at least 40% to 70% of selected thymocytes undergo negative selection.

Clonal Deletion in the Thymic Medulla

Evidence that clonal deletion can still occur even after thymocytes have reached the single-positive stage in the medulla is very compelling. For T cells reactive with endogenous superantigens, the tolerance process often begins only after birth. Mtv-7 reactive CD4$^+$CD8$^-$ Vβ6$^+$ thymocytes disappear during the first week of life, when B1 cells expressing the viral ORF arrive in the thymic medulla *(89,153)*. *In vitro* culture of these Vβ6$^+$ cells demonstrated that the disappearance was not just a migration out of the thymus, but an active death process that could be inhibited by low temperature, cycloheximide, or actinomycin D. *In vivo* experiments have suggested that it is the earliest CD24^{high} CD4$^+$8$^-$ cells that are being deleted (154). The mechanism includes costimulation, with both CD40L/CD40 and often CD28/B7 interactions being required for maximum effect (*145*,148). Involvement of other molecules such as ICAM, CD5, and CD43 has also been suggested (146,*147*). Thus, again, full activation leads to negative selection, indicating that even semimature thymocytes are tolerizable only.

These cells are also susceptible to glucocorticoid-induced cell death and are functionally immature like DP thymocytes *(155–157)*. Thus, this thymocyte subpopulation appears to be in transition from an immature to a mature T-cell stage. This is quite similar to the transitional stage in B-cell development, which occurs after the immature B cells migrate from the adult bone marrow to the spleen. In that stage, they are still highly susceptible to BCR-induced cell death (see later discussion). The thymic medulla can in some sense be regarded as a peripheral lymphoid organ, like the spleen, as it is readily accessible to circulating antigens and to recirculating activated lymphocytes such as the B1 cells and effector T cells *(88,158–160)*. Thus, in both lineages, these semimature cells are still preferentially susceptible to cell death following strong receptor stimulation. Other mechanisms of tolerance can also be induced at this stage and will be discussed in the sections on peripheral tolerance mechanisms. The importance of the medullary tolerance process has recently been shown in CCR7 and CCR7 L gene-targeted mice (161). Cortical cells in these mice leave the thymus after the DP-to-SP transition, instead of moving into the medulla under CCR7 chemokine direction. As a consequence, the mice are not fully tolerant, and develop autoimmune disease of the salivary and lacrimal glands. Presumably some of the T cells reactive against the autoantigens in these tissues are normally inactivated in the thymic medulla.

Signaling Aspects of T-Cell–Negative Selection

Burnet (11), Talmage *(162)*, and Lederberg *(163)* postulated early on that negative selection occurs by signaling through the antigen-specific receptor followed by cell death. Although histologic examination of the thymus does not reveal much evidence for ongoing cell death, kinetic labeling studies have demonstrated that about 95% of the cells generated in the thymus die there *(164)*. Experiments using a more sensitive TUNEL assay to detect DNA strand breaks showed that macrophages contain the debris of thymocytes that have died by apoptosis (79). In a TCR Vβ5 transgenic mouse expressing MHC class II I-E molecules and an endogenous Vβ5-reactive Mtv-9 ORF-superantigen, the medulla of the thymus was found to contain aggregates of apoptotic cells that were engulfed by MAC3$^+$ macrophages. This first visualization of apoptosis established that the final death process induced by superantigens was taking place in the thymic medulla. Others have since used this technique to visualize apoptosis in the cortex with TCR transgenic models (108,138).

Although a consensus now exists that thymocytes die by apoptosis during negative selection, the molecular pathways leading to this programmed cell death are not fully understood *(165)*. Negative selection is a process elicited by TCR stimulation and needs to be distinguished from the death by neglect that occurs at the DP stage, when thymocytes fail to have their TCR engaged for positive selection. A strong receptor occupancy signal leads to a conformational change in the cytoplasmic domain of the CD3ε chain of the TCR, which is thought to reflect the initiation of signal transduction (108). An exposed proline-rich sequence then binds the SH3 domain of the Nck adaptor protein, which recruits the serine/threonine kinase MINK to activate the negative selection pathway *(166)*.

MINK-deficient mice display enhanced production of TCR^{high} DP and CD4 SP thymocytes, including Vβ5$^+$ T cells that are normally deleted by the Mtv-9 superantigen. MINK deficiency also completely prevents clonal deletion of DP thymocytes in the H-Y male transgenic model. MINK expression is greatly up-regulated at the DP stage of thymocyte development and then declines back down at the SP stage, suggesting that it might be a critical component of the signaling machinery that makes thymocytes tolerizable only.

In addition to MINK activation, the more conventional tyrosine kinase activation pathway is also critical for negative selection. A point mutation in the SH2 domain of Zap-70, which interferes with TCRζ binding and Zap-70 phosphorylation following anti-CD3 cross-linking, leads to impaired positive and negative selection in TCR transgenic models. Interestingly, these mice develop an autoimmune arthritis (167). To achieve negative selection, Zap-70 must adequately phosphorylate LAT, which then recruits Grb2 and PLCγ1 to the plasma membrane. The adaptor protein Grb2 is involved in activation of Ras at the plasma membrane via the guanine nucleotide exchange factor mSOS. The lipase PLCγ1 generates diacylglycerol and inositoltris-phosphate/calcium release and facilitates N-Ras activation via activation and recruitment of RasGRP1 to the plasma membrane or Golgi (168,169). Ras activation at the plasma membrane is the critical event. This is followed by activation of the mitogen-activated protein (MAP) kinase family of enzymes (170). All experiments support a role for sustained Jun N-terminal kinase (JNK) activity (171), and the Grb2-SOS pathway of Ras activation plays a key role in this process (168). The p38 pathway is also activated via Zap-70 phosphorylation (172). Data for involvement of the extracellular signal-regulated kinase (ERK) pathway has been conflicting; however, an early peak of ERK activation at the plasma membrane is now thought to be required (169,173,174,175,176). Interestingly, MINK-deficient DP thymocytes show an impairment in receptor-induced JNK phosphorylation, but not in ERK phosphorylation (166), reinforcing the importance of JNK in clonal deletion. The involvement of the calcium/calcineurin pathway is also controversial, but most of the experiments using cyclosporin A, which inhibits calcineurin in this pathway, suggest that NF-AT activation does not play a key role in cases of strong deletion, although elevated intracellular calcium levels are critical (104,177–179). Finally, experiments expressing a superinhibitory form of the NF-κB inhibitory protein in the T-cell lineage had no effect on the negative selection of two different CD8-restricted TCR transgenics (180).

Further downstream there is good evidence for the induction of the proapoptotic transcription factor Nur77, an "orphan" steroid nuclear receptor (178,181). Transcription of this receptor is negatively controlled by HDAC7, a thymocyte-enriched histone deacetylase that normally resides in the nucleus (182). On TCR engagement, activation of protein kinase delta1 leads to serine phosphorylation of HDAC7 and redistribution of the protein into the cytoplasm (183,184). Within 1 hour this facilitates transcription and translation of Nur77. In the presence of adequate intracellular calcium, the protein activates transcription of downstream genes. Although the Nur77 knockout mouse shows normal clonal deletion (185), a DN form of Nur77 inhibits negative selection in the F5 and H-Y transgenic mouse models, suggesting redundancy in the pathway, possibly mediated by other family members such as Nurr1 (181,186). Nur77 is also induced in mature T cells following TCR and CD28 signaling. Under these circumstances, however, the protein is hyperphosphorylated by continued signaling through the PI3 K/Akt and Erk/MAP kinase pathways (187). This inactivates its DNA binding domain, allowing the protein to be removed from the nucleus to the cytoplasm, where presumably it is inactive (188). The difference in the response between immature thymocytes and mature T cells is not fully understood, but one observation is that immature thymocytes fail to strongly activate Akt kinase activity (187). Finally, gene knockout experiments have shown that the BH3-only Bcl-2 family member BimL is required for complete thymocyte negative selection (189). This protein is up-regulated in thymocytes following TCR ligation and combines with Bcl-X$_L$ to inhibit its survival function (190). Transcription of BimL requires both protein kinase C (PKC) activation and an increase in intracellular calcium (179). BimL up-regulation is attenuated in MINK-deficient cells (166) and its induction has been shown to require JNK activation in neurons (191). In the autoimmune prone NOD mouse both Nur77 and BimL up-regulation are impaired (192). BimL is a critical initiator of apoptosis in both DP and semimature CD4 SP thymocytes (193); however, the KO phenotype is fairly mild (only late B-cell–mediated immune complex glomerulonephritis) (194) and its effect in reversing deletion in the male H-Y transgenic model was only partial (189). This suggests that other BH3-only family members, such as PUMA, may also play a role in negative selection (195). Null mutations in death receptors and their ligands, such as TNF, TRAIL, and TNF-receptor, have no effect on thymic negative selection (196,197), but the role of the Fas/FasL pair still remains controversial (193,198,199). Some experiments suggest that Fas-mediated deletion of semimature CD4$^+$ SP thymocytes can occur at high levels of receptor cross-linking (199); other experiments do not (193).

Activation Versus Tolerance Thresholds

After T cells complete their maturation in the thymus, they are capable of responding to a foreign antigen when the concentration of peptide/MHC complexes derived from that antigen reach a certain critical density for activation. The relationship between this threshold and the concentration of intact antigen depends on processing

and presentation requirements, in addition to the intrinsic affinity of the TCR for the peptide/MHC complex. An important question is the relationship between this threshold for peripheral activation and the one involved in negative selection. If a self-antigen presented in the thymus induces clonal deletion in only a subset of high-affinity T cells, what happens if that antigen is subsequently expressed or processed in peripheral tissues in increased amounts during tissue destruction in an inflammatory response? Will T-cell clones with slightly lower affinity for the self-peptide MHC complexes now become activated? This usually is not the case; that is, trauma rarely leads to autoimmunity. The question is, why?

Early observations on endogenous viral superantigens suggested that T cells bearing certain Vβs could be deleted *in vivo* if the mice carried the proper Mtv, but that these same cells could not be stimulated *in vitro* to give a T cell proliferative response with APCs expressing that Mtv *(200)*. This suggested that tolerance induction in the thymus was achieved at a lower threshold than peripheral T-cell activation. The use of thymic organ cultures and TCR transgenic mice allowed a more quantitative analysis of this comparison. Deletion of TCR^{high} Vβ8$^+$ cells by the superantigen SEB in thymic organ culture occurred at concentrations that were 30- to 100-fold lower than those required to activate mature CD4$^+$ cells to proliferate *(201)*. For T-cell help generated in FTOC, exposure to the liver F protein during *in vitro* culture induced tolerance at a tenfold lower concentration than that required for proliferation of mature T cells (202). Finally, for CD8 responses, variant lymphocytic choriomeningitis viruses were compared for their ability to elicit antiviral responses in TCR transgenic mice and for their ability to induce neonatal tolerance in these mice *(203)*. One viral variant could not activate a CTL response or be cleared by the animal over a 1000-fold range of viral challenge doses; yet it was capable of inducing a partial deletion (40%) of transgenic TCR CD8$^+$ T cells in the thymus after neonatal tolerization. Thus, all the experiments suggest that the concentration threshold required for tolerance induction of immature T cells is lower than the threshold required by the mature T cell for activation.

A direct estimate of the sensitivity of immature thymocytes to clonal deletion in FTOC established from a TCR transgenic showed that as few as three to four peptide/MHC complexes were sufficient to delete 50% of the cells *(149)*. This, however, was with the strong, high-affinity agonist peptide. More revealing results have emerged in experiments performed with partial (weak) agonist peptides. In some cases these peptides allowed development of TCR transgenic thymocytes that were no longer responsive to the partial agonist after maturation, suggesting that the T cells had somehow altered their threshold for activation during the selection process *(204)*. Another study, using a CD69 expression assay for the readout of a response, revealed the requirement for a 10- to 30-fold

higher concentration of partial agonist to stimulate peripheral CD4$^+$ T cells compared with DP transgenic thymocytes (205). In contrast, there was little or no difference in the response of cells from the two tissues using a high-affinity peptide agonist. Thus, the adjustment in the responsiveness threshold has its critical impact only on low-avidity interacting ligands. Biochemical experiments showed that these functional observations were associated with decreases in proximal TCR signaling of the mature cells by the weak agonist peptides, affecting the level of tyrosine phosphorylation of TCRζ and ZAP 70. Similar observations have been made for CD8$^+$ T cells, where the weak agonist peptide could elicit both CD69 and a calcium response from DP thymocytes, but no detectable calcium response from mature CD8$^+$ T cells *(206)*. Recently, it was suggested that this difference might be due to increased sialylation of the T cell on maturation, which reduces the avidity of the CD8 coreceptor for MHC class I molecules *(207)*. The general conclusion from these studies is that T-cell maturation is accompanied by a raising of the activation threshold of the cell, which helps prevent the activation of low-affinity anti–self-clones in the periphery by small changes in the concentration of self-peptide/MHC complexes. A conceptually similar maturation phenomenon occurs for B cells, as discussed earlier.

In addition to this differentiation event for altering thymocyte activation thresholds, there also exists mechanisms for altering thresholds in response to environmental cues. This process has been referred to as *T-cell tuning (208)*. The best example involves the cell surface molecule CD5 *(209)*. The membrane levels of CD5 increase as thymocytes mature from DN to DP to SP cells. The final level achieved on a particular T cell depends on its TCR avidity and the strength of signal it transmits into the cell. Transgenic TCRs of higher avidity emerge as cells with higher levels of CD5, while TCRs with impaired signaling function, such as those with inactivated TCRζ ITAMS, emerge with lower levels of CD5 (210). T cells from CD5$^{-/-}$ mice display an enhanced responsiveness to antigen, suggesting that the molecule has a negative impact on TCR signaling. This involves ITAM and ITIM motifs in its cytoplasmic domain, but the exact biochemical mechanism of its negative signaling and the mechanism by which TCR strength of signal is converted to alterations in CD5 levels are not understood. Nonetheless, the consequences for thymocyte positive and negative selection are clear. In the case of a TCR with a high avidity for a positively selecting self-peptide/MHC ligand, gene targeting of CD5 can create an environment in which many of the cells are negatively selected *(209)*. In a TCR transgenic mouse with weak alloreactivity, introduction of the alloantigen leads to deletion of many of the cells, but those that exit the thymus have higher levels of CD5 (210). This "adjustment" occurs at the DP stage. In contrast, high constitutive expression of a CD5 transgene had the opposite effect. This
FIGURE 29.1 Selection of the T-cell repertoire as a consequence of T-cell receptor avidity for self-antigens expressed in the thymus. The 10% of cells whose receptors have an avidity greater than that indicated by the thin vertical bar on the left undergo positive selection. Of those, cells with receptors of the highest avidities (to the right of the thick vertical bar) undergo negative selection by clonal deletion.

prevented positive selection in both the female CD8$^+$ MHC class I-restricted H-Y TCR transgenic mouse and the CD4$^+$ MHC class II-restricted DO11.10 TCR transgenic mouse *(211)*. These results suggest that thymocytes use the regulation of CD5 expression to fine tune their TCR responsiveness during selection, and could explain some of the puzzling observations made with weak peptide agonists *(204)*. This adjustment would optimize the capture of cells by positive selection and minimize the loss of cells from negative selection at the DP stage.

Despite these mechanisms to fine tune the negative selection process to ensure the optimum deletion of self-reactive T cells, the cutoff inherently has an arbitrary aspect to its nature. If one thinks of the generated T-cell repertoire as having various degrees of affinity for a particular self-antigen (pedtide/MHC complex), then only a small fraction of TCRs will have a high enough avidity to be negatively selected (Figure 29.1). Another, presumably larger, cohort of cells of more modest affinity would be positively selected during thymic development. But where do you set the line that distinguishes between these two cohorts? Studies on a set of peptide analogs with differing avidities for a particular TCR showed that the distinction is quite sharply demarcated *(169)*. Most analogs are either only positively selected or negatively selected in FTOC, no matter what dose of antigen was added. However, a rare few could do both, positively selecting at low doses and negatively selecting at high doses. How the T-cell molecularly makes such a sharp distinction is not understood, but these rare peptides that can do both clearly present a potential challenge to self-tolerance if they are subsequently expressed at high levels in the periphery.

DOMINANT TOLERANCE: NATURAL T REGULATORY CELLS (NTREGs)

Perhaps because of this inherent leakiness of negative selection, the immune system seems to have evolved an additional mechanism to deal with the problem of autoreactivity at the T-cell level. This entails the selection of a subpopulation of CD4$^+$ T cells that expresses the transcription factor Foxp3 and low levels of the alpha chain of the IL-2R (CD25) *(212–214)*. Nishizuka and Sakakura (215) first showed that neonatal thymectomy of female mice at 3 days of age (but not at day 1 or 7) led to oophoritis and sterility. Subsequent studies showed that other organs could be affected such as the thyroid, stomach, prostate, and testis, and that the target tissue varied depending on the genetic background of the inbred mouse strain *(216,217)*. Disease could be prevented either by thymus grafting or by injection of normal day 7 or adult spleen cells. A transfer model into lymphopenic hosts eventually allowed the identification of the protecting cells as CD4$^+$ T cells *(218)* and then later as constitutively expressing CD25$^+$ (219) and the transcription factor Foxp3 (220,221,222). These cells are referred to as *natural T regulatory cells* (nTregs)

The presence of CD4$^+$CD25$^+$Foxp3$^+$ T cells in the thymus suggests that they develop there, although the possibility that the cells recirculate back from the periphery had to be considered. The first convincing evidence that nTregs arise in the thymus came from studies on embryonic epithelial grafts of thymic primordium (223,224). These experiments were initially done in a chicken/quail chimera model and then in the mouse using different strains. They showed that allogeneic grafts were tolerated because of a dominant suppressive mechanism directed against the epithelial cell alloantigens. Subsequently, a mouse expressing MHC class II molecules only in the thymic cortex was shown to support the development of CD4$^+$CD25$^+$ immunoregulatory T cells, while mice deficient in all MHC class II molecules did not *(225)*. Finally, nTregs develop in FTOC *(213,226)*, and a mouse in which an eGFP reporter protein was knocked into the Foxp3 locus revealed selection of T cells into this lineage at the transition from DP to SP thymocytes *(227)*, although recent work suggests that initial commitment might occur earlier at the DN2 stage *(228)*.

What antigens do nTregs recognize? Most TCR transgenic mice made with receptor genes from CD4$^+$ helper T-cell clones do not contain nTregs when expressed on a Rag-deficient background (so there are no other receptors expressed), suggesting that the repertoires of these two subsets do not overlap much. This has recently been confirmed by extensive sequencing of TCRs from both CD4 subsets selected under conditions of restricted TCR diversity (229). Not only was there little overlap, but the diversity was greater in the nTreg subpopulation. One TCR transgenic mouse has been described, however, which
FIGURE 29.2 The same as Figure 29.1 except that the proposed repertoire for natural T regulatory cells (nTregs) is superimposed. They are mainly cells with receptors of high enough avidity to choose this alternative fate rather than die from negative selection by clonal deletion.

gives rise to a high frequency of both CD4$^+$CD25$^-$ helper T cells and nTregs; but the latter were only generated when the animal was also engineered to express the antigen to which the TCR is specific (230). Interestingly, a second TCR transgenic with a lower-affinity receptor for the same antigen did not generate nTregs under the same conditions. This observation suggests that a relatively high affinity for the selecting ligand is required to generate nTregs. This concept is supported by the observation that nTregs are generated in higher frequency in SHP-1 phosphatase-deficient mice (which signal more strongly through their TCR) *(226)*. The current working model for how this might happen is shown in Figure 29.2. Positive selection of CD4 thymocytes is favored when TCR signaling is relatively strong or sustained. If the avidity of this interaction is too high, however, the cell undergoes a different fate. This can be deletion by negative selection or alternatively a commitment to the nTreg lineage. Which fate is adopted may be influenced by exposure to the growth factor, thymic stromal lymphopoietin, which favors survival and differentiation *(231)*, or other *trans* signals delivered by DP thymocytes *(228)*. In either case, though, only a few of the T cells would have receptors with affinities in the usual positive selection only range. Hence, little overlap would exist in the repertoires between nTregs and conventional CD4$^+$ effector T cells.

The self-antigen recognition by nTregs can be organ-specific, at least in the way the cells prevent autoimmune disease. For example, in the day 3 thymectomy models for orchitis and prostatitis, CD4$^+$CD25$^+$ regulatory T cells from the spleens of normal male mice were tenfold more effective at preventing disease than spleen cells from either female mice or males that had been castrated at birth (and who therefore do not express antigens of the testes or the testes-dependent prostate) *(232)*. Tissue ablation experi-

ments in adults suggest that peripheral antigen expression is needed to sustain prolonged survival and/or expansion of the CD4$^+$CD25$^+$ T cells in the periphery *(233)*. Whether the generation and continued presence of these cells in the thymus requires ectopic expression of peripheral antigens in epithelial cells of the thymic medulla (see later discussion), or cross-reaction with other self-antigens expressed only in the thymus, remains to be determined.

Peripheral and thymic CD4$^+$CD25$^+$ regulatory T cells have an activated phenotype. In addition to being CD25$^+$, they express high levels of CD44, CD5, and CD54 as well as low levels of CD45RB and the glucocorticoid-induced TNF-receptor family-related protein (GITR) *(234)*. They also express CTLA4, and there is some evidence that this molecule is involved in their *trans* suppressive function *(235–237)*. The molecule is not essential, however, because CTLA4$^{-/-}$ gene-targeted mice show normal nTreg development and function *(238)*. Interestingly, the resting CD4$^+$CD25$^+$ T cells appear to be in a clonal anergic state (see later discussion). They do not make IL-2 or proliferate when stimulated through their TCR *in vitro*. This is partly due to alterations in diacylglycerol kinase activity *(239)* and partly because Foxp3 competes with AP-1 for NF-AT binding to the IL-2 promoter, preventing transcription of this gene (240). The cells can proliferate if IL-2 is added to the cultures along with anti-CD3 *(241)* and this approach has been used to expand them *in vitro (242)*. *In vivo* their expansion and survival also seems to depend on IL-2 *(243)* because gene-targeted mice deficient in either IL-2 or its co-signaling receptors, CD28 and CD40L, have fewer numbers of CD4$^+$CD25$^+$ cells *(244,245,246,247)*. IL-2 does not appear to be required for nTreg development *(248,249)*.

In vitro studies have shown that nTregs function either by suppressing the proliferative response of naive CD4$^+$ and CD8$^+$ T cells through blocking of their IL-2 production and arresting the cells in the G1 phase of the cell cycle *(250)* or by consuming IL-2 in the culture, leading to apoptosis of these cells by cytokine withdrawal *(250a)*. To accomplish these things the regulatory cells must be activated through their TCRs and come into close proximity with the naive T cells. Once Treg activation is initiated by antigen or anti-TCR antibodies, the suppression becomes completely antigen independent. There is some controversy about whether an APC is also involved in the process *in vitro (250–252)*, but recent evidence *in vivo* suggests they can play a critical role in the effector function of Tregs *(214,253)*. Another controversy is whether the mechanism of inhibition involves cytokines such as IL-10 and TGF-β *(254–256)*. The regulatory cells clearly make these cytokines when they are stimulated, and in some cases this is required for suppressive function *(257–259,260)*. They also produce IL-9, which can recruit and activate mast cells to mediate immune suppression *(261)*. In any case, the antigen-nonspecific, bystander mechanism(s) of the suppression makes it hard to understand why these

cells do not also suppress responses to foreign antigens *(262)*. Some experiments suggest that activation of the innate immune system might lead to an inactivation of nTregs while at the same time facilitating naive T-cell actvation via up-regulation of costimulation by APCs *(263)*. TLR-mediated stimulation of IL-6 and IL-1 production has been shown to be critical in this regard *(264)*.

In addition to CD4$^+$ nTregs, recent experiments have suggested that there might also be populations of CD8$^+$ nTregs. Mice deficient in the CD122 IL-2R beta chain show enhanced granulopoiesis and severe anemia that is caused by the expansion of hyperactivated T cells *(265,266)*. This defect was corrected by the addition of CD8$^+$CD122^{high} T cells *(267)*. In addition, Rag2$^{-/-}$ mice injected with normal CD8$^+$CD122^{low} T cells die within 10 weeks of transfer, and this autoimmunity could also be prevented by the addition of CD8$^+$CD122^{high} T cells *(267)*. *In vitro* experiments showed that the regulatory T cells suppressed both proliferation and interferon (IFN)-γ production by the CD8$^+$CD122^{low} T cells via an IL-10-dependent mechanism (268). A very different population of nTregs that is CD8$^+$CD25$^+$ has been detected in MHC class II-deficient mice and it has almost all of the properties of CD4$^+$CD25$^+$ T cells *(269)*. It is Foxp3$^+$GITR$^+$CTLA-4$^+$, found in the thymus, and inhibits CD25$^-$ naive T-cell responses to anti-CD3 stimulation *in vitro*. However, it produces IFN-γ in addition to IL-10 on stimulation, and proliferates without the addition of IL-2. The exact functional role for either of these types of CD8$^+$ nTregs is still not clear.

TOLERANCE TO PERIPHERAL ANTIGENS

At the completion of development, T and B cells emerge from the primary lymphoid organs and enter the recirculating pool of peripheral lymphocytes. One of the first things these naive cells encounter in their fully mature state is antigens from various nonlymphoid organs that were thought to be restricted in their expression to a particular peripheral tissue. These antigens would be processed by dendritic cells in the tissues and brought to the draining lymph nodes for presentation to the naive lymphocytes. In this section is discussed whether these tissue-restricted antigens are recognized by the immune system, whether the antigens are only expressed in the peripheral tissues, and whether the immune system is tolerant to them.

Tissue-specific Antigens

When Medawar was asked if he could distinguish dizygotic from monozygotic bovine twins, he was certain this could be done by skin grafting; however, when his group attempted to test this, they found that most of the time (7/8) skin grafts exchanged between dizygotic twins were not rejected (270). This surprising result led them to conclude that skin does not contain any unique transplanta-

tion antigens, that is, none other than those found on the hematopoietic cells for which the twins were chimeric (3). Thus, the concept emerged that blood cells tolerize for all tissues.

The first challenge to this intellectual framework came from the studies of Billingham and Brent (271) on neonatal tolerance in mice. They found that B6 newborns injected with A spleen cells were not tolerant of A skin grafts. Boyse and colleagues *(272)* corroborated this finding in radiation-induced bone marrow chimeras [(A × B6)F$_1$ → B6], where they were able to show that the recipient contained (A × B6)F$_1$ hematopoietic cells but still rejected A skin. Tolerance could be induced, however, if A strain epidermal cells were injected along with the F$_1$ bone marrow (273). They concluded that there must be a skin-specific transplantation antigen (Sk) expressed by A and not by B6 mice. Subsequent studies showed that two genes controlled the expression of this antigen(s) *(274)* and that Sk antigens could be identified in other strain combinations *(275)*. These studies thus appeared at odds with the original Medawar results (270). A resolution of the contradiction was achieved by Emery and McCullagh (276). They repeated the early experiments with a small technical modification. In the original study, skin grafts were prepared from the ears of the donor and placed on the back (whithers) of the recipient. Instead, Emery and McCullagh exchanged flank skin grafts. In this case, all dizygotic twins rejected their sib's graft. Repeating the technique of Anderson et al. (270), they confirmed that many animals did not reject under these conditions (in their hands, 50%). Thus, cattle also have skin-specific antigens.

The failure to elicit a rejection with ear skin grafts most likely relates to the "strength" of antigen presentation (e.g., the density of Langerhans cells), which has been shown to vary in different areas of mouse skin *(277)*. Although Medawar's group demonstrated that their ear skin grafts were antigenic across a complete MHC genetic disparity (i.e., outbred cattle), differences in skin-specific (minor histocompatibility) antigens between dizygotic twins is a situation in which the two immune systems are tolerant to all processed peptides derived from proteins of hematopoietic cells, but not to peptides derived from proteins unique to the skin. In the cases in which the gene encoding a skin protein exists in two allelic forms, the potential arises for peptides to be expressed by the graft tissue that are not present in the host's skin. To elicit an immune response such peptides have to be able to bind (one each) to the MHC class I and class II molecules, perhaps explaining why two genes "control" the expression of the Sk antigen. These three constraints could explain why not all mouse strain combinations reveal an immune response to skin-specific antigens: (a) requirement for allelic polymorphism, (b) requirement for peptide binding to MHC molecules (immune response [Ir] gene control), and (c) tolerance to minor histocompatibility antigens that

are also expressed by hematopoietic cells. Outbred animals like cattle, however, should show this reactivity more frequently because of potentially greater diversity in the genes encoding their skin-specific proteins.

The concept of tissue-specific antigens is not unique to skin. The experiment of Triplett (13) demonstrating that immunologic tolerance is an acquired state showed that frog pituitary also expresses tissue-specific antigens. Because an attempt to confirm that study for pituitary, thyroid, and eye in other species of frog failed *(278)*, McCullagh (279) also readdressed this issue using the thyroid of fetal lambs. At 54 days of gestation, the lamb's immune system has not yet developed and the animal will accept allografts of adult skin. If the thyroid gland was removed at that time, implanted into a nude mouse (lacking T cells for rejection) for 5 to 9 weeks, and then reimplanted subcutaneously into the same lamb after birth, autoimmune thyroiditis developed. Partial thyroidectomized lambs did not get the disease, arguing that the immune response was specific for thyroid antigens and not any xenogeneic mouse tissue. These observations demonstrate that the immune system normally learns to become tolerant of other self-tissues and that it has mechanisms for dealing with the problem of tolerance to antigens that are predominantly synthesized in peripheral nonlymphoid tissues or that are expressed later in development (e.g., at puberty). These other mechanisms will be the topic of the rest of this chapter.

Ectopic Expression of Peripheral Antigens in the Thymus

The existence of tissue-specific antigens (TSAs) creates a problem for the immune system because the primary mechanism for induction of tolerance in the T-cell compartment is by clonal deletion or generation of nTregs, processes which both occur in the thymus. One possible solution to this problem is for these antigens to also be expressed in the thymus. The first hint that this might occur came from studies with transgenic mice expressing foreign antigens under the control of tissue-restricted promoters *(280,*281). In particular, the rat insulin promoter was found to sometimes express in the thymus in addition to the beta cells of the pancreas *(282–284)*. This expression was initially viewed as an artifact resulting from insertion of the transgene into regions of active chromatin *(285)*; however, the expression was observed in the thymus by several groups, a similar phenomenon was also seen when using other promoters, and importantly was not observed very often in other nontarget tissues *(286–288)*. In most cases the expression levels in the thymus were very low (e.g., for the rat insulin promoter 3,000 to 10,000 times less than in the pancreas) and could only be detected at the message level by reverse transcription polymerase chain reaction (RT-PCR) *(284)*; yet this expression

had clear immunologic effects. For example, the LCMV glycoprotein expressed under the control of the rat insulin promoter produced two types of transgenic founders, one with detectable expression in the thymus, the other not *(283)*. The former showed only a slow onset of diabetes following LCMV infection, mediated by low-affinity CD8 T cells requiring CD4 help, while disease onset in the latter was rapid and independent of CD4 help. These observations suggested that the thymic expression had induced a partial state of tolerance. Convincing evidence that it is only the thymic expression that is responsible for the tolerance process was achieved in the insulin and other models (LCMV, lactalbumin, elastase, and C-reactive protein) in which the thymus from the transgenic mouse was transplanted to a normal recipient and found to induce the same tolerant state *(282,283,288,289,290)*.

Subsequent studies using RT-PCR on human and normal murine thymuses revealed expression of many peripheral antigens, including somatostatin, insulin, myelin basic protein, glutamic acid decarboxylase 67, glucagon, elastase, trypsin, astrocyte S100β, C-reactive protein, lactalbumin, and thyroglobulin, although a few proteins such as human glutamic acid decarboxylase 65 and mouse preproinsulin 1 were not detected (291). Again, the expression was mostly confined to the thymus and the amounts expressed were small. In some cases sensitive assays were used to detect protein expression *(292)*. Which cell types in the thymus express these proteins was initially controversial (281). All investigators agreed that they were rare cells, mostly in the medulla *(293)*, and bone marrow chimera experiments showed that the cells were radioresistant *(290)*. Subsequent experiments using cell isolation and RT-PCR found that almost all of the TSAs were expressed in purified populations of medullary epithelial cells (291). A few antigens such as elastase, trypsin, somatostatin, lens crystallin, and retinal S antigen were also expressed in cortical epithelial cells. Very few were expressed in dendritic cells and then only at low levels. Thus, the current model is that TSA expression is mostly confined to the epithelial lineage and the expression begins in the common precursor to cortical and medullary epithelial cells, but increases enormously in diversity at the fully differentiated medullary stage, peaking in the mature MHC class II$^+$ and CD80$^+$ cells of this lineage, which are capable of presenting the antigen to both CD4$^+$ and CD8$^+$ thymocytes (294). Interestingly, for any given TSA, only 1-3% of medullary cells seem to express it *(295)*. This explains why the mRNA levels are so low in the whole thymus, but creates the cellular problem of how the system screens all maturing thymocytes for potential autoreactivity. It is estimated that scanning 30,000 mTECs by 15 million medullary thymocytes would take about 4 days (294). BrdUrd-labeling studies, however, have shown that maturing thymocytes can spend from 9 to 14 days in the medullary compartment *(296,297)*. Furthermore, for some antigens, transfer and cross-presentation by dendritic cells

has been shown to be required and achieved for negative selection *(298)*.

A critical question is whether the low levels of expression of TSAs play a role in the tolerance process. Detectable expression of TSAs in the thymus has been correlated with resistance to autoimmune disease induction among mouse and rat strains, for example, for interphotoreceptor retinoid-binding protein in experimental autoimmune uveoretinits *(299)* and for myelin basic protein in experimental autoimmune encephalomyelitis (EAE) *(300)*. For EAE caused by immunization with proteolipid protein, the dominant immunogenic epitope is encoded by an exon that is not present in the mRNA splice variant expressed in the thymus, suggesting that the T cells responsive to all other potential epitopes have been tolerized by the thymic expression *(301)*. This mechanism also influenced strain susceptibility to EAE as SJL mice could recognize an immunodominant peptide from this region, while B6 mice could not.

For insulin, an interesting correlation exists in the human population between a genetic susceptibility locus for diabetes (IDDM2) and proinsulin expression in the thymus. Two groups showed that variation in a minisatellite repeat element (VNTR) 0.5 kb upstream of the human insulin gene results in variation in proinsulin expression *(292,302)*. The higher expressing alleles (three- to fourfold) show a dominant form of protection with a three- to fivefold reduction in the risk of developing Type 1 diabetes. Finally, impairment in the development of mature (UEA-1$^+$) mTECs occurs in TRAF6- and RelB-deficient mice *(303)*, and this is accompanied by multiorgan autoimmunity (304). Grafting thymuses from these knockouts into nude mice recapitulated the disease as did thymic grafts from NF-κB-inducing kinase mutants *(305)*. All three proteins are part of the NF-κB signaling pathway. The disruptions of this pathway in mTECs resulted in abnormal nTreg development and decreased expression of TSAs. Reconstitution of thymus-grafted mice with CD4$^+$CD25$^+$ T cells reduced the severity of the autoimmunity, but did not totally eliminate it, suggesting that the decreased TSA expression was also contributing to the disease process *(305)*. Overall, these results suggest an important tolerogenic role for the ectopic expression of TSAs in the thymus.

How do thymic medullary epithelial cells express proteins normally functioning in other tissues? Some insight into this mechanism has come from the characterization of mutations in a gene called *AIRE* (autoimmune regulator) (306). Such mutations were first identified as responsible for a human autosomal recessive disease called autoimmune polyendocrine syndrome type-1 (APS-1) *(307,308)*. When an *AIRE*-deficient mouse was created, it became clear that many TSAs were no longer expressed in the thymic medulla and this correlated with an increase in autoimmunity against the peripheral tissues expressing those antigens (306). In transgenic models, *AIRE*-deficient mice (in a gene dosage-dependent manner) lost the ability to delete high avidity CD4$^+$ T cells recognizing their antigen expressed under the control of the insulin or thyroglobulin promoter *(309)*. The molecular mechanism of action of the *AIRE* gene is still not clear, but it can transactivate in a GAL4 transcription assay and has been found associated with the general transcription regulatory protein CBP in nuclear bodies *(310,311,312)*. Not all TSA genes require *AIRE* for expression *(313)*, but those that do tend to be clustered *(314)*. The imprinted genes Igf2, insulin2, and H19 all require *AIRE* for ectopic expression, but only Igf2 loses its imprinting in mTECs *(315)*. Thus, generalized DNA demethylation does not seem to be involved. Finally, *AIRE* has effects beyond just regulation of the expression of TSAs. The presence of *AIRE* is associated with increased expression of MHC class I and II genes as well as a cluster of chemokine genes *(314)*. Interestingly, isolated mTECs from *AIRE*-deficient mice were less efficient at presenting antigen to T cells *in vitro (316)*. Thus, *AIRE* might also help to facilitate tolerance induction by enhancing antigen presentation of TSAs by mTECs.

A role for TSAs in the selection of CD4$^+$ nTregs was initially postulated when both were first located to the thymic medulla. Subsequently, however, mice in which MHC class II molecules were limited to expression in the thymic cortex, using the K14 promoter, were found to develop normal numbers of functional nTregs *(225)*. In more recent experiments, *AIRE*-deficient mice (with normal nTreg numbers) and the Foxp3-scurfy mutant (deficient in nTregs) were crossed *(317)*. The offspring showed an additive effect of the two genetic alterations on the shortening of lifespan. Half the double-mutant mice died by 16 days of age from lymphocytic infiltration and severe inflammation of the lung and liver, whereas the parents lived well beyond 35 days of age and showed less severe pathology. It is still possible, however, that a subset of ectopically expressed, *AIRE*-dependent TSAs are involved in selecting a part of the nTreg repertoire.

Delivery of Peripheral Antigens to the Thymus

The presence of a mechanism for ectopic expression of TSAs in the thymus would now seem adequate to explain the original observations of Boyse et al. *(272,273)* described previously, wherein the irradiated host would lack A-type antigens in the thymus as well as the skin, thus preventing tolerance induction. In contrast, this mechanism cannot explain the observations of Triplett (13) or McCullagh (279) because removal of the peripheral organ (pituitary or thyroid) should not eliminate the central tolerance mechanism. It is possible that expression of some TSAs from these tissues is not *AIRE*-dependent, but then how would tolerance come about normally? Another plausible mechanism for achieving central tolerance to molecules that are not normally expressed in the thymus is to bring them there. Proteins and their fragments derived from

peripheral tissues through secretion or cell necrosis could easily enter the thymic medulla through its arterial circulation *(318)*. Exogenous antigens injected intravenously can reach and be processed by thymic dendritic cells as well as presented on MHC class II molecules in a form that stimulates T-cell clones to proliferate *(158,319)*. Early experiments showed that direct injection of soluble proteins into the thymus could induce tolerance to them, as measured in antibody responses and prevention of EAE *(320,*321). More recently, in a double-transgenic model with a TCR specific for the human C-reactive protein (hCRP), central tolerance could be mediated by bone marrow-derived dendritic cells when the transgenic antigen was induced in the liver of females (289). This T-cell deletion occurred even if the thymus was replaced with a nontransgenic thymus graft so that ectopic expression of hCRP in mTECs could not take place. Experiments on the fifth component of complement also showed that circulating proteins could reach the thymus and induce central tolerance (97,107).

Another possible mechanism for antigens to be transported to the thymus is for dendritic cells to pick them up in the periphery and then migrate back to the medulla. Small numbers of DCs have been detected in thoracic duct lymph returning to the bloodstream *(322)*. The first convincing data for migration to the thymus came from parabiosis experiments in which DCs from one CD45-marked host were found in low levels in the thymus of the other host after the shared blood vessel circulation was created *(323,324)*. In addition, intravenous injection of labeled CD11c$^+$ DCs yielded a small fraction appearing in the corticomedullary region of the thymus next to endogenous DCs *(324)*. This immigration process required recognition of endothelial P-selectin, integrin VLA4/VCAM-1 interaction, and activation of a pertussis toxin sensitive chemokine receptor, a three-step process normally required for most hemopoietic cell transcytosis events. Only immature CD11c$^+$ DC could do this and their ability disappeared if they were preactivated with LPS (possibly in order to prevent the delivery of foreign antigens to the thymus). When injected into irradiated mice prior to reconstitution with bone marrow cells from a TCR transgenic mouse, the DCs induced clonal deletion, if they had been preloaded with the OVA peptide recognized by the TCR. Finally, OVA transgenic mice expressing antigen in cardiac myocytes were also shown to delete the TCR transgenic thymocytes, and this negative selection was prevented by treatment with an anti-VLA4 mAb, which presumably prevented peripheral DC from entering into the thymus *(324)*. The number of such DCs in the thymus is estimated from the parabiosis experiments to be about 14,000. Although these experiments demonstrate that peripheral DCs can deliver TSAs back to the thymus to mediate negative selection, it should be noted that this process has not been detected in several other experimental models *(301,325)*. Nonetheless, this tolerance mechanism is capable of explaining the Triplett (13) and McCullagh (279) experiments described earlier.

Despite the clear evidence for two ways that the immune system has for bringing TSAs into the thymus to mediate a central tolerance mechanism, the possibility that the antigens could also induce tolerance in the periphery was raised by experiments in which allogeneic MHC class I and II molecules were expressed in the periphery using tissue-restricted promoters. In contrast to soluble proteins, these MHC class I molecules must remain intact in order to present their tissue-specific peptides. In other words, if shed and processed by dendritic cells for presentation in the thymus, they would not tolerize T cells that are specific for the peptide/MHC complexes expressed in the original peripheral tissue.

The first transgenic model of this type expressed the MHC class II E molecule either in β cells of the pancreas under the control of the rat insulin promoter (326) or in acinar cells of the pancreas under the control of the elastase promotor *(327)*. These animals were tolerant of the E molecule in a MLR, and they failed to eliminate certain Vβ-expressing T cells that are normally deleted by endogenous superantigens when this E molecule is expressed in the thymus. Some of the cells expressing those Vβs were unresponsive when stimulated in culture with anti-Vβ antibodies immobilized on a plate *(328)*. This tolerance process is referred to as *anergy* and will be discussed further in a later section. The possibility that the tolerance was induced by low-level ectopic expression of the transgenic E molecule in the thymus was eliminated by introducing nontransgenic thymus grafts into adult thymectomized, lethally irradiated and bone marrow-reconstituted (AT $\times$ BM) transgenic mice. Under these conditions the T cells mature in a thymic environment that does not endogenously express the transgene. These mice were also tolerant, arguing in favor of a peripheral mechanism for the tolerance induction. However, the possibility that the tissue-specific peptide/MHC molecules were transferred intact (via episomal bodies) to pancreatic DCs, which then migrated to the thymus to induce central tolerance, has not been ruled out. A similar series of experiments was done with MHC class I molecules expressed in a variety of peripheral tissues and the outcome was the same *(329–331)*, although thymic transplant experiments were rarely performed to rule out ectopic expression. Interestingly, the tolerance mechanism(s) involved in these situations, similar to the I-E molecule example discussed, were often not deletional. In the next sections of this chapter such mechanisms will be examined in more detail.

PERIPHERAL TOLERANCE MECHANISMS

Transitional B Cells

Peripheral tolerance deals with events that take place once the lymphocyte has fully matured and entered the peripheral circulation. For the T cell, this process is completed

in the thymic medulla, and naïve T cells that seed out into the spleen and lymph nodes are viewed as mature. B cells, however, must travel to the spleen to complete their maturation. Here they are called *transitional cells* (T1 to T3) and are defined by a series of cell surface markers (such as CD21 and CD23) that they acquire during final maturation (see Chapter 7 for a review of B-cell development). During this stage the B cell is still subject to negative selection and clonal deletion. In contrast to the bone marrow environment, BCR-stimulated transitional cells can no longer escape by receptor editing, but rather die by apoptosis if they encounter high-avidity multivalent antigen (*332,333*). Alternatively, the B cell can undergo a process of receptor desensitization and developmental arrest at the T1/T2 stage if it encounters persistent, soluble antigen of lower avidity and valency *(29,334)*. This process is known as *B-cell anergy* and will be discussed in detail later. In contrast, if the B cell also receives T cell help, it survives and both proliferates and differentiates into an antibody-forming cell (335). In early experiments, neonatal spleen cells were transferred at limiting dilution to keyhole limpet hemocyanin (KLH) carrier-primed irradiated recipients (38,*336*). As the naive B cells matured in splenic focus cultures *in vitro*, presentation of the DNP hapten coupled to KLH led to an IgM antibody response. In contrast, if the hapten was presented on another carrier (DNP-HGG), to which the T cells were not primed, then there was no antibody made to DNP. The antigen was recognized, however, because an initial 24-hour exposure to DNP-HGG prevented the antibody response to DNP-KLH. This showed that the developing immature B cells were tolerized to the hapten in the absence of T-cell help. Thus, the same B cells could be activated or tolerized depending on the presence of helper T cells.

In more recent studies, transitional B cells stimulated *in vitro* with anti-μ antibodies were shown to die by apoptosis; however, if IL-4 was also added to the cultures, the apoptosis was prevented and some of the B cells proliferated (333,*337*). IL-4 is one of the known cytokines to participate in T-cell help. At a molecular level, the anti-IgM–induced cyclin-dependent kinase (CDK)-4 and its regulatory subunit cyclin D2, which only allowed the cell to go from G0 into the G1 phase of the cell cycle. With the addition of IL-4, however, the expression of cyclin E and CDK2 was also induced, and this allowed some of the cells to transit into the S phase of the cell cycle. More complete help is provided by signaling through CD40 (333,*338*). These experiments support the idea that tolerizable immature B cells can be rescued by T-cell help.

These observations are not consistent with the clonal selection ideas proposed by Burnet (11), but fit nicely with the general model for B-cell activation originally proposed by Bretscher and Cohn (339). In an attempt to explain why immune responses require the recognition of two different determinants on the antigen and how the same antigen could both tolerize and immunize when given at different doses, these theoreticians first suggested that antibody-forming cells must be only tolerizable when stimulated through their antigen-specific receptor (this was referred to as signal one), but activated if they also received a second signal (referred to as signal two). This second signal was also postulated to be antigen-specific, and both antigenic determinants were required to be linked together on the same molecule. In the original model, the second signal was delivered by antibody from another B cell via an antigen bridge. With the subsequent discovery of T lymphocytes, the second signal became help from T cells specific for the same antigen. In today's way of thinking, the B cell binds the antigen via its BCR, which then transduces the first signal into the cell by activation of tyrosine kinases, such as Lyn and Syk. The receptor-antigen complex is then internalized, the antigen processed, and peptide/MHC complexes displayed on the B-cell surface. If T cells exist with receptors that can recognize these peptide/MHC complexes, then the ensuing T-cell/B-cell interaction provides the second signals in the form of a CD40 ligand/CD40 interaction and the release of stimulatory cytokines such as IL-4 and IL-5. In this framework then, antigen stimulation of B cells in the absence of T-cell help leads to peripheral tolerance, while stimulation in the presence of antigen-specific T-cell help leads to B-cell proliferation and differentiation. Based on the experiments described previously, it appears that these rules govern the response of transitional B cells to antigens.

Costimulation and the Two Signal Model for T-Cell Activation

The population of naive T cells that shows up in a lymph node on any given day is largely devoid of T cells with high-avidity receptors specific for self-antigens. Nonetheless, there are plenty of cells with low-avidity receptors and possibly a few with high-avidity receptors that have escaped central tolerance mechanisms. What happens if they encounter peptide/MHC complexes from a self-antigen that has been picked up in the tissues by DCs and brought to the draining lymph node? The immune system has a failsafe mechanism to thwart the stimulation of such high-avidity naive T cells, and that is the activation state of the APCs. Resting and immature DCs are not very effective in stimulating naive T cells, even when fully loaded with the proper peptide/MHC complexes (*340,341*).

Our understanding of this phenomenon traces back to the original dispute between Ehrlich and Morgenroth (1) and Metchnikov (2) discussed in the introduction section of this chapter. Immunizing with self-tissues often produces tissue-specific antibodies but these seldom caused any disease *(342)*. This changed in 1942 when Freund and McDermott introduced the use of an oil in water emulsion containing mycobacterial extracts as an adjuvant to enhance the magnitude of antibody responses *(343)*.

When Kabat et al. *(344)* used this complete Freund's adjuvant (CFA) to immunize monkeys with rabbit brain extracts, three of four animals developed a demyelinating encephalitis. When CFA was later tried by Freund et al. *(345)* with a guinea pig testis suspension (a variant of the Metchnikov experiment), all the guinea pigs developed aspermatogenesis. Thus, the animals appeared not to be tolerant to their own tissues if these were presented to the immune system in the presence of CFA.

Further insight into this phenomenon emerged from the work of Dresser *(346)*. He discovered that protein antigens could be tolerogenic when injected into adult mice, if the preparations were first spun in an ultracentrifuge to remove protein aggregates. Interestingly, this same preparation was immunogenic (produced an antibody response) if administered in CFA. Dresser concluded that paralysis (failure to produce an antibody response following prior exposure to antigen) ensued when lymphocytes recognized the deaggregated antigen alone. In contrast, if this was accompanied by a second component, which he termed *adjuvanticity*, then an antibody response was obtained. Claman (347) subsequently reproduced these observations and showed that an antigen-nonspecific, bacterial endotoxin (LPS) could work as an adjuvant. Frei et al. *(348)* then demonstrated that *in vivo* filtration of protein antigens in rabbits could remove the aggregated material and convert an immunogen into a tolerogen. They interpreted the role of the adjuvant to be the stimulation of antigen uptake by macrophages. The proper role for the APC, however, was subsequently elucidated by Lafferty and Woolnough *(349)*. In their studies of allogeneic reactions, they found that only hemopoietic cells could stimulate an MLR, because in addition to expressing the alloantigen (signal 1) they delivered a nonspecific "inductive stimulus" (signal two) that they called *costimulation* (350). This antigen-nonspecific signal could be eliminated by ultraviolet irradiation without affecting the presentation of specific alloantigens. Using a related approach, Jenkins and Schwartz (351) extended this work to the study of protein antigens. They showed that cloned CD4$^+$ T cells failed to produce IL-2 and proliferate when stimulated with chemically fixed, antigen-bearing APC. In addition, these cells entered a state of hyporesponsiveness in which they persisted in not responding even when rechallenged with antigen and normal APCs. Consistent with the loss of a nonspecific "costimulatory activity" following chemical treatment of the APCs, the addition of allogeneic APCs (which were not capable of presenting the antigenic peptide) promoted proliferation of the T cells and prevented development of the unresponsive state *(352)*. Similar observations were made with purified peptide/MHC complexes presented in planar lipid membranes, showing that signal one was indeed solely TCR occupancy *(353)*. Taken together, these *in vitro* studies provided the basis for our current thinking that APCs must provide both a stimulatory peptide/MHC complex as well as an antigen nonspecific costimulatory activity to promote T-cell clonal expansion and IL-2 production.

What then is the role of CFA in this two signal model? Note that this model is different from the one proposed by Bretscher and Cohn (339). In the latter, the second signal needs to be antigen-specific. In the Lafferty/Cunningham model the second signal is not antigen-specific (350). This requires one to rethink the importance of self-nonself discrimination in the induction of tolerance because the APC providing the nonspecific costimulation has no obvious direct way to tell whether it is presenting a self or a foreign antigen. The first person to confront this problem was Janeway *(354,355)*, who suggested that costimulation (and not foreign antigen) was the switch that controlled whether the organism made an immune response. He proposed that the innate immune system first evolved to recognize and respond to pathogen-associated molecular patterns (PAMPS) that were common to infectious agents and absent from the host (see Chapter 14 on innate immunity). At a later time in evolution, the adaptive immune system emerged with the recognition of foreign determinants by antigen-specific receptors as a means to focus and sustain the immune response initiated by the detection of PAMPs. In his model, the PAMPS activate pattern recognition receptors (PRRs) on APCs and this leads to the up-regulation of costimulatory activities, which subsequently deliver the second signals required to activate naive T cells. Thus, the absence or presence of a PAMP signal becomes the critical determinant in peripheral self/nonself discrimination. The subsequent discovery by Medzhitov et al. *(356)*, as well as many others, of multiple NOD and Toll-like receptors (TLRs) in and on innate immune cells (which are capable of mediating the recognition of PAMPs and activating APCs) has provided considerable support for this model (357,358,*359*,360). These receptors recognize lipids, carbohydrates, or nucleic acids specifically produced by pathogens and then activate the APCs through the NF-κB signaling pathway. The mycobacterial extract in CFA is now known to contain several PAMPs that act on TLRs 2 and 9 *(361–363)* and the incomplete oil in water emulsion (IFA) alone has been shown to up-regulate TLR2 in the liver *(364)*.

Despite this elegant framework, PRRs cannot be the whole explanation for how adaptive immune responses are initiated. For example, graft rejection following transplantation usually does not involve exposure to infectious agents. The first person to conceptualize that there must be other mechanisms for activating APCs was Matzinger (365), who presented the idea that the immune system distinguished not between self and nonself, but between things that were dangerous and things that were not ("The Danger Model"). In this model, the response would be initiated by perturbations in the organism's internal environment and propagated by alarm or "danger" signals, which

in turn would stimulate the ability of the APCs to deliver costimulation. In the case of transplantation, it would be the response to injury, initiated through necrotic cell death that would provide the inductive signal. The molecular stimuli are thought to come from heat-shock proteins released into the environment by the dying cells *(366)*. These molecules carry potentially immunogenic peptides that are first internalized by binding to CD91 receptors on the APCs *(367)* and then cross-presented by MHC molecules to T cells (368,369,370). Interestingly, the heat-shock proteins also interact with TLRs 2 and 4 *(371,372)* to activate expression of costimulatory molecules and proinflammatory cytokines such as TNF-α and IL-1-β through stimulation of the NF-κB signaling pathway *(366)*. However, the possibility of trace contamination with endotoxin to explain this result has been difficult to exclude (373). Such indirect pathways could also be triggered by pathogens, which might infect and kill host cells, or otherwise perturb the host's internal milieu in a manner that could be recognized by a family of molecular sensors. A conceptually similar model called the "guard hypothesis" was subsequently proposed to explain certain aspects of plant immunity (374). In a recently described new twist, it was discovered that mycobacterial HSP-70 molecules from infected immature DCs, can stimulate human T cells through their CCR5 chemokine receptor to cluster with the DCs and activate them to kill the bacteria *(375)*. In this case, a chemokine receptor involved in the normal physiology of the immune system has been co-opted to function as a PRR.

In general, tissue dendritic cells can be activated by a variety of endogenous alarm signals generated by stressed or necrotic peripheral tissues. Dead cells can serve as adjuvants when coinjected with foreign antigens *(376,377)*. Recent studies have shown that uric acid released from these dying cells can stimulate dendritic cell maturation (B7 expression) and act as an adjuvant for enhancing the cytotoxic response of CD8$^+$ T cells to 3T3 cells expressing HIV gp120 *(378,379)*. It is actually crystalline monosodium urate (MSU) that is the biologically active form and this phase change *in vivo* may be the critical initiating danger signal. Depletion of uric acid with a combination of allopurinol to block its synthesis and uricase to metabolize it inhibited the CTL response to gp120 by 80% (380). Another strong candidate for an endogenous danger signal is the high mobility group one protein (HMGB1) which normally bends gene-targeted DNA in the nucleus, but which can be released from necrotic (but not apoptotic) cells *(381)* and induce inflammation by binding to the RAGE receptor *(382)*. Freeze/thawed necrotic fibroblasts from Hmgb1$^{-/-}$ mice fail to elicit tumor necrosis factor (TNF)-α production from monocytes or bone marrow cells the way WT cells do *(381,383)* and antibodies to HMGB1 can attenuate endotoxin-induced lethality in mice (384). Activated macrophages can also secrete HMGB1 but only after

overnight stimulation with LPS (*381*,384). The mechanism for release from dying cells is more rapid and does not depend on TLRs.

Such endogenous danger signals may in fact play the dominant role in the facilitating effects seen with adjuvants. Gene-targeted mice lacking both MyD88 and TRIF, the two critical intracellular signaling components required for all Toll receptor function, still showed normal augmentation of antibody responses to protein antigens by adjuvants such as CFA or alum *(385)*, although other PRRs such as NODs might be playing a role (360). Thus, it could be argued that danger signals were in fact the first form of defense involved in recognizing both tissue injury and infection. It is even possible that the PRRs evolved from the original receptors concerned with sensing danger during wound repair and the clearance of molecular waste *(386)*.

Costimulatory Molecules

Activated DCs up-regulate their level of MHC class II molecules *(387)* and express a number of costimulatory molecules that facilitate their ability to activate naive T cells (341). Two critical ones are the B7 family member CD86 *(388)*, and the TNF superfamily member CD40 *(389)*. B7 molecules engage the CD28 receptor on T cells and promote naive T-cell proliferation by lowering the threshold for cell activation in response to a given number of serial engagements by the TCR and its associated coreceptor CD4 or CD8 *(390)*. CD28 costimulation induces the movement of lipid- and kinase-rich membrane raft microdomains to the interface between the T cell and the APC *(391)*, leading to more effective and persistent tyrosine kinase activity, c-Jun N-terminal kinase activation, and NF-κB translocation to the nucleus *(392)*. As a consequence, CD28 costimulation has the capacity to enhance transcription of the *IL-2* gene and increase the stability of resulting *IL-2* transcripts, as well as induce Bcl-xL protein expression, leading to greater proliferation, differentiation to cytokine production, and improved T-cell survival (393,394,395).

CD154/CD40 interactions at the T cell/APC interface during antigen priming can also act to amplify costimulatory signaling within CD4$^+$ T cells *(396)*. In contrast to CD28, CD154 is not constitutively expressed on the naive T cell. Its expression requires TCR- and CD28 stimulation. Subsequently CD154 binds to CD40 molecules on the APC, which have been up-regulated following APC activation by PAMPS or danger signals. CD40 signaling then reinforces the priming of the T cells by, among other things, promoting higher levels of expression of the B7 molecules (397). In the absence of CD154, this positive feedback loop is disrupted and antigen-bearing APC remain only weak stimulators of CD4$^+$ T cell growth and helper cell differentiation. Similarly, mice treated with a neutralizing anti-CD154 mAb demonstrate only a suboptimal CD4$^+$ T cell

clonal expansion following immunization in the presence of antigen and adjuvant.

Following CD40 stimulation of the APC, another important molecule that is up-regulated is OX40 ligand (OX40L) (*398*,399). This molecule interacts with CD134 (OX40), which is expressed on activated T cells 1 to 2 days after stimulation with antigen and adjuvant. This up-regulation is partially dependent on CD28 signaling and augmented by costimulation with proinflammatory cytokines such as IL-1. During the response to antigen, agonist anti-CD134 mAb prolongs T cell proliferation through a molecule called Survivin *(400)* and reduces apoptosis by augmenting *Bcl-xL* and *Bcl-2* expression *(401)*. This provides better help for antigen-specific IgG production and enhances the frequency of the memory T-cell population. Genetic deficiency of OX40L leads to defective contact hypersensitivity as a consequence of poor naive T-cell priming. Similarly, mice treated with a neutralizing anti-OX40L mAb show defective priming for T-cell proliferation and recall lymphokine production. Finally, treatment of mice with ongoing inflammatory bowel disease using a blocking CD134/Fc fusion protein reduces both the number of T cells infiltrating the lamina propria as well as the amount of proinflammatory cytokine gene expression. The effect on migration is likely a consequence of OX40L expression on vascular endothelial cells where it facilitates adhesion and migration into tissues by activated T cells.

These experiments illustrate that costimulation is a series of positive feedback loops required to sustain an immune response (399). The process involves multiple receptor/ligand interactions. In addition to CD28/B7, CD154/CD40, and CD134/OX40L, there are also CD137/4-1BBL, ICOS/ICOSL, LIGHT/HVEM, and CD27/CD70, which coordinately amplify T-cell proliferation, differentiation, and survival. In addition, proinflammatory cytokines such as IL-1 help to amplify the immune response by enhancing the expression of these receptors (CD134 and CD154) on T cells *(402)*. Thus, the original idea of costimulation as a simple second signal required to allow TCR occupancy to lead to an immune response (350,351) has now given way to the idea of a family of non–antigen-specific positive signals that help both initiate and sustain the immune response *(403)*.

APCs Favor Tolerance in the Absence of Activation

What happens in the opposite situation, when the naive T cell encounters DCs in the absence of PAMPs and danger signals? In the complete absence of costimulatory ligands, isolated CD4$^+$ TCR ligation by solid-phase high-affinity peptide/MHC complexes (immobilized on plastic culture plates, latex beads, or gluteraldehyde-fixed cells) elicits only a weak and transient proliferative response that is accompanied by suboptimal IL-2 secretion

(351,*353*,*404*,*405*). In addition, the studies on CD4$^+$ T cell clones showed the induction of a peripheral tolerance process called *clonal anergy* (see later section). However, these CD4$^+$ T cells were already preactivated. The induction of this tolerance has been more difficult to show with naive T cells *in vitro* (406). It cannot be easily demonstrated with immature dendritic cells because these cells become activated in culture when they adhere to the plastic culture dish *(407)*. The best data have been generated using as APCs Drosophila cells transfected with MHC class II molecules and various additional costimulatory molecules *(408)*. It was assumed that the Drosophila cells did not express any other molecules that could play a role in a mammalian immune response. These experiments revealed that mouse peptide/MHC complexes alone could elicit little or no naive T cell response, while the addition of ICAM-1 for an LFA-1 interaction to improve cell adhesion resulted in the induction of anergy. Further addition of CD86 for the delivery of CD28 costimulation caused the cells to proliferate and differentiate into preactivated T cells. Thus, adequate TCR signaling in the absence of CD28 costimulation could induce a hyporesponsive state. By contrast, for CD8$^+$ T cells, experiments with high-avidity peptide Ag/MHC class I tetramers showed that single, isolated naive TCR transgenic T cells could be stimulated to proliferate *(409)*. Adding costimulation in the form of CD28 cross-linking did not enhance this response. In addition, populations of these cells produced IL-2 and differentiated into cytotoxic effector cells making IFN-γ. When the tetramers for the H-Y peptide were injected into female mice, they primed for a more rapid graft rejection of male skin *(410)*. Thus, under very strong TCR stimulating conditions it appears that the need for costimulation can initially be bypassed for CD8$^+$ T cells without inducing an unresponsive state (but see later discussion). Interestingly, however, multiple injections *in vivo* induced a partial tolerant state by a mechanism involving the generation of CD8^{low} regulatory T cells *(411)*.

A more compelling case for what happens to naive T cells in vivo has emerged from experiments designed to target foreign protein/peptide antigens to DCs using mAbs directed against their cell surface molecules, such as 33D1 or DEC-205, that do not activate the dendritic cells (412). The first experiment looked at the mouse antibody response to rat IgG2b. Pretreatment with small amounts of a monoclonal rat IgG2b directed against the 33D1 molecule greatly reduced the subsequent antibody response to a stimulatory IgG2b Ab (413). This tolerant state also involved a reduction in T-cell cytokine production (both IL-4 and IFN-γ) and could be prevented by coinjection of the proinflammatory cytokine IL-1 along with the anti-33D1 mAb. In contrast, a mAb directed against the CD11c molecule was immunogenic. Later experiments looked directly at T cells using CD4$^+$ cells from a TCR transgenic mouse specific for lysozyme (HEL) *(414)*. In this case, the HEL peptide was engineered to be part of a mAb specific

for the DEC-205 protein on DCs. Injection of the antibody stimulated CD4[+] T cell proliferation and IL-2, but not IFN-γ or IL-4 production. After four to seven rounds of division, most of the T cells disappeared and the remaining cells were anergic. This tolerance induction was prevented by simultaneous administration of an agonist anti-CD40 mAb, a potent stimulator of the NF-κB pathway and an activator of the APCs. Subsequent studies with OVA delivery to DCs *in vivo* showed a similar phenomenon for CD8[+] T cells *(415)* and studies with the MOG peptide in an EAE model showed some evidence for involvement of the CD5 molecule in the tolerance process *(416)*.

Are these abortive responses a consequence of partial activation of the APCs by the mAbs against 33D1 and DEC-205? Arguing against this is a series of experiments in which CFSE-labeled, naive TCR transgenic T cells were transferred into an unmanipulated host expressing native or transgenic antigen in a tissue-specific manner *(329,417,418,419)*. The CD4[+] or CD8[+] T cells that entered the draining lymph node of that tissue were observed to initially proliferate, and then they either died off or became anergic. It is thought by many that this abortive response represents the consequence of antigen-induced T-cell activation in the absence of costimulation, although this has not been rigorously demonstrated in most of these *in vivo* models. The general strategy is to show that addition of a costimulatory signal allows for a full response *(419)*, but seldom is the inverse experiment done to genetically remove the possibility of costimulation and show that this abortive response still takes place.

Another postulated reason for the failure to sustain an immune response has been attributed to the induction of molecules that exert negative feedback on TCR signaling. The two best-studied molecules are CTLA-4 *(420)* and PD-1 *(421)*. Soon after activation, T cells express the CD28-homolog CTLA-4, and ligation of this receptor by B7 molecules on the APC promotes the activation of an associated SHP-2 tyrosine phosphatase, leading to reduced IL-2 production and inhibited progression through the cell cycle. *In vivo*, the cells stop interacting with the APCs *(422)*. This inhibition is in part responsible for the anergy induction that occurs *in vivo* under conditions wherein B7 levels have not been sufficiently up-regulated by infection or injury *(423,424)*, although not in all cases *(425,426)*. Because CTLA-4 has a higher affinity for the B7 molecules than does CD28, its negative signaling can be expected to dominate under conditions of weak APC activation and limiting B7 expression *(427)*. The PD-1/PD-L1/2 receptor/ligand pair also inhibits T-cell activation by recruitment of the SHP-2 phosphatase to this receptor *(428)*, although its exact molecular mechanism of inhibition seems to be different than that of CTLA-4 *(429)*. Both PD-ligands are inducible on APCs with IFN-γ, but PD-L1 is constitutively expressed on many peripheral tissues such as heart, lung, and kidney, and thus may be mostly involved in downregulation of T cells during their effector phase. Blocking

PD-L1 in chronic LCMV infection allows the anergic effector CD8[+] T cells to become more active and greatly reduces the viral load in the mouse *(430)*. Deficiency for CTLA-4 leads to the development of a T-cell lymphoproliferative disorder with massive lymphocyte infiltration of many organs and early death of the mouse *(431)*. PD-1 deficiency is less severe and leads to selective autoimmune disease with different phenotypes depending on the genetic background of the animal *(432,433)*. Targeting of CTLA-4 has a much more rapid and profound effect than targeting PD-1, possibly because the former also plays an important role in nTreg function *(237)*. Therefore, it is likely that in the absence of serious infection or injury, ligation of CTLA-4 and/or PD-1 by their respective ligands on the APC limits T-cell responsiveness and favors the maintenance of a hyporesponsive state.

Despite the existence of these two negative-feedback mechanisms and the ability to bypass costimulation under strong TCR occupancy conditions that avoid tolerance induction, it is quite clear that B7 molecules (CD80 and CD86) do become more highly expressed on APC *in vivo* following exposure to agonist anti-CD40 mAb, PAMPS such as LPS, or danger signals (341). Thus, their presence or absence could still play a critical role in the induction decision between tolerance and immunity under suboptimal activation conditions. *In vivo* blocking experiments with soluble CTLA-4, especially those in which the receptor has been mutated to have a higher affinity for masking B7 molecules, have revealed modest, but clinically significant, disruption of immunity, mostly involving negative effects on antibody responses *(434–437)*. Similar partial effects were observed with CD28 knockout mice, but these are complicated by the continued presence of CTLA4 *(438)*. The most revealing experiments on this issue have been carried out with gene-targeted mice lacking both B7-1 and B7-2 (439). These mice fail to reject heart allografts *(440)*, do not get allergic pulmonary inflammation following sensitization to OVA *(441)* or experimental autoimmune encephalomyelitis following injection of myelin oligodendrocyte glycoprotein (MOG) in CFA *(442)*, although the last outcome is strain-dependent *(443)*. When crossed onto the MRL/Mp-*lpr/lpr* background, the mice failed to develop autoimmunity *(444)*. An analysis *in vitro* showed that B7-deficient APCs are impaired in stimulating IL-2 production and proliferation from both naive and primed CD4[+] T cells *(445)*. In addition, the differentiation of naive CD4[+] T cells into IL-4 producers was impaired, although IFN-γ production was not, resulting in a T-helper cell 1 (Th1) bias to the weak response *(445)*. CD8[+] T-cell–mediated contact sensitivity was impaired at low antigen doses, but not at high doses *(446)*. Thus, B7 molecules play a critical role in the tolerance/immunity decision *in vivo*; however, they do not represent the only molecules involved in the process of costimulation and their absence can be circumvented in some immune responses of either a Th1 or Th2 nature *(446,447)*.

In general, unperturbed dendritic cells appear to be maintained in a state that predisposes to tolerance rather than immunity. This is achieved by the steady-state phagocytosis of apoptotic cell products from their environment (448,449). Unlike necrotic cells that promote the maturation of dendritic cells and increase their expression of costimulatory activities, many apoptotic cell products inhibit the production of proinflammatory cytokines such as IL-1, IL-8, TNF-α, granulocyte macrophage-colony stimulating factor, leukotriene C$_4$, and thromboxane B2 (448,450) and down-regulate the activation phenotype of dendritic cells by decreasing MHCII and B7-2 expression (451). They also actively inhibit the response of DCs to proinflammatory stimuli such as LPS and promote the production of anti-inflammatory substances such as TGF-β1, IL-10, prostaglandin-E$_2$ and platelet-activating factor (448,450,452). This process can be prevented by coating the apoptotic cells with antibodies that signal the phagocytic cell through the Fc receptor (450,453). The induction of the "anti-inflammatory" cell program occurs via the recognition and binding of apoptotic cell products to surface receptors such as the phosphatidyl serine receptors, CD36, thrombospondin, the αvβ3 and αvβ5 integrins, pentraxins including serum amyloid P and C-reactive protein, collectins such as the mannose binding lectin, and the complement component C1q (452,454–458). Receptor tyrosine kinases of the Tyro3/Axl/Mer family and their ligands GAS6 and protein S have been shown to be necessary for the phagocytosis of these apoptotic cell products and these receptors act as intermediates in the production of the immunosuppressive activities (459). Notably, mice that are genetically deficient for one or more of these kinases are selectively impaired in their ability to phagocytose apoptotic cells (460–462). They constitutively express high levels of costimulatory molecules and develop spontaneous systemic autoimmunity. Thus, the quiescent immune system normally acts as a buffer against immune responses to discarded self-components from peripheral tissues by efficiently removing these antigens without activating costimulation.

Finally, there is the question of what happens when a dendritic cell simultaneously ingests apoptotic cells and an infectious agent expressing PAMPs? Recent work suggests that each phagocytic vacuole is independent of the other, and that TLRs in the PAMP-containing vessicle can signal the NF-κB pathway without interference from the Mer signaling pathway (463). This allows strong enough danger signals to override the anti-inflammatory program and activate the APC.

Priming of CD8$^+$ Cytotoxic T Cells Requires Three Signals

Naive CD8$^+$ T cells can be directly activated to proliferate by antigen and APC or peptide/MHC tetramers (409,464). Nevertheless, many normal cytotoxic responses depend on concomitant priming of CD4$^+$ T cells in order to be sustained. Furthermore, in the Qa1 CTL model of Keene and Forman (465), it was shown that activation of the CD8$^+$ T cells in the absence of CD4$^+$ T cell help resulted in CD8$^+$ T cell tolerance (466,467). The nature of the help in this model was initially viewed as a three-cell interaction in which a single APC presented the antigen to activate both T cells in close proximity; then the activated CD4$^+$ T cell produced IL-2, which helped the CD8$^+$ T cell to expand and differentiate (465). Subsequent studies, however, demonstrated that the information actually flows through two sequential two-cell interactions (468,469). The need for CD4$^+$ T-cell help could be bypassed by antibodies to CD40, which made the APC competent to present the antigen to naive CD8$^+$ T cells. B7 molecules were essential for effective stimulation, but they were not sufficient, suggesting the need for another form of costimulation. *In vitro* studies from Mescher's laboratory with a microbead presentation system showed that IL-12 can synergize with antigen and either B7 or IL-2 to prime naive CD8$^+$ T cells for IFN-γ production and CTL activity as well as stimulating proliferative expansion and increased survival through a Bcl-3–mediated mechanism (470,471). Several laboratories have also shown *in vivo* that IL-12 can act as well as CFA as an adjuvant to prime naive transgenic CD8$^+$ T cells (470,472). Because CD40L stimulation of APCs through CD40 greatly increases APC expression of IL-12 (473), this molecule would seem to be one good candidate for the third required signal induced by CD4$^+$ T-cell help. However, it is not the only one as CD8$^+$ T-cell priming can occur in IL-12 p40-deficient mice if they are stimulated with antigen in CFA (474). Recent experiments have demonstrated that type I IFNs can also subserve the third signal function by stimulation through a STAT4-dependent pathway (475). Finally, once the CD8$^+$ T cells have been activated, they express CD137, which can interact with the 4-1BB ligand on the APC to sustain CD8$^+$ T-cell proliferation and prevent apoptosis in long-term culture (476).

In the absence of a third signal, the naive CD8$^+$ T cells are tolerized even though the APCs express B7 (468). As shown by Albert et al. (472), the T cells undergo a weak expansion and then many of them die, similar to what is observed *in vivo* during the cross-presentation of self-antigens (325). They may also undergo activation-induced cell death through a TRAIL/DR5-dependent mechanism when restimulated with antigen and APCs (477). However, many of the remaining cells appear to be anergic, that is, they fail to produce IL-2 on restimulation (470). In this regard, addition of IL-12 augments the amount of CD25 expression and proliferation, which helps prevent anergy induction. It also is required for granzyme B production (478). The model can also explain why CD8$^+$ T-cell priming occurs in certain viral infections in the absence of CD4$^+$ T-cell help (479,480). If the virus is capable of infecting the APC, the cell can turn on IFN-$\alpha\beta$ production and up-regulate B7 expression to provide the optimal

costimulatory environment required for priming of CD8[+] T cells.

TOLERANCE INDUCTION IN MATURE B CELLS

Receptor Blockade

The induction of tolerance to foreign antigens in adult animals has a long experimental history because of its importance for potentially treating autoimmune diseases and facilitating organ transplantation. One of the earliest bodies of work was performed by Felton and colleagues (481,482). They studied the immunogenicity of polysaccharides from *Pneumococcus pneumoniae* and found that a dose of 0.5 mg paralyzed the immune system such that subsequent infection with the bacterium often led to death of the animal. The major immunologic effect appeared to be an inhibition of the antibody response to an optimal dose (0.5 μg) of the polysaccharide. This paralysis was specific for the particular polysaccharide used, was induced in adult animals, and lasted for a long time, presumably because of the poor degradability of the molecules. Although Felton was sure that the effect was on antibody-forming cells, it was difficult at the time to rule out a masking of the antibody response by adsorption on the persisting antigen.

In the 1950 s, a number of investigators extended these observations to protein antigens by showing that high doses of protein would paralyze the immune system and prevent it from making an antibody response to a subsequent immunogenic dose of the antigen *(346,483)*. Subsequently, Katz and colleagues *(484–486)* extended the polysaccharide experiments of Felton by examining haptens coupled to poorly degradable synthetic D amino acid copolymers. They showed that guinea pig B cells were directly affected by these antigens, even if the cells had been primed. Initially, it was thought that the B-cell unresponsiveness induced in these models might be due to receptor blockade by poorly degradable antigens stuck to the B-cell surface. Diener and Paetkau *(487)* were the first to discover that antigen given to adult animals in tolerogenic doses could persist on the surface of lymphocytes. Such cells with bound antigen were also observed in the hapten IgG model of Aldo-Benson and Borel *(488,489)*. Only tolerogenic conjugates such as DNP_{12} IgG_1 produced these cells, not closely related nontolerogenic conjugates such as DNP_{52} IgG_3 (490). At high doses of tolerogen the cells persisted for weeks, as did the tolerance, and when the tolerance waned, the cell-bound antigen was no longer detected. Culturing the cells *in vitro* allowed the antigen to be shed and the tolerance to disappear on adoptive transfer.

Physical properties of the antigen, such as size *(491–493)* and hapten density *(494)*, were shown to be important variables in receptor blockade. In a rigorous series of experiments, Dintzis et al. (495,496) made linear polymers of acrylamide of various lengths, coupled with haptens at various densities, and found that large polymers with high hapten density were immunogenic, whereas small polymers with low hapten density were not. The latter, however, could block activation by the former. These results were interpreted as the need for B-cell receptors to be clustered into complexes of 10 to 15 receptors each in order to signal the cell. The small polymers with low hapten density could not achieve this configuration but they were able to tie up receptors in nonproductive complexes and therefore block activation by the larger polymers. This model provides one molecular mechanism for a receptor blockade, although the type of B cell being affected (B1 vs. B2) was never fully characterized.

Another mechanism emerged from the comparison of DNP_{12} IgG_1 and DNP_{52} IgG_3 by Waldschmidt et al. (490). The class of antibody turned out to be the critical variable in determining the outcome. TNP_{11} IgG_1 induced tolerance, while TNP_{11} IgG_3 was immunogenic. Furthermore, removal of the Fc portion of the antibody from human gamma globulin to make TNP_{10} $F(ab')_2$ created an immunogen out of a tolerogen. These results suggested that engagement of the Fc receptor on B cells might be responsible for the tolerance (497,498). More recent studies have shown that signaling through the BCR can be inhibited if Fc receptors are simultaneously engaged in the same complex, most typically brought about by the binding of antigen-antibody complexes *(499)*.

B-Cell Anergy

The early studies convincingly demonstrated that some forms of tolerance induction in adult B cells could be reversed by trypsinization of the cells to remove bound antigen and the receptors *(500)*. This was followed by receptor re-expression. Unresponsiveness in these cases was likely caused by receptor blockade without signaling. Tolerance induced by other antigens, however, could not be reversed by simply removing the surface molecules, indicating a requirement for active metabolic processes during induction *(501)*. For example, the D amino acid copolymers induced unresponsiveness at 37°C even if the B cells were subsequently trypsinized to clear the bound immunoglobulin receptors from the cell surface. In contrast, exposure of the cells to antigen at 4°C did not induce tolerance. The low temperature presumably prevented the necessary signaling to the cell required for the tolerance. In several other systems, stimulation with mitogens such as LPS was also required to reverse B-cell tolerance *(502,503)*. These observations suggested that there might exist a stable but reversible unresponsive state for mature B cells in the short-term absence of antigen.

The introduction of fluorescein-tagged and radiolabeled antigens in the late 1960s allowed for the first time the

quantitation of antigen-binding cells. Most of the cells detected were B cells as defined by the expression of surface immunoglobulin. When this technique was applied to tolerant animals, whether natural or acquired through injection of high doses of antigen, the surprising observation was made that the animals had antigen-binding cells specific for the tolerogen. For example, cells binding thyroglobulin were observed repeatedly in human peripheral blood, but cells specific for human serum albumin were not *(504)*. This suggested that self-tolerance did not always involve deletion of clones as postulated by Burnet (11). Similar observations were made for protein antigens administered to adult animals *(505)*. Because the total number of B cells capable of binding labeled antigen was not diminished in these models, the tolerant state was referred to by Nossal as clonal anergy rather than clonal deletion or abortion *(505)*. This was difficult to prove, however, because in a normal mouse only 1% to 3% of the antigen-binding cells (assayed at limiting dilution) were responsive to antigen or produced specific antibodies when stimulated with LPS. Thus, a small fraction of functionally important cells might have been deleted, but their absence would have been hard to detect amidst the mass of low-affinity antigen-binding cells. Subsequent limiting dilution experiments, with a more potent mitogenic mixture of dextran sulfate and LPS as a stimulant, revealed that at least some tolerized B cells could be stimulated to differentiate into antibody-forming cells when the BCR was bypassed (503). This reversal suggested that at least a portion of the cells had been rendered functionally unresponsive (anergized) rather than deleted.

A much clearer picture of the nature of B-cell anergy became possible with the introduction of BCR transgenic mice (*334,506*). A mouse model was created by Goodnow and colleagues that expressed on its B cells a high-affinity receptor (both IgM and IgD) specific for HEL (506). About 90% of the B cells in this mouse expressed the transgenic receptor. When this BCR transgenic mouse was crossed with a second transgenic mouse constitutively expressing the lysozyme antigen in a soluble form, the double-transgenic offspring still expressed large numbers of lysozyme-binding B cells in their spleens and lymph nodes. On immunization with lysozyme, however, these B cells failed to make an antibody- or plaque-forming cell response. Because the failure to respond could have been caused by tolerance at the level of the T cells, spleen cells from these animals were transferred to irradiated, nontransgenic recipients along with spleen cells from mice primed to horse or sheep RBCs as a source of T-cell help. The recipients were then boosted with lysozyme-RBC conjugates. Compared with control BCR transgenic mice, the B cells from double-transgenic mice made a 10- to 100-fold lower plaque-forming cell response. Thus, not only had the B cells not been deleted, but they also appeared to be functionally hyporesponsive. Such a lymphocyte intrin-

sic, functionally unresponsive state has become the general definition for anergy.

Why are the lysozyme-specific B cells not negatively selected in the bone marrow by a central tolerance mechanism? When the gene encoding the transgenic BCR light chain was inserted into the immunoglobulin kappa locus, receptor editing was observed *(507,508)*. If lysozyme was then introduced as a transgene expressed in a membrane-bound form, all of the developing B cells underwent editing; however, if lysozyme was introduced in a soluble form, only 50% of the B cells escaped by editing *(29)*. The other 50% were found in the spleen arrested between the immature T1 (CD23^{low}) and T2 (CD23^{high}) stages *(509)*. The cells still expressed the transgenic BCR and were in an anergic state. B-cell tolerance to secreted self-antigens is thus different from that to antigen presented in a membrane-bound form. From the early *in vitro* experiments of Metcalf and Klinman (38) it is clear that to induce B-cell tolerance a molecule must be presented in a multivalent form, be present at a high enough concentration, and react with the BCR with a high enough affinity. The affinity of the transgenic BCR for lysozyme is 2×10^9 M^{-1} *(334)*. The importance of antigen concentration was confirmed *in vivo* with a series of transgenic mice that expressed lysozyme at different circulating levels (510). When the serum concentration was greater than 10^{-10} M, the B cells were anergic and the animals were tolerant, even if they were immunized in Freund's complete adjuvant with lysozyme coupled to a foreign carrier to provide T-cell help. Below 10^{-10} M, the animals were still tolerant at the T-cell level, but they could make a normal high-affinity antibody response if given heterologous T-cell help. This model for natural tolerance is also consistent with the early mouse experiments of Chiller et al. (511) done with injection of the foreign antigen human gamma globulin, where the soluble antigen dose required to tolerize T cells was lower than that required to tolerize B cells. Both these experiments support the notion that available antigen concentrations can produce situations in which only the T-cell compartment is unresponsive. The absolute concentrations required to tolerize a particular B cell will obviously vary with the affinity of the receptor; but the valency of the antigen is also critical. Basten et al. *(512)* have suggested that the tolerogenic form of lysozyme is in fact molecules bound to a high-molecular-weight serum protein, a modification that presumably would make the lysozyme multivalent. However, why this form of antigen induces anergy while a membrane bound form induces central tolerance is still not clear.

The most striking characteristic of the anergic state is a 90% reduction of IgM on the surface of the B cells resulting from endocytosis and a block in IgM re-expression during transport from the endoplasmic reticulum to the Golgi *(513)*. IgD levels are normal, as are other surface markers such as B220 and CD24. Hence, the cells are still capable of binding lysozyme and the antigen was detected

on the surface of B220$^+$ cells freshly isolated from both the bone marrow and the spleen. When the BCR transgenic was crossed to an inducible lysozyme transgenic, which expressed tenfold lower levels of circulating antigen, the B cells were not tolerant and no decrease in surface IgM was noted *(514)*. Interestingly, if these animals were then fed zinc in their drinking water, induction of the metallothionein promoter of the lysozyme transgene enhanced the circulating concentrations of lysozyme by 70-fold during a 4-day period. During this time membrane IgM gradually decreased on the surface of all the transgenic BCR-bearing B cells, eventually reaching the low levels found in the initial double-transgenic mice previously described. These mature cells appeared to have been tolerized as they failed to respond well to lysozyme-RBC conjugates when adoptively transferred into irradiated mice along with horse RBC-primed helper T cells. Similar results were observed when B cells from the BCR-transgenic mice were transferred into a lysozyme transgenic mouse expressing high levels of circulating antigen. Thus, the anergic state could be induced in mature adult B cells within 4 days.

The impairment in anergic B-cell activation appears to be at the level of BCR signaling because activation for proliferation through either CD40 or TLR-2/4 is unaffected in the absence of antigen *(515,516)*. Biochemically, the anergic block is at the earliest events in signal transduction, as tyrosine kinase activity is greatly reduced *(517)*. In the presence of antigen, the IgD receptor continuously recycles between the plasma membrane and endosomes, and a large fraction is always found intracellularly, in contrast to the BCR on nonanergic B cells (518). This results in diminished calcium oscillations and a failure to activate the transcription factor NF-κB, as well as the JNK MAP kinase pathway *(519)*. In contrast, activation of the NF-AT transcription factor and stimulation through the ERK pathway is normal. The former induces the negative regulator CD5, while the later inhibits plasma cell differentiation *(520,521)*. The BCR signaling block prevents the normal up-regulation of the B7 costimulatory molecules *(522,523)*. Finally, PKC-δ is required to achieve an anergic state as shown by the development of autoimmunity instead of anergy when a PKC-δ–deficient mouse was crossed onto the lysozyme double-transgenic background *(524)*. PKC-δ seems to be necessary for the IgD endocytosis (518).

The anergic state can be reversed in culture by stimulation with LPS *(515)*. Although the initial proliferative response is somewhat less than for normal B cells, the anergic B cells fully re-express surface IgM by 2 days and after 3 days their antibody production increases. If antigen was included in the culture along with LPS, however, the B cells' ability to secrete antibody remained inhibited, even though they proliferated just as well during the treatment. This suggests that BCR occupancy by antigen is the critical signal for maintaining the state as well as inducing it. In this sense anergy can be viewed as a BCR-desensitization process stemming from the constant signaling of the receptor.

The fate of anergic B cells *in vivo* was examined by bromodeoxyuridine-labeling studies to determine the turnover of the cells *(525)*. In contrast to normal mature B cells, which have a half-life of 4 to 5 weeks, anergic B cells were found to last for only 3 to 4 days, and they tended not to enter into lymphoid follicles during their migration *(526)*. The rate of emergence of B cells into the mature pool was similar for the two types of cells, suggesting that anergic B cells died more quickly in the periphery *(525)*. These events, however, occurred only in the presence of antigen. If the anergic B cells were adoptively transferred into irradiated, antigen-free recipients, the cells survived as long as normal B cells *(515,526)*. Interestingly, their IgM levels returned to normal after 5 to 10 days, but when challenged with antigen, they still did not respond well. Thus, decreased IgM serves as a marker for some anergic cells, but it is not the only component needed for the unresponsiveness.

Surprisingly, the fate of the anergic cells in response to antigen and T-cell help turned out to be cell death *(527)*. Nontolerant B cells from the BCR single-transgenic mice proliferated and made antibodies against lysozyme when stimulated with antigen in the presence of CD4$^+$ T cells from a lysozyme-specific TCR transgenic. In contrast, if the B cells came from a double-transgenic mouse, where they had been exposed continuously to soluble circulating lysozyme, the anergic B cells underwent cell death by apoptosis in response to the same stimulus. Death was prevented on a CD95-deficient (lpr) background, suggesting that the Fas/Fas ligand pathway was necessary for the killing. Subsequent studies demonstrated that the CD40 receptor also had to be engaged in order to obtain cell death, because signaling through CD40 was required to up-regulate Fas expression on anergic B cells (528). Normal transgenic B cells did not die under the same circumstances and in fact required both CD40 ligation and Fas expression for optimal clonal expansion and antibody production (528,*529*). If, however, BCR occupancy by antigen was bypassed, by pulsing the B cells with the peptide recognized by T cells, then even nontolerant B cells were killed (528). These results suggest that for mature B cells signal two alone (as might occur in certain bystander situations) can be tolerogenic. Thus, signaling through the BCR is critical for determining the outcome of helper T-cell/B-cell interactions, and, presumably, anergic B cells die because of their partial block in BCR signaling.

In contrast, two other groups were able to get the anergic B cells to make an antibody response in an *in vivo* adoptive transfer system by providing antigen-specific T-cell help *(516,529)*. In the lysozyme system they achieved this by immunizing with the antigen in CFA *(516)*. One interpretation of this result is that the PAMPS and danger signals provided by the adjuvant induced the up-regulation of antiapoptotic proteins (such as bcl-2), which counteract

the elevated levels of Bim present in anergic B cells, and thus protect the cells from apoptosis (530). In a like manner, anergic B cells survive poorly when in the presence of other B cells because of competition for the costimulatory molecule BAFF, which maintains B-cell viability through enhancement of the levels of NF-κB p52 and the prosurvival kinase Pim2 (530). When on their own, however, a large fraction of the anergic B cells survive much longer as there is now sufficient BAFF available per cell to stimulate them adequately through the BAFF-R. Low levels of CD40 signaling from CD40L engagement can also help sustain these cells (531).

Recently a number of investigators have examined BCR transgenics specific for autoantigens involved in systemic lupus erythematosus pathogenesis such as double-stranded (ds) and single-stranded (ss) DNA and the ribonucleoprotein Smith antigen (Sm) (529,532). Several of these transgenes were placed on a Rag2$^{-/-}$ or a C$\kappa^{-/-}$ background to eliminate complications in the phenotype stemming from receptor editing. These studies have revealed a spectrum of tolerance states that the B cell can adopt to suppress antibody production against self-antigens. At one extreme is a high-affinity BCR for ds-DNA in which all of the cells in the transgenic mouse are deleted in the bone marrow (533). In contrast, another transgenic with the same heavy chain and a different light chain showed modest deletion in the bone marrow and a significant cohort of cells surviving in the spleen (534). The latter manifested an unusual surface phenotype that was immature for B-cell maturation markers, for example, CD24^{int}, but showed the presence of activation markers such as CD44^{high}. Their IgM levels were decreased tenfold and the cells did not proliferate *in vitro* to either LPS or anti-IgM stimulation. They also did not differentiate into antibody-secreting cells. This anergic state could be partially overcome *in vitro* by stimulation with CD154 and IL-4, which restored IgM expression, tyrosine phosphorylation of Syk, up-regulation of B7, and proliferation. However, the cells did not differentiate into antibody-forming cells even if IL-5 was added to the cultures. *In vivo*, the anergic cells were found only at the T-B interface of splenic follicles; they did not secrete antibodies; and they had a very fast turnover rate, suggesting that they were dying quickly. However, if given strong T-cell help, the B cells lost their anergic phenotype and secreted autoantibody (529). Interestingly, this secretion could be prevented if the anergy was reversed in the presence of CD4^{+}CD25^{+} Tregs.

At the other end of the spectrum are transgenic mice with BCRs specific for ss-DNA (535) and one with a low-avidity BCR for Sm (532). In both cases, the B cells fully matured and had a normal follicular distribution and lifespan. IgM levels were normal or only slightly decreased and signaling for tyrosine phosphorylation of Syk and increases in intracellular calcium were intact. Nonetheless, the cells showed decreased antibody and proliferative responses to both LPS and anti-IgM stimulation *in*

vitro and did not secret antibody *in vivo*. The proliferative block could be overcome by addition of CD154 and IL-4 to the anti-IgM, but antibody production was still impaired, most likely because of continued antigen stimulation of the ERK Map kinase pathway (520). This maturational arrest occurs at an early CD138^{+} preplasma cell (Blimp-1–negative) stage and is followed by B-cell apoptosis (536). Overall, this anergic state appears to be less profound than that observed for B cells in the soluble lysozyme double-transgenic mouse, while the lysozyme BCR transgenic is less repressed than the state for ds-DNA. These experiments suggest that B-cell anergy (like T-cell anergy) can exist at different levels, consistent with the tuning idea of Grossman and Paul (537).

B-Cell Clonal Deletion

The first experiments to show peripheral clonal deletion with BCR transgenic mice were done by Russell et al. (538) using a receptor specific for the K^{b} MHC class I molecule. This mouse was crossed to an MHC transgenic mouse expressing K^{b} in the liver, pancreas, and kidney, under the control of a metallothionein promoter. The double-transgenic offspring had only a few transgene-receptor positive B cells in the spleen and lymph node, although there were large numbers in the bone marrow. Because the number of B220^{+} cells was also greatly reduced in the peripheral lymphoid tissues and because no mRNA encoding the transgenic receptor could be detected, it was concluded that the B cells had been deleted. Thus, B-cell recognition of K^{b} in certain peripheral tissues, even with low affinity in this particular case, resulted in a tolerant state. The mechanism of this tolerance is likely to be clonal deletion, but cells undergoing apoptosis were not detected. In contrast, expression in thyroid epithelium of a membrane-bound form of lysozyme under the control of a thyroglobulin promoter did not lead to either clonal elimination or functional inactivation of BCR-transgenic B cells specific for lysozyme (539). The reason for the discrepancy between the two models is not known, but may relate to the accessibility of naive B cells to the antigen in the different target tissues.

In general, once a B cell has been activated by a foreign antigen and divides, many of its progeny terminally differentiate into antibody-forming cells and die. This process is retarded in *lpr* and *gld* mice because of genetic defects in the Fas or Fas ligand molecules required for cell death (540). These mice get an antibody-mediated autoimmune disease similar to systemic lupus erythematosis in humans with the production of anti-ds DNA autoantibodies and the development of glomerulonephritis (541). B-cell death is also impaired in bcl-2 transgenic mice, which express the antiapoptotic bcl-2 protein at high levels in the B-cell lineage (542). These mice get B-cell lymphomas (543) as well as autoimmunity (544). Based on these indirect experiments it is assumed that apoptotic cell death is a

normal part of the B-cell response to foreign antigens and that this is at least in part Fas/FasL-mediated. The observations also suggest that Fas-dependent death helps maintain self-tolerance by deleting peripheral B cells that have generated autoreactive receptors.

A substantial portion of the activated B cells also migrate to germinal centers where they undergo the process of somatic hypermutation *(545)*. These B cells first remove the BCR from their surface, undergo several rounds of division, and re-express mutated immunoglobulin receptors *(546)*. The cells then undergo a negative selection process similar to that of transitional B cells. The antigen is provided from antigen-antibody complexes on follicular dendritic cells *(547)*. Survival requires the receptor to be of high enough affinity to out-compete the already circulating antibody and allow B-cell uptake and processing of antigen for display of peptides to primed helper T cells, which have also moved into the germinal centers (*545*,*548*). If the B cell receives T-cell help it survives and is stimulated to undergo another round of expansion and differentiation. If T-cell help is not received, the B cells can become anergized or die by apoptosis. Apoptotic cell death was demonstrated by two groups by giving large amounts of soluble antigen at the time of optimal germinal center formation (*549*,*550*). The antigen was selected to either lack the critical T-cell determinant required for help or deaggregated by ultracentrifugation (in the manner of Dresser *[346]*) to reduce APC processing for T-cell activation. In each case, the high-affinity B cells, located in both the germinal centers and the nearby lymphoid zones rich in T cells, underwent apoptosis rather than the affinity maturation seen with T-cell help. Thus, just as for transitional B cells, signaling of primed B cells in the absence of T-cell help can result in deletional tolerance. In the opposite vein, if excess costimulation is provided by microbial infection, then even low-avidity T cells that have escaped central tolerance might migrate into germinal centers and provide help to low-avidity cross-reactive or somatically mutated autoreactive B cells. An ENU-induced mutation in an E3 ubiquitin ligase that normally down-regulates mRNA stability, resulted in an overexpression of CXCR5, ICOS and IL-21 in all its T cells *(551)*. This led to an excess of follicular T cells in an increased number of germinal centers, and resulted in high titers of autoantibodies and a lupus-like immunopathology.

TOLERANCE INDUCTION IN MATURE T CELLS

Activation-induced Cell Death and Homeostasis

The frequency of responding T cells in an MLR is quite high, ranging from 2% to 5% of the $CD4^+$ T-cell population *(552)*. Proliferation following priming does not in-crease this frequency, suggesting that many of the dividing cells must die *(553)*. Sprent *(554)* and Sprent and Miller *(555)* followed the fate of the reactive cells in this assay by isolating 4-day blasts from the thoracic duct of F_1 mice injected with parental cells, labeling the cells and transferring them back to syngeneic parental hosts. These cells homed to the spleen and intestine and then most of them disappeared, appearing to die *in situ* and be degraded by macrophages or be excreted into the lumen of the gut over a 2-week period. Only a few survived to become memory cells, which were capable of responding more rapidly.

Modern studies on the fate of T cells stimulated with superantigens have confirmed these early findings with alloreactive T cells. Injection of spleen cells expressing Mtv-7 into mice lacking Mtv-7 (556) or injection of staphylococcal enterotoxin B (SEB) *(557)* or A *(558)* into strains expressing $V\beta8$ and/or $V\beta3$ T cells, results in an initial expansion of the reactive T cells followed by extensive death via apoptosis. This is not simply a phenomenon observed with superantigens because transfer into male nude mice of spleen cells from a transgenic female mouse expressing the $TCR\alpha\beta$ anti-H-Y receptor resulted in a similar expansion and disappearance of $CD8^+$ T cells (559). The general pattern of response to all of these stimuli is shown in Figure 29.3.

The biochemical pathway responsible for signalling the cell to die is still not fully understood. *In vivo* studies have suggested that killing of $CD4^+$ T cells can be mediated by reactive oxygen species *(560)*. Also in an *in vitro* reactivation model it was shown that IFN-γ produced by activated $CD4^+$ cells could stimulate granulocytes to make NO and reactive oxygen intermediates, which in turn killed the activated $CD4^+$ cells *(561)*. For death receptor (e.g., Fas)-mediated killing, the activated T cell is initially resistant because the cells express a signaling antagonist called *c-Flip (562)* and because the costimulation accompanying T-cell stimulation increases the synthesis of antiapoptotic bcl-2 family members such as Bcl-2 and Bcl-X_L (190,420). When the latter decay, however, the proapoptotic BH3-only molecule Bim predominates and the cell becomes vulnerable to apoptotic cell death (563). If restimulated through the antigen-receptor, the surviving cells can now be killed by a rapid re-expression of Fas or TNF ligands (*564*,*565*) (see discussion of active death in Chapter 27). Other cells die simply when their growth factors are withdrawn (passive death) *(566)*. This last mechanism involves down-regulation of the glucose transporter, atrophy of the cell, and mitochondrial changes leading to cytochrome c release and apoptosis (567). These mechanisms are important for maintaining peripheral tolerance as shown by genetic mutations in their pathways (e.g., *lpr* [Fas] and *gld* [FasL]), which lead to autoimmune disease *(568)*.

Several experiments have demonstrated that the initial expansion phase of the T-cell response is started by the
FIGURE 29.3 The general pattern of *in vivo* responses of CD4$^+$ and CD8$^+$ T cells to superantigen and antigen stimulation. The response of Vβ8$^+$ T cells to staphylococcal enterotoxin B is shown as a model. The response occurs in four phases. During the first 12 hours, the massive release of cytokines from memory T cells can result in significant cell death in the stimulated cells. In the second phase, the remaining stimulated cells divide, increasing two- to eightfold over a period of 4 days. In the third phase, CD4$^+$ T cells die off rapidly but leave a residue of cells that appear to be anergized. In the fourth phase, the anergized cells slowly disappear. CD8$^+$ T cells, in contrast, slowly decrease in number from their peak expansion, returning to normal levels after 30 days. Whether these cells become anergic depends on the presence or absence of effective CD4$^+$ T-cell help.

first encounter with antigen and that the cells are then programmed under optimum conditions to go through four to eight rounds of division without any restimulation (569,*570,571*). At the end of this period the cells stop proliferating and then must receive further instructions to determine their fate. Death is only one possible outcome and all the quantitative parameters that influence the cell's fate at this point are not understood. CD28 signaling does not protect against activation-induced cell death induced by superantigens or antigen (572). Only LPS or proinflammatory cytokines such as IL-1 and TNF-α prevented it (572,*573*). One way these molecules act is through up-regulation of the IκB family member Bcl-3, which in expression experiments was shown to have antiapoptotic effects *(574)*.

Interestingly, only the CD4$^+$ T cells die rapidly at day 4 following SEB injection; CD8$^+$ T cells do not (Figure 29.3). Thus, a completely different explanation for CD4$^+$ T cell depletion has been proposed. Removal of CD8$^+$ T cells from the mice prior to SEB injection, by treatment with anti-CD8 antibody, prevented the rapid loss of CD4$^+$ T cells *(575)*. Similar results were observed with CD8 re-

moval in an EAE resistance model following secondary immunization with myelin basic protein (576). The authors postulated that the activated CD8$^+$ T cells kill off the activated CD4$^+$ T cells by a perforin/granzyme-mediated cytotoxicity mechanism involving recognition of the Qa-1 molecule. Recent experiments with Qa-1–deficient mice have demonstrated that both antigen- and superantigen-mediated CD4$^+$ T cell secondary expansion is greatly exaggerated in the knockout, which can lead to augmented autoimmune disease subsequent to decreased CD8$^+$ T-cell–mediated inhibition (577). The molecular mechanism for initiating this inhibition is not known, but may involve a TAP-independent, Qa-1 presentation of hydrophobic peptides derived from the CD4$^+$ TCR *(578–580)*.

One of the most interesting aspects of all these observations is that 90% of T cells responding to antigen or superantigen die. This is best understood in the context of homeostatic regulation of the immune system rather than antigen-specific tolerance per se. There is only so much space in the body for lymphocytes and room must be maintained for the influx of new naive cells from the thymus as well as the preservation of memory T cells for an extended period of time. Transfer of splenic T cells into nude mice showed that the cells could expand only until a critical cell number is reached (approximately 2×10^8 cells per mouse) *(581–583)*. Surprisingly, memory T cells and naive T cells were independently regulated, that is, each subpopulation did not influence the expansion of the other (584). Their half-lives were also controlled in different manners as many naive T cells were dependent on TCR recognition of self-MHC molecules for survival, whereas memory T cells were not *(585–587)*. The latter depended on cytokines such as IL-7 and IL-15 (*588*,589). In the immune response to a virus, Masopust et al. *(590)* have shown that the frequency of the responding antigen-specific cells increases dramatically over an 8-day period, up to a frequency of 80% or more of the total CD8$^+$ T cells in the spleen. As these cells begin to effectively eliminate the virus, however, their frequency drops and in the memory phase of the response it becomes only 1/300 to 1/1000 of the total CD8$^+$ pool *(591)*. Thus, homeostasis is maintained by allowing most of the newly generated cells to die by an apoptotic mechanism once the antigen is cleared *(592)*.

T-Cell Anergy

Anergy is a peripheral tolerance mechanism in which the lymphocyte intrinsically becomes functionally inactivated following an antigen encounter, but remains alive for an extended period of time as a hyporesponsive cell (406). The first description of a CD4$^+$ T-cell anergic state was in human (593) and mouse (351) clones and is now referred to as T-cell clonal anergy (406). Activation of CD4$^+$ Th1 clones to proliferate requires intact APCs. If the APCs are chemically treated with fixatives such as paraformaldehyde

and then used to present peptide antigens, the T cells do not proliferate. Instead, by 6 to 18 hours they have entered a new state in which they fail to make IL-2 or proliferate when restimulated with normal APC and antigen (351). The T cells are still alive because they can proliferate in response to added IL-2, and in fact this response brings them out of the state (594,595). Without IL-2 the unresponsiveness can last for several weeks in the absence of any further antigen addition. Simultaneous studies using planar lipid membranes, composed of MHC class II molecules on a plastic surface and pulsed with peptide antigen, induced the same state (353). This suggested that TCR occupancy was all that was required to induce clonal anergy. Subsequent reconstitution experiments supported this idea. Addition of untreated, allogeneic APC (which could not present the peptide), along with chemically fixed syngeneic APC and peptide, prevented the induction of the unresponsive state (352). It also reconstituted the initial proliferative response. This suggested that the fixed cells were presenting antigen properly but that the fixation prevented other signals from being delivered by the APC. No soluble cytokines were effective in substituting for the allogeneic APC, and eventually the CD28 molecule was identified as the costimulatory receptor on the T cell required for the IL-2 production (596). Agonist anti-CD28 antibodies were subsequently shown to prevent clonal anergy induction (597). The ligand on the APC could be either B7-1 (CD80) or B7-2 (CD86). The biochemical block in clonal anergy was subsequently shown to be at the level of activation of the Ras/MAP kinase pathway by inhibiting the usual increase in GTP-p21^{Ras} following TCR stimulation (598,599) Recent experiments suggest that this stems at least in part from an increased expression of the protein diacylglycerol kinase-α, which depletes the second messenger diacylglycerol by phosphorylating it; this prevents RasGRP1 from mobilizing to the plasma membrane and activating Raf (600,601). The block in MAP kinase activation prevents the induction of transcription factors such as AP-1, and this in turn prevents the production of IL-2 (602).

In addition to induction by TCR occupancy in the absence of costimulation, clonal anergy has also been achieved by stimulation with low-affinity peptide ligands (partial agonists) in the presence of costimulation (603,604). This stimulus represents a suboptimal activation of the T cell that is inadequate to drive the cell into division, but adequate to induce the dominant biochemical feedback mechanism(s) that blocks subsequent proliferative responses to normal activating stimuli. Both types of clonal anergy induction require activation of the calcium/calcineurin pathway with mobilization of NF-AT to the nucleus and activation of genes not requiring AP-1, such as Egr2/3 (605,606). Induction can be partially mimicked by calcium ionophore stimulation (605,607), but the fully stable state also requires other signaling pathways such as PKC activation (606). Activation of the MAP kinase

pathway is not required. Elevations of E3 ubiquitin ligases such as Cbl-b, Itch, and Grail have been implicated in the induction process (608,609,610). A role for the cell-cycle inhibitor p27^{kip1} has also been suggested for anergic states derived from costimulatory blockade (611,612). CD28 costimulation prevents anergy induction indirectly by its enhancement of IL-2 production, and subsequent IL-2R signaling to activate the downstream kinase mTOR (613). Thus, the drug rapamycin, which blocks mTOR function, favors anergy induction even in the presence of costimulation. How activation of mTOR prevents or reverses the increase in the level of diacylglycerol kinase-α, which maintains the state of clonal anergy, is currently not understood.

Murine T-cell clonal anergy is primarily a growth arrest state (406). The production of cytokines such as IL-2 and IL-3, which can augment T-cell proliferation, is strongly inhibited, while IL-4 production is unaffected (595). Instead, the proliferative response to IL-4 is blocked (614). C-C chemokine production is also unaffected and there is only a small effect on IFN-γ production in Th1 clones (615). This pattern, however, is not universal for all models of clonal anergy. In humans, antigen presentation by T cells to a CD4$^+$ T cell clone, even in the presence of costimulation, leads to an unresponsive state (593). In mice, overnight treatment of T-cell clones with just a calcium ionophore can induce a similar state (605). In these cases the anergic cells fail to produce IL-4 and IFN-γ in addition to IL-2. The cells also display a block in calcium signaling (605,616), which is not observed in other murine models (617), and which could account for their more profound inhibition. There are also cases of deeper states of clonal anergy in other murine systems (618,619). In several of these, CTLA-4 signaling has been shown to play a critical role in preventing certain of the T-cell responses and inducing anergy (423,424,620,621), but not in other models (425,426).

CD8$^+$ murine T-cell clones can also be induced into a clonal anergic state by antigen/APC stimulation in the absence of costimulation (622). The phenotype is again an inhibition of IL-2 production and proliferation with little effect on IFN-γ production or CTL activity. More recently, a form of clonal anergy has been described following CD8$^+$ T-cell stimulation called *activation-induced nonresponsiveness* (AINR) (474). This state ensues several days after optimal T-cell stimulation through the TCR, CD28, and the IL-12R. The CD8$^+$ T cells lose the capacity to proliferate in response to the continued presence of antigen (623). They also lose their ability to make IL-2, but retain effector functions such as IFN-γ production and CTL activity. AINR biochemically resembles the clonal anergic state of CD4$^+$ T cells in that activation of all the MAP kinase pathways (ERK, JNK, and p38) is inhibited (624). Also similar is the fact that AINR can be overcome if large enough quantities of IL-2 are provided either by CD4$^+$ T-cell help or by IL-2 added exogenously during the course of the immune

response (625). The induction of AINR even in the presence of B7 costimulation and some division is presumably because the CD8$^+$ T cells cannot produce enough IL-2 on their own (usually 1/8 of what a CD4$^+$ T cell produces under optimal stimulation conditions *[626]*) to generate sufficient mTOR activation. This phenomenon helps to make long-term CD8$^+$ T cell expansion dependent on CD4$^+$ T-cell help *(627)*.

The first description of an anergic state *in vivo* was made in mice injected with superantigens (628). In animals given SEB or Mtv7$^+$ spleen cells, there remains a population of Vβ8$^+$ CD4$^+$ T cells that fails to proliferate or produce IL-2 on restimulation with the superantigens *in vitro (629–631)* (Figure 29.3). These cells stay in this functionally unresponsive state for weeks, especially if the animals have been thymectomized, but eventually the state reverses or the cells disappear (556,*558*). Similar phenomena were observed in radiation-induced bone marrow chimeras expressing MHC Class II E molecules and Mtv7 solely in cells of the irradiated host (632). The Vβ6$^+$ and Vβ17$^+$ T cells (CD4$^+$ and CD8$^+$) interacting with the Mtv superantigen were not deleted, although these cells (either mature thymocytes or peripheral lymph node cells) appeared to be functionally unresponsive in a MLR *in vitro* as well as in a graft-versus-host response following adoptive transfer *in vivo*. Furthermore, attempts to directly stimulate the cells to proliferate using anti-Vβ antibodies on a plate were unsuccessful. Addition of exogenous IL-2 gave only a partial recovery of the proliferative response, suggesting that both IL-2 production and responsiveness to IL-2 were blocked. Subsequent experiments showed that the unresponsive state could be reversed if the T cells were cultured in the absence of antigen (either *in vitro* or *in vivo*), thus proving that the cells had not been deleted *(633)*. This tolerance process most likely ensued in the thymic medulla, but it is not clear at which T-cell stage.

Such observations were extended to conventional antigens with TCR transgenic mice either by crossing them to a mouse expressing the antigen they recognized or by transferring their mature T cells directly into this second mouse (559,634,*635–637*). In the H-Y transgenic model described earlier (638), the CD8$^+$ T cells become unresponsive when the cells are put into an environment in which the male antigen they recognize is highly expressed and cannot be eliminated (e.g., following transfer into a male nude mouse). If the CD8$^+$ T cells are subsequently removed from this environment and placed in a female nude mouse, they recover their function *(639)*. Dependence of CD4$^+$ T cell unresponsiveness on the persistence of antigen has also been reported *(636)*. The unresponsiveness in these models has been called *adaptive tolerance* (406), and appears to be similar to anergic states seen following certain persistent viral and bacterial infections (*640,641,642*). Another possibly similar *in vivo* anergic state has been described when CD4$^+$ transgenic T cells are first transferred into a syngeneic host and then stimulated with soluble peptide ligand in the absence of a costimulatory signal such as LPS *(643)*.

The unresponsive state for both CD4$^+$ and CD8$^+$ T cells involves a failure to produce IL-2 on restimulation with the antigen and APC; however, the production of other cytokines varies with the model. In many cases, all cytokine production is inhibited *(636)*, while in others the cells were found to make IL-10 (634). Proliferation in most of these models is inhibited, and a few also show a failure to respond to IL-2. In all of them, the T cells regain responsiveness if they are transferred into an environment that is no longer expressing the antigen *(633,636,637,643)*. If transferred into a host expressing the antigen, the T cells can sometimes even go into a more profound unresponsive state *(636)*. Persistent antigen expression is the critical variable determining the fate of the T cells *(644)*, with repetitive low doses favoring deletion and high doses favoring anergy *(645)*. Even if the T cells are initially activated in the presence of strong costimulation (such as anti-CD40), their eventual fate is tolerance if the antigen persists *(637)*.

A number of biochemical studies have been done with the *in vivo* models involving TCR transgenics, because there is a large enough number of cells to study. It appears for many of them that the anergic state represents a block at the earliest steps of TCR-induced tyrosine phosphorylation *(631,646–648)*. Activation-induced ZAP-70 phosphorylation is generally reduced and the downstream phosphorylation of the LAT adaptor molecule is strongly inhibited *(648–650)*. This impairs PLC-γ1, Grb2-mSOS, and RasGRP1 activation, resulting in inhibition of both calcium mobilization and activation of the Ras/MAP kinase pathway. This pattern is different from some of the *in vitro* clonal anergy models *(648)*. In addition, the individual *in vivo* models show their own idiosyncrasies. For example, in the superantigen models, Cbl-b appears to play a critical role in maintaining the unresponsive state (608,*609*), as does an enhancement in the activity of the p38 pathway *(651)*. The former acts in preactivated T cells by ubiquitination and targeting of PLC-γ1 for degradation; the latter acts by inhibiting activation of the ERK pathway. Neither of these components, however, plays a critical role in adaptive tolerance. Similarly, a key role has been demonstrated for CTLA-4 signaling in the anergy induced by soluble peptide stimulation *(423)*, but it plays no role in the onset of adaptive tolerance *(426)*. Overall, these studies suggest that there may be multiple ways in which a T cell can exert negative feedback on its TCR signaling pathways. Thus, *in vivo* anergy models may have several different molecular mechanisms operating to ensure unresponsiveness.

What is the biological purpose of *in vivo* anergy? Because in many cases the state reverses when the antigen is removed, perhaps it represents an adaptation of the cell to the persistence of antigen in its environment, a form of TCR desensitization consistent with the Tunable Activation Threshold model of Grossman and Paul (537). In a

CD4 adaptive tolerance model, it was possible to show that the biochemical and functional response to the same dose of antigen of a TCR transgenic, anergic population varied depending on the level of chronic antigen exposure responsible for first inducing the state *(652)*. Thus, the function of the anergic state would be to retain a potentially useful cell in a harmless mode by raising its threshold for activation for a certain period of time until a decision can be made as to whether it is autoreactive or critical for host defense. The half-life of these cells in the absence of other T cells is long, but in the presence of normal T cells the anergic cells disappear more quickly by an unknown competitive or suppressive mechanism (653). In these transgenic models, the anergic T cells often retain partial effector functions and can eventually cause autoimmunity (653,*654*). In the case of chronic viral infections, however, the dampening of proliferative capacity is followed by the dampening of effector function: B-cell help for CD4$^+$ cells and TNF-α and IFN-γ production as well as CTL-activity for CD8$^+$ cells (641,*655*,*656*). In CD8$^+$ T cells the anergic state has been called *functional exhaustion*. It can be tuned to different levels of unresponsiveness, at least partly depending on signaling through the PD-1 receptor *(430)*. The anergic antiviral CD4$^+$ and CD8$^+$ cells persist for a long period of time even in the presence of normal T cells, possibly because the viral load continually fluctuates from replication or because the virus continues to elicit danger signals and costimulation. Premature entry into this anergic state can have deleterious effects, such as impairment of an effective immune response to a subsequent viral infection *(657)*. However, if appropriately timed with the clearance of the virus it can reduce immunopathology. When this state is induced in the thymus, it can also serve as a central tolerance mechanism in cases where the antigen is expressed both there and in the periphery *(658)*.

IMMUNOREGULATION

Once an immune response is underway, the nature of that response can feed back on the system in a number of ways to focus it on particular effector functions or to inhibit immunopathologic consequences. This section will briefly outline some of these mechanisms as they can formally be considered tolerance mechanisms when the immune system fails to reject the antigen because of them. A number of these topics, however, are covered in much greater detail in other sections of this book.

Immune Deviation (Th1 vs. Th2 and Th17 CD4$^+$ helpers)

The phenomenon of immune deviation was first described by Asherson and Stone (659). They injected guinea pigs with soluble or alum-precipitated antigens 2 weeks prior to challenge with the same antigen in Freund's complete adjuvant. The pretreatment prevented the usual delayed-type hypersensitivity (DTH) response measured as 24-hour skin reactions on rechallenge. In contrast, antibody production was normal, although the class of antibody was deviated from IgG2 toward IgG1 *(660)*. Parish and Liew (661) subsequently discovered a general reciprocal relationship between antibody production and DTH reactions as a function of antigen dose. When small doses of antigen were administered, the immune response was predominantly DTH. As the antigen dose was increased, an antibody response was observed, while the DTH response diminished. At very high doses of antigen, the antibody response also declined and in some cases the DTH response re-emerged. With the introduction of T-cell cloning technology, Mosmann et al. *(662)* discovered that fully differentiated mouse T-cell clones generally exhibit one of two discrete lymphokine production profiles *(662)*. Th1 cells make IL-2, IFN-γ, and TNF-β, while Th2 cells make IL-4, IL-5, and IL-13. This cellular dichotomy provided a potential explanation for immune deviation because these two cell types could cross-regulate each other. Lymphokines produced by Th1 cells turned out to be primarily mediators for stimulating macrophage activation via induction of IFN-γ and complement fixing IgG$_{2a}$ antibodies, as well as CD8 T-cell activation for viral clearance, while those produced by Th2 cells were primarily activators of eosinophils and mediators of helper T-cell function for IgG$_1$ and IgE antibody production to aid in the clearance of parasites (663,*664*). The cross-regulation is also mediated by these lymphokines. Thus, IFN-γ produced by Th1 cells inhibits the proliferation of Th2 cells *(665)* by blocking costimulation by IL-1 *(666)*. A comparable antagonism occurs within the Th1 cell, where up-regulation of the transcription factor T-bet opposes the expression of the Th2 master regulator GATA-3 *(667)*. In a reciprocal manner, in Th2 cells GATA-3 expression inhibits STAT4 and the IL12Rβ2 protein preventing IL-12 augmentation of Th1 differentiation *(668)*. In naive cells IL-4 signaling also prevents colocalization of the IFN-γ receptor with the TCR at the immunologic synapse, which impairs Th1 development *(669)*. The initial discovery of IL-10 was as an inhibitory cytokine produced by Th2 cells *(670)*. It prevented the stimulation of Th1 cells by blocking APC function and by preventing lymphocyte production of IL-2 and TNF-α *(670,671)*. However, subsequent work showed that both cell types could produce IL-10 (672) and that it primarily facilitates the generation of T-regulatory 1 (Tr1) cells from naive CD4$^+$ T cells (673). It also can augment the effector function of both B cells *(674)* and CD8$^+$ T cells *(675)*. Thus, IL-10 is now generally thought of as immunosuppressive for both Th1 and Th2 cell differentiation.

The forces that operate to determine the dominance of Th1 versus Th2 cells in any given immune response are not completely understood. The dose of antigen is critical

and the genetic constitution of the responding individual determines which particular doses are perceived as high and low. In the *Leishmania major* parasite model, BALB/c mice make predominantly a nonprotective Th2 response, whereas C3H and C57BL/6 mice make predominantly a protective Th1 response *(676)*. If, however, the BALB/c mice are inoculated with a minute number of parasites (less than 30), they become protected against a normal challenge dose because of immune deviation toward an IFN-γ response *(677)*. The antigen specificity of the response is also a critical variable. A single immunodominant determinant of the *Leishmania* is recognized in the early response of the BALB/c mouse *(678)*. If tolerance is induced to the protein containing this determinant, then the mouse mounts a protective Th1 immune response *(679)*. Another critical parameter is the cytokine milieu. High concentrations of IL-4 deviate the response toward Th2 (680), while high concentrations of IL-12 deviate the response toward Th1 *(681)*. Furthermore, the molecular form of the antigen is also influential, with particulate antigens favoring macrophage uptake and IL-12 production, which helps skew the response toward a Th1 phenotype *(681,682)*. CD8$^+$ T cells can similarly be affected by these parameters to give rise to Tc1 and Tc2 cells (683).

Recently another subset, Th17, has been described that augments recruitment of neutrophils to sites of inflammation to deal with extracellular bacterial pathogens (684). This subset is uniquely induced by the combined stimulation of naive T cells with IL-6 and TGF-β *(685–687)* through activation of the orphan nuclear receptor RORγt *(688)*, and is augmented in number and survival by subsequent stimulation with IL-23, once the IL-23R is induced *(689–691)*. The molecular details of how this subset is regulated have not yet been fully worked out, but it is already clear that Th1 and Th2 cells compete with it and that IFN-γ and IL-4 negatively regulate Th17 generation *(692,693)*. Thus, the principle of class regulation of the immune response by different T-cell subsets will most certainly be a generalizable phenomenon. A tolerance process could then be defined from this regulation as one that deviates the immune response toward a class of effector cells that does not cause immunopathology.

Induced CD4$^+$ T Regulatory Cells (Tr1 and iTreg)

Tr1 cells were first discovered in severe combined immunodeficient (SCID) patients who had received HLA-mismatched hemopoietic stem cells and appeared to be tolerant *(694,695)*. The cells were CD4$^+$ and produced IL-10 on stimulation with host APC. They also made TGF-β, IL-5, and small amounts of IFN-γ, but not much IL-2 and no IL-4 *(696)*. They did not proliferate well when stimulated through their TCR and were described as anergic *(697)*. This clonal anergy also included a lack of IL-2R expression.

Most interestingly, the cells were found to suppress the activation of other naive and memory CD4$^+$ and CD8$^+$ T cells by indirectly inhibiting APC function, through down-regulation of both MHC class II molecules and costimulatory molecules *(675)*, as well as by directly inhibiting T-cell cytokine production: IL-2, TNF-α, and IL-5 *(671,698,699)*. Much of this suppression was of a bystander nature, mediated by the cytokines IL-10 *(700)* and TGF-β *(701)* released from the cells following antigen stimulation; however, in transwell experiments the suppression was only optimum if the two T cells were in contact, suggesting that there might also be cell-surface molecule(s) participating in the negative regulation (702). Tr1 cells can be differentiated from naive T cells in human by stimulating with antigen plus IL-10 and IFN-α *(703)*. In the mouse the cells emerge following antigen activation in the presence of vitamin D$_3$ and dexamethasone to suppress Th1 and Th2 responses *(704)*. They also can be induced by bone marrow-derived DC that had been previously exposed to IL-10 *(705)*. The major growth factor for Tr1 cells is IL-15 *(706)*. Naive CD8$^+$ T cells can also differentiate into Tr1-like cells in the presence of plasmacytoid DCs *(707)*.

The effector properties of Tr1 cells have many things in common with the CD4$^+$CD25$^+$Foxp3$^+$ nTreg population generated in the thymus (see earlier discussion). The possibility that such Tregs could also be induced in the periphery from CD4$^+$CD25$^-$ T cells was first raised for human T-cell populations *(708)*, and then more rigorously demonstrated in murine systems using low-dose antigen stimulation in thymectomized animals (709) and by transfer of monoclonal-naive TCR transgenic T cells into antigen-bearing hosts *(710)*. Subsequently it was discovered that such a switch could be greatly facilitated by stimulation with antigen/APC in the presence of TGF-β1 (711). Since then these so-called induced (or adaptive) T-regulatory cells (iTregs) have been generated under a variety of conditions including during transplantation tolerance *(712,713)* and chronic infectious diseases *(714,715,716)*. They are distinguished from Tr1 cells in terms of their expression of CD25 and Foxp3 and in terms of the cytokines that generate them (TGF-β1 vs. IL-10) (673). In functional properties, however, they are very similar. In fact, under some conditions both types of cells can be found at the same site of inflammation *(714,717)*. Under other conditions, however, they can inhibit different aspects of the same immune response *(717)*.

Tr1 and iTreg cells negatively regulate many cells in the immune system, including APCs, B cells, and T cells. In mouse models they can suppress Th1-mediated inflammatory bowel disease (698,718) as well as Th-2–mediated immediate hypersensitivity responses *(719)*, the latter by blocking IgE production and Th2 cell priming. For CD8$^+$ targets, TGF-β1–induced inhibition of granule exocytosis (initiated by Tregs) can prevent CTL activity *(259)*. In humans, Tr1 cells have been observed in patients tolerant

to kidney, liver, and bone marrow grafts, although a causal role in the tolerance process has not been established (673). Administration of alloreactive CD25$^+$ Tregs in bone marrow transplantation has been used to prevent acute graft-versus-host disease while sparing graft-versus-leukemia function *(720)*. In mice, pancreatic islet grafts have been facilitated by administration of IL-10 in addition to rapamycin *(721)*. In NOD mice these manipulations delayed disease onset by generating both Tr1 and iTregs. The former were found in the spleen and blocked proliferation and migration to the pancreas of effector T cells, while the latter were found in the islets of the pancreas and prevented diabetes *(717)*. In chronic infectious diseases caused by organisms such as the parasite *Leishmania major* (260) and the nematode *Onchocerca volvulus (722)*, the presence of Tr1 and/or Treg cells and their cytokine production (mostly IL-10) has been associated with persistence of the infection. Interestingly, the response can give rise to a state of concomitant immunity in which the host is resistant to rechallenge with the same parasite while still harboring the organism at a local site (260). This creates a state of equilibrium between host and parasite in which neither is completely destroyed by the other. In this regard a number of pathogenic viruses (Epstein-Barr virus, cytomegalovirus, and Pox) (723,724,725) have also taken advantage of the negative regulation of Tr1/iTreg cytokines such as IL-10 by evolutionarily capturing and modifying these genes for their own use in down-regulating host immune responses.

Mucosal Tolerance

The route of antigen introduction is a critical variable in determining the outcome of an immune response. Intravenous administration generally favors induction of tolerance *(726,727)*, whereas subcutaneous administration favors immunity (728). Intravenous injection might allow antigen presentation by costimulatory molecule-deficient naive B cells in the spleen *(729)*, whereas subcutaneous injection would favor uptake and presentation by Langerhans cells, which, following activation, are very effective at initiating immune responses in the draining lymph nodes *(730)*.

Oral and nasal administration of antigen have also been shown to favor tolerance induction (731,732). From the earliest studies of Wells *(733)* and Chase (734), it was clear that the oral route of administration induces some form of immunoregulation. Orally immunized animals usually make an initial systemic antibody response that subsequently diminishes (735). The tolerance state is often associated with large amounts of IgA production in the gut *(736)*. In other cases (e.g., for myelin basic protein), in which the antigen is administered in a form (peptides) preferentially recognized by T cells rather than B cells

(737), the immunoregulation has been reported to be mediated either by T cells that secrete TGF-β on antigen stimulation *(738)* or by induction of anergy and deletion *(739,740)*. The mechanism observed depends on the antigen dose, with high doses inducing direct inactivation of the antigen-specific T cells and low doses eliciting TGF-β–mediated immunoregulation *(741)*. These cells and cytokines precondition the environment of the gut so that APCs become educated to present antigen to naive T cells in a skewed fashion, propagating the induction of T cells producing IL-4, IL-10, and TGF-β *(742)*. Nasal administration of soluble proteins or peptides prevents or reduces ongoing Th1 IFN-γ responses by similar mechanisms. In this model, roles for $\gamma\delta$ T cells *(743)* and dendritic cells *(744)* secreting IL-10 have also been suggested.

The T cells in the gut, referred to as *Th-3 cells*, are unusual in that they can make substantial amounts of TGF-β following antigen stimulation *(745)*. This cytokine acts as a critical switch factor for B cells, favoring the production of IgA *(746)*. TGF-β, however, is also an anti-inflammatory cytokine that blocks T-cell proliferation by inhibiting IL-2 production and cell-cycle progression, although at the same time it also enhances T-cell survival *(747,748)*. TGF-β–deficient mice as well as mice harboring a dominant negative form of the receptor transgenically expressed in T cells develop inflammatory bowel disease, suggesting that this cytokine, like IL-10, is critical for anti-inflammatory immune regulation (749,750). After initial activation in the gut, Th-3 cells can leave and migrate to other sites in the body, where they can act as direct or indirect (bystander) suppressor cells, if they recognize their peptide/MHC ligand at that site and release TGF-β. In this sense oral tolerance is not really the absence of an immune response, but rather a form of immune regulation initiated in the gut to deal with the problem of the large number of commensal bacteria that colonize this tissue in a symbiotic fashion *(751,752)*. The relationship among Th-3, Tr1, and iTreg cells in the mucosa has not been clearly established. These cell types may represent a family of regulatory CD4$^+$ T cells whose members have differentiated in different places and times to produce (to varying degrees) the same set of inhibitory cytokines (IL-10 and TGF-β) required to provide negative feedback regulation on T-cell immune responses.

Indoleamine 2,3-Dioxygenase and Suppressive APC

A subset of plasmacytoid DCs (CD8α^+, CD19$^+$) can produce indoleamine 2,3-dioxygenase (IDO), an enzyme that catabolizes the essential amino acid tryptophan *(753)*. IDO expression is induced in these cells by either IFNs or LPS and TNF signaling (754,755). IDO can also be induced by cross-linking B7 molecules on the DC, which stimulates

IFN-α production and STAT1 and IRF1 signaling *(756)*. B7 cross-linking can be achieved experimentally with soluble CTLA4-Ig and it may be accomplished physiologically by CD4$^+$ regulatory T cells, which constitutively express CTLA4 on their surface (754). Mature DCs that express active IDO can inhibit T-cell expansion by depleting tryptophan in the environment *(757)*. This is sensed by the T cell as an increase in uncharged tRNA and leads to activation of the stress kinase GCN2, which inhibits entry into cell cycle *(758)*. Instead, the T cell enters an anergic state and can differentiate into iTregs in the presence of TGF-β *(758,759)*. Furthermore, toxic metabolites of tryptophan following its IDO breakdown to kynurenine (such as 3-hydroxy-anthranilic acid) can induce apoptosis in thymocytes and Th1 clones *in vitro (760,761)*. The role of IDO in immune responses *in vivo* has been explored by using the pharmacologic inhibitor 1-methyl-tryptophan to block the enzyme. This drug increased the severity of EAE *(762)* and inflammatory bowel disease *(763)* in mouse models and prevented CTLA4-Ig from facilitating islet transplantation *(756)*. When administered during pregnancy it resulted in rejection of allogeneic but not syngeneic fetuses *(764)*. In contrast, overexpression of IDO in tumors and lung tissue makes them resistant to rejection *(765–767)*. *In vitro*, IDO-expressing APC dominate, that is, they inhibit an MLR even when mixed with stimulatory APC not expressing IDO *(753,757,767)*. Although IDO has an inhibitory effect on the adaptive immune response, which favors the induction of tolerance, it can also function as an innate host defense because it inhibits the replication of pathogens that cannot synthesize their own tryptophan, such as *Toxoplasma gondii*, mycobacteria, and group B streptococci *(768–770)*. How the DCs maintain their own function and survival under these tryptophan-depleted conditions is still not understood.

CD8$^+$ iTregs and Anti-TCR Regulation

Studies on CD8$^+$ suppressor T cells in immunoregulation and tolerance were a dominant theme in cellular immunology in the 1970s. Looking back at those systems now, it is possible to classify some of them as forms of immune deviation. For example, CD8$^+$ T cells are particularly good at making IFN-γ *(771)*; thus, they should be capable of functioning as potent suppressors of Th2 and Th17 responses *(665,692)*. Furthermore, recent experiments have demonstrated that Th2-like CD8$^+$ T cells (Tc2) can be generated in the presence of IL-4 and these could function as suppressors in CD4$^+$ Th1 DTH responses (772,773). Thus, regulatory cytokines could provide a sufficient explanation for some of the old experiments.

One clear exception to this cytokine model, however, is the Qa1-restricted CD8$^+$ regulatory T-cell population discussed earlier (774). The original observation in the 1970s was that CD4$^+$ T cells were necessary to induce CD8$^+$ suppressor T cells and that this interaction required the presence of Qa-1 *(775)*. In rats, lines of these CD8$^+$ T cells could mediate resistance to EAE induction when transferred *in vivo (776)*. More recently the CD8 cells were shown to play a key role in the prevention of relapses in mouse EAE and to require Qa-1 for their generation *(575,576,577,777, 778)*. Interestingly, these CD8 suppressor cells showed specificity for the Vβ^+ subset of CD4$^+$ T cells involved in the response *(575,777)*. How this specificity is generated is not completely clear. Standard T-cell activation involves recognition of antigenic peptides bound to MHC molecules. However, the generation of regulatory T cells that can suppress an immune response by recognizing the receptor on responding T cells requires the recognition of unique peptides derived from that TCR. Evidence that this can occur comes from the EAE studies of Vandenbark and colleagues (779,780,781). The CD4$^+$ T-cell response to myelin basic protein in Lewis rats is dominated by cells expressing Vβ8. Animals immunized with a synthetic peptide corresponding to the CDR2 region of this Vβ were protected against the demyelineating disease. Not all TCR peptides were effective, presumably because of the failure of some to bind to that animal's MHC molecules. Thus, a possible regulatory mechanism is that the Qa1/TCR peptide-specific CD8$^+$ T cells generated are cytotoxic for the activated CD4$^+$ T cells expressing the Vβ8 receptor *(782)*.

Another model of CD8$^+$ suppressor T cells has been described in humans *(783)*. These cells were generated by multiple rounds of antigen stimulation and inhibited either alloantigen or protein antigen proliferative and antibody responses in a specific manner. The cells were subsequently shown to lack expression of CD28 and to express all the markers of CD4$^+$Foxp3$^+$CD25$^+$ Tregs *(784)*. However, they did not produce IL-10 or TGF-β. Their mechanism of action was through alteration of the APC (785). When the CD8$^+$ iTregs were activated by peptide/MHC class I complexes on the APC, they induced the expression of a pair of KIR-like inhibitory receptors, ILT3 and ILT4, on the APC surface *(786)*. These two molecules could also be up-regulated on DCs by IL-10 and/or IFN-α stimulation *(787)*. ILT4 recognizes the α3 domain of HLA class I *(788)* and, like inhibitory NK cell receptors, recruits a phosphatase to prevent calcium signaling and NF-κB-mediated up-regulation of B7 costimulatory molecules on the APC (785,789,790). ILT3, in contrast, directly alters CD4$^+$ T cells. In response to antigen presentation in its presence, CD4$^+$ cells up-regulate Foxp3 and become anergic instead of differentiating into effector cells *(787,791)*. This same effect could be achieved with soluble recombinant ILT3-Fc and this form of the molecule could induce new CD8$^+$ iTregs in primary mixed leukocyte cultures *(792)*. Thus, the net result from the actions of ILT3 and ILT4 is to induce naive T cells into the Treg lineage. This represents

another example of how a preconditioned APC can dictate the nature of the response by a naive T cell.

CD8$^+$ Veto Cells

A mechanism for directly tolerizing naive CD8$^+$ precyto-toxic T cells has been described that involves negative immunoregulation by previously activated CD8$^+$ cells (T cells or NK cells) *(793,794)*. In the model system, a population of precultured MHC-incompatible CD8$^+$ T cells was recognized by unprimed allogeneic CD8$^+$ T cells and the former inactivated the latter. Hence, the name *veto cells*. These cells acted late in culture (after 20 hours), mediated their effects by cell-cell interaction (not secreted products), and did not compete for lysis of target cells in the CTL assay (as they could be eliminated prior to the assay with anti-MHC antibodies and complement without reversing the effect) *(795,796)*. The TCR specificity of the veto cell did not matter and engagement of its TCR was not required for its veto function *(797,798)*. Instead, it was the recognition of cell surface peptide/MHC class I antigens on the veto cell by the responding CD8$^+$ T cell that led to the latter's inactivation. Evidence that the veto phenomenon can also operate *in vivo* has come largely from the experiments of Rammensee, Fink, and Bevan *(796,799–800,*801). Injection of splenic CD8$^+$ T cells into mice differing at MHC class I loci resulted in inhibition of a subsequent *in vitro* CTL response by the recipient's T cells against donor class I molecules.

A molecular mechanism for vetoing has been described that involves signaling back through the MHC class I molecule following its interaction with CD8 on the veto cell *(802)*. CD8-negative variants of clones otherwise capable of vetoing were found to lose their ability to veto. Furthermore, cell lines expressing the correct peptide/MHC complex, but which were not veto cells, became veto cells when transfected with a CD8 gene. Finally, a veto effect could be activated with peptide/MHC-positive, CD8-negative cells by adding a monoclonal antibody against the α3 domain of the MHC class I molecule (the molecular region for CD8 binding). Conversely, a CD8$^+$ veto cell could be prevented from killing by a monoclonal antibody against CD8, which blocked its interaction with the MHC molecule. These results suggest that the veto signal is initiated by the interaction of CD8 on the veto cell with the α3 domain of an MHC class I molecule on the target cell, but only when the latter cell simultaneously becomes activated through its TCR via recognition of a peptide/MHC molecule on the veto cell. The effect of this dual signaling by veto cells is to make the responding T cells susceptible to Fas/FasL-mediated apoptosis *(803,804)*. The function of this mechanism in self-tolerance is not clear, but it may play a role in eliminating autoreactive CD8$^+$ T cells specific for blast antigens expressed on activated CTLs. In a clinical setting CD8$^+$ veto cells raised against irrelevant third-party tar-

gets have been used to prevent graft rejection in allogeneic bone marrow transplantation using large doses of CD34$^+$ stem cells under minimal conditioning regimens such as treatment with rapamycin *(805–807)*.

Antibody-mediated Immunoregulation

Passive transfer of antibodies into a naive animal often prevents the priming of that animal with a subsequent injection of antigen (808). High-affinity antibodies are more effective than low-affinity ones *(809)*. Some of this effect is the result of formation and clearance of antigen-antibody complexes. The antibodies can also prevent the formation of particular peptides during antigen processing that are needed for T-cell recognition *(810,811)*. The antigen-antibody complexes are also likely to be responsible for the phenomenon known as *original antigenic sin* (*812*,813), in which memory B cells, generated during a prior exposure to a cross-reacting antigen, prevent or down-regulate the response to the unique new determinants on the antigen *(814)*. Memory B cells seem to have an advantage for rapid activation and this produces antibodies that feed back to inhibit the priming of naive B cells possessing receptors that are specific for unique determinants of the second immunogen. This feedback mechanism is most likely mediated through antigen-antibody complexes that interact with the FcγRIIb1 receptors on the naive B cells (815) and inhibit signal transduction through their IgM receptors by bringing the SHIP phosphatase into the receptor complex *(816,817)*. The sialylation state of the Fc core of the antibody is also critical for favoring its interaction with inhibitory Fcγ receptors *(818)*.

Anti-Idiotypic B-Cell Regulation

In 1974 Jerne *(819)* proposed that antibody production could be regulated by other antibodies that recognized unique idiotypic determinants in the V regions of the first antibody. He postulated that an increase in the production of the first antibody could negatively regulate the production of anti-idiotypic antibodies, and vice versa. Because of the interconnected pathways in such a network, perturbation of one segment would be dampened by the presence of other segments and thus the original steady state would be buffered.

In recent years, studies have focused on the analysis of IgM hybridomas from nonimmunized neonatal mice *(820)* or IgM antibodies derived from human cord blood Epstein-Barr virus–transformed B cells (46,48,821,822). Individual antibodies show the ability to react with several different self-ligands, many of which are intracellular proteins, such as cytoskeletal proteins *(47,48,821–825)*. In both species their major source appears to be B1 and marginal zone B cells *(49,50,826)*. The relation to immunologic networks is that these antibodies also interact with other members

of the set *(820,827)*. Administration of such antibodies to neonatal mice perturbs the B-cell repertoire and affects the subsequent adult response to particular antigens (828,829). This effect is either positive or negative depending on the timing and the antibody. Whether the natural dominance of B cells expressing certain idiotypes is related to such network interactions *(826)* or is due to early exposure to commensal bacteria *(830)* remains controversial. However, clonally dominant idiotypes emerge in germ-free animals *(831,832)* and can be disrupted in their appearance by early antigen priming with heat-killed bacteria *(833)*. Interestingly, the non–idiotype-positive antibodies elicited by the premature priming proved *not* to be protective for subsequent challenge with virulent bacteria, suggesting that the natural network-derived antibodies played a crucial role in host defense (829).

IMMUNE PRIVILEGED SITES

Transplant surgeons have known for a long time that certain areas in the body are more favorable than others for grafting of tumors *(834)* and normal allogeneic tissues *(835)*. In particular, the brain, the anterior chamber of the eye, and the testis in rodents as well as the cheek pouch in hamsters seem to be privileged in their capacity to accept grafts readily *(836)*. The idea thus emerged that antigens contained in these tissues could not be seen by the immune system because they were sequestered in some way, for example, by the blood–brain barrier or because the grafts failed to become vascularized (e.g., corneal transplants) (837). Subsequent studies, however, have shown that activated lymphocytes can migrate into most of these tissues *(838)*. Nonetheless, the tissues do have mechanisms for curtailing the initiation of an immune response. The nervous system has very few dendritic cells and little lymphatic drainage *(839)*. Instead, antigens end up via lymphatic links in the cerebrospinal fluid *(840)*. The hamster cheek pouch also has very few lymphatic vessels *(841)*. In fact, even the skin can be converted into a privileged site for primary grafts, if one surgically creates an alymphatic skin pedicle *(842)*. On the effector end, neurons express few if any MHC molecules, and, even in the presence of inflammatory cytokines, they only express low levels of MHC class I molecules for effector T cells to recognize *(843,844)*. Another mechanism by which a tissue may obtain privileged status, even if exposed to activated T cells, is by the expression of Fas ligand (845). This was first demonstrated for Sertoli cells of the testes *(846)*. In a transplantation model, testis grafts from normal mice survived indefinitely under the kidney capsule of allogeneic recipients while similar grafts from mice carrying a mutation in the Fas ligand gene (*gld*) were rejected. Similarly, in a tissue-destruction model, viral infection of the anterior chamber of the eye of *gld* mice caused mas-

sive tissue damage, whereas the same infection in normal mice resulted in Fas/FasL-dependent killing of the inflammatory lymphoid cells *(847)*. Fas ligand expression has been detected in both corneal epithelial and endothelial cells *(848)*.

Another mechanism that has been described to participate in the immune privilege of the eye is called *anterior chamber-associated immune deviation (849)*. Injections of exogenous antigens and allogeneic tissues into the anterior chamber results in a systemic impairment of the production of complement-fixing antibodies and DTH to that antigen, that is, Th1 responses are blocked *(850)*. The immune deviation appears to be an effect of inhibitory cytokines such as TGF-β secreted from the iris and ciliary body cells in the eye and IL-10 released from ocular APC *(851)*, as well as neuropeptides such as α MSH and vasoactive intestinal peptide released by corneal nerves *(852)*. These molecules alter the presentation properties of the F4/80[+] APCs in the eye. The APCs then migrate to the thymus *(853)* and spleen *(854)* where they induce NK T cells to make IL-10 *(855)*. The NK T cells, along with $\gamma\delta$ T cells *(856)* and B cells *(857)*, somehow induce Qa-1 class Ib–restricted CD8[+] regulatory T cells *(850,858)*. How these effector T cells suppress the CD4[+] DTH response in an antigen-specific manner has yet to be clearly elucidated *(859,860)*. Finally, recent studies have demonstrated that some privileged sites can favor the induction of T-regulatory cells in response to tissue grafts *(861)*.

THE FETAL-MATERNAL RELATIONSHIP

A number of examples exist in the reproduction of vertebrates in which one organism successfully grafts itself onto another as a parabiont, completely circumventing rejection by the host's immune system (862). Perhaps the most interesting example of this natural tolerance induction is in viviparous mammals, where the fetus successfully implants itself in the uterus *(863)*. When any inbred mammalian strain A female is mated to a strain B male, the (A × B)F$_1$ fetus expresses histocompatibility antigens of the father to which the mother is not tolerant; yet the fetus is not rejected. This is also true for completely allogeneic fetuses that have been experimentally created by embryo transfer *(864,865)*.

The possibility that the fetal trophoblast represents a privileged immunologic tissue was first tested by transferring day 2 fertilized (A × B)F$_1$ ova or day 7.5 F$_1$ ectoplacental cones under the kidney capsule of strain A females *(866)*. These grafts were not rejected even if the recipient had been primed with strain B skin grafts. Witebski and Reich *(867)* were the first to suggest that this protection from immune attack might be because the placenta does not express histocompatibility antigens. Evidence to support this idea is very good in primates *(868,869)*.

Syncytiotrophoblasts of the human fetus do not express polymorphic MHC class Ia or class II molecules (with the exception of HLA-C) *(870)*. These cells are the closest in proximity to the maternal blood vessels in the villi of the placenta, and even when stimulated with IFN-γ, they do not express HLA-A and HLA-B class I molecules *(871)*. The remaining cells, cytotrophoblasts, express only the relatively nonpolymorphic class Ib MHC molecules, HLA-G and HLA-E *(872,873)*. Although early ideas suggested that the function of these molecules is to provide a ligand for the inhibitory receptor(s) on maternal NK cells and CD8$^+$ T cells, thus preventing them from killing fetal cells (874), more recent work has raised the possibility that instead they play a role in controlling vascularization of the maternal decidua (875).

One puzzling fact, however, is that rodent placental cells do express classical polymorphic MHC class Ia molecules, although at significantly lower levels in the fetus than in the adult *(876)*. Hence, other mechanisms must also play a role in preventing maternal immune attack. Of note is the fact that syncytiotrophoblasts synthesize the enzyme indoleamine 2,3-dioxygenase *(877)*, which, as discussed earlier, breaks down the essential amino acid tryptophan and has negative effects on T-cell activation. If a pharmacologic inhibitor of this enzyme is administered at the time of embryo implantation, it causes the loss of allogeneic fetuses in normal, but not Rag1-deficient, mice *(764)*. There was no effect on syngeneic litters. Conversely, feeding hamsters a high-tryptophan diet has been reported to cause fetal loss *(878)*. These observations suggest that control of tryptophan availability is a key mechanism by which trophoblasts maintain their immune privilege. However, it is not the only mechanism because IDO-deficient female mice produce normal litters when crossed to allogeneic IDO-deficient males *(877)*.

In the early experiments on multiparous rodents, allogeneic paternal skin grafts placed on mothers that had been mated several times to males of that allogeneic strain were rejected more slowly than the same grafts placed on mothers that had been mated to syngeneic males *(879–882)*. Also, the response of multiparous inbred females to the male-specific antigen H-Y is usually impaired *(883,884)* even though primed CD8$^+$ CTLs can be detected with tetramers (885). This suggests that there exists an immunosuppressive effect of the fetus on the mother's T-cell immune responses *(884)*. This was demonstrated clearly in TCR transgenic female mice whose CD8$^+$ T cells were specific for a paternal MHC class I molecule (K^b) (886). During pregnancy these cells were reduced in numbers and appeared to have down-regulated their receptor levels. They were also functionally impaired as the mother failed to reject Kb-bearing tumor grafts during this period. Following birth, the immune system returned to normal. Furthermore, these effects were antigen-specific as they were not observed in syngeneic or non-K^b allogeneic preg-

nancies. In another study, CD8$^+$ transgenic T cells specific for the male H-Y antigen were tolerized during pregnancy by mechanisms involving anergy and Fas-dependent deletion *(887)*. In a similar manner, a B-cell receptor transgenic mouse specific for K^k deleted about 80% of its idiotype$^+$ B cells starting at midpregnancy and then reverting to normal levels at birth *(888)*. Thus, pregnancy transiently can result in a state of specific tolerance to paternal alloantigens.

Several mechanisms have been proposed for this transient immunosuppressed state. One is expression of Fas ligand in the placenta, which, similar to its action in other privileged sites, would kill activated T cells entering the tissue *(889)*. In the human placenta, Fas ligand is expressed early on cytotrophoblasts as well as at term in syncytiotrophoblasts *(889,890)*. In the *gld* mouse, which lacks a functional Fas ligand, fetal resorption sites are common and litter sizes are small *(890)*. A second mechanism is the presence of suppressor T cells *(891)*. There is a generalized increase in the percentage of CD25$^+$Foxp3$^+$ Tregs that occurs during pregnancy (892). In the uterus about 30% of the CD4$^+$ T cells are Tregs by embryonic day 10.5, and this occurs in syngeneic as well as allogeneic matings. Depletion of CD25$^+$ cells prior to T-cell adoptive transfer into nude females led to gestational failure when these mice were bred to allogeneic males, but not if they were bred to syngeneic males. In the allogeneic combination fetal resorption was detected at embryonic day 10.5 and characterized by infiltration of CD3$^+$ T cells and hemorrhage at the maternal-fetal interface. Thus, the physiologic enhancement of Tregs during pregnancy may play a key role in preventing alloreactivity against paternal antigens. This enhancement may also be responsible for the amelioration of autoimmune diseases, such as rheumatoid arthritis, that often occurs with pregnancy *(893,894)*.

A third mechanism to explain systemic immunosuppression in pregnancy is the production of cytokines and hormones by the placenta, which would inactivate T cells or deviate them away from a cell-mediated immune response *(895)*. Progesterone, which is present in high concentrations in the placenta, has been shown to prolong allogeneic skin graft survival *(896,897)* and to favor the development of Th2 responses from antigen-specific T-cell lines and clones *(898)*. IL-4, IL-5, and IL-10 have been detected in the placenta, as has an immunosuppressive cytokine related to TGFβ2 *(895,899–901)*. The latter is made by trophoblasts rather than immune cells, as is much of the IL-10 produced in the placenta (902,*903*). A study of the effect of pregnancy on susceptibility to *Leishmania* infection in B6 mice, which normally resist the parasite with a vigorous Th1 response, showed an impaired clearance of the organism resulting from a general decrease in IFN-γ production (904). Reciprocally, infection with *Leishmania* enhanced both spontaneous abortion and failed implantation rates, as well as decreasing the production of IL-4

and IL-10 in the placenta *(905)*. In humans, spontaneous abortions are also associated with an increased capability of producing IL-2 and IFN-γ and a decrease in IL-4, IL-10, and leukemia inhibitory factor production *(906,907)*. Finally, the excess fetal loss observed in the CBA and DBA/2 mouse mating combination, which is mediated by activated NK cells and macrophages, is associated with decreased IL-4 and IL-10 production and can be reversed by administration of IL-10 or anti–IFN-γ antibody *(144*,902). Although not all Th-2 cytokines are necessary for a successful pregnancy *(908)*, the cytokine milieu of the placenta does appear to play an important role in the maternal acceptance of the fetus, and may provide another example of where immune deviation contributes to tolerance.

Often after multiple pregnancies the mother makes an antibody response to the father's histocompatibility antigens *(909,910)*. Occasionally, the antibodies formed are harmful to the fetus, as in Rh incompatibility causing erythrocyte destruction *(911)*, but for the most part the antibodies are not destructive. Several laboratories have demonstrated that many of these antibodies do not fix complement *(912)*. When they do fix complement, cells in the placenta are equipped with molecules such as decay-accelerating factor and membrane cofactor protein, which destroy or block the binding of complement (see Chapter 33). The importance of these protective mechanisms has been shown in a targeted mutation of a broadly distributed complement regulatory protein called *Crry*, a major complement inactivator in rodents (913). Homozygous knock-out mice die *in utero* around embryonic day 10. The embryos at this time have C3 deposited in the placenta and the tissue is invaded with granulocytes. Crossing these mice to C3-deficient mice corrected the defect, demonstrating that the regulation of complement was an important variable in fetal survival.

SUMMARY

The immune system is often thought of as a protective device for responding to the dangers of pathogenic invaders and injury. However, one of the most serious threats to the organism is the immune system itself. Without the various phenomena referred to as tolerance, the organism would surely self-destruct. Hence, the mechanisms required to guard against this possibility are numerous and nonredundant (Table 29.1). First, in the central lymphoid organs, cells reactive to available endogenous antigens are

▌ **TABLE 29.1 Tolerance Mechanisms**

Central Lymphoid Tissues	Peripheral Lymphoid Tissues
T cells in the thymus	**T cells in the spleen and lymph nodes**
1. Negative selection via clonal deletion by thymic dendritic cells presenting ubiquitous self-antigens	1. Programmed cell death following stimulation by antigen-bearing APCs. Usually mediated by growth factor withdrawal.
2. Deletion or anergy resulting from self-antigen presentation by thymic epithelial cells. This includes ectopically expressed tissue-specific antigens.	2. Clonal anergy due to TCR occupancy that is unaccompanied by sufficient costimulation
3. Deletion of thymocytes recognizing tissue-specific antigens by dendritic cells migrating to the thymus from the peripheral tissues	3. Receptor desensitization resulting from persistent antigen stimulation
4. Generation of CD4$^+$CD25$^+$Foxp3$^+$ regulatory T cells that act in the periphery to inhibit self-antigen reactivity	4. Th1/Th2/Th17 immune deviation via cytokine cross-regulatory effects
	5. Tr1, Th3 and iTreg cells acting via suppressive effects of IL-10 and TGF-β
	6. CD8$^+$ veto cells delete naive CD8$^+$ T cells by a Fas/FasL mechanism
	7. CD8$^+$ T cells delete activated CD4$^+$ T cells by recognition of TCR peptides presented on Qa1 molecules
	8. CD8$^+$ suppressor cells induce inhibitory receptors on APC
	9. Plasmacytoid DC inhibition of T-cell proliferation thru tryptophan depletion by indoleamine 2,3-dioxygenase
B cells in the bone marrow	**B cells in the spleen and lymph nodes**
1. Receptor editing as a consequence of growth arrest and immunoglobulin V-region substitution in response to polyvalent, high concentration self-antigens	1. Clonal anergy due to persistent antigen stimulation that leads to B-cell receptor desensitization and functional unresponsiveness
2. Clonal deletion following persistent stimulation of high-affinity clones by polyvalent, high concentration self-antigens leading to apoptosis	2. Clonal deletion by high concentration, high affinity, polyvalent antigens in the absence of T-cell help
3. Clonal anergy as a result of maturation arrest and subsequent loss of antigen-responsiveness to soluble self-antigens	3. Receptor blockade by smaller, soluble, low-valency antigens that tie up antigen receptors in nonfunctional clusters
4. Differentiation to B1 cells to allow survival of intermediate-affinity self-antigen reactive clones early in life	4. Antibody feedback inhibits naive B-cell activation via Fc receptors
	5. Anti-idiotypic IgM antibody network regulates levels of natural antibodies

APC, antigen-presenting cell; TCR, T-cell receptor; Th, T-helper cell; TGF-β, transforming growth factor-β; IgM, immunoglobulin M.

clonally deleted by an apoptotic process. In addition, editing allows B cells to replace their receptors in order to avoid autoimmunity. As the lymphocytes mature they next encounter peripheral antigens. Some of these are brought to the primary lymphoid organs by the bloodstream and migrating immature DCs. Other antigens are expressed ectopically in the medulla of the thymus. Here the cells are tolerized by a deletional or anergic process. In addition $CD4^+CD25^+Foxp3^+$ regulatory T cells are selected, which later can dampen immune responses against many peripheral self-antigens. Maturing transitional B cells can also be tolerized by an anergic or deletional process if they encounter antigen in the absence of T-cell help.

Once T cells have matured, their activation to antigen is still constrained by the requirement for two types of signaling, one antigen-specific and the other costimulatory. APCs are normally in a quiescent state and thus only present antigens in a tolerogenic fashion (signal one alone). The cells may respond to this stimulation and even divide, but the process is ultimately abortive and the cells either die or become anergic. B cells require T-cell help as their form of costimulation and antigen encounter without it leads to anergy or death. Finally, even following a strong immune response, the system can regulate itself by negative feedback mechanisms, which include various induced T-regulatory cells making IL-10 and TGF-β in response to antigen, cells killing effectors by recognizing idiotypic determinants or vetoing them, or by deviating the response toward a nonharmful state. B cells can be turned off by antibody signaling through Fc receptors.

Despite this plethora of mechanisms that exists to ensure that tolerance is enforced in the immune system, the safeguards can occasionally break down, resulting in autoimmune disease. When and how this occurs is the topic of Chapters 41 and 42 on systemic and organ-specific autoimmunity.

Regulatory/Suppressor T Cells

Ethan M. Shevach

INTRODUCTION

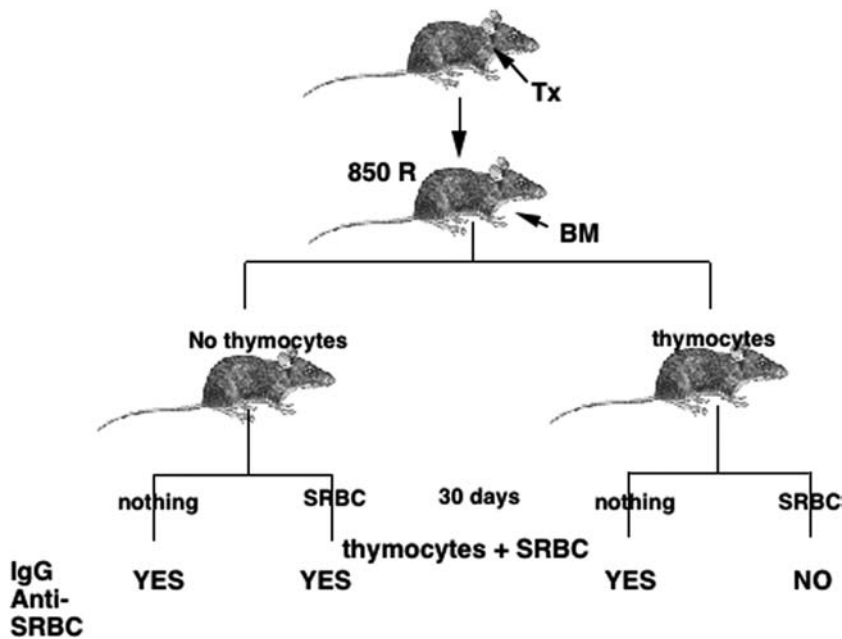
T cells are crucial in the immune response because they can function as both effector cells in cell-mediated responses and as helper cells in both humoral and cell-mediated responses. Most biologic systems are subject to complex regulatory controls, and the immune system is not an exception. In addition to T cells that upregulate (help), other populations that downregulate (suppress) the immune response must exist. Once a normal immune response is initiated by antigenic stimulation, mechanisms must be in place to control the magnitude of that response and to terminate it over time. Downregulation should contribute to the homeostatic control of all immune responses, serving to limit clonal expansion and effector-cell activity in response to any antigenic stimulus. An active mechanism of T-cell suppression is also needed to control potentially pathogenic autoreactive T cells. The primary mechanism that leads to tolerance to self-antigens is thymic deletion of autoreactive T cells, but some autoreactive T cells may escape thymic deletion or recognize antigens that are expressed only extrathymically. T-cell anergy *(1)* and T-cell ignorance/indifference *(2)* have been proposed as the primary mechanisms used to control autoreactive T cells


FIGURE 30.1 First demonstration of suppressor T cells. Adapted from Gershon RK, Kondo K. Cell interactions in the induction of tolerance: The role of thymic lymphocytes. *Immunology.* 1970;18:723–735.

in the periphery, although these "passive" mechanisms for self-tolerance may not be sufficient to control potentially pathogenic T cells.

It was proposed more than 30 years ago that a distinct subset of T cells is responsible for immune suppression (3). A suppressor T cell is functionally defined as a T cell that inhibits an immune response by influencing the activity of another cell type. Although a strong theoretical basis exists for T-cell–mediated suppression, this area of immunologic research has been plagued by controversy. The past decade has seen a resurgence of interest in the concept of T-cell suppression mediated by a distinct subset of T cells that are uniquely equipped to mediate suppressor activity.

HISTORICAL PERSPECTIVE

Suppressor T cells were first identified by Gershon and Kondo (3,4) during studies designed to understand the process of "high-zone" tolerance. Injection of supraoptimal doses of an antigen including sheep red blood cells (SRBC) resulted in specific tolerance or nonresponsiveness to subsequent challenge with that antigen. It was believed at that time that the antibody-producing B cell was rendered nonresponsive by exposure to the high concentration of antigen. To investigate whether B-cell tolerance was dependent on the presence of T cells, Gershon and Kondo injected high doses (2.5×10^{10}) of SRBC into thymectomized (Tx), irradiated, bone marrow–reconstituted mice and then assayed the functional status of B cells from these mice by a secondary challenge with SRBC in the presence of added thymocytes as a source of T-cell help. Surprisingly, nonresponsiveness as measured by deficient antibody produc-

tion was only induced in the B cells of animals that had received thymocytes as well as bone marrow cells during the initial exposure to high-dose antigen, but not in mice that received bone marrow alone (Figure 30.1). This result fulfilled Gershon's prediction that under certain conditions antigen seen by T cells can induce not only helper and effector cells, but also cells that are able to suppress immune responses. Furthermore, when spleen cells from tolerized animals were transferred into secondary recipients together with normal thymocytes and bone marrow cells, they were capable of suppressing the otherwise competent response of these animals to SRBC. This suppression, or "infectious tolerance," as it was originally termed, was antigen-specific, as the immune response to an unrelated antigen, horse RBC, was not inhibited (4). T cells were necessary for the induction of B-cell tolerance, and these T-suppressor cells were assumed to be a distinct cell population with a fully differentiated gene program that allowed them to perform a very specialized function. Other studies (5,6,7) during the 1970s supported the existence of T-cell–mediated suppression.

Most of the early studies in these models demonstrated that the T cells mediating suppression were distinct from T cells mediating help because the former were CD8$^+$, whereas the latter were CD8$^-$. The finding that T-suppressor effector cells were CD8$^+$ distinguished them from helper cells, but did not allow them to be distinguished from cytotoxic cells, which are also CD8$^+$. It remained possible that suppressor T cells were actually cytotoxic cells that killed the helper or effector T cells. A cell surface marker that seemed to identify a suppressor-cell–specific antigen was discovered in 1976. It was found that an antiserum raised by immunizing the congenic strains

B10.A(3R) with cells from B10.A(5R) mice or vice versa gave rise to an antiserum that seemed to react exclusively with suppressor cells (8). $CD8^+$ suppressor cells were also shown to bind antigen in the absence of MHC molecules. These experiments suggested that the suppressor effector cells differed from other T cells in that they were capable of binding antigen directly, and did not recognize processed antigenic peptides in association with products of the major histocompatibility complex (MHC) on the surface of antigen-presenting cells (APC). Soon after the existence of T-cell–mediated suppression was appreciated, some studies suggested that interactions among multiple distinct T-cell subpopulations might be involved. A $CD4^+$ cell was described that appeared to induce $CD8^+$ suppressor cells and was called the suppressor inducer cell. Contrasuppressor T cells had no independent helper, suppressor, or cytotoxic activity on an immune response, but enhanced immune responses by preventing the downregulation mediated by suppressor cells.

Research in this area rapidly shifted from studies of the function of intact T cells to studies of their soluble products *(9)*. By the late 1970s, soluble factors from T-suppressor cells were described by several groups, and cloned T-cell hybridomas that produced such factors were generated. T-cell suppression was regarded as being mediated by numerous soluble antigen-specific and nonspecific factors that comprised a functionally unique network (10,*11,12*). The cascade involved antigen-specific, I-J–restricted $CD4^+$ suppressor inducer cells (Ts1 cells), $CD8^+$ anti-idiotype–specific cells (Ts2 cells), followed by $CD8^+$ antigen-specific effector cells (Ts3 cells), whose suppressor function was not restricted by the MHC. Some of these cells were capable of binding directly to immobilized antigen in the absence of MHC molecules. Connectivity in this cellular cascade was mediated by a series of soluble factors: TsF1 was idiotypic, antigen-specific, and immunoglobulin heavy-chain variable (V_H) region restricted. TsF2 was anti-idiotypic and required delivery by a macrophage. TsF3 acted totally nonspecifically. TsF1 and TsF2 required antigen-presenting cells, but TsF3 did not. Most of these factors were composed of two polypeptide chains, one of which was capable of binding native antigen and the other of which bore a determinant recognized by anti-I-J antibodies.

These elaborate, highly convoluted suppressor cell pathways and circuits fell out of favor in the mid-1980s for a number of important reasons. The existence of I-J was called into question by the finding that the region of the MHC complex to which I-J mapped did not contain a gene that could encode a unique I-J polypeptide *(13)*. When the genes encoding the T-cell receptor were isolated, they were completely unrelated to the genes encoding Ig heavy chains, thereby calling into question the existence of T-cell factors that expressed Ig V region products. Many of the suppressor T-cell hybridomas that produced antigen-

specific suppressor factors were found either to have unrearranged genes for the α or β-chains of the TCR or to have deleted genes for TCR β chain (14). No studies were ever performed that convincingly characterized at the molecular level any of the suppressor T-cell factors. These studies, together with the inability to identify a marker specific for suppressor T cells and the inability to purify suppressor T cells, raised considerable doubts about the existence of a distinct functional lineage of suppressor T cells.

Two completely different approaches to the demonstration of the importance of regulatory or suppressor T cells in the prevention of organ-specific autoimmunity were also developed in the 1970s. In one, mice that were Tx on the third day of life (d3Tx) were shown to develop organ-specific autoimmune diseases (Figure 30.2). The specific disease that developed varied with the strain of mouse under study; more than one organ could be involved in a given mouse. Most important, autoimmunity was not seen if the mouse was Tx on day 1 or day 7 of life, and disease could be completely prevented if the d3Tx mouse received a thymus transplant between days 10 and 15 of life (15). These observations led to the hypothesis that autoreactive T cells were exported from the thymus during the first 3 days of life and that somewhat later in ontogeny a population of suppressor cells emigrated from the thymus that controlled

the autoreactive T cells. Removal of the thymus before the suppressor cells reached the periphery resulted in autoimmune disease. A number of other protocols (Table 30.1) that induced a lymphopenic state also resulted in the development of organ-specific autoimmunity. It was believed that these procedures resulted in a selective depletion of suppressor T cells, while leaving the autoreactive effector populations intact. Subsequent studies demonstrated that the effector cells in this model were CD4[+] T cells. The suppressor T cells were also CD4[+] cells, and the development of autoimmune disease could be prevented by reconstitution of the d3Tx animals with peripheral CD4[+] T cells from normal adult mice *(16)*.

A second approach to define the role of T-regulatory cells (Treg) in the control of autoimmunity was described by Penhale and coworkers in the 1970s (17,*18*). They devised a procedure to deplete Treg from adult animals, while leaving the helper population responsible for autoantibody production intact. The disease model was autoimmune thyroiditis, because circulating antibody to thyroglobulin was believed to play an important pathogenic role. Spontaneous thyroiditis and circulating IgG autoantibodies developed in 60% of rats following the selective depletion of T cells by adult Tx followed by irradiation. Tx was performed between 3 and 5 weeks of age, and the rats were then given four to five repeated doses of 200 rad at 14-day intervals (Figure 30.3). No evidence of thyroiditis was seen in rats that received only local irradiation to the thyroid region, indicating that irradiation itself did not induce pathologic changes. The conclusion drawn from these studies was that in the normal animal, B cells that recognized thyroid antigens were prohibited from differentiating into autoantibody-producing cells by an active controlling T-cell mechanism. It was assumed that the suppressor T-cell population was mediating its functions by acting directly on the B cell and not by regulating other T cells. The active role of T cells in preventing the development of autoimmunity in this model was confirmed by reconstituting, shortly after the final dose of irradiation, the Tx-irradiated mice with lymphoid cells from normal donors. Penhale and colleagues (*19*) also demonstrated that autoimmune diabetes

3-5 weeks of age

Organ-Specific Autoimmunity
FIGURE 30.3 Induction of organ-specific autoimmunity in rats by adult thymectomy and irradiation. Adapted from Penhale WJ, Farmer A, Irvine WJ. Thyroiditis in T cell-depleted rats: influence of strain, radiation dose, adjuvants and antilymphocyte serum. *Clin Exp Immunol.* 1975:21:362–375.

would develop following the Tx-irradiation protocol in a strain of rats that was normally not susceptible to this disease. Taken together, the d3Tx model in the mouse and the Tx-irradiation model in the rat demonstrated that normally autoreactive helper and suppressor cells may coexist and that certain autoimmune responses are held in check by the equilibrium favoring suppressor activity.

IDENTIFICATION OF CD4[+]CD25[+]Foxp3[+] Treg

An important extension of this hypothesis was that inhibition of autoreactive T cells by suppressor T cells was not a phenomenon unique to the neonate, but that in the normal adult animal, autoreactive T cells are also under the constant control of the suppressor T cells. If the suppressor lineage was deleted, damaged, or compromised in the adult animal, autoimmune disease might develop. Although a number of studies suggested that the regulatory T cells in the normal adult animal might be identified by the expression of certain membrane antigens, for example, high levels of CD5 *(20)*, a major advance in our understanding of the role of regulatory T cells was the demonstration

by Sakaguchi et al. (21,*22*), that a minor population of CD4$^+$ T cells (10%) that coexpressed the CD25 antigen (the IL-2R α chain) appeared to function as regulatory T cells in the normal adult. When CD25$^+$ T cells were depleted from a population of normal adult CD4$^+$ T cells and the remaining CD4$^+$CD25$^-$ T cells transferred to an immunocompromised recipient such as a *nu/nu* mouse, the recipients developed a spectrum of autoimmune diseases that closely resembled those seen following d3Tx (Figure 30.2). Co-transfer of the CD25$^+$ cells prevented the development of autoimmunity. Similarly, the induction of disease post-d3Tx could also be prevented by reconstitution of the animals with CD4$^+$CD25$^+$, but not CD4$^+$CD25$^-$, normal adult T cells before day 14 of life (23). CD8$^+$CD25$^-$ T cells alone were not capable of inducing autoimmunity and enhanced the induction of disease induced by CD4$^+$CD25$^-$ T cells. These studies solidified the role of the CD4$^+$CD25$^+$ T cells as a major subset of cells that plays a unique role in the regulation of the immune response. The autoimmune diseases induced by depletion of CD4$^+$CD25$^+$ T cells are uniformly accompanied by the development of organ-specific autoantibodies, suggesting that this mode of loss of T-cell tolerance results in the breakdown of B-cell tolerance as well. It is likely that the activated self-reactive T-helper cells provide signals to self-reactive B cells, rescue them from apoptosis, and stimulate autoantibody production.

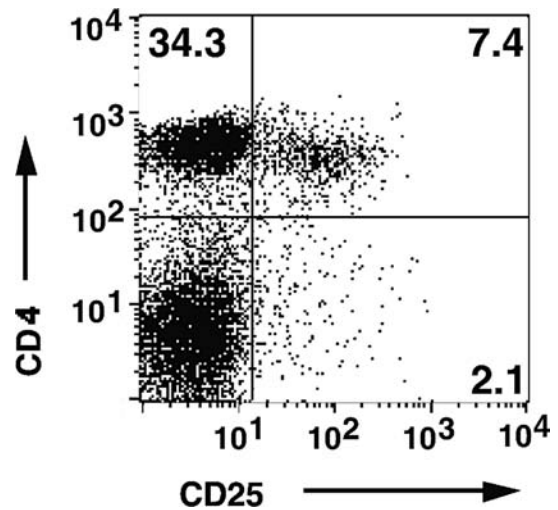
Powrie and Mason (24) were the first to identify cell surface markers that distinguished between regulatory and effector T-cell populations in the rat. When athymic rats were reconstituted with small numbers of CD4$^+$CD45RC^{high} T cells, they developed a severe wasting disease characterized by extensive mononuclear cell infiltration in the lungs, liver, thyroid, stomach, and pancreas 6 to 10 weeks later. No pathology developed in rats that received unseparated CD4$^+$ T cells or CD45RC^{low} cells. It seemed likely from these studies that the CD45RC^{low} subset controlled the capacity of the RC^{high} subset to mediate the wasting disease. The suppressive effect of the RC^{low} subset was directly demonstrated by Fowell and Mason (25) using the Tx-irradiation model develped by Penhale. Transfer of RC^{low} CD4$^+$ T cells completely inhibited the development of diabetes and insulitis. RC^{low} T cells from long-term Tx donors could protect as efficiently as cells from normal donors, demonstrating that the regulatory T cell is long-lived in the periphery. Subsequently, CD4$^+$CD45RB^{low} subset in the mouse was shown to have regulatory properties similar to the CD4$^+$CD45RC^{low} subset of the rat (26). Taken together, these studies in mouse and rat model systems demonstrated for the first time that two well-characterized cell surface antigens (CD25 and CD45RC^{low}/CD45RB^{low}) could be used to identify suppressor CD4$^+$ T-cell subpopulations present in normal animals. More recent studies have shown that the majority of the suppressor activity of the CD4$^+$CD45RB^{low} population is mediated by the CD25$^+$ T cells within that population (27).


FIGURE 30.4 Identification of CD4$^+$CD25$^+$ T cells in normal mouse lymph node. Adapted from Thornton AM, Shevach EM. CD4$^+$CD25$^+$ immunoregulatory T cells suppress polyclonal T cell activation *in vitro* by inhibiting interleukin 2 production. *J Exp Med.* 1998;188:287–296.

CD4$^+$CD25$^+$ T cells typically represent 5% to 8% of the total population of T cells in the normal mouse lymph node (LN), or 10% to 15% of mouse CD4$^+$ T cells (Figure 30.4). CD4$^+$CD25$^+$ T cells can also be found in the thymus, where they also represent about 5% to 10% of the mature CD4$^+$CD8$^-$ population, or 0.5% of mouse thymocytes (21,*28*). A population with an identical phenotype has been identified in the rat, in human peripheral blood, and in human thymus (29,*30*,*31*,32,33,*34*,*35*,36). When compared directly to CD4$^+$CD25$^-$ T cells, CD4$^+$CD25$^+$ T cells express slightly higher levels of CD5, have a slightly higher proportion of CD62L^{low} cells, and have a higher proportion of CD69$^+$ cells. They express both intermediate and low levels of CD45RB, and are completely absent from the CD45RB^{high} population *(37)*. All of the CD4$^+$CD25$^+$ T cells express the TCR α/β receptor and are NK 1.1–negative. The distribution of expression of a given TCR Vα or Vβ specificity is similar on CD4$^+$CD25$^+$ and CD4$^+$CD25$^-$ T cells *(28)*. One other unique property of CD25$^+$ T cells in both mouse and human is that they are the only nonactivated T-cell population that expresses high levels of the CTLA-4 antigen intracellularly (27,38,39). The glucocorticoid-induced TNF-like receptor (GITR, TNFRSF18) has also been shown to be expressed on the majority of resting CD4$^+$CD25$^+$ T cells and to be expressed at very low levels on CD4$^+$CD25$^-$ T cells (40,41). The GITR is upregulated on CD4$^+$CD25$^-$ T cells following TCR-mediated activation.

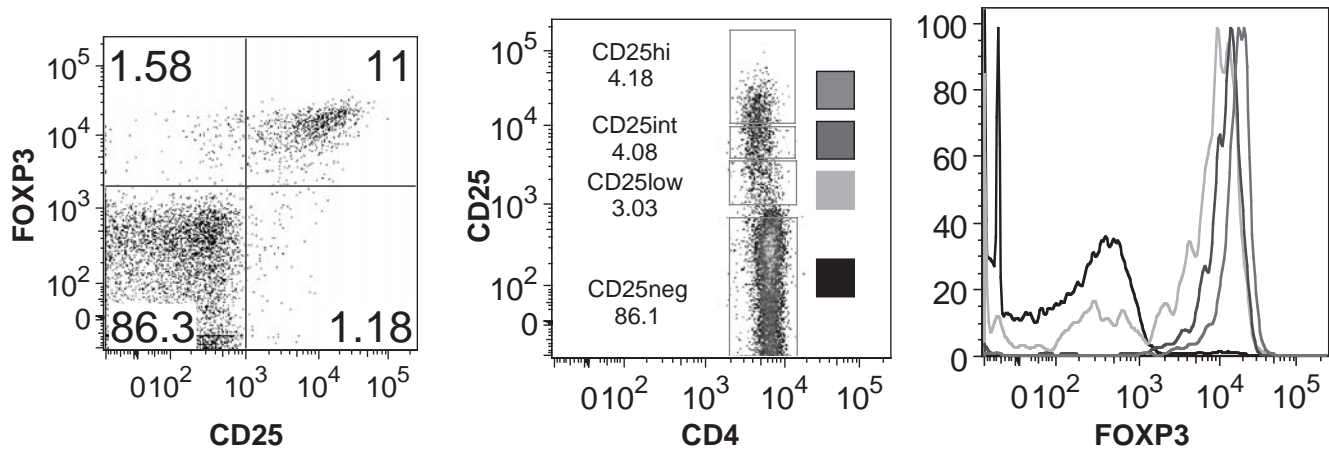
A major advance in the study of Treg was derived from two related experiments of nature. Although CD4$^+$CD25$^+$ T cells were shown to display suppressive properties in multiple disease models, the value of CD25 has a marker is limited, as CD25 is highly expressed on both activated CD4


FIGURE 30.5 Correlation between CD25 expression and Foxp3 expression in mouse CD4$^+$ cells.

and CD8 T cells, compromising its usefulness in studying Treg cells in settings of immune activation. Studies over the past 5 years have identified the X-chromosome–encoded forkhead transcription factor, Foxp3, as the key player in the biology of CD4$^+$CD25$^+$ Treg (*42*,43–45). Young males with the IPEX syndrome (immune dysregulation, polyendocrinopathy, enteropathy, X-linked) or a mutant mouse strain, scurfy, both succumb to similar autoimmune and inflammatory diseases as a result of uncontrolled activation and expansion of CD4$^+$ T cells. Both IPEX patients and scurfy mice have mutations in a common gene, *Foxp3*, which encodes a forkhead-winged-helix transcription factor. There is an excellent correlation between expression of Foxp3 and CD25, but a minor population (∼10%) of Foxp3$^+$ cells is CD25$^-$ and about 10% of CD25$^+$ cells are Foxp3$^-$ (Figure 30.5). It is likely that the latter represent activated effector cells. Expression of Foxp3 only in the thymus using a proximal lck-driven transgene does not prevent disease in scurfy mice. Foxp3 expression in peripheral T cells is thus required for maintenance of Treg function. Retroviral-mediated transduction of Foxp3 expression in naïve T cells can convert these cells to a regulatory phenotype functioning *in vitro* in a manner similar to CD4$^+$CD25$^+$ Treg. Furthermore, Foxp3-transduced naïve CD25$^-$ T cells also manifest suppressor activity *in vivo* and can inhibit the weight loss, diarrhea, and histologic development of colitis induced by transfer of CD25$^-$CD45RB^{high} cells as effectively as Treg.

Fontenot et al. (46) generated Foxp3-deficient ($^{-/-}$) mice and demonstrated that Foxp3 is specifically required for the thymic development of Treg. Mixed bone marrow chimeras using wild-type (WT) and Foxp3$^{-/-}$ bone marrow demonstrated that Foxp3$^{-/-}$ T cells behaved normally in the presence of wild-type Foxp3$^+$ Treg. Thus, the lethal autoimmune syndrome in Foxp3$^{-/-}$ mice results from a deficiency of Treg and not from a cell-intrinsic defect of CD4$^+$CD25$^-$ T cells. Further study of the role of Foxp3 in

Treg function has been greatly facilitated by the development of strains of mice in which a fluorescent protein such as GFP has been "knocked in" to the Foxp3 locus, permitting ready identification and isolation of Foxp3$^+$ Treg by cell sorting (47). Studies of Treg development in the thymus of the Foxp3^{gfp} mice demonstrated that less than 0.1% of the CD4$^+$CD8$^-$ thymocytes expressed Foxp3 within 12 hours after birth, and that the percentage of Foxp3$^+$ CD4 SP thymocytes increased slowly over the following days and reached a plateau of ∼4% at ∼21 days after birth. The largest single-day change in the percentage of Foxp3 expressing SP occurred between days 3 and 4. Eighty percent of the Foxp3$^+$ T cells on day 1 were CD4$^+$CD8$^-$ SP cells. No DP-to-SP developmental progression was observed. This result correlates with the early studies on the d3Tx mice that suggested that the generation of Treg cells is delayed relative to generation of nonregulatory CD4$^+$ T cells. Foxp3 was not expressed in nonhematopoietic tissues. Foxp3 expression in peripheral TCR $\alpha\beta+$ T cells regardless of CD25 expression correlates with suppressor activity.

Direct proof that Foxp3$^+$ T cells maintain control of autoreactive T cells in the periphery has been shown by using a targeting construct encoding the human diptheria toxin receptor fused to sequences encoding GFP and equipped with an internal ribosome entry site into the 3′-untranslated region of Foxp3 (48). Complete elimination of Foxp3$^+$ cells was achieved after 7 days of treatment with diptheria toxin. Foxp3 elimination at birth led to a syndrome very similar to that seen in Foxp3$^{-/-}$ mice. Treg cell elimination in adult nonlymphopenic mice resulted in an even more rapid development of terminal autoimmune disease than in neonates. This study demonstrates that self-reactive T cells, in the peripheral T-cell compartment of normal mice, must be controlled by Foxp3$^+$ Treg cells to prevent the development of autoimmunity. Furthermore, Foxp3-independent recessive and dominant tolerance mechanisms established in adult mice are not sufficient
FIGURE 30.6 Correlation between CD25 expression and Foxp3 expression in human CD4$^+$ cells.

to protect mice from fatal autoimmunity after elimination of Treg.

Isolation of human Treg continues to be a problematic, as one must rely on expression of cell surface antigens. It was reported that among T cells, only the highest expressors of CD25 ($\sim$2% of CD4$^+$ T cells) exerted significant suppressive effects *in vitro (29)*. This observation was substantiated by a comparison of Foxp3 expression with CD25 expression on human CD4$^+$ T cells. Almost all human CD4$^+$CD25^{high} cells are Foxp3$^+$, but a variable percentage of CD25^{int} cells express lower, but substantial, amounts of Foxp3 (Figure 30.6). Flow cytometric isolation of the CD25^{high} cells does allow one to obtain a population that is almost uniformly Foxp3$^+$, but a substantial subset of Foxp3$^+$ cells present in the CD25^{int} population will be lost. It has been proposed that almost all of human Foxp3$^+$ T cells can be identified as expressing low levels of the IL-7 receptor (CD127), and that CD127^{low} expression can be used to isolate human Treg (48). However, CD127 is downregulated early in the course of T-cell activation, so the CD127^{low} phenotype is also unlikely to be Treg-specific during an ongoing immune or inflammatory response. In addition, only about 40% of the CD127^{low} population is Foxp3$^+$, and even purified CD4$^+$CD127^{low}CD25$^+$ cells were only 85% to 90% Foxp3$^+$. The utility of using the differential expression of CD127 for the isolation of human Treg requires further study.

Because the number of CD4$^+$CD25$^+$Foxp3$^+$ T cells is remarkably constant in normal animals in the absence of perturbation of the immune system, they have been frequently referred to as thymic-derived, "naturally occurring" Treg (49). This nomenclature is not accurate, as biologically active Foxp3$^+$ Treg can also be generated extrathymically in peripheral lymphoid tissues as well as *in vitro*. Many of the studies described in this chapter characterizing CD4$^+$CD25$^+$ T cells were performed prior to the availability of antibodies that recognized Foxp3. We will therefore use the terminology, Treg, to refer all T cells with

regulatory properties, and we will attempt to further define the population where appropriate.

BIOLOGIC PROPERTIES OF CD4$^+$CD25$^+$ Foxp3$^+$ Treg

Thymic Origin of Treg

The potential role of the thymus in the generation of regulatory T cells was first described several years ago *(50)*. Most studies strongly support the view that the Foxp3$^+$ Treg population is produced in the thymus as a functionally mature, distinct T-cell subpopulation. Thymic Foxp3$^+$ Treg is not derived from peripheral cells that have recirculated from the periphery to the thymus, because Treg developed *in vitro* in organ cultures of fetal thymus. CD4$^+$CD25$^+$ thymocytes are nonresponsive and suppress T-cell activation *in vitro* in a manner similar to Treg derived from the periphery *(28)*. The capacity of CD25$^+$ T cells to migrate from the thymus to the periphery was documented by injection of FITC intrathymically. The percentage of CD4$^+$CD25$^+$ T cells within migrants and resident T cells was identical, suggesting that CD25$^+$ T cells in the periphery can originate in the thymus *(51)*. Thymectomy at 4 to 5 weeks of age did not modify the number of CD25$^+$ T cells in the periphery even when tested 19 months later.

It is widely accepted that conventional CD4$^+$ and CD8$^+$ T cells develop in the thymus by a process of positive and negative selection. Positive selection is mediated by interaction of developing T cells with MHC antigens on thymic cortical epithelium. Negative selection is mediated both by DC and thymic medullary epithelium. It is not known if a similar process is used for selection of Foxp3$^+$ Treg. A number of studies have suggested that Treg undergoes a unique developmental process during its generation in the thymus. When TCR transgenic mice bearing a TCR specific

for a determinant (S1) derived from influenza hemagglutinin (HA) in association with I-E^d were crossed to mice expressing the HA transgene, the transgenic T cells were not deleted and a large proportion expressed CD25 and functioned as Treg (52). Radioresistant elements of the thymus were shown to be both necessary and sufficient for the selection of CD25$^+$ T cells in these doubly transgenic mice. Similar results were obtained when TCR transgenic mice on a RAG$^{-/-}$ background were mated to the HA transgenic mice, clearly indicating that thymocytes that can only express a single transgenic TCR can undergo selection to become Treg.

A second TCR transgenic mouse was generated that expressed a variant determinant of HA, but that recognized the S1 determinant with 100-fold less affinity. When these mice were bred to the HA transgenic mouse (S1), they did not have an increased frequency of CD25$^+$ T cells. Thus, thymocytes with a low intrinsic affinity for the S1 peptide did not develop into CD25$^+$ thymocytes in response to HA. These data are consistent with a model in which selection of Treg that expresses a transgenic TCR depends on a high-affinity interaction of the TCR with its ligand. It could not be determined from these studies whether this selection process occurs on cortical or medullary epithelial cells. It is also not clear why only 50% rather than 100% of the exported thymocytes express CD25.

Although the affinity-based model of selection of Treg in the thymus is attractive and supported by some experiments, an alternative model for the differentiation of Treg in the thymus has been proposed by van Santen et al. (53). Most of the studies that demonstrated that MHC class II–restricted TCR transgenic thymocytes differentiated into Treg when they encountered their peptide/MHC ligand in the thymus demonstrated an increase in the relative percentage of Treg in the thymus and periphery, but failed to demonstrate an absolute increase in the numbers of Treg. If Treg in the thymus are more resistant than their non-Treg counterparts to clonal deletion, then conventional CD4$^+$ T cells will be deleted when they recognize their ligand in the thymus, and an increase in the proportion, but not the absolute numbers, of Foxp3$^+$ Treg will be observed. As a significant component of the repertoire of Treg is normally self-reactive, the repertoire of Treg cells molded by resistance to clonal deletion will be enriched in self-reactive specificities. The conventional CD4$^+$ repertoire will be decreased in self-reactive cells, as most will be removed by clonal deletion.

Other approaches (54) have suggested that the process of selection of CD4$^+$CD25$^+$ T cells is precisely the same as that involved in positive/negative selection of CD4$^+$CD25$^-$ T cells. Studies comparing the differentiation of Treg in mice expressing a single or many different peptides coupled to MHC class II demonstrate that the proportion of CD25$^+$ T cells in the CD4$^+$CD8$^-$ T-cell pool remains constant and that their total number reflects the complexity of the peptide/MHC class II complexes. This result is not consistent with the hypothesis that the selection of Treg requires a unique high-affinity interaction with MHC peptide complexes, but that Treg are selected in a manner similar to conventional CD4$^+$CD25$^-$ T cells. Further studies on the pathways involved in the differentiation of Foxp3$^+$ Treg in the thymus are needed to resolve the differences observed in these studies.

TCR Repertoire Analysis of Foxp3$^+$ Treg

Several lines of evidence suggest that Treg development hinges on a particular TCR specificity. Foxp3$^+$ Treg do not develop in TCR transgenic mice that lack RAG genes, suggesting that only cells with certain TCR specificities can develop into Treg. Very few studies have addressed in detail either the TCR repertoire of Foxp3$^+$ Treg or their antigen specificity. Hsieh et al. (55) have directly compared the sequences of the CDR3 region on Treg and conventional T cells and found that they are only partially overlapping. When immunodeficient mice were reconstituted with T cells expressing diverse Vα2 TCR α chains from Treg or conventional T cells paired with a single Vβ chain, some of the Treg TCR-reconstituted T cells were self-reactive, as they induced wasting disease in lymphopenic hosts but not in conventional recipients. Although 40% of the TCR were strongly self-reactive *in vivo*, others were only intermittently and moderately self-reactive or nonreactive as measured by T-cell expansion in lymphopenic hosts.

TCR repertoire analysis has also been used to determine the relationship between Foxp3$^+$ Treg cells generated in the thymus and Foxp3$^+$ Treg generated in the periphery. When thymic and peripheral Foxp3$^-$ and Foxp3$^+$ T-cell clones in mice that express a controllable set of TCR encoded by a transgenic TCR α-chain minilocus, the TCR from Foxp3$^+$CD4$^+$ peripheral T cells resembled those of thymic precursors and differed from TCR expressed by Foxp3$^-$CD4$^+$ T cells; in addition, the diversity of Foxp3$^+$ TCR was greater than TCR on Foxp3$^-$CD4$^+$ naïve T cells (56). These studies support the view that the great majority of peripheral Foxp3$^+$ Treg derive from thymic precursors and that peripheral conversion from Foxp3$^-$ to Foxp3$^+$ is rare. Nevertheless, the intrathymic pathway of Treg maturation is still unclear. They may separate from conventional T cells during thymic selection of CD4$^+$CD8$^+$ thymocytes in the cortex or differentiate later from more mature CD4$^+$ thymocytes in the medulla. Although some studies have raised the possibility that Treg are generated in the thymic cortex (57), others favor the view that the thymic medulla is the site where Treg precursors mature after contacts with tissue-specific peptides presented by thymic medullary epithelial cells (58) or DC. However, Treg maturation is normal in AIRE$^{-/-}$ mice that have impaired presentation of either tissue-specific antigens and in CCR7$^{-/-}$ mice that have defects in thymocyte trafficking, raising the

possibility that the cortex and not the medulla is required for Foxp3 induction.

TCR repertoire analysis has also been applied to autoreactive T cells in mice deficient in Foxp3 (59). These mice did not exhibit a defect in negative selection. Activated, but not naïve, T cells in Foxp3$^{-/-}$ mice often used TCR found in the Foxp3$^+$ Treg TCR repertoire of normal mice, suggesting that T cells expressing these self-reactive TCR are not eliminated, but instead contribute to the pathology associated with Foxp3 deficiency. Thus, thymocytes expressing Treg cell TCR survive thymic deletion in Foxp3$^{-/-}$ mice, complete thymic development as non-Treg expressing self-reactive Treg TCR, and enhance the severity of disease in Foxp3$^{-/-}$ mice. It is also possible that WT mice have a population of self-reactive non-Treg that express the Treg self-reactive TCR repertoire that are not subject to negative selection, but potentially can induce autoimmune disease.

Extrathymic Origin of Foxp3$^+$ Treg

One important question that must be addressed is whether the thymus is the only site for the generation of Foxp3$^+$ Treg. A number of studies performed both *in vivo* and *in vitro* have demonstrated that under certain conditions Foxp3$^+$ Treg can be generated extrathymically and that TGF-β is a key component in this process. Administration of peptide antigen to TCR transgenic mice bred onto the RAG background, which lack Treg, resulted in prolonged expression of CD25 only when the antigen was administered under tolerogenic conditions *(60)*. The CD25$^+$ cells had some Treg properties. Similarly, when Apostolou et al. (61) transferred splenic CD4$^+$CD25$^-$ T cells specific for HA from RAG$^{-/-}$ mice to sublethally irradiated recipients that express HA under control of the Ig promoter, 5% of the injected T cells were CD25$^+$, while 95% of the cells were CD25$^-$. Both populations were anergic and were able to suppress the response of naïve T cells expressing the transgenic TCR. The mechanism of suppression used by these induced Treg was not explored. One highly effective method for the induction Treg with antigen was to expose TCR transgenic T cells on a RAG$^{-/-}$ background *in vivo* to a continuous supply of subimmunogenic doses of agonist peptides delivered via a mini-osmotic pump. Many of the T cells became Foxp3$^+$ and resembled thymic-derived Treg in all their phenotypic and functional properties (62). It was postulated from these studies that low doses of peptide presented over relatively long periods of time on nonactivated DC represented a important mechanism by which Treg could be generated in the periphery particularly to self-components that do not lead to tolerance in the thymus. Further evidence in support of this hypothesis was obtained from studies in which peptide agonist ligands were targeted to DC in minute doses by coupling them to antibodies directed to DC under conditions of
FIGURE 30.7 Naïve Foxp3$^-$ T cells were cultured and stimulated in the presence of TGF-β. Foxp3 expression was determined by intracellular staining at the indicated times. Adapted from Davidson T, DiPaolo RJ, Andersson J, Shevach EM. Cutting Edge: IL-2 is essential for TGF-β-mediated induction of Foxp3$^+$ regulatory cells. *J Immunol.* 2007;178:4027–4032.

suboptimal DC activation (63). Treg induced with subimmunogenic conditions could subsequently be expanded by delivery of antigen in immunogenic conditions.

A number of groups (64–67) have presented studies that demonstrate a pivotal role for TGF-β in the generation of Foxp3$^+$ Treg *in vitro*. TCR activation in the presence of TGF-β converted naïve T cells into Foxp3$^+$ (Figure 30.7) cells with an anergic/suppressor phenotype. IL-2 plays a nonredundant role in TGF-β–mediated induction of Foxp3 expression in mouse CD4$^+$ T cells. Once induced, Foxp3 expression was maintained both *in vitro* and *in vivo* in the absence of IL-2. Other cytokines utilizing the common γ chain as part of their receptors were unable to induced Foxp3 expression in IL-2$^{-/-}$ cells. The converted cells not only exhibit unresponsiveness to TCR stimulation, they also suppress normal CD4$^+$ T-cell activation and Th1 and Th2 cytokine production *in vitro*. The induction of Foxp3 results in downregulation of Smad7 and renders T cells highly susceptible to the regulatory effects of TGF-β signaling via Smad3/4 (65). Foxp3$^+$ T cells induced *in vitro* can suppress antigen-specific proliferation of CD4$^+$ T cells *in vivo* and prevent house dust mite–induced mouse asthma. The ability of TGF-β to induce Foxp3 expression and endow the cell with a suppressive phenotype suggests a potential therapeutic intervention whereby antigen-specific, autoaggressive effector T cells could be transformed ex vivo into antigen-specific suppressors. Some studies suggest that TGF-β may also be capable of inducing Foxp3 expression *in vivo*. Peng et al. (68) used an inducible system for the transient induction of TGFβ in the pancreatic islets during the priming phase of diabetes. Approximately 40% to 50% of intraislet CD4$^+$ T cells expressed CD25 and other characteristics of Treg. However, it is not clear if high levels of TGF-β resulted in the in situ expansion of the

small numbers of Treg already present in the islets or if TGF-β induced the conversion of CD25$^-$ T cells to CD25$^+$ suppressors.

It thus remains unresolved whether and under what conditions Foxp3$^-$ T cells are converted to Foxp3$^+$ Treg *in vivo*. It is unknown whether any of the Foxp3$^+$ T cells in normal mice or, more important, in humans, are derived in the periphery by this TGF-β–dependent induction pathway. It is likely that inflammatory infiltrates would contain sufficient quantities of IL-2 and TGF-β, so this induction pathway should be operative *in vivo*. Thus far, it has not been possible to induce stable expression of Foxp3 in naïve human peripheral blood CD4$^+$ T cells by TCR stimulation in the presence of TGF-β. One additional major unresolved issue in humans relates to the origin of Foxp3$^+$ Treg in adults. Whereas mice live for 2 to 5 years, humans can live for eight decades, well beyond thymic involution early in life. It is far from clear whether the full complement of Foxp3$^+$ Treg is generated early in life and then persists for decades or if Treg might be generated from antigen-specific CD4$^+$ T cells that are approaching end-stage differentiation. A subpopulation of human Treg was highly proliferative *in vivo* with a doubling time of 8 days (69). However, these cells were also susceptible to apoptosis and had critically short telomeres and low telomerase activity, raising the possibility that they must be produced from another population source. Heteroduplex analysis of TCR from memory T cells and Treg suggested that they are closely clonally related, raising the possibility that some human Treg are not thymus-derived, but are generated from rapidly dividing, highly differentiated, memory CD4$^+$ T cells.

Cytokine Requirements for the Generation and Maintenance of Treg

It was initially observed that CD4$^+$CD25$^+$ T cells were absent from the periphery and from the CD4$^+$CD8$^-$ thymocyte population of IL-2$^{-/-}$ mice (51). Partial or more profound defects both in the number and function of CD4$^+$CD25$^+$ T cells have been reported in mice deficient for CD28 *(38)*, CD80/CD86, CD40 *(70)*, CD40L (71), CD122 (IL-2Rβ, (72)), and Stat5a (73). The one common factor that characterizes these mice is that the products of all the deficient genes have important roles in the production or responsiveness to IL-2. Treatment of mice with anti–IL-2 or with CTLA-4Ig to inhibit co-stimulatory signals also leads to a rapid decline in the number of CD4$^+$CD25$^+$ T cells (38). As CD25$^+$ T cells do not produce IL-2, this deficiency may be secondary to the capacity of CD25$^-$ T cells to produce IL-2, or to some intrinsic defect in the CD25$^+$ T cells in their capacity to respond to IL-2. Many, but not all, of these strains develop an autoimmune syndrome associated with lymphoproliferation. NOD mice have also been

reported to have a defect in the numbers of CD25$^+$ T cells, but these cells appear to function normally (38). Blockade of the TRANCE-RANK pathway also has been shown to inhibit the generation and/or function of CD4$^+$CD25$^+$ T cells in a model of autoimmune diabetes (74).

IL-2 could be required for the generation of CD4$^+$ CD25$^+$ T cells in the thymus and/or for their maintenance and survival in the periphery. One study (72) that suggests that IL-2 plays a nonredundant role in the differentiation of CD4$^+$CD25$^+$ T cells in the thymus was performed in mice deficient for the CD122. CD122$^{-/-}$ mice rapidly develop a lethal autoimmune syndrome. Transgenic expression of CD122 exclusively in the thymus prevents the development of autoimmunity and prolongs the lifespan of these mice from 8 to 12 weeks up to 12 to 16 months. CD4$^+$CD25$^+$ T cells are barely detectable in the thymus and absent from the periphery of CD122$^{-/-}$ mice. In contrast, CD122$^{-/-}$ mice with thymic-only expression of CD122 had twofold higher numbers of CD4$^+$CD25$^+$ T cells in the thymus and lymph nodes than WT mice. The CD4$^+$CD25$^+$ T cells from these mice were also fully capable of suppressing proliferative responses of T cells from WT mice. As cells from the peripheral lymphoid tissues of these mice are completely unresponsive to IL-2, these results suggest that IL-2 may only be required for the growth or survival of CD4$^+$CD25$^+$ T cells in the thymus, not in the periphery. It remains possible that other cytokines (e. g., IL-4) may in some circumstances be able to maintain CD4$^+$CD25$^+$ T cells in the periphery or that a higher output of CD4$^+$CD25$^+$ in the mice that express CD122 exclusively in the thymus may compensate for a lack of IL-2 in the periphery.

Other studies have proposed that in the absence of IL-2, Treg cannot survive or expand their numbers in the thymus or in the periphery (75), while other functional studies have suggested that IL-2 is directly required for Treg cell function and that in its absence Treg cells fail to suppress T-cell proliferation (76). One major problem with all these experiments is that they have relied on CD25 as a Treg cell marker. As CD25 expression is directly linked to IL-2 signaling, it has been impossible to detect and isolate Treg from mice with impaired IL-2 signaling based on CD25 expression. Fontenot et al. (77) analyzed mice expressing Foxp3$^{\text{gfp}}$ knock-in allele that were genetically deficient in either IL-2 or CD25. They found that IL-2 signaling was not required for the induction of Foxp3 expression in developing thymocytes, as Foxp3 was induced in a subset of developing thymocytes and Foxp3$^+$ Treg cells were present in substantial numbers, though reduced by one half compared to WT mice. BrdU incorporation of cells in the thymus differentiating into the Treg lineage was not substantially affected by the absence of IL-2. Thus, IL-2 signaling is not required for the development of Foxp3$^+$ Treg cells in the thymus. Both IL-2$^{-/-}$ and CD25$^{-/-}$ Treg cells were able to suppress T-cell proliferation *in vitro*. However,

the numbers of Foxp3$^+$ Treg cells in the periphery of IL-2$^{-/-}$, IL-2Rα, and IL-2R$\beta^{-/-}$ mice were substantially decreased or almost absent (78) and Foxp3$^+$ IL-2R$\alpha^{-/-}$ T cells in mixed bone marrow chimeras had a substantially decreased competitive fitness compared to wild-type Foxp3$^+$ Treg. The conclusion drawn from these studies was that IL-2 is an essential Treg cell growth factor *in vivo* and that in the absence of IL-2, Treg cells exhibit impaired metabolic fitness. IL-2 may be important in the maintenance of Foxp3 expression, as Foxp3 is increased in both wild-type and IL-2$^{-/-}$ mice after overnight treatment with exogenous IL-2. It appears that Foxp3 expression in Treg establishes a gene expression program that renders Treg critically dependent on paracrine IL-2 signaling, resulting in repression of IL-2 production and the induction of high IL-2Rα. No Foxp3-expressing thymic and peripheral CD4$^+$ T cells can be detected in IL-2R$\gamma^{-/-}$ mice, indicating that other cytokines that utilize the common γ chain as part of their receptor complex may compensate for the absence of IL-2.

Analysis of Gene Expression by Foxp3$^+$ Treg

Both DNA microarray technology and serial analysis of gene expression (SAGE) technology have been used to compare patterns of gene expression among different cell types (40,79,80). These technologies have also been applied to compare the patterns of gene expression in Treg with CD4$^+$CD25$^-$ T cells and other cell types with regulatory functions. One major goal of this approach is to determine whether Treg simply represent a population of previously activated T cells, or whether they display a unique pattern of gene expression that is correlated with their functional properties. Most of the results are consistent with the latter possibility. Some genes are differentially expressed between the resting CD25$^-$ T cells and Treg, whereas others are differentially expressed following activation. A comparison of a number of these studies has permitted the identification of groups of genes that are relatively Treg-specific and allow one to begin to define a distinct Treg molecular signature (Table 30.2). Many of these identify activa-

tion antigens expressed on activated conventional T cells, including CTLA-4, GITR, and other members of the TNF-receptor superfamily that are expressed by activated effector cells. Some, including neuropilin, GITR, CD38, and CD5, appear to be shared with Foxp3$^-$-anergic T cells that do not exert suppressive functions (81). Although some of the data from the SAGE analysis (80) suggested that Treg may be related to the subpopulation of T cells that secrete Th2 cytokines, on balance the studies on global gene expression indicate that Treg express a unique pattern of gene expression that may contribute to their survival and anergic state.

A Foxp3 chromatin immunoprecipitation method has been used to analyze the direct targets of Foxp3 (82,83). About 700 to 1,000 genes contain Foxp3-binding regions, and many of these genes are up- or downregulated in Foxp3$^+$ T cells confirming that Foxp3 can function as both a transcriptional activator and a repressor. However, Foxp3 target genes comprise only a small portion of Foxp3-dependent gene expression, suggesting that Foxp3 regulates a large part of its transcriptional program by acting on other transcription factors (Table 30.3). It is likely that some genes encoding molecules that could potentially mediate suppressor function (e. g., IL-10, Granzyme B) are secondary Foxp3 targets, as they are not found in the group of genes that are direct Foxp3 targets.

One novel approach to understand the role of Foxp3 in directing Treg function is to engineer a mouse expressing the coding sequence of GFP knocked into the *Foxp3* locus together with disruption of Foxp3 protein expression (84,85). Surprisingly, the GFP$^+$Foxp3$^-$ T cells in these mice shared many phenotypic features with their GFP$^+$Foxp3$^+$ counterparts. The former are what might be termed Treg "wannabees," as they develop in normal mice and respond to signals required to induce Foxp3 expression. The GFP$^+$Foxp3$^-$ cells were unable to produce IL-2, effector cytokines, expressed elevated levels of CD25, were relatively nonresponsive to TCR stimulation, but lacked suppressor activity. Therefore, it is likely that Foxp3 does not function as the master inducer of the Treg lineage, but rather to stabilizes or enhances certain Treg characteristics. Suppression is exclusively dependent on Foxp3.

SUPPRESSOR MECHANISMS UTILIZED BY Foxp3[+] Treg

In vitro Studies

An *in vitro* model system has been established for the analysis of CD4[+]CD25[+] Treg cell function that allows rapid assays and that may offer some insights to the mechanism of action of Treg function *in vivo* (37,86,87,88). This approach also allows a comparison of the requirements for activation (co-stimulation, antigen concentration) of CD25[+] T cells compared to CD25[-] T cells. Purified CD25[+] T cells were completely unresponsive to high concentrations of IL-2 alone, to stimulation with plate-bound or soluble anti-CD3, or to the combination of anti-CD3 and anti-CD28. They could be induced to proliferate when stimulated with the combination of anti-CD3 and IL-2, but not by stimulation of endogenous IL-2 production with anti-CD28. The most striking property of the CD25[+] T cells is their ability to suppress proliferative responses of both CD4[+] and CD8[+]CD25[-] T cells (Figure 30.8). The CD25[+] T cells must be activated via their TCR to suppress. No suppression was seen when CD25[+] T cells were separated by semipermeable membrane from the CD25[-] T cells. This demonstrates that cell contact between CD25[+] and CD25[-] T cells is required. Neutralization of the suppressor cytokines IL-4, IL-10, and TGF-β individually or in combination also had no effect on the CD25-mediated suppression. Similarly, CD25[+] T cells from mice deficient in IL-4, IL-10, or TGF-β were fully competent suppressors. Indo-1–loaded CD25[+] T cells did not flux calcium in response to TCR stim-
FIGURE 30.8 CD4[+]CD25[+] T cells suppress the proliferative response of CD4[+]CD25[-] T cells. Graded numbers of CD4[+]CD25[+] T cells were mixed with 5 × 10⁴ CD4[+]CD25[-] T cells, T-depleted spleen cells, and soluble anti-CD3. Proliferation was measured after 72 hours. ulation (79), suggesting that they have a block in proximal signaling similar to that seen in T cells rendered anergic *in vitro*.

CD25[+] T cells mediate suppression by inhibiting the induction of IL-2 mRNA in the responder CD25[-] T cells. Thus, the trivial explanation for their suppressive properties that they bind IL-2 and function as IL-2 "sinks" *(89)* is completely ruled out, as no IL-2 is produced in the co-cultures. Suppression can be abrogated by the addition of IL-2, thereby circumventing the block. Although IL-2 gene transcription was inhibited in the presence or absence of exogenous IL-2, the addition of anti-CD28 overcomes suppression by potently stimulating the production of endogenous IL-2 and overriding the suppressive effects of the CD25[+] cells. Surprisingly, transcription of IL-2 mRNA was also restored in the co-cultures in the presence of anti-IL-2. These results suggest that Treg do not suppress the initial activation of CD4[+]CD25[-] T cells, but mediate their suppressive effects following production of IL-2 by the responder cells, resulting in both the expansion of the Treg and induction/enhancement of their suppressor functions (76). CD25[+] T cells do not directly mediate the death of the responders, but induce a cell-cycle arrest at the G_1-S phase of the cell cycle. Such a cell-cycle arrest is often followed by cell death, and it is difficult to recover significant numbers of viable cells when the suppressors and responders are co-cultured for periods longer than 48 hours. Suppression of T-cell proliferation is the exclusive property of CD25[+] T cells isolated from normal animals. The induction of CD25 expression by stimulating CD25[-] T cells via the TCR, in the absence of TGF-β, does not render the stimulated cells suppressive. In this regard, it is important to emphasize that expression of CD25 does not indicate that a cell is likely to have suppressive properties.

CD25[+] T cells can be easily propagated *in vitro* for 3 to 14 days by stimulation initially with anti-CD3 and IL-2 and then expansion in IL-2 alone (88). It has also been possible to clone murine CD25[+] T cells by repeated stimulation with anti-CD3 and IL-2 (41). Following 7 to 14 days of activation and culture in IL-2, activated CD25[+] T cells remain nonresponsive and cannot be induced to proliferate when restimulated via their TCR in the absence of IL-2. The activated CD25[+] T cells have more potent suppressor activity on a per-cell basis (three- to fourfold) than freshly explanted CD25[+] T cells. CD25[+] T cells that appear to be antigen-specific can be identified in mice that express a transgenic TCR. In general, the percentage of CD25[+] cells is reduced in TCR transgenic mice (3% to 5%, compared to 10% in normal animals). The expression of the transgenic TCR α chain is a convenient tool that allows activation of the CD25[+] T cells with peptide/MHC rather than with anti-CD3 (88). When T cells from TCR transgenic mice are activated with their peptide/MHC ligand and then expanded *in vitro* in IL-2, the activated suppressors are subsequently capable of suppressing the

▶ **TABLE 30.4 The Suppressor Effector Function of Activated CD4+CD25+ T Cells Is Completely Nonspecific**

proliferative responses of fresh CD4+CD25− T cells from mice that express a different transgenic TCR. There is no MHC restriction in the interaction of the activated suppressors and the CD25− responders. Therefore, the suppressor effector function of activated CD25− T cells is completely nonspecific (Table 30.4).

CD25-mediated suppression is highly sensitive to antigenic stimulation. For example, when CD25+ and CD25− T cells are prepared from the same TCR transgenic mouse and stimulated with a specific peptide, the antigen concentration required to stimulate the CD25+ T cells to suppress is 10- to 100-fold lower than that required for triggering the proliferation of the CD25− T-cell population (86). The partially activated phenotype of CD25+ T-cell population, combined with their enhanced sensitivity to antigen stimulation, suggests that they are highly differentiated in their function and are ready to mediate their suppressive functions immediately upon encounter with their target antigens. Their capacity to rapidly suppress responses *in vitro* suggests that they have been continuously stimulated by self-antigens in the normal physiologic state and continuously exert some degree of suppression *in vivo*.

CD25+ T cells suppress the proliferative responses of CD8+ T cells in a manner similar to that seen with CD4+ CD25− responders (90). Marked suppression of the effector cytokine IFN-γ, is also seen in the presence of CD25+ T cells. Whereas suppression of the proliferation of CD4+ responders by CD25+ T cells can be completely reversed by the addition of IL-2 or anti-CD28, the suppression of CD8+ T-cell responses is not reversed by the addition of IL-2 or anti-CD28. The failure of IL-2 to abrogate suppression is secondary to a failure of full upregulation of the expression of CD25 on the responder CD8+ T cells. CD4+CD25+ T cells thereby prevent responses mediated by CD8+ T cells both by inhibiting their ability to produce IL-2 and by inhibiting their ability to respond to IL-2, thus disrupting CD4+ T cell help for CD8+ T cells.

Recent studies have attempted to define the biochemical and molecular pathways that mediate the anergic or nonresponsive state of Foxp3+ Treg (91,92). A number of studies have shown that Treg exhibit diminished responses of both proximal and distal signaling pathways both in absolute amplitude and in duration when compared to the responses of CD25− T cells. Treg have reduced phosphorylation of the TCR ζ chain, reduced recruitment of ZAP-70, and reduced phosphorylation of SLP-76. Defects were seen in the activity of PLC-γ1 and in signals downstream of this enzyme, including calcium mobilization, NFAT, NF-κB, and Ras-ERK-AP-1 activation. The diminished activity of PLC-γ1 in Treg is likely to contribute not only to the delay and reduced appearance of NFAT in the nucleus, but also to the attenuated activation of the PKC and Ras-ERK–directed pathways as well. Other studies (93) have suggested that the proximal promoter of the IL-2 gene fails to undergo chromatin remodeling and remains in a closed chromatin configuration.

Foxp3+ Treg constitutively express all three chains (α, β, and γ) of the high-affinity IL-2 receptor. Despite the widely recognized importance of IL-2 in Treg homeostasis, very little is known about the intracellular mechanisms that regulate IL-2R signaling in Treg. Indeed, a defining characteristic of Treg is their inability to expand *in vitro* upon stimulation with IL-2 alone, despite expression of all three chains of the high-affinity IL-2 receptor. It has been shown that JAK/STAT-dependent signaling is intact in Treg stimulated with IL-2, but that downstream mediators of PI3 K are not activated (94). The nonresponsiveness of Treg is associated with elevated levels of PTEN, a phosphoinositol 3,4,5-triphosphatase, which catalyzes the reverse reaction of PI3 K, negatively regulating the activation of downstream signaling pathways. In conventional T cells, the level of PTEN is downregulated after T-cell activation, but PTEN remains highly expressed in Treg. A critical role of PTEN in the nonresponsiveness of Treg to IL-2 was established by studying PTEN$^{-/-}$ mice (95). PTEN$^{-/-}$ Treg proliferated readily after stimulation with IL-2 alone *in vitro* and exhibited enhanced peripheral turnover *in vivo*. They retained their ability to suppress effector T-cell

responses both *in vitro* and *in vivo*. Forced expression of PTEN in recently activated non-Treg inhibited their ability to expand in response to IL-2, confirming the ability of this lipid phosphatase to negatively regulate IL-2–dependent proliferation.

Until very recently, little was known about the direct involvement of Foxp3 in controlling the activation of Treg. Bettelli et al. (96) have shown that forced expression of Foxp3 dramatically suppressed endogenous cytokine expression driven by NFAT and NF-κB. Foxp3 was shown to associate physically with the REL-domain proteins NFAT and NF-κB and to suppress their transcriptional activity. Many of the genes regulated by Foxp3 are also target genes for NFAT. The IL-2 and IL-4 genes are activated by NFAT and repressed by Foxp3, whereas the CD25 and CTLA-4 genes are upregulated by both NFAT and Foxp3. It is possible that Foxp3 represses IL-2 expression by competing with NFAT for binding to DNA. Alternatively, based on the finding of Bettelli et al. that NFAT and Foxp3 interact physically in cell lysates, Foxp3 might repress NFAT-driven cytokine transcription by sequestering NFAT away from DNA. Examination of the crystal structure of an NFAT:FOXP2:DNA complex revealed an extensive protein–protein interaction interface between NFAT and Foxp2 (97). Structure-guided mutations of Foxp3, predicted to disrupt its interaction with NFAT, interfere in a graded manner with the ability of Foxp3 to repress expression of IL-2 and upregulate Treg markers CTLA-4 and CD25. Thus, NFAT can switch its transcription partner from AP-1, which drives T-cell activation, to Foxp3, which programs Treg function. Foxp3 also has been shown to interact with the transcription factor AML1/Runx1, which is required for normal hematopoiesis, as well as activation of IL-2 and IFN-γ gene expression (98).

Much less is known about the molecular/biochemical signals generated in the responder cell following interaction with Foxp3$^+$ Treg. Detailed time-course studies *in vitro* have shown that suppression is established after 6 to 12 hours of contact with Treg, and that responders are refractory to suppression after 12 hours of activation. As suggested by the requirements for IL-2 to activate suppressor function (76), the IL-2 response of the responders is normal for the first 6 hours of the co-culture and then abruptly terminates. Co-stimulation with anti-CD28 generated resistance to suppression by stabilizing IL-2 transcripts, enabling the responder T cells to counterbalance transcriptional downregulation by Treg (99). Treg do not inhibit the induction of CD69 or CD25 early, and viability of responder cells was excellent at 36 hours. Gene expression analysis in responder T cells using a microarray approach has shown that one set of genes was expressed after culture with Treg and this set of genes was distinct from genes induced in anergized T cells, T cells deprived of IL-2, or T cells treated with TGFβ$_1$ (100). Hopefully, further detailed studies of these genes will elucidate the specific pathways involved in Treg-mediated inhibition.

Cellular Targets for Suppression *in vitro*

In general, murine Treg failed to inhibit responses induced by plate-bound anti-CD3, but readily inhibited responses induced by soluble anti-CD3 (37). This finding raised the possibility that the cellular target of the Treg was the APC rather than the responder T cell, as responses to plate-bound anti-CD3 are relatively APC-independent. It was originally proposed that the Treg target APC by inhibiting the induction of the expression of costimulatory molecules, or perhaps by competition for costimulatory signals. In cocultures of CD4$^+$CD25$^+$ T cells, CD4$^+$CD25$^-$ T cells, and T-depleted spleen cells as APC, the induction of expression of CD80, CD86, CD54, and CD40 on the APC (primarily B cells) appeared to be normal. Treg were also potent suppressors of T-cell proliferation when LPS-activated APC were used, suggesting that they did not inhibit the expression of an unknown costimulatory molecule. Suppression was also observed when the LPS-activated APC were fixed with paraformaldehyde. Lastly, suppression could not be overcome by adding an excess of LPS-activated APC to the cocultures (88).

These studies strongly suggested that the APC was not the target of Treg-mediated suppression. To prove that the Treg were capable of acting directly on the responder T-cell population, the effects of the Treg on the responses of CD8$^+$ T cells to activation by soluble MHC tetramers in a completely APC-independent cell culture system were studied (90). Both T-cell proliferation and IFN-γ production were markedly inhibited by activated CD25$^+$ T cells in the complete absence of APC. This result is most consistent with the view that CD25$^+$ T cells mediate suppression *in vitro* via a T–T cell interaction and that the APC is not directly required for delivery of the suppressive signal. Similar conclusions were drawn in other studies in which CD25$^+$ T cells were shown to suppress responses of either mouse *(101)* or human (33) CD25$^-$ T cells induced by anti-CD3 coupled to beads in the absence of APC.

In contrast to these studies that support the concept that Treg function by directly suppressing responder T cells, a number of studies have shown that Treg can suppress the maturation of DC. In short-term cultures, Treg cells downregulated the expression of markers on immature bone marrow–derived DC and inhibited their ability to elicit antigen-specific CD8$^+$ T cell responses *in vitro*. Activation of immature DC with CpG DNA or LPS abrogated the ability of the Treg to downregulate DC activation markers or to inhibit T-cell activation. Similarly, systemic activation of DC with CpG DNA or an agonistic anti-CD40 antibody completely inhibited the antidiabetogenic activity of Treg cells in NOD mice (102). Although these results

suggest that Treg exert their suppressive effects by keeping DC in an immature state and that mature DC are resistant to the effects of Treg, other studies have shown that Treg are capable of inactivating CD40L-prestimulated human DC (103) and that Treg can dampen immune responses induced by fully mature DC *in vivo*. Some of the differences in these studies may be secondary to Treg modulation of cytokine production by the DC. For example, although Treg were unable to prevent DC maturation or induction of IL-6 transcription in the presence of strong inflammatory stimuli, they were still able to modulate mature DC responses by enhancing transcription of the anti-inflammatory cytokine IL-10 (104). Treg-mediated enhancement of IL-10 production by fully mature DC may result in inhibition of T-cell activation and is one mechanism by which Treg can modulate the function of mature DC.

Although the preceding studies focused on the inhibition of DC-induced effector cell activation by Treg, a number of studies have suggested that certain subpopulations of DC can modulate the function of the Treg. Treg will proliferate when stimulated with mature bone marrow DC in the absence of IL-2 in an antigen-specific manner *in vitro* and *in vivo* for several days at a rate that is comparable to that of $CD25^-$ T cells (105). The expanded T cells, after several cycles of cell division, retain their suppressor phenotype and function. Cell contact is essential and CD80/CD86 on the DC is required. Because DC induce proliferation of both $CD25^+$ and $CD25^-$ T cells in cocultures, it is impossible to assay the suppressive functions of $CD25^+$ T cells in proliferation assays. However, when IL-2 production was measured using an IL-2 secretion assay, Treg still suppressed IL-2 secretion by $CD25^-$ T cells without inhibiting their proliferation (106). These results suggest that DC can induce the expansion of Treg cells while simultaneously activating their ability to suppress cytokine secretion by effector cells. Because mature DC are likely to represent the major population of APC during inflammatory states and are also likely to be activated by TLR ligands, one must therefore question the relevance of the anergic/suppressor phenotype of Treg when they are stimulated with a heterogeneous population of splenic APC.

In the d3Tx model of organ-specific autoimmune disease, Treg cells suppressed the activation of autoantigen-specific T cells and inhibited the production of autoantibodies to the target organ. As B cells and autoantibody production are prominent mediators of pathology in many autoimmune diseases, it is critical to understand the potential for Treg to control autoantibody production. Although it is clear that Treg can suppress antibody production by blocking T-helper functions, a number of other studies have suggested that Treg can exert a direct effect on certain B-cell functions. Bystry et al. *(107)* were the first to suggest that Treg cells could inhibit LPS-mediated B-cell activation. Lim et al. (108) demonstrated that human

Treg cells can suppress B-cell–dependent immunoglobulin production and class switch recombination by a cell contact–dependent mechanism in the absence of T-helper cells. $Foxp3^+$ Treg cells were identified in T–B area borders and within germinal centers of human lymphoid tissues (109). Treg cells were also able to suppress the expression of AID, a key enzyme involved in class-switch recombination and affinity maturation. The biochemical mechanisms for the suppression of B-cell function in these studies remain unclear.

Zhao et al. (110) demonstrated that Treg cells, that had been activated/expanded in the presence of TCR stimulation and IL-2 inhibited the proliferative responses of B cells to polyclonal B-cell activators. Suppression of proliferation was a result of increased cell death caused by the Treg cells in a cell contact–dependent manner. The induction of B-cell death was not mediated by Fas-Fas ligand pathway, but depended on the upregulation of perforin and granzymes in the Treg. One of the most interesting findings in this study was that activated Treg cells selectively killed activated antigen-presenting B cells and not bystander B cells in the cocultures (Figure 30.9). This result raised the possibility that one site of action of regulatory T cells in mediating suppression *in vivo* is the APC. If activated Treg cells are also lytic for activated DC, lysis of DC by activated Treg cells may be an important mechanism whereby they produce suppression of T-cell activation *in vivo*.

Although a role for Treg in modulating the function of NK cells was suggested in some of the early experiments describing enhancement of NK function following
FIGURE 30.9 Activated OVA-specific Treg were mixed with activated B cells that were pulsed (P) or unpulsed (N) with OVA-peptide. Cell death was determined after 6 hours of culture. depletion of Treg (111), Treg–NK cell interactions have not been widely studied. Treg were shown to inhibit NKG2D-mediated cytolysis *in vitro* largely by a TGF-β–dependent, IL-10–independent mechanism. Similarly, Treg directly inhibited NKG2D-mediated NK-cell cytotoxicity *in vivo*, resulting in suppression of NK-cell–mediated tumor rejection (112). Other studies have shown that human Treg could also directly inhibit NK cell effector functions by a TGF-β–dependent mechanism with a concomitant downregulation of NKG2D receptors on the NK-cell surface (113). NK-cell cytotoxicity was restored in the presence of Treg when the cocultures were performed in the presence of cytokines known to activate NK cells, such as IL-2, IL-4, IL-7, and IL-12. Curiously, in both of these studies, Treg cells did not induce a global inhibition of NK-activating receptors, but only an inhibition of NKG2D. In other experiments, depletion of Treg resulted in enhanced proliferation of NK cells as well as their cytotoxic potential. Treg may normally control NK-cell functions, but any imbalance in the frequency of Treg may affect NK-cell homeostasis. One explanation for the susceptibility of NK cells to Treg control is that uninhibited NK cells might be a danger to the host in autoimmune diseases. Future studies need to carefully examine Treg–NK interactions in situations that involve activation of the innate immune response, particularly during the course of an infectious challenge. The role of Treg in the regulation of NK-cell function has also been studied in a bone marrow graft rejection model (114). Following depletion of Treg *in vivo*, graft rejection was increased in both fully allogeneic and hybrid resistance situations. Rejection was dependent on host NK cells, because it was significantly impaired in NKcell–depleted recipients. TGF-β also appeared to play a role in this, as injection of anti-TGF-β before grafting significantly increased rejection.

Role of TGF-β

Although TGF-β has been clearly shown to play a critical role in the induction of Foxp+ Treg *in vitro*, its role as a suppressor effector molecule remains controversial. Although the majority of studies with either human or mouse Treg that have studied suppression of T-cell activation *in vitro* have failed to identify a soluble suppressor cytokine, it is very difficult to rule out the involvement of a cytokine that acts over short distances or a cell-bound cytokine. Nakamura et al. (115) have raised the possibility that TGF-β produced by Treg and then bound to their cell surface by an as yet uncharacterized receptor might mediate suppression in a cell contact–dependent fashion. In their studies, TGF-β was detected on the surface of resting and activated CD25+ T cells, and suppression could be reversed by high concentrations of anti-TGF-β mAbs. They postulated that latent (inactive) TGF-β, bound to the cell surface of activated Treg is delivered directly to responder CD25− T cells

and is then locally converted to its active form. In contrast to these studies, Piccirillo et al. (116) were unable to show a requirement for either the production of TGF-β or responsiveness to TGF-β in Treg-mediated suppression. CD25− T cells from *Smad3*−/− and from mice expressing a dominant negative form of the TGF-β receptor II (TGFβRII), which are completely resistant to the immunosuppressive effects of TGF-β, were readily suppressed by Treg cells from WT mice (Table 30.5). Treg from TGF-β−/− mice were as efficient as Treg from WT mice in mediating suppression of WT CD25− T cells. High concentrations of anti-TGF-β did not reverse suppression, nor did anti-TGF-β or a soluble form of the TGF-βPII inhibit suppression mediated by activated CD25+ T cells.

A number of *in vivo* experiments have also demonstrated that autocrine TGF-β1 expression is not essential for Treg suppression *in vivo*. Transfer of TGF-β1−/− splenocytes to RAG-2−/− mice induced disease with features similar to those of the TGF-β1−/− mice, and disease transfer was accelerated by the depletion of TGF-β−/− CD25+ T cells. Importantly, cotransfer of TGF-β1−/− Treg clearly attenuated disease in RAG2−/− recipients of CD25-depleted spleen and lymph nodes, but suppression was incomplete when compared to WT Treg (117). Although TGF-β appears to play a nonredundant role in control of intestinal inflammation, Treg from TGF-β1−/− mice were capable of inhibiting IBD induced by CD45RB^{high} (118) or CD4+CD25− T cells (119) *in vivo*. Furthermore, Treg from mice expressing a dominant negative form of the TGF-βRII are also capable of inhibiting colitis, suggesting that TGF-β is not required for the development or peripheral function of thymic-derived Treg. Importantly, the function of TGF-β−/− Treg cells was abrogated by anti-TGF-β, indicating that TGF-β is absolutely required for protection from IBD in this model, but can be provided by a non-Treg cell source. The requirement for non-Treg–produced TGF-β was confirmed by demonstrating that CD4+CD45RB^{high} cells from the mice expressing the dominant negative

receptor escaped control by Treg cells *in vivo*. It is possible that Treg induce TGF-β production by other hematopoietic cells or that production of TGF-β is independent of Treg and produced by healing gut epithelial cells.

These studies argue strongly against a role for secreted or cell surface–associated TGF-β as a major mediator of the *in vitro* or *in vivo* suppressive functions of Treg. An alternative possibility is that TGF-β plays a role in the enhancement or maintenance of Foxp3$^+$ Treg-suppressor activity. Indeed, Marie et al. (120) have demonstrated that peripheral TGF-β1$^{-/-}$ Treg expressed diminished levels of Foxp3. These studies suggested that TGF-β is required for maintenance of Foxp3 expression in peripheral Treg, that the source of the TGF-β is not the Treg, and that paracrine production of TGF-β by APC is needed for optimal Treg survival and suppressor function. Further evidence for the role of TGF-β in the maintenance of Treg was derived from studies of mice with T cell–specific deletion of TGF-βRII (121). In these mice, TGF-β was not required for induction of Foxp3 expression in the thymus and for the thymic development of Treg cells. In fact, TGF-βRII$^{-/-}$ mice have an increase in the percentage and number of Foxp3$^+$ T cells in the thymus and increased BrdU uptake, suggesting that TGF-β normally inhibits the proliferation of thymic Treg. Increased Treg proliferation was also seen in the periphery of TGF-βRII$^{-/-}$ mice, but these mice have a decrease in the percentage of Foxp3$^+$ Treg in the periphery, consistent with the possibility that TGF-β is essential for their survival in the periphery. When mixed bone marrow chimeras between TGF-βRII$^{-/-}$ and WT mice were generated, the knockout CD25$^-$ T cells demonstrated complete resistance to suppression by WT Treg. Although one interpretation of this experiment is that Treg-derived TGF-β mediates suppression, preliminary studies using TGF-$\beta^{-/-}$ and Foxp3$^{-/-}$ bone marrow chimeras show that TGF-$\beta^{-/-}$ Treg cells are fully capable of preventing systemic lymphoproliferation associated with Foxp3 deficiency. This result suggests that there is a defect in a cell intrinsic mechanism of TGF-β–mediated control of T-cell reactivity in the TGF-βRII$^{-/-}$ T cells.

Role of CTLA-4

Considerable controversy exists regarding the significance of the expression of CTLA-4 on Treg and its potential involvement in their suppressor function. Takahashi et al. (39) have shown that the addition of the Fab fragment of anti-CTLA reverses suppression in cocultures of Treg and CD4$^+$CD25$^-$ T cells. This finding, together with the observation of Read et al. (27) that treatment of mice with anti–CTLA-4 abrogates suppression of inflammatory bowel disease (IBD) mediated by Treg T cells, has been interpreted as indicating that a costimulatory signal mediated by interaction of CTLA-4 with its ligands, CD80/CD86, is required for activation of Treg to mediate their sup-

pressive effects. Reversal of suppression by anti–CTLA-4 or its Fab fragment *in vitro* has not been seen in all studies (31,32,33,*34*,35,36,37). In studies (101) in which Treg suppress the activation of CD25$^-$ T cells in the absence of APC, the addition of anti-CTLA-4 or anti-CD80/CD86 did not reverse suppression, suggesting that engagement of CTLA-4 is not required for suppressor function. Treg from CTLA-4$^{-/-}$ mice are as efficient as WT Treg in mediating suppressor function *in vitro*, but, in contrast to WT Treg, their suppressive effects were partially dependent on TGF-β (122). One possible functional role for CTLA-4 on Treg would be to ligate CD80/CD86 on DC. Some (123) but not all studies (124) have claimed that CD80/CD86$^{-/-}$ CD25$^-$ T cells are refractory to Treg suppression *in vivo* and *in vitro*, and that interaction of CD80/CD86 on CD25$^-$ T cells with a molecule on Treg, most likely CTLA-4, is needed for suppression to be manifest.

Other Potential Suppressor Mechanisms

Overall, studies over the past 10 years have failed to identify a single molecular species that is responsible for Treg-mediated suppression *in vitro*. It remains possible that other well-characterized suppressor mechanisms may contribute, in part, to the suppressor function of Treg. The interaction of CTLA-4 on Treg with CD80 or CD86 on DC results in the activation of indoleamine 2,3-dioxygenase (IDO). IDO is responsible for the metabolism of the essential amino acid tryptophan. Reduced amounts of tryptophan after induction of IDO are associated with decreased activation of T cells. Induction of IDO production would represent an APC-dependent mechanism of *in vitro* suppression (125), but suppression by Treg can readily be observed in APC-free cultures.

One other potential mechanism for Treg-mediated suppression would be cytolysis of target cells. Human CD4$^+$CD25$^+$Foxp3$^+$ Treg can be activated by a combination of antibodies to CD3 and CD46 to express granzyme A and kill activated CD4$^+$ and CD8$^+$ T cells and other cell types in a perforin-dependent, Fas-FasL–independent manner (126). Significant cell death occurred at very low effector-to-target cell ratios (1:1), indicating potent cytotoxicity by the activated Treg. Activation of mouse Treg also results in upregulation of granzyme B expression, and one report has claimed that suppression of T-cell activation by Treg was mediated by a perforin-independent, granzyme B–dependent mechanism (127). These findings could not be confirmed in a second study that demonstrated that highly activated Treg could kill antigen-presenting but not bystander B cells or T cells (110). Nevertheless, these studies suggest that one should re-evaluate the concept of "cytotoxic/suppressor cell," because it appears at least *in vitro* that Treg can mediate both of these functions. It remains to be determined whether Treg can develop into cytotoxic cells *in vivo*.
FIGURE 30.10 Anti-GITR reverses suppression by inducing resistance to suppression in responder CD4+CD25− T cells. **A:** CD4+CD25+ T cells were cultured with CD4+CD25− T cells in the presence of T-depleted spleen cells and soluble anti-CD3. Normal goat IgG or polyclonal goat-anti-mouse GITR were added as indicated. Proliferation was measured at 72 hours. **B:** CD4+CD25+ T cells from WT or GITR−/− mice were cocultured with CD4+CD25− T cells in the presence or absence of anti-GITR. Engagement of glucocorticoid-induced TNFR family related receptor on effector T cells by its ligand mediates resistance to suppression by CD4+CD25+ T cells. *J Immunol.* 2004;173:5008–5020.

Resistance to Suppression

Although the mechanism of Treg-mediated cell contact–dependent inhibition of T-cell activation remains unknown, one approach to determining potential cell surface antigens involved in this process has been to reverse suppression with antibodies to candidate antigens. One member of the TNFRSF, the GITR (TNFRSF18), has been shown to play an important role in regulation of T-cell suppressor activity. Both a polyclonal antiserum and an mAb to the GITR appeared to be able to reverse suppression (Figure 30.10A), mediated by freshly isolated CD25+ T cells (40,41). However, the GITR is expressed on two populations of cells (resting Treg and activated CD4+CD25− cells) that do not manifest suppressor activity. It is therefore very unlikely that the GITR is the molecule responsible for mediating suppressor effector function. Surprisingly, culturing CD25+ T cells with the anti-GITR in the presence of IL-2, but in the absence of anti-CD3, resulted in a vigorous proliferative response and breaking the nonresponsive state of the Treg to stimulation with IL-2.

Although these studies were originally interpreted as indicating that anti-GITR functioned as an agonist for the GITR, resulting in a signal that instructs the Treg not to mediate their suppressive functions, more recent studies have suggested an alternative explanation. As both CD25− and Treg can express the GITR, it was impossible to conclude that the anti-GITR mediated its effects by acting solely on the Treg. When combinations of WT and GITR−/− CD4+CD25− and Treg were used in coculture experiments (Figure 30.10B), ligation of the GITR on the CD25− responders, not the Treg, was required to abrogate suppression (128). These results suggest that interactions of the GITR with its ligand, the GITR-L, provided a signal that renders effector T cells resistant to the inhibitory effects of Treg. Similar conclusions were drawn from studies in which the costimulatory effects of anti-GITR *in vivo* were maintained following depletion of Treg (129). The GITR-L was shown to be expressed on a number of different resting APC populations, including DC, macrophages, and B cells, and to be downregulated upon activation. Thus, engagement of the GITR on effector cells by its ligand on APC early during the course of an immune response may render the responder cells resistant to suppression by Treg. This model is also compatible with the observations of Pasare and Medzhitov (130) that soluble factors released by activated DC can act directly on effector, but not Treg, to render them resistant to suppression.

In addition to the role of APC-derived signals in rendering responder cells resistant to suppression, a number of mutations in TCR signaling and costimulatory pathways also appear to render responder cells completely resistant to the inhibitory signals delivered by Treg. One of the best examples of a defect in resistance to regulation is the cbl-b−/− mouse. Cbl-b is an E3 ubiquitin ligase that negatively regulates the CD28 costimulatory pathway and downregulates the PI3 K/Akt pathway. In the absence of cbl-b, mice develop CD28-independent hyperactive

responses and autoimmunity. Treg from cbl-b$^{-/-}$ mice function normally *in vitro*, but CD25$^-$ T cells from cbl-b$^{-/-}$ mice are resistant to suppression *in vitro* and *in vivo* by wild-type Treg (131). Effector T cells from a number of other mutant mouse strains exhibit a resistance to suppression similar to that seen with cbl-b$^{-/-}$ effectors (Table 30.6). Many of these strains have in common a hyperactivated PI3 K/Akt pathway that may be a direct or indirect target for Treg-mediated suppression.

Suppression *in vivo*

As has been summarized, a clear understanding of the molecular mechanism(s) for Treg-mediated inhibition of T-cell activation *in vitro* has remained elusive. Analysis of the potential pathways of Treg suppression *in vivo* is even more complex. The Treg must able to localize to various parts of the body such that close contact with most effector T cells with a given antigen specificity, either directly or through an APC intermediate, becomes possible. Unlike the culture situation, there is ample space for T cells to evade suppression *in vivo* unless Treg can localize with them in response to antigenic stimulation that begins in antigen-draining lymph nodes. There are also a number of major differences between the properties of Treg *in vivo* compared to *in vitro*. First, although Treg are nonresponsive or anergic to stimulation via the TCR *in vitro*, Treg expand following engagement of their TCR by cognate antigen in a manner indistinguishable from conventional CD4$^+$ T cells *in vivo* (132). Second, most studies of Treg suppression *in vitro* have failed to define a role for suppressor cytokines, whereas multiple studies have shown that secretion of suppressor cytokines by Treg constitutes an important component of their suppressive effects *in vivo*. Lastly, the major effect of Treg on T-cell activation *in vitro* is to inhibit IL-2 production and effector-cell expansion. The role of IL-2 in the antigen-driven expansion of CD4$^+$ T cells *in vivo* is not clear, as antigen-specific T cells from IL-2$^{-/-}$ mice expand normally following stimulation by antigen *in vivo*.

Some studies have suggested that the primary effect of Treg *in vivo* is to inhibit the differentiation, but not the expansion, of T effector cells *in vivo*. Klein et al. (133) cotransferred into normal mice equal numbers of effectors and Treg, expressing the same transgene, followed by immunization with the antigen in incomplete adjuvant. For the first 4 days after transfer, both populations expanded in an equivalent manner. However, 6 to 8 days after transfer, the expansion of the Treg continued, but additional accumulation of effectors was suppressed. In contrast to the studies demonstrating inhibition of T effector differentiation, the remaining effector cells appeared to be fully competent to produce either IL-2 or IFN-γ. One problem with the interpretation of this study is that the studies can be conducted only for short periods of time, as the transferred cells migrate out of the draining lymph nodes.

Very little is known about the cell surface antigens that might play a role in Treg-mediated inhibition *in vivo*. Anti-CTLA-4 has been shown to abrogate suppression of IBD *in vivo* by Treg. In order to distinguish whether the effects of anti-CTLA-4 on reversal of Treg suppression of IBD are mediated indirectly by hyperactivation of effector T cells or directly via their effects on Treg, Treg were derived from CTLA-4$^{-/-}$ mice on a CD80/CD86$^{-/-}$ background that do not develop an autoimmune syndrome (134). When combinations of genetically deficient mice and WT T cells were used, it could be shown that anti-CTLA-4 or its Fab fragment disrupts Treg activity by targeting Treg and not the effector T cells. Anti-CTLA-4 did not overcome the regulatory activity of CTLA-4$^{-/-}$ Treg, showing that ligation of CTLA-4 on the effector population had limited impact on the induction of colitis in this system. The effects of anti-CTLA-4 were not mediated by depletion of CTLA-4$^+$ Treg. Although anti-CTLA-4 Fab may block the interaction of CTLA-4 with its ligands, it is also possible that the interaction of CLTA-4 with antibody, or even Fab fragments, may modulate the expression of CTLA-4 on the cell surface or inhibit its recycling and thereby block the TCR-mediated signals required for induction of suppressor activity.

Many of the *in vitro* studies of Treg function have concluded that the target for suppression is the responder T cell. In contrast, recent studies suggest that the suppressive effects of Treg *in vivo* might also be mediated by the reduction of the stimulatory capacity of DC or other types of APC. Intravital two-photon laser scanning microscopy has been used to visualize the behavior of autoantigen-specific T cells in the presence or absence of Treg in intact lymph nodes (135,136). In the absence of Treg cells, the locomotion of autoantigen-specific T cells inside lymph nodes is decreased, and the contact between effector T cells and antigen-loaded DC are prolonged, while contacts between T cells and antigen-presenting DC are of shorter duration in the presence of Treg cells. Thus, Treg attenuate the establishment of stable contacts during priming of naïve T cells by DC and thereby may decrease the magnitude of TCR activation. Importantly, no stable interactions between the Treg cells and effector T cells were observed

in these studies. These observations are most consistent with the concept that Treg cells can inactivate DC directly or that DC-activated Treg cells produce soluble mediators that prevent T effector–DC interactions.

Foxp3⁻ Treg

Thymic-derived Foxp3$^+$ Treg or Foxp3$^+$ Treg induced in peripheral sites represent the major population of Treg that have been characterized in both normal physiologic studies and in disease models. A number of other Treg populations have been described in both mouse and human, and many of these also appear to exert potent Treg functions in certain defined situations. One important distinction between these induced populations of Treg and the Foxp3$^+$ Treg is that the former are very frequently specific for known antigens, whereas the antigen specificity of the latter remains to be defined.

Th3 Cells

One of the first approaches used for the induction of Treg was the administration of antigen via the oral route. Oral tolerance takes advantage of the normal physiologic process that is needed to prevent systemic immune responses to ingested proteins. Oral administration of antigen at low doses induces populations of Treg that secrete suppressor cytokines, whereas higher antigen doses result in deletion or clonal anergy of autoreactive precursors. Pretreatment with orally administered antigen induced suppressor populations that suppressed pathology in a number of different animal models of autoimmunity, including experimental allergic encephalomyelitis (EAE), collagen-induced arthritis (CIA), and uveitis (137). Bulk T cells from orally tolerized animals can suppress active immune responses to other antigens in the microenvironment, a phenomenon called antigen-driven bystander suppression. The suppressor cells from orally tolerant mice have been termed Th3 cells and mediate their suppressive effects primarily by secreting TGF-β. A major advance in our understanding of the function of regulatory cells following oral tolerance was a study by Chen et al. (138), which successfully isolated T-cell clones from the mesenteric lymph nodes of SJL mice that had been orally tolerized to MBP. These clones produced large amounts of TGF-β and varying amounts of IL-4 and IL-10. Most important, upon adoptive transfer to normal recipients, they suppressed EAE induced with either myelin basic protein (MBP) or proteolipid protein (PLP). Their *in vivo* suppressive activity could be neutralized with anti-TGF-β. The selective induction of Treg via the oral route is thought to be secondary to certain poorly characterized properties of the gut mucosal microenvironment, most likely the type of resident APC (139,*140*).

Although the oral administration of antigen represents a potentially easy way to induce Treg, progress in this area has been slow because it has been difficult to determine the antigen concentration that is capable of inducing Treg but that does not induce deletion. It has also been very difficult to isolate the types of clones described earlier in the EAE model in other systems or to identify Treg cells that exclusively produce TGF-β in other models. The therapeutic utility of orally administered antigens in autoimmunity has primarily been demonstrated in pretreatment protocols, and oral administration of antigen has been ineffective in treating animals once disease has been initiated.

T Regulatory 1 (Tr1) Cells

One important lesson that can be derived from the experiments on oral tolerance is that the milieu in which T cells are primed is critically important in determining whether regulatory rather than effector T cells will be generated. Decreased expression of costimulatory molecules on APC or the presence of suppressor cytokines such as IL-10 and TGF-β may generate suppressor T cells rather than effector T cells. The production of these suppressor cytokines by Treg may lead to the generation or expansion of additional regulatory cells via a positive feedback loop (Figure 30.11).

One of the first studies demonstrating the potential importance of IL-10 in the generation of Treg was derived from an analysis *(141)* of patients with severe combined immunodeficiency who received transplants of HLA-mismatched hematopoietic stem cells. Complete immunologic reconstitution was achieved in the absence of graft-versus-host disease. CD4$^+$ T-cell clones reactive with host MHC antigens from these patients produced IL-10, but not IL-2, after antigen-specific stimulation *in vitro*. It therefore seemed likely that endogenous IL-10 production in the transplanted patients was responsible for maintaining tolerance *in vivo*. The IL-10 may prevent the activation
FIGURE 30.11 Multiple factors can induce the differentiation of IL-10–producing T cells.

of host reactive T cells or suppress APC function and cytokine production by host APC. The high IL-10 production *in vivo* may reflect a chronic activation of donor T cells and host monocytes.

IL-10 is a cytokine produced by numerous cell types, including activated T cells, B cells, mast cells, and macrophages, and acts primarily by inhibiting the maturation and function of APC. The activation of CD4+ human T cells in the presence of IL-10 renders them nonresponsive or anergic (142). Activation of human CD8+ T cells with allogeneic APC and IL-10 also results in reduced proliferation and cytotoxicity. T cells rendered anergic by the addition of exogenous IL-10 in an MLR become unable to respond to a rechallenge with the same antigen. IL-10–induced anergy is strictly antigen-specific, because treated T cells retain normal proliferative and cytotoxic responses toward other protein antigens and third-party alloantigens.

Collectively, these studies suggested that IL-10 itself is a major factor for the induction of suppressive IL-10–producing T cells. Culture of mouse or human CD4+ T cells with antigen or alloantigen in the presence of IL-10 results in the generation of IL-10–producing T-cell clones. Most of these T-cell clones produce high levels of IL-10 and TGF-β, moderate amounts of IFN-γ and IL-5, but not IL-2 or IL-4. CD4+ T cells generated in this manner have been termed T regulatory 1 (Tr1) cells (143). Tr1 cells proliferate poorly following polyclonal TCR-mediated or antigen-specific activation and do not expand significantly under standard T-cell culture conditions. This low proliferative capacity is a result in part to autocrine production of IL-10, because anti–IL-10 mAbs partially restore proliferative responses. The intrinsic low proliferative capacity of Tr1 cells has been a major limitation and has hindered their detailed characterization. The ability to generate human Tr1 cells is enhanced by the addition of IFN-α *(144)*. Tr1 cells can be generated from human cord blood with IFN-α alone, as cord blood T cells have the intrinsic ability to produce IL-10. IFN-α and IL-10 do not act as general antiproliferative agents, but rather as factors that induce the differentiation of Tr1 cells and inhibit the growth of non-Tr1 cells in the culture. TGF-β played no role in the induction of Tr1 cells in this model. A global suppression of all cytokine production was seen when TGF-β was added to the cultures.

Tr1 cells do not express Foxp3 and can be generated in the absence of Foxp3+ Treg. Both human and mouse Tr1 clones suppress immune responses *in vitro*. Antigen-induced proliferation of naïve CD4+ T cells was dramatically reduced following coculture with activated Tr1 clones that were separated from the responding cells by a transwell insert. The capacity of either human or mouse Tr1 clones to suppress CD4+ T cells proliferation was reversed by the addition of anti-TGF-β and IL-10 mAbs (143). Some IL-10–producing Tr1 cells suppress the proliferation of

naïve CD4+ T cells by an IL-10–independent, cell contact–dependent mechanism (145). Human Tr1 cell clones also suppress the production of immunoglobulin by B cells, as well as the antigen-presenting capacity of monocytes and DC. Most important, it could be shown (143) that mouse Tr1 clones have regulatory effects *in vivo* and suppress Th1-mediated colitis induced by transfer of CD45RB^high cells into SCID mice. Suppression was seen only if the Tr1 clones were activated by antigen-specific stimulation via their TCR. Because the function of Tr1 cells is mediated by IL-10 and TGF-β, these studies imply that Tr1 clones can suppress active immune responses to unknown antigens in the microenvironment by an antigen-driven bystander suppression mechanism similar to the mechanism proposed for Th3 cells in oral tolerance. Although IL-10 was originally described as a product of mouse Th2 cells, Tr1 clones are also capable of regulating Th2 responses, including antigen-specific IgE production (146). Anti-IL-10R antibodies reversed this inhibitory effect.

An alternative approach to the generation of Tr1 cells *in vitro* has involved pharmacologic manipulation of the microenvironment during T-cell priming (147). The immunosuppressive drug 1, 25(OH)2-vitamin D3 (VitD3), acts on APC and activated T cells. VitD3 inhibits antigen-induced T-cell proliferation, cytokine production, and the maturation of human DC, leading to inhibition of the expression of CD40/CD80/CD86. Similarly, the glucocorticoid dexamethasone inhibits key transcription factors involved in the regulation of a number of inflammatory cytokine genes. When naïve CD4+ T cells were stimulated through their TCR in the presence of the combination of VitD3 and dexamethasone, the primed T cells produced IL-10, but not IFN-γ, IL-4, or IL-5 (79). The IL-10–producing cells developed independently of Th1 (IL-12, IFN-γ) and Th2 (IL-4) polarizing cytokines, and addition of these cytokines inhibited the development of the IL-10–producing cells. Although the induction of these Treg could not be induced by IL-10, endogenous IL-10 production was required, because addition of anti-IL-10R antibodies substantially reduced the number of IL-10–producing T cells. These cytokines have the potential to mediate inflammatory pathologies. The development of the IL-10–producing T cells occurred under conditions in which the expression and/or activation of key transcription factors involved in Th1 (T-bet) and Th2 (GATA3) differentiation was minimal, suggesting that the IL-10 producers were completely unrelated to conventional Th1 or Th2 cells. VitD3/dexamethasone-induced Tr1 cells are also capable of inhibiting the induction of Th1-mediated autoimmune disease *in vivo*.

One common theme to emerge from the studies on the *in vitro* induction of Tr1 cells, by the addition of either IL-10 or pharmacologic agents, is that both of these modalities are likely to inhibit the maturation and activation of DC and to generate what has been termed "tolerogenic DC." Treg have been generated by culturing

human CD4$^+$ cord-blood lymphocytes with allogeneic immature DC (iDC). Stimulation with mature DC resulted in expansion of alloreactive T cells of the Th1 phenotype, but stimulation in the presence of iDC resulted in the induction of poorly growing IL-10–producing T cells (148). These T cells suppressed the alloantigen-driven proliferation of syngeneic Th1 cells in cocultures in a cell contact–dependent manner. The suppressor effector function was nonspecific and was not mediated by IL-10 or TGF-β, but suppression could be partially be overcome by addition of IL-2. The suppressor population generated by stimulation with iDC in many respects resembles naturally occurring CD25$^+$ cells. It is not known if these iDC-induced Treg express Foxp3.

CD8$^+$ Treg

Most of the early studies on T-suppressor cells in the mouse demonstrated that they were confined to the CD8$^+$ subset. Although almost all of the recent studies on suppressor/regulatory T cells in mouse or human have focused on CD4$^+$ T cells, a number of recent studies have suggested that potent CD8$^+$ suppressor cells may also exist. Repeated stimulation of human T cells in the MLR resulted in a progressive decrease of the capacity of CD4$^+$ T cells to proliferate when rechallenged with the APC used for priming. The relative nonresponsiveness of the stimulated CD4$^+$ T cells could be restored by depletion of CD8$^+$CD28$^-$, but not CD8$^+$CD28$^+$, T cells from these cultures. The stimulated CD8$^+$CD28$^-$ T cell population was devoid of cytotoxic activity for either CD4$^+$ T cells or the APC used for priming. When the CD8$^+$CD28$^-$ T cells were added to mixtures of CD4 cells and APC, they inhibited proliferation (149), but suppression was observed only when the stimulatory APC shared at least one HLA class I allele with the original stimulator population. The regulatory effect of the CD8$^+$ suppressors was not restricted either by class I or class II MHC antigens expressed by the responder CD4$^+$ T cells. Suppression mediated by CD8$^+$CD28$^-$ T cells required cell–cell contact and was not reversed by antisuppressor cytokine antibodies. Coincubation of the CD8$^+$ suppressors with CD4$^+$ responders had no effect, whereas coincubation of the CD8$^+$ T cells with the APC rendered the APC unable to stimulate CD4$^+$ proliferation. Phenotypic analysis indicated that the CD8$^+$ suppressors blocked the upregulation of costimulatory molecules such as CD80/CD86, CD54, and CD58 on the APC *(150)*. The mechanism by which the CD8$^+$ suppressors deactivate APC functions has been shown to involve upregulation of the genes encoding immunoglobulinlike transcript 3 (ILT3) and ILT4 (151). These inhibitory receptors are structurally and functionally related to killer cell–inhibitory receptors (KIR). Thus far, the biologic activity of these CD8$^+$CD28$^-$ suppressor populations has only been studied *in vitro*. Their potential roles in mediating immunosuppression *in vivo* as well

as their relationship to CD4$^+$ suppressor cells remain to be explored. It has been proposed that antigen-specific MHC class I–restricted CD8$^+$CD28$^-$ Treg first induce ILT-expressing tolerogenic DC, which in turn generate CD4$^+$ Treg (152).

Regulatory CD8$^+$ T cells have also been generated *in vitro* by stimulation with unique subpopulations of DC *(153)*. When naïve CD8$^+$ T cells were stimulated *in vitro* with CD40L-activated, monocyte-derived DC (DC1), the primed CD8$^+$ T cells proliferated when restimulated with allogeneic targets, secreted large amounts of IFN-γ and had potent cytotoxic activity. In contrast, when naïve CD8$^+$ T cells were stimulated with CD40L-activated plasmacytoid DC (DC2), the primed CD8$^+$ T cells proliferated poorly, displayed weak cytotoxic activity, and secreted primarily IL-10. DC2-primed CD8$^+$ T cells inhibited the ability of naïve CD8$^+$ T cells to proliferate to allogeneic monocytes, iDC, or mature DC. Both the generation of CD8$^+$ suppressor cells and their suppressor function could be markedly inhibited by anti-IL-10, but not by anti-TGF-β. Dhodapkar et al. *(154)* have measured the ability of iDC1 cells to modulate the immune response *in vivo* in humans. Injection of iDC pulsed with influenza matrix peptide resulted in an expansion of antigen-specific, tetramer-binding CD8$^+$ T cells. These CD8$^+$ cells were capable of proliferating when stimulated with antigen *in vitro*, but were defective in IFN-γ secretion and lacked cytotoxic function. These findings indicate that iDC can dampen pre-existing antigen-specific effector function in humans. The potential suppressive function of the CD8$^+$ T cells that responded to the iDC was not studied. The relationship of these CD8$^+$ T cells to those induced *in vitro* with DC2 cells is unknown. Wei et al. (155) have isolated plasmacytoid DC from malignant ascites of patients with ovarian cancer. These DC, upon CD40L activation, could induce antigen-specific CD8$^+$ IL-10, producing Treg that suppressed the responses of tumor antigen-specific CD4$^+$ T cells.

CD8$^+$CD122$^+$ Treg

A unique subpopulation of CD8$^+$ T cells that expresses high levels of the IL-2R β chain (CD122) has been shown to have immunoregulatory activity (156). The percentage of CD8$^+$CD122$^+$ T cells is high in young mice ($\sim$50%), but decreases to $\sim$10% at 7 to 10 weeks of age. CD122$^{-/-}$ mice develop an autoimmune syndrome that can be prevented when neonates are injected with CD8$^+$CD122$^+$ T cells. Importantly, RAG$^{-/-}$ mice reconstituted with CD8$^+$CD122$^-$ T cells develop an autoimmune syndrome that can be prevented by cotransfer of CD8$^+$CD122$^+$ T cells, but not CD4$^+$Foxp3$^+$ T cells. CD8$^+$CD122$^-$ are Foxp3$^-$ and inhibit the activation of both CD8$^+$ and CD4$^+$ T cells *in vitro* by an IL-10–dependent mechanism, as CD8$^+$CD122$^+$ T cells from IL-10$^{-/-}$ could not suppress T-cell activation *in vitro*, but may exert some suppressive effects *in vivo* (157).

Qa-1 Restricted CD8⁺ Treg

Mice that are genetically deficient or depleted of CD8⁺ T cells have demonstrated a clear role for CD8⁺ T cells in regulating EAE. CD8⁺ T cells from mice that had recovered from EAE downregulated or killed some CD4⁺ neuroantigen-specific T-cell clones. Inhibition was blocked by antibodies to the MHC class Ib molecule Qa-1, but not by anti-MHC class Ia molecules (158). It has been proposed that Qa-1 self-peptide complexes expressed by activated CD4⁺ T cells trigger the TCR on CD8⁺ cells. These CD8⁺ T cells then differentiate into suppressor cells that in turn suppress the CD4⁺ T cells that express the same Qa-1 self-peptide complex. Other studies suggest that a peptide from the conserved region of the TCR is targeted by the CD8⁺ Treg population (159). The mechanism of suppression has not been fully defined, although it may involve cytotoxicity or the secretion of suppressor cytokines. Human CD8⁺ T cells restricted by HLA-E, the human homolog of mouse Qa-1, may have similar functions (160).

Double-Negative (DN) Treg

The majority of T cells in normal mice and humans that express the TCR $\alpha\beta$ chains also express either the CD4 or CD8 co-receptor molecules. However, 1% to 5% of the peripheral TCR $\alpha\beta$ population expresses CD3, but not CD4 or CD8. DN T cells can be divided into NKT cells and NK-marker-negative DN Treg. DN Treg do not develop from CD8⁺ precursors, nor is CD8 expression required for their development *in vivo* (161). Functional DN Treg develop outside of the thymus and may mature from a previously uncharacterized lineage of T cells. DN T cells have been shown to have immunoregulatory activity both *in vivo* and *in vitro* in both mouse and human (162). These DN populations were derived following administration of donor antigens to induce tolerance to allografts, and are presumably derived from precursors present in normal peripheral lymphoid populations (163). DN suppressors generated in this way kill alloreactive CD4⁺ and CD8⁺ T responders that express functional Fas by a mechanism involving Fas/Fas-L interactions. These activated DN cells were only able to kill syngeneic targets activated by the same alloantigenic stimulus.

Treg-Induced Treg

One possible mechanism to increase the efficiency of Treg is that Treg induce anergy or suppressor activity in the CD25⁻ responders as a form of infectious immunologic tolerance. It has been shown that human CD4⁺CD25⁺ T cells induce CD4⁺CD25⁻ T cells to become Treg that are capable suppressing by producing IL-10 *(164)* or TGF-β (165) and thereby mediating suppression of naïve CD4⁺ T cells. Similar studies in the mouse demonstrated that coculture of Treg with Foxp3⁻ responder cells resulted in the induction of both TCR and IL-2 unresponsiveness in the responder population (166). The responder cells remained Foxp3⁻ and exerted suppressor activity in a cell contact–dependent manner that was partially abrogated by anti-TGF-β.

CONTROL OF AUTOIMMUNE DISEASE BY Treg

Autoimmune Gastritis (AIG)

The role of Treg in the prevention of organ-specific autoimmune diseases has been studied in a number of different animal models. One of the best-studied models is autoimmune gastritis (AIG) that develops when BABL/c mice are subjected to d3Tx or when *nu/nu* mice on a BALB/c background are reconstituted with CD4⁺CD25⁻ T cells. A large body of evidence had implicated the major protein pump of the gastric parietal cell, the H/K ATPase, as the target antigen for the CD4⁺ T cells that are responsible for inducing this disease *(167,168)*. To evaluate whether Treg could prevent disease induced by primed, fully differentiated effector-cell populations, two H/K ATPase-reactive T-cell lines were derived from d3Tx animals *(23)*. Both of these lines were CD4⁺, I-A^d–restricted and recognized distinct peptides derived from the H/K ATPase α chain. One of the cell lines secreted Th1 cytokines and the other Th2, but both were equally pathogenic in inducing gastritis when transferred to immunocompromised, but not normal, recipients. The capacity of both of these clones to transfer disease to *nu/nu* recipients could be inhibited by cotransfer of CD4⁺CD25⁺ Treg from normal BALB/c mice. Thus, Treg are able to inhibit not only the initiation of disease after d3Tx, but also the function of fully activated effector cells. To address the possible involvement of cytokines in suppression of AIG, Treg from a number of different cytokine deficient mice were utilized to prevent induction of disease either after d3Tx or in *nu/nu* recipients of CD25⁻ T cells. Treg from both IL-4 and IL-10$^{-/-}$ mice were as efficient as wild-type Treg in preventing the induction of disease (169,*170*). Furthermore, the protective capacity of Treg from wild-type mice was not reduced when the reconstituted mice were treated with an antibody to TGF-β (116).

It remains unknown whether Treg prevent autoimmune disease by inhibiting the priming and expansion of effector cells, by acting on APC, by preventing migration from the draining LN into the target organ, or by preventing the differentiation of naïve precursors into pathogenic effector cells. One important tool in furthering our understanding of the mechanism of action of Treg-mediated inhibition of AIG was the development of a line of TCR transgenic mice whose receptors recognize a defined peptide of the H/K
FIGURE 30.12 Treg do not block the expansion of effector T cells in the gastric lymph node, but they do inhibit the total number of cells. Adapted from DiPaolo RJ, Glass DD, Bijwaard KE, Shevach EM. CD4$^+$CD25$^+$ T cells prevent the development of organ-sepcifc autoimmune disease by inhibiting the differentiation of autoreactive effector cells. *J Immunol.* 2005;175:7135–7142.

ATPase and that spontaneously develop AIG (171). Small numbers of CD4$^+$CD25$^-$ thymocytes from this transgenic line can transfer AIG, home to the gastric lymph node, and be activated by DC that have acquired the H/K ATPase from parietal cells in the gastric mucosa. Cotransfer of polyclonal Treg with a small number of naïve auto-antigen–specific T cells under conditions in which lymphopenia-induced proliferation was partially controlled, was quite effective in inhibiting the development of AIG, demonstrated by suppression of parietal cell destruction and lack of autoantibody production. Treg failed to inhibit the migration of autoreactive T cells into the gastric lymph or into the target organ and did not inhibit the antigen-driven expansion of autoreactive T cells in the gastric lymph node (Figure 30.12). The primary effect of the Treg appeared to be inhibition of the differentiation of the self-specific T cells to Th1 effector cells, as reflected by a decrease in antigen-stimulated IFN-γ production and reduction in Tbet expression. A decrease in the total cellularity of the gastric lymph node was also seen in recipients of the Treg and likely reflects decreased cytokine/chemokine production by the effector T cells secondary to the suppressive effects of Treg.

It is widely assumed that Treg must be activated via the TCR to exert their suppressive effects *in vitro* and *in vivo*. The source of the TCR signal during *in vivo* activation of polyclonal populations of Treg is not known. In the AIG model, suppression of the antigen-specific induction of IFN-γ production could be observed as early as 7 days after transfer. It seems highly unlikely that this suppression is secondary to the activation and expansion of the limited number of gastric antigen-specific Treg within the polyclonal population. An alternative possibility is that Treg are able to control various responses because they are continuously recognizing and being partially activated by ubiquitous self-peptides.

To evaluate whether organ or antigen-specific Treg are more efficient at preventing autoimmunity than a polyclonal population of Treg with diverse antigen specificities, antigen-specific Foxp3$^+$ Treg were generated from naïve H/K ATPase-specific T cells following *in vitro* activation in the presence of TGF-β. After transfer, they maintained Foxp3 expression and inhibited the development of AIG. The mechanism of action of the antigen-specific-induced Treg was different from that of the polyclonal Treg, as they suppressed disease by preventing the initial activation and expansion of the autoreactive effector cells. The major effect of the induced Treg was to inhibit the priming of autoreactive T cells within the gastric lymph node. A 40-fold reduction in the number of autoreactive effectors was observed within the first 5 days. DC that had been in the presence of the induced Treg had a reduced capacity to present endogenous antigen compared to those from noninjected mice or mice injected only with effector cells. Thus, one mechanism by which induced Treg exert their function *in vivo* is by reducing the ability of DC to prime autoreactive T cells, hence stopping the autoimmune reaction before it even starts. The data from the AIG studies are most consistent with a model in which the Treg exert their negative effect by decreasing the stimulatory capacity of DC, rather than by competing with the effectors for antigen or by acting directly with the effectors to prevent their interaction with DC.

Inflammatory Bowel Disease (IBD)

The differential expression of the CD45RB isoforms initially used to define effector and regulatory T cells in the rat was extended to the mouse. Transfer of CD4$^+$CD45RB^{high} cells to SCID mouse recipients resulted in the development of a wasting disease and colitis 6 to 8 weeks after T-cell transfer. This disease was characterized pathologically by epithelial cell hyperplasia, goblet cell depletion, and transmural inflammation (172). There was a 20- to 30-fold accumulation of Th1 cells in the intestine compared to normal mice. Treatment of recipients with anti-IFN-γ, anti-TNF-α, or anti-IL-12 inhibited the induction of disease. Transfer of CD45RB^{low} cells did not induce colitis, and cotransfer of RB^{high} and RB^{low} cells prevented the development of colitis. A ratio of 1:8 RB^{low} to RB^{high} was able

▌ **TABLE 30.7** **Role of Cytokines in the Pathogenesis and Treatment of Inflammatory Bowel Disease**

Treatment	Effect on Disease
Anti-IFN-γ (d 1 + 4)	Substantial protection
Anti-TNF-5α (d 1 + 4)	No protection
Anti-TNF (weekly)	Protection during treatment only
IL-10	Protection during treatment only
IL-4	No protection
CD4$^+$CD25$^+$ T cells	Complete protection
CD4$^+$CD25$^+$ T cells + anti-IL-4	Complete protection
CD4$^+$CD25$^+$ T cells + anti-IL-10R	Protection with naïve CD45RB^{high}
CD4$^+$CD25$^+$ T cells + anti-IL-10R	No protection with naïve CD45RB^{low}
CD4$^+$CD25$^+$ T cells + anti-TGF-β	No protection

Adapted from Powrie F, Leach MW, Mauze S, et al. Inhibition of TH1 responses prevents inflammatory bowel-disease in SCID mice reconstituted with CD45RB^{high} T cells. *Immunity.* 1994;1:553–562; Asseman C, Read S, Fowrie F. Colitogenic Th1 cells are present in the antigen-experienced T cell pool in normal mice: Control by CD4$^+$ regulatory T cells and IL-10. *J Immunol.* 2003;171:971–978; and Powrie F, Carlino J, Leach MW, et al. A critical role for transforming factor-β but not interleukin 4 in the suppression of T helper 1-mediated colitis by CD45RB^{low}CD4$^+$ T cells. *J Exp Med.* 1996;183:2669–2674.

to prevent disease. When CD45RB^{low} cells were fractionated into CD25$^+$ and CD25$^-$ fractions, control of intestinal inflammation was mediated primarily by the CD25$^+$ fraction (27). CD45RB^{low} CD25$^-$ cells did exert some suppressive function when transferred at high cell concentrations.

Treatment of recipients of RB^{high} cells with IL-10 inhibited the development of colitis (Table 30.7). This treatment inhibited the accumulation of Th1 cells in the intestine, but did not induce Treg, because colitis developed when IL-10 administration ceased. Treg isolated from IL-10$^{-/-}$ mice are able to inhibit colitis induced by CD4$^+$CD45RB^{high} cells, indicating that IL-10 secretion by Treg themselves is not required. However, control of colitis induced with CD25$^-$CD45RB^{low} cells was found to be highly dependent on IL-10 (173). The ability of Treg to inhibit colitis did not involve IL-4, but was dependent on TGF-β, because administration of anti-TGF-β abrogated the protective effect of these cells (174). It should be emphasized that Treg-mediated suppression of AIG involves a cell contact–dependent mechanism of suppression, and IL-10 and TGF-β are not involved, whereas Treg-mediated suppression of IBD is abrogated by anti-IL-10 and/or anti-TGF-β. One reason for this difference is that the pathogenesis of AIG and IBD are quite distinct. Bacteria play a required role in IBD, whereas AIG can be induced by d3Tx of germ-free mice. It remains possible that suppression of IBD involves both the cell contact–dependent and the cytokine-mediated pathways of suppression. IL-10 and TGF-β are required to first dampen the inflammatory response induced by intestinal bacteria. Once this response is reduced, cell contact–mediated suppression can become operative.

Mice with colitis have an accumulation of activated CD4$^+$ T cells in the mesenteric LN and colon. This T-cell infiltrate is accompanied by an accumulation of DC that in the mesenteric LN, but not the colon, express CD134L (OX-40L). Binding of CD134L to CD134 on T cells provides a costimulatory signal for T-cell activation. Administration of anti-CD134L prevented the development of colitis (175). Blockade of CD134/CD134L interactions does not inhibit signals involved in the early activation of pathogenic T cells, but may inhibit amplification of the response. DC may pick up intestinal antigens in the colon and transport them to the mesenteric lymph node, where they activate T-effector cells. In the absence of Treg, CD134$^+$ DC may magnify this response leading to colitis. Treg may inhibit the migration of DC to the lymph node or inhibit macrophage activation in the colon.

One advantage of the IBD model is that CD4$^+$CD25$^+$CD45RB^{low}, but not CD4$^+$CD25$^-$CD45RB^{low}, T cells can cure ongoing colitis 4 weeks after transfer of CD4$^+$CD45RB^{high} T cells *(176)*. Treg proliferate and accumulate in the mesenteric LN and also in the colonic lamina propria. At both sites, the progeny of the Treg are in direct contact with CD11c$^+$ DC as well as effector T cells. These findings suggest that regulation of an active immune response by Treg occurs in the draining LN as well as at the site of inflammation. During the cure of intestinal inflammation, the majority of the Foxp3$^+$ T cells are IL-10–secreting cells. Whereas Foxp3$^+$ cells are present in similar frequencies in both the secondary lymphoid organs and lamina propria of colitic animals, the IL-10–producing cells are selectively enriched in the colonic lamina propria. The gut environment may condition the Treg to differentiate into IL-10–producing Treg in the colon. Alternatively, the accumulation of Treg in the colon may be attributed to the preferential expansion of a minor subset of IL-10 producers contained in the transferred population. Treg from IL-10$^{-/-}$ mice, although less potent than wild-type Treg, are able to cure colitis. It is also likely that other cell types, possibly under the instruction of Treg, can make a significant amount of IL-10 and contribute to the cure of disease. Cure of colitis was not dependent on a reduction the proportion of IFN-γ–secreting cells among the effector cells, but the total number of CD4$^+$ T cells was greatly reduced.

Autoimmune Thyroiditis

In studies using the adult Tx-irradiation model for the induction of autoimmune thyroiditis, Seddon and Mason *(176)* demonstrated that disease could be prevented by the injection of CD4$^+$CD45RC^{low} peripheral T cells or by CD4$^+$CD8$^-$ thymocytes. In fact, the thymocytes were 10 times more potent that the Treg derived from the periphery. Suppression of thyroiditis mediated by both cell populations could be reversed by treatment of the recipients

with either anti-IL-4 or anti-TGF-β. These studies strongly suggest that the mature CD4$^+$CD8$^-$ thymocyte population contains a high frequency of Treg or Treg precursors with the potential to differentiate in the periphery into Treg that prevent organ-specific autoimmunity. Detailed studies of Foxp3 expression by CD25$^+$ and CD25$^-$ T cells in this rat model have not as yet been performed.

Insulin-Dependent Diabetes Mellitus (IDDM)

The nonobese diabetic mouse (NOD) represents the best experimental model for autoimmune diabetes. It is widely accepted that CD4$^+$ Treg play a critical role in the regulation of disease in this animal model *(177)*. The islets of Langerhans become rapidly infiltrated with immune cells several weeks before the onset of diabetes. Diabetes progression may relate to a subsequent failure in the maintenance of Treg function. Because diabetes could only be transferred from sick mice to normal syngeneic recipients if the recipients were less than 5 weeks of age (female) or 3 weeks of age (male), it was assumed that Treg was deficient in young mice. Cyclophosphamide treatment, which may preferentially deplete Treg, accelerated the development of disease in young NOD mice. CD4$^+$ T cells from nondiabetic NOD mice could prevent the transfer of diabetes from overtly diabetic mice into sublethally irradiated NOD recipients. The protective cell population was not present in the spleen until 3 weeks of age and reached its highest activity at 8 weeks of age; suppressor cells were present in the thymus of neonates, which may explain why thymectomy at weaning accelerated disease. Diabetes could also be efficiently transferred to nonirradiated adult NOD recipients, if they were Tx and depleted of CD4$^+$ T cells. Depletion of T cells alone was not sufficient for disease transfer, suggesting that Tx was needed to limit emergence of newly generated CD4$^+$ Treg from the thymus. Islet infiltrating T cells from young nondiabetic mice could transfer diabetes to NOD/SCID mice, but cotransfer of CD4$^+$CD45RB^{low} T cells from spleen of the same mouse delayed the onset of disease. Some studies demonstrated that the Treg could also be distinguished from the effector T cells by differential expression of CD62L.

Chatenoud et al. (178) have examined whether CD4$^+$CD25$^+$ Treg play a protective role in the NOD mouse. Young NOD/SCID recipients were injected IV with mixtures of splenocytes from diabetic NOD mice, and Treg and CD25$^-$ T cells from the spleens of prediabetic NOD mice. Treg from young (6-week-old) prediabetic mice significantly protected against diabetes in this model. Protection could be reversed by treatment of the recipient mice with anti-TGF-β, but not anti-IL-4 or anti-IL-10. Interestingly, anti-TGF-β did not reverse protection mediated by Treg derived from the thymus. CD4$^+$CD25$^-$ T cells from young NOD mice could also exert some degree of pro-

tection in adoptive transfer studies. Analysis of Treg function in the NOD mouse is difficult because not all animals will develop disease and it takes a long time for disease to develop. Green et al. (74) have developed a model of IDDM in which a regulatable TNF gene is expressed in the pancreatic islets. When these mice were crossed to mice expressing CD80 in their islets and TNF was expressed for 25 days from birth, diabetes was delayed. In contrast, if TNF expression was allowed to continue for 28 days, the regulatory mechanisms were overcome and the animals rapidly developed diabetes. The autoreactive effector cells in this model are exclusively CD8$^+$ T cells. Treg could be isolated from the islets and draining pancreatic node, but not from other nodes or spleen, and they could suppress the development of disease in animals in which TNF was expressed for 28 days. These regulatory cells were extremely potent, and protection could be transferred with as few as 2×10^3 Treg. This site-specific accumulation of regulatory cells may be the result of localized production of chemokines that specifically recruit Treg to the site of inflammation. Alternatively, the Treg in the draining node may be antigen-specific and generated in situ by stimulation by islet-derived antigens.

Antigen-specific Treg from the TCR transgenic BDC2.5 mice that recognize an islet-derived antigen have been expanded with co-immobilized anti-CD3/anti-CD28 in the presence of IL-2 (179). These expanded Treg prevented the development of diabetes in NOD mice, survived long-term *in vivo*, but required antigen exposure for functional activity. Islet autoantigen-specific BDC2.5 Treg were significantly more effective than polyclonal Treg in regulating autoimmune responses *in vivo*. Importantly, expanded BDC2.5 Treg were able to reverse diabetes when transferred into NOD mice that had been diabetic for 2 weeks in conjunction with 500 syngeneic NOD islets. The expanded Treg were also capable of inhibiting diabetes in newly diagnosed NOD mice.

These results raise the possibility that Treg might be isolated from patients during remission or soon after disease onset, expanded, and used to treat patients at the time of maximal disease activity to moderate the inflammatory response. Indeed, Masteller et al. (180) were able to expand Treg with the BDC2.5 specificity by stimulating NOD Treg with beads coated with a mimitope peptide complexed to MHC class II (I-Ag^7) that is recognized by the BDC2.5 TCR. The expanded Treg were more efficient than polyclonal Treg in suppressing autoimmune diabetes. Thus, small numbers of autoantigen-specific Treg may be clinically efficacious because they can suppress polyclonal pathogenic T-cell responses either by bystander cytokine production or by recruitment of endogenous Treg, while avoiding pan-immune suppression that might be induced by polyclonal Treg. As many organ-specific antigens have been identified, it may be possible to use human MHC

multimer reagents to expand organ-specific Treg from peripheral blood for effective treatment of human autoimmune disease.

Several studies have explored the site of action and mechanisms of action of Treg in autoimmune diabetes models (181). Treg had little or no effect on the activation of effector cells but suppressed IFN-γ production by the effectors in the pancreatic LN and seemed to slow the migration of effector cells into the islets, perhaps through a reduction in CXCR3 in the pancreatic LN. One problem with studies of Treg-mediated protection from autoimmune disease is that they frequently involve transfer into lymphopenic hosts, where interpretation of the results may be difficult secondary to stimulation of the effector population that is seen in response to lymphopenia. Foxp3$^{-/-}$ NOD mice have been used to analyze where and how Treg cells exert their control on diabetes under experimental conditions not influenced by homeostatic expansion of effector populations (182). Treg did not delay or hinder the activation and expansion of anti-islet T cells in the pancreatic LN nor the timing of their infiltration into the islets, but primarily prevented locally damaging consequences of autoimmune infiltration in the islets. It appears the Treg primarily impinge on autoimmune diabetes by suppressing destructive T cells inside the islets, more than during the initial activation in the draining LN. Further studies are clearly needed to resolve these conflicting findings, as a detailed understanding of the site and mechanism of suppression of experimental autoimmune disease will facilitate translation of the therapeutic use of Treg for treatment of autoimmune disease in humans.

Experimental Autoimmune Encephalomyelitis (EAE)

EAE is the major animal model for the study of multiple sclerosis, and Treg have been shown to play a role in this model. When the Treg population of naïve C57 BL/6 mice was supplemented with CD4$^+$CD25$^+$ Treg from a normal donor before the active induction of EAE by immunization with an encephalitogenic peptide from myelin oligodendrocyte glycoprotein (MOG), the Treg conferred significant protection. Protection was associated with the presence of Th2 cytokines and a marked decreased CD4$^+$ T-cell and APC infiltrates in the central nervous system (CNS) (183). These studies suggested that Treg might inhibit the homing of pathogenic T cells to the CNS. McGeachy et al. (184) demonstrated that that the accumulation of CD25$^+$Foxp3$^+$ cells in the CNS correlated with the recovery phase of EAE. As few as 10^4 CNS-derived CD25$^+$ cells significantly reduced disease severity in recipients, whereas the same number of naïve CD25$^+$ T cells had no effect. Although the mechanism of action of the Treg in protection from EAE was not completely elucidated, CD25$^+$ T cells were the ma-

jor source of IL-10 in the CNS and IL-10 production was crucial for full recovery from EAE.

Antigenic Specificity of Treg in Autoimmunity

Very little progress has been made in the identification of the target antigen recognized by polyclonal Treg. They could recognize ubiquitously expressed self-peptides or a target antigen derived from the organ that is under autoimmune attack. A number of studies have shown that when the developing immune system is prevented from gaining access to a tissue-specific antigen, tissue specific tolerance fails to develop. For example, when fetal rat thyroid glands were destroyed by exposure to radioactive iodine and syngeneic thyroid tissue was then implanted into the athyroid rats as adults, autoimmune thyroiditis developed in the grafted tissue *(185)*. The development of thyroiditis in such rats could be prevented by parabiosis to normal syngeneic partners. Parabiosis was protective only if it was instituted at the time of thyroid grafting, but not 1 to 2 weeks after graft implantation. This approach was extended by Seddon and Mason (186) to demonstrate that peripheral CD45RC^{low} T cells from rats rendered athyroid were unable to prevent thyroid-specific autoimmunity induced by the adult-Tx irradiation protocol. The loss of Treg was specific for the extirpated organ, as T cells from the athyroid rats could prevent the development of diabetes. CD4$^+$CD8$^-$ thymocytes from the same athyroid donors were effective at preventing thyroiditis. It appears that regulatory T cells were normally generated in the thymus in the absence of the target organ, but the target organ was needed for their survival and/or expansion in the periphery.

Spleen cells from normal adult male mice were much more effective suppressors of autoimmune orchitis induced post-d3Tx than were spleen cells from female mice or male mice that had undergone a neonatal orchiectomy (187). In contrast, spleen cells from male and female mice exerted equivalent potency in protecting against gastritis. Taguchi et al. *(188)* have shown that the suppressor-cell population that was capable of inhibiting the induction of prostatitis was organ-specific, because cells from males, but not females, or males orchiectomized at birth, inhibited disease post-d3Tx. Other studies in autoimmune prostatitis suggested that the differences were relative rather than absolute, because protection could be achieved with 4×10^6 cells from normal males, but only with 4×10^7 spleen cells from females. Moreover, normal male, normal female, and spleen cells from females that were oophorectomized at birth were found to suppress d3Tx-induced oophoritis with comparable efficiency *(189)*.

Important insights into determining the antigenic specificity of regulatory T cells have also been derived from studies of the requirements for induction of organ-specific

autoreactive effector cells (190). When susceptible strains of mice are immunized with the ovary-specific antigen, pZP3, 100-fold more pZP3 in CFA was required to elicit the same pathogenic response in female mice compared to male mice that had been grafted with an ovary. This differential responsiveness to stimulation by the autoantigen indicates that female mice have a certain level of tolerance to pZP3 that is dependent on the presence of physiologically expressed ZP3 antigen. Neonatal oophorectomy converts the female response to that of a male. Oophorectomy between the ages of 1 and 6 weeks also leads to conversion of the female to a male responsiveness profile when the ovaries are removed for more than 7 days, but not 3 days, before challenge with pZP3 in CFA. It remains to be determined whether tolerance in the female is mediated by Treg and whether continued expression of the endogenous antigen is required for the maintenance/survival of the Treg in the periphery. More recent studies (191) have demonstrated that Treg from lymph nodes draining the target organ were 15 to 50 times more efficient than Treg from the nondraining lymph node in suppressing oophoritis, prostatitis, and dacryoadenitis that developed post-d3Tx. It was concluded from these studies that the accumulation of Treg is not random and that organ-specific Treg are increased in frequency where they are needed to protect against autoimmunity that might develop in their target organ in response to infection or inflammation.

Treg and Th2-Mediated Diseases

Several early studies suggested that CD4$^+$CD25$^+$ Treg cells bias the differentiation of CD4$^+$ T cells toward Th2 cells and might express a subset of Th2 genes, indicating that Treg might promote Th2 development. However, more recent studies have reported that the depletion of CD25$^+$ Treg cells *in vivo* led to an in increased development of Th2 cells. It has also been shown that Treg suppress the differentiation and function of Th1 and Th2 cells *in vitro* and *in vivo* (192,193). Other studies (194) have shown that freshly isolated Treg inhibited the IL-4–induced development of Th2 cells, but had no influence on established Th2 cells. In contrast, preactivated Treg inhibited cytokine production and proliferation of established Th2 cells.

CD4$^+$Foxp3$^+$ Treg modulate the development of experimentally induced asthma in mice genetically predisposed or comparatively resistant to the development of AHR. *In vivo* depletion of Treg in resistant animals before initial antigen contact increased airway hypersensitivity reaction (AHR), airway eosinophilia, and IgE synthesis, and was associated with Th2 cytokine production, whereas Treg cell depletion had no effect on allergen-driven AHR in susceptible mice (195). Enhancement of allergic phenotype in resistant mice was associated with stimulation of DC function, suggesting that the Treg do not act on effector T cells, but act indirectly via the DC. Similarly, Th2 po-

larized CD4$^+$ T cells depleted of CD25$^+$ cells induce increased airway eosinophilia after adoptive transfer (196). Allergen-specific CD4$^+$CD25$^+$ T cells from TCR transgenic mice inhibited the classical pathology associated with allergic asthma, including AHR, lung eosinophilia, and Th2 cytokine production in immunocompetent mice. Their effects were dependent on IL-10, but Treg cells exerted their suppressive effects *in vivo* independently of their capacity to produce IL-10, by inducing IL-10 production from recipient CD4$^+$ T cells (197).

Mice with an established helminth infection are less prone to allergic airway inflammation as measured by inflammatory infiltrate in bronchial lavage fluid or peribronchial and perivascular inflammation. Helminth infection with *Helicobacter polygyrus* protects from allergic airway responses by acting downstream from allergen sensitization, and protection can be transferred from infected mice to uninfected presensitized animals by CD25$^+$ T cells. Th2 effector cytokines (IL-5 and IL-13) were diminished, but allergen-specific IgE responses were not changed. Thus, chronic parasite infection may maintain a high level of activation in Treg, so that they primarily target the effector mechanisms resulting in decreased inflammation in a previously sensitized allergy-prone host (198).

Lymphocyte Homeostasis and Autoimmunity

Lymphocyte numbers in a normal adult animal remain stable throughout life. A homeostatic equilibrium exists among the numbers of newly produced cells, self-renewal of peripheral T cells, and the numbers of dying cells. The mechanism that controls the number of peripheral lymphocytes is unknown. The regulation of the numbers of naïve and memory CD4$^+$ and CD8$^+$ T cells is independently controlled. Most studies of the effects of Treg *in vivo* in the suppression of autoimmune disease involve the transfer of the effector populations to a T-cell–deficient mouse. T lymphocytes undergo a rapid, vigorous proliferative response when transferred to an immunodeficient recipient. We assume that some of the inhibitory effects of Treg in autoimmunity are related to their ability to be specifically activated by autoantigens. An alternative possibility is that a major component of Treg function is to nonspecifically inhibit lymphopenia-induced proliferation (199) and thereby prevent the development of autoimmune disease. CD4$^+$Foxp3$^+$ T cells might be potent inhibitors of lymphopenia-induced proliferation, but any T-cell population with an activated effector/memory phenotype might also be capable of mediating inhibition (200).

Surprisingly, both CD4$^+$CD25$^-$ (including RB^{high} cells) T cells and CD4$^+$CD25$^+$ T cells were capable of proliferating in a lymphopenic host, with proliferation beginning on day 3 or 4 posttransfer, and reaching as many as eight divisions by days 21 to 28 after transfer. CD4$^+$CD25$^+$ T cells did
FIGURE 30.13 Induction of regulatory T cells for tolerance to alloantigens.

not inhibit this early phase of "homeostatic proliferation" of CD4$^+$CD25$^-$ T cells *(201)*. Although CD4$^+$CD25$^+$ T cells have been shown to inhibit the accumulation of CD25$^-$ T cells 2 to 6 months after transfer to a RAG$^{-/-}$ recipient by an IL-10–dependent mechanism, this result must be interpreted with caution (202). The fact that CD25$^-$ T cells almost always induce some form of organ-specific autoimmune disease demonstrates that CD25$^-$ T cells have undergone some form of autoantigen-specific proliferation in addition to the lymphopenia-induced proliferation. As described previously, CD4$^+$Foxp3$^+$ T cells are highly efficient inhibitors of the induction of these autoimmune diseases. It should be noted that transfer of CD25$^+$Foxp3$^+$ T cells to immunodeficient mice results in loss of expression of CD25 by a majority of the transferred cells (79). The significance of this finding is unknown, as the recovered CD25$^-$ T cells retain the ability to suppress T-cell activation *in vitro*.

Although the role of Treg cells in controlling lymphopenia-induced proliferation remains unresolved, one major factor that has only recently been considered is the avidity of the TCR for self-ligands. When monoclonal or polyclonal T cells with low avidity for self, as determined by expression of low levels of CD5, were transferred to lymphopenic recipients, their proliferation was substantially inhibited by CD4$^+$CD25$^+$ Treg. In contrast, T cells with high avidity for self-antigens that expressed high levels of CD5 entered the cell cycle in the presence of Treg, but failed to differentiate from naïve to memory phenotype (203).

CONTROL OF ALLOGRAFT REJECTION AND GRAFT-VERSUS-HOST DISEASE (GVHD) BY Treg

A considerable body of data exists that regulatory/suppressor T cells exist in patients and animals with long-term surviving allografts *(204)*. Analysis of the properties of these cells *in vitro* has been hampered because bulk populations of T cells from tolerant recipients proliferate normally when cultured *in vitro* with donor alloantigens and

frequently secrete a proinflammatory Th1 pattern of cytokines. It appears that the Treg are masked by the presence of naïve T cells responding to alloantigens. In animal models, a number of protocols have been used to induce tolerance to allografts (Figure 30.13). Tolerance to cardiac allografts in mice can be induced by pretreatment with a donor-specific blood transfusion combined with depleting or nondepleting anti-CD4 antibody. It is likely that the protective effects of this protocol were mediated by the induction of CD4$^+$ Treg, because complete depletion of CD4$^+$ T cells fails to induce tolerance. Pretreated mice accepted cardiac grafts, and cells from these mice could transfer tolerance to naïve recipients. CD4$^+$ T cells were responsible for both the induction and maintenance of tolerance.

In studies of allograft rejection across a full H-2 difference, the differential expression of CD45RB has facilitated separation of nontolerant naïve T cells from the induced regulatory T cells *(204)*. RB^{high} cells from tolerant mice responded normally to challenge with alloantigen *in vitro* and were able to reject allogeneic skin grafts when transferred alone to T-cell–deficient mice. In contrast, CD45RB^{low} cells failed to mount a proliferative response, to secrete cytokines in response to alloantigen *in vitro*, and to induce allograft rejection *in vivo*. The addition of CD45RB^{low} cells to an MLR with CD45RB^{high} cells as responders resulted in inhibition of proliferation. CD45RB^{low} T cells from long-term-tolerant mice were able to suppress responses to alloantigen *in vitro* only when the donor alloantigens were presented by the indirect pathway of allorecognition by the APC present in the culture. One explanation for this result is that it is potentially advantageous for the Treg to respond to alloantigens via the indirect pathway because Treg may require constant stimulation to maintain their function. Passenger leukocytes rapidly migrate out of the graft, and the graft tissues lack costimulatory molecules. Donor-derived allopeptides must be presented by recipient APC for stimulation of the Treg *in vivo* and for the detection of functional activity of these cells *in vitro*. All of the suppressive activity of the CD45RB^{low} cells was mediated by the CD4$^+$CD25$^+$ T-cell

subset contained in that pool. The suppressive capacity of the regulatory T cells in this model *in vitro* and *in vivo* was reversed by anti-IL-10R, but not by anti-IL-4.

Treg can also be isolated from mice pretreated with donor alloantigen in combination with depleting anti-CD4, but not transplanted with an allograft (205). These cells are fully competent in prolongation of cardiac graft survival when transferred to naïve recipients. Treg can be isolated 28 days after pretreatment, and regulation is antigen-specific. Both treatments are required, and CD25$^+$ T cells from naïve donors do not prolong graft rejection. It is possible that the precursor frequency of alloantigen-specific regulatory CD25$^+$ T cells from naïve animals is too low to observe suppression at the cell doses used, and that the pretreatment regimen serves to increase their frequency. No major increase in the percentage of CD25$^+$ cells is observed in the pretreated animals, and it remains to be proven that the CD25$^+$ T cells isolated from the pretreated animals are derived from the Treg pool and not generated from CD25$^-$ T cells. In either case, it is likely that the pretreatment protocol maximizes the conditions for activation of Treg.

In studies examining induction of tolerance to minor histocompatibility antigens on allografts following protocols similar to those used above, both CD4$^+$CD25$^+$ and CD4$^+$CD25$^-$ T cells from tolerant mice could mediate suppression, but suppression required 10 times more CD4$^+$CD25$^-$ T cells (206). Both populations may have a significant role in maintaining transplantation tolerance, as the number of CD25$^-$ T cells is 10 times higher than the number of CD25$^+$ T cells in the tolerant mouse. It is possible that some of the CD25$^+$ T cells have lost expression of CD25 during the tolerance-induction protocol, that effector cell death in the CD25$^-$ T-cell pool unmasked the presence of Treg, or that some of the CD25$^-$ T cells express Foxp3. In contrast to the results with a major MHC difference, CD4$^+$CD25$^+$ T cells from naïve mice could also prevent naïve T cells from rejecting skin grafts, although five times more cells were required than from tolerant donors. The enhanced potency of CD25$^+$ T cells from tolerant mice may be secondary to expansion of an alloantigen-specific population. The capacity of T cells from tolerant donors or CD25$^+$ T cells from normal mice to mediate their suppressive function could not be neutralized by anti-CTLA-4, anti-IL-10, or anti-IL-4 (205).

A short treatment of mice with saturating amounts of nondepleting anti-CD4 can induce tolerance to foreign protein antigens and enables long-term survival of minor antigen–mismatched skin or MHC-mismatched cardiac grafts. The addition of anti-CD40L can extend this effect to full donor-specific tolerance, such that second donor grafts are accepted at any later time, while third-party grafts are rapidly rejected. The maintenance of tolerance is dependent on CD4$^+$ Treg that can suppress both CD4$^+$ and CD8$^+$ naïve T cells after transfer into secondary recipients. Treg cells are found not only in recipient lymphoid tissue after transplantation, but also at the graft site. The localization of Treg cells at more than one site *in vivo* is important if Treg are to control aggressive immune reactivity to the graft effectively. In lymphoid tissues, Treg cells might be effective at blocking the initiation of an aggressive response against the graft, whereas at the graft site, they can inhibit the effector activity of aggressive cells that have escaped regulation and migrated to the graft.

Regulation observed in therapeutic tolerance probably is maintained both by pre-existing Treg together with induced Treg. In the continued presence of donor antigen, CD4$^+$ Treg are able to convert naïve, potentially aggressive CD4$^+$ T cells into Treg, a process termed infectious tolerance. Little is known about the molecular mechanisms involved in the conversion, whether they act systemically or within the graft, and how they relate to Foxp3$^+$ Treg. In one model, antigen stimulation in the presence of a nondepleting anti-CD4 has been shown to convert CD4$^+$Foxp3$^-$ T cells into Foxp3$^+$ Treg in a TGF-β–dependent manner *in vivo*, and this correlates with life-long acceptance of the graft (207). Treg cells that recognize donor MHC molecules through the indirect pathway of allorecognition have been shown to be responsible for the phenomenon of linked unresponsiveness (208). Linked suppression *in vivo* seems to correlate with the *in vitro* finding that once Treg are activated, they can suppress the activation of other T cells responding to antigen presented by the same APC in an antigen-nonspecific manner.

The inability of T-cell populations containing large numbers of CD25$^+$ T cells to mediate GVHD strongly raised the possibility that CD25$^+$ T cells might actually be capable of inhibiting CD25$^-$ effectors in cotransfer studies. Freshly isolated CD25$^+$ T cells only modestly inhibited GVHD when mixed with CD25$^-$ T cells in equal numbers, while alloantigen-stimulated, cultured CD25$^+$ T cells profoundly inhibited the capacity of CD25$^-$ T cells to inhibit rapidly lethal GVHD *(209)*. In murine models, transplantation of bone marrow into a lethally irradiated host does not cause GVHD, and cotransfer of naïve donor T cells (CD4$^+$, CD8$^+$, or both) is required to induce GVHD. The onset and course of GVHD depends on the degree of major and minor MHC disparity and the T-cell dose. Depletion of Treg from the donor graft accelerated the course of GVHD and increased lethality. These findings provided evidence for the role of Treg in suppressing GVHD. Transfer of Treg with naïve T cells from the donor protected lethally irradiated recipients from GVHD morbidity and decreased GVHD-related mortality (210) across minor and major MHC class I and/or class II barriers in various mouse strain combinations. The mechanisms by which Treg suppress GVHD is not well understood. The effect of Treg on GVHD is likely to be early and to affect the maturation and expansion of effector cells. CD62L^{high} Tregs are more potent suppressors of GVHD, presumably because of their ability to migrate to secondary lymph nodes, where they are primed and

activated *(211)*. Because host APC are necessary to trigger acute GVHD, it is possible that the activated Treg function by downregulating costimulatory molecules and thereby prevent the activation of effector T cells. Hoffman et al. showed decreased protection from GVHD with Treg derived from IL-10$^{-/-}$ animals (212).

The most analogous model to the murine models of GVHD induction is the administration of donor lymphocyte infusions to humans with relapsed leukemia after allogeneic hematopoietic cell transplantation (HCT) so as to obtain a graft-versus-tumor effect. The development of GVHD after donor lymphocyte infusion is associated with tumor clearance. However, Treg controlling GVHD may also cause suppression of tumor immunity. Edinger and coworkers (213) found that adoptive transfer of donor Treg effectively decreased the incidence and severity of GVHD without abrogating the graft-versus-tumor response. In this model, cotransfer of Treg markedly decreased the proliferation of alloreactive effector cells in secondary lymphoid organs by >90% at day 7, but did not inhibit the activation of the effectors as judged by activation-marker expression and cytokine production. One possibility is that the decrease in the proliferation and expansion of the alloreactive T-effector cells was sufficient to control acute GVHD, but this decrease was not complete, and the remaining donor T-effector cells were sufficient to mount an effective graft-versus-tumor effect.

Treg also play a facilitating role in bone marrow engraftment. Joffre et al. (214) found that Treg provided allospecific protection of transplanted bone marrow from host rejection. Enhanced engraftment with Treg also increased long-term donor chimerism in animals that received Treg compared to those that received bone marrow transplants only. Recipients of Treg demonstrated tolerance to host and donor antigens, but mounted responses to third-party antigens (215). Encouraging preclinical data have set the stage for the potential therapeutic application of Treg in patients. Patients undergoing haploidentical transplantation are at high risk for severe GVHD and therefore are the ideal candidates for adoptive transfer of donor Treg.

REGULATORY T CELLS AND TUMOR IMMUNITY

Studies by R. North and associates in the early 1980s (216) demonstrated the role of suppressor T cells in the prevention of tumor immunity. In their studies, primed antitumor T cells were incapable of causing regression of a tumor when passively transferred into a normal host. If the tumor recipient was rendered T-cell–deficient by Tx and lethal irradiation, followed by bone marrow reconstitution combined with sublethal irradiation, or treated with cyclophosphamide, the transferred cells could induce tumor regression. Cotransfer of T cells from tumor-bearing recipients prevented T-cell–mediated tumor regression. T cells taken on day 6 after tumor implantation were capable of transferring protection to T-cell–depleted recipients. By day 9 of tumor growth, the antitumor T cells were lost, and transfer of cells from the tumor-bearing animals suppressed antitumor immune effectors. Immediately after tumor implantation, mice developed concomitant immunity and would reject a challenge implant of cells of the same tumor given at another site. Later in the course of tumor development, concomitant immunity decayed.

The suppressor T cells in the experiments of North and coworkers were shown to be CD4$^+$CD8$^-$, but were not characterized further *(217)*. Their susceptibility to sublethal irradiation and cyclophosphamide is similar to that of CD4$^+$CD25$^+$ T cells. As most tumor antigens are normal self-antigens, it is likely that those mechanisms that maintain immunologic tolerance to self-antigens may impede the generation of effective tumor immunity against autologous tumor cells. In many cases, successful immunotherapy of cancer often leads to the appearance of autoimmunity because of cross-reactions between antigens expressed on tumors and normal tissue antigens. Onizuki et al. (218) were the first to suggest that CD4$^+$CD25$^+$ T cells played an important role in inhibiting tumor immunity. They first depleted CD4$^+$CD25$^+$ T cells by injecting a depleting anti-CD25 mAb and noted that this led to regression of a number of tumors that grew progressively in nondepleted mice. The depletion had to be performed not later than day 2 after injection of the tumor. Coadministration of anti-CD8 inhibited the tumor regression induced by anti-CD25 depletion, suggesting that CD8 T cells were responsible for tumor regression. Similar conclusions were drawn by Shimizu et al. (111), who transferred CD25-depleted or CD25-containing spleen cells to *nu/nu* recipients and then challenged them with normally nonimmunogenic tumors. In the recipients of CD25-depleted cells, tumors grew, but regressed; in contrast, all recipients of spleen cells containing CD25$^+$ T cells died from rapidly growing tumors. Long-lasting tumor immunity to rechallenge could also be demonstrated in the recipients of the CD25-depleted spleen cells.

Taken together, the studies on depletion of CD4$^+$CD25$^+$ T cells and the transfer of CD4$^+$CD25$^-$ T cells suggest strongly that the effectiveness of a tumor vaccine would be greatly enhanced by removal of CD4$^+$CD25$^+$ T-cell suppressor activity. Indeed, Sutmuller et al. (219) were able to demonstrate that antibody-mediated depletion of CD25$^+$ T cells followed by vaccination with a GM-CSF–transfected melanoma cell line resulted in enhanced tumor rejection. Tumor rejection was accompanied by skin depigmentation, suggesting that autoreactive immune responses are involved in this process. Depletion of CD25$^+$ T cells followed by anti-CTLA-4 treatment and vaccination resulted in the most potent antitumor response (Table 30.8). Thus, CD25 depletion and anti-CTLA-4 treatment increase the

▌**TABLE 30.8 Depletion of CD4$^+$CD25$^+$ T Cells Augments the Immune Response to a Tumor Vaccine**

Treatment	Percent Surviving at d 90
None	0
Anti-CD25 (d −4)	20
GM-CSF vaccine (d 0, 3, 6) + Anti-CD25 (d −4)	50
GM-CSF vaccine (d 0, 3, 6) + Anti-CTLA-4 (d 0, 3, 6)	50
GM-CSF vaccine (d 0, 3, 6) + Anti-CD25 (d −4) + Anti-CTLA-4 (d 0, 3, 6)	100

Adapted from Sutmuller RPM, van Duivenvoorde LM, van Elsas A, et al. Synergism of cytotoxic T lymphocyte-associated antigen 4 blockade and depletion of CD25$^+$ regulatory T cells in antitumor therapy reveals alternative pathways for suppression of autoreactive cytotoxic T lymphocyte responses. *J Exp Med.* 2001;194:823–832.

immunogenicity of a tumor vaccine by distinct mechanisms that involve nonredundant pathways. CTLA-4 blockade enhances the induction of antitumor effector cells by removing the normal inhibitory signals generated by CD80/CD86 interactions with CTLA-4.

Experiments with adoptively, transferred mouse Treg cells provided a direct link between Treg cells and reduced tumor immunity. Tumor-specific CD8$^+$ T cells were transferred with either Treg cells or conventional T cells into mice bearing B16 melanoma. In mice that received Treg cells, but not in mice that received CD25$^-$ T cells, CD8$^+$ T-cell–mediated immunity was abolished. Treg cells may mediate their suppressive effect by inhibiting T-cell priming in lymphoid organs or by reducing the effector function of tumor antigen-specific cells. Antony et al. (220) have shown that transfer of Treg cells reduced the therapeutic efficiency of adoptively transferred tumor antigen-specific effector T cells in a mouse melanoma model. Depletion of intratumoral Treg cells induced potent T-cell tumor immunity and resulted in regression of large established tumors. Administration of anti-GITR antibody protected mice from B16 tumor challenge and induced tumor regression in mice bearing carcinogen-induced sarcomas and colon carcinomas (221). The anti-GITR likely costimulates T-effector functions to make the effector cells resistant to Treg-mediated suppression.

Although the preceding studies in well-characterized animals models demonstrate the role of CD4$^+$CD25$^+$ T cells in inhibiting tumor rejection, it is often difficult to extrapolate from tumor immunity studies in rodents to humans. Woo et al. (222) have shown that CD4$^+$CD25$^+$ T cells exist in high proportions (~33%) in the tumor-infiltrating lymphocytes of patients with non-small-cell lung cancer. It is not known if these tumor-infiltrating CD4$^+$CD25$^+$ T cells arise from the naturally occurring CD4$^+$CD25$^+$ population or are generated from CD4$^+$CD25$^-$ T cells. Nevertheless,

these findings suggest that one component of the immune response to tumors in humans is the generation of tumor-specific suppressor T cells. A high frequency of Treg cells has been noted in many other human cancers. Treg cell have been extensively studied in human ovarian cancer (223). Treg cells within the ovarian tumor microenvironment expressed Foxp3, inhibited tumor antigen-specific CD8$^+$ T-cell cytotoxicity, and contributed to tumor growth *in vivo* in a human–SCID mouse chimeric model. An accumulation of Treg cells in the tumor predicted a striking reduction in survival.

A number of mechanisms have been proposed for Treg-mediated suppression of tumor immunity. Because Treg express CTLA-4, one possible model is that engagement of CD80/CD86 on tumor APC may induce production of the immunosuppressive molecule, IDO. IDO-expressing APC are found in human tumors and within draining lymph nodes. Alternatively, ovarian tumor-associated macrophages, but not normal macrophages, express B7-H4, a negative regulator of T-cell responses. B7-H4$^+$ macrophages isolated from tumors inhibited tumor antigen-specific responses, and suppression could be reversed by anti-B7-H4 (224). Treg, but not normal, T cells induced B7-H4 on monocytes, macrophages, and myeloid DC and rendered them immunosuppressive through B7-H4.

The spectrum of tumor-specific antigens recognized by Treg has not yet been defined. In one case, cloned Treg from a melanoma recognized LAGE-1, a cancer- and testis-specific antigen, and suppressed LAGE-1-specific T-cell activation (225). It is important to identify the ligands for Treg cells to compare them to the ligands for tumor-specific effector cells and to determine whether there are ligands that are exclusively recognized by Treg cells and whether Treg cells recognize mutated tumor antigens. A major concern that remains to be addressed is whether vaccination with certain tumor antigens might promote Treg cell clonal expansion.

The concept of reversing immunosuppression in cancer has merit as a therapeutic approach. CTLA-4 blockade improves tumor immunity but also resulted in severe manageable autoimmune responses in patients (226). The mechanistic link between the effects of treatment with anti-CTLA and Treg function remain to be determined. Depletion of Treg should be beneficial for cancer patients. Denileukin diftitox (Ontak), a ligand-toxin fusion protein, consists of full-length IL-2 fused to the enzymatically active and translocating domains of diptheria toxin. It has been hypothesized that this agent will lead to depletion of Treg *in vivo*, but it also might deplete CD25$^+$ effector cells. In one trial, patients received a single does of Ontak followed by vaccination with DC transfected with total tumor RNA (227). Treg cells were eliminated in a dose-dependent manner, and Ontak-treated vaccinated patients had an improved tumor-specific effector T-cell response. In other studies, Ontak had variable effects on Foxp3 mRNA

expression in CD4$^+$ T cells in patients with melanoma, and no significant clinical efficacy was observed (228). Further clinical trials are needed to link Treg depletion with improved immunity and an objective clinical response. An alternative strategy would be to selectively block Treg trafficking into tumors.

Although the majority of studies indicate that Treg cells suppress tumor immunity, other models raise the possibility that Treg may have a beneficial effect in preventing tumorigenesis. A widely used model for human colorectal carcinogenesis is the multiple intestinal neoplasia mouse, which has a germline mutation in the *Apc* tumor suppressor gene (229). Transfer of CD4$^+$CD25$^+$ Treg cells reduced the multiplicity of epithelial adenomas in these mice by an IL-10–dependent mechanism. Recipients of Treg showed increased apoptosis and downregulation of cyclo-oxygenase-2 within tumors, coinciding with tumor regression. In this model, aspirin and cyclo-oxygenase inhibitors also decrease the risk for colon cancer by inhibiting cyclo-oxygenase-2. Because Treg can suppress bacterially triggered inflammatory responses in the bowel of mice, the ability of Treg to traffic and suppress inflammation likely explains their therapeutic efficacy in this model. As inflammatory mediators drive tumor development, Treg and anti-inflammatory drugs exert their effect by modulating the levels of these molecules.

Treg CONTROL OF IMMUNITY TO INFECTIOUS AGENTS

Most of the studies of Treg have focused on their role in the suppression of the immune response to autoantigens, tumor antigens, or alloantigens. One of the most important roles of Treg may, in fact, involve modulation of the immune response to infectious agents to prevent the lethal consequences of an overwhelming inflammatory response during the course of a productive immune response to an invading microorganism. Treg and effector cells must maintain equilibrium between no immunity at all and immunopathology. This critical role of Treg is well illustrated by the immune response of mice to infection with *Pneumocystis carinii* (PC). When SCID mice chronically infected with PC are reconstituted with CD4$^+$CD25$^-$ T cells, they develop a severe inflammatory response in their lungs that is ultimately fatal. Animals injected with CD25$^+$ T cells alone did not become moribund and only manifested transient weight loss. Cotransfer of CD25$^+$ T cells prevented the development of the PC-driven fatal pulmonary inflammation induced by CD25$^-$ T cells, but also suppressed the elimination of PC mediated by the CD25$^-$ T cells. Protective CD25$^+$ T cells are needed to inhibit the lethal immunopathologic response mediated by the PC-specific CD4$^+$CD25$^-$ T cells, but they also inhibited complete clearing of the organism (230). PC-associated immunopathol-

ogy is often seen in lymphopenic animals/humans, and this may reflect a relative deficiency in regulatory T cells. Although Treg may target CD4$^+$ and CD8$^+$ T cells responding to an infectious challenge, Treg have also been shown to act on the innate immune system in the response to *Helicobacter hepaticus* (231).

The role of CD4$^+$CD25$^+$ T cells in the immune response to infection includes more than suppression of inflammation (232). CD4$^+$CD25$^+$ T cells also maintain persistence of infection and promote chronicity. The persistence of pathogens following clinical cure is a hallmark of certain viral, bacterial, and parasitic infections. In clinical and experimental forms of leishmaniasis, small numbers of viable organisms persist within lymphoid tissue and within the site of former skin lesions following self-cure or successful chemotherapy. Because low numbers of parasites persisting in the dermis can be efficiently transmitted back to their vector sandflies, the expansion and/or recruitment of regulatory T cells to the site of *L. major* infection might reflect a parasite adaptive strategy to maintain its transmission cycle in nature. Despite the absence of sterilizing immunity, these individuals maintain strong life-long immunity to reinfection, a status similar to the concomitant immunity described in tumor models *(233)*.

In healed C57 BL/6 mice, CD4$^+$CD25$^+$ regulatory T cells accumulate in sites of *L. major* infection in the skin (Figure 30.14) (234). These cells are derived exclusively from CD25$^+$ T cells and not from activated CD25$^-$ T cells. They suppress the expansion of and killing mediated by *L. major*–specific effector cells. Although IL-10 produced by CD25$^+$ T cells is essential to the establishment of persistent infection, early in the infectious process CD25$^+$
FIGURE 30.14 CD4$^+$CD25$^+$ T cells comprise ∼50% of the CD4$^+$ T cells in chronic *L. major* infection. Adapted from Belkaid Y, Piccirillo CA, Mendez S, et al. CD4$^+$CD25$^+$ immunoregulatory T lymphocytes control *Leishmania major* persistence and the development of concomitant immunity. *Nature.* 2002;420:502–507.

T cells can promote parasite survival and growth in an IL-10–independent manner. Later in the course of infection, IL-10 is absolutely required for development of the chronic lesion, Because recipients of CD25$^+$ T cells from IL-10$^{-/-}$ mice ultimately healed and completely cleared the parasite from the site. IL-10 produced by Treg contributes directly to parasite persistence by either modulating APC function, inhibiting cytokine production by Th1 cells, or rendering macrophages refractory to IFN-γ, which is needed for intracellular killing.

Although one consequence of this regulation is parasite persistence and the potential for disease reactivation, parasite persistence itself is a major benefit to the host that is needed for life-long immunity to reinfection. When rechallenge studies were performed in IL-10$^{-/-}$ mice or in WT mice that were treated during the chronic stage of their primary infection with anti-IL-10R, conditions that result in complete clearance of parasites from the skin and draining lymph node, reinfection at a site distant from the initial infection resulted in parasite loads that were comparable to those following primary infection in naïve mice. Healed mice treated with control antibody maintained strong immunity to reinfection, so the maintenance of a residual source of infection, secondary to IL-10 production by CD25$^+$ T cells at the lesion site is required for preservation of acquired immunity to *L. major*. One important question that must be addressed is whether the regulatory function of Foxp3$^+$ Treg cells is associated with their capacity to recognize foreign antigens or is the result of bystander activation through self-antigen recognition. Treg cell lines isolated from chronic *L. major* are able to respond to parasite-infected DC by proliferating and producing IL-10 (235). The cells that have undergone proliferation express and maintain Foxp3 expression. It appears that the parasite has specifically evolved to manipulate DC in a manner that favors and sustains Treg proliferation. Most important, the *L. major*–specific cell lines maintain their suppressive functions *in vivo*, as transfer of the lines to chronically infected mice results in massive disease reactivation and dissemination.

Certain pathogen-derived molecules such as bacterial DNA containing CpG motifs are powerful inducers of the differentiation of Th1 effector cells, but other pathogen-derived components might induce the differentiation of Treg. Although Th1 effector cells are induced during the course of infection with *Bordetella pertussis* and ultimately play a critical role in the clearance of bacteria from the respiratory tract (236), antigen-specific Th1 responses in the lung and local lymph nodes are severely suppressed during the acute phase of infection. *B. pertussis* has evolved a number of strategies to circumvent protective immune responses. One bacterial component, filamentous hemagglutinin (FHA), is capable of inhibiting LPS-driven IL-12 production by macrophages and DC and stimulating IL-10 production. FHA may contribute to the suppressed Th1

responses during acute infection with *B. pertussis* by the induction of T cells with regulatory activity as a result of its interactions with cells of the innate immune system. Repeated stimulation of T cells from the lungs of mice acutely infected with *B. pertussis* resulted in the generation of Tr1 clones that were specific for FHA. Tr1 cells could only be generated from the lungs of infected animals, and not from spleen. These Tr1 cells secreted high levels of IL-10 and inhibited protective immune responses against *B. pertussis in vivo* and *in vitro*. Suppression was substantially reversed by anti-IL-10 *in vivo*. The capacity to induce Tr1 cells is thereby exploited by a respiratory pathogen to evade protective immunity and suppress protective Th1 responses at local sites of infection.

Analysis of cytokine production by T cells from patients with chronic hepatitis C virus (HCV) infection identified antigen-specific regulatory T cells that secreted IL-10 in addition to IFN-γ circulating Th1 cells (237); no IL-4 producing T cells were identified. IL-10–producing cells were detected in a higher proportion of patients with chronic infection than in those who had cleared the virus. Taken together with the studies on *L. major* and *B. pertussis*, these studies on HCV strongly support the general concept that many infectious agents have evolved mechanisms for selective activation of either naturally occurring CD25$^+$ T cells or the generation of IL-10–producing Tr1 cells from CD25$^-$ T cells. The ultimate result is perpetuation of the chronic infectious state, with incomplete clearing of the infection. Depending on the extent of suppression of effector T cells in the host, the consequences of the chronic state may be protective immunity (*L. major*) or continued pathogen-mediated organ destruction (HCV).

Many viruses, such as herpesviruses, hepatitis viruses, and retroviruses, evade immunologic destruction during acute infection and establish chronic persistent infections that may culminate in life-threatening diseases. Friend virus (FV) infection in mice has been used as an experimental model to study retrovirus-induced immunosuppression and may offer insights into our understanding of immunosuppression associated with HIV. Mice that are chronically infected with FV are unable to reject both FV-induced and unrelated immunogenic tumors. CD8$^+$ T cells from acutely infected mice produced perforin, granzyme A, and granzyme B and display recent evidence of degranulation and *in vivo* cytotoxicity. Activated T cells from chronically infected mice were deficient in cytolytic molecules and showed little evidence of recent degranulation and *in vivo* cytotoxicity. These results demonstrate a broad impairment of cytotoxic CD8$^+$ T-cell effector function during chronic retroviral infection and explain the inability of virus-specific CD8$^+$ T cells to eliminate persistent virus. CD4$^+$, but not CD8$^+$, T cells from infected mice can transfer suppression to normal mice and can inhibit the generation of CTL in culture (238). Suppression could be substantially reversed by the addition of anti-CTLA-4, but

not anti-IL-10R, to the cultures. FV-induced Treg suppress CD8$^+$ T cells *in vitro* regardless of the TCR specificity of the CD8$^+$ T cells (239). It is unknown whether the Treg in chronically infected mice are specific for any viral proteins or whether they are derived from Foxp3$^+$ Treg. Nevertheless, it appears that an important component of the generalized immunosuppression seen in retroviral infections involves the induction of suppressor T cells.

As HIV infection in humans in many respects mimics the animal models of chronic retroviral infections, several studies have begun to examine Treg function as different stages of HIV infection. Kinter et al. (240) found that in a majority of HIV-infected, but still healthy, individuals, CD25^{high} Treg cells significantly suppressed cellular proliferation and cytokine production by CD4$^+$ and CD8$^+$ T cells in response to HIV antigens *in vitro*. Suppression was cell contact–dependent and IL-10– and TGF-β–independent. Patients with strong HIV-specific suppression *in vitro* had lower levels of viremia and higher CD4/CD8 T-cell ratios than patients who did not have Treg activity. These data suggest that the suppression of CD4$^+$ T-cell activation by Treg may make HIV replication less favorable, as the virus must replicate within the CD4$^+$ T cell itself. Thus, in this chronic infection model, the suppressive functions of Treg may actually be beneficial to the patient.

The role of Treg has been most clearly shown in responses to chronic infections. Much less is known about the role of Treg in modulating acute viral infections. In the murine model of herpetic stromal keratitis, depletion of Treg before infection resulted in lesions of greater severity and permitted the induction of disease with lower infecting doses of virus (241). Cotransfer of Treg with CD25$^-$ T cells reduced lesion severity and diminished the Ag-specific cytokine response of splenic CD4$^+$ T cells. The mechanism of action of Treg in this model is not fully elucidated. Treg inhibit the induction of virus-specific CD4$^+$ T-cell induction but may also modify the expression of homing molecules involved in T-cell migration to the ocular inflammatory site or the extra-lymphoid inflammatory sites of pathogenic T cells. Treg can also control the intensity of secondary responses to HSV and may also influence the magnitude of immunologic memory.

Treg FUNCTION IN HUMAN DISEASE

In this chapter a number of distinct Treg populations have been described, and their potential role in the regulation of the immune response in animal models of disease has been reviewed. A large body of data supports the existence of CD4$^+$CD25$^+$Foxp3$^+$ T cells in humans (29,*30*,*31*,32,33,*34*,*35*,36), and the *in vitro* characterization of human CD4$^+$CD25$^+$Foxp3$^+$ cells suggests that they are identical to their murine counterpart. Tr1 cells have been readily induced in cultures of human T cells, and a num-

▎**TABLE 30.9 Human Diseases with Abnormal Treg Function**

HIV/AIDS	*250*

ber of studies have supported the existence of cell populations with Tr1-like properties in humans. The finding that autoreactive T cells found in patients with autoimmune disease are more easily activated compared to those from normal subjects suggests that Treg are either reduced in number or have reduced suppressor effector function. More important, Danke et al. (242) have shown that deletion of Treg *in vitro* allows marked clonal expansion of autoreactive T cells *in vitro*.

A number of studies in a wide variety of autoimmune diseases have demonstrated a defect in the function of Treg, raising the issue of whether this may be a common denominator in the cause of human autoimmune disease (Table 30.9). In many of these studies, it was definitively shown that the decrease in Treg function was due to defect in Treg subset rather than secondary to responder T cells that were refractory to suppression. One possibility is that Treg may have migrated into the target tissue, so that blood Treg function is depressed but Treg function from the target tissue may actually be enhanced. For example, the frequency of CD25^{high} T cells was much greater in synovial fluid compared to peripheral blood in adult patients with rheumatoid arthritis, and synovial fluid Treg demonstrated normal suppressive activity *in vitro (251)*.

Appropriate caution should be exercised in interpretation of these studies. As discussed previously, identification of human Foxp3$^+$ Treg is difficult, and many of the studies published thus far have only utilized high levels of CD25 expression to identify human Treg and did not validate the isolated populations for Foxp3 expression by intracellular staining. An additional issue is whether Foxp3 expression is a bona-fide marker of human Treg, as some studies have suggested that Foxp3 can be induced in activated effector cells, but such cells do not adopt a regulatory phenotype (252,253). Thus, human CD25^{high}Foxp3$^+$ T cells from inflammatory sites may not be true Treg.

Enhancement of either the numbers or the function of Treg represents a goal for the treatment of autoimmune and allergic diseases as well as for inhibition of allograft rejection. One might expand either CD4$^+$CD25$^+$ T cells or Tr1 T cells to generate sufficient numbers of cells for

infusion back into patients (254). If Foxp3[+] Treg recognize organ-specific antigens, and if these antigens can be identified, it may be possible to generate lines or clones of antigen-specific suppressor T cells *in vitro* that could be used therapeutically. Such an approach will probably need to be combined with attempts to delete or anergize the effector cells. Organ-specific Treg would home to their target, be activated by their target autoantigen, but mediate bystander suppression, because their effector function would be nonspecific. Alternatively, as a number of factors (e. g., IL-6 or the GITR-L) can render effector cells resist to the suppressor function of Treg, blocking or neutralizing these factors may enhance Treg function. Ultimately, further studies of the molecular basis of Treg-mediated suppression should allow the development of mAbs or small molecules that could enhance their suppressor effector function.

A second issue related to the therapeutic modulation of Treg function in humans is the development of approaches to decrease the numbers or function of Treg either to augment tumor immunity or increase the immunogenicity of weak vaccines. Depletion of CD4[+]CD25[+] T cells with a depleting anti-CD25 mAb has resulted in potent antitumor immune responses in mouse models. Humanized anti-CD25 mAb approved for human use are nondepleting and block the binding of IL-2 to CD25. Even in the mouse, the mechanism of action and the extent of depletion of CD4[+]CD25[+] T cells remain controversial (255). Depletion of CD25[+] T cells would also not affect the Foxp3[+]CD25[−] Treg compartment. Caution should also be used to develop better approaches to deplete Treg, as Treg play an important role in the modulation of the acute inflammatory response that is an integral part of the response to any infectious agent. In the absence of Treg, the consequences of this exuberant response can be deleterious. If future studies successfully define the cell surface molecules on Treg cells that deliver the suppressive signal to the responder cell, then an antibody to this molecule(s) might be the ideal reagent to transiently inhibit suppressor cell activity, facilitating immune responses to tumor antigens. An alternative approach to the downmodulation of suppressor T-cell function might be to increase the resistance of the responder cells to Treg-mediated suppression by using an agonistic anti-GITR mAb or soluble GITR-L or by administering anti-CTLA-4 (226).

The Mucosal Immune System

Hiroshi Kiyono, Jun Kunisawa, Jerry R. McGhee, and Jiri Mestecky

INTRODUCTION

The most important source of stimulation of the entire immune system is the external environment comprising the indigenous mucosal microbiota, potential pathogenic microorganisms, abundant food antigens (Ags), and allergens, all of which are encountered mainly at the vast surface areas of mucosal membranes. This enormous and highly variable antigenic load has resulted in a strategic distribution of cells involved in the uptake, processing and presentation of Ags, production of antibodies (Abs), secretion of cytokines, and cell-mediated immune (CMI) defenses at the front line of defense—mucosal tissues and associated secretory glands. Quantitative data concerning the distribution of phagocytic cells, T and B lymphocytes, and Ab-producing cells illustrate the point: mucosal tissues, particularly those of the intestinal tracts, contain more macrophages (MΦ), plasma cells (PCs), and T cells than any other lymphoid tissue in the entire immune system.

Notwithstanding the global importance of systemically acquired infections such as malaria and neonatal tetanus, the majority of infectious diseases worldwide either directly afflicts or is acquired through mucosal surfaces of the gastrointestinal (GI), respiratory, and genital tracts. Consequently, innate and adoptive immune mechanisms operational at mucosal surfaces are of great importance to the protection and survival in a hostile environment. The induction of preventive and protective immune responses to mucosal infectious agents, and to ingested food Ags and environmental allergens that would limit their absorption, is usually the most emphasized functional aspect of the mucosal immune system. Yet, recently revived interest in the induction of systemic unresponsiveness to Ags applied

first by the mucosal route, so called *oral* or *nasal* (mucosal) *tolerance,* has directed the attention of immunologists working in the field of autoimmunity, transplantation, and hypersensitivity to the exploitation of this fundamental principle. Although there are limited numbers of clinical successes, the phenomenon of mucosal tolerance is an essential feature and critical functional component that efficiently prevents and suppresses otherwise unavoidable overstimulation of the entire immune system by the most common environmental Ags primarily of food and indigenous bacterial origins. The enhancement of protective mucosal immune responses to infectious agents sought by vaccinologists, and the desired suppression of systemic immune responses to autoAgs and transplantation Ags, may seem paradoxical. Yet, such outcomes are not mutually exclusive due to the hierarchy in the quality of immune responses induced by mucosal Ag delivery: Mucosal immunity manifested by the appearance of secretory Abs and systemic tolerance evaluated by diminished CMI-responses may be concomitantly induced. Thus, the fundamental objectives of the mucosal immune system—containment of the vast onslaught of environmental Ags without compromised integrity of mucosal barriers and prevention of overstimulation of the systemic compartment—are achieved by concerted interactions of lymphoid and nonlymphoid cells, epithelial cells (ECs) in particular, and their respective products as a mucosal internet of communication. Thus, an orchestrated mucosal immune system consisting of innate immunity as well as acquired immunity including secretory IgA (S-IgA) Abs and mucosal cytotoxic T lymphocytes (CTLs), add additional layers of host defense.

INNATE MUCOSAL IMMUNE SYSTEM

Epithelial Cells

Physical Barrier Function of ECs

The epithelium of the mucosa-associated lymphoid tissues (MALTs) of the lung, gut and genitourinary tracts, and, others have been clearly shown to play an active role in both innate and adaptive types of mucosal immunity. Given the physical proximity of the ECs to the external milieu and, therefore, the primary site of initial Ag exposure, ECs may be a central cell type in both defining the Ags with which the mucosal immune system is confronted and regulating the ultimate responses to these antigenic exposures. Initially, prevention of luminal Ag transport is through a thick layer of mucus. Mucin 2 (MUC2) is a dominant intestinal mucus-formation molecule that is abundantly produced by goblet cells located at the intestinal villous epithelium (1). Mucus not only provides a physical and biological protective barrier, but also ensures maintenance of an appropriate concentration of Abs at the mucosal surface by preventing Ag-specific S-IgA Abs from being phys-

ically carried away. Additionally, paracellular transport of luminal Ag is prevented by the juncture between adjacent ECs that is mediated by physical structures associated with the epithelium including the tight junctions (TJs) and the subjacent desmosomes and adherence junctions (2). The TJs are composed of a number of interacting cellular proteins, which include claudin, occuludin, ZO-1, ZO-2, and cingulin, among others. Under normal circumstances, the TJs exclude Ags greater than 6 to 12 Å ($>$ 500 to 900 Daltons) in molecular diameter.

In addition to these physical barrier functions of ECs, the epithelium of the MALTs of the lung, gut and genitourinary tracts, have been clearly shown to play an active role in both innate and adaptive types of mucosal immunity by collaboration with adjunct neighboring ECs as well as subjacent parenchymal cells (fibroblasts and mesenchymal cells and their connective tissue substances) and hematopoietic cells [MΦ, dendritic cells (DCs), polymorphonuclear cells (PMN) and lymphocytes] and likely microbial components in the lumen (3).

Antimicrobial Peptides

The epithelium also secretes a variety of antimicrobial peptides (defensins, cathelicidins, cryptdin-related sequence [CRS] peptides) and bacteriolytic enzymes (lysozyme, secretory phospholipase-A2 [PLA2], peroxidase, and lactoferrin), and others (Figure 31.1). In the intestinal epithelium, ECs, Paneth cells, and PMNs mainly produce these molecules (4,5). Paneth cells reside at the base of the crypt regions of the small intestine, but not the stomach or colon. They produce α-defensins constitutively. In contrast, β-defensins are produced by ECs of the whole intestine, which requires microbial stimulation (4,5). Both defensins are cationic small peptides with a characteristic β-sheet–rich fold and a framework of six disulphide-linked cysteines and exhibit antimicrobial activity by damaging and permeabilizing the bacterial cell membrane by pore formation. Defensins also inhibit viral infection (e.g., human immunodeficiency virus [HIV], herpes simplex virus [HSV], vesicular stomatitis virus, and influenza virus) by interupting their invasion at an early step, such as receptor binding (4,5). In addition to the antimicrobial properties, defensins have chemotactic activities for monocytes, T cells, and B cells, implying that defensins may bridge between mucosal innate and acquired immunity via the augmentation of T and B cell interactions (6). The cathelicidin is also a cationic small peptide containing a cathelin-like domain produced by ECs, PMNs, and keratinocytes (4,5). The expression of cathelicidin by ECs is regulated by butyrate and other short-chain fatty acids produced by fermenting bacteria. The CRS peptide is produced by Paneth cells and shows antimicrobial activity through its cationic feature (4,5).

Antimicrobial enzymes are other molecules showing antimicrobial activities (Figure 31.1). PLA2 is a small
FIGURE 31.1 Various types of antimicrobial molecules protect mucosal surfaces against invading microbes. Epithelial cells (ECs) and Paneth cells secrete bacteriolytic enzymes (lysozyme, PLA2, peroxidase, and lactoferrin) and antimicrobial peptides (defensins, cathelicidins and cryptdin-related sequence [CRS]) in mucosal sites. Neutrophils also produce antimicrobial molecules. Defensins have been shown to possess the capability to recruit immunocompetent cells for the initiation of innate and adaptive immune responses.

enzyme produced by Paneth cells and PMNs, which degrades bacterial phospholipids and subsequently disrupts bacterial integrity (4,5). Lysozyme is another bactericidal component produced by Paneth cells, PMNs, and ECs. Lysozyme is a muramidase cleaving the glycosidic linkage between *N*-acetylglucosamine and *N*-acetyl muramic acid of peptidoglycan, and thus it is preferentially effective against gram-positive bacteria (4,5). Surfactant proteins A-D (SPs) are highly hydrophobic proteins in the lung produced by alveolar type II cells. Several lines of evidence revealed that SPs are actively involved in lung innate immunity following bacterial penetration into the lower airways (7). SPs bind to LPS and the interaction between SPs and CD14 may explain their ability to affect some LPS responses.

Antimicrobial molecules are also produced by PMNs induced following infection by pathogens. It is well established that PMNs take up invading microorganisms through a complement lysis-dependent phagocytosis and kill them by antimicrobial tools such as toxic oxygen radicals, cationic peptides, and lytic enzymes in the phagocytic vacuoles. In addition, PMNs produce extracellular fibers containing DNA, histones, and granule proteins after stimulation by bacterial endotoxins (8). These fibers are known as *neutrophil extracellular traps* (NETs). NETs bind to both gram-negative and -positive bacteria, and kill them by their esterase and antimicrobial peptides and enzymes.

Cytokines and Cytokine Receptors

ECs are able to secrete both constitutively and inducibly a large number of inflammatory and regulatory cytokines. Using EC lines, it has been shown that the epithelium can constitutively express proinflammatory cytokines such as IL-1-α, IL-1-β, IL-15, TNF-α, and IL-6 and anti-inflammatory and barrier-promoting cytokines such as TGF-β and IL-10, whose levels may be further increased by interactions with pathogens and their toxic products

(3). The production of these cytokines by the epithelium is likely to play an important role in both promoting intestinal inflammation (e.g., IL-1 and TNF-α), regulating the activation and expansion of mucosal T cells within the epithelium (e.g., stem cell factor [SCF], IL-5, IL-7, and IL-15), regulating local B cell production of Igs (e.g., TGF-β, IL-5, IL-6, and IL-10), and, finally, regulating barrier function, *per se* (IL-10, IL-15, and TGF-β). With regards to barrier function, ECs also express a large number of cytokine receptors (3). Intestinal EC (IEC) lines and freshly isolated IECs express mRNA for the common IL-2 receptor γ-chain and specific α-chains of the receptors for IL-2, IL-4, IL-7, IL-9, and IL-15. IECs also express receptors for TNF and IFN-γ, which not only regulate the expression of a wide variety of other immunologically important molecules such as the polymeric Ig receptor (pIgR), for example, but also tend to diminish epithelial barrier function. The expression of these cytokines and cytokine receptors thus further emphasize the integration of the epithelium into the network of cellular interactions associated with the MALTs. In this regard, bacterial infection can influence the interactions of the EC-mediated mucosal internet with mucosal T and B cells via IL-7/IL-7R and IL-15/IL-15R.

Transcellular Transport Functions of the Epithelium

Another aspect of epithelial barrier function that represents a link between the epithelium and the adaptive components of the MALT is the ability of the epithelium to transport macromolecules, especially Igs, transcellularly in a process termed *transcytosis*, which reflects the polarized nature of the epithelium. Two receptors for Ig have been shown to have such properties. The pIgR, whose itinerary is now well defined, transports polymeric forms of IgA (pIgA) and IgM (pIgM) from the basal to apical direction with unloading of its cargo in association with an extracellular proteolytic fragment of the pIgR receptor (secretory component, SC) (9). This pathway is not only able to deliver large quantities of secretory Ig onto the mucosal surfaces, but it is also able to exclude Ags that have entered the secretory pathway either apically or basally (discussed later). This type of defense, which takes advantage of a component of the adaptive immune response, is likely to be important in resistance against pathogenic viral infections.

In a related but distinct manner, the epithelium also expresses the neonatal Fc receptor for IgG (FcRn) (10). Recent evidence indicates that this molecule is expressed by adult human epithelium and MΦ of the intestine (and, likely, other surfaces) and thus is not strictly limited to neonatal life as predicted by earlier studies in rodents wherein the FcRn was responsible for the passive acquisition of IgG neonatally (10). In the context of expression postnatally in adult humans, FcRn may therefore be in a position to provide luminal immunosurveillance against pathogenic exposure. FcRn binds IgG, its cargo, in a pH-dependent process (pH 6 on, pH 7.4 off) due to critical histidine residues in the Fc-region of the IgG molecule. In contrast to the itinerary associated with pIgR-associated transport, the transport pathway associated with FcRn is bidirectional; both apical to basal and basal to apical (10). In addition, the FcRn is not associated with proteolytic cleavage allowing for reiterative rounds of transport. It is predicted, therefore, that the FcRn is at least in part responsible for the steady state distribution of IgG on either side of an epithelial barrier given the unlikely possibility that paracellular transport of this macromolecule occurs due to the molecular exclusion of the TJs.

Pattern Recognition Receptors

Toll-like Receptors

The extrinsic barrier functions of the epithelium associated with innate immunity are at least partially mediated by the interaction with luminal microbiota. It is well established that pattern recognition receptors (PRRs) play an important role in the recognition of microbial products (Figure 31.2) (11,12). Most prominent among PRRs that regulate innate immune responses are an array of Toll-like receptors (TLRs). ECs in the respiratory, genital, and GI tracts were reported to express several types of TLRs binding to signature microbial products such as peptidoglycan of gram-positive bacteria (TLR2), viral double-stranded RNA (dsRNA) (TLR3), bacterial LPS of gram-negative bacteria (TLR4), bacterial flagellin (TLR5), and microbial CpG motifs of DNA (TLR9) (13,14). Pathogens have more than one TLR ligand so multiple TLRs are co-ordinately regulated. These molecules were initially characterized as the pathogen-associated molecular patterns (PAMPs), but these are produced by both pathogenic and commensal microorganisms. Although TLR signaling induces an inflammatory cascade in the sterile circumstance of the systemic immune compartment, mucosal TLRs should take a different strategy to distinguish pathogenic microorganisms from commensal microorganisms for the immunosurveillance in the mucosal tissues directly and continuously exposed to the large numbers of commensal as well as occasional pathogenic microorganisms.

Evidence has been emerging that underlying molecular pathways exist to achieve the discrimination of pathogenic from commensal microorganisms in the innate mucosal system (Figure 31.2). First, it has been proposed that decreased surface expression of TLRs and coreceptors leads to the down-regulation of TLR signaling (13,14). Notably, peptidoglycan and LPS are abundantly produced by the commensal microflora, and thus their receptors (TLR2 and TLR4) should have an immune quiescent system against these commensal-derived PAMPs. Along these lines, TLR2 and TLR4 are expressed on the surface of ECs but
FIGURE 31.2 Uniqueness of recognition and discrimination of microbes. Toll-like receptors and nucleotide-binding oligomerisation domains (NODs) recognize bacterial products (peptidoglycan [PG], lipopolysaccharide [LPS] and CpG DNA). The host mucosal immune system employs various mechanisms to distinguish pathogenic from commensal bacteria: 1, continuous bacterial stimulation leads to down-regulation of TLR expression; 2, TLR5 is preferentially expressed on the basolateral side of ECs; 3, pathogenic bacteria are recognized by LP DCs which express TLR5; 4, TLR9 signals through the basolateral side induces the activation of the NF-κB pathway while apical TLR9 stimulation prevents NF-κB activation; 5, LPS from commensal bacteria induces regulatory T cell differentiation.

prolonged stimulation with their ligands resulted in their down-regulation. Thus, TLR2 and TLR4 are expressed on fetal ECs and adult crypt ECs, but their expression was lost on mature ECs (15). In addition to ligand stimulation, down-regulation of TLR expression is induced by TGF-β, a regulatory cytokine predominantly produced in the intestine (12). In the case of TLR4, LPS recognition is coupled to CD14 binding of LPS, wherein LPS bound to CD14 interacts with a TLR4/MD-2 protein heterodimer. The absence or reduction of CD14 and MD-2 expression on ECs was reported, which presumably was associated with a lack of reactivity with LPS (14).

Secondly, the reduced reactivity of ECs to PAMPs is explained by the unique distribution of TLRs. For exam-

ple, it has been shown that the LPS-induced reduction of TLR2 and TLR4 was mediated by the alteration of their distribution from the apical site to intracellular compartments (13). It is interesting to note that intracellular TLR4 maintains its activity to detect intracellular bacteria. This unique intracellular distribution of TLR4 but not outer cell membrane allows the EC to discriminate pathogenic cells invading the ECs and commensal cells generally attaching on their cell surface. Another example of this was shown by TLR5, which recognizes bacterial flagellin. TLR5 is exclusively expressed on the basolateral site of ECs, allowing them to sense bacteria when they invade into the lamina propria (LP) regions (14). A recent study has provided an additional example of polarity-mediated regulation of TLR

signaling in the ECs by showing that TLR9 signals through the basolateral site and induces the activation of the NF-κB pathway, while apical TLR9 stimulation prevents NF-κB activation (16).

As the third mechanism, several negative regulatory pathways for TLR expression have been identified. It was reported that the loss of postnatal LPS responsiveness of ECs was associated with a post-transcriptional down-regulation of the IL-1 receptor-associated kinase 1 (IRAK1), an essential molecule for epithelial TLR4 signaling (15). ECs also express a negative regulator of TLR signaling (12–14). For instance, toll-interacting protein (Tollip) is induced in the EC by bacterial stimulation and plays an important role in the negative regulation of TLR signaling through its suppression of the IRAK activation pathway. Single Ig IL-1-related receptor (SIGIRR, also known as TIR8) is a negative regulator of IL-1 and TLR signaling expressed in the ECs, which attenuates the recruitment of receptor-proximal signaling components to the TLRs. Other negative regulators have been identified, such as intracellular antagonists of TLR signaling (MyD88s [splice variant of MyD88], IRAKM [homolog of IRAK1], and IRAK2c/d [splice variants of IRAK2]) and ubiquitin ligase of TLR-mediated signaling molecules (A20 and TRIAD3A), but their involvement in the down-regulation of TLR signaling in the mucosal tissues remain to be investigated (12–14).

Cells other than ECs also possess a unique system to achieve effective intestinal immunosurveillance without excess immune responses against commensal microbiota. Like the ECs, LP MΦ lack reactivity to LPS due to failure to express CD14 (17). It is interesting to note that the unresponsiveness of intestinal MΦ to LPS was intrinsic but that of EC was acquired immediately after birth by exposure to exogenous LPS, as mentioned earlier (15). Additionally, LP MΦ selectively express IκBNS, an inhibitor of NFκB activation (18). In the case of mucosal DCs, a unique pathogen recognition system is achieved by the distinct expression of TLR4 and TLR5. Unlike conventional DCs in systemic immune compartments (e.g., spleen), intestinal LP DCs predominantly express TLR5, but not TLR4 (19). Thus, the LP DCs can detect pathogenic bacteria in a TLR5-dependent manner when luminal pathogens break the epithelial barrier and become exposed to LP DCs. However, these DCs do not secrete pro-inflammatory cytokines after exposure to commensal bacteria.

Cytoplasmic PAMPs Receptors

Besides the TLRs, other receptors for detecting cytoplasmic PAMPs have been identified (Figure 31.2). Nucleotide-binding oligomerization domain 1 (NOD1) and NOD2 are well-characterized cytoplasmic PRRs expressed by both ECs and MΦ, which recognize a peptidoglycan motif containing a diaminopimelate-containing

N-acetylglucosamine-N-acetylmuramic acid tripeptide in gram-positive and gram-negative bacteria (11,12). Thus, the NOD family plays a crucial role in distinguishing invading pathogens and commensal bacteria. For the detection of invading viruses, retinoic acid inducible gene-I (RIG-I) and melanoma differentiation-associated gene 5 (MDA5) have been identified. Both recognize dsRNA generated during viral replication and trigger the activation of NF-κB and IRF3/7 with subsequent production of antiviral type I IFN (11,12). The family of intracellular PRRs provides another layer to the innate system for production of the mucosal epithelium and the immediate underlying region of the mucosal compartment enriched with T cells, B cells and Ag presenting cells (APCs).

Unique PRRs Function in Mucosal Immunity

Although these PRR-mediated signals activate mucosal immune responses by producing inflammatory cytokines and chemokines, the mucosal immune system is equipped with additional unique activation pathways for enhancing mucosal innate responses as well. For instance, TLR-mediated signals enhance antimicrobial peptide (e.g., β-defensin) production by ECs and Paneth cells (4,5). TLR ligand stimulation of ECs also leads to the tightening and sealing of the TJ protein ZO-1 (13,14). Simultaneously, mucosal TLR stimulation by commensal microbiota enhances anti-inflammatory activities. Peroxisome proliferator-activated receptor γ (PPARγ) was induced by commensal microbiota-mediated TLR signaling (14). PPARγ serves as an inhibitor of colonic inflammation through its ability to inhibit NF-κB activation. Additionally, LPS from the commensal microbiota, but not from pathogenic bacteria, induces the development of regulatory T (Treg) cells producing an inhibitory cytokine, IL-10 (12). In the lungs, TLR stimulation induces the production of indoleamine 2,3-dioxygenase (IDO) in the parenchyma. The lung-specific production of IDO leads to the inhibition of T cell–mediated lung inflammation and airway hyperreactivity by inhibiting T cell migration into the lung and by killing T cells (20).

An Involvement of PRRs in the Development of Mucosal Inflammation and Allergy

As one may envision, a dysregulated mucosal innate system leads to inflammatory responses in mucosal tissues. For instance, TLR2 and TLR4 expression is upregulated during inflammatory bowel disease (IBD) development, and polymorphisms in TLR4 have been shown to be linked to IBD development (13). Similarly, mutation of NOD2 contributes to IBD pathogenesis (21). Additionally, mutation or down-regulation of negative regulators for TLR signaling (e.g., IκBNS) resulted in IBD development (18). It is interesting to note that MyD88-deficient mice showed a higher mortality than wild-type mice when exposed to

dextran sulfate sodium (DSS)-induced colitis (22). The disease susceptibility was at least partially attributable to an impaired epithelial proliferation caused by the TLR-mediated signaling. Commensal bacteria and TLRs are also involved in the development of food allergy, another serious mucosal disease. It has been shown that commensal biota-derived signaling through TLR provides a protective function against food allergy (14).

In addition to intestinal inflammation, PRRs are involved in airway inflammatory diseases such as asthma. It was previously reported that an insertion-deletion polymorphism of NOD was strongly associated with asthma (23). Additionally, a recent study suggests that TLR4-mediated signaling is involved in the development of allergic airway inflammation through a modification in mast cell function (24). These studies indicate that signaling through PRRs is also important for the creation and maintenance of a quiescent status in the immune environment of mucosal compartments. This includes intestinal homeostasis rather than induction of inflammatory responses since the destruction of the PRR system is associated with the development or acceleration of mucosa-associated diseases. Taken together, PRR-mediated signals play an important role in both immunosurveillance and immune homeostasis in mucosal tissues.

Intraepithelial T Lymphocytes

Close Communication between ECs and Intraepithelial Lymphocytes

The major interface between internal organs and the outside environment is the columnar intestinal epithelial cell (IEC) layer, which covers mucosal tissues. In addition to IECs, the columnar epithelium includes a population of lymphocytes commonly termed *intraepithelial lymphocytes* (IELs) (25). As their name implies, IELs reside between the basolateral surfaces of IECs. It has been estimated that 1 IEL occurs for every 4 to 10 IECs seen in the small intestine and for every 30 to 50 IECs found in the large intestine. This shows that large numbers of lymphocytes are situated in the surface regions of intestinal mucosal tissues. Thus, IELs have been shown to closely communicate with each other and with the IECs that surround them. Indeed, several interacting molecules were expressed between IECs and IELs. For example, CD103 (α_E integrin) expressed on IELs interacts with the E-cadherin expressed on IECs, playing an important role in the retention of IELs in the intestinal epithelium (26). Additionally, IEL retention may be mediated by expression of certain integrins (e.g., $\alpha_1\beta_1$, $\alpha_4\beta_1$, and β_2 integrins), the adhesion molecule, Ep-CAM and TJ molecules (e.g., ZO-1 and occludins) (25). These intimate biological interactions between IECs and IELs provide physiological barriers that act as a first line of innate defense in the intestine.

As mentioned earlier, IECs are in constant contact with the luminal microbiota. In addition, IECs become the target of microbial pathogen attachment and replication leading to the establishment of infection. Given the presence of immune and inflammatory cells within the epithelium and their obvious changes during infection or inflammation, it is worthwhile to consider the role of IECs and IELs in orchestrating these responses. It is logical to assume that these IELs are important lymphoid cells that participate in the mucosal innate response. Indeed, the majority of human and murine IELs are classified as T cells because they express the CD3 molecule in association with either of the two forms of T cell receptor (TCR), $\gamma\delta$ or $\alpha\beta$. Concerning the expression of CD4 and CD8 by IELs, it has been shown that approximately 80% of small intestinal IELs belong to the CD8 subset; however, a substantial number of IELs can be grouped as CD4-bearing cells including CD4$^+$CD8$^-$ and CD4$^+$CD8$^+$ subsets. The CD8 molecules expressed on IELs consist of either $\alpha\beta$ heterodimeric or $\alpha\alpha$ homodimeric chains. CD8$\alpha\beta^+$ IELs express Thy-1 and express the $\alpha\beta$ TCR. In contrast, CD8$\alpha\alpha^+$ IELs and CD4$^-$CD8$^-$ double-negative (DN) IELs contain both TCR$\gamma\delta$ and TCR$\alpha\beta$ fractions (25).

Innate Homeostatic and Protective Immune Function of $\gamma\delta$ IELs

Among IELs, those expressing the TCR$\gamma\delta$ ($\gamma\delta$ IELs) have been considered to be involved in mucosal innate defense because cell-transfer studies have indicated that the $\gamma\delta$ IELs have only minimal pathogen-specific activity (25,27). The less Ag-specificity of $\gamma\delta$ IELs is supported by the finding that $\gamma\delta$ IELs are present in mice deficient in the transporter associated either with antigen processing (TAP) or with the classical class I molecules (K$^{b-/-}$ D$^{b-/-}$), while $\gamma\delta$ IELs were drastically reduced in numbers in β2-microglobulin–deficient mice (25,27), suggesting that $\gamma\delta$ IELs recognize a TAP-independent nonclassical MHC molecule (Figure 31.3). In humans, the TCR$\gamma\delta$ expressed by IELs predominantly use Vδ1. These human TCR$\gamma\delta$ recognize the MIC molecules MICA and MICB, members of the nonclassical MHC molecule family (27). MIC molecules on ECs are induced by stress such as heat shock and microbial infections and are not capable of presenting peptides, but instead act as ligands for $\gamma\delta$TCRs. In mice, $\gamma\delta$ IELs predominantly use the Vγ5 (also known as Vγ7) gene segment together with several Vδ genes. Although mice do not have a functional MIC gene ortholog, they express molecules that resemble MIC such as H60, members of the RAE class I–like family, and other nonclassical MHC class I molecules (e.g., T10/T22) (Figure 31.3) (27).

Upon TCR$\gamma\delta$-mediated stimulation by nonclassical MHC molecules, $\gamma\delta$ IELs synthesize an array of cytokines that includes IL-2, IL-3, IL-6, IFN-γ, TNF-α, and TGF-β
FIGURE 31.3 Molecular machinery for mucosal lymphocyte and EC interactions. Unique populations of mucosal lymphocytes are located in or underneath the intestinal epithelium. Immunological functions of these lymphocytes are regulated via molecular interactions between MHC family molecules and corresponding receptors. The ECs express MHC molecules including broad types of nonclassical MHC molecules interacting with specific receptors expressed on lymphocytes, which allow the establishment of induction of productive and quiescent immune responses in mucosal tissues.

(25,27). It was also shown that freshly isolated and activated $\gamma\delta$ IELs express high levels of mRNA specific for lymphotactin, a chemokine important for CD8$^+$ T cell chemotaxis (27). These results suggest that IELs actively produce cytokines and chemokines to provide specific immunologic functions in the mucosal compartment. In addition to cytokine production, $\gamma\delta$ IELs produces cytotoxic molecules such as perforin, granzyme, and Fas ligand, and show cytotoxic activity against stressed or microbial infected IECs (28).

Alternatively, because activated $\gamma\delta$ IELs can produce keratinocyte growth factor (KGF), which is important for epithelial growth and repair of damaged tissues, some $\gamma\delta$ IELs could be involved in repair of tissue damage elicited during inflammatory responses (27). In addition to KGF, $\gamma\delta$ IELs synthesize anti-inflammatory and regu-

latory cytokines such as TGF-β and IL-10. In agreement with production of these cytokines, TCRδ chain–deficient mice show an increased susceptibility to epithelial damage caused by dextran sulfate sodium (DSS)-induced colitis (27). Thus, $\gamma\delta$ IELs also play a critical role in the maintenance of mucosal homeostasis in epithelial regions. However, not all immune responses mediated by $\gamma\delta$ IELs are beneficial. For example, it was shown that dysregulated production of IL-15 and overexpression of MICA/MICB on IECs led to the aberrant activation of IELs in the case of celiac disease (29).

To prevent the disruption of the epithelium by activated IELs, it is essential that IELs produce cytokines without self-proliferation. To achieve this opposite regulation (cytokine production without proliferation), the mucosal immune system has evolved a unique interaction

between IECs and IELs. Thymus leukemia antigen (TL) is a nonclassical MHC molecule expressed almost exclusively by IECs of the small intestine (Figure 31.3) (27). Like other nonclassical MHC molecules, TL does not present antigenic peptides but strongly interacts with CD8$\alpha\alpha$ on IELs. The interaction between CD8$\alpha\alpha$ and TL enhances cytokine production by IELs but inhibits self-proliferation and cytotoxic activity. By inhibiting proliferation, CD8$\alpha\alpha$-TL interactions prevent the disruption of a sheeted form of epithelium that results from attack by dividing IELs (27).

Recent studies show that a naïve population of IELs is made up of recent CD8$^+$ thymic emigrants (RTEs) (30). RTEs are distinguished by their ability to migrate into the small intestine without activation because of their expression of $\alpha_4\beta_7$ integrin, α_E integrin, and CCR9 in the thymus (30). After migrating directly into the intestinal epithelium from the thymus, these RTEs begin to proliferate in response to Ag exclusively present in the gut. These IELs show diverse TCR repertoires, which is important in their maintenance of TCR diversity in the intestine.

Unique Developmental Pathways for IELs

In addition to their immunological uniqueness, IELs also have a special development pathway, even though controversy remains as to what extent the IELs require thymic dependency (31,32). Like naïve lymphocytes circulating in systemic immune compartments, the major IEL populations in CD4 or CD8$\alpha\beta$ subsets expressing TCR$\alpha\beta$ originate from conventional single-positive (SP) thymocytes. In contrast, some populations of double-negative (DN) IELs and CD8$\alpha\alpha$ IELs expressing either TCR$\alpha\beta$ or TCR$\gamma\delta$ originate from unconventional thymocytes. Several lines of evidence have revealed that these IEL precursors in the DN thymocytes, including TCR$\alpha\beta^+$ DN thymocytes, TCR$\gamma\delta^+$ DN thymocytes, and TCR$\alpha\beta^-$ CD4$^-$ CD8$^-$ triple-negative (TN) thymocytes (31). TCR$\alpha\beta^+$ DN thymocytes are thought to be mature postselected DN thymocytes because they arose from the CD8$\alpha\alpha^+$ CD4$^+$ CD8$\alpha\beta^+$ triple-positive (TP) thymocytes after agonist selection and migration into the intestine where they further reinduce CD8$\alpha\alpha$ under the influence of IL-15 (31). In addition to the postselected DN thymocytes, some subsets among the TN thymocytes emigrated from the thymus during the CD44$^+$ CD25$^+$ TN2 or the CD44$^-$ CD25$^+$ TN3 stages and migrated into the intestinal epithelium where they characteristically expressed *c-kit* and IL-7 receptor (IL-7R) and subsequently expressed TCR$\alpha\beta$ or TCR$\gamma\delta$ (31). It was recently found that thymic IEL precursors could be divided into two groups based on the requirement of sphingosine 1-phosphate (S1P), a lipid mediator, in the regulation of trafficking of thymic IEL precursors into the intestine (33). CD4 or CD8$\alpha\beta$ naïve IELs originating from single-positive (SP) thymocytes express high levels of type 1 S1P

receptor. In contrast, unconventional thymic IEL precursors, including RTEs and DN thymocytes expressing either TCR$\alpha\beta$ or TCR$\gamma\delta$, migrate into intestine in a S1P-independent manner (33).

In addition to the conventional and unconventional thymic IEL precursors, it has been proposed that certain populations of IEL subsets (e.g., TCR$\gamma\delta$ CD8$\alpha\alpha$ IELs) develop extrathymically (32,34). As a candidate lymphoid tissue for extrathymic IEL development, cryptopatches (CryPs) were identified (35). CryPs were shown to be lymphocyte clusters in the crypt LP of the murine small and large intestine. Cells within the CryPs are composed mostly of lymphoid progenitors expressing stem cell factor (SCF) receptor (c-kit), and IL-7Rα, but lacking the lineage markers (CD3, B220, Mac-1, Gr-1, and TER-119). They possess transcripts for germline TCR genes, mRNA for CD3ε, as well as proteins (i.e., *RAG*-2 and preTα) involved in TCR gene rearrangement and are able to generate CD8$\alpha\alpha$ $\alpha\beta$ as well as $\gamma\delta$ IELs, albeit with a strong bias toward the generation of $\gamma\delta$ T cells, in irradiated severe combined immunedeficient (SCID) mice. These findings demonstrated that c-kit$^+$ CryP cells are committed to the T cell lineage and are competent for the generation of IELs.

Natural Killer and NKT Cells

In addition to the T cells, the epithelium includes natural killer (NK) and NKT cells. For instance, the human nonclassical MHC molecules MICA and MICB predominantly expressed on damaged or transformed IECs act as ligands for the NK receptor, NKG2D (Figure 31.3) (27). Interestingly, as mentioned earlier, TCR$\gamma\delta$ recognizes the same MICA and MICB molecules (Figure 31.3), implying that the mucosal immune system can use both TCR$\gamma\delta$ and NKG2D to recognize damaged or stressed IECs through the nonclassical MHC molecules. Additionally, the expression of HLA-E on the epithelium is associated with ligation of killer inhibitory-related receptors (CD94/NKG2) on activated mucosal NK cells in humans (Figure 31.3) (29). It was previously shown that the cytotoxic effects of NK IELs were enhanced by IL-15 through the up-regulation of IFN-γ production and Fas ligand-mediated killing activity and simultaneous enhancement of MICA expression (29).

NKT cells also play an important role in mucosal innate immunity (Figure 31.3). NKT cells express invariant TCR. The TCRα chain comprises a Vα14 in the murine system, and TCR Vα24 is a homologue expressed on human NKT cells (36). In contrast to the invariant expression of TCRα, NKT cells possess a wide variety of TCRβ chains (36), which allows them to contribute to various immune responses including mucosal homeostasis. These NKT cells recognize lipid-derived Ag presented by the CD1d, one of the nonclassical MHC molecules (Figure 31.3). IECs and DCs in the intestinal compartments express the CD1d (37). However, several studies have identified lipid

Ags presented by CD1d, such as α-glucuronosylceramine and α-galacturonosylceramide from nonpathogenic sphingomonas bacteria and a diacylglycerol from pathogenic *Borrelia burgdorferi* (36). In addition, it has been proposed that infection with bacteria (e.g., *E. coli, Bacillus subtilis, S. aureus,* or *Mycobacterium bovis-Bacillus Calmette Guerín*) or their derived bacterial components such as LPS, lipoteichoic acid, or Pam$_3$CysSerLys$_4$ (P$_3$CSK$_4$) allows CD1d$^+$ cells to present endogenous glycosphingolipid, isoglobotrihexosylceramide, and stimulate NKT cells, which may contribute to initial sensing of pathogenic or infected cells (Figure 31.3) (36).

After stimulation via CD1d, NKT cells can secrete both Th1- and Th2-type cytokines (Figure 31.3). It is still unclear how the hierarchy between Th1- and Th2-biased NKT cells is determined, but this may account for the contribution of NKT cells to both protective and anti-inflammatory functions (36). Consistent with this, it was reported that CD1d-deficient mice were susceptible to infections (e.g., *Listeria* and *Pseudomonas aeruginosa*) at mucosal sites. NKT cells are also involved in the amelioration of DSS-induced colitis through their ability to produce regulatory cytokines such as IL-4 and IL-10. NKT cells are also thought to be involved in the suppression of allergen-induced airway hyperreactivity by the induction of a Th1 shift from an allergy-associated Th2 environment or the creation of anergy. These results generally suggest a critical role for NKT cells in the down-regulation of inflammatory responses; however, other studies demonstrated that NKT cells induced asthma. Although the NKT cell subset is a minor population of mucosal immune compartments, the cells are involved in the recognition of self- and exogenic-glycolipid Ags as a part of the mucosal innate defense system (36).

Mucosa-associated Invariant T Cells

A recent study has discovered MHC-related 1 (MR1)–restricted mucosal-associated invariant T cells (MAIT cells) as a novel subset of unconventional T cells abundantly present in the intestinal LP (Figure 31.3) (38). MAIT cells express invariant TCR α chain, TCR Vα7.2-Jα33 in humans and TCR Vα19-Jα33 in mice. Like conventional T and NKT cells, MAIT cells develop in the thymus, but their selection is independent of the TAP and invariant chain, suggesting that putative ligands presented by MR1 are different from those presented by conventional MHC class I and II molecules. In this context, several lines of evidence have revealed that MAIT cells can be activated by both peptide Ag and glycolipid Ags (e.g., α-GalCer and other α-mannosylceramides) (Figure 31.3). MAIT cells additionally require MR1$^+$ B cells for their development. It is interesting to note that MAIT cells are markedly decreased in germ-free mice, suggesting that some microbial stimulation is required for the selection, migration, and expansion

of MAIT cells. MAIT cells have been suggested to be involved in the immunosurveillance and the establishment of immunological homeostasis in the intestine, because MAIT cells possess regulatory functions where the cells inhibit autoimmune responses (39).

ACQUIRED MUCOSAL IMMUNE SYSTEM

Mucosal Migration System for Acquired Immunity

In addition to the innate mucosal immune system, the mucosal immune system is equipped for well-organized and controlled acquired immunity. The mammalian host has evolved organized secondary lymphoid tissues in the upper respiratory and GI tract regions that facilitate Ag uptake, processing, and presentation for priming immunocompetent cells for subsequent induction of Ag-specific mucosal immune responses. Collectively, these tissues are termed mucosal inductive sites. The gut-associated lymphoid tissues (GALT) consist of several family members of inductive sites including the Peyers patches (PPs), colonic patches (CPs), the appendix, and isolated lymphoid follicles (ILFs) (34). The major inductive tissues for nasal/inhaled Ags in humans, and primates appear to be the palatine tonsils and adenoids (nasopharyngeal tonsils), which together form a physical barrier of lymphoid tissues termed the *Waldeyers ring,* as well as nasal-associated lymphoid tissues (NALT) for mice and rats (40). To summarize, then, NALT and GALT in humans and mice and possibly primates comprise a MALT network.

Through the interaction with APCs in MALTs, naïve B and T cells are primed by Ag and then emigrate from the inductive environment via lymphatic drainage, circulate through the bloodstream, and home to mucosal effector sites, especially the LP regions of the intestinal, respiratory, and reproductive tracts where they further differentiate into effector cells that protect mucosal surfaces (41,42). These mucosal networks are known as the common-mucosal immune system (CMIS) or recently suggested to be named as mucosal migration system (MMS) bridging between the inductive (e.g., MALTs) and effector sites (e.g., LP), a network that plays a key role in the induction of Ag-specific acquired immunity against mucosally encountered Ag.

Structure and Cellular Composition of Mucosal Inductive Sites

Among several MALTs, the most extensively studied mucosal inductive tissues are the PPs of the murine GI tract. PPs are large enough to be observed upon gross examination, and usually number 8 to 10 in murine small intestine. In humans, up to 200 PPs were detected. Like PPs in the small intestine, there are lymphoid organs in the
FIGURE 31.4 Multiple Ag uptake pathways for the induction of mucosal immune responses. At least three distinct Ag sampling sites have been reported. M cells were originally discovered in FAE of MALTs including PPs, ILFs, and NALT for sampling of orally administered Ags. In addition to MALT-associated M cells. M cells are also capable of developing at the tip region of villous epithelium from FAE of MALTs and have been termed villous M cells. Finally, DCs can extend their dendrites expressing the TJ molecule claudin between ECs and directly take up GI tract luminal Ags.

large intestine. These tissues are known as CPs, or rectal-associated lymphoid tissue (RALT), which are smaller in size than PPs (34). An additional lymphoid structure resembling PPs and CPs in composition and architecture has been identified as numbering at least 30,000 (in humans), and 100 to 200 (in mice) clusters on the antimesenteric wall of the murine small intestine, which are now known as solitary lymphoid follicles or ILFs (34). In the respiratory tract, NALT is found on both sides of the nasopharyngeal duct dorsal to the cartilaginous soft palate in rodents (40). In humans, there are unpaired nasopharyngeal tonsils (adenoids) and the paired palatine tonsils that play an important role for human airway immunity. The latter makes up most of Waldeyers ring in humans (40). Further, a NALT-like structure of lymphocyte aggregation with follicle formation was identified in human nasal mucosa, especially that of the middle concha in children less than 2 years old (43). In the bronchial tract, bronchus-associated lymphoid tissues (BALT) was classically defined as an aggregated lymphoid structure separated from the bronchial lumen by a specialized lymphoepithelium in several species, including rats, rabbits, and sheep, although the presence of murine and human BALT as an aggregated lymphoid follicle under normal conditions remains a subject of debate (40).

Although each MALT exists in different regions of the mucosal tissues, MALTs share several interesting features associated with their role as the major mucosal inductive tissue (41,42). First, MALTs are unique in that they contain efferent lymphatics but no afferent lymphatics, reducing the possibility that an Ag will be encountered via the afferent lymphatics. Instead, MALTs are covered with the specialized EC termed a *follicle-associated epithelium* (FAE). FAE contains a specialized cell type called a *mi-crofold/membraneous cell* (*M cell*) that is closely associated with lymphoid cells (Figure 31.4) (44). M cells are noted in the MALTs of both humans and rodents (e.g., PPs, ILFs, CPs, and NALT). The M cells, which have short microvilli, small cytoplasmic vesicles, and few lysosomes, are adept at takeup and transport of luminal Ags, including proteins and particulates such as viruses, bacteria, small parasites, and microspheres, allowing the selective transport of these Ag into the MALTs. The human palatine and nasopharyngeal tonsils (adenoids) are largely covered by a squamous epithelium and are often not appreciated as mucosal inductive tissues. However, the palatine tonsils usually contain 10 to 20 crypts that increase their surface area where M cells locate in the deeper regions (44). Although this issue remains a subject of debate, several studies demonstrated that M cells could be differentiated from the absorptive ECs through interactions with B cells (45).

MALTs contain organized regions for the generation of IgA-committed B cells. Distinct B cell zones are located beneath the dome area of PPs and contain germinal centers (GCs) where significant B cell division is seen (Figure 31.5). These GCs contain the majority of surface IgA-positive (sIgA$^+$) B cells (46), but, unlike the spleen and secondary lymph nodes (LNs) in the systemic compartment, PC development does not effectively occur. In addition to the GCs, the underlying dome region of the PPs consist of sparse sIgA$^+$ cells that may provide a first line of IgA-mediated defense for the dome region of PPs. Since germ-free mice have PPs but lack GCs, it has been postulated that the continuous exposure of the PPs to the commensal bacteria or viruses from the outside environment induce the constant GC formation seen in PPs (47). In contrast to the PPs, GCs are absent in the NALT of normal mice (41,42). Thus, PPs contain a high frequency (10% to 15%)
FIGURE 31.5 Segregated cell distribution in the PPs. CD4$^+$ T cells (green) are mainly present in the intrafollicular regions (IFRs) and B cells (red) are located in the subepithelial dome (SED) and follicle (FO) regions. DCs (blue) are distributed in the SED and IFRs. GCs are enriched in B cells with small numbers of T cells and DCs for the creation of a cellular environment for the efficient generation of IgA-committed B cells. (See color insert.)

of sIgA$^+$ B cells, while NALT was found to contain fewer IgA-committed B cells, even though nasal immunization induces higher numbers of sIgA$^+$ B cells in NALT (41,42). In human tonsils, approximately one half of cells are B lymphocytes, and they mainly occur in follicle-containing GCs (46). Most human tonsillar B cells are actually surface IgG-positive (sIgG$^+$); however, significant numbers of sIgM$^+$ and sIgA$^+$ B cells are also present. The human palatine tonsil also contains a distinct subepithelial B cell population, as is seen in the FAE region of PPs. This B cell subset differs from both GCs and follicular mantle B cells (46). These subepithelial B cells located in NALT and GALT may play a crucial role in immediate Ab production toward Ag taken up through M cells.

All major T cell subsets are found in the T cell–dependent areas adjacent to follicles, the interfollicular regions (IFRs) (Figure 31.5). The parafollicular T cells are mature and $> 97\%$ of these T cells use the $\alpha\beta$ heterodimer form of TCR. Approximately two-thirds of TCR$\alpha\beta^+$ T cells in the PPs are CD4$^+$ and exhibit properties of Th cells, including support for IgA Ab responses (48). Approximately one-third of the TCR$\alpha\beta^+$ T cells in the PPs are CD8$^+$; this cell subset contains precursors of CTLs (28). These IFRs contain high endothelial venules (HEVs), a main entry site for lymphocytes into PPs. The HEVs express mucosal vascular addressin cell adhesion molecule 1 (MAdCAM-1), a ligand for the $\alpha_4\beta_7$ integrin, which determines a selective gut-tropism migration for lymphocytes (49,50). The T cell–rich IFRs overlap with the B cell follicles in some areas, providing an important place for initial T–B cell interactions.

Immunohistologic studies have revealed the unique distribution of DCs. In the PPs, DCs are divided into at least three distinct populations (51,52). First, myeloid-type DCs expressing CD11b are located in the subepitheliual dome (SED) region. The second DC population in the PPs is CD8α^+ lymphoid DCs residing in the T cell–rich IFRs. Additionally, PPs contain DCs expressing neither CD11b nor CD8α, which are called DN DCs. The DN DCs are exclusively found in both SED and IFRs. The distribution of different populations of DCs in the PPs is at least partially determined by chemokines and their receptors (51,52). CD11b$^+$ myeloid DCs express CCR6, which allow their migration toward CCL20 selectively expressed by FAE. Consistent with this, CD11b$^+$ DCs were markedly reduced in the SED of PPs in CCR6-deficient mice (53). In addition to the interaction between CCR6 and CCL20, the interaction between CCR1 and CCL9 plays a nonredundant role in the migration of CD11b$^+$ DCs into the FAE of PPs. Additionally, all DCs in the PPs expressed CCR7, allowing them to migrate into the IFRs toward cells producing CCL19 and CCL21. It has been demonstrated that DCs also play an important role in the respiratory immune system; however their distribution remains unclear.

Distinct Pathway for MALT Organogenesis

GALT Organogenesis

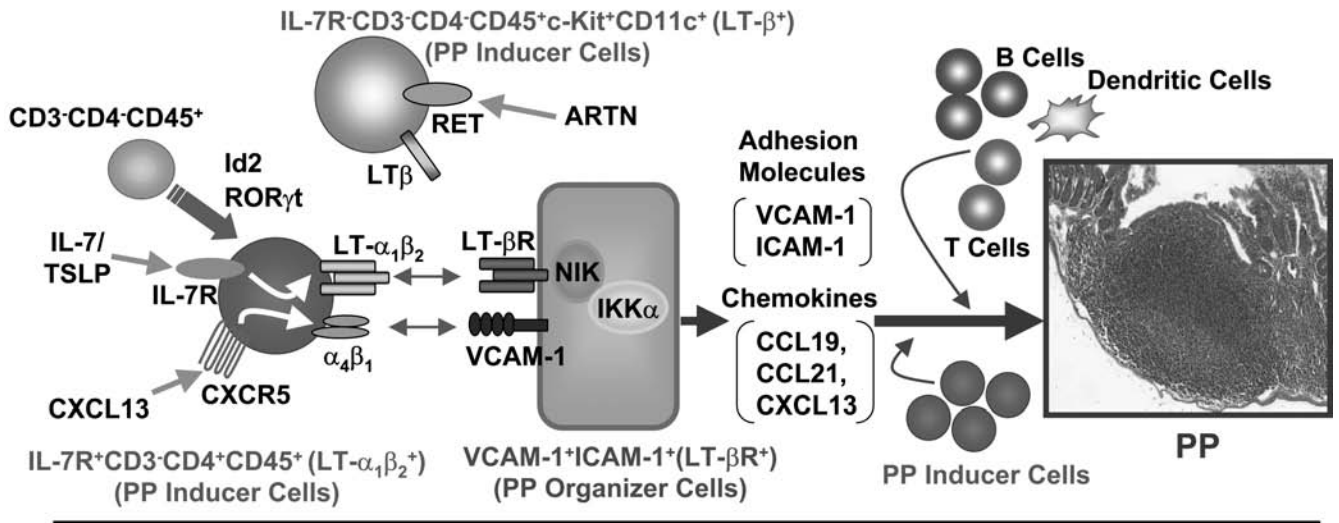
Although similar in terms of anatomy and histology, the MALTs of the respiratory and intestinal immune system differ in their organogenesis (34,41,42). The models


FIGURE 31.6 Distinctively orchestrated organogenesis of MALTs of PPs and NALT. Initial phase of the tissue genesis program of PPs operates during embryogenesis. The development of IL-7R$^+$CD3$^-$CD4$^+$CD45$^+$ PP inducer cells requires Id2 and RORγt genes. IL-7R$^+$CD3$^-$CD4$^+$CD45$^+$ PP inducer cells accumulate initially at the tissue anlagen and specifically interact with VCAM-1$^+$ PP organizer cells. This cell-to-cell interaction induces subsequent activation of LT-βR–associated molecules such as NIK and IKKα for the induction of adhesion molecules and chemokines by PP organizer cells, which leads to the further recruitment of T cells, B cells, and DCs. Recently, RET$^+$CD11c$^+$ cells expressing LT-β have been identified as a new member of inducer cells that contribute to the initiation phase prior to the appearance of IL-7R$^+$CD3$^-$CD4$^+$CD45$^+$ PP inducer cells. In comparison to the PP organogenesis program, NALT organogenesis is initiated in a postnatal manner and is totally independent of IL-7R-LT/LT-βR-NIK–mediated tissue genesis signaling pathway. For the development of NALT inducer cells, like PPs, Id2 is necessary for the differentiation of CD3$^-$CD4$^+$CD45$^+$ NALT inducer cells but does not require RORγt.

describing the development of PPs have been studied in some detail in mice. A cluster of mesenchymal-lineage VCAM-1$^+$/ICAM-1$^+$ cells occur in the upper small intestine beginning at embryonic day 15 to 16 (Figure 31.6). These cells are termed *PP organizers* and express lymphotoxin β receptor (LT-βR). Subsequently, lymphoid-lineage IL-7R$^+$CD3$^-$CD4$^+$CD45$^+$ PP inducer cells appear to be the anlagen of the PPs at embryonic day 17.5. Following stimulation signals provided through IL-7R, PP inducer cells express LT-α1β2 to activate PP organizer cells through LT-βR, and then PP organizer cells produce chemokines such as CXCL13 and CCL19 to stimulate PP inducer cells through CXCR5 and CCR7 (Figure 31.6). The reciprocal

interaction between inducer and organizer cells through the chemokine and cytokine receptors is essential for the initiation of PP formation, and the loss of any part of the signaling program is sufficient to disrupt PP development, as evidenced by the loss of PPs in LTβR$^{-/-}$ and IL-7R$\alpha^{-/-}$ mice and the partial reduction in the formation and number of PPs in CXCR5$^{-/-}$ mice (34,41,42). In addition, alymphoplasia (*aly/aly*) mice, with a mutation in the NF-κB-inducing kinase, which appears to act downstream of LT-α1β2/LT-βR signaling, also fail to develop PPs (54). Further evidence in support of this model comes from studies showing that mice lacking the CD3$^-$CD4$^+$CD45$^+$ IL-7R$^+$ inducer cells due to genetic deletion of the

transcription regulators Id2 or RORγt also completely lack the formation of PPs and LNs (34,41,42). Another study revealed that defects in the Foxl1 gene, which encodes a winged helix transcriptional regulator expressed in the mesenchymal layer of both the developing and mature GI tract resulted in the delayed formation of PP organizing centers as revealed by the expression of VCAM1 and IL-7R at 17.5 days postcoitus (55). In addition to IL-7R⁺CD3⁻CD4⁺CD45⁺ PP inducer cells and stromal organizer cells, a recent study has shown that the IL-7R⁻CD3⁻CD4⁻CD45⁺c-kit⁺CD11c⁺ hematopoietic population expressing LT-β has an important role in the initiation stage of PP formation (56). These cells express the receptor tyrosine kinase (RET), which is essential for the mammalian enteric nervous system formation and is also crucial for PP formation. Thus, the RET ligand ARTN induces the formation of ectopic PP-like structures. In humans, PPs develop during prenatal life, a situation also seen in sheep, pigs, dogs, and horses, and it is thought that a similar tissue genesis program is involved.

The formation of ILFs also requires LT-β and LT-βR–dependent events (34,41,42). However, the LT-β and LT-βR–dependent events in ILF formation are chronologically different from PP development. ILF formation can occur postnatally and requires LT-β-expressing B lymphocytes (34). Consistent with this fact, treatment with LT-βR-Ig fusion protein during the postnatal period suppresses ILFs but not PPs (42). It was also demonstrated that immature ILFs with clusters of B220⁺ cells are present in the intestine of germ-free mice, but exogenous stimuli including bacterial Ags/mitogens are required for the completion of the lymphoid organization of ILFs, including GC formation (34,41,42). In activation-induced cytidine deaminase (AID)-deficient mice, ILFs developed hyperplasia. A subsequent study demonstrated that the lack of hypermutated IgA production into the intestinal lumen resulted in the expansion of segmented filamentous bacteria in the small intestine of AID-deficient mice (57). Since antibiotic treatment of AID-deficient mice abolished the hyperplasia, it was proposed that anaerobic bacterial growth induced ILF hyperplasia. Taken together, these findings suggest that postnatal and physiological inflammatory signals are essential for the formulation of ILFs in the small intestine.

Like the PPs, inhibition of LT-β–mediated signaling during the embryonic stage leads to the inhibition of CP formation in the large intestine (34,41,42). In contrast, increased numbers and enlargement of CPs were noted in Foxl1-deficient mice, while the size and numbers of PPs were decreased (55). Additionally, ILFs in the large intestine showed a different requirement for LT-β signaling for their development. Normal ILFs were present in the small intestine of mice treated with LT-β-Ig fusion protein *in utero* (42). However, the same treatment resulted in the acceleration of ILF formation in the large intestine (58), suggesting that LT-mediated signaling behaves as a negative regulator for ILF formation in the large intestine

during the gestational period. One study demonstrated a critical involvement of the GI tract flora for the development of ILFs in the small intestine. Thus, the development of ILFs in the small intestine did not occur in germ-free mice, but modest numbers of mature ILFs developed after the conventionalization of germ-free mice. In contrast, the development of ILFs in the large intestine is independent of the gut microbiota (58). These data indicate that small and large intestines share some parts of a tissue genesis-associated molecular signaling program for their development, but they also possess unique development pathways to adjust to environmentally different circumstances that occur between the small and large intestines.

Distinct Features of NALT Organogenesis Compared with PPs

NALT formation has not been observed during embryogenesis or in newborn nasal tissue. The HEV structure is first detected in bilateral nasal tissue 1 week after birth, and the complete bell-shaped NALT formation with lymphoid cells is seen 8 weeks after birth (40–42). These findings indicate the presence of a distinct tissue genesis program in the PPs and NALT, although these tissues have a similar structure and immunological function as inductive tissues (Figure 31.6). As mentioned earlier, PP organogenesis requires a cytokine-signaling cascade involving IL-7R and LT-βR, and these deficiencies resulted in the lack of PP formation. However, mice lacking PPs or both PPs and LNs due to a deficiency in the LT-βR–mediated inflammatory cytokine cascade, including LT-β–deficient, IL-7R–deficient, and *aly/aly* mice, and mice treated *in utero* with LT-β-Ig fusion protein have a normal NALT structure (40–42). These findings further support the idea that NALT genesis does not follow the "programmed physiological inflammation" model typical of PPs. In contrast, deletion of Id2, which is responsible for the induction of CD3⁻CD4⁺CD45⁺ inducer cells, impaired the genesis of all secondary lymphoid tissues including both NALT and PPs (Figure 31.6) (40–42). However, the deletion of the gene encoding RORγt, the additional transcriptional regulator for the development of CD3⁻CD4⁺CD45⁺ inducer cells, resulted in the suppression of PP organogenesis, while NALT development was normal (40–42). These findings suggest that although NALT and PPs development depends on inducer cells of the same phenotype, CD3⁻CD4⁺CD45⁺, those inducer cells can be categorized as those either dependent on Id2 alone (for NALT) or dependent on both Id2 and RORγt (for PPs).

Antigen Sampling and Presentation in MALTs

As mentioned earlier, MALTs have unique epithelial regions or FAE containing specialized ECs, termed *M cells*, to achieve preferential transport of luminal Ag (Figure 31.4) (44). M cells are characterized by a pocket structure (M cell

pocket) at the basolateral side harboring a wide variety of lymphoid cell subsets such as DCs, MΦ, and lymphocytes. Unique features of M cells include the fact that in spite of high uptake of luminal Ag via pinocytosis and endocytosis, they contain only a few lysosomes. In addition, IgA preferentially binds to the apical sides of M cells (44,59). Thus, it has been suggested that M cells contribute to the transport of luminal Ags to underlying APCs without any Ag digestion or processing.

In addition to serving as a means of transport for luminal Ags, the unique structural features of M cells (e.g., short microvilli and the thick glycocalx) and their predominant expression of receptors for some microorganisms also provide entry sites for pathogens (44,59). For instance, *Yersinia* adheres to M cells via the invasin and the β1 integrin expressed on the *Yersinia* and M cells, respectively. *Salmonella* initiate murine infection by invading the M cells of the PPs. Reoviruses also initiate infection of the mouse through the M cell, an ability that has been associated with the reovirus sigma protein. It has also been suggested that M cells act as the entry site for Prions. Lung M cells were reported to be the site for entry of *Mycobacterium tuberculosis* into the host, with subsequent uptake in draining LNs (60). Thus, M cells act as a gateway to the outside environment, delivering antigenic substrate to the underlying immune-competent cells for the subsequent induction of Ag-specific immune responses.

Several lines of evidence demonstrated that DCs are present in the MALTs. Among them, detailed studies have been performed mainly using PPs and showed that there are several distinct types of DCs in the PPs, which are distinguished by the surface expression of CD11b, CD8, and B220, as described earlier (51,52). In the FAE regions, CD11b$^+$ DCs and CD11b$^-$CD8$^-$ DN DCs are present, and some of them are associated with M cells, suggesting that they reside in the M cell pockets (44,52). Upon stimulation of CD11b$^+$ DCs and DN DCs through microbial infection or uptake of their products, CD11b$^+$ DCs and some populations of DN DCs begin to express CCR7, allowing them to migrate into the IFRs of PPs. Hence, it is likely that blood-derived CCR6$^+$ DCs migrate into FAE regions via interactions with CCL20, and their activation by microbial stimulation through M cells results in their migration into the IFRs. Here, they present Ag to T cells for priming and subsequent induction of the productive phase of the Ag-specific immune response. In the IFRs, additional types of DCs occur. These DC subsets express CD8, but not B220. The exclusive expression of CCR7 on CD8$^+$ DCs allows them to reside in the IFRs. A fourth population, the B220$^+$ plasmacytoid DCs (pDCs), are also present in the IFRs and FAE (51,52). The pDCs perhaps are involved in the generation of Treg cells for the establishment of a quiescent state of immune response (termed *tolerance*) in the harsh environment of mucosal tissues. These different types of DCs cooperatively regulate the activation or inhibition of immune responses induced via MALTs.

Priming of T Cells in Mucosal Inductive Sites

As CD4$^+$ Th cells mature in response to foreign Ags, they assume unique characteristics, such as production of distinct cytokine arrays. The naïve CD4$^+$ T cells have substantial plasticity for development of distinct effector or regulatory lineages (Figure 31.7). The environment and cytokine milieu greatly influences the differentiation of naïve T cells into Th1 (IFN-γ), Th2 (IL-4, IL-13), Th3 (TGF-β), Th17 (IL-17) T cells, or CD25$^+$ Foxp3$^+$ IL-10–producing Treg cells (48). For example, the differentiation of Th1 cells producing IFN-γ was induced by certain pathogens. These cells often develop following production of IL-12 by DCs. In this context, it was previously reported that both DN DCs and CD8$^+$ DCs secreted high levels of IL-12p70 following microbial stimulation, which led to the predominant Th1-type responses (51,52). However, CD11b$^+$ DCs predominantly exist in the FAE regions and produce high levels of IL-10 in response to microbial stimulation, but produce little IL-12, which leads to the induction of Ag-specific T cells secreting IL-4 and IL-10. Of note, IL-10–producing Treg cells are preferentially induced by CD11b$^+$ DCs, indicating that CD11b$^+$ DCs have a unique ability to induce Treg cells.

Recently, an IL-17–producing T cell subset, termed *Th17 cells,* has also been identified as a new subset of the intestinal T cell repertoire and considered to be responsible for pathologic inflammatory reactions (61). It is interesting to note that stimulation of naïve T cells with both TGF-β and IL-6 resulted in the induction of Th17 cells, while IL-6 inhibited the development of Treg cells in the presence of TGF-β (62,63). Taken together, the mucosal immune system has unique T cell–inducing and balancing mechanisms for matching CD4$^+$ T cell effector and regulatory lineage specification, and clearly DCs play a central role in the education of naïve T cells to be an immunosuppressive and active under normal conditions.

Other T cell families involved in mucosal immunity are CTLs. Most CTLs are CD8$^+$ TCRαβ$^+$ and recognize antigenic peptides through MHC class I–restricted presentation by infected cells. An obvious question is how a CTL immune response is initiated given that mucosal inductive sites, which harbor CTL precursors (pCTLs), are separate from effector sites, such as infected ECs where activated CD8$^+$ CTLs function. A partial answer is that the M cell has specific receptors for mucosal viruses, best exemplified by reovirus. As described earlier, using the sigma one protein, the reovirus enters the M cell in both NALT and GALT (44,59). It is likely, though less well documented that other enteric viruses, such as rotavirus and respiratory pathogens, such as influenza and respiratory syncytial virus (RSV), also enter the mucosal inductive pathway via M cells (44,59). Further, it was shown that administration of attenuated virus into the GI tract results in the induction of increased pCTL
FIGURE 31.7 Various induction pathways for the generation of versatile mucosal T cells for the induction of productive and quiescent immune responses. Naïve T cells are primed and stimulated via a molecular network with the recognition of peptide Ag presented by MHC molecules, costimulatory molecules, and cytokines. After receiving stimulation, naïve T cells differentiate into immunologic (effector T cells) or tolerogenic (Treg cells) cell types for subsequent immunity.

frequencies in the PPs (64). Similarly, virus-specific CTLs were detected in NALT as well as in mediastinal, submandibular, and cervical LNs after nasal immunization with attenuated virus (65). These findings clearly demonstrate that PPs and NALT play a pivotal role in the induction of Ag-specific CTLs in addition to the generation of Ag-specific IgA-committed B cells; the molecular and cellular pathways underlying the CTL induction in the inductive tissues (e.g., involvement of DCs) remain obscure.

Immunoglobulin Isotype Switching in Mucosal Inductive Sites

T Cells for IgA Class Switching

The cross-talk among DCs, T cells, and B cells in mucosal inductive tissues promotes the IgA-commitment of B cells, which undergo μ to α isotype class swich recombination

(CSR) (Figure 31.8) (66). This μ to α isotype CSR is likely dependent on Ag stimulation in GCs, where naïve B cells interact with local CD4$^+$ T cells and with follicular Ag-trapping DCs (FDCs) in the presence of specific cytokines. Hence, depletion of CD4$^+$ T cell subsets markedly affects mucosal immune responses, including diminished levels of sIgA$^+$ B cells (67). Consistent with this, clear evidence was presented that clones of T cells from murine GALT, when mixed with noncommitted sIgM$^+$ B cells, induced isotype switching to B cells expressing surface IgA (sIgA$^+$) (68). The initial studies with murine T switch (Tsw) cells used T cell clones derived by mitogen stimulation and IL-2 supported outgrowth, and when Tsw cells were added to sIgM$^+$ sIgA$^-$ B cell cultures resulted in marked increases in sIgA$^+$ cells (68). This result suggests that cognate interactions between Tsw and B cells are required for induction of the IgA class switch. Other studies have revealed that
FIGURE 31.8 MALT-dependent and alternative pathways for the production of intestinal S-IgA Abs. In the MALT-dependent pathway (e.g., Peyer's patch), DCs take up luminal Ag via M cells, and then present the peptide to CD4$^+$ Th cells after intracellular processing of Ags in PPs. Ag-primed Th cells produce IL-4 and TGF-β, allowing B cells to undergo μ to α CSR. Simultaneously, retinoic acid (RA) produced by DCs increases gut homing receptors ($\alpha_4\beta_7$ integrin and CCR9) on Ag-primed IgA-committed B cells. In the LP, Th2 cell-derived IL-5 and IL-6 induce terminal differentiation of sIgA$^+$ B cells to become IgA-producing PCs secreting dimeric (or polymeric) forms of IgA. The dimeric IgA (dIgA) binds to the pIgR expressed on the basolateral surface of ECs and transports the dIgA into the lumen as S-IgA. In the alternative pathway, peritoneal B cells (mainly B1 cells) migrate into the LP, where they differentiate into IgA-producing PCs under the influence of IL-5 and IL-15.

T–B cell interactions support B cell switches and have postulated a major role for the CD40 receptor on GC B cells with CD40 L on activated T cells (66,69). Evidence for Tsw cells in human IgA responses has stemmed from an earlier study with T cell clones obtained from human appendix. These T cell clones and their derived culture supernatants exhibited preferential help for IgA synthesis (70).

Cytokines for IgA Class Switches

The most definitive studies to date suggest that several cytokines are involved in the B cell switching to IgA (66). The first studies showed that addition of TGF-β to LPS-triggered mouse splenic B cell cultures resulted in switching to IgA, and IgA synthesis was markedly enhanced by IL-2 (71) or IL-5 (72). It was also shown that TGF-β induced sterile Cα germline transcripts (72), an event that clearly precedes actual switching to IgA. Molecular pathways of TGF-β–induced Cα germline transcripts have been clarified (46). For example, transcriptional activation of the C$_H\alpha$ gene requires the TGF-β–mediated activation of Smad3/4 and the *de novo* synthesis of core-binding factor (CBF) α3 that binds to the Smad-binding elements (SBEs) and CBF sites on the intronic C$_H\alpha$ promoter region (46,66). Other studies showed that TGF-β induced human B cells to switch to either IgA1 or IgA2, an event clearly shown

to be preceded by formation of Cα1 and Cα2 germline transcripts (46). It can be presumed that TGF-β induces μ to α switches in normal physiologic circumstances, since sIgM$^+$, sIgD$^+$ B cells triggered through CD40 were induced to switch to IgA by TGF-β and to secrete IgA in the presence of IL-10 (73,74).

Although one would predict that deletion of the TGF-β gene would lead to a negative influence on the IgA immune system, the TGF-β gene knockout mice unfortunately die from a generalized lymphoproliferative disease 3 to 5 weeks after birth, making it difficult to use this model to investigate the role of TGF-β in IgA regulation *in vivo*. Nevertheless, conditional mutagenesis (Cre/loxP) was used to knock out the TGF-β receptor in B cells, showing that these mice exhibited expanded peritoneal B1 cells and B cell hyperplasia in PPs and a complete absence of serum IgA (75).

Molecular Mechanisms of IgA Class Switch Recombination

Isotype switching involves the recombination between tandem repetitive DNA sequences (switch or S regions) located 5′ of the respective C$_H$ genes. Switching is an irreversible DNA deletional event in which recombination between upstream and downstream S regions forms a DNA circle containing the deleted intervening C$_H$ genes. Isotype switching can also be induced by cytokines in combination with activation signals provided by mitogens such as LPS or through the more physiological T cell CD40 L and B cell CD40 interactions as discussed earlier (46,66). Several tangible events, including demethylation of 5′ flanking region DNA, DNAse hypersensitivity, and transcription of unrearranged H chain genes, precede cytokine-induced switching. Germline transcription initiates 5′ of the targeted C$_H$ gene upstream of so-called *I region exons* that contain stop codons in all translational reading frames, thus the resulting transcripts are "sterile." I exons have been identified for all isotypes and subclasses, and in general their deletion, for example, in I exon-knockout mice, results in impaired switching to that isotype or subclass (76). An apparent exception has been observed for IgA switching, where replacement of the Iα exon with an irrelevant human gene construct in the gene transcriptional orientation did not impair B cell switching to IgA (77). These studies rule out a direct role for the I exon in controlling switch recombination. However, transcription of the Cα locus was found to be constitutive in the Iα-targeted mice, in contrast to other I region KO mice. It seems likely that cytokine-induced germline transcripts themselves direct cytokine-regulated isotype switching (46,66).

A dramatic breakthrough in our understanding of CSR came with the discovery of the AID gene, initially identified in GC B cells and subsequently cloned from B lymphoma cells stimulated with CD40 L, IL-4, and TGF-β, which were

undergoing μ to α switches (78). AID exhibits a single-stranded DNA deaminase activity and associates with the CSR target chromatin in a germline transcription-coupled manner (78). As may be expected given the ability of PPs, ILFs, and NALT to induce the generation of IgA-committed B cells, AID expression and Iα-Cμ circle transcripts and their reaction products are always detected in these inductive tissues (79).

The dogma that μ to α switching only occurs in mucosal inductive sites is challenged by several recent findings. Overexpression of AID in μ^+ B lymphoma cells resulted in spontaneous class switching from IgM to IgA in the complete absence of TGF-β or other cytokines. Mice defective in the AID gene (AID$^{-/-}$) exhibit a hyper IgM syndrome with no evidence of downstream switching (78). However, studies revealed that AID$^{-/-}$ mice have a subset of B220$^+$ sIgA$^+$ B cells in LP (an effector site) and the presence of circles of "looped out" DNA suggest that μ to α switching had just occurred in this site (80). Along these lines, it was also revealed that B cell–deficient μMT mice also exhibit LP IgA$^+$ PCs, suggesting that switches to IgA can occur even during preB cell development (81). Although this issue is still a subject of debate, μ to α B cell switches may occur throughout the mucosal immune system and in the complete absence of GCs.

In contrast to the dominant class switch to IgA in the PPs, B cell development in NALT leads to the production of both IgA and IgG (41,42). It had been previously established that the development of IgA-committed cells in the presence of TGF-β was characterized by sequential CSR from Cμ to Cα via a Cγ pathway-mediated by CD40 engagement (82). It is also interesting to note that human tonsils have been shown to contain a high frequency of IgG B cells in addition to IgA (83). These findings may explain the equal commitment of B cells to IgG and to IgA in NALT, but further analysis will be required to reveal the molecular mechanism involved in the generation of mucosal B cells with those two different isotypes.

Trafficking and Homing from Mucosal Inductive into Effector Sites

Following T cell priming and CSR to IgA-committed B cells through their interaction with DCs, both B and T cells emigrate from the inductive tissue (e.g., PPs and NALT), circulate through the bloodstream, and home to distant mucosal effector compartments, especially the LP regions of the GI, respiratory and reproductive tracts (Figure 31.8).

Several early studies demonstrated that lymphocytes circulated from blood to LNs and that thoracic duct lymphocytes were retained primarily in the intestine (50). A direct route for B cell migration between PPs and distant LP was revealed by the finding that rabbit GALT B cells repopulated the gut with IgA PCs (84). Further, the mesenteric lymph nodes (MLNs) of orally immunized

animals were found to contain Ag-specific precursors of IgA PCs that repopulated the LP of gut and mammary, lacrymal, and salivary glands (50). Studies of the origin, migration, and homing of lymphoid cells from mucosal inductive to effector tissues were of basic importance for parallel attempts to induce Ag-specific immune responses. Consequently, specific Abs in glandular secretions could be induced in human and animal experiments by oral or bronchial immunization. These studies served as the basis for demonstrating the existence of a CMIS. This may explain the phenomena that immunization via one mucosal site often activates other, remote mucosal sites. However, immunization via certain mucosal inductive tissues can lead to the preferential induction of humoral immune responses in the same mucosal site, which is basically determined by site-specific combination of adhesion molecules and chemokines.

Recently, a lipid mediator, S1P has been identified as a key regulator of lymphocyte emigration from the organized lymphoid structures including the thymus and secondary lymphoid organs (85). Lymphocytes increase the S1P receptor, especially type 1 S1P receptor, when they emigrate from the secondary lymphoid organs, allowing them to emigrate from the lymphoid tissues to the blood where S1P is present in high concentrations (100 nM to 300 nM) (85). Several studies have now suggested that the S1P-mediated pathway is involved in the regulation of T cell emigration from mucosal inductive tissues (e.g., PPs) (85). In addition to T cells, it was recently found that B cell trafficking, especially IgA$^+$ plasmablasts, is selectively regulated by S1P in the emigration of B cells from the PPs and their entry into the macosal migration pathway for the final destination of LP (85a).

Lymphocyte Homing in the GI Tract

Lymphocytes enter mucosal or systemic lymphoid tissues from the blood through specialized HEVs, which consist of cuboidal endothelial cells. In GALT, HEVs are present in the interfollicular zones rich in T cells (41,42,50). The endothelial venules in effector sites such as the LP of the GI tract are less pronounced and tend to occur near villus crypt regions. Mucosal addressin cell adhesion molecule-1 (MAdCAM-1) is the most important addressin expressed by HEVs in the PPs and LP (Figure 31.9) (50). Likewise, peripheral lymph node addressin (PNAd) and vascular cell adhesion molecule (VCAM)-1 are the principal addressins expressed by peripheral lymph node (PLN) and skin HEVs, respectively. The major homing receptors expressed by lymphocytes are the integrins, a large class of molecules characterized by a heterodimeric structure of α and β chains. In general, the type of homing receptor is determined by the integrin expressed with the α_4 chain; the β_1 integrin characterizes the homing receptor for the skin and the β_7 integrin that for the GI tract. Thus, the pairing of α_4

with β_7 represents the major integrin molecule responsible for lymphocyte binding to MAdCAM-1 expressed on HEVs in the PPs and LP (Figure 31.9) (49). In addition to $\alpha_4\beta_7$ integrin, the C-type lectin family of selectins that includes L-, E-, and P-selectins, also serve as homing receptors. L-selectin has a high affinity for carbohydrate-containing PNAd, and this lectin addressin is of central importance in PLN homing of B and T cells (41,42,50). Despite this homing pair, L-selectin can also bind to carbohydrate-rich MAdCAM-1 and is an important initial receptor for homing into GALT HEVs. Interestingly, naïve B and T cells destined for GALT express L-selectin; moderate levels of $\alpha_4\beta_7$ ($\alpha_4\beta_7{}^+$) and memory lymphocytes destined for LP express higher levels of $\alpha_4\beta_7$ ($\alpha_4\beta_7^{\text{high}}$) and lack L-selectin (Figure 31.9). Similarly, human tissues revealed naïve T and B cells in HEVs, which expressed both L-selectin and $\alpha_4\beta_7$ integrin, while memory T and B cells in efferent lymphatics expressed $\alpha_4\beta_7$ integrin but not L-selectin (86). These data indicate that naïve and memory lymphocytes utilize a different regulation pathway for their migration into the GI tract.

In addition to the integrin-mediated regulation, chemokines have been directly involved in lymphocyte homing, and different chemokine-receptor pairs control migration into different lymphoid tissues (Figure 31.9) (50,85). For example, loss of secondary lymphoid tissue chemokine (SLC/CCL21) results in lack of naïve T cell or DC migration into PPs or spleen. Further, the chemokine receptor CCR4, which responds to the thymus activation-regulated chemokine (TARC/CCL17) and MΦ-derived chemokine (MDC/CCL22), mediates arrest of skin-homing T cells but does not affect $\alpha_4\beta_7^{\text{high}}$ T cell migration in the GI tract. However, gut-tropism, especially into the small intestine, is determined by the CCR9, selectively expressed on IgA-, but not IgM- or IgG-committed B cells (Figure 31.9) (50,85). The ligand of CCR9 is CCL25, also known as thymus-expressed chemokine TECK, which is produced dominantly by the small intestinal epithelium, determining the selective homing of sIgA$^+$ B cells into the small intestinal LP (50,85). Although the detailed mechanism remains to be investigated, it has been reported that the migration of sIgA$^+$ B cells to the large intestine may be due to the expression of MEC/CCL28 (50). Similarly, human memory T cell migration into the LP of the GI tract is mediated by the TECK/CCL25 expressed on intestinal epithelium, and gut-homing $\alpha_4\beta_7^{\text{high}}$ T cells specifically express CCR9 (50). In addition to the LP T cells, $\alpha_E\beta_7{}^+$ and $\alpha_4\beta_7^{\text{high}}$ IELs also expressed CCR9 in human and mouse, suggesting that TECK-CCR9 is also involved in lymphocyte homing and arrest of IEL in the small intestinal epithelium (50).

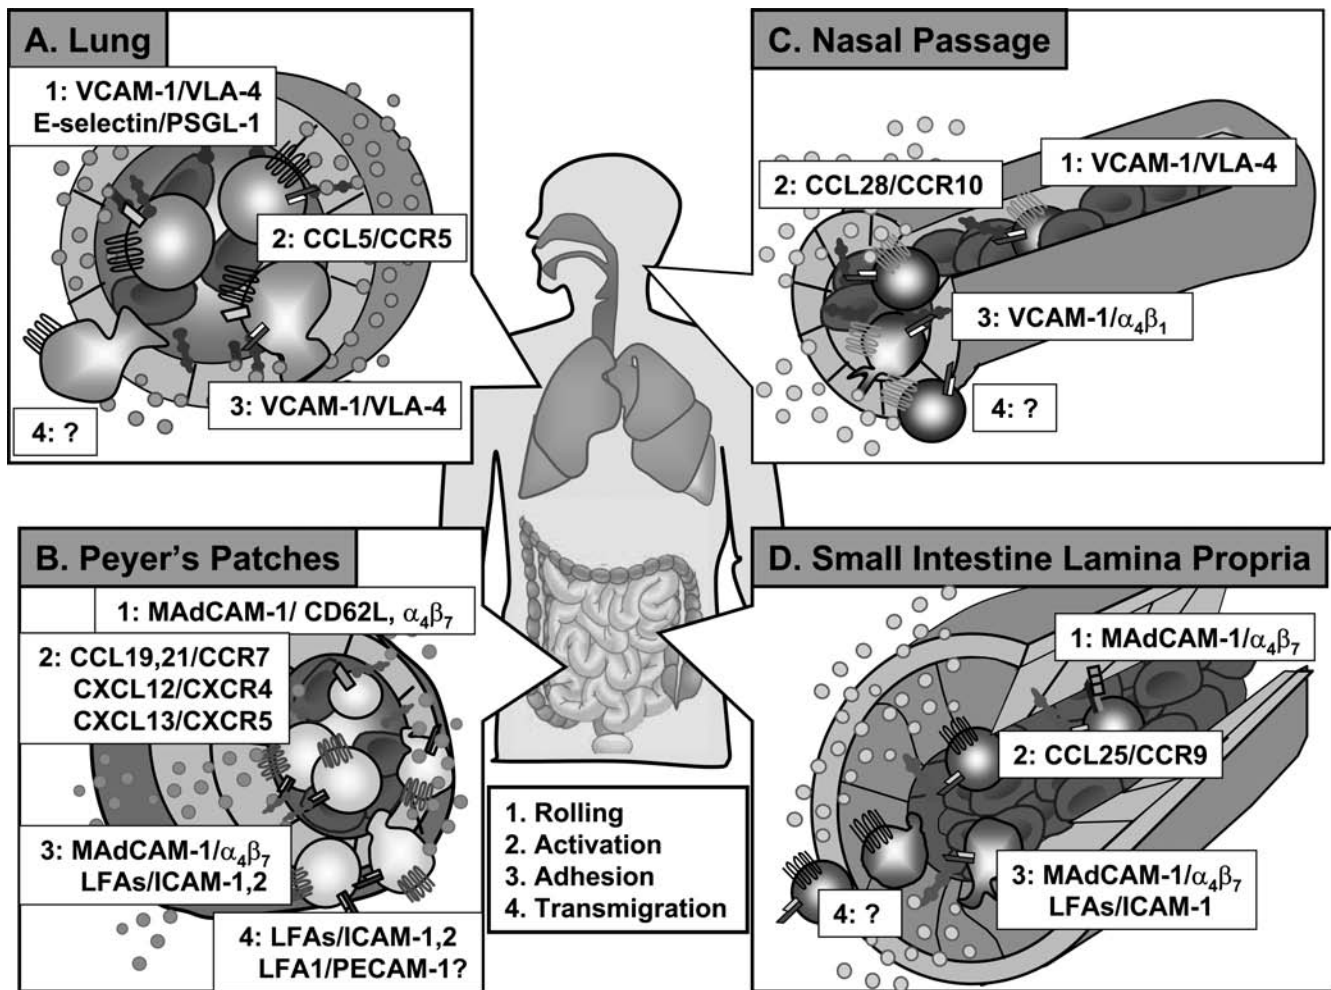
Several lines of evidence have suggested that GALT DCs play a crucial role in determining the gut tropism of T and B cells (Figure 31.8) (87). $\alpha_4\beta_7$ integrin and CCR9 were induced on Ag-primed T cells by GALT DCs, but not


FIGURE 31.9 Mucosal lymphocyte migration-adhesion pathway. Lymphocyte migration is consistent with 1) rolling, 2) activation, 3) adhesion, and 4) transmigration or diapedesis. Effector/activated lymphocytes migrate to the mucosal effector sites, such as pulmonary tissue via the pulmonary vasculature (**A**), nasal passages (**C**), and intestinal LP (**D**) via endothelial venules. Naïve lymphocytes migrate into the PPs with interaction of lymphocytes and HEVs (MadCAM-1/$\alpha_4\beta_7$ integrin) in a chemokine-dependent pathway (e.g., CCL19, 21/CCR7 (T cells), CXCL12/CXCR4, CXCL13/CXCR5 (B cells) (**B**).

other DCs, respectively interacting with the MAdCAM-1 expressed by HEVs in the intestinal LP and the TECK/CCL25 produced by small IECs. Recent work has revealed that retinoic acid (RA) produced by GALT DCs is involved in the imprinting of T and B cells for gut homing (88,89). RA is a metabolite of vitamin A, and GALT DCs express RA-producing enzymes (alcohol dehydrogenases). Thus, significantly decreased numbers of gut T and B cells were noted in vitamin A–deficient mice (88,89).

Although CD8$^+$ CTLs utilize similar migration pathways into mucosal immune compartments, CD8$^+$ CTLs additionally migrate into the epithelium. This is reasonable because ECs are the primary cells infected with many viruses and bacteria and should be recognized by CD8$^+$ CTLs. Although mucosal effector tissues such as the in-

testinal epithelium contain high numbers of $\gamma\delta$ T cells as key players in innate immunity as mentioned earlier (25), virus-specific CTLs in IELs greatly contribute to the acquired phase of immunosurveillance in the epithelium itself. The homing of IELs into the epithelium is also determined by the adhesion molecules and chemokines (25). Like migration of other T cells into the intestinal compartment, CCR9 play an important role in the determination of IEL trafficking into the epithelium. In addition, the various chemokine receptors expressed on IELs, such as CCR3, CCR4, CCR5, and CXCR3, may play pivotal roles in the alternative pathway of IEL trafficking (Figure 31.9) (25). The $\alpha_4\beta_7$ integrin also contributes to the regulation of IEL trafficking. Thus, β_7 integrin-deficient mice showed critically reduced numbers of IELs in the

intestine (49). Integrin-mediated interactions between IECs and IELs play a pivotal role not only in the migration of the IELs into the intestine, but also in the retention of IELs at the epithelium. CD103 (α_E integrin) is exclusively expressed on IELs; it interacts with E-cadherin expressed on ECs (Figure 31.9) (26). It was previously reported that TGF-β induced down-regulation of $\alpha_4\beta_7$ integrin and simultaneously up-regulated CD103. Thus, $\alpha_4\beta_7$ integrin expression was reduced following IEL entry into the small intestinal epithelium, a reduction that coincided with an increase in CD103 expression (87). In addition to the TGF-β–mediated pathway, a recent study proposed that CCR9-mediated signaling promoted the induction of CD103, a retention molecule of IELs in the epithelium (87).

Lymphocyte Homing in NALT and Lung-associated Tissues

Unlike PP HEVs, which are found in T cell zones, murine NALT HEVs are found in B cell zones and express PNAd either alone or associated with MAdCAM-1 (Figure 31.9) (41,42). Further, anti-L-selectin but not anti-MAdCAM-1 Abs blocked the binding of naïve lymphocytes to NALT HEVs, suggesting predominant roles for both L-selectin and PNAd. Consistent with this, the failure of human tonsillar cells to demonstrate selective $\alpha_4\beta_7$ expression and the lack of MAdCAM-1 expression on tonsil or adenoid HEVs make it likely that gut-homing does not extend to human NALT and associated LNs. However, nasal immunization induces up-regulation of $\alpha_4\beta_1$ integrin and CCR10, allowing selective trafficking of B cells to nasal passage epithelium expressing their ligands, VCAM-1 and CCL28, respectively (Figure 31.9) (41,42). It is interesting to note that the same molecules are involved in the trafficking to the genitourinary tract (41,42), which may explain why high levels of Ag-specific immune responses are induced in the genital tract after nasal immunization (Figure 31.9).

Early induction of VCAM-1, E-selectin, and P-selectin in the pulmonary vasculature was reported during pulmonary immune responses with an initially increased expression of P-selectin ligand by peripheral blood CD4$^+$ and CD8$^+$ T cells (50). The number of cells expressing P-selectin ligand then declined in the blood as they accumulated in the bronchoalveolar lavage fluid. The very late antigen (VLA-4) could be an important adhesion molecule involved in the migration of activated T cells into the lung since migration of VLA-4$^+$ cells into bronchoalveolar fluid is impaired following treatment with anti-α_4 Ab. Other investigators have shown that Ag-specific L-selectin^{low} CTL effectors rapidly accumulate in the lung following adoptive transfer to naïve mice with reduced pulmonary viral titers early during infection.

An interesting approach used to address the homing of human cells in the NALT was the analysis of tissue-specific adhesion molecules after systemic, enteric, or nasal immunization (90). This study showed that following systemic immunization, most effector B cells expressed L-selectin, with only few cells expressing $\alpha_4\beta_7$, while after enteric (oral or rectal) immunization the opposite held true. Interestingly, effector B cells induced by nasal immunization displayed a more promiscuous pattern of adhesion molecules with a large majority of these cells expressing both L-selectin and $\alpha_4\beta_7$ integrin.

S-IgA Formation and Transport

Distribution of Ig Isotypes

Measurement of combined synthesis of Ig of all isotypes indicates that in a 70 kg individual, around 8 g of Ig are produced every day (Table 31.1) (91). Divided by individual isotypes, humans produce ~5 g IgA, ~2.5 g IgG, ~0.6 g IgM, and trace amounts of IgD and IgE per day. Approximately one half of IgA is internally catabolized mainly in the liver, and the remainder is actively and passively transported into external secretions (91). It is estimated that ~50% to 70% of total IgA is selectively transported into external secretions; daily, over 3 g of IgA are deposited on a large surface area of mucosal membranes. Studies that addressed the tissue origin of S-IgA demonstrated that ~99% is produced locally in mucosal tissues and glands. Extensive studies of the distribution of Ig-producing cells in various mucosal tissues and glands by the immunofluorescence technique and ELISPOT convincingly

TABLE 31.1 Levels of Immunoglobulins in Human External Secretions (μg/ml)[a]

	IgA	IgG	IgM
Tears	80–400	trace–16	0–18

demonstrated a remarkable preponderance of IgA-producing cells in all such tissues (Figure 31.10A) (46). The only exception is the uterine cervix, where the numbers of IgG-producing cells are equal or slightly exceed IgA-producing cells (91). However, there are tissue-specific differences in the proportions of IgA-, IgG-, IgM-, and IgD-positive PCs. For example, nasal mucosa contains on average 69% IgA-, 17% IgG-, 6% IgD-, and 6% IgM-positive cells, while in the large intestine 90% of cells are positive for IgA, 6% for IgM, and 4% for IgG (46). Moreover, cells producing IgA1 or IgA2 also display a characteristic tissue distribution (Figure 31.10B) (46,91). Systemic lymphoid tissues (e.g., spleen, tonsils, LNs, and bone marrow), as well as most of the mucosal tissues (nasal, gastric, and small intestinal mucosa and to a lesser degree glandular tissues) contain more IgA1- than IgA2-producing cells, while in the large intestine and the female genital tract tissues, IgA2-producing cells are more frequent than IgA1 cells (Figure 31.10B). Although direct experimental evidence is not available, it has been speculated that this tissue-specific distribution of IgA1- or IgA2-producing cells is related to the differences in the origin of IgA1 and IgA2 precursors and perhaps their distinct homing patterns. Alternatively, Ag-driven clonal expansion in various mucosal

tissues may also be involved. For example, most of the naturally occurring S-IgA Abs to bacterial endotoxin is associated with the IgA2 isotype (91). Thus, it is likely that endotoxin abundantly present in the large intestine induces clonal expansion of IgA2-producing cells in this locale.

Distribution of Polymeric or Monomeric IgA-Producing Cells

Analyses of molecular forms of IgA in supernatants of cells and tissue explants obtained from systemic and mucosal compartments, tissue perfusates, and immunohistochemical studies of such tissue demonstrated that the separate populations of pIgA- and monomeric IgA (mIgA)-secreting cells display a characteristic tissue distribution (46,91). Typically, almost all IgA-producing cells in the normal bone marrow produce mIgA (Figure 31.10C). The admixture of peripheral blood in the bone marrow specimens grossly influences the results because peripheral blood lymphocytes secrete, especially after stimulation, predominantly pIgA and little mIgA (92). Supernatants collected from *in vitro* cultured human LNs and spleen contained both forms, usually with the preponderance of mIgA. In contrast, such supernatants or perfusates of mucosal tissues, especially

in the GI tract, contain pIgA as the dominant form (Figure 31.10C).

Structure of Secretory IgA (S-IgA)

When compared to its serum counterpart, IgA in external secretions (called S-IgA) displays unique structural features with respect to its molecular form, chain composition, and IgA subclass distribution (91). Examinations of sera and mucosal secretions, culture supernatants, and cell lysates, and immunohistochemical studies of systemic and mucosal lymphoid tissues indicated that pIgA contains joining (J) chain as a typical component and that J chain–containing pIgA is capable of binding to pIgR and its extracellular region, SC (9). Consequently, the presence of intracellular J chain and the ability to bind SC have been taken as markers for pIgA- or IgM-producing cells. In humans, almost all serum IgA is present in a monomeric form (sedimentation constant 7S) and contains two heavy (α) and two light (either κ or λ) chains, and ~85% belongs to the IgA1 and ~15% to the IgA2 subclass. Only a small but variable fraction (1% to 10%) of serum IgA is found in a polymeric form and contains an additional polypeptide-joining (J) chain. In contrast, ~90% of S-IgA occurs in a polymeric form (dimers and tetramers with sedimentation constants 11S and 15.5S, respectively) and is associated with J chain acquired during the transepithelial transport via the pIgR. The structure of a typical dimeric IgA molecule is shown in Figure 31.11. Two mIgA molecules are mutually linked by disulfide bridges through their Fc regions; J chain is bound to the penultimate Cys residues of α chains. Although SC interacts noncovalently with the Fc regions of both monomers, it is attached by disulfide bridges to only one of them, and there are no covalent bonds formed between J chain and SC.

Mammalian α chains with molecular mass ~50 kDa contain one variable and three constant region domains. There are high numbers of Cys residues involved in the formation of intrachain and interchain disulfide bridges with another α chain, L and J chains, and SC (91). In addition, α chains can form complexes with a number of plasma and secretory proteins including albumin, amylase, lactoferrin, glycosyltransferases, and proteolytic enzymes. An unusual hinge region is present in the middle of the α chain of IgA1, between Cα1 and Cα2 domains (46,91). This 13 amino acid–long hinge region is reminiscent of mucin (high content of Pro, Ser, and Thr residues) and carries 3-5 O-linked oligosaccharide side chains (Figure 31.11). Although IgA is quite resistant to common proteolytic enzymes, the hinge region contains peptide bonds susceptible to the cleavage by highly substrate-specific IgA1 proteases of bacterial origin (e.g., *Streptococcus pneumoniae, Neisseria meningitidis, N. gonorrhoeae, Haemophilus influenzae,* and several other species of bacteria) (93). Comparative structural and genetic studies of IgA molecules from many species indicate that molecules of the IgA2 subclass represent phylogenetically older forms and that the IgA1 subclass arose in hominoid primates by insertion of a gene segment encoding the hinge region (91). The Fcα region, particularly its C terminus, displays a high degree of sequence homology to the μ chain of IgM, including the characteristic C terminae "tail" (an ~18 amino acid extension over the C terminus of γ, δ, and ε chains of corresponding Ig isotypes) involved in the polymerization and ability of α and μ chains to bind J chain. Both IgA1 and IgA2 contain 6% to 8% of glycans associated in the form of ~2 to 5 N-linked side chains within the Fc region; as described earlier, the hinge region of IgA1 also contains O-linked glycans (91).

J chain is a chacteristic polypeptide chain present in pIgA and IgM (94). It has a molecular mass of 15 kDa

~ 125 Å

and a single *N*-linked glycan chain and displays an Ig domain folding pattern. Of eight Cys residues, six are involved in three intrachain disulfide bridges, and two participate in linkages to the penultimate Cys residues of α and μ chains. A very high degree of homology exists in the primary structures and antigenic cross-reactivities of mammalian and avian J chains, indicating that the basic properties have remained conserved throughout evolution (91). PCs in mucosal effector tissues and glands assemble pIgA intracellularly from mIgA and J chain as a last step before its externalization (Figure 31.12). Although the incorporation of J chain is not absolutely required for polymerization, the ability of pIgA and IgM to interact with pIgR expressed on ECs or SC depends on the presence of J chain as demonstrated in J chain knockout mice (95).

The pIgR specific for the J chain-containing pIgA and IgM is expressed on the basolateral surfaces of EC of the GI tract and endocervix, acinar, and ductal epithelia of the small and large secretory glands (e.g., lacrimal, mammary, and major and minor salivary glands) in humans (Figure 31.12) (9). In some other species (rats, mice, and rabbits, but not humans), pIgR is also expressed on hepatocytes (9). Structurally, pIgR comprises an extracellular region composed of five Ig domain-like structures, with ~560 amino acids, a 23 amino acid membrane-spanning region, and a cytoplasmic region with ~103 amino acids; the molecular mass of pIgR with attached glycans is ~110 kDa to

120 kDa. The similarity of the general structural features of pIgR from a number of mammalian species indicates that this receptor and its ability to interact with pIg are conserved in phylogeny.

The N-terminal domain of pIgR interacts with Cα domains (9). The pIgA-pIgR complex is internalized, transcytosed, and finally released at the apical end of the ECs with the entire process taking ~30 minutes (Figure 31.12). Signals for basolateral targeting of pIgR, its endocytosis, and its transcytosis are encoded in the cytoplasmic region of pIgR as revealed by deletion mutants. In the final steps, pIgR is proteolytically cleaved, thus releasing the pIgA-SC complex; the intracellular and transmembrane regions are endocytosed and degraded or released from the apex. Unlike several other receptors, pIgR does not recycle; instead, it remains permanently associated with the ligand as bound SC (9). Therefore, the transport of pIgA and IgM is directly dependent on the availability of pIgR on EC (or hepatocyte) membranes. A number of substances of local and distant origin influence pIgR expression. Cytokines produced locally in mucosal tissues and glands (e.g., IFN-γ, IL-4, TNF-α, and TGF-β) up-regulate in an additive or synergistic pattern the expression of pIgR on established EC lines, usually of intestinal or endometrial origin (9). Similarly, ECs from the female genital tract and mammary gland express pIgR as a consequence of stimulation with hormones, particularly with estrogens, prolactin, and androgens.

Other IgA Receptors

The Fc region of IgA can interact with other receptors expressed on structurally and functionally diverse cell populations including monocytes/MΦ/mesangial cells, PMNs, granulocytes, ECs, hepatocytes, B and T cells, and PCs (96). Some of these receptors have been structurally defined and specific reagents are now available for their detection.

The best-characterized receptor expressed on monocytes, neutrophils, and eosinophils recognizes Fcα regions of both IgA1 and IgA2 with a certain degree of preference for pIgA, probably due to the presence of multiple binding sites on pIgA. This Fcα receptor, designated as FcαRI (CD89) and detectable by monoclonal Abs, occurs in several isoforms and is heavily glycosylated (96). Another study indicates that CD89 is present in minute quantities also in the circulation in complexes with high molecular mass IgA (96). Additionally, eosinophils, but not PMNs, express a receptor for SC, suggesting that S-IgA has the potential to stimulate eosinophils through an interaction with SC. Detailed analysis of the molecular properties of such complexes revealed that FcαRI and IgA were covalently linked, but the high molecular mass IgA complexes lacked J chain; it can be speculated that the soluble FcαRI is linked to the binding site occupied in pIgA by J chain.

Binding studies indicate that the sites of interactions include the first extracellular domain of FcαRI and the boundary between the Cα2 and Cα3 domains of IgA heavy chains (96). Cross-linking of FcαRI on cell surfaces triggers phagocytosis, superoxide generation, and release of inflammatory mediators from PMNs, eosinophils, and MΦ (Table 31.2). A receptor specific for the Fc regions of IgA and IgM has been described and designated as Fcα/μR (97). However, the biological function of the receptor remains to be elucidated.

It has been previously reported that the transferrin receptor (CD71) is surprisingly effective in binding IgA1 molecules, especially in their monomeric form (98). Because the binding of IgA1 is inhibitable by transferrin, it appears that this novel receptor binds two structurally highly dissimilar ligands—transferrin as well as IgA1. Although the function of this receptor remains to be determined, its expression on intestinal ECs suggests it may be involved in the appearance of mIgA in GI tract secretions.

T Cell Help for IgA Production

Earlier studies revealed that addition of culture supernatants from DC-T cell clusters, T cell clones, or T cell hybridomas to cultures of PP or splenic B cells resulted in enhanced secretion of IgA (99). One factor responsible for this activity was subsequently shown to be IL-5 (Figure 31.8) (66,72). Removal of sIgA⁺ B cells from PP B cell cultures abrogated IgA synthesis, demonstrating that this cytokine affected postswitched IgA-committed B cells (100).

TABLE 31.2 Functions/Biological Properties of IgA

Protective Functions in External Secretions

Prevention of Ag absorption from mucosal surfaces due to the formation of Ag-IgA complexes

Mucus trapping (IgA-mucin complexes entrap microorganisms)

Virus neutralization (in some experiments nonneutralizing Abs may also be protective)

Enzyme and toxin neutralization

Enhancement of antimicrobial activities of innate factors (e.g., lysozyme, lactoperoxidase, and lactoferrin)

Biological Activities in Tissues

Inhibition of C activation in some experiments (polymeric IgA or glycan-altered IgA may activate complement by the alternative or lectin pathways)

Enhancement (opsonization) or inhibition of phagocytosis

Inhibition of type I and II hypersensitivity reactions (e.g., anaphylaxis and Arthus reaction)

Degranulation of eosinophils

Intracellular virus neutralization

Elimination of Ag-IgA immune complexes by ECs and hepatocytes expressing IgA receptors

Ab-dependent cell-mediated cytotoxicity

Inhibition of NK cell activity

Regulation of the release of inflammatory cytokines

If splenic B cells were used, these cells required stimulation with LPS before increased IgA secretion occurred. Taken together, these results suggest that IL-5 induces sIgA⁺ B cells that are in cell cycle (blasts) to differentiate into IgA-producing cells. Human IL-5 is thought to act mainly as an eosinophil differentiation factor and thus may have little effect on B cell isotype switching and differentiation. It has been reported, however, that human B cells, when stimulated with the bacterium *Moraxella (Branhamella) catarrhalis,* could be induced by IL-5 to secrete IgA, and also to possibly undergo isotype switching to IgA (99). This effect could not be demonstrated using other more conventional B cell mitogens, a finding that demonstrates the importance of the primary *in vitro* activation signal for B cell switching.

IL-6, when added to PP B cells in the absence of any *in vitro* stimulus, causes a marked increase in IgA secretion with little effect on either IgM or IgG synthesis (46,66). IL-6–induced two- to three-fold more IgA secretion than IL-5 (101). The removal of sIgA⁺ B cells abolished the effect of IL-6, demonstrating that like IL-5, this cytokine also acted on postswitched B cells. In IL-6⁻/⁻ mice, the numbers of IgA⁺ B cells in the LP were markedly reduced, and Ab responses following mucosal challenge with OVA or vaccinia virus were greatly diminished (102). It was shown that human appendix sIgA⁺ B cells express IL-6 receptors, while other B cell subsets do not. Further, appendix B cells were induced by IL-6 to secrete both IgA1 and IgA2 in the

absence of any *in vitro* activation (103). This effect was also shown in IgA-committed B cells, again demonstrating the importance of IL-6 for inducing the terminal differentiation of sIgA$^+$ B cells into IgA-producing PCs (Figure 31.8).

An additional Th2 cytokine, IL-10, has also been shown to play an important role in the induction of IgA synthesis in humans (46,66). Stimulation of human B cells with anti-CD40 and *Staphylococcus aureus* Cowan (SAC) resulted in B cell differentiation for IgM and IgG synthesis in patients with IgA deficiency. Further, naïve sIgD$^+$ B cells could be induced to produce IgA after co-culture with IL-10 in the presence of TGF-β and anti-CD40 (74). Taken together, these findings demonstrate that Th2 cytokines such as IL-5, IL-6, and IL-10 all play major roles in the induction of IgA responses by the generation of IgA-producing cells (Figure 31.8).

Since IL-2 has been shown to enhance IgA synthesis in LPS-stimulated B cell cultures, it would be too simplistic to conclude that Th2-type cells and their derived cytokines are the only elements important in the generation of IgA responses. IL-2 also synergistically augmented IgA synthesis in B cell cultures in the presence of LPS and TGF-β (46,66). Although IFN-γ is not directly involved in the enhancement of IgA B cell responses, this cytokine has been shown to enhance the expression of pIgR, an essential molecule for the transport of S-IgA (9). In summary, an optimal relationship between Th1- and Th2-derived cytokines is essential for the induction, regulation and maintenance of appropriate IgA responses in mucosa-associated tissues.

Further, a helper function of IELs has been proposed for support of IgA synthesis (104). Thus, IELs may be actively involved in the induction and regulation of S-IgA Ab responses at mucosal surfaces. It was shown that the numbers of IgA-producing cells in mucosa-associated tissues, such as the intestinal LP of TCR$\gamma\delta^{-/-}$ mice, was significantly lower than that observed in control (TCR$\gamma\delta^{+/+}$) mice of the same genetic background (104). In contrast, identical numbers of IgM- and IgG-producing cells were found in systemic compartments of TCR$\gamma\delta^{-/-}$ and TCR$\gamma\delta^{+/+}$ mice. Further, when TCR$\gamma\delta^{-/-}$ mice were orally immunized with tetanus toxoid (TT) plus cholera toxin (CT) as mucosal adjuvant, significantly lower IgA anti-TT Ab responses were induced in PPs and LP when compared with identically treated TCR$\gamma\delta^{+/+}$ mice. These findings indicate that $\gamma\delta$ T cells are involved in the induction and regulation of Ag-specific IgA Ab responses in both mucosal and systemic compartments.

ALTERNATIVE INDUCTION PATHWAY FOR MUCOSAL IMMUNITY

Although the MALT (e.g., PP and NALT)-mediated pathway is a major mechanism for the induction of Ag-specific mucosal immune responses, an alternative way (or MALT-independent pathway) exists for the induction of appropriate productive immunity at mucosa-associated tissues. This is supported by the fact that Ag-specific immune responses have been induced in PP- and/or ILF-null mice following oral immunization (41,42). Indeed, a number of those pathways have been identified, especially in the GI tract at the levels of Ag sampling and S-IgA Ab production.

Other Ag Sampling Systems in the Intestinal Epithelium

In the MALT-independent acquired immune system, the epithelium is also likely to play an important role as alternative Ag-sampling routes. At least three different scenarios have been offered regarding the alternative Ag-sampling routes in the epithelium. First, M cells were identified on the intestinal villous epithelium (villous M cells), not in proximity to PPs (Figure 31.4) (105). Villous M cells developed in various PP/ILF-null mice and are capable of taking up bacteria, such as *Salmonella, Yersinia,* and invasin-expressing *Escherichia coli* (105). A recent study has suggested that villous M cells locate closer to the upper half of the villus and are preferentially observed in the terminal ileum when compared with other parts of the small intestine, suggesting that the microbiota influences villous M cell development (106). In addition, villous M cells are present in mice lacking both B and T cells, indicating that villous M cell differentiation and maintenance does not require lymphocytes (106).

A second route for Ag uptake is the EC itself. As mentioned earlier, ECs are involved in innate immunity by expressing nonclassical MHC molecules that can be sensed by $\gamma\delta$ IEL and NK cells (25,27,37). In addition, there is evidence to suggest that ECs could process and then present Ags to T cells via MHC class I as well as class II molecules in humans and rodents (37). The presentation by MHC class II exhibits polarity with uptake of Ag primarily apical and presentation basal under normal noninflammatory conditions and in inflammatory conditions when MHC class II expression is enhanced through the action of the MHC class II transactivator, CIITA (37). Under normal circumstances, ECs do not express classical costimulatory molecules such as CD80 and CD86 but may do so, at least in the case of CD86, in the context of intestinal inflammation (37). However, intestinal ECs express a number of potential costimulatory molecules, which, in certain circumstances, are functional. For example, LFA-3 or CD58 is constitutively expressed on ECs *in vivo* and *in vitro,* is upregulated in response to inflammation, and may provide crucial costimulatory signals to mucosal T cells through its ligand, CD2, which is constitutively expressed on mucosal T cells (107).

Recent studies identified various DC populations in the unorganized intestine (Figure 31.4). Among them are DCs located between intestinal ECs. These intraepithelial

DCs are frequent in the terminal ileum and express TJ-associated proteins (e.g., occuludin, claudin 1, and *zona occuludens* 1), and thus are capable of extending their dendritic arms into the lumen via the TJ between ECs (108). A previous study had already demonstrated that CD18-expressing phagocytes were involved in an M cell–independent pathway for bacterial invasion (109). A recent study has revealed that these intraepithelial DCs are characterized by the expression of CX_3CR1 and that the interaction between CX_3CR1 and its ligand fractalkine/CX_3CL1 is required for extension of transepithelial dendrites into the epithelium (110). Once intraepithelial DCs take up luminal Ags, it is likely that they leave the epithelium and migrate into the LP or draining LNs for the presentation of Ag to T cells.

A recent study has demonstrated that Ag/IgG complexes from the intestinal lumen can be taken up into the LP across intestinal ECs through FcRn *in vivo* (10,37). These transported Ag/IgG complexes may be captured by LP DCs because they express FcRn (10). In addition to sampling a wide variety of foreign Ags, the mucosal immune system must contend with the high number of apoptotic ECs that result from the frequency with which the epithelium is replaced. Although most of these apoptotic ECs are shed by the epithelium to the lumen, some of these apoptotic ECs have been shown to be potentially immunogenic and transportable to T cell areas of MLNs by mucosal DCs (111).

Contribution of B1 Cells for Mucosal IgA Responses

In addition to conventional B cells (or B2 cells) located in MALTs (e.g., PPs), peritoneal B1 cells have been considered to be a precursor of intestinal IgA PCs (112,113). B1 and B2 cells can be distinguished by their cell surface molecules (*e.g.*, B220, IgM, IgD, CD5, and Mac-1), origins, and growth properties (112). Further, B1 cells exhibit different V_H repertoires and Ig specificities, and they are thought to be specialized in responding to T cell–independent Ag conserved on common pathogens like DNA and phosphatidylcholine, while B2 cells recognize most T-dependent protein Ags (112). Consistent with this notion, IgA production from B1 cells was noted in MHC class II–deficient mice as well as TCR β and δ chain–deficient mice (114,115). Of note, about 65% of fecal bacteria were reactive with B1 cell–derived IgA, and 30% of bacteria were bound with B2 cell-derived IgA, indicating that S-IgA derived from B1 cells recognized a large population of commensal bacteria as well as pathogenic bacteria (112).

B1 and B2 cell responses have distinct IgA-associated cytokine requirements. It was shown that IL-5, a well-known IgA-enhancing cytokine, and IL-15 are also involved in the proliferation and differentiation of B1 but not of B2 cells into IgA-producing cells (113). Thus, mucosal EC-derived IL-15 promoted the proliferation and differentiation of B1 cells into IgA-producing cells. Based upon these findings, it appears that intestinal B1 cells migrate presumably from the peritoneal cavity into mucosal effector sites, where they further differentiate into IgA-producing PCs under the influence of IL-5 and IL-15 for IgA production against T-independent Ags and commensal microbiota-associated Ags.

Although precisely where CSR might occur for B1 cells is an unresolved issue, several lines of evidence have demonstrated B1 cell migration into intestinal LP. Using *aly/aly* mice that carried a point mutation in the NIK, there was a complete absence of B cell populations in the intestinal LP, but elevated B cell levels were seen in the peritoneal cavity (54). In this context, another report proposed that the migratory pathway of B1 cells to the peritoneal cavity depended upon the BCL/CXCL13 produced by peritoneal MΦ (85). These results imply that the NFKB-inducing kinase (NIK)-mediated pathway is involved in the B1 cell mucosal migration, which may be dependent on specific but not yet identified chemokine receptor(s). Additionally, a recent study showed that peritoneal B cells express comparable levels of the receptor for S1P, a lipid mediator, and that S1P plays an important role in the regulation of peritoneal B cell trafficking into the intestine (116). It was also previously reported that B1 cells existed in nasal passages (113), but the actual molecular machinery for B1 cell migration into nasal passages remains an open question. These findings suggested the presence of a unique migration mechanism for the continuous supply of B1 cells as a part of a MALT-independent mucosal immunity.

MICROBIAL MUCOSAL IMMUNE SYSTEM

Protection

Mucosal Igs

Large amounts of Ig are delivered onto mucosal surfaces as a result of receptor-mediated transepithelial transport and passive transudation of plasma-derived Igs. Depending upon the species as well as type of external secretion, IgA, IgM, and IgG are present in variable proportions (Table 31.1). Igs of all of these isotypes provide, by different mechanisms, protection against pathogenic microorganisms, interact with commensal microbiota, and interfere with the absorption of undigested food Ags from the large surface area of the digestive tract.

The dominant presence of S-IgA has several important functional advantages that render Abs of this isotype and molecular form particularly suitable for functioning in the mucosal environment (Table 31.2) (117). Dimeric and tetrameric S-IgA and pentameric S-IgM display 4 to 10 Ag binding sites. Although of lower affinity than, for example, IgG Abs of the same specificity, this multivalency of pIg enhances their effectiveness over mIg by at least an order

of magnitude. The presence of such low-affinity IgA Abs that are also "polyreactive" and thus are capable of binding to a variety of bacterial Ags, and autoAgs have been shown in human external secretions. Further, the intrinsic resistance of pIgA to proteolysis, enhanced by association with SC, is of functional advantage in secretions, particularly those of the GI tract rich in proteolytic enzymes. Finally, due to the inability to activate complement (C) and thus generate C3 and C5 fragments, IgA displays strong anti-inflammatory properties (Table 31.2). This fact is of special importance in the GI tract in which the external milieu rich in microbial and food Ags, and the internal milieu are separated by only a single layer of ECs.

As demonstrated in a number of studies, mucosal Ig inhibits the absorption of soluble and particulate Ags from mucosal surfaces by forming large immune complexes. Further, endogenous commensal microorganisms are coated *in vivo* with corresponding Abs that, in turn, prevent their adherence to epithelial receptors. In this respect, mucosal Abs and especially IgA may function by two independent mechanisms. Specific Abs interact with corresponding Ags through the Ag binding site. In addition, glycans that are abundant on the Fc region of IgA can aggregate bacteria based upon the interaction of bacterial glycan-binding lectins, with glycan side chains present on IgA molecules (117). Consequently, such IgA-coated bacteria are prevented from adhering to ECs expressing analogous mannose-rich glycans on their luminal surfaces without the need for Ag-specific Abs.

Biologically active Ags such as viruses, enzymes, and toxins can be effectively neutralized by mucosal Abs (117). The neutralization activity that is operational in a fluid phase may also extend to the intracellular compartment. In addition, it was demonstrated that virus-specific pIgA also exhibit their neutralization activity intracellularly (117). Apparently, the transcytosis route of pIgA intercepts the pathways involved in virus assembly, resulting in intracellular neutralization. Further, elimination of immune complexes composed of noninfectious Ags, absorbed by ECs and corresponding internalized pIgA Abs, has been demonstrated *in vitro*. Small circulating immune complexes containing soluble Ags and pIgA can be eliminated from the circulation into the bile by binding to hepatocytes that in some species (e.g., rats, mice, and rabbits) express pIgR (117). It appears that this mechanism of disposal of immune complexes is primarily restricted to species whose plasma IgA is dominated by pIgA, which in humans represent normally only a minor component (117). However, it is possible that immune complexes containing locally produced pIgA and absorbed Ags that may be formed within mucosal tissues are eliminated by this mechanism.

The noninflammatory nature of IgA is probably of considerable importance for the maintenance of the structural and functional integrity of mucosal tissues (117). The con-

cept that IgA Abs are anti-inflammatory is exemplified by studies in which intact, native, and fully glycosylated human IgA Abs failed to activate C when complexed with Ags; actually in competition experiments, IgA effectively inhibited C activation by IgM and IgG Abs (Table 31.2) (117). Close examination of the frequently cited ability to activate C reveals that this may be largely due to artificial aggregation and conformational alterations caused by purification procedures and binding to hydrophobic surfaces in C activation assays and aberrancies in glycosylation frequently seen in IgA proteins. Indeed, specific IgA Abs with modified glycan moieties have been shown to activate the alternative and perhaps the lectin pathways of C activation.

Although phagocytic cells including monocytes/MΦ, PMNs, and eosinophils express receptors for the Fc region of IgA (96), the ability of IgA alone to effectively promote phagocytosis of bacteria remains controversial and depends upon the experimental system used in such studies. However, the binding of IgA and IgA-containing immune complexes to such receptors may provide transducing signals for cell activation, proliferation, and oxidative metabolism and prompt degranulation of eosinophils with local inflammatory consequences and extensive tissue damage (96).

The function of mucosal S-IgA also depends on the subclass distribution of specific Abs (46,91,117). Naturally occurring and immunization-induced Abs to protein and glycoprotein Ags are predominantly present in the IgA1 subclass, while Abs to polysaccharide Ags, LPS, and lipoteichoic acid are mainly of the IgA2 subclass. Because of its unique hinge region, IgA1 is susceptible to the cleavage by bacterial IgA1 proteases that are considered as one of the virulence factors produced by *S. pneumoniae, H. influenzae, N. gonorrhoeae, N. meningitidis,* and other microorganisms (93). It was also shown that bacteria coated with Fabα are refractory to IgM- and IgG-mediated and C-dependent killing action due to blocking. The antibacterial activity of IgA may be further potentiated by cooperation with innate factors of immunity including the peroxidase system, mucin, lactoferrin, and lysozyme (Table 31.2) (117).

Although S-IgA is the dominant isotype in most external secretions, the protective effects of Abs of IgM and IgG isotypes are evident from many studies. In external secretions of some IgA-deficient individuals, S-IgM and IgG may functionally compensate for the absence of S-IgA (118). Further, systemic immunization, particularly with conjugated polysaccharide-protein vaccines induces, vigorous and long-lasting IgG immune responses that protect children from infections with upper respiratory tract pathogens causing otitis media and meningitis (*H. influenzae, N. meningitides*) (119). In animal species (e.g., horses, cows, and pigs) in which prenatal transplacental active transport of IgG is not operational, consumption of milk

rich in IgG is of life-saving importance. Abs of this iso-type are absorbed during the first 7 to 14 days of life from the gut into the circulation presumably by the action of FcRn (10).

Mucosal CTLs

In the mucosal setting, natural infection of the epithelium by enteric (rotavirus or reovirus) or by respiratory viral pathogens (influenza or RSV) leads to endogenous viral peptide processing that induces pCTLs to become effector (activated) and memory CTLs. Most virus-specific CTLs are $CD8^+$ $TCR\alpha\beta^+$, and recognition of viral peptides is associated with MHC class I presentation by infected cells. In this regard, high numbers of $CD8^+$ T cells reside in the mucosal epithelium as a subpopulation of IELs (25). These $CD8^+$ IELs are thought to represent an important cytotoxic effector population that can eliminate virus-infected ECs. When freshly isolated IELs were examined using a redirected cytotoxicity assay, these T lymphocytes were found to constitutively possess lytic activity (28).

Significant progress is being made in areas related to the roles of APCs for induction of pCTLs and for mechanisms of perforin-mediated or Fas-Fas ligand-associated killing of target cells (28). It should be noted that the same processes occur during host responses to intracellular bacteria, to tumor-associated antigens, and in certain mucosal parasite infections. Although this focus is on $CD8^+$ CTLs, cell- and Ab-mediated cytotoxicity and NK cell activity are major responses associated with IELs (28).

An obvious question is how a CTL immune response is initiated given that mucosal inductive sites, which harbor pCTLs, are separate from effector sites, such as infected ECs where activated $CD8^+$ CTLs function. A partial answer is that the M cell has specific receptors for mucosal viruses, best exemplified by reovirus. As described earlier, the sigma protein of the reovirus enters the M cell in both NALT and GALT (59). It is likely, though less well documented, that other enteric viruses, such as rotavirus and respiratory pathogens, such as influenza and RSV, also enter the mucosal inductive pathway via M cells (59). Further, it now established that administration of virus into the GI tract results in the induction of increased pCTL frequencies in PPs (28). These findings suggest that, after enteric infection or immunization, Ag-stimulated CTLs are disseminated from PPs into MLNs via the lymphatic drainage. Further, virus-specific CTLs were also found among LP lymphocytes, IELs, and spleen cells of mice mucosally immunized with reovirus or rotavirus (28). Although mucosal effector tissues such as intestinal epithelium contain high numbers of $\gamma\delta$ T cells in addition to $\alpha\beta$ T cells, virus-specific CTLs in IELs were associated with the latter T cell subset (25,28). These studies suggest that oral immunization with live virus can induce Ag-specific CTLs in both

mucosal inductive and effector tissues and in systemic lymphoid tissues.

Detailed studies of immune responses after nasal infection with influenza virus have also revealed that both humoral and cellular pathways are involved in virus clearance (120). However, it was shown that using mice lacking $CD8^+$ T cells ($\beta2$-microglobulin knockout mice) or treating with anti-CD8 mAbs did not alter clearance of influenza (121). These results support the presence of multiple pathways for immunity and suggest that $CD4^+$ Th cell pathways are important for mucosal Ab responses and $CD8^+$ CTLs for respiratory tract immunity. Several studies have also established that effector CTLs protect mice from RSV infection. The murine RSV model was used to determine the relative importance of $CD4^+$ T cells, including Th1 and Th2 subsets, which resulted in inflammation versus immunity. These studies clearly suggest that $CD4^+$ IFN-γ-producing Th1 cells as well as $CD8^+$ T cells are associated with recovery, while $CD4^+$ Th2-type pathways are not (122). Interestingly, priming with inactivated RSV or F glycoprotein induced $CD4^+$ Th2 cells while live RSV elicited the Th1-type pathway. When one considers mucosal vaccine development for virus infections, these findings suggest that the outcome of Th1- (including induction of CTLs) and Th2-type immune responses could be regulated by the nature and form of viral Ag used for immunization.

CTLs also play an important role in the inhibition of HIV infection. It was shown that CTLs recognized Ags derived from gp120, p27, nef, gag, tat, and pol proteins (123,124). Thus, infection of rhesus macaques with simian immunodeficient virus (SIV) resulted in the induction of CTL responses in the vaginal mucosa, which played a crucial role in the control of viral replication in the acute phase of viral infection. CTLs killed HIV-infected cells in a granzyme, perforin, or FasL-dependent manner. It is interesting to note that chemokines (e.g., CCL3, 4, and 5, and CXCL12) were produced by CTLs, which prevented HIV infection by blocking CCR5 and CXCR4, which are specific receptors for HIV infection.

Symbiotic Interactions with the Mucosal Microbiota

Mucosal surfaces of the oral cavity; the GI, genital, and respiratory tracts; and conjunctiva are populated by a large number of bacteria of more than 200 species with a characteristic distribution (Figure 31.13) (125). The mucosal microbiota comprises some 10^{14} bacteria present mostly in the large intestine. Considering the relative numbers of host's eukaryotic cells and prokaryotic bacteria, it is estimated that the mucosal microbiota outnumbers mammalian host cells by a factor of at least 10. Mutually beneficial coexistence of the mucosal microbiota with the effective mucosal immune system is one of the most
FIGURE 31.13 Symbiotic interactions between the mucosal immune system and commensal microbiota. Most microorganisms are present in the lumen and some preferably reside in the mucous layer. The host mucosal immune system regulates the diversity and quantity of intestinal microbiota by secreting S-IgA Abs into the lumen. In mice, these Abs have been suggested to originate from B1 cells. These Abs may limit the adherence of commensal bacteria to ECs for an appropriate cohabitation environment and thus their ability to continuously produce beneficial bioactive molecules such as vitamins, fatty acids, carbon, and butyric acid for the host.

interesting problems in mucosal immunology. Although the innate and specific immune factors present in the mucosal secretions and tissues may limit the adherence of bacteria to mucosal ECs and prevent penetration of such bacteria into the mucosal tissues with subsequent systemic dissemination, the mucosal microbiota continues to survive with remarkable tenacity in the presence of an immune response manifested by corresponding Abs (47). As a matter of fact, oral, intestinal, and probably other mucosal bacteria are coated *in vivo* with Abs, particularly of the IgA isotype, that may prevent their adherence to the epithelial receptors but do not significantly interfere with their elimination and metabolism (112). Therefore, products generated as a result of fermentation by mucosal bacteria such as butyric acid, fatty acids and vitamins can be important sources of energy and carbon for the human host, thus further stressing the immunological and physiological interdependence of the host on the mucosal microbiota (Figure 31.13) (125).

Quantitative and Qualitative Aspects of the Mucosal Microbiota

Quantitative data concerning the distribution of the indigenous microbiota on mucosal surfaces of the oral cavity, conjunctiva, and genital, GI, and respiratory tracts indicate that of approximately 10^{14} of bacteria, 99.9% are present in the large intestine (125). In this locale, bacteria are found free in the lumen and in feces, bound to the desquamated ECs, entrapped in the mucus layer, and deep in intestinal crypts (Figure 31.13). Despite the inherent difficulties with representative sampling, culture conditions, identification of cultured bacteria, as well as obvious host variables (e.g., hormonal status, diet, use of antibiotics, etc.), hundreds of species in 40 to 50 bacterial genera have been identified and described. These studies revealed that gram-negative and gram-positive, spore- and non–spore-forming, and aerobic as well as strictly anaerobic bacteria are present and are characteristically distributed in specific mucosal compartments. Although it is beyond the scope of this chapter to provide detailed information concerning the specific species distribution of indigenous microbiota in individual mucosal compartments, a brief summary of the colonic microbiota may illustrate the most important points. The intestinal microbiota is acquired shortly after birth and its composition is greatly influenced by the route of delivery (vaginal versus Cesarean section), the environment, and most profoundly by the diet (breastfeeding versus bottled formula and addition of solid food). Colonic microbiota changes from the dominant

bifidobacteria at the initial stage to other species, particularly *Bacteroides* and anaerobic cocci with a significant presence of coliforms, streptococci and clostridia. Quantitative representation of bacteria in feces from adults indicates the dominance of bacteria of the genera *Bacteroides, Clostridium, Eubacterium, Lactobacillus, Streptococcus,* and *Bifidobacterium*; *E. coli* constitutes only a minor contribution (~1%) of the colonic microbiota.

Regulation of Mucosal Immune Development and Immunological Homeostasis by Commensal Microbiota

The presence of the mucosal microbiota has a profound influence on the evolution and functionality of the immune system (47,126,127). As evidenced by a large number of studies performed on gnotobiotic (germ-free) animals, the development of both mucosal and systemic lymphoid tissues and the hosts' ensuing ability to respond to environmental Ags is, to a large extent, dependent on the previous exposure to a mucosal microbiota. Specifically, when compared to conventionally reared animals, lymphoid tissues of germ-free animals are hypotrophic, lack well-developed GCs, display minute numbers of mucosal PCs, and respond poorly to mitogens and polyclonal stimulants. Upon colonization with even a few representative species of mucosal microbiota, a prompt development of lymphoid tissues and restoration of responsiveness to a plethora of Ags and other stimuli ensues. Importantly, the development and responsiveness of both humoral and cell-mediated compartments of the immune system are profoundly affected by the mucosal microbiota as documented by the presence and numbers of B cells and ultimately AFC or PCs in mucosal and nonmucosal tissues, levels of mucosal and plasma Abs, and T cells of various phenotypes in the IEL and LP compartments of mucosal tissues, as well as in the systemic secondary lymphoid tissues (47,126,127).

The presence of the mucosal microbiota in the intestinal lumen induces S-IgA Ab synthesis. It was shown that induction of polyreactive S-IgA Ab responses to commensal bacteria is mainly derived from T cell–independent B1 cells (112). The T cell–independent IgA Abs originating from B1 cells possessed reactivity to conserved bacterial products (e.g., phosphorylcholine), which resulted in the nondiscriminating blockade of commensal bacterial attachment to mucosal surfaces. In this B1 cell Ab production pathway, IL-15 may be involved in IgA production facilitated by the intestinal microbiota, since it was previously reported that B1 cells proliferated in the LP when reacted with IL-15, an event induced by TLR-mediated signaling (113).

Another study revealed a unique pathway for specific Ab production against commensal microbiota in the intestine. It was shown that intestinal MΦ rapidly kill commensal bacteria, while intestinal DCs retain small numbers of

live commensal bacteria and migrate only into MLNs but do not penetrate beyond MLNs (128). This function ensures a commensal bacteria-specific IgA Ab response that is specifically produced at the gut mucosa, but not in systemic immune compartments.

Mucosal microbiota-mediated innate immunity (e.g., TLR-mediated signaling) also plays an important role in the maintenance of mucosal homeostasis (47,126,127). For instance, the TLR-mediated cross-talk between the mucosal microbiota and IECs is biologically significant in the maintenance of epithelial homeostasis. EC cycles such as renewal, differentiation, and mitosis are significantly changed in germ-free or MyD88-deficient mice (22). In this regard, it was shown that TLR-mediated signals from the intestinal microbiota regulated the production of tissue protective factors such as IL-6, KC-1, and heat shock proteins (22). In addition to ECs, it was shown that TLRs were selectively expressed on $CD25^+$ $CD4^+$ Treg cells, which have been considered to be involved in the induction of oral tolerance, as discussed later in this chapter (129). Thus, bacterial products such as LPS directly enhance their survival and proliferation. These products and host responses may explain why C3H/HeJ mice lacking TLR4-mediated signaling and germ-free mice show less sensitivity to oral tolerance induction (130).

Additional examples of molecules in the microbiota-dependent intestinal homeostasis are bacterial DNA. Bacterial DNA contains unmethylated CpG motifs within consensus sequences and is the ligand for TLR9 (11). Several lines of evidence have demonstrated that CpG targets DCs to induce the inhibitory environment (131), and it has been considered that some types of DCs are involved in these inhibitory immune responses (51,52); it appears that the intestinal microbiota stimulates intestinal DCs through the interactions between CpG and TLR9 for the maintenance of intestinal homeostasis. These inhibitory effects of bacterial DNA have led to the development of probiotics-mediated anti-inflammatory therapy, as discussed later in this chapter (131).

MUCOSAL TOLERANCE

Basic Concepts

In addition to the protective function of Ag-specific S-IgA and serum IgG Ab responses after mucosal immunization, the mucosal route of Ag delivery can also induce systemic unresponsiveness (132). Oral administration of a single high dose or repeated oral delivery of low doses of proteins has been shown to induce systemic unresponsiveness. Additional studies have shown that the nasal administration of proteins also induces systemic unresponsiveness and has led to the more general term mucosal tolerance to include nasal or oral Ag induction of unresponsiveness (132). The inhibition of Ag-specific immune responses in

systemic compartments by mucosal Ag delivery is important for the prevention of overstimulation of responses and frequently encountered and hypersensitivity responses to food proteins and allergens. Further, this system could potentially be applied to the prevention and possibly treatment of autoimmune diseases by feeding relevant Ags.

Role of PPs in Oral Tolerance

The precise site of Ag uptake in the GI tract during oral tolerance induction has not been firmly established. One possible route is that Ags may enter the GALT via M cells and lead to APC–T cell interactions that down-regulate T and B cell responses. Some investigators have suggested that organized lymphoid tissue in the GI tract was not required for oral tolerance to OVA, since B cell–defective mice, which contain poorly developed PPs, were fully tolerized at the level of T cells (133). The availability of mice without PPs has allowed reinvestigation of the notion that GALT may be involved in oral tolerance. In one study, it was shown that mice that lack GALT but retain MLNs could be orally tolerized to OVA (134). However, others found that mice that lack PPs but retain MLNs were resistant to oral tolerance to protein (135); however, these mice showed normal mucosal S-IgA Ab responses to oral protein given with CT as adjuvant (41,42). Although one cannot yet conclude whether GALT is a strict requirement for oral tolerance to proteins, it is plausible to suggest that the nature of the Ag itself may influence the site of entry into the host.

CD4$^+$ T Cells in Oral Tolerance

The $\alpha\beta$ T cells appear to be the major players in down-regulation of systemic immune responses to orally administered Ags. It is generally agreed that the status of oral tolerance can be explained by: 1) clonal anergy or deletion of T cells, or 2) by active suppression by regulatory-type T cells through the secretion of inhibitory cytokines (132). Low doses of oral Ag tend to favor the latter form of inhibition, while higher doses of feeding induce clonal anergy of immunocompetent T cells. These two forms of oral tolerance are not mutually exclusive and may occur simultaneously following oral administration of Ags.

Anergy is defined as a state of T cell unresponsiveness characterized by the lack of proliferation and IL-2 synthesis and diminished IL-2R expression, a condition reversed by pre-culturing T cells with IL-2 (132). It was shown that Th1-type cells appear to be more sensitive to the induction of tolerance *in vitro* than Th2-type cells; *in vivo* evidence has demonstrated that Th1 cells are likely to be anergized in oral tolerance. This may be an oversimplification since it has been shown that oral tolerance can be induced in mice defective in Th1 (STAT4$^{-/-}$) or Th2 (STAT6$^{-/-}$) cells (136). Further, to identify which lymphocyte compartment (e.g., CD4$^+$ versus CD8$^+$ T cells) preferentially mediates

the induction of oral tolerance, cell transfer experiments were performed using SCID and *nu/nu* mice, demonstrating that oral tolerance was induced by anergized CD4$^+$ but not CD8$^+$ T cells (137).

Clonal deletion has been considered as another pathway for the induction of oral tolerance. Clonal deletion of Ag-specific CD4$^+$ T cells was detected after oral feeding of high doses of Ag (132). Accumulating evidence has revealed that the clonal deletion induced by feeding high doses of Ag was due to an increase in the susceptibility of lymphocyte apoptosis via increased expression of caspase.

Mucosal Regulatory T Cell Networks

Regulatory- and suppressor-type T cells are crucial players in the induction of peripheral tolerance to self and foreign Ags. It is now accepted that several populations of T cells expressing CD4 or CD8 show regulatory or suppressive functions to other T cell-mediated mucosal immune responses. They can be classified as: 1) naïve, or those which have not yet encountered Ag; 2) activated (effector); and 3) memory, where both effector and memory T cells have engaged in the regulation of immune responses (48,132). CD4$^+$ T cells including CD4$^+$CD25$^+$Foxp3$^+$ Treg cells, Th3 cells (secreting TGF-β), and Tr1 cells (secreting IL-10) and CD8$^+$ T cells were shown to be key players for the creation of a mucosal regulatory T cell network in the establishment of quiescent immunity (or mucosal tolerance) (Figures 31.7, 31.14).

CD25$^+$ CD4$^+$ Treg Cells

Recent evidence has revealed that naturally arising CD25$^+$ CD4$^+$ Treg cells play a pivotal role in the negative control of a variety of physiological and pathological immune responses (138). Naturally arising Treg cells specifically express a forkhead winged-helix transcription factor family member (Foxp3) for the process of Treg cell lineage commitment. Thus, Foxp3 deficiency results in early onset, fatal, systemic autoimmune disease. The Foxp3$^+$ CD25$^+$ CD4$^+$ Treg cells are present in the PPs, suggesting that Foxp3$^+$ CD25$^+$ CD4$^+$ Treg cells are involved in the maintenance of intestinal homeostasis.

In addition to inhibitory cytokines, such as IL-10 and TGF-β, several inhibitory molecules have been shown to be expressed on CD25$^+$ CD4$^+$ Treg cells (138). Although naïve T cells express CTLA-4 (or CD152) after activation, which competes with the cellular interaction between CD28 on effector T cells and CD80/CD86 on APCs, CD25$^+$ CD4$^+$ Treg cells constitutively express CTLA-4 (Figures 31.7, 31.14). The CTLA-4 on Treg cells plays a pivotal role in the maintenance of mucosal homeostasis (139). Thus, anti-CTLA-4 mAb treatment inhibited the regulatory function of CD25$^+$ CD4$^+$ Treg cells and subsequently led to the development of IBD. Several mechanisms have been proposed for the
FIGURE 31.14 Cellular and molecular mechanisms for the induction and regulation of mucosal immunity and tolerance. A unique aspect of the mucosal immune system is the simultaneous presence of active (e.g., effector T cells and S-IgA Abs) and quiescent (e.g., Treg cells and mucosal tolerance) immunity. To smoothly operate two opposite types of immunity, ECs, DCs, and T cells play central roles by providing appropriate inflammatory and anti-inflammatory cytokine networks together with costimulatory and chemokine molecular families.

inhibitory function of CTLA-4 on Treg cells, including the enhancement of Treg cell activity through the interaction with CD80/CD86 on APCs (138). Since ECs also express CD80 as mentioned earlier (37), it is possible that Treg cells recognize CD80 on the ECs in order to exhibit their immunosuppressive function. Another possible mechanism is the induction of the inhibitory molecule, IDO (140). As mentioned earlier, IDO exhibits immunosuppressive effects by catalyzing the catabolism of tryptophan, an essential amino acid for T cell proliferation (20). In addition to CTLA-4, Treg cells also express high levels of glucocorticoid-induced TNF-like receptor (GITR), another important suppressive function-associated molecule, that contributes to the maintenance of a quiescent condition in mucosal immune compartments (138). Thus, transfer of

GITR^{high} Treg cell–depleted spleen cells to athymic nude mice resulted in the development of autoimmune diseases including gastritis (141). GITR-mediated signaling triggers Treg cell proliferation, which has been considered to be one molecular mechanism for GITR-mediated suppressive function of Treg cells in the presence of IL-2, but detailed mechanisms remain unclear.

Although naturally arising CD25$^+$ CD4$^+$ Treg cells develop in the thymus and their survival in the periphery is dependent on IL-2 (138), accumulating evidence has demonstrated that Foxp3$^+$ Treg cells can be induced from Foxp3$^-$ precursors and, like naturally arising CD25$^+$ CD4$^+$ Treg cells, the induced Treg cells express CD25 and CTLA-4, and also produce IL-10 and TGF-β (142). It is interesting to note that cytokines such as TGF-β and IL-10 contribute

to the differentiation of Treg cells (142). As mentioned earlier, TGF-β and IL-10 are predominantly produced in the intestinal compartments; thus, the GI tract seems to be an optimal environment for naturally inducing the differentiation of Treg cells for the creation of immunologic homeostasis in the otherwise harsh environment of the gut.

Th3 Cells

Th3 cells were initially discovered as a form of suppressor T cell subset that accounted for oral tolerance (Figures 31.7, 31.14) (48,132). The finding of CD4$^+$ T cell clones generated after induction of oral tolerance to myelin basic protein (MBP), led to the description of a new phenotype of regulatory or suppressor T cell. Clones of CD4$^+$ T cells were MBP-specific, and of 48 clones assessed, 42 produced the active form of TGF-β, which is also an essential cytokine to induce Th3 cells (143). Th3 cells have different cytokine requirements for their growth from CD25$^+$ CD4$^+$ Treg cells. As mentioned earlier, the survival of CD25$^+$ CD4$^+$ Treg cells is dependent upon IL-2 (138), while *in vitro* differentiation of Th3 cells is enhanced by TGF-β, IL-4, and IL-10 (48). These findings suggest that Th3 cells are a different linage from naturally arising CD25$^+$ CD4$^+$ Treg cells, but it is still unclear whether Th3 cells are the same as induced Treg cells because of the lack of a specific marker for Th3 cells. It was previously shown that TGF-β was produced by intestinal DCs (51,52), which has been considered to be the source of cytokines for the induction of Th3 cells in the intestine. Additionally, since TGF-β production was induced by CTLA-4, which is constitutively expressed on naturally arising Treg cells (142), it is possible that TGF-β production from Treg cells through CTLA-4–mediated signaling may stimulate the differentiation of both induced Treg cells and Th3 cells.

Tr1 Cells

Another regulatory type of T cell is one that secretes IL-10 and TGF-β and has been termed a Tr1 cell (Figures 31.7, 31.14) (144). Similar to IL-10–secreting induced-type Treg cells, Tr1 cells are induced by Ag stimulation in the presence of IL-10, which is abundantly produced by DCs in GALT and in pulmonary tissues, as mentioned earlier (51,52). The function of Tr1 cells is to suppress Ag-specific effector T cell responses in a cytokine-dependent manner. Ag-specific activation of TCR is required for the Tr1 suppressive function, but Tr1 cells can also mediate bystander suppressive activity against other Ags once they are activated. Although the migratory capacity of Tr1 cells has not been elucidated yet, it is interesting to note that Tr1 cells in the blood circulation express the GI tract migration chemokine receptor, CCR9, suggesting that these cells intrinsically home to the intestine (145). Consistent with this idea, previous studies reported an important role for Tr1 cells in IBD and celiac diseases (144,146). Although

Tr1 cells do not express Foxp3 the lack of Tr1 cells resulted in the development of intestinal inflammation. Hence, Tr1 cells have been considered to be a unique subset of regulatory T cells, which is distinct from the CD4$^+$ CD25$^+$ Treg cell subset, important in the control of undesired hyperimmune responses in the intestine.

CD8$^+$ Suppressor T Cells

The first identified population of regulatory T cells thought to be involved in oral tolerance was a CD8$^+$ suppressor T cell subset (Figure 31.14) (147). However, their functions and characteristics have not been clearly defined. It was reported that CD8$^+$ CD28$^-$ suppressor T cells induced the up-regulation of Ig-like transcript 3 (ILT3) and ILT4 expressed on human monocytes and DCs, rendering these APCs tolerogenic by inducing Ag-specific unresponsiveness of CD4$^+$ T cells through reduced expression of costimulatory molecules (148). Subsequent study has revealed that ILT3/4 expression in human vascular endothelial cells was up-regulated by IL-10 (149). Since IL-10 is abundantly produced in the intestinal compartments, it is plausible that IL-10 produced in the intestinal compartments may regulate ILT3/4-mediated suppressive function as suppressor T cell–mediated maintenance of intestinal homeostasis. In addition, it was suggested that CD8$^+$ CD122$^+$ (IL-2/IL-15 receptor β chain) T cells behave like naturally occurring regulatory T cells, where the depletion of the CD8$^+$ T cells resulted in the high incidence of pulmonary inflammation (150). Although CD8$^+$ CD122$^+$ T cells are also involved in the intestinal immune system, the finding further suggested the existence of multiple layers of a mucosal regulatory network for the creation and maintenance of the quiescent status of the immune environment in the mucosal compartments of both the GI and respiratory tracts.

Factors in Determining the Type of Regulatory T Cells

Recent studies have identified several factors determining whether T cells differentiate into pathogenic or regulatory T cells. For instance, as mentioned earlier, TGF-β is known to be an essential molecule for the induction of Treg cells and Th17 cells; however, Th17 cells additionally require IL-6 for their development. Therefore, in the presence of IL-6 plus TGF-β, only Th17 cells developed (62,63). A recent separate study shows that stimulation with TGF-β and IL-6 triggers initial lineage commitment of Th17, but IL-23 is required for the full differentiation of Th17 cells (151). In contrast to the effects of IL-23 for the full differentiation of IL-6– and TGF-β-treated T cells into Th17 cells, IL-27 plus IL-6 and TGF-β–induced T cells producing IL-10, which resembled Tr1 cells (152,153). Thus, it

seems that IL-23 and IL-27 both play important roles in the fate decision of IL-6– and TGF-β–exposed T cells either become pathogenic Th17 cells or regulatory Tr1 cells. Several separate studies have revealed that mucosal DC–derived retinoic acid, a key molecule for the induction of gut-homing $\alpha 4\beta 7$ integrin and CCR9, as mentioned earlier (88,89), also enhanced conversion of TGF-β–treated T cells to Treg cells and simultaneously suppressed the differentiation to Th17 cells (154–157). These data suggest the presence of versatile pathways for regulating T cell fate.

Role of IELs in Mucosal Tolerance

Since the intestinal epithelium is directly and continuously exposed to gut environmental Ags, it was logical to consider that IELs and IECs contribute to the mucosal regulatory network for the induction of mucosal tolerance (25,132). Interestingly, it has been shown that depletion of TCR$\gamma\delta$ cells resulted in the failure to induce the systemic unresponsiveness after oral administration of Ags (158). Another study demonstrated that when either TCR$\delta^{-/-}$ or TCR$\delta^{+/+}$ mice were immunized orally with a high dose of OVA prior to parenteral challenge, systemic IgG and IgE Ab responses were markedly reduced in both types of mice (159). Reduced T cell proliferative responses and delayed-type hypersensitivity were seen in both TCR$\delta^{-/-}$ and TCR$\delta^{+/+}$ mice given high-doses of OVA. In contrast, while oral tolerance associated with increased levels of IL-10 synthesis was induced by low-dose OVA in TCR$\delta^{+/+}$ mice, TCR$\delta^{-/-}$ mice were not tolerized and failed to produce IL-10 (159). These findings indicate that $\gamma\delta$ T cells play an important role in IL-10–mediated, low-dose oral tolerance induction, but are not essential participants in the induction of systemic tolerance induced by oral administration of large doses of Ag. It has been suggested that oral tolerance induced by repeated administration of small doses of Ag is mediated by T cells involved in the generation of active suppression, while systemic unresponsiveness induced by large doses of Ag is caused by clonal anergy or clonal deletion (132). Thus, it is likely that $\gamma\delta$ T cells play regulatory roles for the induction of active suppression, although they are not involved in the induction of clonal anergy or deletion.

DCs and IECs in Oral Tolerance

It has been demonstrated that intestinal DCs contribute to the induction of tolerance. The initial evidence of DC involvement in the induction of oral tolerance was provided by the demonstration that Flt3 ligand-mediated expansion of DCs led to enhanced oral tolerance (160). Among several kinds of DCs in the intestinal compartments, two subsets of DCs have gained attention. As mentioned earlier, CD11b$^+$ myeloid DCs in the PPs have the unique feature of produc-

ing predominantly IL-10 in response to CD40 ligation or receptor activator of NF-κB (RANK)/RANK ligand interactions (51,52). A second DC population involved in the induction of oral tolerance is pDCs. One study described that CD11c^{low} DCs displayed a plasmacytoid morphology and a stable immature phenotype and secreted IL-10 for the induction of IL-10–secreting Tr1 cells, and a recent study has revealed that inducible costimulator ligand (ICOS-L) plays an important role in pDC-mediated Tr1 induction (161). High levels of ICOS-L expression on pDCs allow them to induce the differentiation of naïve CD4 T cells to IL-10 but not the other Th2 cytokines (161). In addition to Tr1 cells, pDCs induced IL-10–producing CD8$^+$ regulatory T cells (162). Taken together, IL-10 produced by DCs is a key factor in the differentiation of regulatory-type T cells.

ECs are also thought to contribute to the induction of oral tolerance by capturing and presenting luminal Ag by MHC molecules with low expression of costimulatory molecules (37). As an additional pathway of IEC-mediated oral tolerance, it was demonstrated that gp180, an associated molecule with cold, mediated interaction between IECs and CD8$^+$ CD28$^-$ CD101$^+$ CD103$^+$ cells, causing the CD8$^+$ CD28$^-$ CD101$^+$ CD103$^+$ cells to develop into regulatory cells (37,163). IECs also mediated suppression of CD4$^+$ T cell activation in a cell contact-dependent and TGF-β–independent manner (164). A recent study has demonstrated that IEC-primed T cells secreted lower amounts of IFN-γ and IL-2 and exhibited an increased expression of IL-10 and Foxp3, providing direct evidence that IECs induced IL-10–producing Foxp3$^+$ T cells (165). Thus, IECs can be involved in the creation of a mucosal regulatory network in two phases including Ag-presentation and priming of regulatory-type T cells.

Nasal Tolerance

The initial dogma that mucosal tolerance requires intestinal processing of the Ag was challenged by the observation that systemic unresponsiveness could be achieved by administration of the Ag via the nasal or aerosol routes (132). These routes were found to require lower doses of Ags than did oral administration, a discrepancy that can be explained by the dilution effect, as well as the potential degradation of the Ag in the GI tract. Although the precise mechanism behind nasally induced tolerance is not yet known, several studies have demonstrated a similar pathway for the induction of both nasal tolerance and oral tolerance. For example, the membrane-bound form of TGF-β–expressing CD4$^+$ Foxp3$^+$ T cells are involved in tolerance induction to inhaled Ag (166). It was also shown that airway pDCs suppressed the generation of effector T cells primed by myeloid DCs via the induction of IL-10–producing Treg cells (167).

Mucosal Tolerance in Humans

Increasing attention is being paid to oral tolerance and the role it could play in the prevention or treatment of autoimmune diseases, including multiple sclerosis, rheumatoid arthritis, uveitis, as well as type I diabetes and contact hypersensitivity (132). Indeed, humans immunized with the neoantigen keyhole limpet hemocyanin (KLH) either by the oral or nasal route developed systemic unresponsiveness evaluated by delayed type hypersensitivity (DTH) and T cell proliferative responses. However, B cell responses were primed in both systemic and mucosal sites. In other studies, humans naturally ingesting the dietary Ags bovine gamma globulin, OVA, and soybean protein developed a T cell tolerance characterized by anergy (132). Antigen-specific Th3 cells secreting TGF-β have been observed in the blood of multiple sclerosis patients orally treated with a bovine myelin preparation, demonstrating that oral administration of autoantigen can induce antigen-specific TGF-β–secreting cells in a human autoimmune disease.

Pilot clinical trials of oral tolerance have been conducted in patients with autoimmune diseases, and promising clinical benefits have been reported (132). Despite encouraging initial results regarding oral delivery of autoantigens for the treatment of human autoimmune diseases, a followup study did not demonstrate statistically significant beneficial effects. Further, oral feeding of autoantigen in mice resulted in the generation of antigen-specific CD8$^+$ CTL responses that could lead to the aggravation of autoimmune disease (132). Thus, one must also keep in mind that oral administration of autoantigen may induce undesirable CD8$^+$ CTLs that may worsen the disease instead of preventing the development of autoimmunity.

A description of extensive experiments and clinical studies based on the exploitation of principles of mucosal tolerance in the prevention and treatment of T and B cell–mediated hypersensitivity diseases (e.g., contact dermatitis and inhalation allergies), other autoimmune diseases (e.g., uveoretinitis, glomerulonephritis, and diabetes), and prolonged survival of allografts are beyond the scope of this review. However, these efforts have not yet reached fruition. Thus, the experience of most investigators is that once antigen-specific systemic immune response has been induced, it is difficult to achieve a reversal through mucosal tolerance.

MUCOSAL IMMUNE SYSTEM FOR HOST DEFENSE

Mucosal Vaccines

Mucosal surfaces are also the most frequent portals of entry of common viral, bacterial, fungal, and parasitic agents causing both local and systemic infectious diseases. The fascinating characteristics of the mucosal immune system in the prevention of infections by pathogens has led to much attention for the development of mucosal (e.g., oral and nasal) vaccines (6). Mucosal vaccines offer numerous advantages over traditional injection-type parenteral vaccines, including needleless and easy administration. Most important, mucosal vaccines can induce both mucosal and systemic immune responses, while parenteral immunization yields only systemic immune responses. Hence, traditional parenteral immunization does not induce mucosal immunity, which would inhibit the initial attachment of pathogens, while mucosal vaccines can establish a first line of immunological defense at mucosal sites as well as provide a systemic immune surveillance to detect and destroy invading pathogens. Therefore, numerous studies have been conducted to harness the enormous potential of the mucosal immune system to induce protective immune responses at the site of entry of infectious agents.

However, due to the difficulties with dosing of relevant Ags, their limited absorption, proteolytic degradation, low pH, and detergent activity by bile salts, unique Ag delivery systems and mucosal adjuvants have been explored to avoid such problems (6). At a minimum, these systems should protect the Ag from physical and biological elimination. In addition, a major research focus has been aimed at molecular and cellular elucidation of key immunological mechanisms for the simultaneous induction and regulation of active (e.g., S-IgA) and silent (e.g., mucosal tolerance) immune responses.

Administration Route of Mucosal Vaccines

Stimulation of local and generalized mucosal immune responses can be achieved by ingestion of Ags or their introduction by the rectal route. The former route exploits the inductive potential of lymphoepithelial tissues distributed in the small intestine, while the latter route primarily stimulates cells accumulated in structures termed *rectal tonsils* (6). Immune responses induced by infections or immunization through the nasal mucosa and oropharyngeal lymphoid tissues (Waldeyers ring or NALT) have been evaluated with particular emphasis on local respiratory tract pathogens such as influenza, parainfluenza, and RSV (120). Individuals naturally infected or locally immunized with attenuated viruses responded by formation of S-IgA and IgG Abs in nasal secretions and when examined also in saliva (120). In general, nasal immunization in contrast to intestinal administration, induces prominent systemic immune responses manifested by the presence of AFCs in peripheral blood with mucosal as well as systemic homing receptors, and plasma Ab responses. Examination of other external secretions of nasally immunized humans and animals revealed another significant feature: the female genital tract secretions contained high levels of antimicrobial Abs of IgA and IgG isotypes, which, in some experiments,

were higher than those induced by local, oral, rectal, or systemic immunizations (168). Thus, it appears that nasal exposure with Ags is the route of choice for the induction of female genital tract responses.

The mucosal immune system of the female and male genital tracts displays several features distinct from other mucosal sites, such as the absence of lymphoepithelial structures analogous to intestinal PPs, and a dominance of IgG-AFCs in tissues and IgG in cervical mucus, vaginal washes, and serum (168,169). Although repeated administration of Ags with adjuvants, or infection with live viruses generated local immune responses, Abs were absent or present in low levels in secretions of remote glands, probably due to the lack of organized inductive sites, equivalent to PPs, in the genital tract. However, systemic immunization followed by local mucosal booster or targeted immunization in the vicinity of local LNs enhanced genital tract responses (168,169). Further, sequential combination of several immunization routes (systemic, oral, rectal, vaginal, tracheal, or nasal) generates better results than repeated immunization at a single site.

Enterotoxin-based Mucosal Adjuvants

Two bacterial enterotoxins, CT and the closely related heat labile toxin (LT), are the most well-studied mucosal adjuvants, which are derived from *Vibrio cholerae* and *Escherichia coli,* respectively (6,170,171). They are not only potent immunogens, but also adjuvants that enhance both mucosal and systemic immune responses against mucosally coadministered Ags. CT and LT are structurally similar (83% homology at the amino acid level) hexameric toxins consisting of two structurally and functionally separate A (CT-A or LT-A) and B (CT-B$_5$ or LT-B$_5$) subunits (6,170,171). The A subunit possesses ADP-ribosyltransferase activity, and the B subunit participates in the binding to host cells. Different binding activities between CT-B and LT-B have been reported. The CT-B binds to GM1-ganglioside, whereas the LT-B binds to GM1-ganglioside as well as asialo GM1 and GM2. The binding of B subunits to their receptors on ECs allows the A subunit to reach the cytosol of target cells, where it binds to nicotinamide adenosyl diphosphate (NADP) and catalyzes the ADP ribosylation of Gsα. The latter GTP-binding protein activates adenyl cyclase with subsequent elevation of cAMP in ECs, followed by secretion of water and chloride ions into the intestinal lumen. Although both CT and LT have strong adjuvant activities, the clinical use of CT and LT has been hampered by the fact that both enterotoxins induce severe diarrhea after oral administration or from natural infection. Both enterotoxins also have undesirable side effects involving their entry into the central nervous system when given by the nasal route (6,170,171).

To circumvent toxicity linked to these enterotoxins, several groups have attempted to generate mutants of CT

(mCT) and LT (mLT) devoid of their toxic activity or replacement of the toxic A subunit (6,170,171). The first approach involves the introduction of single amino acid substitutions in the active site (i.e., the site responsible for the ADP-ribosylation activity) of the A subunit of CT or LT or in the protease sensitive loop of LT. mCTs constructed by substitution of serine by phenylalanine at position 61 (CT-S61F) and glutamate by lysine at position 112 (CT-E112K) in the ADP-ribosyltransferase activity center of the CT gene from *V. cholerae* 01 strain GP14 display no ADP-ribosyltransferase activity or enterotoxicity (6,170,171). The levels of Ag-specific serum IgG and S-IgA Abs induced by the mutants are comparable to those induced by wild-type CT. Further, the mutant CT-E112K, like native CT, induces Th2-type responses through a preferential inhibition of Th1-type CD4$^+$ T cells. Subsequent studies demonstrated that the mutant forms of CT were effective for the induction of immune responses against tetanus toxin, *S. pneumoniae,* influenza virus, diphtheria toxin, HIV, and botulinum neurotoxin (6,170,171). Mutations in other sites of the CT molecule were reported to induce nontoxic derivatives, but the adjuvant activity was also affected. Similarly, mLTs have also been successfully developed as safe mucosal adjuvants and used with vaccines against measles virus, tetanus toxin, *Helicobacter pylori,* and influenza among many others, and some of them have been examined clinically (6,170,171).

Another strategy that exploits the binding potential of CT and CT-B to gangliosides on mucosal cells involves the genetic construction of recombinant chimeric proteins. The toxic subunit A of CT consists of two segments, A1 (carrier of toxicity) and A2, that interact with the B subunit. Genetic replacement of the A1 segment with DNA encoding a desired Ag (e.g., Ag I/II of *Streptococcus mutans*) results in the assembly of a molecule composed of CT-B/A2-Ag (6,170,171). When given intragastrically and especially nasally, potent Ag-specific humoral immune responses were generated in mice.

In addition to CT and LT, several toxins have been shown to exhibit mucosal adjuvant activity. For instance, Shiga toxin 1 (STX1) and the mutant form of STX1 have been shown to exhibit mucosal adjuvanticity. A genetically engineered pertussis toxin (PTX) developed by removal of its ADP-ribosylating activity was an effective adjuvant for enhancing mucosal immune responses (6). The PTX recognizes glycoprotein with a branched mannose core and an N-acetyl glucosamine expressed on various types of mammalian cells. Nasal immunization with tetanus toxoid and PTX augmented parenteral and mucosal Ab responses. *Zonula occludens* toxin (Zot) is a single polypeptide encoded by the filamentous bacteriophage infecting toxigenic strain of *V. cholerae*. Nasal or rectal immunization with Zot resulted in the induction of plasma IgG and mucosal S-IgA Ab responses against coadministered Ag mediated by both Th1- and Th2-type cells (6). CTA1-DD

is composed of an enzymatically active CT-A and a dimer of an Ig-binding element of *S. aureus* protein A. Thus, it targets to B cells (172). When CTA1-DD was applied nasally, it enhanced Ag-specific immune responses in both mucosal and systemic sites without causing inflammation. A subsequent study indicated that the adjuvanticity of CTA1-DD was at least mediated by promoting GC formation (172). Surprisingly, CTA1-DD is nontoxic although it contains the intact form of holotoxin.

It should be noted that, except for a few results, almost all mutant forms of adjuvants derived from the bacterial toxin retained full adjuvant activity at least after nasal and parenteral immunization, but possess less adjuvant activity when they were given orally. The reasons for different adjuvant activities after nasal versus oral delivery remains an open question, and further experiments are necessary for effective oral delivery use of toxin-based mutant adjuvants.

Mucosal Cytokines, Chemokines, and Innate Factors as Adjuvants

Mucosal delivery of cytokines allowed the use of these molecules that primarily interact with their corresponding receptors without the important adverse effects that are often associated with the large and repeated parenteral cytokine doses generally required for the effective targeting of tissues/organs. Considerable numbers of cytokines such as type I IFNs, IL-1, IL-2, IL-12, IL-15, and IL-18 have been shown to have mucosal adjuvant activity (6). Although these cytokines showed adjuvant activities after a single use, previous reports have provided evidence for synergistic effects of cytokines. For instance, the adjuvant activity for induction of mucosal S-IgA and systemic IgG Abs after simultaneous administration of IL-1, IL-12, and IL-18 was much stronger than those induced by the treatment with each cytokine alone or a combination of IL-12 plus IL-18. In contrast to the synergistic effects of IL-1, IL-12, and IL-18, coexpression of IL-15 with IL-12 did not enhance adjuvanticity. These findings suggest that the adjuvant mechanism mediated by cytokines is complex and should be carefully examined for the suitability of a particular cytokine for use in the development of effective mucosal vaccines.

In addition to cytokines, chemokines have been shown to act as innate-type mucosal adjuvants (6). For instance, nasal administration of XCL1/lymphotactin with Ag resulted in the marked enhancement of Ag-specific S-IgA Abs in various mucosal secretions (e.g., feces, saliva, vaginal, and nasal washes) and plasma IgG Ab responses. Similarly, nasal coadministration of RANTES with Ag induced high levels of S-IgA, plasma IgG, and preferential Th1-type responses. MIP-1 is another CC chemokine that was analyzed for its ability to act as a mucosal adjuvant. MIP-1 contains two homologous subtypes, MIP-1α and MIP-1β.

It was demonstrated that nasal administration of MIP-1α enhanced Ag-specific Ab responses to coadministered Ag in systemic but not in mucosal sites. In contrast, MIP-1β promoted mucosal S-IgA Ab responses with less efficient induction of systemic immune responses, although they both share the same ligand (CCR5).

Defensins belong to a family of antimicrobial peptides produced by Paneth cells, as mentioned earlier (4,5). Defensins also possess chemotactic activity against T cells and exert adjuvant activity (6). It is interesting to note that no mucosal S-IgA Ab responses were induced after nasal immunization with defensins, although they promoted systemic IgG Ab responses associated with IFN-γ, IL-5, IL-6, and IL-10 production. Thus, defensins are unique adjuvants that enhance systemic immune responses without induction of mucosal S-IgA Ab production.

PRR-Targeted Mucosal Adjuvants

Innate immunity plays a pivotal role in host defense against invading microbial pathogens at early stages of infection through recognition by PRRs (11). The PRR-mediated signals induce cytokine production like type I IFN, IL-1 and IL-12, as well as antimicrobial peptides like defensins that are all known to have adjuvant activity, as discussed earlier. As one may expect from the fact that cytokines that function as mucosal adjuvants, PAMPs, also act as mucosal adjuvants. For example, monophosphoryl lipid A (MLA) that has already been shown to be a systemic adjuvant pre-clinically and clinically effectively works as a mucosal adjuvant (6). Until now, the target cells of TLR agonists remained obscure but were presumably DCs, since TLR4 expression is very low or absent on ECs, as mentioned earlier. TLR2 is also a target of a specific mucosal adjuvant. Muramyl dipeptide (MDP) is derived from the cell wall of mycobacteria and has been shown to be one of the ligands for TLR2. Before identification of TLR2, MDP was shown to stimulate PP cells for the enhancement of IgA Ab responses (6). Recent studies have demonstrated that mycoplasma-derived MΦ-activating 2 kDa lipopeptide (MALP-2) promoted Th2-type responses, plasma IgG, and mucosal S-IgA Ab responses against coadministered Ags such as β-galactosidase and HIV-1 Tat protein through TLR2 (173).

The discovery that gene-associated molecules (e.g., DNA and RNA) had immune-stimulating activities allowed us to extend this system for development of mucosal adjuvants. Bacterial, but not eukaryotic, DNA generally contains nonmethylated "CpG motifs" and acts as a ligand for TLR9, thus, initiating innate and adaptive immunity (11). Thus, plasmid DNA for gene vaccination can be functionally divided into two distinct units: a transcription unit and an adjuvant/mitogen unit (131). The latter unit contains immunostimulatory sequences consisting of short palindromic nucleotides centered on a CpG dinucleotide

core. It is now clear that CpG motifs can induce B cell proliferation and Ig synthesis as well as cytokine secretion (i.e., IL-6, IFN-α, IFN-β, IFN-γ, IL-12, and IL-18) by a variety of immune cells (131). Numerous studies have shown that mucosal administration of Ag with CpG promoted mucosal S-IgA, plasma IgG, and T cell responses, including CD8$^+$ CTLs and CD4$^+$ Th1 cells accompanied with type I IFN production by DCs, which induced protective immunity against various types of infections, such as *S. pneumoniae,* HIV, HSV-2, and *Helicobacter pylori* (131).

Mucosal Ag Delivery Systems

The mucosal delivery of Ag is another important subject in the area of mucosal vaccine development. Various approaches toward the development of an ideal mucosal Ag delivery system have been developed using inert particles, including biodegradable polymer-based particles (microspheres and nanospheres) as well as lipid-based particles such as liposomes and ISCOMs (6,174). Incorporation of Ags into these particles usually protects them from proteolytic degradation by mucosal enzymes and acids; however particles by themselves are nonimmunogenic. Further, variation in microsphere chemical composition allows generation of particles with fast or slow degradation to stimulate long-lasting responses. Several different Ags can be incorporated into a single preparation, and other substances such as cytokines can be co-incorporated with Ags to show ensuing immune responses (6). These obvious attractive features are, however, counterbalanced by serious disadvantages. Specifically, the disappointingly low uptake from mucosal surfaces (<1%), low rate of incorporation, and the use of organic solvents that may denature Ags are negative features.

To overcome this limitation, several modifications have been attempted to deliver the Ag selectively to M cells, the major targets for delivery of encapsulated Ag. Lectins have been widely exploited to gain or to enhance access to M cells. It has been considered that *Ulex europaeus agglutinin* 1 (UEA-1), a lectin specific for α-L-fucose residues, binds almost exclusively to the apical surface of M cells of murine PPs and NALT (44). The unique reactivity of UEA-1 to M cells allowed the selective and effective delivery of microspheres or liposomes to M cells after oral administration, which led to the significant enhancement of Ag-specific Ab responses (175). Recent advances in biomedical technology have been utilized to identify organic molecules or peptides that mimic the functional activity of UEA-1 using mixture-based positional scanning of synthetic combinatorial libraries or of phage peptide libraries. The former study revealed that a digalloyl D-Lysine amide construct and a tetragalloyl D-Lysine amide construct bound effectively to M cells, and the coating of particles with these compounds resulted in the selective delivery of the particles to M cells with high efficacy (176). The latter study

demonstrated that specific peptide (YQCSYTMPHPPV) selectively bound to the M cell–rich subepithelial dome region of the PPs and enhanced the delivery of microspheres to M cells (177). In addition to these molecules, an M cell–specific monoclonal antibody (mAb) (NKM16-2-4) was recently developed, which can be used for the M cell–targeted delivery of vaccine antigen (178). This mAb recognized carbohydrate-modified molecules selectively expressed on M cells and thus, effectively delivered the conjugated vaccine Ag to M cells for the induction of mucosal and systemic Ag-specific immune responses (178).

Microbial adhesins have been applied to the targeted delivery of synthetic particles to M cells. As expected given the selectivity of ligands, enhanced Ag uptake was achieved by coating polystyrene nanospheres with *Yersinia*-derived invasin, a ligand for β1 integrins on the apical side of M cells (44,59). Similarly, reoviruses are known to invade through M cells using a 45-kDa viral haemagglutinin σ1 protein (44,59). Subsequent studies demonstrated that mucosal immune responses were significantly increased by mucosal immunization by coupling a reovirus-derived σ1 protein (179). As another approach, hybrid Ag delivery vehicles have been developed (180). These vehicles are composed of a synthetic liposome and virus, such as influenza and Sendai viruses (6). Using fusion activity that originates from the virus, the virus-mimicked liposomes could effectively deliver the encapsulated Ag to MALTs and induce high levels of Ag-specific immune responses.

Attenuated live microorganisms have been developed as vaccines, and some of them have already been used as mucosal vaccines (e.g., poliovirus, *S. typhi* Ty21a, and *V. cholerae*) (6,181,182) since the attenuation may not affect the natural abilities of bacteria to survive in the hostile environment of the intestinal and respiratory tracts and to bind to M cells to promote vaccine uptake for the effective induction of mucosal and systemic immune responses. Recent progress in genetic technology has allowed the creation of a new application of attenuated vaccines for Ag delivery, namely recombinant attenuated vaccines carrying DNA encoding heterologous Ag (6,181,182). In the attenuated recombinant vaccines, several genes determining pathogenicity have been mutated or disrupted, and a gene encoding a heterologous Ag has been inserted, which ensures both safety and effectiveness. Vectors that have been tested include various species of attenuated bacteria such as *S. typhi*, *Shigella flexneri*, and *Listeria monocytogenes*, *V. cholerae*, *Lactobacillus*, and *Y. enterocolitica* (181). Similarly, recombinant viruses have been established as vehicles for mucosal vaccine delivery (182). Since CTL responses appear to be pivotal in chronic viral infections, these efforts have been aimed at developing mucosal vaccines that induce both mucosal S-IgA and CTL responses to prevent initial contact of pathogens with host cells in mucosal sites and for surveillance of virus-infected cells, respectively. Several types of viruses have the advantage

of their natural transmission via mucosal sites. These include poxvirus, adenovirus, HSV, adeno-associated virus, alphavirus (e.g., Semliki Forest virus and Sindbis virus), vesicular stomatitis virus, and poliovirus (182).

Novel molecular methods have allowed the production of subunit vaccines in transgenic plants (183). Plant-based vaccines offer some advantages over other systems, including: 1) the ability to carry out posttranslational modifications similar to eukaryotes; 2) ease of production of large quantities at reduced costs; 3) no requirement to use a human pathogen. Assemblies of one or more Ags that retain both T and B cell epitopes have been expressed in genetically modified plants (GM plants) and are now being tested for their potential use as human or animal vaccines. To date, many plant species have been employed for vaccine usage. Early studies used tobacco and potato plants, but now tomato, banana, corn, lupine, lettuce, wheat, rice, and other plants are being used for this purpose (183). To circumvent potential denaturation of Ag during cooking, recombinant plants such as tomatoes, lettuce, and bananas have been developed. To overcome the "cold chain" problem, grain (e.g., corn, wheat, and rice) are suitable because they can be stored at ambient temperature for a long time. Along these lines, a rice-based vaccine technology was introduced. In mice orally immunized with rice expressing CT-B kept over 18 monthes under normal temperature condition (or without any refergriration), CT-B–specific intestinal S-IgA Ab responses were elicited, which enabled them to protect against CT-induced diarrhea (183a). Like this one example, considerable progress has been achieved to show that protective immune responses are induced in animal model studies and, more recently, in completing application trials for target animals for veterinary vaccines (183). Thus, although many problems need to be overcome for use of this technology clinically, including low yields and inconsistent product quality for GM plant standards, there is no doubt that plant-based vaccines are still considered to be a most promising mucosal vaccine system.

MUCOSAL DISEASES AND IMMUNOTHERAPY

IgA Deficiency

Deficiency of IgA is the most common primary immunodeficiency disease in humans (184). Serological data indicate that in Western Europe and the United States, one out of 400 to 700 individuals are affected; in Japan, the disease is less frequent ($\sim$1:18,000). Deficiency of IgA frequently escapes detection, because a large percentage of afflicted individuals have no clinical symptoms. In an absolute majority of cases, both serum IgA1 and IgA2 are either deficient or are present in low levels ($<$50 mg/100

ml). Although rare, selective deficiencies of IgA1 or IgA2 subclasses, due to the deletion of Cα1 or Cα2 genes, have been described (184). It is well recognized that the majority of IgA-deficient individuals are asymptomatic presumably due to alternative compensatory presence of S-IgM in external secretions that functionally substitutes for the deficient S-IgA. However, it appears that in comparison to normal individuals, patients with IgA deficiency have a higher incidence of recurrent infections, especially in the upper respiratory tract, allergic diseases, autoimmune disorders, and malignancies, particularly intestinal adenocarcinomas (184). Absence or low levels of S-IgA Abs to microbial and food Ags may result in higher rates of absorption of such Ags from mucosal surfaces, induction of higher levels of corresponding Abs in plasma, and formation of circulating immune complexes. Although S-IgM may replace S-IgA in deficient patients, it appears that S-IgM does not fully substitute for the IgA-associated functions. This may be partly ascribed to the anti-inflammatory nature of IgA manifested by its inability to activate C with potential inflammatory consequences. In contrast, both IgM and IgG are potent C activators, and it has been demonstrated that the formation of immune complexes composed of protein Ags and IgM or IgG within mucosal tissues leads to local damage and increased absorption of bystander Ags. Diminished functional substitution of S-IgA with S-IgM is also apparent in frequency of viral and bacterial infections, and responses to vaccines (184).

HIV-1 Infection and the Mucosal Immune System

Mucosal tissues of the genital and intestinal tracts are the most important portals of entry of HIV (124). Epidemiological studies indicate that worldwide $\sim$80%–90% of HIV infections are acquired by mucosal routes through heterosexual and homosexual intercourse and the vertical transmission route *in utero,* during delivery or by breast feeding (124). Further, application of SIV on the surfaces of vagina, penile urethra, or nasopharyngeal lymphoid tissues was sufficient to infect rhesus monkeys (123).

Several mucosal cell types may be involved in the initial uptake of HIV and SIV (123,124). In animal models, specialized M cells found in the intestinal PPs, in analogous lymphoepithelial structures of the rectum, and also in tonsils are capable of internalization of HIV/SIV and presumably passing the virus to adjacent infectable cells including T cells, MΦ and DCs (123,124). Human intestinal and oral EC lines and primary IECs internalize HIV and are infectable *in vitro* due to the expression of HIV receptors/coreceptors (CD4, galactosyl-ceramide, and CC-chemokine receptors, mainly CCR5 and to a lesser extent CXCR4) on their surfaces (185). However, direct *in vivo* evidence for the presence of HIV in enterocytes is not available. In rhesus macaques vaginally exposed to cell-free

SIV, Langerhans cells dispersed in the stratified squamous vaginal epithelium were the first cells that were infected (185). Previous studies indicate that SIV and HIV primarily targets and destroys mucosal $CD4^+$ cells perhaps due to the selective expression of chemokine receptors (123,124). Isolated mucosal $M\Phi$ are less permissive for HIV infection than phenotypically distinct blood monocytes probably due to the reduced expression of HIV coreceptors (123,124). In addition to the initial HIV infection sites, mucosal tissues, especially gastrointestinal sites, are involved in the chronic activation of the systemic immune system, a hallmark of progressive HIV infection. A recent study demonstrated that chronically HIV-infected individuals and rhesus macaques infected with SIV showed increased amounts of LPS in the blood, which was presumably derived from commensal microbiota in the GI tracts (186). It was also shown that the microbial translocation from gastrointestinal mucosa to systemic compartments correlated with chronic activation through both innate and acquired immune systems, providing evidence for chronic systemic immune activation in HIV infection mediated by the GI mucosa.

HIV-1–specific Abs become detectable in sera shortly after infection. In all seropositive individuals, these Abs are of the IgG isotype; IgA Abs are present less frequently and occur at much lower levels. Extensive studies of external secretions, including tears, saliva, nasal, intestinal, and vaginal washes; semen; cervical mucus; milk; fecal extracts; and urine yielded often controversial results with respect to the presence and isotypes of HIV-1–specific Abs (123,124). Differences in the collection procedures, processing of samples, dilutions of some secretions by washing fluids, and methodologies used for Ab detection may account for some of these discrepancies. Surprisingly, HIV-1–specific Abs of the IgG isotype are dominant in all secretions despite the overwhelming levels of total IgA and route of infection (systemic or mucosal) (123,124). For example, in human milk, intestinal fluid, and saliva, in which IgA represents ∼98% to 99% and IgG only ∼1% of total Igs, HIV-1–specific Abs are present mainly in the IgG isotype. In external secretions of individuals with HIV-1–specific IgA Abs, there is a pronounced restriction to the IgA1 subclass (187). Absence or presence of levels of HIV-1–specific IgA Abs in external secretions is not due to a defect in the production of total IgA or unresponsiveness to viral Ags: IgA Abs to, for example, influenza virus are readily detectable in secretions of HIV-1–infected individuals (188). The mechanisms involved in this diminished responsiveness to HIV-1 but not the influenza virus in the S-IgA isotype have not been clarified. The site of original infection and the presence of effective mucosal inductive sites in the upper respiratory tract but not in the genital tract may play a role. Initial reports (188) of the selective occurrence of HIV-1–specific Abs in secretions of

HIV-1–exposed but seronegative individuals have not been confirmed in other studies. Studies concerning the presence of CTLs in mucosal tissues of HIV-infected individuals are rather limited mainly due to the unavailability of tissues to perform extensive analyses. The progressive decline of immune functions in long-term HIV-1–infected and untreated individuals also compromise the mucosal immune system. An increased incidence of infections with mucosal opportunistic pathogens, including viruses, bacteria, fungi and protozoa, and of mucosal neoplasms has been observed.

IBD

IBD represents a chronic, relapsing, and remitting inflammatory condition of the GI tract that is manifest as one of the two, usually distinct but significantly overlapping, clinical entities, ulcerative colitis (UC) and Crohn's disease (CD). Increasing evidence suggests that IBD is a dysregulated mucosal immune response to components of the normal commensal luminal microbiota in a genetically susceptible host that is further modified by a variety of environmental factors. The majority of these insights have come through a variety of animal models of IBD, including those that occur spontaneously and those that are induced by administration of exogenous agents, gene targeting through knockout or transgenic approaches, or transfer of cells into immunodeficient animals (189,190).

The incidence of IBD is reduced when bacterial colonization is eliminated through germ-free conditions or reduced such as through antibiotic administration, suggesting that the intestinal microflora is involved in the development of IBD (189,190). However, not all bacteria are equal in this regard. For example, some groups of organisms are known to trigger colitis in genetically susceptible animal strains, such as the ability of *Bacteroides vulgatus* to stimulate colitis in HLA-B27 transgenic rats (191). However, some groups of organisms are able to prevent colitis such as *Lactobacillus sp.*, which are considered to be probiotics and are known to prevent colitis in genetically susceptible hosts such as IL-10 knockout mice (192). Consistent with the protective role of MyD88 signaling in the intestine as mentioned earlier (22), it is now clear that probiotics mediate their anti-inflammatory effects at least partially through TLR9-mediated CpG signaling (131). Thus, $TLR9^{-/-}$ mice showed impaired inhibitory function of probiotics or CpG against experimental colitis. Further, methylated probiotic DNA, calf thymus DNA, and DNase-treated probiotics had no effect on the inhibition of colitis (131).

In addition, colitis in mouse models appears to be triggered by a subset of protein Ags that largely activate effector T cells as manifested by the evidence of private and, to a lesser extent, public TCR motifs in bacterially driven

disease models such as the CD45RB^{high} transfer model in *scid/scid* mice consistent with observations in humans (189,190). Interestingly, the response in the involved IBD intestine is associated with T cell activation and production of Th1 (IFN-γ), Th2 (IL-4), Th17 (ZL-17) and regulatory cytokines (IL-10 and TGF-β). This is consistent with the concept that the final common pathway of excessive Th1, Th2 or Th17 cytokine production that underlies the pathogenesis of these IBDs is achieved by either excessive Th1 or Th2 effector T cells or ineffective counterbalance of effector T cells by regulatory subsets of cells that secrete anti-inflammatory cytokines such as IL-10 and TGF-β. This has placed significant emphasis on defining the regulatory subsets of cells involved in blocking disease pathogenesis and has allowed for drawing significant similarities between and insights from mechanisms previously related to the study of oral tolerance. Indeed, oral tolerance has been shown to be effective in the prevention of IBD through production of these regulatory cytokines in animal models (132). Additionally, a recent study reveals evidence of a genetic defect in oral tolerance in IBD patients (193). As such, the role of Treg cells in intestinal homeostasis has been gained from studies using the T cell transfer colitis model. In this model, cotransfer of CD4$^+$ CD45RB^{low} T cells together with CD4$^+$ CD45RB^{high} T cells prevents the pathology due to the IL-10– and TGF-β–dependent activity of Treg cells (139). In addition to Treg cells, the iNKT cell type has also been shown to inhibit IBD (194). Thus, an amelioration of IBD symptoms was noted in mice treated with αGalCer, but not αManCer, via the IL-10 production by iNKT cells.

Mucosal Allergies

The majority of allergic immunologic diseases are of mucosal origin, and their clinical manifestations are locally expressed. The diseases tend to mainly affect the upper respiratory and GI tracts. Numerous anti-allergic drugs have been developed, but these drugs do not achieve a permanent cure for the allergic diseases. There is a general belief that this increase is due to "cleanliness" in our environment so that exposure to allergens can more often result in hypersensitivity and not classical immunity to infections like tuberculosis, measles, or hepatitis A (195). Asthma is the most common of the severe atopic diseases, which also include allergic rhinitis. The three hallmarks of asthma include: 1) variable airflow obstruction, 2) airway hyperresponsiveness (AHR), and 3) airway inflammation (196). However, hypersensitivity in the GI tract emanates from ingestion of large amounts of food Ags, including cow's milk proteins, eggs, and peanuts (197). It is generally agreed that Th2-type responses, characterized by the enhanced production of IL-4, IL-5, IL-9, and IL-13, and IgE-mediated Ab responses to common inhaled and fed

allergens are major factors in the development of both asthma and food allergy (196,197). Therefore, inhibition of allergen-specific Th2 cells and blocking Th2 differentiation among new responses are reasonable goals for disease manipulation. The former is achieved, for example, by treatment with anti-IL-4 or IL-13 mAbs or soluble cytokine receptors, and the latter was mediated by blocking the interaction between CD28 and CD80/CD86, inhibiting ICOS function, or IL-12 expression (197). In addition, new drugs targeting Th2 effector molecules include PPAR agonists (e.g., cyclopentenone, prostaglandins, and thiazolidinediones) (198). The treatment with PPAR agonists inhibited GATA-3, a Th2-specific transcription factor, and decreased Th2-driven IgE production and inhibited asthma. Further, a Th1-dominant environment is also achieved by TLR-mediated stimulation because these triggers tend to induce Th1 responses as mentioned above. Thus, some TLR ligands (e.g., CpG oligodeoxynucleotides) have been established as agents effective against mucosal allergy in animal models, and clinical trials have been initiated (131). Similarly, blocking IgE activity resulted in the inhibition of allergic responses by suppression of inflammatory cell (e.g., mast cells and basophils) migration and degranulation (199).

Induction of tolerance is another strategy against mucosal allergy (132). Induction of tolerance by repeated subcutaneous injection of allergen has been used in clinical practice for nearly 100 years and is successful in selected allergic patients sensitive to a limited number of allergens. In addition to subcutaneous injection, oral or nasal administration has been employed to induce tolerance in animal models and clinical trials against various allergens such as pollen and house dust (132). In this context, a rice-based vaccine system expressing multiple T cell epitopes has been developed to induce oral tolerance and inhibit allergy (200). In addition to allergy, mucosal tolerance has been applied to other diseases, including EAE, arthritis, diabetes, myasthenia gravis, transplantation, and others (132).

As mentioned earlier, Treg cells play an important role in the induction of mucosal tolerance (132,139). The relationship between Treg cells and mucosal allergy was implicated by reports that the ratio of allergen-specific effector Th2 cells and Treg cells may be linked to the pathogenesis of food allergy (201). Among several types of Treg cells (e.g., naturally arising Treg cells, Tr1, and Th3), allergen-specific IL-10–producing Treg cells display strong immunosuppressive potential (201). Consistent with this, several studies suggested that IL-10 levels were inversely correlated with the severity of human allergic disease (201). However, recent studies revealed a novel pathway mediated by naturally arising Treg cells to inhibit asthma via an IL-10–independent pathway (202), suggesting that mucosal allergies can be treated by the versatile Treg cell system.

The recruitment of effector cells at the sites of allergen exposure is a target for treating mucosal allergy (197). This could be achieved by interfering selectively with the system of adhesion molecules regulating the trafficking of Th2 cells and inflammatory cells (e.g., eosinophils, basophils, and mast cells). For example, blocking the adhesion molecule LFA-1 has been shown to be effective in the inhibition of airway inflammation in animals and in allergic patients (197). Chemokines are other target molecules in preventing allergic inflammation (197). A recent study demonstrated that Th17 cells reduced AHR by down-regulation of CCL11/eotaxin and CCL17/TARC production in the lungs (203). In addition, several other chemokines (e.g., CCL17, CCL1, and CXCL12) have been considered to facilitate preferentially the development of Th2 inflammation (204). Using a food allergy model, it was recently reported that S1P, a lipid mediator, contributes to the regulation of migration of pathogenic CD4 T and mast cells from the systemic immune compartment into the large intestine and inhibition of S1P-mediated pathway results in the inhibition of development of allergic diarrhea (205).

Celiac Disease

Celiac disease is another related disorder of mucosal immunity, which is characterized by small-intestinal mucosal injury in response to the dietary ingestion of gluten (29). Gluten is a proline- and glutamine-rich protein that is found in wheat, rye, and barley. Pathologic features of celiac disease include increased numbers of IELs and less extensive villous atrophy and crypt hypertrophy (29). IELs from patients with celiac disease preferentially include NK-like cells, which recognize stress-induced MICA molecules expressed on IECs (29). This process has been considered to be mediated by IL-15. IL-15 induces increased expression of MICA and subsequent interaction between MICA and its receptor, NKG2D, and up-regulates gluten-specific CTL activity in the small intestine (206). Gluten-free diet currently is the only accepted therapy for celiac disease, and various immunological approaches such as blocking IL-15 and treatment with IL-10 have been examined (29). However, in terms of quality of life, it is doubtful that this treatment will be effective with so many potential side effects. Thus, it is essential to identify the gluten-specific pathogenic immunocompetent cell population for the development of novel strategies to selectively delete the specific pathogenic populations.

Neural Immune Interactions

Jeanette I. Webster Marketon and Esther M. Sternberg

INTRODUCTION

A bidirectional communication exists between the central nervous system (CNS) and the immune system whereby neurotransmitters and neurohormones regulate immunity and, in turn, immune molecules signal the central nervous system to activate these extra–immune system regulatory pathways in a negative feedback loop that maintains homeostasis. Perturbation of this balance in either direction results in disease. Overregulation of the immune system results in an ineffective immune response and increased susceptibility to infections, whereas underregulation results in an unchecked immune response and the development of autoimmune/inflammatory disease. This chapter focuses on these routes of communication, with particular emphasis on the hypothalamic-pituitary-adrenal (HPA) axis and resultant glucocorticoid release. Dysregulation of the HPA axis and glucocorticoid signaling is discussed.

EFFECTS OF IMMUNE FACTORS ON THE CNS

Immune factors, including immune cells and cytokines, affect the CNS at molecular, cellular, and whole-organ levels.

These factors have different effects on the CNS depending on whether they are expressed within the CNS or produced at peripheral sites.

Effects of Immune Factors Within the CNS

Cells of the brain, such as glia, neurons, and macrophages, are able to produce cytokines locally, which have been shown to be involved in neuronal cell death (1,2,3,4) and survival (5,6). Cytokine-mediated neuronal cell death is believed to play an important role in several neurodegenerative diseases, such as neuroAIDS, Alzheimer's disease, multiple sclerosis, stroke, and nerve trauma (7,8–10).

Effects of Peripheral Immune Factors on the CNS

Cytokines produced at peripheral sites during inflammation are able to signal the brain and change brain function and in this sense act like hormones. In addition to inducing fever, cytokines induce a set of symptoms called "sickness behavior." The symptoms include decreased locomotion, depressed cognition, memory, and mood, decreased appetite, and decreased interest in social interactions and

sexual behavior (11,*12*,13). Peripherally produced cytokines can access and stimulate the CNS by several routes. They can cross the blood–brain barrier (BBB) at "leaky points" such as at the organum vasculosum lamina terminalis (OVLT) or median eminence, and they can also be actively transported in small amounts across the BBB (14). In addition, they can activate the vagus nerve to signal the CNS rapidly by binding to receptors on paraganglia cells adjacent to vagal ganglia (15,16,17). Finally, they can activate second messengers, such as nitric oxide and prostaglandins, by binding to receptors on brain endothelial cells (15,*18–20*). For further reading the reviews by Masek et al. (21) and Sternberg (22) are recommended.

CNS REGULATION OF THE IMMUNE SYSTEM

The CNS is able to communicate with the immune system through both neural pathways and hormonal pathways. In general, neural routes innervate immune organs and regulate immunity at regional and local levels, and hormonal routes regulate immunity systemically.

Neural Pathways That Regulate Immune Function

Neural pathways that participate in CNS regulation of the immune system include the sympathetic nervous system (SNS), the parasympathetic nervous system, and the peripheral nervous system (PNS).

Sympathetic Nervous System

The SNS regulates the immune system at a regional level, through innervation of immune organs. Norepinephrine and neuropeptide Y, synthesized and secreted together from nerve endings (23), regulate the immune system regionally. In contrast, when these neuropeptides are released into the bloodstream from the adrenal medulla they regulate the immune system at a systemic level. Extensive studies indicate that norepinephrine affects adaptive immunity and antibody production (24). The effects on innate immunity have not been as well studied and are reviewed by Sternberg (22) and Maestroni (25). Norepinephrine and neuropeptide Y together inhibit interleukin-6 (IL-6) secretion from macrophages (*26*,27). Recent comprehensive reviews are available of the regulation of the immune system by the sympathetic nervous system (25,28).

Parasympathetic Nervous System

The parasympathetic nervous system regulates immune responses regionally through the vagus nerve. The primary parasympathetic neurotransmitter is acetylcholine, which binds to nicotinic and muscarinic cholinergic receptors (22). During inflammation, IL-1 is released by activated immune cells; this then activates the afferent fibers of the vagus nerve, which rapidly activate the parasympathetic brainstem regions through IL-1 receptors on the parasympathetic ganglia (29). This is the first step in the "inflammatory reflex" that leads to acetylcholine release from efferent vagus nerve fibers as a negative feedback control of inflammation (30). Cutting the vagus nerve prevents immune signaling to brain and activation of parasympathetic brainstem regions and, in turn, prevents vagal control of inflammation and toxic shock (29,30,*31*).

Peripheral Nervous System

At sites of inflammation, the PNS releases neurotransmitters from sensory peripheral nerves that are generally proinflammatory and increase local inflammatory responses. These neuropeptides include corticotrophin-releasing hormone (CRH), substance P, and calcitonin gene–regulated peptide (CGRP) (*32*,33,*34*). Vasoactive intestinal peptide (VIP) is released by peripheral nerves and microglia (35) and inhibits inflammation through G protein–coupled receptors VPAC1 and VPAC2 (36).

Neuropeptides released centrally from the CNS or pituitary gland have different effects and tend to be antiinflammatory. For example α-melanocyte-stimulating hormone (α-MSH), a 13–amino acid peptide, has antiinflammatory actions (*37*,38). It is released from the pituitary, the neurons of the arcuate nucleus and paraventricular nucleus of the hypothalamus, and the peripheral nerves (*39*,40). Opioids, synthetic (morphine) and endogenous (endorphins and enkephalins), are also antiinflammatory molecules released by pituitary (41). These can also stimulate HPA axis and glucocorticoid release (42).

Hormonal Pathways That Regulate Immune Function

In addition to neural control of inflammation, hormones are also released in response to stimuli of brain regions that control the immune system. Prolactin secreted by the pituitary gland binds to the prolactin receptor on immune cells and enhances immune function. Hyperprolactinemia has been described in some autoimmune diseases (43,*44*). Growth hormone, another pituitary hormone also produced by lymphoid organs such as the thymus, spleen, and peripheral blood, also plays a role in enhancing immune function, stimulating T and B cell proliferation and antibody production (45). Ghrelin is predominantly produced in the stomach after stimulation through the gut–brain axis and has been shown to have antiinflammatory actions (46,47). Leptin, also part of the gut–brain axis, has been shown to act as a proinflammatory hormone (48,*49*) and signals the hypothalamus from adipose tissue, forming a negative feedback loop (47).

FIGURE 32.1 Two-way communication between the immune and nervous systems. The immune system and the central nervous system (CNS) communicate with and regulate each other. Cytokines made in the periphery signal the CNS by several routes, including passage across the blood–brain barrier and via the vagus nerve. Peripheral cytokines affect many aspects of CNS function, including activation of the neuroendocrine stress response, or hypothalamic-pituitary-adrenal (HPA) axis. When activated, the hypothalamus releases corticotrophin-releasing hormone (CRH) and arginine vasopressin (AVP), which together stimulate the pituitary grand to release adrenocorticotrophin (ACTH). This in turn stimulates the adrenal cortex to release glucocorticoids. These hormones suppress immunity at a molecular, cellular, and organ level. Other routes by which the CNS regulates immunity are through the sympathetic nervous system (SNS) and peripheral nervous system (PNS). Stress both activates the HPA axis to release these immunosuppressive hormones and activates the SNS. The HPA axis and SNS communicate through brainstem routes that involve noradrenergic nuclei, including the locus ceruleus, C1, C2, A1, and A2. Cytokines are also expressed within the CNS, and in this compartment they play a role in neuronal cell death and survival.
The Hypothalamic-Pituitary-Gonadal Axis

The hypothalamic-pituitary-gonadal (HPG) axis is also involved in regulation of immune responses (50,*51*). Estrogen is generally immunoenhancing at lower concentrations (*52–54*,55,*56*), whereas testosterone and progesterone are generally immunosuppressive (55,56). Increases in estrogens relative to androgens have been shown in rheumatoid arthritis and lupus (57). The differences in immune regulation by the sex hormones may, at least in part, explain the well-recognized phenomenon that females of all species are more susceptible to autoimmune and inflammatory diseases than males, expressing a 2-

10-fold higher incidence or severity of autoimmune diseases compared to males (52,55).

The Hypothalamic-Pituitary-Adrenal Axis

The HPA axis is a major regulator of the immune system via the production of adrenal glucocorticoids (Figure 32.1). The HPA axis consists of the paraventricular nucleus (PVN) of the hypothalamus, the anterior pituitary gland located at the base of the brain, and the adrenal glands. CRH is secreted on stimulation from the PVN into the hypophyseal portal blood supply. This subsequently stimulates the

anterior pituitary gland to secrete adrenocorticotropic hormone (ACTH) into the systemic circulation. In turn, this induces the adrenal glands to synthesize and release glucocorticoids.

The HPA axis is regulated by both factors within the central nervous system and from the periphery. Glucocorticoids, the end product of the HPA axis, negatively regulate the axis at the level of the hypothalamic and pituitary. The HPA axis is also regulated by other factors, such as neurotransmitters and neuropeptides of the sympathetic nervous system, other neuropeptides (e.g. arginine vasopressin [AVP]), and cytokines (*58–60*,61). CRH is positively regulated by the serotonergic, cholinergic, and histaminergic systems but is negatively regulated by itself and by ACTH, as well as by other neuropeptides and neurotransmitters in the brain (e.g., γ-aminobutyric acid–benzodiazepines and opioid peptide systems) (*62–64*,65,66,67).

GLUCOCORTICOID RESPONSES

Glucocorticoids have been known for many years to influence the immune system and because of this have been used in the treatment of inflammatory diseases since the 1940s. The Nobel prize was awarded to Kendall, Reichstein, and Hench for the discovery of this effect in 1950 (68). Since then, extensive research has investigated the pharmacologic effects of glucocorticoids on many aspects of immune cell function (69–70,*71*). However, only relatively recently has the essential physiologic role of glucocorticoids in the regulation of the immune system in health and disease been fully appreciated. To understand the pathogenesis of inflammatory/autoimmune disease and ultimately to develop effective therapies for such diseases, one needs a better understanding of the mechanisms involved in glucocorticoid secretion/production and regulation of the immune system both under normal and disease conditions.

The Glucocorticoid Receptor

Glucocorticoids function through a cellular receptor to modulate gene transcription. Two receptors are activated by glucocorticoids: the higher-affinity type I receptor, the mineralocorticoid receptor (MR); and the lower-affinity type II receptor, the glucocorticoid receptor (GR). Glucocorticoids bind preferentially to MR at low concentrations, and only at high stress levels do they bind to GR (72). It has been suggested that MR functions in a proactive capacity in the maintenance of homeostasis in the brain, whereas GR functions in a reactive role in the recovery from disturbance (73). However, GR is the primary receptor for glucocorticoids in immune cells. Other factors can regulate the availability of glucocorticoids, such as the expres-
FIGURE 32.2 Molecular structure of the glucocorticoid receptor. The areas associated with the functions of transactivation, DNA binding, ligand binding, nuclear localization, dimerization, and Hsp90 binding are shown.

sion of 11β-hydroxysteroid dehydrogenase (11β-HSD), an enzyme that converts the active form of steroids, for example, cortisol and corticosterone, into the inactive form, for example, cortisone and 11-dehydrocortisone (74,75,*76*).

The glucocorticoid receptor (NR3C1) is a member of the steroid and thyroid hormone receptor superfamily, which also includes the receptors for progesterone, estrogen, mineralocorticoid, and thyroid hormones. These receptors can essentially be thought of as ligand-dependent transcription factors that mediate the endpoint tissue effects of such hormones (77). The nuclear hormone receptors all share a common three-domain structure (Figure 32.2) consisting of an N-terminal transactivation domain, a central DNA-binding domain (DBD), and a C-terminal ligand-binding domain (LDB) (78,79).

Circulating glucocorticoids are bound to cortisol-binding globulin (CBG) or albumin in the peripheral blood stream. Glucocorticoids are small hydrophobic molecules that can enter the cell mainly by passive diffusion, although evidence exists for some active transport processes *(80)*. GR is located in the cytoplasm and held in a conformation accessible to the ligand by a multiprotein complex containing Hsp90 and immunophilins. On activation by ligand binding, GR dissociates from the Hsp complex, dimerizes, and translocates to the nucleus, where it binds as a homodimer to a specific DNA sequence—hormone response element (HRE) or glucocorticoid response element (GRE). GR can modulate gene expression, either upregulating or downregulating target genes, by interacting with many coactivators or corepressors (Figure 32.3) (78,*81*,82). Repression of target genes by GR can occur via a negative glucocorticoid response element (nGRE), for example, the bovine prolactin gene and the POMC gene (83,*84*,85), but primarily occurs by interaction with other transcription factors, such as activator protein-1 (AP-1) and nuclear factor-kappa B (NF-κB) (82,86,87,*88*,89). Similarly GR activity can be repressed by AP-1 and NF-κB (*90*,91).

The presence of other receptors that also bind glucocorticoids would affect glucocorticoid responses. Such receptors include the mineralocorticoid receptor and an inactive splice variant of the glucocorticoid receptor, GRβ, which
FIGURE 32.3 Molecular mechanisms of glucocorticoid effects on immune cell function. Schematic diagram of the mechanism of action of the glucocorticoid receptor, including interactions with the NF-κB and AP-1 pathways. Dotted lines represent repressive pathways.

differs in the C-terminal LBD (92). Like GR, GRβ is also found in the cytoplasm complexed to hsp90, but, in addition, it is also located in the nucleus regardless of ligand status. Due to a unique 15–amino acid C-terminus, GRβ is unable to bind ligand or activate gene transcription. It has been suggested that GRβ forms transcriptionally inactive heterodimers with GRα, thereby acting as a dominant negative receptor or, effectively, as a GR antagonist *in vitro* (*93–98*,99). However, this mechanism is still under dispute because other studies have shown no effect of GRβ on GRα-mediated transactivation or transrepression (100,*101*,102,*103*). Monocytes and T cells exhibit differential GR sensitivity, and this has been suggested to be due to the differential expression of GRβ (104). GRβ has also been shown to repress MR (105).

Effects of Glucocorticoids on Immune Responses

Pharmacologic and physiologic doses or forms of glucocorticoids exhibit very different responses. Physiologic doses of glucocorticoids modulate transcription of inflammatory genes, whereas pharmacologic doses totally suppress the inflammatory response (106). In addition, different immune responses are elicited by synthetic glucocorticoids, such as dexamethasone, compared to natural glucocorticoids, such as hydrocortisone. For example, dexamethasone exerts a greater suppression on IL-12 than does hydrocortisone, consistent with the greater affinity of dexamethasone than hydrocortisone for GR (107). Physiologic doses of the natural glucocorticoid corticosterone have been shown to have immunoenhancing effects in skin delayed-type hypersensitivity (DTH) in rats. However, if the dose of corticosterone is increased to pharmacologic concentrations or the pharmacologic glucocorticoid dexamethasone is used, immunosuppressive effects are observed (108). This suggests that acute administration of a natural glucocorticoid is immunoenhancing, whereas chronic administration of a natural glucocorticoid or administration of a pharmacologic glucocorticoid is immunosuppressive. This is in agreement with the observation that acute stress can be beneficial, for example, in enhancement of immune function, whereas chronic stress is detrimental to health, for example, in enhancing susceptibility to infections and impaired wound healing (109,*110–114*,115,*116–118*).

A wide variety of immune genes and immune cell functions are regulated by glucocorticoids through GR and the molecular mechanisms described earlier. For example, glucocorticoids modulate gene expression of cytokines,

▌**TABLE 32.1 Summary of Immune-Related Genes Regulated by Glucocorticoids**

Increase	Decrease
Cytokines	**Cytokines**
IL-4, IL-10, IL-RI, IL-1 receptor antagonist	IL-1, IL-2, IL-3, IL-4, IL-5, IL-6, IL-8, IL-11, IL-12, IL-13, TNFα, GM-CSF, IFNγ
	Chemokines
	RANTES, eotaxin, MIPα, MCP-1, MCP-2, MCP-3, CINC/gro
Inflammatory mediators	**Inflammatory mediators**
Lipocortin-1 (annexin-1), SLPI, MKP-1	Prostaglandins, NO, NOS II, iNOS, COX-2, cPLA$_2$
	Adhesion molecules
	ICAM-1, ELAM-1, VCAM-1, E-selectin, L-selectin
Receptors	**Receptors**
β_2-Adrenoceptor	IL-2R, NK$_1$R, NK$_2$R, IL-4Rα
IκBα	

CINC, cytokine-induced neutrophil chemoattractant; COX-2, cyclooxygenase type 2; cPLA$_2$, cytosolic phospholipase A$_2$; ELAM-1, endothelial-leukocyte adhesion molecule-1; GM-CSF, granulocyte-macrophage colony-stimulating factor; ICAM-1, intracellular adhesion molecule-1; INFγ, interferon-γ; iNOS, inducible nitric oxide synthase; IL, interleukin; NO, nitric oxide; NOS II, nitric oxide synthase II; MCP, monocyte chemoattractant protein; MKP-1, mitogen-activated protein kinase phosphatase-1; SLPI, secretory leukocyte protease inhibitor; TNFα, tissue necrosis factor-α; VCAM-1; vascular adhesion molecule-1.

adhesion molecules, chemoattractants, inflammatory mediators, and other inflammatory molecules (Table 32.1); for a comprehensive review see Webster et al. (119).

Cytokines

In general, proinflammatory cytokine gene expression is repressed by glucocorticoids, for example, IL-1 (*120,121*, 122), IL-2 (123), IL-5 (124,*125*,126,*127*), IL-6 (*128,129*,130, 131), IL-8 (131,132,*133,134*), IL-11 (135), IL-12 (*136,137*, 138,139), tumor necrosis factor-α (TNFα) (*140,141*,142), interferon-γ (IFNγ) (123,143) and granulocyte-macrophage colony-stimulating factor (GM-CSF) (131,*144*,145), whereas antiinflammatory cytokine expression is upregulated, for example, IL-4 (*125,146*,147) and IL-10 (143,148).

Regulation of cytokine expression by glucocorticoids can also be achieved by modulation of mRNA stabilization, for example, IL-1β (*120,121*,122), IL-5 (124), IL-8 (132), and IL-11 (135); modulation of receptors and decoy receptor expression, for example, IL-1R II (*149,150*,151,*152*), IL-1 receptor antagonist (153),and IL-12R (*136,137*,138); regulation of translation, for example, TNFα (*140*,142); or modulation of cytokine signaling pathways, for example, dexamethasone inhibition of IL-2 signaling via the Janus

kinase (Jak)–signal transducers and activators of transcription (STAT) cascade (154). As mentioned, glucocorticoids are generally thought to upregulate antiinflammatory cytokines; however, there are some specific cell- and dose-dependent effects. For example, IL-10 is upregulated by pharmacologic doses of glucocorticoids, whereas physiologic doses suppress IL-10 (143,148). IL-4 is induced by physiologic concentrations of glucocorticoids in the lymph nodes and spleen of mice (*155*,156) but is downregulated in T cells by high stress levels of dexamethasone (123).

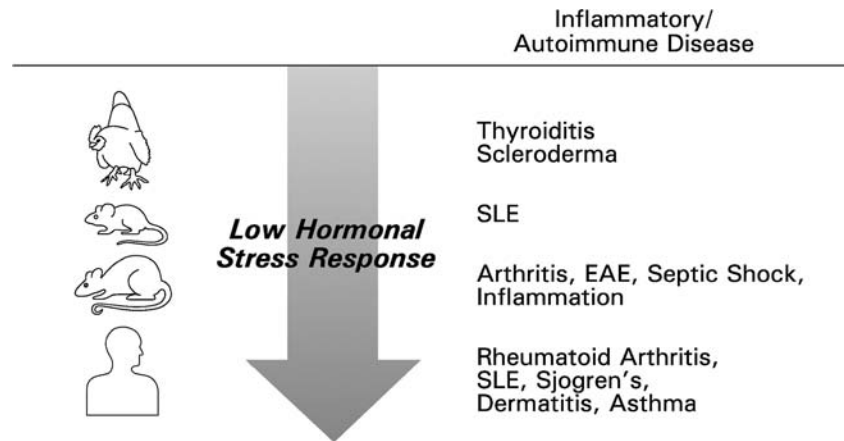
Modulation of cytokine expression by glucocorticoids causes a shift from a T helper (Th) 1 (cellular immunity) to a Th2 (humoral immunity) pattern of immunity. This is evident in some autoimmune diseases, such as rheumatoid arthritis, multiple sclerosis (MS), and type 1 diabetes mellitus, where a shift toward Th1 immunity has been observed, however, in systemic lupus erythematosus (SLE) there is a shift toward Th2 immunity (*136*,157,158). In cases of excessive glucocorticoid production, for example, in animal models with a hyperactive HPA axis (F344/N rats) or in women in the third trimester of pregnancy, a relative resistance to Th1-associated autoimmune diseases has been described (158). However, in cases of low glucocorticoid production, for example, animals lacking glucocorticoids or exhibiting a hypoactive HPA axis (LEW/N rats), susceptibility to Th1-associated autoimmune diseases has been described (*159*,160).

Cell Adhesion Molecules and Chemoattractants

The proteins involved in the attraction and adhesion of leukocytes to areas of inflammation are also downregulated by glucocorticoids. These include intracellular adhesion molecule-1 (ICAM-1) (91,*161,162*,163,164,*165*), endothelial-leukocyte adhesion molecule-1 (ELAM-1) (164), vascular adhesion molecule-1 (VCAM-1) (*165,166*, 167), E-selectin (168,*169*), L-selectin (*170*,171), cytokine-induced neutrophil chemoattractant (CINC)/gro (172), eotaxin (*173,174*), RANTES (regulated on activation normal T cell expressed and secreted) (175), and monocyte chemoattractant protein-1 (MCP-1), MCP-2, and MCP-3 (176,*177–179*).

Inflammatory Mediators

Glucocorticoids also suppress the production of inflammatory mediators, such as prostaglandins and nitric oxide (NO). Glucocorticoids inhibit prostaglandin synthesis at multiple stages; they repress expression of the key enzymes cytosolic phospholipase A$_2$ (PLA$_2$) and cyclooxygenase type 2 (COX-2) (180,*181,182*) and induce lipocortin-1 (or annexin-1), an inhibitor of arachadonic acid release (*183*,184,*185*). NO is suppressed by glucocorticoids by repression of cytokine induction of nitric oxide synthase II (NOS II) (186) and inhibition of inducible nitric oxide

FIGURE 32.4 Blunted hypothalamic-pituitary-adrenal (HPA) axis associated with autoimmune/inflammatory disease. The diagram shows animal models and human studies in which a blunted HPA axis has been found to be associated with autoimmune/inflammatory disease.


synthase (iNOS) gene transcription (*187,188*,189). In addition, secretory leukocyte protease inhibitor (SLPI), an inflammatory gene, is enhanced by GR (82,190), and mitogen-activated protein kinase (MAPK) phosphatase-1 (MKP-1), an inhibitor of the MAPK pathways that induce inflammatory genes, is induced by GR (*191*,192,*193–196*).

Other Inflammatory Response Factors

Glucocorticoids also regulate several receptors involved in the regulation of the immune system. For example, glucocorticoids upregulate the β_2-adrenergic receptor, which is involved in the adrenergic control of the immune system (197,*198,199*), and downregulate the NK_1 receptor, the receptor for substance P (200), and the NK_2 receptor (201).

DYSREGULATION OF HPA AXIS IN THE PATHOGENESIS OF IMMUNE-RELATED DISEASES

Fluctuations in glucocorticoid levels, such as during exercise and with circadian rhythm, have been shown to be associated with changes in cytokine levels and production by leukocytes (202,*203–205*), suggesting a role of physiologic glucocorticoids in the regulation of the immune system. However, animal models have provided the strongest evidence that endogenous glucocorticoids are essential physiologic regulators of the immune response and that disruption of this regulation plays a role in inflammatory/autoimmune disease.

Blunted HPA Axis Associated with Immune Disease: Animal Models

Blunted HPA axis responses have been shown in a number of animal models that are predisposed to autoimmune disease, such as the obese strain (OS) chicken (a model for autoimmune thyroiditis) (206); certain mouse SLE models (MRL strain but not NZB/NZW) (*207*,208); and the inbred Lewis rat strain (LEW/N) (160) (Figure 32.4). For a review of animal models of inflammatory diseases see Jafarian-Tehrani and Sternberg (209) and Tonelli et al. (160).

Two histocompatible inbred rat strains—LEW/N and Fischer (F344/N) rats—that exhibit differential HPA axis responsiveness and differential susceptibility and resistance to autoimmune/inflammatory disease have been extensively used to examine this relationship between HPA axis responses and autoimmune/inflammatory disease. LEW/N rats exhibit a blunted HPA response on stimulation and are highly susceptible to development of a wide range of autoimmune/inflammatory diseases in response to a variety of antigenic or proinflammatory stimuli, whereas F344/N rats have a hyperactive HPA axis and are relatively resistant to such disease on exposure to the same stimuli (210–213,*214*). For example, LEW/N rats, but not F344/N rats, develop experimental allergic encephalomyelitis (EAE) on immunization with myelin basic protein (215) and develop arthritis in response to heat-killed *Mycobacterium tuberculosis* in adjuvant or streptococcal cell walls and inflammation in response to carrageenan (212,213,216,*217*). The molecules involved in the HPA axis regulation and glucocorticoid action have been shown to be different in these two rat strains, for example, hypothalamic CRH (213), pro-opiomelanocortin (POMC) (211), CBG (210), and GR expression and activation (210,218,219).

In a model for Hashimoto's thyroiditis, OS chickens, which have a blunted HPA axis, spontaneous develop thyroiditis (206). These chickens also have increased CBG, which results in decreased free corticosterone levels (220). In a model for human scleroderma, UCD-200 chickens exhibit an ACTH-hyporesponsive adrenal gland (221). Blunted HPA axis responses have also been shown in MRP lupus-prone mice (*207*,208) but not other strains, such as NZB. These associations between a blunted HPA axis and susceptibility to inflammatory/autoimmune disease do not prove cause and effect. Intervention studies, such as those described later, must be performed to do this.

▌**TABLE 32.2 Increased Mortality Rates After Intervention of Hypothalamic-Pituitary-Adrenal (HPA) Axis and Subsequent Survival After Glucocorticoid Replacement**

Infection/Disease	HPA Axis Intervention	Mortality Rate (%)	Mortality Rate After Corticosterone Replacement (%)	Reference
Streptococcal cell wall–induced arthritis	Glucocorticoid receptor antagonist RU486	100	13	212
Myelin basic protein–induced EAE	Adrenalectomy	80	22	229
Salmonella	Hypophysectomy	100	5	227

Anthrax LeTx	Adrenalectomy	90	N/A	231

EAE, experimental allergic encephalomyelitis; LeTx, lethal toxin; MCMV, murine cytomegalovirus; N/A, not available.

It must be emphasized that HPA axis responsiveness is just one variable among many factors that contribute to overall susceptibility and resistance to such complex autoimmune diseases. Genetic linkage studies in rat models have identified genes in more than 20 regions on 15 chromosomes involved in susceptibility and resistance to inflammatory arthritis (*222,223,224,225*). These include many genes that are related to immunity and some neuroendocrine genes but also many that are unknown. Similarly, in humans there are likely to be many factors that contribute to susceptibility/resistance to autoimmune/inflammatory disease.

Interruption of the HPA axis, either surgically or pharmacologically, can alter the course and enhance the severity of inducible autoimmune/inflammatory disease in rodents. This link between the requirement of an intact HPA axis for survival from exposure to proinflammatory stimuli is further enforced by the demonstration that the inflammatory disease is attenuated and mortality rates deceased in these animal models by reconstitution of the HPA axis, pharmacologically with glucocorticoids, or surgically by intracerebral fetal hypothalamic tissue transplantation. Administration of the glucocorticoid receptor antagonist RU486 together streptococcal cell walls in otherwise inflammatory resistant F344/N rats results in severe arthritis and high mortality rates that can be reversed by low-dose dexamethasone treatment (212) or prevented by intracerebroventricular transplantation of F344/N hypothalamic tissue (226). Increased mortality rates after *Salmonella typhimurium* infection were also observed in hypophysectomized rats compared to nonhypophysectomized animals (227). Similarly, adrenalectomy resulted in increased mortality following murine cytomegalovirus (MCMV) virus infection, which could be reversed by glucocorticoid treatment (228), and in myelin basic protein (MBP)–induced experimental allergic EAE in LEW/N rats (229). Increased mortality rates in response to Shiga toxin (230) and *Bacillus anthracis* lethal toxin (231) have also been observed in adrenalectomized animals (Table 32.2). These animal models provide evidence for the critical importance of an intact HPA axis and glucocorticoids in protection against septic shock after exposure to a wide range of antigenic, proinflammatory or infectious stimuli.

Blunted HPA Axis Associated with Immune Disease: Human Disease

A blunted HPA axis with resultant low glucocorticoid levels or low glucocorticoid responses has been associated with a number of inflammatory diseases in humans. For example, dysregulation of HPA axis and glucocorticoid responses have been shown in rheumatoid arthritis (*232,233,234,235–237,238*), SLE (*234,239*), Sjogren's syndrome (*234,240,241*), allergic asthma and atopic skin disease (*242,243,244*), chronic fatigue syndrome (CFS) (*245,246,247,248,249*), fibromyalgia (*234,246,250*), multiple sclerosis (*251,252,253,254*), and inflammatory and irritable bowel syndrome (*255,256*) (Table 32.3).

Conversely, excessive stimulation of the HPA axis and chronically elevated glucocorticoid levels that result from chronic stress situations, such as those experienced by caregivers of Alzheimer's patients, students taking exams,

▌**TABLE 32.3 Human Diseases That Exhibit a Blunted Hypothalamic-Pituitary-Adrenal Axis**

couples during marital conflict, and Army Rangers undergoing extreme exercise, have been associated with enhanced susceptibility to viral infection, prolonged wound healing, or decreased antibody production after vaccination (*114*,115,*116*,257,*258*,*259*,260).

HPA axis responses can be measured in patients by stimulation of the HPA axis using, for example, exogenous hormones (ovine CRH, AVP, ACTH) (*247*,253), physical stress (exercise) (*203*,248), psychosocial stress (the Trier Social Stress Test [TSST], which involves public speaking and mental arithmetic) (*242*,*244*,248), or insulin hypoglycemia (*239*,248).

Glucocorticoid Resistance in Immune Disease

Glucocorticoid resistance is a phenomenon exhibited in many autoimmune/inflammatory diseases. This resistance can be hereditary or acquired. The molecular mechanisms by which glucocorticoid resistance can occur are described in the following.

Glucocorticoid Receptor

Several mutations and polymorphisms have been found in the glucocorticoid receptor associated with defective glucocorticoid signaling and glucocorticoid resistance. Familial glucocorticoid resistance, a hereditary disease, results from mutations of GR that may result in decreased number, stability, nuclear translocation, or ligand binding of GR. Three different point mutations in the LBD of GR—one in the hinge region—and a deletion in the LBD have been identified in families with familial glucocorticoid resistance [for a review see Charmandari et al. (261)]. Some GR mutations and polymorphisms have been found in other diseases and glucocorticoid resistance states. For example, a phase shift mutation in GR has been described in patients with lupus nephritis (262), and a mutation in the LBD has been found in patients with lupus (263). A mutant GR (amino acid 559 Ile-Asn) that cannot translocate to the nucleus and therefore prevents translocation of wild-type GR was found in a heterozygotic patient with severe glucocorticoid resistance (264). The majority of GR mutations found in glucocorticoid resistance patients affect ligand binding; however, other mutations in GR could affect GR function. A mutation in the DBD of GR has been described in a patient with primary cortisol resistance (*265*,266). Recently, a novel C-terminal mutation that interferes with GR–p160 coactivator interactions was found in a French family with familial glucocorticoid resistance (267). Another mutant has been described that prevented GR–glucocorticoid receptor interacting protein-1 (GRIP1) binding (268). However, not all GR polymorphisms result in glucocorticoid resistance. For example, a polymorphism in GR (codon 363) has been associated with increased sensitivity to glucocorticoids (269), but five polymorphisms in GR (including the one at codon 363) have been described in a normal population (270).

In some patients with glucocorticoid resistance no mutation in GR has been detected, and it is plausible that in these patients there is a defect in another aspect of GR function (271). Defects in other aspects of GR signaling may also result in glucocorticoid resistance without a mutation in the receptor. Decreased glucocorticoid receptor numbers may play a role in glucocorticoid resistance, as is seen in pulmonary fibrosis (272). Decreased ligand affinity has been described in Cushing's syndrome (273). Defective GR transactivation and reduced stability of the receptor can be the result of a mutation in the phosphorylation sites on GR (274). Although no such mutation has yet been identified, phosphorylation of GR has been implicated in a group of steroid-resistant asthma patients. In this case, IL-2 and IL-4 have been suggested to activate p38 MAPK phosphorylation of GR, resulting in reduced nuclear GR activity and glucocorticoid resistance in these patients (275). A defect in GR nuclear translocation has been described in a group of glucocorticoid resistance patients (276). In another group, nuclear translocation was normal but there was a defect in histone acetylation (276).

Glucocorticoid resistance can occur without a mutation in wild-type GR by differences in the expression of the splice variant and proposed dominant repressor GRβ. This could potentially contribute to enhanced inflammatory susceptibility in these subjects through relative antagonism of the GR and resultant relative glucocorticoid resistance. However, the physiologic significance of GRβ as an endogenous GR antagonist is not clear; *in vivo* GRβ exists in a very low ratio compared to the fully active GRα (277). Nonetheless, supporting the physiologic relevance of GRβ abnormalities in disease is the finding of increased expression of GRβ relative to GRα, which has been described in other diseases, including rheumatoid arthritis (*278*,*279*,280), asthma (*281*,*282*,283,*284–288*,289), Cushing's syndrome (290), Crohn's disease (291), ulcerative colitis (*292*,293), inflammatory bowel disease (294), chronic lymphocytic leukemia (295), septic shock (280), ankylosing spondylitis (296), and nasal polyposis disease (*297*,298). Another splice variant, GRγ, has an insertion of three bases in the DBD of GR. This insertion decreases the transactivation activity of GR (299). However, it has been suggested that it does not play a role in glucocorticoid sensitivity (300).

Cortisol-binding Globulin

CBG limits the amount of free cortisol available in the blood. Therefore, theoretically, changes in the expression of this protein or in its binding capacity can also affect the availability of cortisol and glucocorticoid responses. Changes in CBG have not been overly implicated in

patients with glucocorticoid resistance. However, increased expression of CBG has been suggested to be responsible for the partial or complete resistance to steroids described in some patients with long-standing Crohn's disease (301). In chronic fatigue syndrome patients, a similar increase in CBG levels has also been described (250).

11β-Hydroxysteroid Dehydrogenase

Glucocorticoid availability can also be regulated by other factors, such as the expression of 11β-HSD, an enzyme that converts the active form of steroids, for example, cortisol and corticosterone, into the inactive form, for example, cortisone and 11-dehydrocortisone (74,75). Changes in the levels of this enzyme could, therefore, cause differences in circulating or tissue glucocorticoid concentrations and glucocorticoid resistance (302). For example, decreased plasma cortisol levels were noted in obese men as a result of type I 11β-HSB impairment (303), and decreased 11β-HSD mRNA was shown in ulcerative colitis (304).

Cofactors

GR is able to influence gene transcription by interacting with the basal transcription machinery through many cofactors, coactivators, or corepressors. Thus, defects in these cofactors could also affect GR function. However, no mutations in cofactors have been found associated with glucocorticoid resistance. However, one interesting recent study showed that a viral protein acting as a cofactor can alter GR responses. The human immunodeficiency virus (HIV-1) accessory protein virion-associated protein (Vpr) binds directly to GR and p300/cAMP-response element binding protein (CREB)–binding protein (CBP) cofactors, thereby functioning as an adapter protein between these components and enhancing GR-mediated gene transaction. This explains the observed glucocorticoid-hypersensitive state associated with HIV-1 infection (305,306). Vpr has been shown to enhance the endogenous glucocorticoid suppression of IL-12 but not IL-10 in human peripheral blood monocytes (307). There is one example in which a cofactor defect is thought to be involved in glucocorticoid resistance in two sisters with resistance to multiple steroids (308,309). Smoking has been shown to cause oxidative stress, and this can reduce the expression of histone deacetylases (HDACs). There is a decrease in HDAC2 in chronic obstructive pulmonary disease, a glucocorticoid-resistant disease (310,311).

Transport Proteins

Intracellular ligand concentration is yet another factor that if altered could affect GR function. Although glucocorticoids are believed passively to diffuse into cells, evidence for an active transport process out of cells ex-

ists. Multidrug resistance (MDR) proteins, members of the ATP binding cassette (ABC) family of transporters (312), have been shown to transport glucocorticoids out of cells (313,314,315,316,317), and their involvement in glucocorticoid-unresponsive disease states has begun to be investigated. Increased expression of the human MDR1 (ABCB1) has been shown in patients with inflammatory bowel disease who have failed medical therapy (318,319,320,321,322) and also in patients with rheumatoid arthritis (323), Crohn's disease (320), and SLE (324). The novel orphan receptor pregnane X receptor (PXR) (also known as steroid and xenobiotic receptor [SXR]) or PXR ligands have been shown to be regulated by these transporter proteins (325–328). This receptor is activated by many ligands, including glucocorticoids (329), suggesting a possible mechanism by which acquired glucocorticoid resistance during long-term therapy might develop.

EFFECTS OF INFECTION ON HPA AXIS AND GR FUNCTION

Another possible mechanism by which glucocorticoid resistance may occur is through bacterial or viral infections. As one might expect, such infections activate the HPA axis, but, as will be discussed, some bacterial and viral proteins are known directly to interfere with GR signaling. We have recently shown that the anthrax lethal toxin is also able to repress GR signaling, as will be described.

Effect of Infection as a Stimulus to the HPA Axis

Many bacterial and viral infections result in an activation of the HPA axis and increased glucocorticoid release. These include endotoxins, such as lipopolysaccharides, *Mycoplasma fermentans*, *Clostridium difficile* toxin A, Shiga toxin 2, tetanus toxoid, bacterial superantigens, MCMV, lymphocytic choriomeningitis virus (LCMV), herpes simplex virus type 1 (HSV-1), the Sindbis virus, Newcastle disease virus (NDV), influenza virus, and HIV. This activation of the HPA axis is probably the result of the action of inflammatory mediators such as cytokines. In some cases the inflammatory mediators have been identified. Activation of the HPA axis will not be further discussed here; we recently reviewed it elsewhere (330) (Table 32.4).

Direct Effects of Infection on GR Signaling

Several bacterial infections/proteins have been shown to influence GR signaling. These include endotoxin (331,332–336), *Chlamydia pneumoniae* (337), bacterial superantigens (338), Shiga toxin 2 (230), and the anthrax lethal toxin (231,339,240,341) (Table 32.5). In addition, some viral proteins also interfere with GR signaling. The best studied is

▌ **TABLE 32.4 Bacterial and Viral Infections That Activate the Hypothalamic-Pituitary-Adrenal Axis**

Bacterial	Viral
Lipopolysaccharide	Murine cytomegalovirus
Endotoxin	Lymphocytic choriomeningitis virus
Mycoplasma fermentans	Poly(I:C)
Clostridium difficile toxin A	HIV
Shiga toxin 2	Herpes simplex virus type 1
Tetanus toxoid	Sindbis virus
Staphylococcal enterotoxin A	Newcastle disease virus
Staphylococcal enterotoxin B	Influenza virus

▌ **TABLE 32.6 Viruses That Interact with the Glucocorticoid Receptor (GR)**

Virus/Viral Product	Effect	Ref.
HIV (Vpr)	Enhances GR activity (acts as cofactor)	*305*,306,307
Poxvirus MC protein MC013L	Inhibits GR activity	342
Influenza virus	Increases GR activity	343
HSV-1	Increases GR number and activity	344
Epstein-Barr virus	Increases GR number	*345*,346
Murine cytomegalovirus	Decreases GR binding in spleen	347

the HIV protein Vpr, which we have previously described. Others include the poxvirus MC protein MC013L (342), influenza virus (343), HSV-1 (344), Epstein-Barr virus (EBV) (*345*,346), and MCMV (347) (Table 32.6). For a comprehensive review of these interactions see our recent review article (330).

Effect of Anthrax Lethal Toxin on GR

We recently showed that a bacterial toxin—the anthrax lethal toxin (LeTx)—represses the glucocorticoid receptor and other members of the nuclear hormone receptor superfamily, such as the progesterone receptor. LeTx is a noncompetitive inhibitor that does not affect GR numbers or interfere with ligand binding or nuclear translocation. It does prevent GR binding to DNA in the context of a na-

tive gene. We have suggested that LeTx interferes with one of the many cofactors involved in GR signaling (340,341). Adrenalectomy has been shown to convert a LeTx-resistant animal into one that is susceptible to lethality from LeTx, suggesting the importance of an intact HPA axis response and glucocorticoids in protection from the lethal effects of LeTx (231). Further studies are underway further to understand these effects and to determine the generalizability of this phenomenon to other bacterial toxins and its role in contributing to shock.

CONCLUSION

A bidirectional regulation occurs between the CNS and immune system. Perturbations of this balance result in disease. An intact HPA axis and glucocorticoid signaling are essential for survival from a number of proinflammatory insults. Dysregulation of this HPA axis has been shown in many autoimmune/inflammatory diseases, and defects in all aspects of GR signaling can result in glucocorticoid resistance. In addition, bacterial or viral infections can also affect GR signaling. Thus, all aspects of this bidirectional communication should be considered when assessing risk factors for immune-mediated diseases.

▌ **TABLE 32.5 Bacteria That Interact with the Glucocorticoid Receptor (GR)**

Bacteria/Bacterial Product	Effect	Ref.
Endotoxin	GR downregulation	*331*,332
	Downregulation of leukocyte GR number	333
	Inhibition of dexamethasone binding (rat liver nuclei)	334
	Inhibition of dexamethasone binding (peritoneal macrophages)	335
	Increased GR number, reduced affinity (bronchial epithelial cells)	336
Chlamydia pneumoniae	Activation of GR	337
Superantigen SEB	Induction of GRβ	338
Shiga toxin 2	Increased GR expression	230
Anthrax lethal toxin	Repression of GR activity	231,*339*, 340,341

Complement

Cornelia Speth, Wolfgang M. Prodinger, Reinhard Würzner, Heribert Stoiber, and Manfred P. Dierich

OVERVIEW

Complement as a Functional System

Complement, with its more than 35 plasma or membrane proteins (Table 33.1), serves as an auxiliary system in immunity and antimicrobial defense. Its activation is due predominantly to a cascade of proteolytic steps, performed by serine protease domains in some of the components. Three different pathways of activation are distinguished (Figure 33.1), triggered by either target-bound antibody (the classical pathway), by microbial repetitive polysaccharide structures (the lectin pathway), or by recognition of other "foreign" surface structures (the alternative pathway). The alternative pathway also amplifies C3 activation triggered by the other pathways. All three merge in the pivotal activation of C3 and, subsequently, of C5 by highly specific enzymatic complexes, so-called convertases. In the common terminal pathway, downstream of C5 further complement components are activated in a nonproteolytic manner and assembled into the membrane attack complex (MAC). The entire powerful activation machinery is controlled redundantly by >10 negative regulators.

Complement can be activated by a variety of stimuli, such as immune complexes, appearance of apoptotic cells, presence of non–self-tissue (e.g., after transplantation) and microbial surface patterns directly (Figure 33.2). The broad spectrum of effector functions includes clearance of immune complexes or apoptotic cells, enhancement of inflammation (e.g., by the anaphylatoxins C3a and C5a), and cooperation with other host defense mechanisms as well as direct antimicrobial attack with subsequent opsonization and/or lysis.

Historical Roots

In the second half of the nineteenth century a first concept of complement emerged with the distinction of "alexin," a heat-labile fraction in normal serum that, in addition to antibody, is necessary for killing of bacteria. The term *complement* was introduced by Paul Ehrlich in 1899. In the 1950s, Louis Pillemer advanced the concept of complement, which at that time comprised primarily the classical pathway, by postulating an antibody-independent mechanism of activation (1) that is now referred to as the alternative pathway. As in archeological excavations, however, the oldest layer is often discovered last: The third and phylogenetically old lectin pathway was discovered a little more than 10 years ago and, despite recent cloning of several new components, remains incompletely understood.

Phylogenetic Aspects

It is difficult to define exactly when the complement system emerged in evolution, because the precise consensus definition of early precursor molecules may be ambiguous. At the preceding stage of complement evolution, between emergence of metazoa and emergence of deuterostomes, the individual domains used by mammalian complement components were created. Being absent from plants and yeast, primitive protostomes such as *Limulus* or the dipterans *Drosophila* and *Anopheles* possess proteins of the C3/α_2-macroglobulin superfamily of thioester proteins that are either homologues of α_2-macroglobulin (and thus unspecific protease inhibitors) or opsonins (and, as such, upregulated during infectious challenges). Between the emergence of deuterostomes and the emergence of jawed vertebrates, the unique combination of complex domain structure and proteolytic cleavage/activation sites in complement factors C3, C4, and C5 evolved, suggesting that basic functions of these complement components were established at this stage. The lectin and alternative pathways can be seen as descendants of a primordial surveillance system for microbes. At the modern stage, after emergence of jawed vertebrates and evolution of the adaptive immunity, the classical pathway was "added" and developed into a major effector mechanism for the powerful humoral immune system. This immunologic extension with the classical pathway involved gene duplication events with subsequent modification and functional divergence leading to pairs of related genes in the old (lectin or alternative) and new (classical) pathways, e.g., factor B and C2 (2).

Nomenclature

Classical and terminal pathway components were early designated C1 through C9. Notably, the (later-determined) activation sequence of the cascade is C1–C4–C2–C3–C5–C6–C7–C8–C9. Alternative pathway components are called *factors* and are distinguished by letters (factors B, D, H, I, P). Proteolytic activation of C2 through C5 produces smaller fragments and larger ones remaining in a complex required for the next activation step. The small, liberated fragments are denoted by the letter *a* (e.g., for C4, C4a), the larger ones by *b* (e.g., C4b), the notable exception being C2 (i.e., C2a is the large active fragment). Inactivation of C3b or C4b yields even smaller fragments (C4c, C4d, etc.). These must not be confused with the chains of C3 and C4 (e.g., C4α, C4β, C4γ) or isotypic proteins (e.g., C4A and C4B derived from two genetic C4 loci).

BIOSYNTHESIS OF COMPLEMENT: LOCATION AND REGULATION

The majority of plasma complement components are synthesized in the liver (3), which therefore represents the major site of complement protein synthesis. Exceptions are C1 (produced in the intestinal epithelium) and factor D (produced in adipose tissue). C7, of hepatic origin, was found to contribute less than 60% to plasma C7, with bone

▶ **TABLE 33.1 Complement Components**

Component	Molecular Weight (in kDa) of Intact Protein (Subunits)	Plasma Concentration (μg/mL)	Chromosomal Assignment
Classical pathway			
C1q	460 (6 subunits each of 3 chains: A, 26; B, 26; C, 24)	150	1p34-1p36: 3 genes for A, B, C
C1r	85	50	12p13
C1s	85	50	12p13
C4	205 (α, 97; β, 75; γ, 33)	300–600	6p21: 2 loci (*C4A*, *C4B*), MHC-III region
C2	102	20	6p21: MHC-III region
C3	185 (α, 110; β, 75)	1,200–1,300	19p13
Alternative pathway:			
Factor B	93	200	6p21: MHC-III region
Factor D	24	2	19
Properdin	Oligomers of 110, 165, 200 (monomer: 55)	25	Xp11
Lectin pathway			
MBL	200–600, i.e., 2–6 subunits (1 subunit = 3 chains, each 32)	0.05–5	10q22
M-ficolin (ficolin-1)	Oligomer (monomer: 35)	n.d.	9q34: tail to tail with L-ficolin
L-ficolin (ficolin-2, ficolin/p35)	Oligomer: up to 320 (monomer: 35)	3	9q34: tail to tail with M-ficolin
H-ficolin (ficolin-3, Hakata antigen)	Oligomer: up to 650 (monomer: 34)	18	1p35.3
MASP-1	90	2–12	3q27-3q28: splice variant of MASP-1/3 gene
MASP-2	74	0.4	1p36: splice variant of MASP-2/sMAP gene
MASP-3	94	3	3q27-3q28: splice variant of MASP-1/3 gene
sMAP/MAp19	19	n.d.	1p36: splice variant of MASP-2/sMAP gene
Terminal pathway			
C5	190 (α,115; β, 75)	80	9q33
C6	110	45	5p14-5p12: MAC gene cluster
C7	100	90	5p14-5p12: MAC gene cluster
C8	150 (α, 64; β, 64; γ, 22)	55	1p22: genes for α, β 9q22-9q32: gene for γ
C9	70	60	5p14-5p12: MAC gene cluster
Control proteins (in plasma)			
Factor I	88	35	4q25
C1-INH	105	240	11q12-11q13
Factor H	150	300–450	1q32
FHL-1	42	5–20	1q32: splice variant of Factor H/ FHL-1 gene, *RCA* gene cluster
C4bp	550 (7 α chains each 70, 1 β-chain, 45)	250	1q32: *RCA* gene cluster
S protein (vitronectin)	84	500	17q11
Clusterin (SP-40,40)	70 (2 × 35)	50	8p21-8p12
Carboxypeptidase N	280 (2 × 83 and 2 × 50)	35	8p23-8p22: 83-kDa subunit 10: 50-kDa subunit
Membrane-bound complement control proteins			
CR1 (CD35)	190–280 (due to isoforms)	—	1q32: *RCA* gene cluster
DAF (CD55)	70	—	1q32: *RCA* gene cluster
MCP (CD46)	45–70 (due to glycosylation)	—	1q32: *RCA* gene cluster
CD59	18–20	—	11p13

(*continued*)

▶ **TABLE 33.1 Complement Components** (Continued)

Component	Molecular Weight (in kDa) of Intact Protein (Subunits)	Plasma Concentration ($\mu g/mL$)	Chromosomal Assignment
Complement proteins with unclear function			
FHR-1	39 and 42 (due to glycosylation)	60	1q32: *RCA* gene cluster
FHR-2	24 and 29 (due to glycosylation)	40	1q32: *RCA* gene cluster
FHR-3	55	n.d.	1q32: *RCA* gene cluster
FHR-4A	86	n.d.	1q32: splice variant of FHR4 gene, *RCA* gene cluster
FHR4B	42	n.d.	1q32: splice variant of FHR4 gene, *RCA* gene cluster
FHR-5	80	5	1q22-1q23

MBL, mannan-binding lectin; MHC, major histocompatibility complex; MASP, MBL-associated serine protease; sMAP/MAp19, small MBL-associated protein or MBL-associated protein of 19 kDa; MAC, membrane attack complex; n.d., not determined; C1-INH, C1 inhibitor; RCA, regulator of complement activation; FHL, factor H–like protein; C4bp, C4-binding protein; CR, complement receptor; DAF, decay-accelerating factor; MCP, membrane cofactor protein; FHR, factor H–related protein.

marrow–derived cells, in particular granulocytes, representing a major alternative source (4). The local contribution of C7 may exert an even stronger modulating effect than the concentration of complement inhibitors (5).

In addition to the liver, complement components are synthesized in many cell types, such as epithelial and endothelial cells, lymphocytes, and in reproductive organs. Recently, synthesis of complement components has been demonstrated in the retina (6). Notably, production of virtually all components has been observed not only in monocytes/macrophages, but also in dendritic cells (7) and astrocytes (8). Extrahepatic complement production appears to be important: Like astrocytes or other glial cells, it is the only source for complement behind an intact blood–brain barrier. At sites of infection, effective upregulation of local complement synthesis may contribute to host defense (9). Local complement production also plays a somewhat neglected role in transplantation, promoting allograft rejection (10).

The production of plasma complement components is augmented in the acute-phase response. The main common transcriptional inducer of complement genes is IFN-γ, others being IL-1- and IL-6–type cytokines (i.e., IL-1α, IL-1β, IL-6, IL-11, and others) (11). Cell surface–bound complement regulators are expressed on a variety of tissues (3).

COMPLEMENT COMPONENTS: A NETWORK OF PROTEIN FAMILIES

Complement C3/α_2-Macroglobulin Superfamily

C3, C4, and C5 (Figures 33.1, 33.3) are derived from one ancestral protein that supposedly has served as a multispecific protease inhibitor. Detailed structural insights of C3 have been provided recently (12). A pivotal feature is an internal thioester formed during biosynthesis in C3, C4, and α_2-macroglobulin, which allows the activation-dependent formation of covalent bonds. This thioester is formed between a cysteine and a glutamine residue three positions apart (Figure 33.3) (13). In C5, no thioester is formed. C3, C4, and C5 are activated by proteolytic cleavage at a conserved peptide bond that induces a gross conformational change and new epitopes being exposed, e.g., the then-protected thioester in C3 or C4. This leads to the formation of a reactive intermediate that enables the glutamyl residue to form a covalent ester or amide bond with water or with NH_2 or OH residues of surrounding molecules. C3 and the C4B isotype of C4 possess a histidine positioned in close proximity to the thioester, which acts as the catalyst for the formation of ester bonds. In contrast, the C4A isotype lacks this histidine and preferentially forms amide bonds (14).

Proteins with Short Consensus Repeat Units

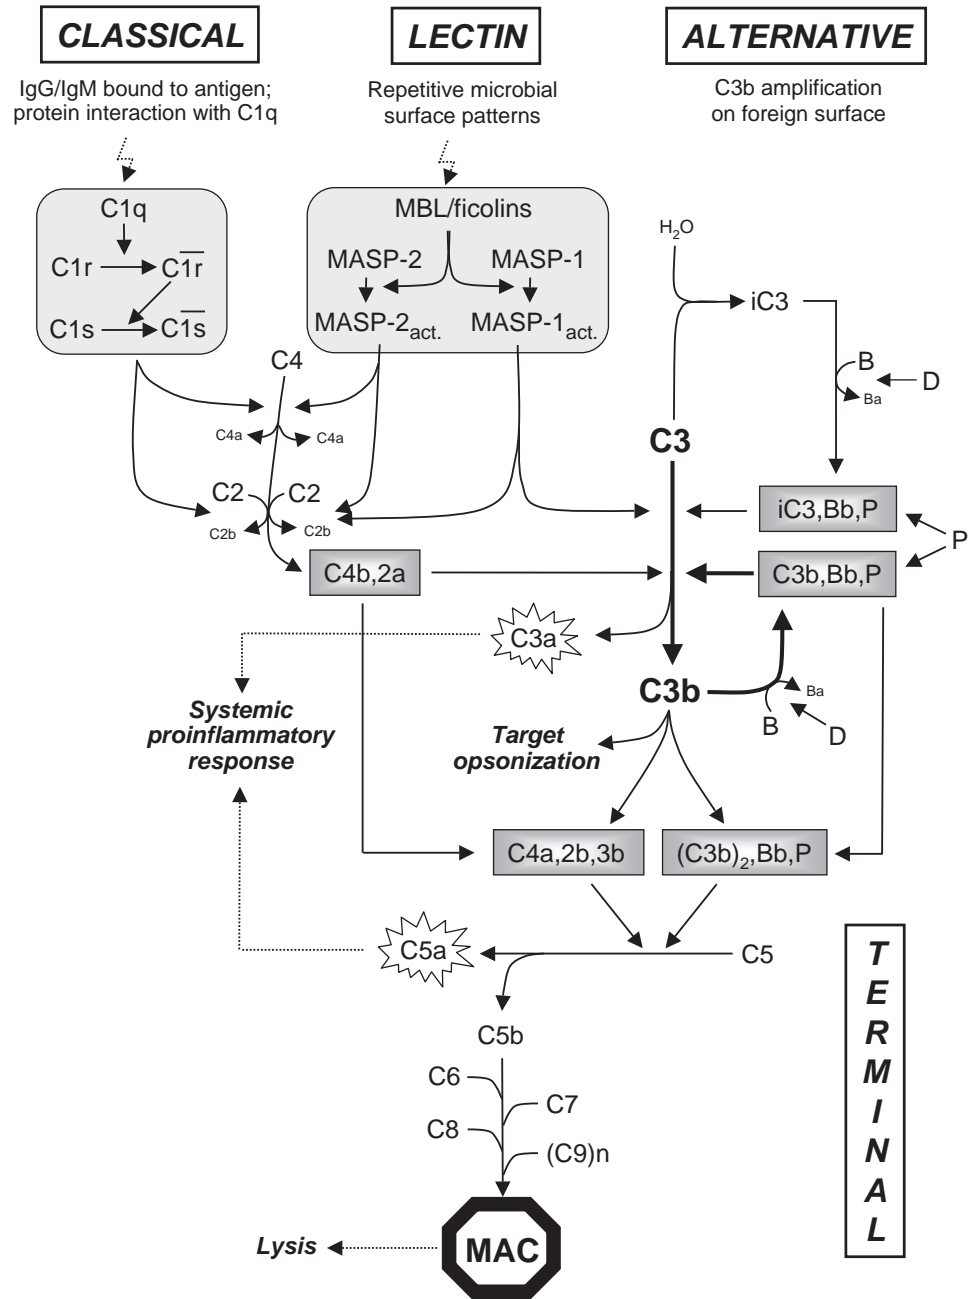
Short consensus repeats (SCRs) or, synonymously, complement control proteins (CCP) modules, are individually folding domains of about 60 amino acids displaying a β-barrel structure (15) and distinct conserved residues, e.g., tryptophane, prolines and—most important—four cysteines, which form two disulfide bonds (Cys$_1$ to Cys$_3$ and Cys$_2$ to Cys$_4$) (16). Although SCRs can be found in various noncomplement proteins (e.g., in the selectins), proteins that consist predominantly of SCRs are encoded by genes in the *R*egulator of *C*omplement *A*ctivation (*RCA*) gene cluster. The *RCA* comprises the genes for factor H and the factor H-family proteins, for C4bp, DAF, CR2, CR1, and MCP (17). The number of SCRs in these proteins ranges from 4 to 34, and some proteins possess


FIGURE 33.1 Overview of complement activation pathways (detailed explanation in the text). The C3 and C5 convertases of the pathways are boxed. The alternative-pathway amplification loop of C3b generation is indicated by bold line arrows. Note the systemic action of the anaphylatoxins in contrast to the effect of opsonization or lysis via membrane-attack complex, which occur on the target surface.

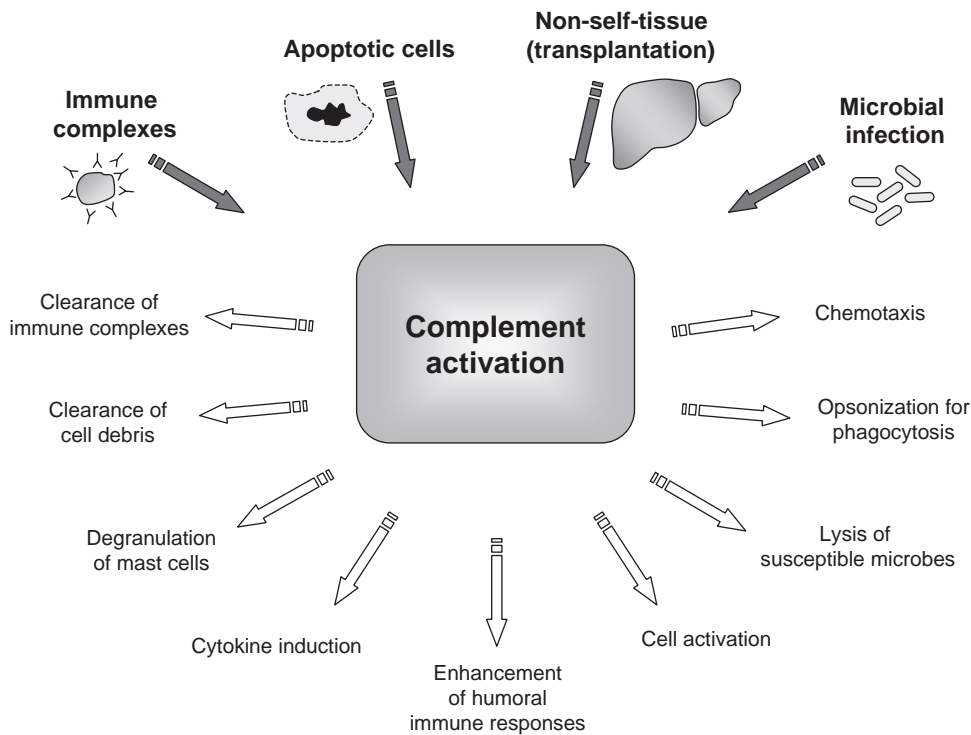
transmembrane and short intracytoplasmic parts (CR1, CR2, MCP) or glycosylphosphatidylinositol (GPI) anchors (DAF, CD59). RCA proteins are elongated in shape: e.g., CR1 extends 90 nm from the cell membrane.

The *RCA* is thought to have evolved from one ancestral prototypic SCR by duplication and gene conversion events as a family of genes for proteins controlling C3 and C4 activation. Nevertheless, the binding of activated C3 or C4 can be attributed to distinct, often adjacent, SCRs in each member. Few SCRs are present in mosaic proteins like factor B, C2, the members of the MASP-like family (C1r, C1s,

MASP-1, MASP-2, MASP-3), C6, and C7, all of which interact with thioester proteins.

Proteins with a Serine Protease Module

Proteins with serine protease activity are crucially involved in the early, amplifying steps of complement activation. Serine protease domains are present in the two homologous proteins C2 and factor B, and, furthermore, in factor I, factor D, and in the members of the MASP-like family. The latter proteins contain a serine protease domain


together with two CUB domains,[1] an epidermal growth factor–like (EGF-like) domain, and two SCRs.

Protein Motifs Found in Terminal Pathway Components

C6 through C9 have an amphiphilic character that allows them to act in plasma and on lipid membranes, an important feature for MAC formation. As true mosaic proteins, they assemble a variety of modules in a characteristic sequence: thrombospondin type 1 repeats (TSRs), also found in the extracellular matrix protein thrombospondin and in properdin; a low-density lipoprotein receptor (LDLR) domain; a conserved cysteine-poor region (18) also found in perforin; an EGF module; SCRs; and factor I modules (FIMs). Functional activity is preserved even in the absence of the latter, at least for C6 (19).

ACTIVATION OF C3: THE CRUCIAL STEP

The three aforementioned pathways lead to activation of C3 (Figure 33.1). The physiologically relevant activators of C3 are the C3 convertases, although proteases such as plasmin can activate C3 *in vitro*. Four distinct protein entities act on C3 or C3b:

---

[1] CUB domains are widespread protein modules and are found (among others) in complement C1r/C1s, sea urchin EGF (Uegf), and bone morphogenetic protein-1.

1. *The C3- convertases.* C3b,Bb and C4b,2a consist of proteins with an activated serine protease domain in complex with C3b and C4b, respectively; each cleaves C3 into C3a and C3b.
2. *Factor I.* A plasma serine protease specific only for C3b and C4b, factor I inactivates C3b and C4b by cleaving them into iC3b and iC4b, respectively. Factor I requires a cofactor.
3. *RCA family proteins composed of SCRs.* These negatively regulate C3 and C4 activation by disintegrating the C3 convertases and serving as cofactors for factor I.
4. *The receptors for fragments of C3.* this heterogeneous group comprises integrins, seven-transmembrane receptors, and RCA-family members: They use C3-activation products to mediate induction of phagocytosis or chemotaxis.

The native C3 molecule becomes cleaved at a conserved arginine residue in the α chain into C3a and C3b. The peptide C3a (77 amino acids) is a potent anaphylatoxin. The large "nascent" C3b has a half-life of 60 microseconds, during which it changes its conformation, exposes the internal thioester bond, and binds through the now highly reactive thioester to nearby nucleophils, e.g., OH groups of any surrounding molecule, including H_2O.

ACTIVATION VIA THE CLASSICAL PATHWAY

C1, C4, C2, and C3 (in this order) represent the activation cascade of the classical pathway. C1-INH, C4bp, CR1,

FIGURE 33.3 Activation and inactivation of C3. The thioester bond (bold line) formed between Cys and Glu is shown for native C3 (amino acids of the thioester region are in circles). (*1*) Activation of native C3 by C3-convertases yields C3a and C3b bound to an acceptor R (here via ester linkage). (*2*) C3b inactivation by factor I and a cofactor. (*3*) iC3b is further degraded by factor I and CR1. (*4*) Acceptor-bound C3dg is trimmed by unspecific plasma proteases to C3d.

factor I, DAF, and MCP function as control proteins. C1 consists of one C1q molecule bound noncovalently to two C1r and two C1s molecules (Figure 33.4). Calcium ions are required for formation of the stable C1 complex. About 70% of the C1 components in plasma are present in C1 complexes at a given time. One C1q protein is assembled from six identical subunits. In turn, each subunit consists of three homologous chains (A, B, and C) that form a globular domain at the C terminus, followed by the "neck" and a coiled coil in the "stalk." The six subunits are held together by the collagenous stalk parts (a "bunch of six tulips" appearance under the electron microscope). The stalks also interact with the $C1r_2C1s_2$ tetramer assembled in a linear chain (20). Each C1s and C1r possesses a serine protease domain (catalytic domain) and a contact domain. Before activation, all four catalytic domains remain inside the cone-shaped stalk of C1q (21) (Figure 33.4).
FIGURE 33.4 Assembly of the C1 complex. The model for the C1 complex proposes that the folding of the rodlike $C1r_2$-$C1s_2$ tetramer around the arms of C1q causes the catalytic domains of C1s to contact the catalytic domains of C1r. Inactivation of C1 occurs by covalent binding of C1r and C1s to C1 inhibitor.

Initiation of the Classical Pathway

The physiologically most important activation of C1 is initiated by binding of the globular domains of C1q to antigen-bound IgG or IgM. C1q must bind to at least two of the conformationally altered Fc portions, implying that one single IgM, but at least two IgG molecules in sufficient proximity (i.e., <40 nm apart) are required. This restricts C1 activation by IgG to substrates with a critical density of bound antibody. The C1q-binding potential of human IgG subclasses is highest with IgG3 (followed by IgG1, IgG2, and IgG4), which is important with regard to the humanization of murine monoclonal antibodies.[2]

Other triggers of C1 activation include bacterial lipopolysaccharide, polyanionic compounds, myelin, C-reactive protein (CRP), and viral envelopes (e.g., of HIV-1). C1q binding followed by classical pathway activation also plays a role in the clearance of apoptotic cells through phagocytosis by macrophages (22). This mechanism may explain the strong association of systemic lupus erythematosus with complete deficiencies of classical pathway components, especially C1q (23).

The binding of C1q to its substrate induces a conformational change in C1q and subsequently a change in position of the two C1r serine esterase domains relative to each other. This allows for reciprocal cleavage of the C1r molecules. Such activated C1r in turn cleaves and activates C1s, which is the enzyme to activate C4 and C2. Cleavage of C1r and C1s does not liberate proteolytic fragments. Altogether, one active C1 molecule can produce about 35 C4b molecules, as a result of its low K_m value and the high plasma concentration of C4 (24).

C4 is cleaved into the small C4a and the large C4b fragment (termed nascent C4b), which undergoes a gross conformational change. The internal thioester in C4b becomes exposed and able to form covalent bonds with surrounding molecules. These reactions take place within microseconds (13), and most nascent C4b are "lost" by reacting with water. About 5% of the C4b become covalently attached to the surface, clustered around the activating Ig–C1 complex.

C2 activation proceeds more slowly than C4 activation, because of the lower plasma concentration of C2 (25). C2 forms a complex with C4b in a Mg^{2+}-dependent manner and within this complex becomes accessible for cleavage by C1s into C2a (*larger* fragment) and C2b (released *smaller* fragment). C2b exhibits kinin activity and is held to be responsible for the generation of the pathogenic peptide in hereditary angioedema (see "Complement Deficiencies"). C2a is the enzymatically active fragment in the C4b,2a protein complex, termed the classical pathway C3-convertase. C2a is active only as long as it is associated with C4b and,

once it is dissociated, cannot bind to C4b again. With the C3-convertase formation, the classical pathway leads into the common step of C3 activation (see below). Recently, a C1r-like protease (C1r-LP) has been identified that represents a different way to generate a classical-pathway C3- and C5-convertase (26).

Regulation of the Classical Pathway

C1s and C1r are tightly controlled by C1-INH, a member of the *serpin* family (*ser*ine *p*rotease *in*hibitors) and inactivate serine proteases by a suicide substrate mechanism, i.e., forming a covalent bond with the active serine of the substrate protease domain. C1-INH is already associated with native C1, which tends toward autoactivation. Activated C1r and C1s are rapidly bound by C1-INH in a stoichiometric relation, yielding two C1rC1s(C1-INH)$_2$ molecules per C1. Notably, C1-INH, unlike other complement inhibitors, is not abundant in plasma. It may become a limiting factor, e.g., in septic shock, where extensive complement activation control is required. Inhibitors downstream of C1 are C4bp, DAF, and CR1 (Table 33.2). C4b,2a disassembles spontaneously, but its decay is accelerated by CR1 or DAF, and C4b is inactivated through factor I (Table 33.2).

ACTIVATION VIA THE LECTIN PATHWAY

The concept of the lectin pathway of complement activation has emerged relatively recently and therefore not all details are yet fully understood. Its main constituent is the plasma protein mannan-binding lectin or mannose-binding lectin, MBL (27). MBL is a member of the *collectins*, proteins with *coll*agenlike stalk parts and *lectin* domains (28). It is made up of subunits that consist of three polypeptide chains, each with an N-terminal cross-linking region followed by a collagenlike region, a neck par,t and a globular carbohydrate recognition domain (CRD). The three collagenous parts form a coiled-coil structure, and this subunit structure is stabilized by interchain disulfide bonds and hydrophobic interactions. Two to six subunits (i.e., 6 to 18 CRDs), held together by disulfide bonds in the crosslinking region, form an MBL oligomer with a multipronged appearance. Plasma MBL is a mixture of these oligomers, but the complement-activating potential is associated only with the higher oligomeric forms in which multiple CRDs facilitate multivalent ligand binding. The two major MBL forms present in human serum are MBL-I and MBL-II, which contain 9 and 12 disulfide-linked chains, respectively, and therefore are trimers and tetramers of the structural unit (27).

The broad variation of MBL plasma levels among presumably normal individuals (up to 1,000-fold) is largely influenced by the alleles of the *MBL* gene. Different point mutations in exon 1 result in altered collagenous domains

---

[2] Some mouse IgG subclasses (e.g., IgG2a, but not IgG1) can also activate human complement that is exploited for selective *in vitro* killing of human cells by monoclonal antibodies.

▶ **TABLE 33.2 Mode of Action of Complement Control Proteins**

Regulator	Site of Action	Mode of Action			
Early activation steps, anaphylatoxins

[b]CR1 has a narrow tissue distribution, in contrast to DAF, MCP, and CD59.

and, as a consequence, interfere with the formation of high-order oligomers. This impairment of polymerization for the three variant *MBL* alleles (B, C, D variants) is associated with low MBL plasma levels compared to the wild type *MBL* allele (termed A variant) (28). Additionally, promoter polymorphisms influence MBL plasma levels. Nevertheless, there is still considerable variation in MBL plasma levels even among individuals with the same genotype.

Many studies underline that MBL plasma levels and allotypes influence the predisposition to infections (29). MBL-deficiency is not considered a major risk factor, but may coexist with other common deficiencies in the immune system. A population-based prospective study showed twice as many acute respiratory infections in infants with MBL deficiency, although that risk is largely confined to a "window of vulnerability" at the age of 6 to 18 months, when maternal antibodies disappear (30). On the other hand, a positive correlation between the presence of low-producer MBL alleles and a low incidence of both HIV infection and active tuberculosis has been discussed (31).

MBL in plasma is found in complexes with the proenzymes *M*BL-*a*ssociated *s*erine *p*roteases, MASP-1, MASP-2, and MASP-3 (Table 33.1). A large proportion of the MASPs in circulation, however, are not complexed with MBL. MBL can also form complexes with MAp19 or sMAP (small MBL-associated protein), a truncated version of MASP-2 without serine protease domain that is generated by alternative splicing. The role of the nonenzymatic sMAP is not clear.

In addition to MBL, the ficolins also form aggregates with MASPs. *Ficolins* are lectins with a *fi*brinogenlike and a *col*lagenlike domain. Three types of ficolins have been identified in humans, L-ficolin, H-ficolin, and M-ficolin.

The two serum lectins L-ficolin and H-ficolin associate with MASPs, and both activate the lectin pathway (32). Recent reports describe similar results for M-ficolin, which is detected on the surface of monocytes, but also in secretory granules of neutrophils, monocytes, and lung epithelial cells. Forming complexes with MASP-1 and MASP-2, it functions as a pattern-recognition molecule and activates complement (33).

Initiation of the Lectin Pathway

The CRDs of MBL function as C-type lectins, as they recognize a range of carbohydrates such as D-mannose, N-acetyl-glucosamine, N-acetyl-mannosamine, glucose, and L-fucose. The affinity of a single CRD to these ligands is low ($K_d = 10^{-3}$M), so multiple CRDs have to interact for avid binding, which is best achieved with repetitive carbohydrate structures found as common constituents of bacterial, viral, fungal, and parasitic surfaces. MBL is also involved in the recognition of self-targets, such as apoptotic and necrotic cells, thus being a prototypic pattern-recognition molecule of the innate immune system (34).

Carbohydrate binding is also performed by ficolins via their fibrinogenlike domains. The sugar specificity is still unclear but might include N-acetyl-glucosamine for L-ficolin and N-acetyl-glucosamine, N-acetyl-galactosamine and fucose for H-ficolin (35), and acetyl groups for M-ficolin (36). Similar to MBL, H-ficolin and L-ficolin also recognize apoptotic cells and subsequently activate complement.

Upon ligand binding by CRD (MBL) or fibrinogenlike domains (ficolins), MASPs are auto-activated from a single-chain zymogen precursor by proteolytic cleavage

(37). Activated MASP-2 seems to be the main mediator of complement activation because it cleaves and activates the complement proteins C2 and C4, thereby generating the C3 convertase C4b,2a in a C1-independent manner (38). MASP-1 cleaves C2 almost as efficiently as MASP-2 does, but it does not cleave C4 (39). In addition, MASP-1 cleaves C3, although much less efficiently than the convertases, and this mechanism has been hypothesized to provide an initial source for amplification of surface-deposited C3b by alternative pathway activation (27). Compared to MASP-1 and MASP-2, MASP-3 has distinct substrate specificity and inhibitor profile, and its role in complement activation is unclear (40).

Regulation of the Lectin Pathway

Control of the lectin pathway seems to be exerted mainly through covalent binding of C1-INH to active MASPs and to be very similar to control of the classical pathway in general, although the different effects of synthetic inhibitors suggest that differences do exist (41). Furthermore, altered mammalian cell membranes can trigger lectin pathway activation via MBL in situations such as ischemia followed by reoxygenation (42). Complement activation does not appear to be the only contribution of MBL to host defense.

An MBL receptor or collectin receptor has long been postulated, but not identified unequivocally. An MBL receptor is thought to mediate a C3b-independent opsonic effect on phagocytes that may also attribute a new role to the noncomplement-activating forms of MBL.

ACTIVATION VIA THE ALTERNATIVE PATHWAY

Alternative pathway activation requires C3 and C3b, factors B, D, and properdin. Alternative pathway activation is a positive feedback mechanism to augment C3b generation (C3b-amplification loop). The starting C3b is generated through either of the other two pathways. The alternative pathway may also be triggered directly via iC3.

The C3b-Amplification Loop

Whether a given structure (e.g., a cell membrane, viral envelope, bacterial polymer) will allow alternative pathway activation depends on the affinity of factor H for C3b deposited on that structure and on the presence of other regulators (Figures 33.5, 33.6). Surface structures that allow alternative pathway activation are called activator
FIGURE 33.5 Generation of the alternative-pathway C3 convertase. Upon cleavage of C3 to C3b, the reactive thioester (full black circle) is exposed and forms covalent bonds to activator surface molecules. C3b associates with factor B in the presence of Mg^{2+}, which is then cleaved by factor D. Bb bound to C3b is the proteolytically active part of the convertase C3b,Bb. Dashed-lined arrows represent enzymatic action, dotted lines within molecules indicate cleavage sites for enzymes.

(A) FLUID PHASE

(B) ACTIVATOR SURFACE

(C) NONACTIVATOR SURFACE

= sialic acid residues on host glycoproteins

FIGURE 33.6 Control of C3b amplification by factor H depends on its binding affinity to the respective C3b target. **Upper part:** In the fluid phase, C3b,Bb is rapidly disassembled through factor H binding. C3b cleavage through factor I generates iC3b, which has no complement-activating potential. **Lower part:** Factor H binding to C3b is low on activator surfaces such as microbial cell walls, and C3b,Bb remains active. On nonactivator surfaces, e.g., host cells with sialic acid residues, factor H has a higher affinity to C3b, and binding is followed by convertase dissociation and C3b inactivation.
surfaces, whereas those that effectively limit activation are termed nonactivators. When a first C3b molecule becomes covalently attached to an activator surface, factor B subsequently associates with this C3b in the presence of Mg^{2+}. In this complex, the zymogen factor B is accessible to cleavage by factor D, a serine protease present in plasma in minute amounts. Factor D is brought into its active conformation through recognition of its substrates, C3b,B or iC3,B, and returns to its "inactive" state after the cleaved Ba fragment is released from B (43). The enzymatically active Bb fragment remains attached to C3b, forming the C3 convertase of the alternative pathway, C3b,Bb (Figure 33.5). Surface-attached C3b,Bb activates further C3 molecules, and more nascent C3b will attach to the same surface. C3b,Bb remains active as long as Bb remains bound to C3b (half-life 90 seconds). Properdin stabilizes the convertase against decay. A microbe may thus rapidly become covered with C3b, which is slowly (i.e., relatively inefficiently compared to C3b on nonactivators) turned into iC3b. Recently, it has been postulated that rapid alternative pathway activation is facilitated by binding properdin first, followed by C3b attachment (44).

Initiation of the Alternative Pathway via iC3

A long-standing conceptual problem was to explain the generation of the initial C3b and thus whether the alternative pathway can be triggered on its own. The concept of "C3 tickover" provided such an explanation (25). Plasma C3 is constantly transformed at a low rate into inactive C3 (iC3 or "C3b-like" C3) through spontaneous reaction of the C3 internal thioester bond with H_2O. iC3 can be described as uncleaved C3 in a C3b-like conformation and accounts for 0.5% of total plasma C3. Like C3b, iC3 can associate

with factor B in a Mg^{2+}-dependent reaction, thus forming iC3,Bb. It is thought that this initial C3 convertase of the alternative pathway is formed constantly but is rapidly inactivated in plasma. Nevertheless, by this mechanism nascent C3b molecules randomly attach onto nearby microbes and trigger the amplification loop.

The concept of C3 tickover preceded the discovery of the MBL pathway. The targeted generation of C3b via MBL/MASP-1 provides an alternative explanation of initial C3b generation. Even to date, the relative contributions of both mechanisms are not fully understood.

Inactivation and Degradation of C3b and Regulation of the Alternative Pathway

Because of its self-amplifying capacity, C3b circulating in plasma is subject to tight control (Table 33.2). The spontaneous decay of C3-convertases (approximate half-life, 2 minutes) is accelerated by CR1, factor H, or DAF, an activity termed decay acceleration. Considerable redundancy in control proteins exists for these steps, although CR1 can actually substitute for all other regulatory RCA proteins in this respect. Cleavage of C3b and thus its inactivation relies on factor I and its cofactors. Becaue of the high plasma concentration of factor H, virtually all C3b or iC3 present in plasma will quickly bind to H. The low K_m of factor I for C3b,H permits efficient cleavage of C3b into iC3b, which is then split into the biologically inert C3c and the smaller C3dg fragment that remains bound to the target (see Figure 33.3). Thus, C3b degradation eliminates the complement-activating C3b, but produces fragments with other biologic functions. Notably, control proteins of other species normally have no effect on human complement components.

In this respect, the physiologic role of the increasing family of factor H-like or factor H–related proteins (FHR; see Table 33.1) is incompletely understood (45). FHL-1 (reconectin) represents the N-terminal seven SCRs of factor H plus four unique amino acids and has cofactor and decay-accelerating activity. It may play a role in cell–extracellular matrix interaction. All FHRs share homology with the factor-H C terminus that binds C3b. FHR-1, FHR-2, and FHR-4 are constituents of lipoproteins, and FHR-3 binds to heparin. For FHR-3 and FHR-4, interaction with C3b and thus a potential role in C3b regulation has been proposed (45).

ACTIVATION OF THE TERMINAL PATHWAY

Activation of the terminal pathway is initiated by cleavage of C5. The C5 convertases, responsible for this cleavage, are composed of a C3 convertase with an additional C3b molecule deposited covalently in the immediate vicinity: C3b,Bb,C3b or C4b,2a,3b. The (second) C3b acts like an anvil for C5: It interacts with C5 and presents C5 in the correct conformation for cleavage by the C2a or Bb enzyme. Cleavage of C5 in the α chain generates the 11-kDs C5a peptide, whereas C5b starts the membrane-attack-complex formation. It should be noted that the classical C3 convertase together with another C4b was shown to cleave C5 directly to some extent (46). However, C5 may be activated directly by different enzymes (47), in particular thrombin (48).

After cleavage of C5, the terminal complement components C6, C7, C8, and C9 are sequentially, but nonenzymatically, activated, resulting in the formation of the terminal complement complex, TCC (49). On a cellular target membrane, TCC can be generated as the potentially membranolytic membrane attack complex (MAC), or in extracellular fluids as nonlytic SC5b-9 in the presence of S protein (vitronectin). Both forms consist of C5b and the complement proteins C6, C7, C8, and C9. After cleavage of C5, C5b undergoes conformational changes and exposes a binding site for C6. The ability of C5b, staying near the C5 convertase on the target surface, to bind C6 decays rapidly, but once it is bound, C5b6 forms a stable bimolecular complex. C5b6 binds C7, resulting in the exposure of membrane-binding sites and incorporation into target membranes. If C7 concentrations near the site of complement activation are limiting, the stable bimolecular C5b6 complex dissociates from the C5-activating complex and accumulates in solution. In the presence of C7 fluid phase C5b-7 is formed that will not necessarily stay soluble, as it has a transient ability to attach to membranes, bind C8 and C9, and initiate lysis, a process called *reactive lysis* (50). Both the membrane-bound C5b-7 complex as well as the fluid-phase C5b-7 complex can bind C8. C8 consists of three nonidentical polypeptide chains: the α and γ chains

are covalently linked by a disulfide bond, and the β chain is attached by noncovalent forces. Nascent C5b-7 binds to C8β via C5b. The C8 γ chain has no apparent function in complement lysis, probably because it does not lie adjacent to the membrane but faces the extracellular plasma (Figure 33.7).

Efficient lysis is dependent on an interaction of the C8 α-moiety with C9, although some lytic activity is expressed already by the C5b-8 complex alone. C5b-8 acts as a polymerizing agent for C9. The first C9 bound to C5b-8 undergoes major structural changes enabling formation of an elongated molecule and allows binding of further C9 molecules and insertion of C9 cylinders into the target membrane (Figure 33.7). Whereas only one molecule of each C5b, C6, C7, and C8 is involved in TCC formation, the number of C9 molecules varies from one to three in the fluid phase and from one to 12 in the membrane-bound form, although polymers containing up to 15 C9 molecules are also possible.

Two mutually nonexclusive hypotheses have been proposed to explain the precise mechanism of terminal complement-mediated cytotoxicity after insertion of C9. According to one model, the polar domains of inserted complement proteins, particularly C9, cause local distortion of the phospholipid bilayer, resulting in "leaky patches" (51). The other theory postulates that the terminal complement proteins form a hydrophilic channel ("pore") through the membrane, with consequent disruption of the cell (52).

Regulation of the Terminal Pathway

Control is executed before the integration of the assembling MAC into the membrane and at the stage of pore formation, i.e., association of C8 and polymerization of C9 (Table 33.2) A number of different membrane and plasma molecules are involved in modulating TCC assembly, of which C8 is probably the most important. It represents not only an essential component of the lytic complex but, paradoxically, also prevents membrane damage by binding to the nascent C5b-7 complex in the fluid phase, thereby precluding its firm insertion into the membrane (53).

Not only C8 but also the abundant S protein, clusterin, lipoproteins, antithrombin III, proteoglycans such as heparin, and protamine are able to bind to nascent C5b-7 and to prevent its membrane insertion. The final step of MAC assembly, subsequent to C5b-7 insertion, when the MAC becomes more firmly inserted into the lipid bilayer, is safeguarded by a well-characterized 18- to 20-kDa glycolipid-anchored membrane molecule (CD59), which protects against complement-mediated lysis by interfering with polymerization of C9.

Membrane perforation by complement is not a unique feature. Damage to mammalian cells by proteins that destroy target membranes can be also caused by perforin,
FIGURE 33.7 Activation of C5 and terminal complement pathway. C5 is activated by C5 convertases of the classical (CP) or alternative (AP) pathway. Nascent C5b interacts sequentially with C6, C7, and C8, and attaches to lipid membranes. C9 polymerization on C5b-8 completes the membrane attack complex (MAC).

which is contained in the cytoplasmic granules of cytotoxic T lymphocytes and natural killer cells (see Chapters 16 and 34) and actually shows a strong homology with C9 (54).

Biologic Properties of the Terminal Complement Complex

The MAC deposited on cells may either exert lytic properties that are important in host defense (see "Complement Defense against Infection") or may induce so-called sublytic effects on nucleated cells that are not unequivocally identified as "non-self" (55). The term *sublytic* refers to the fact that nucleated cells can withstand single (and erroneous) attacks, unlike erythrocytes. Furthermore, previous sublytic effects may even protect these cells from

further, otherwise lytic effects, favoring the host cells that are constantly in contact with complement (56). Sublytic attack also stimulates protein synthesis and arachidonic acid metabolism and activates attacked polymorphonuclear leukocytes. In particular, sublytic TCC on nucleated cells transiently increases intracellular Ca^{2+}, activates protein kinase C and G proteins, induces procoagulant and proinflammatory activities, and activates cell-cycle activation and transcription (57). Therefore, the presence of TCC on the surface of viable immune cells suggests a modulating role in the physiology of cells to which it attaches (58). In autoimmune demyelination and multiple sclerosis, terminal complement activation exerts a dual role: C5b-9 not only promotes demyelination of oligodendrocytes, it also, in sublytic concentrations, protects them from apoptosis (59). Whether SC5b-9 represents simply the inactivated

form of the TCC or whether it plays a role in immune defence remains controversial.

COMPLEMENT RECEPTORS

The consequences of complement activation encompass changes in cellular functions. Central activated complement proteins or their fragments are recognized by specific receptors found on a variety of different cell types (Table 33.3). Primary consequences of this ligand–receptor interaction are the enhancement of innate immune responses to increase removal of foreign material (pathogens, apoptotic cells, immune complexes) or modulation of cellular responses. The best-studied complement receptors (CR) so far are CR1 to CR4. A common feature of these C3 receptors is the recognition of the C3 fragments covalently bound to surfaces upon complement activation. CRIg represents a further receptor for C3 fragments (60). The anaphylatoxin receptors C3aR, C5aR, and C5L2 bind as ligands the anaphylatoxins C3a and C5a as well as their derivatives C3a^{desArg} and C5a^{desArg}. A growing number of intracellular and cellular surface receptors for C1q have been identified, which are discussed as modulators of cell responses after ligand binding (Table 33.3). This group of receptors includes cloned proteins such as C1qR$_p$, gC1qbp,

TABLE 33.3 Complement Receptors

Type	Ligand	Structure, MW	Distribution	Function
CR1 (CD35)	C3b > C4b > iC3b	Single-chain glycoprotein, 160–250 kDa; allotypes A through D with 30, 37, 23, or 44 SCRs	Monocytes, macrophages, neutrophils, eosinophils, erythrocytes, B and T cells, FDC, mesangium cells in glomeruli	Immune complex clearance, immune complex localization to germinal centers, regulator of C3 and C5 activation
CR2 (CD21)	C3dg/C3d, iC3b, EBV, CD23, IFN-α	Single-chain glycoprotein, 140–145 kDa; two isoforms: CD21S or CD21L (15 or 16 SCRs)	B cells, activated T cells, epithelial cells, FDC (CD21L)	B cell activation, immune complex localization to germinal centers, rescue of germinal center cells from apoptosis
CR3 (CD11b/CD18)	iC3b, ICAM-1, LPS, fibrinogen, clotting factor X, carbohydrates	Heterodimeric glycoprotein, $\alpha + \beta$ chain: 165 + 95 kDa	Monocytes, macrophages, neutrophils, NK cells, FDC, T cells, mast cells	Phagocytosis, cell adhesion, signal transduction, oxidative burst
CR4 (CD11c/CD18)	iC3b, fibrinogen	Heterodimeric glycoprotein, $\alpha + \beta$ chain: 165 + 95 kDa	Monocytes, macrophages, neutrophils, NK cells, T cells, mast cells	Phagocytosis, cell adhesion
CRIg	C3b, iC3b	IgG superfamily	Tissue-resident and sinusoid macrophage	Phagocytosis of circulating pathogens
C3aR	C3a	Single chain of 48 kDa, G-protein–linked receptor	Mast cells, basophils, smooth muscle cells, lymphocytes	Increases vascular permeability, triggers serosal type mast cells
C5aR (CD88)	C5a, C5a$_{desArg}$	Single chain of 43 kDa, G-protein–linked receptor	Mast cells, basophils, neutrophils, monocytes, macrophages, endothelial cells, smooth muscle cells, lymphocytes	Increases vascular permeability, triggers serosal type mast cells, promotes chemotaxis
C5L2	C5a, C5a$_{desArg}$ C3a, C3a$_{desArg}$	Single chain of 37 kDa, G-protein–linked receptor	Neutrophils, immature DCs, preadipocytes, adipocytes	Stimulates triglyceride synthesis Limits pro-inflammatory response
C1qR$_p$	C1q (collagenous part), MBL, SP-A	Single chain of 126 kDa, highly glycosylated	Monocytes, macrophages, neutrophils, endothelial cells, microglia	Phagocytosis
cC1qR "collectin-receptor"	C1q (collagenous part), MBL, SP-A, CL-43	Single chain of 60 kDa, acidic glycoprotein	B cells, monocytes, macrophages, platelets, endothelial cells, fibroblasts	Phagocytosis, localization of immune complexes; enhances ADCC, oxidative metabolism
gC1qR	C1q (globular heads)	Tetramer of 33-kDa subunits, acidic protein	B cells, monocytes, macrophages, platelets, endothelial cells, neutrophils	Inhibits complement activation, phagocytosis

cC1qR (also termed calreticulin or collectin receptor), and a putative C1qR$_{O2}^{-}$ (61).

C3 Receptors

Antigen–antibody complexes or pathogens with C3 fragments linked covalently to their surface are immunologic tags for phagocytes and other immunocompetent cells. Uptake of such opsonized particles and subsequent activation of intracellular pathways are the main functions of C3 receptors (i.e., CR1 through CR4 and CRIg).

Complement Receptor Type 1 (CR1, C3b/C4b Receptor, CD35)

Human CR1 is a multifunctional glycoprotein that belongs to the family of complement regulator proteins (62). A common feature of these proteins is repeats of tandemly arranged modules of about 60 amino acids, referred to as short consensus repeats (SCRs). Within the CR1, larger structural elements are formed, called long homologous repeats (LHRs), each consisting of seven SCRs. The four known polymorphic forms of human CR1 differ in the number of SCRs (up to 34) or LHRs. The ligand-binding sites for C3b and C4b are localized in LHR B (SCR 8–10) and LHR C (SCR 15–17). LHR A harbors an additional C4b-binding region and decay-accelerating activity for both C3 convertases (62). This modular arrangement provides the basis for multivalent CR1–C3b/C4b interactions. In addition to C3b and C4b, CR1 also binds iC3b, although with low affinity. The tissue distribution of CR1 covers a broad spectrum of peripheral blood cells, and it is also found on follicular dendritic cells (FDCs). Because of the numerical predominance of erythrocytes, about 90% of CR1 is found on this cell type.

A main function of CR1 on erythrocytes is a result of its ability to serve as an immune adherence receptor for transport of C3b/C4b opsonized immune complexes (IC), which, after binding, are transported to the liver and spleen. In these organs, IC are transferred to phagocytic cells for removal. On activated phagocytes such as neutrophils or macrophages, CR1 mediates phagocytosis of opsonized pathogens, whereas on nonactivated cells, CR1 cooperates with FcR or CR3 to bind and ingest foreign material. The possible C1q-mediated binding of IC to CR1 for clearing of IC seems to be of minor physiologic importance, because patients who lack complement components downstream of C1q are unable to clear IC via CR1-C1q interactions (63). On B cells, CR1 is suggested to participate in B-cell proliferation and differentiation. In germinal centers of the lymphoid follicles, CR1 expressed on FDC may be of importance in the induction of immunologic memory. CR1 has decay-accelerating activity for the C3 and C5 convertases and cofactor activity for factor I—mediated cleavage of C3b and iC3b. This broad regulatory activity is the basis for the anticomplement therapeutic strategies that use recombinant CR1 (see "Complement in Therapy").

Complement Receptor Type 2 (CR2, C3d Receptor, CD21)

CR2 consists of 15 or 16 SCRs, termed CD21S and CD21L, respectively. CD21L contains an additional exon, which codes for the additional SCR 10a (64). CD21L seems to be selectively expressed on FDC, while CD21S is found mainly on B cells but is also expressed to a small extent on activated T cells and epithelial cells. CR2 interacts with C3d, C3dg, and iC3b, and is the receptor for the Epstein–Barr virus (EBV), facilitating viral entry into B cells and epithelial cells. The binding site for EBV envelope protein gp350/220 within the first two SCRs overlaps with, but is not identical to, the C3d site that has been assigned to SCR 2 (65). CR2 has been reported to interact with CD23, the low-affinity receptor for IgE, which is thought to be involved in regulation of IgE production (66).

The most important role of CR2 is bridging parts of innate and adaptive immunity (67), because it is involved in antibody maturation and induction of B-cell memory. On the surface of human B cells, CD21 is associated with CD19 and CD81, forming a trimolecular coreceptor complex (68). Through C3d-opsonized antigens, the CR2/CD19/CD81 complex is cross-linked with the B-cell–receptor complex (BCR), a process that is stabilized in lipid rafts. As shown in detail in Chapter 8, BCR-associated kinases can phosphorylate cytoplasmic tyrosines of CD19, thus allowing activation of downstream kinases (69). Altogether, cross-linking of the CD19/CR2/CD81 and the BCR complexes lowers the threshold for B-cell activation by the specific antigen by two orders of magnitude compared to antigen alone (68).

Complement Receptor Type 3 (CR3, Mac-1, Mo-1, $\alpha_M\beta_2$, CD11b/CD18)

Together with LFA-1 (CD11a/CD18) and CR 4 (CD11c/CD18), CR3 belongs to the family of β_2 integrins (70). The heterodimeric CR3 consists of a 165-kDa α chain (CD11b) and a 95-kDa β chain (CD18). A remarkable feature of CR3 is its promiscuous interaction with numerous ligands, including the C3 fragment iC3b, ICAM-1 and -2, proteins of the clotting system, or molecules of microbial origin, e.g., from *Leishmania, Klebsiella pneumoniae, Mycobacterium tuberculosis, Candida albicans* (70), and probably HIV (71).

Most ligands investigated so far bind to a specialized region in the α chain, referred to as the I (for "inserted") domain, in a Ca^{2+}-dependent manner (72). In addition, a C-terminal extracellular domain of CD11b has been identified as a high-affinity interaction site for β-glucans, which may interact with carbohydrate structures of different pathogens (73). CR3 is found on mononuclear phagocytes,

neutrophils, mast and NK cells, FDC, and T-cell subsets and contributes considerably to leukocyte adherence and migration. The crucial role of CD11b/CD18 as complement receptor in phagocytosis has been recognized in patients with reduced or absent expression of β_2 integrins, known as leukocyte adhesion deficiency (74). Evidence is provided that interaction of CR3 with iC3b is not sufficient to induce phagocytosis and requires additional coligation of the CR3 lectin site with microbial surface polysaccharides (73); alternatively, CR3 can cooperate with other phagocytic receptors such as FcγRIII, FcαRI, or CD14. CR3 is associated on the cell surface with these GPI-anchored surface proteins and may be used as adaptor for their intracellular signalling (75).

Complement Receptor Type 4 (CR4, p150/95, $\alpha_X\beta_2$, CD11c/CD18)

CR4 belongs to the same β_2-integrin subfamily as CR3 (Table 33.3). Ligand specificities of CR4 tested so far seem to be similar to CR3. Also, the tissue distribution of CD11c is comparable to that of CR3, although CR4 seems to be more prominent on distinct dendritic cell subsets (76).

Complement Receptor CRIg

CRIg, a very recently characterized member of the IgG superfamily, is recognized by C3b and iC3b (60). Expression on Kupffer cells is required for the interaction and internalization of C3-opsonized particles even in the presence of CR3. The absence of CRIg, at least in the mouse, significantly increases the infection and mortality rates of the host for bacterial pathogens. Thus, CRIg seem to play a pivotal role in the clearance of opsonized pathogens (60). In addition, evidence is provided that CRIg acts as an inhibitor of the alternative pathway of complement (77).

Anaphylatoxin Receptors C3aR, C5aR (CD88), and C5L2

As discussed previously, cleavage of C3, C4, and C5 results in generation of the small fragments C3a, C4a, and C5a, with a C-terminal arginine residue, which are termed anaphylatoxins (AT). Although C4a is thought to be inactive, C3a and C5a exert various effects when they are bound to their specific receptors C3aR, C5aR (CD88), and C5L2, respectively (78). C3aR, C5aR, and C5L2 are seventransmembrane receptors of the rhodopsin superfamily. Expression of C3Ra and C5aR was thought to be restricted to cells of myeloid origin, until recent studies demonstrated the presence of C5aR on epithelial, endothelial, and parenchymal cells as well as on B and T lymphocytes. C5L2 is localized on immature dendritic cells (DCs), neutrophils, and in adipocytes and preadipocytes in human subcutaneous and omental adipose tissue (78).

C5a is the best-characterized AT. It is a potent proinflammatory mediator that, via binding to C5aR, induces chemotactic migration and the release of various inflammatory mediators such as histamine or cytokines, enhances cell adhesion, and stimulates the oxidative burst (77). Although the C5a concentration in the blood is 10-fold lower than that of C3a, C3a is believed to be less potent. By binding to C3aR C3a is spasmogenic, stimulates the release of PEG$_2$ from macrophages, induces degranulation and chemotaxis of eosinophils, attracts mast cells, and exhibits proinflammatory characteristics that overlap with C5a-induced responses (79). Phosphorylation of AT receptors is a key event that regulates their biologic function. Because excessive inflammation may result in tissue damage, the biologic activities of C3a and C5a are tightly controlled. Carboxypeptidase N, a plasma enzyme, rapidly removes the C-terminal arginine residue from C3a and C5a, thereby converting the AT into the desArg form. In contrast to C5aR, the third AT receptor, C5L2, binds both C5a and C5a^{desArg} with high affinity. Becaue C5L2 couples only weakly to signaling G proteins, because of the lack of the exact interaction motifs, it seems likely that C5L2 serves as a nonsignaling decoy receptor and thus limits proinflammatory effects of the anaphylatoxin (80). The binding of C3a and C3a^{desArg} to C5L2 is still controversial (81).

C1q Receptors

Several reports indicate that C1q binds to a variety of different cell types, presumably via distinct receptors, and mediates, e.g., enhanced phagocytosis or oxidative-burst metabolism (82). The best-characterized C1q receptor is C1qR$_p$. Monoclonal antibodies against C1qR$_p$ block C1q-mediated enhancement of phagocytosis in human monocytes and macrophages. The receptor has also been localized on human endothelial cells. The collagenlike tail of C1q also interacts with cC1qR, CR1, or a putative C1qR$_{O2}$, whereas the globular region of C1q interacts with gC1qR (83) (Table 33.3). Ligands of cC1qR besides C1q appear to be the collectins MBL and the surfactant protein SpA. Therefore, cC1qR is also referred to as collectin receptor. cC1qR is identical with calreticulin, a chaperone and Ca^{2+}-dependent signaling molecule that is most abundant in the endoplasmic reticulum. It is unclear how calreticulin may become associated with the cell surface, but together with CD91, surface calreticulin is involved in uptake and removal of cell remnants (84) when it is opsonized with C1q.

COMPLEMENT AS PART OF THE IMMUNE NETWORK

The complete understanding of an immune response requires an integrated view of how immunologic entities work together to achieve the range of physiologic and pathologic characteristics of immune function. The

immune network encompasses all of the connections and regulatory associations in the antimicrobial defence armamentarium. Different arms of the innate immunity are activated in parallel by local or systemic infections and closely interact and supplement each other to discriminate between nonself and self and to provide critical danger signals instructing adaptive immune responses. Therefore complement factors maintain a variety of connections to other pathways and elements of innate and adaptive immunity.

Complement, Pentraxins, and Toll-like Receptors

One complement-interacting innate immune molecular family are the pentraxins, a superfamily of conserved acute-phase proteins with characteristic cyclic multimeric structure. Classical short pentraxins are C-reactive protein (CRP) and serum amyloid P (SAP); a prototypic long pentraxin is pentraxin 3 (PTX3). The pentraxins show striking functional parallels to C1q in immune defence to microbes and in scavenging cellular debris.

The major acute-phase protein CRP readily complexes to substances with exposed phosphocholine groups, such as apoptotic cells and C-polysaccharides of the bacterial cell wall (85). Complexed CRP ignites the classical complement pathway by recognition of and interaction with the globular head region of C1q (86). However, CRP-mediated activation of complement proceeds only "halfway," generating C3 convertase but no effective C5 convertase or membrane attack complex (87). The reason for that ineffectual CRP-induced complement flow might be based in the interaction of CRP with factor H and C4bp (88). The collaboration between CRP and complement may nevertheless be functional, resulting in the opsonization of phosphocholine structures by C3 fragments with subsequent phagocytosis. On the other hand, CRP may limit excessive complement activation by directing C4bp and factor H to the targets and thus protecting the host from inflammation-induced tissue damage (88).

A similar Janus-faced role is established for PTX3, which binds to C1q with high affinity and specificity (89). PTX3 enhances C1q binding and complement activation on apoptotic cells but blocks its interaction with immunoglobulins in fluid phase, with subsequent inhibition of complement activation (34).

Toll-like receptors (TLRs) represent another class of pattern-recognition receptors that act as primary sensors of invading pathogens. Both TLRs and complement are activated by invading pathogens, and their cross-talk affects the outcome of infections. Interaction of lipopolysaccharides from gram-negative bacteria with TLR4 induces production of the cytokine IL-12, a key mediator of cell-mediated immunity and a critical link between innate resistance and adaptive immunity (90). Complement factors via binding to their receptors C3aR, C5aR, and CR3 control TLR4-mediated IL-12 release and thus limit the pathogen-induced inflammatory response (90).

Complement and the T-Cell Response

There is increasing evidence for an important role of complement for the induction and promotion of T-cell immunity. Upon infection of mice deficient in C3 ($C^{-/-}$) with influenza virus, the priming of CD4 helper cells and virus-specific CTLs is strongly impaired, resulting in delayed clearance of the infection and increased viral titers (91). Similarly, the induction and expansion of CD8 T cells during infection with lymphocytic choriomeningitis virus relies on C3 (92).

It is likely that macrophages and/or DCs are involved in the C3-mediated T-cell priming. Macrophages derived from $C3^{-/-}$ mice have impaired ability to trigger a robust alloreactive T-cell response. The synthesis of C3 by DCs is thought to be necessary for an alloreactive T-cell activation of a Th1 phenotype in a transplantation model (93). C3 may also play a role in both Th1 and Th2 responses to antigens upon epicutaneous sensitization or intraperitoneal immunization (94).

In addition to C3, membrane-anchored RCAs (CD46, CD55, CD59) modulate the T-cell response. Cross-linking of CD46 with TCR induces regulatory T cells (Treg) (95). CD55 modulates the induction of T cells by controlling T-cell–APC-induced alternative complement activation during cognate interaction (96). A further negative regulator of T-cell activation is CD59. Engagement of CD59 on T cells during APC–T-cell interactions downmodulates T-cell activity in a complement-independent manner (97).

Complement and the B-Cell Response

On mature B lymphocytes, the binding of C3d(g)-opsonized antigens to the CR2/CD19/CD81 complex enables coclustering with the B-cell antigen receptor (BCR). This, in turn, drastically lowers the threshold for B-cell activation by antigens and enhances immunoglobulin production by several orders of magnitude (68). Because this effect is dependent on the amount of C3d molecules interacting with the complex, model vaccines have been designed that include C3d sequences as adjuvant (see: "Complement in Therapy").

The expression of CR2 on FDC in germinal centers (GC) seems to play a profound role in development of antibody response and B-cell memory, too. As soon as low-affinity antibodies are produced during a primary immune response, opsonized immune complexes are trapped on FDC via complement and Fc receptors. C3d-opsonized antigen retained on FDCs via interaction with CR2 provide a survival signal for centroblasts in the GC and thus inhibit their apoptosis (68). The subsequent exposure of trapped

antigen to B cells is critical for induction of B-cell matura-tion and humoral immune response.

Based on results obtained with mice deficient for C4 or CD21/CD35, respectively, CR2 may also be involved in maintenance of B-cell tolerance (98). Normally, self-reactive B cells are either deleted or become anergic. In mice that are deficient for both C4 and CD21/CD35, self-antigens are not efficiently localized in the bone marrow or in GC, which keeps B cells reactive against soluble self-antigens.

Thus, the C3d–CR2 interaction provides an important link between adaptive and innate immunity by contribut-ing to the induction and maturation of the humoral im-mune response and the maintenance of self-tolerance (99).

COMPLEMENT AS A PATHOGENIC FACTOR IN DISEASE

By "complementing" the destructive action of antibodies via an activation of the whole cascade system, complement may become a pathogenic factor in disease, either alone or, more often, together with other cofactors. In addition, complement may contribute to diseases, e.g., by improper clearance and disposal of complement-coated immune complexes from the circulation (100); the fixation of C4 and C3 fragments into the antigen–antibody lattice signifi-cantly reduces the size of the single immune complex, giv-ing rise to a larger number of small complexes ("detergent-like" effect of complement). Furthermore, the presence of C4b and C3b on the immune complexes facilitates efficient fixation of these smaller immune complexes to comple-ment receptors, predominantly erythrocyte-CR1, and en-sures transportation and sequestration into the liver and spleen, where antigenic material can be removed by reticu-lohistiocytic cells, followed by degradation of the antigen. Consequently, pathophysiologically detrimental effects of complement become apparent when a failure in this clear-ance system occurs, leading to an uptake of these immune complexes by endothelial cells and their sequestration into various organs or tissues ("trapping"), giving rise to further inflammation and immune complex formation with con-comitant destruction of surrounding tissue. These patho-logical conditions include:

1. Inherited, often complete, classical pathway comple-ment deficiency (C1q$^-$, C4$^-$ deficiency)
2. Acquired complement consumption resulting from constant activation on continuously generated immune complexes, as in autoimmune diseases or chronic bac-teremia
3. Inherited or acquired low CR1-per-erythrocyte ratio, as in lupus, or low red cell count
4. Extensive liver or spleen disease, impairing the removal of the antigen

Because immune complexes are in particular trapped in small capillaries of the skin or the renal glomeruli, clear-ance disorders manifest predominantly in the skin and the kidney.

Complement also contributes to inflammation and tis-sue damage in neurodegenerative and autoimmune dis-eases, and also in ischemia and reperfusion injury or in shock (Table 33.4). Recently, defects in complement

▌**TABLE 33.4 Human Diseases with a Contribution of Complement to Pathogenesis and/or to Perpetuation**

Biocompatibility/Shock	*Neurologic*	*Rheumatologic*
Postbypass syndrome	Myasthenia gravis	Rheumatoid arthritis
Acute respiratory distress syndrome	Multiple sclerosis	Systemic lupus erythematosus
Anaphylaxis	Cerebral lupus erythematosus	Behcet syndrome
Tissue incompatibility/transplantation	Guillain–Barré syndrome	Juvenile rheumatoid arthritis
Pre-eclampsia	Alzheimer's disease	Sjogren syndrome
Biomaterial-induced inflammation	Stroke	
	Pick disease	
	Parkinson's disease	
	Transmissible spongiform encephalopathies	
Dermatologic	*Renal*	*Other Diseases*
Pemphigus vulgaris/pemphigoid	Lupus nephritis	Liver fibrosis, cirrhosis
Phototoxic reactions	Dense deposit disease	Atheroma
Vasculitis	Membranous nephritis	Thyreoiditis
Chronic urticaria	Atypical hemolytic uremic syndrome	Infertility
		Age-related macular degeneration
		Infectious diseases, sepsis
		Tumorigenesis

inhibitors have been implicated in age-related macular degeneration (AMD) (101), because, e.g., avidity of factor H binding to retinal epithelial cells is dependent on tyrosine at position 402 (102). Such a mutated factor H may not be employable by pathogens (see "Evasion Strategies of Micro-organisms"), so AMD in old age may be the prize to pay for protection from infectious disease in youth.

Complement in Renal Disease

Because complement action takes place not only locally, within tissues, but also in circulation, it is somewhat predictable that the kidney as a major filter organ will be affected in case of complement malfunctions. Indeed, preformed immune complexes are often trapped in the kidneys in case of a clearance disorder and the characteristic hypocomplementemia is usually a result of systemic complement activation in the circulation. Intraglomerular complement activation has only a minimal, if any, effect on serum complement levels. C3 and TCC, however, are frequently found in glomerular deposits. These are usually accompanied by local production of cytokines, prostaglandins, proteolytic enzymes, and reactive oxygen metabolites, which create, together with leukocytes, an extended area of inflammation. The crucial role of complement for this inflammation has long been known from animal studies showing that complement-deficient or -depleted animals do not develop induced nephritis (103).

A second important role of complement in renal disease with increased complement-related inflammation is a result of so called nephritic factors (NeF), circulating IgG autoantibodies that bind and stabilize the alternative pathway C3 convertase (103), slowing down its physiologic decay by more than 10-fold. The respective clinical conditions are partial lipodystrophy, an acute condition characterized by loss of fat from the face and upper body as a result of adipocyte lysis via the alternative pathway (104), and MPGN type II (also termed dense deposit disease, DDD) (105).

DDD may also be caused by complement control protein deficiency. However, whereas homozygous deficiency preferably leads to DDD, heterozygous deficiency of these proteins often leads to atypical (because of the lack of preceding diarrhea) hemolytic uremic syndrome (HUS) (106). Interestingly for the latter, heterozygous factor H mutations do not cluster in the N-terminal part of factor H that is involved in complement regulatory functions, but particularly in the C-terminal part of the molecule, which targets factor H action to the surface of the host cell. Factor H heterozygosity (107) or certain allotypes (not necessarily deficiency mutations) (108) predispose to disease, and it may be that it is not the absence of 50% of functionally active molecules that predisposes to HUS, but rather the presence of dysfunctional molecules, attaching to but not protecting the host cells and also preventing attachment of

the active molecules (109). Antihuman C5 antibodies (see "Complement as Target in Drug Therapy") may represent an interesting therapy option for patients suffering from renal diseases caused by unrestricted complement activation.

Complement in Neurologic Disease

The human brain is immunologically sheltered from the peripheral immune system by the tight and selective blood–brain barrier. Additional immunologic barriers are manifested by limited antigen presentation and expression of immunosuppressive cytokines (110). To adjust this restricted immunosurveillance, astrocytes, microglia, neurons, and oligodendrocytes produce at least some complement proteins, including soluble factors, regulators, and receptors (111). Of these cell types, astrocytes, the most abundant glial cells, are the major source of complement in the brain, thereby providing immune defense against invading pathogens.

However, a harmful role for complement is implicated for tissue destruction and cell damage in some pathologic conditions such as Alzheimer's disease (AD), Huntington disease, Pick disease, multiple sclerosis (MS), and stroke. Complement is also thought to participate in neurodegeneration induced by cerebral infections.

AD, the most common cause of dementia, is characterized by neuronal loss, neuritic dystrophy, and the accumulation of senile plaques in the brain. Activation of the complement system has been widely investigated as a potential mechanism for these processes. Complement components of classical and terminal pathway are highly upregulated in AD brains, especially in the senile plaques (112). The main component of these plaques, the β-amyloid peptide, can activate complement by binding specifically to the collagenlike domain of C1q (113). Consecutive complement-dependent processes likely contribute to neuronal injury in the proximity of these plaques, especially because neurons are extremely sensitive to complement-induced bystander lysis, because of the low or even absent expression of complement inhibitors on their surface.

MS is an inflammatory autoimmune disease characterized by demyelination of axons, failure of remyelination, and loss of oligodendrocytes. Demyelination results not only from an autoimmune response against myelin components and subsequent activation of the classical pathway, but also from direct binding of complement factors to myelin. Myelin oligodendrocyte glycoprotein (MOG) harbors a protein domain similar to the C1q-binding sequence of IgG antibodies (114). Complement activation results in lysis of oligodendrocytes and chemoattraction of phagocytes, which accumulate at the site of inflammation and degrade the myelin sheath. These processes are mediated by complement receptor CR3 on the phagocyte surface and induce production of inflammatory substances such as TNF-α and nitric oxide (115).

Complement is also hypothesized to contribute to pathogen-induced neural damage. The human immunodeficiency virus HIV-1 is detected in >80% of brains from individuals with AIDS and causes meningitis, neuropathies, and a subcortical dementia that manifests in cognitive, motor, and behavioral dysfunctions. Atrophy, appearance of multinucleated giant cells, reactive astrogliosis, microgliosis, loss of neurons, and inflammation are visible. The discrepancy between the small number of HIV-infected brain cells and the severity of neurologic impairment suggests the existence of detrimental mediator molecules rather than direct virus-induced cell damage. Several hints imply a role of complement in this virus-induced neurologic damage. The expression of different complement factors and receptors is upregulated in HIV-infected astrocytes as well as *in vivo* in the brains of HIV-infected patients (116). Complement activation products such as C3a, C5a, and MAC exert a variety of proinflammatory biologic effects on brain cells. Furthermore, the HIV-1 transmembrane protein gp41 downmodulates the expression of CD59 in human neuronal and astroglial cell lines, thus enhancing the susceptibility of neurons toward complement-dependent bystander cell lysis (110).

COMPLEMENT IN DEFENSE AGAINST INFECTION

The dominant role of complement in the innate immune system, as important first-line defence of higher vertebrates against invading microorganisms, is displayed twofold. First, complement recognizes "nonself" immediately after infection as a primitive surveillance system independent of antibodies or immune cells; and second, it serves as an executor of antibody-mediated immunity.

Nonself structures activate the alternative and lectin pathways (triggered by the surface composition of the invader, e.g., lipopolysaccharides, sialic acids, glycoproteins, and peptidoglycans) or the classical pathway, mainly via C1q-binding moieties. Stimulation of phagocytic cells, by generated anaphylatoxins, attract them to the site of infection (chemotaxis). Generation of C3 fragments, mainly C3b and iC3b (opsonization), on the microbial surface and their recognition via complement receptors on phagocytic cells, mainly CR1 and CR3 (see "Complement Receptors"), followed by phagocytosis or lysis of the microbe, then mostly lead to a control of the infection. Intracellular processing in phagolysosomes and presentation of phagocytosed material on the cell surface by professional antigen-presenting cells will initiate adaptive immune responses and trigger production of specific antibodies, thereby linking innate immunity to adaptive response.

Whereas lysis is effective against some viruses and gram-negative bacteria, chemotaxis followed by opsonophagocytosis represents probably the main mechanism for destruction of most viruses, bacteria, and fungi that cannot be lysed by complement.

Not only the number of C3-fragment molecules deposited on the invader, but also the amount of C5b-9 inserted into the target membrane, are decisive for host defense. The particularly frequent occurrence of terminal complement deficiencies in patients with meningococcal infections suggests that the cytolytic activity of complement is especially important in resistance to gram-negative bacteria (117). Lysis is accomplished via induction of injurious processes or by terminal complement components via the outer membrane attack leaks (118).

Evasion Strategies of Micro-organisms

Highly pathogenic microorganisms are attacked by complement, but in turn may evade appropriate recognition or constrain suitable attack and destruction (119) (Figure 33.8). To achieve these goals a range of strategies has been developed during evolution to (a) avoid or minimize complement activation by displaying special surface moieties, (b) resist C3-dependent opsonophagocytosis, or (c) prevent complement-mediated cytolytic damage (119). The two latter are, e.g., facilitated by displaying proteins antigenically and/or functionally mimicking C3, which can bind to complement receptors. This can mediate uptake in a complement-independent manner, i.e., even when the invader has not been opsonized before. Proteolytic degradation of complement proteins by micro-organisms may also protect them from opsonization and/or lysis (119). Cleavage of C1-INH by proteases, e.g., leads to constant activation (and also consumption) of C1. Micro-organisms that evade complement by consuming it must ensure that this occurs at a secure distance from their cellular membranes.

Another mechanism is the use of complement proteins provided by the host. When HIV-1 buds from an infected cell, it is encoated with a lipid bilayer obtained from the host-cell membrane and as a consequence carries, in addition to viral, also host-cell membrane proteins. Of the latter, especially DAF and CD59 are of particular importance, as they protect HIV-1 from complement lysis (120). Attachment of factor H to C3b on the virus and to several sites on the external portion of gp41 and to one site on gp120 confers an additional protective effect against efficient destruction (121). Because of this acquisition of complement regulators, HIV accumulates in the plasma of infected hosts and spreads with the aid of erythrocytes that interact via their CR1 with the C3b deposited on the viral surface. Furthermore, the dynamic processing of virus-coating C3b into iC3b allows the interactions with CR3-positive cells (Figure 33.9). As a consequence, CR-positive cells contribute to the spread of HIV within an infected host. Acquisition of host-derived fluid-phase complement regulatory proteins, in particular factor H and C4bp, is also executed by bacteria in order to evade complement (122).

**Evasion from
destruction by complement**

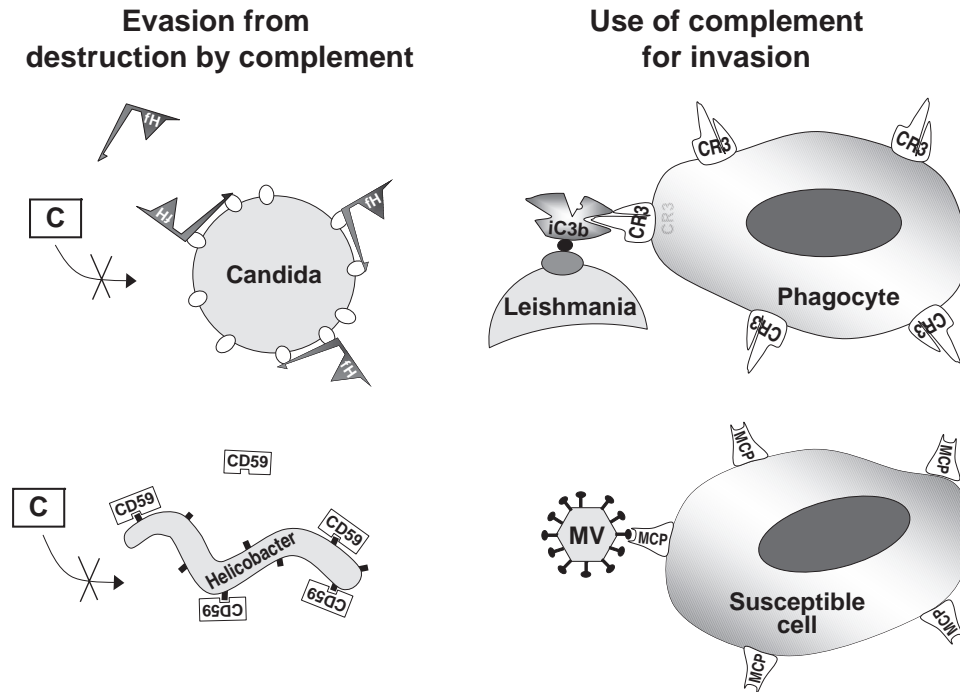
**Use of complement
for invasion**


FIGURE 33.8 Micro-organisms display surface moieties that bind to complement proteins. By employing inhibitors from the fluid phase, microorganisms can evade destruction by complement (C) (defensive manner, *left*). Via binding of factor H or CD59, *Candida (upper left)* or *Helicobacter (lower left)* restrict complement activation or membrane-attack complex assembly, respectively. By allowing complement activation and use of complement receptors or via direct binding, they can invade host cells (aggressive manner, *right*). *Leishmania* induces complement activation by displaying complement-activating structures on its surface, followed by opsonization with iC3b, phagocytic CR3-based recognition, and phagocytosis of the parasite; a small but significant portion of the pathogens will survive this procedure *(upper right)*. Measles virus (MV) uses CD46 (MCP) as cellular receptor directly—previous complement activation does not appear to be necessary here *(lower right)*.

Acquisition of the respective gene during evolution is another sophisticated way of evasion. Vaccinia virus complement control protein (VCP), a functionally CR1-like and structurally C4bp-like protein, has evolved after uptake to retain only the most essential domains; any further manipulation of the small viral protein results in loss of function, indicating that the gene has achieved maximum efficiency (123). In other pathogens, molecular mimicry may represent the conservation of ancestral molecular recognition motifs. Many are related to mammalian CR1, DAF, MCP, or C4bp, confirming the importance of C3- and C4-fragment–binding molecules.

The trematode *Schistosoma mansoni* has a highly elaborated anticomplement arsenal: First, it can modify its surface sialic acids, thus modulating activation; second, it can acquire DAF to accelerate decay of surface bound C3; third, it can bind and cleave C4 and C3, mimicking in part CR1; fourth, it can cleave C9, preventing MAC assembly; and fifth, but probably not last, it encodes a protein that mimics CD59, inhibiting membrane attack (124).

The yeast *Candida albicans* possesses an integrin/CR3-like molecule on its surface (125) that is involved in induc-

ing morphology changes. Furthermore, it facilitates cellular adherence like other human integrins and is not only functionally (125) but also antigenically and structurally related to human CR3. There is strong evidence that HIV-1 is able to bind to *Candida* directly, possibly via C3-like regions on gp41 and the CR3-like molecule on *Candida* (126). This interaction enhances fungal proteinase release and suppresses phagocytosis by PMNs (127). Thus, the concerted mimicry of both pathogens may contribute to the virulence of both *Candida* and HIV (126).

COMPLEMENT GENETICS

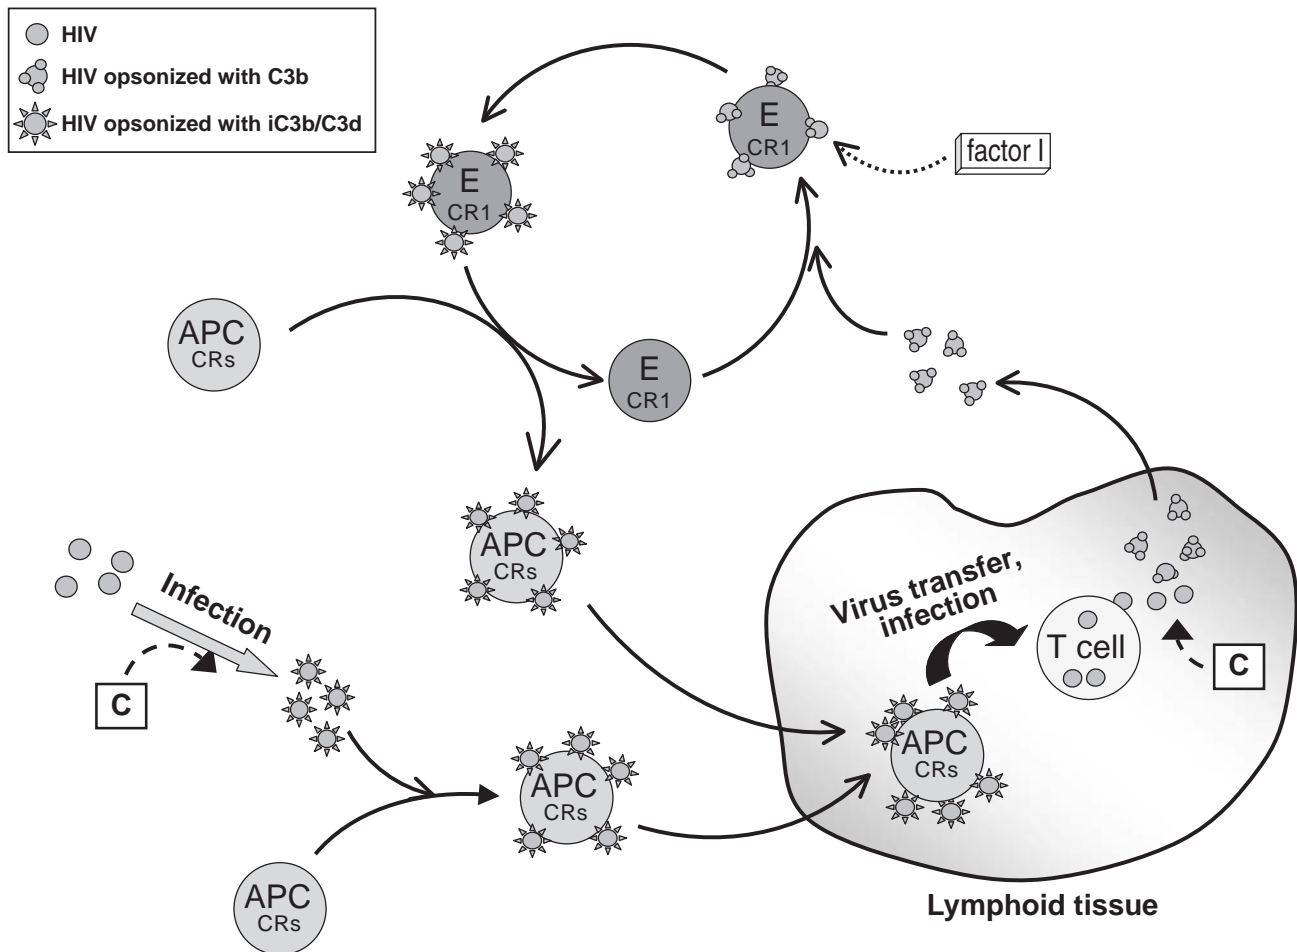
Many decades of complement genetics research has led to the conclusion that usually only homozygous deficient subjects (or animals) show a significant phenotype, whereas specific allotypes do not normally predispose to disease. However, more and more exceptions are being reported, and interestingly, these are often not related to the typical complement-related functions. The donor C3 allotype has been reported to determine late renal transplantation


FIGURE 33.9 Complement-mediated enhancement of viral dissemination in early stages of HIV infection. Complement on mucosal surfaces and in seminal fluid opsonizes HIV even in the absence of virus-specific antibodies. Thus, upon crossing the mucosal barrier and entering the host, opsonized HIV is subsequently trapped by antigen-presenting cells (APC), mainly dendritic cells, via complement receptors (CRs). The APC are thought to transport the viral particles into the lymphoid tissue, where the virus is transferred to T cells. Progenitor viruses produced by the infected T cells are subsequently opsonized with C3b and bind to CR1 on erythrocytes (E). Factor I together with CR1 promotes the cleavage of C3b into iC3b. The low affinity of CR1 to iC3b favors the transfer of iC3b-covered virions to CR3 on APC. APC loaded with HIV migrate into lymphoid tissues again, where further T cells are infected.

outcome (128); the pattern of breast cancer metastasis correlates with a single-nucleotide C1q polymorphism (129); the factor H allotype Y402H is associated with a significantly higher likelihood of developing macular degeneration (see "Complement in Renal Disease") (101); and a common fH polymorphism, with an increased risk of myocardial infarction (130).

Furthermore, complement genetics has also been a valuable tool with which to investigate plasma protein genetics in general and their evolution. The chromosomal locations of the complement protein genes are given in Table 33.1. These are not scattered around the chromosomes, but form linkage groups of structurally homologous com-

ponents, confirming previous assumptions based on homology studies on the protein level that the majority of complement proteins has evolved by duplication and diversion events from only a small number of precursor genes (131).

Because complement receptors and certain regulatory proteins are expressed on erythrocytes, they also represent blood-group antigens; e.g., the Knops, McCoy, Swain-Langley, and York antigens are on CR1. Variations in the DAF antigen are responsible for the Cromer blood-group system, with the rare Inab phenotype lacking DAF altogether. Chido and Rogers blood-group antigens are associated with C4 (131). In this respect, complement genetics

has been widely applied to anthropologic investigations and forensic medicine.

Progress in DNA work has facilitated the characterization of complement allotypes on the molecular level. Both phenotypic assessments of protein variants (phenotyping, e.g., by isoelectric focusing or monoclonal antibodies) and characterizations of genomic DNA (genotyping, e.g., by RFLP or PCR) are currently used (132). Phenotyping has the advantage that the presence and even the functional activity of a protein can be ascertained. Genotyping does not allow identification of silent or null alleles as such, however, once a mutation is known, a defective gene may be traced in family studies, providing a basis for genetic counseling.

COMPLEMENT DEFICIENCIES

Inherited deficiencies, either complete or subtotal, have been described for most complement components and regulatory proteins. These abnormalities are relatively rare and usually inherited in an autosomal recessive manner, which means that only homozygous subjects are readily detected and susceptible to disease. One important exception is the autosomal dominant inherited hereditary angioedema (see below). Another, only recently discovered heterozygous deficiency is that of factor H and other complement-regulatory proteins (see "Complement in Renal Disease").

Complement defects can be ascertained by the traditional total hemolytic complement assays (CH_{50}, $APCH_{50}$) followed by radial immunodiffusion (Mancini), electroimmunodiffusion (rocket electrophoresis, Laurell), or enzyme immunoassays (ELISA) (133). The latter are of particular importance as so-called subtotal deficiencies, in which residual functionally active amounts can only be detected by sensitive ELISA, and may have a different clinical picture and prognosis (134). Low concentrations of terminal components, for example, may be sufficient for preventing meninogococcal disease and can be tested for their ability to incorporate into the TCC by ELISA based on neoepitope-specific anti-C9 monoclonal antibodies (135). None of these quantitative assays allows, although widely practiced, the assumption that approximately half-normal concentrations indicate heterozygous deficiency. Heterozygous subjects may present with almost normal concentrations of the component in question. A very sophisticated assay in ELISA format has recently been elaborated by a European consortium, which can be used as a screening assay for detecting complement deficiencies (136).

Complement-deficient subjects are usually detected because of their increased propensity to infection or, especially for deficiencies of the early classical pathway components, in association with systemic lupus erythematosus (SLE) (Table 33.5). As only *C4* and *C2* are encoded on the same chromosome (within the MHC-III region; see Table 33.1), the possibility that these deficiencies are all linked to a disease-susceptibility gene can be excluded. In contrast, it is the absent "detergentlike" effect of complement (see "Complement as Pathogenic Factor in Disease") that leads to impaired clearance of immune complexes and to their sequestration at peripheral sites, giving rise to further inflammation and immune complex formation.

It is not surprising that deficiency of mannan-binding lectin (MBL), a major plasma protein of the innate immune

▌ TABLE 33.5 **Complement-Deficiency States**

Component	No. of Reported Patients	Functional Defect	Disease Associations[a]
C1	50–100	Impaired immune-complex handling	SLE, bacterial infections
C4	20–50	Impaired immune-complex handling	SLE, bacterial infections
C2	>1,000	Impaired immune-complex handling	SLE, bacterial infections
C3	20–50	Impaired opsonization	Bacterial infections
C1-INH	>>10,000	Excessive C2 and kinin activation	HAE
B	None		Not incompatible with life in mouse
D	<5	Impaired alternative-pathway activation	Bacterial infections?
P	>100	Impaired alternative-pathway activation	Meningococcal infections
H	>100	Excessive alternative-pathway activation	Meningococcal infections, glomerulonephritis
I	20–50	Excessive alternative pathway activation	Bacterial infections
Carboxy-peptidase N	<5	Absent inhibition of C5a and C3a	Angioedema, chronic urticaria
C5	20–50	Impaired chemotaxis, absent lytic activity	Meningococcal infections
C6; C7; C8	>100 each (independent)	Absent lytic activity	Meningococcal infections
C9	>1,000	Impaired lytic activity	Meningococcal infections

[a] Only established and typical disease associations are listed (i.e., >50% of deficient subjects suffering from disease).

system with the ability to initiate antimicrobial and inflammatory actions, results in a higher susceptibility to infection. MBL deficiency is common, as more than 10% of the general population may, depending on definition, be classified as MBL-deficient (137).

In individuals with homozygous C3 deficiency, pyogenic infections with encapsulated bacteria are severe, recurrent, and life-threatening, usually starting in early childhood. Deficiencies of factor I or factor H are associated with the inability to degrade C3b, leading to uncontrolled amplification of cleavage of C3 by C3b,Bb and resulting in a state of acquired, severe C3 deficiency (138).

Whereas deficiencies of properdin predispose to (usually singular) meningococcal infections, deficiencies of a terminal complement component lead to recurrent infections by gram-negative bacteria as a result of an inability to generate a bactericidal membrane attack complex. Recurrent infection or infection with uncommon serogroups should alert the clinician in nonendemic regions, whereas recurrent disease is the important indicator in endemic areas (134). Associations of terminal complement deficiencies with susceptibility to autoimmune diseases, such as SLE, are likely the result of ascertainment artefacts (134).

Hereditary angioedema (HAE), the clinically most relevant, by far most acute, and, if untreated, potentially lethal, complement deficiency, is the clinical manifestation of an inherited or acquired C1-inhibitor deficiency (139). An absent, depleted (also via autoantibodies), or dysfunctional C1 inhibitor will allow unrestricted activation of the classical pathway, as there is no sufficient backup for the C1 inhibitor. The C2b fragment generated also exhibits kinin activity and is thus responsible for the classical symptoms of HAE; affected patients suffer intermittently from multiple edemas, predominantly in the skin, the gastrointestinal tract, or the oropharynx, usually when the patient experiences minor trauma or infection that triggers unrestricted complement activation. Edemas in the larynx may be life-threatening (i.e., danger of suffocation). Although laryngeal edema in HAE usually develops within hours, and not within minutes as does allergic laryngeal edema, HAE is, even today, associated with a high mortality rate. The frequent association with abdominal colic may also delay the correct diagnosis. The acute treatment of HAE consists of replacement of C1 inhibitor in purified form or, if unavailable, infusion of fresh frozen plasma. Testosterone derivatives (e.g., Danazol) have been used successfully for the long-term prevention of attacks.

A particular deficiency, which is primarily not a complement deficiency, is paroxysmal nocturnal hemoglobinuria (PNH). Mutations in the *PIG-A* gene affect the synthesis of a competent glycosylphosphatidylinositol (GPI) anchor, which leads to failure of expression of all molecules attached to the membrane via this anchor, including CD55 and CD59. The lack of these two complement-control proteins is responsible for the extreme susceptibility of PNH erythrocytes to lysis by complement that is either activated by the alternative pathway or via acidic generation of C56, i.e., the activation of C6 without cleaving off C5a, especially at the physiologically lower blood pH at night (140).

COMPLEMENT IN THERAPY: TARGET AND TOOL

The cloning of the complement components, the determination of their functional domains, and increasing knowledge of immunologic relationships have made it feasible to design therapeutic approaches that (a) interfere with excess complement activation in pathophysiologic settings or in therapeutic approaches; (b) stimulate complement attack on tumor cells; or (c) take advantage of complement to optimize therapeutic or prophylactic tools (Table 33.6).

Interference with Complement Activation

Dysregulated complement activation exerts detrimental effects on organs and cells, and is involved in the pathogenesis of a broad variety of diseases. Furthermore, the unintentional activation of the complement cascade can limit therapeutic interventions, such as (xeno)transplantation, gene therapy via viral vectors, or use of biomaterials (hemodialysers, catheters, prostheses, stents, etc.) (141). This situation creates a strong need for controlled and adequate interference with complement activation.

Different mechanistic concepts for the inhibition of complement activation include (a) native or modified complement regulators, (b) transfer of genes encoding complement regulators, (c) monoclonal antibodies recognizing complement factors or fragments derived thereof, or (d) peptides that block complement factors or its receptors (Table 33.6).

Native regulatory proteins generally have the advantage of being perfectly specific and having a low antigenic potential. Plasma-derived C1-INH is used for standard substitution therapy in hereditary or acquired angioedema (142), but also favorably influences the outcome in life-threatening conditions associated with a relative deficiency of functional C1-INH (143). C1-INH substitution has been used with success in animal models or open, uncontrolled clinical trials in septic shock, capillary leak syndrome, or ischemia/reperfusion injury.

Recombinant soluble CR1, designated TP10, is a truncated derivate of the cell surface CR1. Clinical studies showed that TP10 improves the outcome of lung transplant recipients and inhibited complement activation in patients undergoing cardiac surgery on cardiopulmonary bypass (144). However, this was not associated with a reduced morbidity and mortality. New complement-inhibitor substances are often modified to prolong the bioavailability

▶ **TABLE 33.6 Complement in Therapeutic Approaches**

Target/Mechanism	Potential and Established Indication	References
I. Inhibition of complement activation		
Application of soluble CR1 or fragments thereof (e.g., TP10, APT070, TP20) Inhibition of C3/C5 convertases and cofactor activity for factor I	Rheumatoid arthritis Systemic lupus erythematosus Ischemia-reperfusion injury Cardiac surgery Transplantation Acute respiratory distress syndrome ABO incompatibility in blood transfusion	179, 146, 179, 180, 181, 182, 183, 184
Application of C1-INH protein: Inactivation of C1r, C1s, MASP2	Hereditary or acquired angioedema Brain/liver ischemia Septic shock, burn (capillary leakage syndrome) Antiphospholipid syndrome in pregnant women Myocardial infarction, myocardial surgery Transplantation	143, 185, 186, 187, 188, 189, 190
Application of modified soluble CD59 (e.g., sCD59-APT542)	Rheumatoid arthritis Paroxysmal nocturnal hemoglubinuria	145, 190
CD55-transgenic animals, vector-mediated transfer of CD55 Inhibition of C3/C5 convertases	(Xeno)transplantation	147, 149
Incorporation of CD55 into viral vectors Inhibition of C3/C5 convertases	Protection of viral vectors in gene therapy	150, 151
Antibodies to C5 (pexelizumab, eculizumab) Inhibition of C5 cleavage by convertases	Myocardial infarction Stroke Coronary artery bypass, aortic valve replacement Membraneous nephritis Rheumatoid arthritis Paroxysmal nocturnal hemoglobinuria Dermatomyositis	152, 153, 154, 192, 193
Antibodies to C5a Prevention of anaphylatoxin activity	Septic shock Pulmonary edema	194
Antibodies to Factor D Inhibition of factor B cleavage/activation from alternative pathway	Myocardial injury, surgery	155
Synthetic peptides binding to C3 (e.g., compstatin) Inhibition of C3 cleavage by convertases	Hyperacute rejection in transplantation Organ preservation ex vivo	156
Antagonists to C3a receptor (e.g., SB290157) Blocking the anaphylatoxin receptor	Inflammation, e.g., after surgery Allergic asthma Arthritis	157, 195
Antagonists to C5a receptor (e.g., PMX53, PMX205) Blocking the anaphylatoxin receptor	Inflammation after injury or surgery Septic shock Rheumatoid arthritis Ischemia-reperfusion injury Inflammatory bowel disease Abdominal aortic aneurysm Liver fibrosis Neurodegeneration	158, 159, 196
II. Stimulation of complement activation		
Optimization of therapeutic monoclonal antibodies for complement stimulation Complement-dependent lysis of tumor cells	Several forms of tumors	161, 162, 163, 165, 197, 198, 199
Antibodies to CD55 Reduced inhibition of C3/C5 convertases	Several forms of tumors	166
Monoclonal antibody that mimics CD55 Induction of immune response to CD55	Several forms of tumors	166, 167, 168
Small interfering RNA (siRNA) to CD55 Reduced inhibition of C3/C5 convertases	Several forms of tumors	169

Target/Mechanism	Potential and Established Indication	References
III. Exploitation of complement molecules for therapy and vaccination		
CD46 as measles virus receptor	Several forms of tumors	171, 172, 173
Measles virus–induced lysis of tumor cells		
CD46 as receptor for adenovirus subgroup B	Several forms of tumors	174, 175, 176
Adenovirus-induced lysis of tumor cells	Vaccination	
Adenovirus as antigen carrier to CD46-bearing APC	Gene therapy	
Adenovirus as vehicle for therapeutic genes		
CD55 as coxsackievirus receptor	Several forms of tumors	171
Coxsackie virus–induced lysis of tumor cells		
C3d-enhanced DNA vaccination	Vaccination	177, 178, 200
Increase of humoral immune response		

and to retain them after local administration at the inflammatory site(s) of interest. Soluble CR1 or CD59 were chemically coupled to a short synthetic address tag that confers membrane-binding activity. These modified complement regulators are therapeutically effective in animal models of rheumatoid arthritis or paroxysmal nocturnal hemoglobinuria (145,146). In another tagging approach, sCR1 was expressed with high amounts of the sialyl Lewis^x carbohydrate, the ligand for E-selectin. The resulting compound, TP20, is targeted to E-selectin, which is upregulated on inflamed endothelium, and thus blocks the attachment of neutrophils. TP20 showed benefits over the unmodified TP10 in a murine model of stroke and in a rat-lung transplantation model, but has not been studied further (147).

Gene transfer is suggested or under development for complement inhibition in xenotransplantation and protection of viral vectors for gene therapy. In xenotransplantation, hyperacute rejection is due primarily to the attachment of preformed xenoreactive antibodies to the donor vascular endothelium, which results in hyperactivation of the complement system. Organs from donor pigs transgenic for human CD55 showed less parenchymal injury and decreased sequestration of platelets when perfused with human blood, thus representing an interesting organ pool for transplantation (148). Expression of CD55 can also be achieved by adenoviral transduction and results in reduced sensitivity to complement-mediated lysis (149). Incorporation of genes for complement inhibitors protects lentiviral or baculovirus-derived vectors from inactivation by human complement and thereby enables the development of more potent delivery stems for gene therapy (150)

Monoclonal antibodies (mAbs) represent a third strategy to interfere with complement activation. Anti-C5 antibodies (151) are the best-studied representatives of that class. Both pexelizumab and eculizumab are humanized mAbs that bind to C5 with high affinity and prevent C5 cleavage, C5a generation, and MAC formation, but allow C3 activation and deposition. Pexelizumab is currently being tested in a Phase III clinical trial in patients undergoing coronary artery bypass graft surgery, and has significantly reduced mortality and myocardial infarction (152,153). Eculizumab was shown in an open-label extension trial to be well tolerated and to reduce hemolysis in patients with paroxysmal nocturnal hemoglobinuria (154). Surprisingly, data presented with an anti-factor D antibody showed effective complement inhibition, neutrophil activation, and IL-6 production in a baboon model of cardiopulmonary bypass, obviously a result of the selective inactivation of the alternative pathway (155).

Small synthetic molecules inhibit complement activation by binding to complement factors or its receptors. Compstatin is a synthetic 13-residue cyclic peptide that binds to the β chain of C3 and inhibits its cleavage by C3-convertases, presumably by an induced conformational change of C3 (156). Compstatin has been successfully tested in animal models of hyperacute rejection in kidney xenotransplatation and of extracorporeal circulation, where it inhibits the activation of C3 and downstream pathways.

The role of C3a and C5a in anaphylaxis, sepsis, adverse reactions in extracorporeal circulation, or dialysis, has led to the generation of receptor antagonists. The C3a receptor antagonist SB 290157 blocked C3a-triggered effects of the C3aR and showed anti-inflammatory activity in animal models for allergic asthma and intestinal ischemia-reperfusion injury. Recent results, however, implied that SB290157 can also have an unwanted agonist activity, which urgently warrants further studies before any therapeutic use (157). The cyclic hexapeptide PMX53 and its more lipophilic derivative PMX205 competitively inhibit the interaction between C5a and its receptor (158). The substances were tested successfully in animal models of e.g., ischemia-reperfusion injury, rheumatoid arthritis, and neurodegeneration, where they reduced morbidity

and mortality, as well as neutrophil infiltration, apoptosis, and synthesis of inflammatory cytokines (159).

Stimulation of Complement Activation

Immunotherapy using mAbs holds great promise to improve therapy of malignancies, because of its ability to specifically target malignant cells while ignoring surrounding normal tissue. However, only seven mAbs are currently approved for clinical use. To improve antibody tools, it is therefore a priority to optimize their triggering of the complement attack against tumor cells. Complement initiates two mechanisms that are effective against mAb-coated tumor cells: direct killing by MAC (complement-depending cytotoxicity; CDC) and CR3-dependent enhancement of antibody-dependent cytotoxicity (ADCC), in which CR3 binds to iC3b, thus enhancing FcγR-mediated effector-cell binding. A third mechanism, the priming of CR3 by β-glucans, which, in concert with target-associated iC3b, elicit phagocytosis, is usually activated only by microorganisms but not by tumors (160). However, strategies to support this third way, the CR3-dependent cellular cytotoxicity (CR3-DCC), are under investigation.

Many anticancer antibodies (e.g., rituximab against CD20 on B-lymphoma cells) depend strictly on complement activation in their therapeutic activity (161). Subclass IgG1 is especially effective at directing CDC via the classical pathway; novel human mAbs against tumor antigens may be genetically converted to IgG1 to optimize CDC and ADCC activities (162). To fine-tune the immunologic activity of a given IgG1, novel strategies may include the engineering of its hinge region in order to increase C1q binding (163).

Another putative approach to amplify complement-dependent killing of tumor cells by mAbs is the addition of β-glucans, which bind to CR3 and prime it for binding to iC3b. Thus, β-glucans promote killing of the cancer cells by phagocytes in concert with iC3b opsonization of tumor cells, engendered by administration of antitumor antibodies (164). Other ways to increase complement activation include amplification of the amount of mAb deposited on tumor cells by use of a second mAb directed against the iC3b bound on the tumor cell after binding of the therapeutic antibody. Injection of an anti-iC3b mAb following rituximab treatment in a monkey lymphoma model resulted in enhanced complement activation, iC3b deposition, and killing of CD20$^+$ lymphoma cells (165).

Because complement-regulatory proteins are often upregulated on malignant cells and thus provide relative resistance against complement attack, it is desirable to undermine this evasion mechanism. Besides CD46 and CD59, CD55 has been detected in a variety of different malignancies and is regarded as a requisite for cancer development and progression (reviewed in: 166). To restore tumor sen-

sitivity to complement, several studies applying anti-CD55 mAbs or vaccinating against CD55 have been started recently, and first promising results reveal a significant regression of tumor mass. These strategies to block CD55 on the tumor cells are associated with comparatively low toxicity in humans (166).

Anti-CD55 vaccination can be achieved with monoclonal antibodies mimicking CD55. The following immune response directed against CD55 makes the tumor more susceptible against complement attack. The best-known example is the anti-idiotypic antibody 105AD7, which mimics the first two SCR domains of CD55. 105AD7 stimulated strong CD4 and CD8 responses in initial clinical trials in patients with osteosarcoma or colorectal cancer and was surprisingly well tolerated (167,168). The resistance of lymphoma to complement-dependent cytotoxicity may also be overcome by RNA interference. Small interfering RNA (siRNA) designed for CD55 potently decreased CD55 expression and resistance to CDC in breast cancer cells and lymphoma cells (169).

Exploitation of Complement Molecules for Therapy and Vaccination

New strategies to treat cancer include virotherapy with replication-competent viral vectors obtaining oncolytic properties. The selective upregulation of complement regulators on the tumor cell surface makes complement inhibitor–binding viruses attractive tools and permits targeting virus-mediated destruction of malignant cells within nonmalignant tissue. CD55 is the attachment site of a common cold virus, Coxsackievirus A21 (CAV21). CAV21 rapidly destroys human melanoma cells in a mouse model, highlighting its putative application as an effective oncolytic agent (170).

The attenuated measles virus (MV) vaccine strain Edmonston B (MV-Edm) elicits extensive cell-to-cell fusion and ultimately cell death. Tumor cells—e.g., from breast cancer—that normally express high levels of the MV-Edm receptor CD46 are preferentially targeted by the virus (171). The first clinical trials in patients with cutaneous T-cell lymphomas revealed that MV-Edm therapy was well tolerated, with local viral activity in the tumor and increased immune parameters (172). The tumor selectivity of MV-Edm may be enhanced by making the virus dependent from matrix metalloproteinases; by introduction of a specific sequence into the viral fusion protein F, the proteolytic activation of F can be performed exclusively by these proteolytic enzymes that are secreted in high amounts by cancer cells (173).

CD46 is also the receptor for most B-group adenoviruses (Ad). Recombinant Ad-based vectors with B-group fibers target tumors that express CD46 at high levels and revealed oncolytic effects in animal models (174). CD46-binding adenoviruses can also deliver therapeutic

genes to cancer cells, because the CD46 expression on tumor cells was elevated (175). CD46-binding adenoviruses could also be valuable tools for vaccination. B-group adenoviruses encoding test antigens efficiently target CD46+ dendritic cells and antigen-presenting cells in a monkey model, thus enabling an efficient immune response (176).

Complement provides another interesting tool to support vaccination strategies (177). The C3-fragment C3d, when covalently bound to antigen, serves as a molecular adjuvant in immunization by targeting this antigen to CD21 on B cells and follicular dendritic cells. Complement tagging of antigens may thus help to raise an effective immune response against poorly immunogenic but protective antigens (178). It influences the magnitude of humoral immune response, as it may determine the valence of the constructs; polyvalent CR2-ligands have an immunostimulatory effect, whereas monovalent CR2 ligands are immunosuppressive. Recombinantly or chemically attached C3d as a "natural adjuvant" has been shown to elicit enhanced immune response against prominent pathogens such as measles virus, influenza virus, pneumococci, or HIV.

CONCLUSION

Complement comprises plasma proteins (i.e., substrates and regulators of the activation cascades) and cell membrane proteins (i.e., receptors and cell-protecting regulators). Complement activation, triggered by bound antibody or microbial patterns directly, proceeds in three intertwined pathways (classical, lectin, and alternative) and either leads directly to destruction of foreign structures through insertion of a lytic pore or contributes to their elimination, e.g., through promotion of phagocytosis and antibody formation.

Recent findings have advanced our understanding of complement, especially of the ways it can be dealt with in clinical therapy. The genotype of *MBL*, standing for the activity of the lectin pathway, was shown to correlate widely with disposition to infection. The three-dimensional structures of core components (e.g., C3) have been solved. Finally, several specific complement inhibitors (chimeric constructs derived from natural regulators, monoclonal antibodies, or small molecules found by combinatorial approaches) are in the stage of advanced clinical trials. Ischemic and inflammatory diseases, including ischemia-reperfusion injury in surgery and transplantation, are particularly interesting for therapeutic complement inhibition.

Cytotoxic T Lymphocytes

R. Chris Bleackley

The cell-mediated immune system serves to defend organisms against intracellular pathogens through the action of cytolytic effector cells. These effectors can destroy targets infected by a virus or harboring microbes and are also believed to be involved in the eradication of tumors, the rejection of transplants, and the pathogenesis of a number of autoimmune diseases. In vertebrates, defense occurs through two distinct mechanisms: the innate and the adaptive responses. During innate immunity pathogens are destroyed when macrophages and monocytes perform phagocytosis and when granulocytic cells, such as eosinophils, release cytotoxic substances. Natural killer (NK) cells are also considered part of innate immunity. These responses are extremely important for the successful removal of many pathogens and are also involved in the body's ability to inhibit tumorigenesis. How-

ever, the innate immune response is unable to adapt to changing pathogens that may be encountered during the host's lifetime. This is achieved via the adaptive immune response, which is specifically activated by, and targeted against, the antigens expressed by the invading organism. Although this type of response requires a few days to develop, it is able to eliminate the pathogen with minimum damage to noninfected tissues. An adaptive response is also able to retain memory of antigen exposure and thus is able to mount a quicker and more powerful response when again presented with the same antigens. The adaptive immune response therefore possesses two main advantages of specificity and memory that contributes to the success of pathogen removal.

The adaptive effectors are T lymphocytes (both CD8$^+$ and CD4$^+$ cells). It was originally believed that CD4 cells

were exclusively regulators and CD8 the major effectors of cell mediated immune responses. This is still a convenient way of thinking, but it is now clear that there is some overlap in functions. For the sake of simplicity most of the discussion in this chapter will deal primarily with CD8 cells, but it should be realized that CD4 killers can use similar molecules to destroy targets. In addition, T and NK cells are very similar in their mechanisms of killing, although the ways in which they recognize targets are different. NK cells are discussed in detail in Chapter 16.

BASIC BIOLOGY/HISTORY OF CTL-MEDIATED KILLING

The first experimental models of killing were developed in the 1960s with *in vivo* sensitized effectors acting *ex vivo* to destroy targets (1). Early progress was rather slow because there was no easy way to measure lysis other than by direct observation. However, a major breakthrough came with the development of an assay to monitor and quantify lytic activity based on the release of radioactive chromium (Cr^{51}) from targets undergoing lysis (2). Healthy cells will take up the isotope in the form of chromate, and the reduced chromium becomes stably complexed with intracellular proteins. When the cell lyses the chromium is released and can be quantified as a measure of lytic activity. Using this assay, a series of insightful experiments were performed during the next decade that provided the fundamental description of the biology of cytotoxic T lymphocyte (CTL)–mediated killing (3,4). Indeed, this measurement of lysis by chromium release was used by Zinkernagel and Doherty to establish the basis of MHC restriction (5).

Target cell lysis was observed to be quite rapid and was not blocked by inhibitors of protein synthesis (6), suggesting that preformed mediators of cell death were carried by activated CTL. The lytic reaction required cell–cell contact, was unidirectional, and the effector came away uninjured to kill multiple targets (7). In addition, neighboring cells that were not recognized by the effectors were spared which led to the concept of a directed, local mechanism of cytolysis (2).

During these early days, the discovery of interleukin (IL)-2 and its use to generate functional clones of CTL was particularly significant (8). This allowed investigators to generate large numbers of functional cells and thus pursue the biochemical and genetic analyses of CTL-killing mechanisms. The model of killing that was developed divided the process into three stages: CTL-target binding; programming the target for lysis; and finally, target cell death. The initial contact between the cells was independent of antigen and mediated by the interactions of LFA-1 (lymphocyte function-associated antigen 1) and CD2 on the T cell with ICAM-1 and LFA-3 on the target. This early adhesion step required a few minutes and was dependent

on magnesium. The importance of these initial interactions was underscored by transfection experiments showing that antigen-specific lysis does not occur unless the nonspecific binding occurs (9). Indeed, recent data provide evidence that LFA-1 delivers a signal that is essential for the degranulation process discussed later (10). Specific interactions then occur between TCR and antigen/MHC, and without this critical step the cells move apart. Finally, CD8 strengthens the interaction by binding directly to MHC.

The end result of these signal transduction events is a dramatic reorganization of the CTL and the polarized exocytosis of cytoplasmic granules discussed in detail later. After delivery of the kiss of death, it takes a couple of hours to see significant lysis as measured by the chromium release assay. However, recent studies that monitor events, such as mitochondria depolarization and DNA fragmentation, demonstrate that the target is on the road to death much sooner. Interestingly, the killer cell is no longer needed and can detach to go in search of its next target.

CTL DIFFERENTIATION AND FORMATION OF GRANULES

$CD8^+$ T cells are stimulated through recognition of antigen bound to major histocompatibility complex (MHC) class I protein through the T cell receptor (TCR) and CD8 coreceptor. The initial activation involves three cellular players. First, antigen is presented by professional APCs, such as macrophages, which secrete IL-1. This acts on helper T cells to stimulate proliferation and production of IL-2, which stimulate the differentiation of precursor CTL into active killers.

Several intracellular events are triggered by this intimate contact between CTL and antigen presenting cells (APC). The signal transduction pathway involves the TCR-associated CD3 complex and kinases, such as lymphocyte cell kinase ($p56^{lck}$) and protein kinase C. At the same time, inositol triphosphate, produced by the action of phospholipase C on phosphatidyl bisphosphate, induces the release of calcium from intracellular stores. This is accompanied by an influx of extracellular calcium, and a net result is an increase in intracellular calcium. This lymphocyte activation can be duplicated *in vitro* with factors such as CD3 antibodies (αCD3) and concanavalin A (con A) in the presence of the cytokine IL-2.

Early events in effector differentiation have been studied extensively in $CD4^+$ T cells and to a lesser extent in $CD8^+$ T cells. Downstream signaling pathways are initiated almost immediately after TCR stimulation and within hours induce the transcription of hallmarks of early T cell activation such as the IL-2 gene. Effector CTL differentiation occurs 3 to 5 days after activation and a number of CTL effector-specific genes, including the granzymes, granulysin, perforin, and RANTES are up-regulated at this
FIGURE 34.1 CTL binds to an antigen expressing cell. The CTL binds to an APC during the initial activation events. This results in clonal expression, differentiation, and expression of cytotoxicity-related proteins. When the activated CTL then binds to a target, the granules polarize and are released towards the target.

time. For example, granzyme B gene transcription, an important granule constituent of the CTL, begins after 48 hours of *in vitro* activation of primary murine $CD8^+$ T cells, and peaks after 5 days have passed (11). Little is known about the processes inducing transcription of these late genes, many of which are important for the establishment of CTL cytotoxicity and are essential components of the granules that develop in the CTL.

When $CD8^+$ T cells differentiate into effector CTLs, a number of proteins are expressed that allow the CTL to perform their effector functions. Naïve $CD8^+$ T lymphocytes are unable to kill and do not contain cytotoxic granules. During the period of effector differentiation, many effector proteins unique to CTLs are transcribed and translated. These nascent proteins are then packaged within the new cytoplasmic granules. However, MHC class I molecules are not restricted to so-called *professional APCs,* but are expressed by every cell in the body. Therefore, $CD8^+$ T cells can recognize when a cell of the body displays an altered self-protein via the MHC class I receptor. Thus, although the signal transduction events are similar, there is a fundamental difference between a naïve T cell being stimulated and an armed killer that encounters an antigen-positive target (Figure 34.1). In the latter case, the interaction now results in the polarization of granules and delivery of the kiss of death.

CYTOTOXIC GRANULES AND EXOCYTOSIS

Cytotoxic granules are also known as *secretory lysosomes*. They have a dense core of proteins required for granule-mediated target cell death, surrounded by a multilamel-

lar region similar to lysosomes. They first appear as multivesicular structures that slowly acquire dense cores as newly translated secretory proteins accumulate within the organelles (12). The targeting of some of the granule-proteins (e.g., granzymes, discussed later) is directed to the organelle via a mannose-6-phosphate signal, while others (e.g., perforin) must use a different mechanism (13). The organelles are acidic, with a pH around 5, and act in the CTL both as a lysosomal organelle, and as a secretory granule (14).

The secretory lysosome differs from normal lysosomes in that it can fuse with the plasma membrane in a regulated fashion in response to activation of the TCR by a virus-infected or tumor cell. TCR engagement initiates tyrosine kinase signaling cascades and calcium influx that causes a dramatic reorganization of the CTL. Shortly after contact, the microtubule organizing center (MTOC) and Golgi apparatus reorient toward the point of contact with the target, and the nucleus moves away (15). This suggested that a polarized secretory mechanism was involved in the killing process. At around the same time, it was demonstrated that cytoplasmic granules isolated from NK and CTL were cytolytic (16,17). The observations that the granules polarize and contained lytic effectors led to the formulation of the granule exocytosis model of CTL function (18). A simplified view of the process is depicted in Figure 34.2.

Henkart suggested that CTL produce potent lytic molecules and store them in cytoplasmic granules. Upon target cell recognition, the granules move toward the point of contact and the contents are exocytosed to deliver the lethal hit. Immunofluorescent staining revealed that the actin and tubulin in the CTL were also polarized toward the target. These provide the tracks for the movement of granules toward the target. This view was substantiated by direct visualization of cell conjugates using high-resolution Nomarski optics cinematography (19). The
FIGURE 34.2 The steps during CTL-mediated killing. The target is recognized by the CTL via nonspecific adhesion, then specific interaction with the TCR. This latter tight binding results in the polarization of the microtubule organizing center; the Golgi and the granules move toward the target. The nucleus appears to move to the side, and the granules fuse with the CTL membrane in the region of contact with the target. This results in the release of the granule contents including perforin and granzymes.
FIGURE 34.3 Killing in action. This cytotoxic cell appears to contact two targets (red); however, the granules (green) are polarized to the left-hand target. The cell exhibits the characteristic blebbing of apoptosis. The other target seems unaffected. Figure provided by Dr. I.S. Goping, University of Alberta. (See color insert.)

nucleus was seen to be displaced and the granules migrated toward the contact site. Importantly, microtubule-disrupting drugs inhibited target cell lysis (20), suggesting that the polarization of granules toward the target was critically important. Figure 34.3 shows, quite dramatically, a cytolytic cell in action. The granules are polarized toward one cell and the nucleus is shifted aside. Clearly, the target involved in degranulation is dying (the blebbing is characteristic of apoptosis, and this will be discussed later), while the other target appears unaffected.

The movement of the granules has been shown in an *in vitro* assay to be dependent on kinesin (21), but the components of the molecular machinery that control granule exocytosis are only now coming to light. Interestingly, a number of candidates were identified through the analysis of coat color mutant strains of mice when it was realized that melanocytes and CTL share the same unusual secretory lysosome (22). The mouse studies have been complemented by the analysis of albinism and immune deficiencies in patients (23), which has led to the identification of regulators of exocytosis, such as AP3, Rab27a, and Munc 13-4. Although the movement of the granules requires microtubules it appears that the final step of delivery to the plasma membrane is dependent on polarization of the centrosome (24).

After CTL-target conjugation there is also a redistribution of adhesion and signalling molecules to the region of contact (25). The central area, called the *central supramolecular activation complex* (c-SMAC), contains the TCR and CD8 molecules and is surrounded by a ring of

adhesion proteins that constitutes the peripheral-SMAC, or p-SMAC. The contents of the lytic granules are released in a secretory domain between the p-SMAC and c-SMAC (26). The tight synapse formed between target and effector cells ensures that the lytic proteins released from the CTL will be quickly taken up to the target cell, and therefore avoid damage to other neighboring cells. This mechanism of targeted exocytosis of granules allows the CTL killing machinery to be directed very specifically to the target cell and to release the contents of the cytotoxic granules in a very concentrated manner.

GRANULE CONTENTS

The most abundant proteins found in granules are perforin and granzymes. However, proteoglycans, some Fas ligand protein, and a few cytokines are also present. Other proteins that are contained in granules, but not exclusively found in CTLs, are calreticulin, and lysosomal proteins.

Perforin

Perforin was first identified as a lytic molecule found in cytotoxic granules (27,28). The protein, also known as *cytolysin* in the early days, is a 65 kDa polypeptide that can bind to lipids. The gene was cloned (29,30) and the amino acid sequence predicted a region of strong homology to the pore-forming C9 protein of complement (31). Perforin was consequently shown to polymerise and form pores in the membranes of red blood cells (32). It is sorted into lytic granules by a mannose phosphate–independent, unknown mechanism. Once inside the granules perforin is proteolytically activated into a mature form (33). It is inactive in the acidic environment of the cytotoxic granule, but forms pores when released into the neutral environment of the intermembrane space in the presence of Ca^{2+}. This led to the proposition that CTLs caused death by releasing perforin to disrupt the plasma membrane of the target cell through pore formation. However, CTL-induced apoptosis does not only result in cell lysis and membrane damage, but includes DNA fragmentation, suggesting additional factors besides perforin were involved in CTL-mediated cell death (34). These factors were later identified as a family of serine proteases, now called *granzymes,* which will be discussed in the next section.

The generation of perforin knockout mice showed the critical role of perforin for granule-mediated cytotoxicity of the CTL (35), and to allow the delivery of granzymes into the cytoplasm of target cells. This delivery was originally visualized with granzymes simply entering into target cells through perforin pores formed in the plasma membrane. However, addition of sublytic concentrations of perforin that do not form pores in the plasma membrane is still sufficient to enable granzyme entry into target cells.

Surprisingly, granzymes have also been shown to enter into target cells independently of perforin, but the proteases remain harmlessly confined to endocytic vesicles until perforin, or another permeabilizing agent, releases them (36). Granzyme B entry into target cells will be discussed in more detail later.

The structure function analysis of perforin has not been well studied because of the inability to express the recombinant protein. Recently, a baculovirus system has been developed and used to confirm that the carboxyl C2 motif is responsible for membrane binding and to define the residues important for lysis (37). In addition, the functional analysis of a number of the mutant forms of perforin present in patients have been carried out (38).

Granzymes

The granzymes are a family of serine proteinases that colocalize with perforin in the granules. Only granzymes A (grA) and B (grB) are found in any abundance in CTL, and they will be a major focus of discussion in this chapter. Both are synthesized as preproenzymes with the hydrophobic leader sequence removed upon entry into the endoplasmic reticulum. The proenzyme is activated by the removal of the aminoterminal dipeptide by the enzyme cathepsin C as the granzymes are packaged into granules (39). All family members are highly basic, which likely contributes to their interaction with proteoglycans.

The genes for granzymes A and B were first cloned (40,41), and then the proteins isolated (42). Granzyme B was predicted to have unusual substrate specificity for cleavage at aspartate (43), and this was confirmed biochemically (44). No other eukaryotic serine protease cleaves at an aspartic acid, and this specificity allows granzyme B to act like an initiator caspase to activate apoptosis, as will be discussed later. Granzyme A resembles trypsin as it cleaves after argine and lysine residues and can conveniently be detected using benzoyl lysine thioester as a substrate (45). Both granzymes are targeted to granules by the mannose-6-phosphate receptor (46).

Proteoglycan

Serglycin is the proteoglycan that is found in CTL granules. It is believed to be involved in the packing of lytic compounds within the organelles. The protein consists of serine-glycine repeats to which sulphated glycosaminoglycan chains are linked. Overall, the molecule is very negatively charged, which likely contributes to its ability to bind to the basic granule components. In isolated granules, there are stable interactions between the serglycin and granzyme A (47), granzyme B (48), and perforin (49). The interaction appears to be ionic since high salt disrupts the complexes. Knocking out the serglycin gene leads to impaired ability to produce dense granules and a reduc-

tion in granule protease activity (50). The complexes of serglycin with granzymes and perforin are maintained after exocytosis. Interestingly, these complexes can still mediate killing (48,51).

Other Cytotoxic Granule Proteins

Fas ligand was first thought to be present exclusively on the surface of CTLs, but it has also been shown to be stored in cytotoxic granules (52). The protein activates cell death at the plasma membrane, and the stored FasL translocates in a polarized manner to the plasma membrane, where the synapse with the target cell has formed. This allows FasL-induced apoptosis to occur in a directed manner to the target cell and avoids nonspecific bystander killing. The nascent protein is delivered to the granules from the trans-Golgi network following a distinct sorting mechanism (52).

Chemokines, such as RANTES and macrophage inflammatory protein (MIP-1α), have also been found in cytotoxic granules and are important in lysis of virion-producing cells in HIV-1 infection (53). Another protein present is granulysin (54), a member of the saposin-like protein family (55). This novel cationic protein is active against a broad range of gram-positive and -negative bacteria, fungi, and parasites (56). It has been also suggested that granulysin may play a role in CTL action on tumors and act as a chemoattractant and pro-inflammatory mediator (57). Rather surprisingly, no mouse homologue has been described.

Calreticulin (CRT) is a calcium storage protein and chaperone normally found in the endoplasmic reticulum, but has also been found in the cytotoxic granules of CTLs (58). CRT expression is up-regulated upon CTL activation and is found to interact with perforin to inhibit its lytic activity (59). The exact role for CRT in lytic granules is not fully understood, as CTLs derived from knockout mice possess functional lytic machinery. The effectors from the deficient mice did, however, show a compromised level of killing that correlated with reduced conjugate formation and defects in calcium signalling (60,61).

Lysosomal hydrolases, such as cathepsin B, C, D, and cathepsin A-like protective protein, acid phosphatase, arylsulphatase, and α-glucosidase, are found in the periphery of the cytolytic granules. Also present is cathepsin C, which is responsible for the proteolytic maturation of the enzymes granzyme A and B (39). Lysosomal membrane proteins, such as Lamp-1, Lamp-2, and CD63, are also present on the membrane surface of cytotoxic granules.

GRANULE-INDEPENDENT MECHANISMS OF TARGET CELL LYSIS

Although the granule-mediated mechanism became the accepted paradigm for target cell death, it soon became clear that this was not the complete story. CTL lines were

described that would kill targets in the absence of calcium, did not express perforin or granzymes, and were lytic without exocytosis (62,63). This alternate form of death was found to be mediated by Fas ligand on the surface of the CTL, which binds Fas expressed by the target (64). These mechanisms are not mutually exclusive and often may act in concert. Most short-term assays are dominated by granule exocytosis, and Fas is only revealed if this is blocked pharmacologically by, for example, concanamycin A (65) or in perforin knock out CTL (66). For long-term assays, the Fas pathway becomes more important, and death induced by TNF is also apparent (67).

APOPTOSIS AND NECROSIS

The observation that CTL-mediated death was accompanied by fragmentation of the target cell DNA led to the hypothesis that apoptosis was being activated. This, indeed, proved to be the case, but it is now clear that the targets can also die by necrosis, particularly if apoptosis is inhibited. Clearly, the *in vitro* death induced by perforin resembles necrotic death. Necrosis was originally thought to be a passive process resulting from extreme environmental pressure, such as heat or a noxious chemical. The process begins in the cell with organelle swelling and is accompanied by early disruption of the cell membrane resulting in the release of cellular contents that leads to inflammation of surrounding tissues. Apoptosis, in contrast, is a quiet form of cell death where cellular contents remain neatly packaged in membrane-enclosed apoptotic bodies that are rapidly engulfed by phagocytic cells.

Cells undergoing apoptosis can be recognized by a variety of distinct morphological and biochemical changes. There is characteristic blebbing of the plasma membrane, and condensation and fragmentation of the chromatin. The cell breaks up into small apoptotic bodies that are phagocytosed efficiently by macrophages (68). The apoptotic cells are phagocytosed so efficiently because of the appearance of novel molecules on the surface that can be recognized by phagocytes. One such example is the movement of phosphatidyl serine (PS) from the inner to the outer membrane. PS exposure is an "eat me" signal for phagocytic cells like macrophages and dendritic cells (69), allowing apoptotic cells to be removed with minimal inflammation (70). It is rather surprising to realize that the membrane rupture that is revealed by the chromium release assay likely never occurs *in vivo* when a target under attack by a CTL dies by apoptosis. Long before membrane rupture, the doomed cell is removed by the extremely efficient phagocytic process.

The most striking biochemical change during CTL-mediated apoptosis is the characteristic internucleosomal degradation of chromosomal DNA. This creates a "ladder" of oligonucleosomal fragments when apoptotic DNA is visualised by agarose gel electrophoresis (71). Degradation occurs when caspase-activated DNAse, or CAD, is activated in the apoptotic process. The active caspase actually cleaves the inhibitor of CAD (ICAD). The freed nuclease then translocates to the nucleus and induces double-strand breaks between the nucleosomes (hence the ladder). These caspases are at the very heart of apoptosis and, as we will see, are very much involved in granzyme B and Fas-mediated death.

Caspases

Caspases (cysteinyl aspartate-specific proteinases) are proteases that have a cysteine residue in the active site and cleave substrates on the carboxyl side of aspartate residues (72). These proteins are present in every cell as inactive pro-enzymes that contain an inhibitory domain at their amino-terminal and a small and large subunit. The enzyme is activated when the pro-domain is cleaved from the rest of the protein. Upstream or initiator caspases are activated at the beginning of apoptotic cascades, generally after recruitment to a receptor as during Fas-mediated cell death. Downstream or effector caspases are directly or indirectly activated by upstream caspases and can also be cleaved by the CTL protein granzyme B. Effector caspases, such as caspase-3, act as the executioners and cleave substrates throughout the cell.

One of the key substrates is ICAD, or inhibitor of caspase-activated DNAse. This inhibitory protein is normally bound to CAD (caspase-activated DNAse) in the cytoplasm of a healthy cell. When cleaved by an effector caspase, ICAD no longer inhibits the CAD enzyme, which translocates to the nucleus and is responsible for the internucleosomal degradation of the chromosomal DNA (73). Caspases also cleave a number of structural proteins, such as lamins, actin, and fodrin, leading to cell shrinkage and cytoskeletal rearrangements. The loss of mitochondrial potential and leakage of mitochondrial proteins can also be caused by caspase activity during apoptosis. All of these features are seen in CTL-mediated death. As seen in Figure 34.3, the dying target cell shows the classic apoptotic blebbing.

FAS-MEDIATED CELL DEATH

Death receptors of the tumor-necrosis factor receptor (TNFR) family, including the FasL protein, are expressed on the surface of effector CTLs. The FasL protein has been found to induce Ca^{2+}-independent apoptosis in target cells expressing the Fas receptor, also known as CD95 (64). This receptor-ligand binding causes clustering of the receptor molecules and recruitment of signaling molecules to form a multiprotein complex called the DISC, or death-inducing signalling complex (74). The DISC consists of a docking

protein FADD (Fas-associated death domain) and pro-caspase-8. The clustering of the Fas protein causes FADD proteins to bind to the intracellular tail of the Fas receptors via the presence of homologous death domain protein motifs in both FADD and Fas (75). This protein scaffold then recruits pro-caspase-8 molecules by binding of homologous death effector domains (DEDs) present in both FADD and the pro-domain of caspase-8. The close association of a number of pro-caspase-8 proteins allows the slight activity of the pro-enzyme to trans-activate other caspase-8 molecules in close proximity (76).

The consequences of caspase-8 activation are shown in Figure 34.4. Activated caspase-8 initiates apoptosis in one of two ways, depending on the cell type (77). In type I cells, the effector caspase-3 is activated directly by caspase-8, while in type II cells, caspase-8 cleaves Bid, a pro-apoptotic member of the Bcl family of proteins, to create a truncated
FIGURE 34.4 The pathway activated by Fas. Ligation of Fas on the target by Fas-ligand on the CTL results in activation of caspase-8 (C8). This protease can cleave and activate caspase-3 (C3). It also cleaves Bid, which then translocates to the mitochondria. Cytochrome c (cytc) is released and activates caspase-9 (C9) in the apoptosome. The caspase-9 then amplifies the amount of active caspase-3, which acts on ICAD. The released CAD translocates to the nucleus and generates double-stranded breaks.

form, or tBid (78). This protein will move to the mitochondria to initiate the mitochondrial pathway of apoptosis. As a result of cytochrome c release from the mitochondria, caspase-9 is activated in the apoptosome (79). The activated caspase-9 then acts with caspase-8 to amplify cleavage of the executioner caspase-3. This is really the point of no return, as the activated caspase-3 then cleaves a variety of substrates, including ICAD, leading to DNA fragmentation.

GRANULE-MEDIATED CELL DEATH

Granule exocytosis has become well established as the major mechanism of CTL-induced cell death. This pathway begins with the targeted secretion of granules that releases the granule contents into a target cell to induce both caspase-dependent and caspase-independent cell death. The purification and characterization of perforin was critical for our current understanding of CTL-induced death. However, it was soon realized that other components were needed to duplicate all of the features of killing by intact CTL. In particular, perforin could not induce the DNA fragmentation observed in a cell–cell killing assay. Three lines of experimentation came together to conclude that granzyme B was critical for the DNA fragmentation activity. First, a classic biochemical approach to purify the "fragmentin" activity identified the factor as granzyme B (80,81). The second was a more molecular/cell biology investigation in which noncytotoxic RBL mast cell tumors had to be transfected with both perforin and granzyme B cDNAs in order to mediate both membrane damage and DNA fragmentation. Importantly, transfection with just perforin endowed the cell with only membranolytic activity (82,83). The final approach took advantage of knockout technology to develop mice with no functional granzyme B. CTL from the deficient animals could still cause chromium release in targets, but were severely compromised in early DNA fragmentation (84). Although knocking out granzyme A alone had little effect, the combination of removing both A and B reduced DNA fragmentation still further. Cytolytic effectors from these double knockout mice could still mediate membrane damage (85), but their effectiveness *in vivo* was severely compromised (86). Collectively, these results suggest that perforin facilitates entry of granzymes into targets that then actually provide the lethal hit. This results in the activation of the pre-programmed suicide signal within the target and death by apoptosis.

Granzyme Entry into Target Cells

In the presence of high concentrations of perforin, target cells are rapidly lysed. Early EM studies also provided evidence for a putative perforin channel in the membrane

of cells under attack by cytolytic effectors (87). These and other studies led to the hypothesis that perforin polymerized in the target cell membrane to create a channel through which granzymes could pass. However, evidence for a channel large enough to accommodate a 30 kDa protein is lacking (88).

Granzyme B was also found to bind to the cell surface in a saturable manner and to be internalized independently of perforin (36). These results suggested the existence of a cell surface receptor for granzyme B, and a candidate was identified as the cation-independent mannose-6-phosphate receptor (CI-MPR) (89). It was postulated that granzyme B binding occurs through its posttranslational modifications, namely mannose-6-phosphorylation, and the protease entered the target cell through receptor-mediated endocytosis. Although this study showed granzyme B entry into target cells as dependent on MPR expression, other work has suggested that the CI-MPR pathway can be circumvented in cells lacking MPR expression (90,91). Recent evidence suggests that granzyme B is complexed with proteoglycans, specifically serglycin (SG), and this large macromolecule (greater than 250 kDa) is the native form of granzyme B *in vivo* (92,93). This could suggest that granzyme B would not be able to bind directly to a receptor, but also adds a caveat to uptake studies using purified granzyme B. It is entirely possible that there are multiple routes of entry of granzymes into cells depending on the nature of the target. A specific receptor could mediate one mechanism of uptake, but it is also likely that less specific ionic interactions facilitate binding followed by entry via repair-mediated endocytosis induced after perforin damage (94).

Recent results suggest that cell surface heparin sulphate may be important for this nonspecific binding of granzyme B (95,96). The interaction with heparin sulphate could mediate receptor independent uptake, but may also facilitate granzyme B internalization via receptor-mediated endocytosis (51). Indeed, heparin sulfate is an important cofactor in other receptor binding mechanisms (97,98). Whatever the mechanism of internalization, it is believed that once inside the cell, the proteolytic activity of granzymes serves to activate cell death through the cleavage and activation of specific substrates.

Granzyme A Substrates

Granzyme A is the most abundant of the granzymes in the granules of CTLs (45). This protease induces caspase-independent apoptosis by inducing DNA damage by single-stranded nicks (99) and disrupting the mitochondrial membrane potential without the release of cytochrome c (100). Granzyme A cleaves proteins after arginine or lysine and targets proteins found in the SET complex (101–103). This SET complex contains proteins involved with repairing DNA, modulating chromatin, and regulating transcrip-
FIGURE 34.5 The granzyme A pathway. Perforin (pfn) facilitates the entry of granzyme A (grA) into the cytoplasm of the target. The protease cleaves a number of targets, including SET protein, which is an inhibitor of the nuclease NM23-H1. The released nuclease translocates to the nucleus and generates single-stranded DNA breaks.

tion and is also thought to help repair DNA in response to oxidative damage (103). As depicted in Figure 34.5, the cleavage of the SET protein by granzyme A releases the NM23-H1, a nuclease responsible for the single-stranded nicking of the DNA in association with TREX1 (104). The granzyme A–dependent cleavage of Ape1, a SET protein involved in DNA repair, also contributes to DNA damage. Ku70, another key double-stranded repair protein is also a substrate (105), and its inactivation has been shown to facilitate granzyme A–mediated death. Granzyme A also induces nuclear destruction by cleaving nuclear structural proteins lamins (106) and histones, resulting in chromatin unfolding (107). The mechanism of granzyme A–dependent mitochondrial disruption has not yet been elucidated.

Granzyme B Substrates

The discovery of a key substrate for granzyme B came from two rather unrelated observations. First, it had been shown that granzyme B has an unusual ability to cleave

following asparate residues (43,44). Secondly, a mutation in nematodes was described that resulted in defective cell death (108). The gene involved, named ced3, was a caspase essential for apoptosis and required activation at an aspartate. The mammalian equivalent of ced3 was discovered as CPP32 and later named caspase-3 (109). It was, therefore, hypothesized that granzyme B could act to initiate apoptosis through the cleavage of caspase-3. Indeed, granzyme B was shown to cleave directly caspase-3 both *in vitro* and *in vivo* (110). The activation itself was a two-step process in which granzyme B acts to cleave the protein, and this is followed by self-catalytic activation by caspase-3 (111).

A single substrate did not explain all aspects of lysis since granzyme B was also shown to initiate cell death independent of caspases (112). It was also observed that granzyme B–induced cell death still proceeded, in the presence of caspase inhibitors, with a loss of mitochondrial membrane potential and the release of cytochrome c from the intermembrane space (113). However, these were blocked by transfection of the targets with the antiapoptotic gene Bcl2, thus suggesting the existence of a granzyme B substrate upstream of mitochondria. Studies showed that granzyme B–induced mitochondrial damage was the result of granzyme B cleavage of the pro-apoptotic protein Bid to form granzyme B–truncated Bid (gtBid) (114). Another Bcl2 family member, Mcl-1, has also been shown to be a substrate for granzyme B (115). This can interfere with mitochondria via interaction with Bim. The importance of the mitochondrial pathway will be discussed later.

Granzyme B has also been shown to cleave and activate other members of the caspase family, but *in vivo* caspase-3 appears to be the initiating event (116). A number of clinically important auto antigens are also cleaved by granzyme B, and these may be important in autoimmunity (117). Proteomic approaches have also been employed to discover novel granzyme B substrates, but it remains to be seen how many actually play a role in the mode of action of the protease (118). More detailed analyses on some of these other substrates have been conducted, such as α-tubulin (119,120), Hsp-70 (121), and Hop (Hsp-70/Hsp-90 organizing protein), an anti-apoptotic chaperone of Hsp70/Hsp-90 (122). The presence of multiple granzyme B substrates within a cell may enhance apoptosis, but more importantly may provide alternate pathways of cell death in the event of immune evasion of a virally infected or tumor cell.

A Key Role for Mitochondria in Killing

Once granzyme B is released into the cytoplasm, it acts to cleave and activate key substrates to induce apoptosis. It was rather surprising to find that this pathway was blocked by the overexpression of Bcl2. The Bcl2 family is intimately linked to the mitochondria and can either negatively or positively regulate the process of cell death. The anti-apoptotic family member Bcl2 is a membrane protein anchored to the mitochondria. Once in the membrane, Bcl2 and the related protein bcl-x_L associate with the mitochondrial permeability transition pore (PTP), a large multiprotein complex localized to the mitochondrial membrane contact sites. During apoptosis, the PTP has been reported to open, allowing loss of ψ_m along with release of apoptogenic factors such as cytochrome c. Inhibitors of PTP opening, such as cyclosporine A, are unable to inhibit mitochondrial disruption by granzyme B, indicating that the PTP is not the only site of action for Bcl2 in the mitochondria (123). Overexpression of Bcl2 attenuates granzyme B–mediated cell death, revealing a functional requirement for mitochondria in granzyme B–mediated apoptosis. This implied that the mitochondrial apoptotic machinery was activated in cells destined to die due to exposure to granzyme B. Most important, both the loss of ψ_m (123,124) and cytochrome c efflux following granzyme B treatment (125,126) occurred in a caspase-independent fashion, which suggested that granzyme B substrates other than the caspases were involved.

Granzyme B can cleave the pro-apoptotic member of the Bcl2 family, bid. In fact, granzyme B catalyzes bid cleavage more efficiently than caspases 3 or 8 (127). This gr-truncated bid (gtbid) is produced by hydrolysis at D75 and thus has a different amino terminus than the D59-caspase-8 cleaved form (tbid) (128). Nevertheless, both forms of cleaved bid translocate to the mitochondria resulting in the release of cytochrome c. The requirement of bid for cytochrome c release was demonstrated in a cell-free system in which cytosolic extracts immuno-depleted of bid were no longer able to promote granzyme B–induced cytochrome c release from purified mitochondria (114). Importantly, transfection of targets with a noncleavable mutant bid also interfered with apoptosis (129). The cleaved bid was required for the translocation of bax to the mitochondria, and this regulated import of bax was abolished in granzyme B–treated Bcl2-overexpressing cells. Bax, and the related protein bak, have been implicated in pore formation in the mitochondrial outer membrane and may provide the link between granzyme B and cytochrome c release. Indeed, bax/bak null cells do not release cytochrome c after incubation with granzyme B (130).

As described earlier for Fas killing, factors released from mitochondria include cytochrome c, which causes the formation of an oligomeric complex of APAF1 and caspase-9 known as the *apoptosome*. The recruitment of caspase-9 allows its autoactivation, and this, in turn, activates effector caspases. It was therefore possible that the granzyme B death pathway was dependent on this branch of the pathway. Using dominant-negative caspase-9–expressing cells as targets, it was demonstrated that the requirement for caspase-9 activity can be bypassed (131). This was not the case with Fas where the interference with

caspase-9 activity efficiently blocked death. This suggested that in the granzyme B–mediated mechanism some other pathway was involved downstream of mitochondria.

Two other caspase activators have been shown to be released from mitochondria, SMAC/DIABLO (second mitochondrial activator of caspases/direct IAP binding protein with low pI) (132) and HtrA2/Omi. These share a short (~5 amino acids) motif at the N-terminus, which is revealed upon removal of the mitochondrial import signal. This peptide acts as a binding site for the inhibitor of apoptosis proteins (IAPs), which are natural inhibitors of activated caspases. Both SMAC/DIABLO and HtrA2/Omi function by binding IAPs and displace activated caspases associated with the IAP allowing the apoptotic program to proceed. Granzyme B–treated cells released SMAC/DIABLO from the mitochondria and thus relieve the inhibition of caspase-3 by XIAP (131,133). These experiments suggest that although granzyme B is capable of directly cleaving pro-caspase-3, SMAC/DIABLO release is required to allow full caspase-3 enzymatic activity and ultimately, cell death.

This mechanism (outlined in Figure 34.6) has been referred to as the *safety brake model* (134): granzyme B is delivered to the cytosol where it cleaves caspase 3. The foot is on the gas pedal, but the safety brake (IAP) is on. The brake is removed via cleavage of bid and release of SMAC. Now the cell speeds down the road to death. A detailed knowledge of the mechanism of death provides the tools to analyze how it might be defective, for example in tumors, or can be manipulated therapeutically. The clinical relevance has been recently highlighted by a drug designed on the basis of the model, which sensitizes Hodgkin's lymphoma to CTL (135).

Although the major focus of this discussion has been on the control of apoptosis, it should be noted that mitochondria function is also compromised. Mitochondria are also affected by granzyme A. These organelles are the powerhouses of the cell and supply energy in the form of ATP. Thus, by halting energy production the survival of the cell is compromised and, in time, would die by necrosis. This might be quite relevant in cells infected with a virus that encodes anti-apoptotic proteins. Surprisingly, overexpression of Bcl2 has little if any effect on CTL-mediated killing (136). CTLs are, therefore, able to bypass or inactivate Bcl2 in target cells. The mechanism for this is, as yet, unknown.

Extracellular Substrates

The majority of studies on granzyme substrates have focused on proteins within the target cell. It is becoming increasingly clear, however, that significant levels of extracellular granzyme can be detected and that extracellular substrates can be important targets. Indeed, elevated granzyme levels have been measured in numerous diseases ranging from viral and bacterial infections to inflamma-
FIGURE 34.6 The granzyme B pathway. Perforin (pfn) facilitates the entry of granzyme B (grB) into the cytoplasm of the target. The protease cleaves caspase-3 (C3), but the enzymatic activity is inhibited by an IAP. The granzyme B also cleaves Bid and the truncated Bid (gtBid) translocates to the mitochondria. This results in leakage of mitochondrial proteins into the cytosol. One of these, SMAC, binds tightly to IAP and thus relieves the caspase-3 inhibition. The active caspase-3 then acts on ICAD to free CAD. The active nuclease then translocates to the nucleus and generates double-stranded breaks.

tory disorders (137). The exact mechanism of release is not clear, but it may be due to loss of granzyme from the synapse during CTL attack. Alternatively, granzyme may be released through constitutive secretion independent of granules after stimulation of the TCR or by cytokines. Finally, granzyme release has been shown to occur by the presence of bacteria through a cytokine-dependent mechanism (138).

Both granzyme A and granzyme B have been shown to cleave extracellular matrix proteins. This could influence migration of lymphocytes, but may also lead to perforin-independent death due to disruption of cell–cell interactions (139). Granzyme A has been proposed to cleave cell surface receptors, such as the thrombin receptor, that may lead to a cellular response (140). The neuronal glutamate receptor has also been shown to be cleaved by granzyme B (141). Interestingly, this activity was found to be influenced by glycosylation, which was thought to change accessibility of the cleavage site. Degradation of some of the

extracellular matrix (ECM) substrates was also affected by conformation, but this does not seem to be the case for granzyme A (142).

DISTINGUISHING CELL DEATH MECHANISMS

Historically, the two main features of cell death that are convenient to measure are membrane damage (chromium or lactate dehydrogenase (LDH) release) and DNA fragmentation. Although apoptosis is characterized by DNA fragmentation, this is also seen in necrotic death. The key difference in the DNA fragmentation pattern is only revealed by gel electrophoresis. In apoptotic cell death, there is a laddering of the DNA, while in necrosis the stained DNA is just a smear. Typically, the early DNA fragmentation seen with granzyme B is apoptotic, while the late nucleolytic activity induced by granzyme A is necrotic, or at least is a caspase-independent form of death with only single-strand breaks (99). In addition, it should be appreciated that some lines respond preferentially to granzymes. In the mouse lymphoma L1210.3, for example, DNA damage is mediated exclusively by granzyme B, whereas in another lymphoma, EL4.F15, both granzymes contributed (143).

There are now numerous convenient ways to monitor death, but they must be used judiciously (144). For example, exposure of PS on the surface of an apoptotic cell can be monitored by binding of annexin V (145). However, at late stages of necrosis when the membrane is permeable, the annexin can enter the cell and bind to the internal PS. Thus, it is of paramount importance that this assay must be combined with propidium iodide exclusion to monitor membrane integrity. Loss of membrane potential of mitochondria is easily measured by release of fluorescent dyes, such as tetramethyl rhodamine ethyl ester (TMRE) (146). However, apoptosis is not the only way in which mitochondrial dysfunction can occur. Probably the most common method used to measure apoptosis is DNA fragmentation detected by terminal deoxynucleotidyl transferase mediated dUTP-linked nick end labeling (TUNEL) (147). However, this assay will detect any kind of nicking in DNA, not just apoptosis. More recently, reagents that detect caspase activation using either substrates or antibodies to neoepitopes have become available and are very useful (148,149). Probably the bottom line is that the researcher should never restrict analysis to one measure of death.

In the specific case of distinguishing between granzyme- and Fas-mediated killing, there is considerable confusion. The common dogma is that granzyme-mediated killing is dependent on calcium, whereas Fas-induced death is not. Consequently, many investigators distinguish the two on the basis of sensitivity to EGTA. However, as some Fas-ligand has now been shown to be in granules, it will also be inhibited by chelation of calcium. A better method is to use an antibody directed against the Fas receptor that blocks, rather than activates, Fas killing.

PROTECTION OF CTL FROM LYSIS

The granule exocytosis model provides an explanation for the directed lysis of a bound target, but it does not explain why the CTL remains alive. Indeed, if there is enough granzyme and perforin in the synapse, why does the CTL not die? Many explanations have been put forward, but this is still an open question. Originally, it was hypothesized that CTLs were inherently resistant to their own lytic machinery. Indeed, it has been shown that they do express a granzyme B inhibitor (150). However, even though they are more resistant than the typical hemopoietic target cell used in routine assays, they can be killed by other CTLs (151). Protective membrane proteins that bind perforin have also been proposed, but have remained fairly elusive. It is more likely that the process of degranulation may provide the CTL with a transient resistance. As the degranulation is so local, it is possible that the inside of the granule becomes the only region of the CTL that is exposed to the granzyme/perforin. One candidate for such a mechanism is membrane-bound cathepsin B, which is known to be within the granule. According to the model, it was hypothesized that the enzyme would cleave and inactivate perforin (152). Recent experiments with cathepsin B knockout mice, however, have not shown any evidence of death in CTLs after killing (153). Hence, this cannot be the only mechanism for the protection observed.

T CELL HOMEOSTASIS

In addition to a role in target cell lysis, there is increasing evidence that perforin may play a role in lymphocyte homeostasis. Perforin-deficient mice have an increased expansion and persistence of CTL after stimulation. Similar observations were made with alloreactive clones with cells from perforin knockout mice. Taken together, these results suggest a role for perforin in activation induced cell death (154,155). Recently, evidence has been provided for a similar role for granzyme B in TH2 cells (156).

Perforin deficiency has also been documented in children who suffer from familial haemophagocytic lymphohistiocytosis (FHL) (157). This rare disease is characterized by overproduction of T cells and inflammatory cytokines. The activated cells infiltrate various organs, including spleen, lymph nodes, and the central nervous system, leading to a variety of pathologies. Patients with this disorder generally have been found to carry mutations in the perforin gene. This is not always the case, however, and a mutation in a protein involved in granule fusion has also been shown to give rise to the same clinical phenotype

(158). Lymphocytes from the patients have no cytolytic activity, and perforin is absent from the granules.

EXPRESSION OF GRANZYME/PERFORIN IN TREGS

Although most of the chapter has discussed the role of CTLs, there has been considerable excitement generated by the discovery that granzymes and perforin are in a subset of CD4[+] regulatory T cells (159). Both adaptive and activated natural Tregs appear to express perforin and granzymes. These Tregs seem to be able to kill APCs and activated T cells through a granule-dependent mechanism, thus suggesting one pathway by which these cells can regulate immune responses (160). The cytotoxicity is dependent on adhesive interactions, but surprisingly not on MHC/TCR. They do not appear to act through a Fas/Fas-ligand pathway.

EFFECTOR MOLECULES IN DISEASE

Virus Infection

The importance of perforin in mediating protection against viruses, such as lymphocytic choriomeningitis virus and ectromelia, has been firmly established using knockout mice (161,162). The results with granzyme-deficient mice have been less clear-cut, but this is likely due to the functional redundancy of the granzyme family. Although mice deficient in granzyme A and all granzymes in the B cluster are susceptible to ectromelia, they do seem to be able to mount an effective response to other viruses (162). The interpretation of *in vivo* experiments can also be difficult, as it is known that interferon-gamma (IFN[γ]), produced by CTL, can up-regulate Fas on targets (163). Even more confounding, it has also been demonstrated that the granule-mediated mechanism of killing may actually promote immunopathology associated with acute viral infections (164). In humans, we do not generally have knockouts for experimental analyses; rather, results are limited to correlating expression with diseases. It is believed that CD8[+] T cells play a pivotal role in the control of viral infections and expression of key effector molecules is thought to be important. In particular, studies with HIV patients have revealed an interesting reduction in perforin expression in CTL (165). This may not be confined to HIV and might be a general feature of chronic infection (166).

Cancer

The situation with tumor immunosurveillance is also suggestive of a critical role for perforin, particularly in eradication of spontaneous tumors. However, the role for granzyme is not so obvious. It is clear that many tumors are infiltrated by perforin and granzyme-positive CTLs, but often they are ineffective *in vivo*. An interesting speculation is that their cytolytic potential is kept in check by Treg cells (167), so perhaps tumor destruction has to be mediated by other mechanisms. However, if the Treg-mediated block could be reversed perhaps the granule-mediated effector mechanism could be unmasked. *In vivo* experiments with perforin-deficient mice have confirmed an important role for perforin in destruction of tumors (168). In addition, there is an increased incidence of spontaneous malignancy in these knockout mice (169). Whether this is due to the direct involvement of perforin with the lytic machinery or due to its immunoregulatory properties is unclear.

The innate immune response seems to be particularly important in protection against nonlymphoid tumors. Again, this seems, in part, to be due to perforin, but Fas can also be up-regulated on targets leading to death receptor–mediated death (170). Although the evidence for involvement of CTLs is not clear, it should be noted that in states of immunosuppression—for example, HIV—increased cases of malignancy are often seen. Further, with vaccines that stimulate CTLs or with adoptive therapy of tumor-infiltrating lymphocytes, there is clear evidence of protection (171,172).

Autoimmunity

CTLs have long been implicated in the destruction of ß cells during type 1 diabetes. A number of transgenic models of autoimmune diabetes have shown CD8[+] T cells can efficiently kill beta cells (173,174). Perforin-deficient nonobese diabetic (NOD) mice are protected from diabetes (175) and isolated islets are susceptible to granzyme/perforin-induced death (176). However, *in vitro* studies suggest that in the absence of perforin, the Fas pathway is operative (177). In another modal of autoimmune disorder, experimental autoimmune encephalomyelitis (EAE), Fas-mediated killing was required for the pathogic events in perforin-deficient mice (178). However, recent evidence has suggested that granzyme B may be an important mediator of the neuronal injury (179).

Transplant Rejection

Organ allograft rejection is strongly associated with CTLs, and the presence of granzyme and perforin closely correlate with rejection. However, allografts transplanted into hosts with disrupted genes for perforin and granzymes A and B showed no decrease in tubulitis and were still rejected (180). Fas-ligand is also up-regulated in rejecting allografts, but it is not required for graft rejection (181). Thus, despite the striking expression of these potential lytic effectors in the grafts, their activities do not seem to be required for rejection. The effector mechanisms and, indeed, the cells responsible for rejection remain unclear. In

bone marrow transplantation, donor T cells play a key role in preventing graft rejection by the attacking recipient T cells. This can occur by both perforin- and Fas-mediated mechanisms (182,183).

VISUALIZATION OF CTL *in vivo*

One possible reason that the role of effector molecules in disease still remains unclear is that the *in vitro* assays used previously do not truly reflect what occurs *in vivo*. To remedy this, it will be necessary to develop techniques to visualize CTL and immune responses *in vivo*. This is now becoming possible through the generation of transgenic mice that express green fluorescent protein in specific subsets of T cells, and the utilization of two-photon microscopy. Indeed, using this kind of technology, CTLs have now been observed in the act of killing a tumor target (167).

CONCLUSION

This chapter describes the biological features and molecular mechanisms used by CTL to destroy antigen bearing target cells. *In vitro* studies suggest that there are primarily two major pathways used to induce cell death. The first is mediated by effector molecules contained within granules that are vectorally exocytosed upon target cell recognition. The other occurs via ligation of Fas on the surface of the target by Fas-ligand carried by the killer. A detailed knowledge of the mechanisms that lead to the death of the target cell mediated by granzymes A and B, as well as Fas, have now been elucidated. These involve induction of both apoptotic and necrotic death pathways, depend on the proteolytic activities of the granzymes and caspases, and involve target organelles, such as mitochondria. Such knowledge can now be used to design drugs that may modulate CTL activities.

The genes for a number of effector molecules involved in killing have been knocked out, which has allowed investigation of their roles in disease pathogenesis. These studies implicate the effectors in a number of responses *in vivo*, but the results are not definitive. Part of the problem centers on the redundancy of the killing mechanisms used, and when one is inactivated another appears to substitute. However, it is certainly suggested by this line of investigation that alternate killing mechanisms may exist in *in vivo* situations.

It has also become clear that effector molecules, such as perforin and granzymes, may be involved in homeostasis of T lymphocytes. There is also an increasing appreciation that granzymes may act on substrates outside the target and this may play a role in disease pathogenesis. Finally, the effectors may play a role in regulation of immune responses via their expression in regulatory T cells.

All of these new functions suggest very exciting possibilities for the future development of novel immunomodulatory strategies.

Immunity to Infectious Agents

The Immune Response to Parasites

David L. Sacks, Alan Sher, Eleanor M. Riley, and Thomas A. Wynn

PARASITES AND THE IMMUNE SYSTEM

Distinct Features and Global Health Importance of Parasitic Pathogens

The term "parasite" is formally used as a designation for eukaryotic protozoan and metazoan pathogens residing within or on their hosts. The exact origin of this usage is not clear, but almost certainly it relates to the common historical period and tropical disease context in which many of these agents were identified. Indeed, parasites are the most phylogenetically diverse of pathogens, and at the lower end of their evolutionary tree they are often difficult to distinguish from fungi and protista in both their morphology and genomic organization.

Although the taxonomic basis of their classification into a single group is under question, parasites as infectious agents do share many biological characteristics. They frequently (although not always) display complex life cycles consisting of morphologically and antigenically distinct stages and produce long-lived chronic infections to ensure transmission between their hosts. The induction of severe morbidity or mortality is an atypical outcome. However, in the tropical and subtropical regions where transmission is high, the low frequency of disease translates into a major global health and economic problem because of the sheer number of people exposed and because of the confounding issues of malnutrition and coinfection. As illustrated by outbreaks in the last decade of disease caused by the protozoa *Giardia*, *Cryptosporidia*, *Cyclospora*, and *Toxoplasma*, parasites also represent a continuing threat to populations in wealthier countries. Indeed, all of the major food and water-borne protozoa have been classified as Category B bioterrorism pathogens because of their potential to cause acute epidemic illness. The AIDS epidemic has also increased the impact of parasitic disease in both developed and developing regions because immunocompromised hosts become highly susceptible to some normally tolerated parasites such as *Cryptosporidia*, *Toxoplasma gondii*, and *Leishmania*. Finally, parasitic disease remains an important problem in livestock, causing annual economic losses in the billions of dollars and, in the case of trypanosomiasis, limiting the agricultural development of huge areas of potential grazing lands on the African continent.

The immune system plays a central role in determining the outcome of parasitic infection, establishing a critical balance meant to ensure both host and pathogen survival. As with other infectious agents, disease emerges when the scales tip toward either a deficient or excessive immune response. Manipulation of that response by means of vaccination or immunotherapy remains a key approach for global intervention in parasitic disease. A list of the most important parasitic infections of humans, along with estimates of their prevalence, annual mortality, health impact (measured in disability-adjusted life years), and current control methods, is presented in Table 35.1. The data testify to the continued enormity of the problem, reflected in the numbers of people annually infected and dying of diseases such as malaria, schistosomiasis, and trypanosomiasis, as well as the high level of morbidity in those surviving. A striking situation reflected in the data is the complete absence of effective vaccines for protecting human populations. In the case of malaria, the need for a global immunization strategy has become particularly acute as drug resistance spreads worldwide.

Clearly, the development of vaccines to prevent parasitic diseases remains one of the major unachieved goals of modern immunology and one of its greatest and most difficult challenges. The scientific challenge lies with the extraordinary complexity of parasites as immunologic targets and their remarkable adaptability to immunologic pressure. The field of immunoparasitology is focused on developing a basic understanding of this important host–pathogen interface for the ultimate purpose of intervention. At the same time, the work in this area—particularly in recent years—has provided immunology with a series

▌ **TABLE 35.1 Global Impact of Parasitic Disease and Current Control Measures**

	Estimated Prevalence (Millions)	Disease Burden (DALYs, Thousands)[a]	Annual Deaths (Thousands)	Control Method Used
Malaria	515	42,279	1,124	Vector control, chemotherapy
Schistosomiasis[c]	187	4,500	155–280	Chemotherapy, hygiene
Soil-transmitted helminths[b]	2,000	38,900	139	Chemotherapy, hygiene
African trypanosomiasis	0.3	1,332	50–100	Vector control
Leishmaniasis	12	1,757	51	Vector control, chemotherapy
Chagas' disease	10	586	13	Vector control
Lymphatic filariasis	120	4,600	0	Vector control, chemotherapy
Onchocerciasis	37	2,000	0	Vector control, chemotherapy

Data compiled from World Health Organization, *Disease control priorities in developing countries*, 2nd ed., 2006, available at http://www.dcp2.org/pubs/DCP, and from ref. 336.
[a]Disability-adjusted life years, a measure of the time lived with a disability, combined with the time lost due to premature mortality *(337)*.
[b]Hookworm, ascariasis, and trichuriasis. The data are combined values for all three infections.
[c]Currently being revised upward.

of major insights concerning effector and regulatory responses as they occur *in vivo*. Indeed, because of their years of close encounter with and adaptation to the vertebrate immune system, parasites can be thought of as the "ultimate immunologists," and there is much to be learned from them about the fundamental nature of immune responses.

Some Hallmarks of the Immune Response to Parasites

The interaction of parasites with the immune system has several distinguishing features that are of special interest to fundamental immunologists. Most parasitic pathogens are able to survive the initial host response and produce long-lasting chronic infections designed to promote transmission. In the case of many protozoa (e.g., *Toxoplasma, Leishmania*), *chronicity* is characterized by a state of *latency* in which replication of the parasite is minimal and infection cryptic. The development of chronicity depends not only on the ability of the parasite to escape protective immune responses (*immune evasion*), but also on the generation of finely tuned mechanisms of *immunoregulation* that serve both to prevent parasite elimination and suppress host immunopathology. As discussed in detail later in this chapter, the study of these immunomodulatory pathways in both human and experimental parasitic infections has yielded important insights concerning the mechanisms by which regulatory T cells and cytokines control immune effector functions *in vivo*.

An additional prominent feature of the immune response to parasites is *Th1/Th2 polarization*. For reasons that are not entirely clear, parasitic infections often induce CD4$^+$ T cell responses that are highly polarized in terms of their Th1/Th2 lymphokine profiles. This phenomenon is particularly striking in the case of helminths, which, in contrast to nearly all other pathogens, routinely trigger strong Th2 responses leading to high immunoglobulin E (IgE) levels, eosinophilia, and mastocytosis. At the opposite pole, many intracellular protozoa (in common with their bacterial counterparts) induce CD4$^+$ T cell responses with Th1-dominated lymphokine secretion patterns. This striking difference presents a beautiful example of immunologic class selection. Of interest, in murine *Leishmania major* infection, CD4$^+$ cells polarize to either Th1 or Th2, depending on the strain of mouse infected, and the association of these responses with healing or exacerbation provided the first demonstration of a functional role for this dichotomy (1,2). Parasite models have also been used to reveal new effector functions, such as the ability of eosinophils to kill pathogens, and, as discussed later, they are now being used extensively to study microbial innate recognition and immune response initiation. This ability to uncover and investigate basic immune and immunopathogenic mechanisms while studying the host response to a group of phylogenetically unique pathogens

of global importance is perhaps the most engaging and rewarding aspect of research in immunoparasitology.

INNATE RECOGNITION AND HOST DEFENSE

Innate recognition plays an important role in determining the outcome of the host–parasite encounter by both providing an initial barrier to infection and influencing the magnitude and class of the subsequent adaptive immune response. At the same time, from the parasite's point of view, innate immune defenses must be subverted for infection to be established, and it is clear that many parasitic pathogens have evolved specific mechanisms for evading them. Moreover, in some cases parasites appear actually to hijack the process of innate recognition to redirect adaptive immunity to promote their own persistence.

Humoral Mechanisms

Innate resistance against parasitic infection is mediated in part by preexisting soluble factors that recognize and destroy invading developmental stages or target them for killing by effector cells. The alternative pathway of complement activation provides a first line of defense against extracellular parasites. Invading forms of many of these pathogens lack the complement regulatory factors that normally promote the degradation of C3b on the surface of host cells. The resulting activation of the complement cascade leads to formation of the potentially lytic membrane attack complex (MAC), as well as opsonic recognition by C3 receptors on phagocytes. In addition, other products of complement activation are chemotactic and attract immune cells to the site of infection. There is also a lectin-mediated pathway in which recognition of mannose residues on parasite surfaces by a mannan-binding protein triggers the complement cascade.

Because the complement system represents such an important first line of defense in resistance to pathogens, the infectious stages of parasitic protozoa and helminths have developed a variety of strategies to subvert complement-mediated attack. In some instances blood and tissue parasites have evolved redundant mechanisms to ensure their survival during serum exposure. For example, infective metacyclic and bloodstream trypomastigotes of *Trypanosoma cruzi* express multiple stage-specific surface glycoproteins, such as gp160 and the 87- to 93-kDa trypomastigote decay accelerating factor (T-DAF), which are actively released by the parasite and are functional homologs of human DAF, which interferes with assembly of C3 convertases by binding to C3b (3). Another trypomastigote glycoprotein, gp58/68, inhibits alternative pathway C3 convertase assembly by binding to factor B. *T. cruzi* trypomastigotes have also been found continuously to shed acceptor molecules with covalently bound C3

fragments, believed to be due to an endogenous phospholipase that cleaves glycosylphosphatidylinositol (GPI)–anchored membrane proteins. *T. cruzi* amastigotes have been shown to resist complement lysis by preventing membrane insertion of the MAC C5b-9. An identical mechanism of resistance has been observed for the infective-stage, metacyclic promastigotes of *Leishmania*, which expresses an elongated form of the abundant surface lipophosphoglyan, such that it behaves as an effective barrier to membrane insertion and pore formation by MAC *(4)*. Metacyclics also increase expression of the surface metalloproteinase gp63 *(5)*, which can cleave C3b to the inactive iC3b form, thus preventing deposition of MAC *(6)*. Both C3b and iC3b effectively opsonize the complement-resistant forms for uptake by macrophages, its host cell of choice. Tissue-invasive strains of *Entamoeba histolytica* also activate alternative complement pathway but are resistant to lysis due to the action of a Gal/GalNAc lectin, which mediates adherence of trophozoites to host cells and binds to C8 and C9 terminal components (7). Of interest, the lectin shares sequence similarities with CD59, a membrane inhibitor of MAC in human blood cells.

Another set of soluble mediators providing a barrier to parasitic infection comprises the primate-specific trypanosome lysis factors (TLFs) that contribute to the innate resistance of humans to *Trypanosoma brucei* infection. Biochemical analysis of the activity present in human serum revealed that high-density lipoproteins (HDLs) are part of the substance that mediates cytolysis of the parasite, and initial studies demonstrated that this complex, TLF, is composed of several common apolipoproteins, as well as a haptoglobin-related protein (Hpr) and apoliprotein L-1 (ApoL-1) (8–10). Both Hpr and ApoL-1 are cytotoxic to *T. b. brucei* and act synergistically to provide enhanced trypanosome killing when assembled into the same HDL particle. To mediate cytotoxicity, TLF has to undergo receptor-mediated uptake and enter an intracellular acidic compartment. Hpr and ApoL-1 have different proposed activities; ApoL-1 is able to form ion pores in lysosomal membranes, whereas Hpr is able to accelerate lysosomal membrane peroxidation. A combination of these two activities may be needed for the complete protection TLF affords against *T. b. brucei* infection. Whereas TLF is capable of killing *T. brucei*—the species that infect humans—both *T. b. gambiense* and *T. b. rhodesiense* are refractory to TLF-mediated cytolysis. This resistance has been correlated with the expression of a serum resistance associated (SRA) gene that is homologous to the variant surface glycoprotein. Of note, transfection of SRA from *T. b. rhodesiense* into *T. brucei* confers resistance to lysis by human serum, suggesting that its expression may have been a critical step in the adaptation of the former parasite for infection of primates *(11)*.

The damage caused to worms as a consequence of alternative pathway activation is due primarily to the bound C3 activation products that act as ligands for cellular adherence and killing by eosinophils, neutrophils, and macrophages. Unlike the examples of parasitic protozoa cited earlier, worms may not rely on synthesizing their own complement regulatory proteins to subdue the activation cascade, but rely instead on acquisition of these proteins from the host. In the case of *Schistosoma mansoni,* DAF molecules are acquired from the host and incorporated into the worm tegument (12). The infective L3 stage larvae of *Onchocerca volvulus*, the causative agent of river blindness, were shown to bind the main fluid-phase regulator—human factor H—and to promote C3b inactivation *(13)*. By contrast, the infective stage L3 larvae of the mouse nematode *Nippostrongylus brasiliensis* are extremely vulnerable to complement-dependent attack by eosinophils, but by 24 hours the lung-stage L4 larvae no longer fix complement and are no longer susceptible (14). Whether the lung-stage larvae acquire complement-regulatory proteins from the host or secrete/excrete complement-inhibitory proteins, as has been shown for nematode larvae of *Toxocara canis (15)*, has not been determined.

Cellular Mechanisms

Phagocytosis by macrophages represents an innate first line of defense against protozoan pathogens. Macrophages possess primary defense mechanisms, including activation of macrophage oxidative metabolism, that are induced by the attachment and engulfment of microbial agents. The major source of reactive oxygen species (ROSs) in macrophages is the multimeric enzyme complex NADPH oxidase. Early studies suggested that *Leishmania* parasites avoid triggering the oxidative burst by actively inhibiting the macrophage protein kinase C (PKC) activation (16) that is required for phosphorylation of several sites on the cytosolic oxidase subunit p47phox. Inhibition of PKC-mediated protein phosphorylation and suppression of respiratory burst induction was observed using purified lipophosphoglycan (LPG), which is rapidly transferred from the parasite to the inner leaflet of the phagosomal membrane *(17)*. Insertion of the glycolipid has been shown to alter the physical properties of the bilayer to inhibit PKC membrane translocation, and might similarly inhibit translocation of the cytosolic components of the NADPH oxidase. Because some LPG-deficient *Leishmania* strains still manage to survive in macrophages, redundant mechanisms exist for the parasite to avoid macrophage triggering, including opsonic ingestion through receptors that are uncoupled from the activation of NADPH oxidase. A number of "silent" entry receptors have been described that are variably used by different species and developmental stages of *Leishmania,* including complement and mannose receptors *(18)*, galectin-3 *(19)*, and receptors for apoptotic cells (20,*21*). In contrast to *Leishmania*, *Toxoplasma* enters all nucleated cells, including macrophages, by an

active invasion mechanism that excludes most host cell proteins, including membrane components of the NADPH oxidase, from the parasitophorous vacuole (22). Malaria parasites are also sensitive to oxidative stress, in this case generated primarily as a result of the degradation of host hemoglobin within parasitized red blood cells (RBCs) *(23)*. The detoxification of ROS is achieved with a range of low–molecular weight antioxidants, including the tripeptide glutathione, and a number of host- and parasite-encoded enzymes *(24)*.

The development of phagosomes into digestive organelles represents the heart of the defensive machinery of macrophages, and intracellular parasites have evolved diverse strategies to avoid, escape from, or withstand the acidified, hydrolytic environment of phagolysosomes. For *Toxoplasma*, the integral membrane proteins that are excluded from the nascent vacuole include those involved in acidification and fusion with the endosomal network (25). If instead the parasite is forced to enter the cell by a phagocytic pathway, as a consequence of, for example, antibody opsonization, it is targeted through the normal phagolysosomal system and is killed (26). For *T. cruzi*, which trigger a wound repair pathway involving lysosome exocytosis to enter into cells, the early vacuole is acidified and potentially fusogenic. Intracellular survival of *T. cruzi* depends on its ability to escape from the vacuole, a process facilitated by its expression of a homolog of C9 that can disrupt the phagosome membrane and allow egress of the parasite into the cytoplasm (27). *Leishmania* promastigotes, again via transfer of their surface LPG, transiently inhibit normal phagosome maturation (28). LPG was found to increase the periphagosomal accumulation of F-actin and to disrupt phagosome microdomains, which in each case will impair normal endocytic trafficking and fusion. The delay in phagosome maturation may be necessary to allow sufficient time for metacyclic promastigotes to differentiate into more-acidophilic, hydrolase-resistant amastigotes. The various strategies employed by parasitic protozoa to evade the innate defenses of host cell macrophages are depicted in Figure 35.1.

Unlike protozoa, helminths are too big to be engulfed by phagocytes and can only be killed by these cells when the latter have been activated by products of the adaptive immune response. Instead, eosinophils, which frequently accumulate in tissues soon after worm invasion, may mediate innate cellular defense against helminth larvae by the discharge of the major basic protein and cationic proteins present in the granules of these cells (29,30).

In contrast to intracellular killing by phagocytes and extracellular killing by eosinophils, other innate cellular defenses do not eliminate parasites directly but instead trigger other effector cells to do so. Perhaps the best-studied example of this form of innate immunity is the natural killer (NK) cell pathway of interferon-γ (IFNγ) and tissue necrosis factor-α (TNFα) production. NK cell numbers and nonspecific lytic activity are increased as a consequence of a variety of parasitic infections, and *Leishmania* promastigotes, *Plasmodium falciparum*–infected red blood cells, components of *T. gondii*, *T. cruzi*, *E. histolytica*, and *Cryptosporidium parvum* (reviewed in ref. 31), and excretory-secretory (ES) proteins of the hookworm *Necator americanus (32)* all activate human peripheral blood NK cells to produce IFNγ. These findings suggest that NK cells may provide a T lymphocyte–independent pathway for cytokine-mediated defense and as such serve to prevent parasites from overwhelming the host prior to the development of adaptive responses. For the majority of pathogens, NK cell IFNγ is triggered by monokines, critically interleukin-12 (IL-12) *(33)*, produced by macrophages and dendritic cells (DCs) in response to microbial products. Trafficking of NK cells to parasite-infected tissues is critically dependent on chemokines binding to CCR5 *(34)*. Both IL-10 and transforming growth factor-β (TGFβ) have been shown to serve as negative regulators of NK cell IFNγ production by means of their suppression of monokine and B7 expression by antigen-presenting cells (APCs) or, in the case of TGFβ, by directly affecting NK cell function (35). Such suppression may be important in protecting the host against the tissue-damaging effects of excessive NK-derived IFNγ and TNFα. NK cell responses are further regulated by calibration of signals from activating and inhibitory receptors for major histocompatibility class (MHC) molecules; moderation of NK responses to malaria-infected red blood cells by inhibitory receptors such as NKG2A/CD94 and polymorphic killer-cell immunoglobulin-like receptors (KIRs) has been proposed (36). Although NK cell–derived IFNγ can limit the initial phase of protozoal replication (37) and may a play a role in the polarization and expansion of Th1 cells, in some situations adaptive T cell immunity is sufficient to control infection even in the absence of this early NK response (38,39). The role of NK cell cytotoxicity in resistance to protozoan infection is less well understood; for murine malaria it is not required for NK-mediated resistance to blood stages (38), but cytotoxic NK killing of malaria-infected liver cells has been reported *(40)*.

Two other cell populations that may function to provide a rapid cytokine response to invading parasites are $\gamma\delta$ lymphocytes and NK T cells. These "unconventional T lymphocytes" express T cell receptor chains of limited diversity, which may be designed for innate recognition of microbial structures or self-components revealed by infection of host cells. Although the function of NK T cells in innate resistance to parasites is under debate, there is considerable evidence supporting a protective role for $\gamma\delta$ T cells. $\gamma\delta$ T cells can respond to heat shock proteins (HSPs), and because invasion and intracellular replication by different parasites results in increased expression of HSPs, this may provide a mechanism that allows $\gamma\delta$ T cells to nonspecifically restrict infection either by direct host cell
FIGURE 35.1 Evasion of innate immune mechanisms in infected macrophages by parasitic protozoa. Macrophages possess potent antimicrobial functions that are initiated by uptake of pathogens. Opsonization of *Leishmania* with C3 cleavage fragments C3b and C3bi results in uptake by CR1 and CR3 receptors that are unlinked from the signaling pathways involved in induction of reactive oxygen intermediates or proinflammatory cytokines. Silent uptake using receptors for apoptotic, phosphatidyl serine (PS)–positive neutrophils delivering viable promastigotes has also been described. In addition, the transfer of surface lipophosphoglycan (LPG) to the phagosome membrane results in delayed fusion with lysosomes. After transformation to amastigotes, which are more hydrolase resistant due to an abundance of surface glycoinositolphopsholipids (GIPLs), phagosome maturation proceeds. *Toxoplasma* actively invades by rapid discharge of adhesive proteins from secretory organelles called rhoptries, then by inserting and squeezing past a moving junction in the plasma membrane that acts as a molecular sieve, excluding from its vacuole host proteins required for acidification and fusion with the endosomal network. *Trypanosoma cruzi* trypomastigotes enter the macrophage by inducing the recruitment of lysosomes to the plasma membrane; they only transiently reside in the vacuole before escaping into the cytoplasm via secretion of a pore-forming molecule.

lysis or, more likely, by the production of IFNγ and other effector lymphokines. Although $\gamma\delta$ T cells represent a small percentage of lymphocytes in the periphery, they are abundant in epithelial and mucosal tissues, the sites of initial host invasion by many parasites. Moreover, their numbers increase in peripheral blood in response to a number of protozoan infections *(41)*, in which they appear to play a protective role (42,43). Nevertheless, rather than being essential for host resistance, it is likely that $\gamma\delta$ T lymphocytes (in common with NK cells) provide an adjunct to conventional $\alpha\beta$ CD4 and CD8 cells, restricting parasite growth during the vulnerable period when the adaptive responses mediated by these effectors are emerging.

Role of Pattern Recognition Receptors in Innate Recognition of Parasites

The innate immune system, in addition to providing a natural barrier that limits infection, also plays a critical role in the initial recognition of parasites and the triggering of adaptive immunity. Invading parasites, like other pathogens, are sensed by host pattern recognition

receptors (PRRs) that recognize microbe-associated molecular patterns (MAMPs) shared by different groups of organisms. These PRRs are highly expressed on both epithelial and antigen-presenting cells and when ligated trigger cytokine and costimulatory signals that initiate both innate and adaptive cellular responses. Until quite recently little was known about pattern recognition of parasites, which, in contrast to bacteria and viruses, are eukaryotes. The last few years have seen an enormous expansion of research on this topic, in part driven by the need to better understand how specific effector responses against parasitic pathogens are initiated.

Toll-like receptors (TLRs) are the major group of PRRs known to be triggered by parasites (Table 35.2), although the role of non-TLR PRRs (e.g., NOD-like receptors, c-type lectins) has yet to be carefully examined. The study of TLR involvement in parasitic infection began with the identification of parasite ligands that stimulate cytokine production from macrophages and DCs. In the case of protozoa, an important class of such molecular structures is made up of the GPI lipid anchors present on many parasite surface proteins and membrane-associated but nonanchored glycoinositolphospholipids (GIPLs). Thus, GPIs from *T. brucei, Leishmania,* and *P. falciparum* can stimulate macrophages to upregulate inducible nitric oxide synthase (iNOS) expression and produce TNF and IL-1. Similarly, the GPI anchor fraction of mucin-like molecules

from *T. cruzi* trypomastigotes triggers macrophage production of IL-12 and TNF. GIPLS from *T. cruzi, T. brucei,* and *P. falciparum* possess similar agonist activities (reviewed in ref. 44). Studies using reporter cell lines transfected with specific TLR molecules or TLR-specific knockouts have demonstrated that the responses induced by these parasite glycolipids are due to stimulation of TLR2 and to a lesser extent TLR4 (preferentially triggered by GIPLS in the case of *T. cruzi*). Both of the two TLR2 heterodimers have been implicated, with GPIs from *T. cruzi* and *P. falciparum* selectively triggering the TLR2–TLR6 and TLR2–TLR1 complexes, respectively.

A chemically different class of TLR ligands is made up of the profilin proteins expressed by apicomplexan protozoa. These molecules are unique to eukaryotes and are typically associated with intracellular actin. Profilins from *T. gondii, Eimeria,* and *Cryptosporidium parvum* potently trigger IL-12 production from murine DCs as well as systemically following *in vivo* inoculation *(45)*. Studies in the murine *T. gondii* model established that this response is due to the stimulation of TLR11, a TLR that, although present in mice and other lower animals, is not functionally expressed in primates. Finally, genomic DNAs from several protozoan species have been shown to stimulate host proinflammatory cytokine production, presumably through the recognition of unmethylated CpG motifs by TLR9, although this interaction has been directly

▌**TABLE 35.2 Parasite Molecular Patterns (MAMPs) Recognized by Toll-Like Receptors (TLRs)**

MAMPs	Parasite	Structure	TLR Stimulated	Ref.
GPI anchors	*Leishmania* ssp.	LPG	TLR2	44
	Trypanosoma cruzi	GPI anchors containing unsaturated alkylacylglycerol	TLR2	
		GIPLs containing ceramide	TLR4	
	Trypanosoma brucei	GPI anchors of VSG	Undefined	
	Plasmodium falciparum	GPI anchors of merozoite surface proteins	TLR2 TLR4	*338*
	Toxoplasma gondii	GIPLs and GPI anchors	TLR2 TLR4	
Genomic DNA	*T. brucei*	Contain unmethylated CpG motifs	TLR9	*47*
	T. cruzi	Contain unmethylated CpG motifs	TLR9	46,344
Hemazoin	*P. falciparum*	Polymerized heme from degradation of hemoglobin	TLR9	48,345
Protein	*T. gondii* (and related apicomplexa)	Profilin molecules	TLR11	*45*
Phospholipid	*Schistosom mansoni*	Lysophosphatidylserine in tegument	TLR2	51
Phosphorylcholine	Filarial nematodes	Phosphorylcholine-containing glycoconjugates on ES-62 glycoprotein	TLR4	50
RNA	*Schistosoma mansoni*	Double-stranded RNA in parasite ova	TLR3	52

ES-62, filarial excretory-secretory antigen; GIPL, glycoinositolphospholipid; GPI, glycosylphosphatidylinositol; LPG, lipophosphoglycan; VSG, variant surface glycoproteins.

demonstrated only with *T. brucei* and *T. cruzi* DNAs (*46,47*). In the case of *P. falciparum*, hemazoin, a product of malaria-induced hemoglobin degradation, is a TLR9 agonist *(48)*, although there is controversy as to whether this results from contamination with immunostimulatory DNA fragments of parasite origin.

Helminth parasites also appear to express TLR ligands, although, as discussed later, their role in immune response has been harder to define than those characterized in protozoa. Moreover, in many studies the possibility of contamination by bacterial or viral TLR ligands from symbionts has not been systematically ruled out. Indeed, *Wolbachia* symbionts confer strong TLR4 and TLR2 agonist activity on filarial parasites due to endotoxin-like components present in these bacteria (49). Well-studied examples of helminth TLR MAMPs include the phosphorylcholine-containing moieties of the filarial glycoprotein ES-62 (50) and the lysophosphatidylserine components of schistosome membranes (51), which trigger TLR4 and TLR2, respectively. In addition, schistosome eggs possess double-stranded RNA molecules that stimulate TLR3 in DCs (52).

The role played by TLR in the host response to parasites is complex and not fully delineated in any of the host–parasite models studied. The main evidence for TLR involvement comes from experiments in mice deficient in MyD88, a major adaptor protein required for signaling by most TLR/IL-R receptors. These animals exhibit a loss in resistance to *T. gondii, T. cruzi, L. major,* and *T. brucei* and, in the case of *Plasmodium berghei,* decreased immunopathology (44), reflecting the role of TLR signaling in the initiation and maintenance of Th1 responses. Of significance, no major alterations in helminth-induced immune responses have been reported in MyD88-deficient hosts on susceptible genetic backgrounds, arguing against a major role for the TLR signaling in Th2-dependent host resistance and pathology against worm infections.

In contrast to the dramatically increased susceptibility often observed in MyD88$^{-/-}$ mice after protozoan infection, mice deficient in a single TLR exposed to the same parasites rarely show pronounced changes in resistance even when such animals display major immune response impairments. For example, whereas TLR11$^{-/-}$ mice infected with *T. gondii* develop severely blunted IL-12 responses both *in vitro* and *in vivo*, they nevertheless survive the acute-phase infection and show only a minor increase in parasite load in comparison to fully susceptible IL-12–deficient animals *(45)*. Such findings may reflect redundant functions for different TLRs or a requirement for multiple MyD880-dependent TLR (or IL-1/IL-18) signals in host resistance. Indeed, mice doubly deficient in TLR2 and TLR9 show greater susceptibility to *T. cruzi* infection than either of the single knockouts *(46)*. Additional synergy in TLR function is seen in mice engineered to be deficient in both MyD88$^{-/-}$ and TRIF (an adaptor used

by TLR3 and TLR4 in triggering type I IFN production). These double knockouts are even more susceptible to *T. cruzi* than MyD88$^{-/-}$ mice, an effect attributed to defective IFNβ production (53). An additional complexity is that mice deficient in a single TLR may show unaltered (or even enhanced) resistance because the TLR in question controls an immunopathologic response or downregulates host effector functions (54). A major challenge of research in this area is to decipher such positive and negative parasite-induced TLR signals and to elucidate their interactions with other PRRs both within and without the TLR family.

DCs play a major role in linking parasite pattern-recognition signals to the induction of both NK-mediated innate responses and T cell–dependent adaptive immunity *(33)*. As discussed previously, in the case of many protozoa, DC-produced IL-12 provides a major stimulus for the initiation of both host defense pathways. The critical role of DCs is underscored by the impaired IL-12 production as well as control of protozoan *(T. gondii)* infection (55) seen in mice in which CD11c$^+$ DC populations have been genetically depleted. Such DC-depleted mice are also unable to generate CD8$^+$ CTL responses against *Plasmodium yoelii* sporozoites (56). The requirement for protozoan invasion in DC activation is complex and depends on the parasite species and DC subset in question. Indeed, as discussed later, infection of DCs can result in suppressed responsiveness to activation stimuli. Nevertheless, live infection of DCs with, for example, *Leishmania (57)* or *T. gondii (58)* appears to be important for efficient priming of CD8$^+$ T cells despite the sequestration of many of the protozoa in question within parasitophorous vacuoles physically removed from the class I MHC antigen presentation machinery of the host cell. In addition, it appears that under certain situations [e.g., immunization with irradiated sporozoites *(59)*] infected apoptotic host cells are taken up by DCs as a mechanism of CD8$^+$ T cell priming.

Downregulation of Proinflammatory Signaling Pathways in Macrophages and DCs

In addition to upregulating APC function, parasite products can also dampen their activity either as a mechanism of immune evasion or for the purpose of protecting the host against an uncontrolled immune response. *Leishmania*, *T. cruzi*, and *Toxoplasma* have in common their ability to inhibit proinflammatory and IFNγ-inducible responses in infected macrophages, such that the parasites might not only prevent or delay the induction of Th1 responses, but also render infected macrophages unresponsive to activation signals during the effector phase of the immune response. For *Leishmania*, the inhibition is due in part to activation of host cell tyrosine phosphatases, including SHP-1, which inactivates JAK2 and ERK1/2 MAP kinases involved in the IFNγ-inducible phosphorylation

cascade (60). The major *Leishmania* GPI-anchored glycolipids LPG and GIPLS have been shown to inhibit signaling pathways in macrophages, resulting in impaired production of IL-12 *(61)*, essential for the development of protective immunity. By contrast with *Leishmania*, the ability of GPI anchors derived from *T. cruzi* trypomastigotes to trigger macrophages to produce proinflammatory cytokines is, as already discussed, well described (44). The GPI-mucin-like glycoprotein signals through TLR2, and it functions similarly to lipopolysaccharide (LPS) in inducing a state of tolerance in macrophages, such that subsequent responses to itself and even other TLR agonists are suppressed (62). Both LPS and the trypanosome GPI-mucin induce host cell phosphatase activities that are associated with defective MAPK activation and IκB degradation. The GPI anchor substituents associated with the shed variant surface glycoprotein (VSG) of African trypanosomes also potentiate the proinflammatory cytokine response in macrophages exposed simultaneously to IFNγ (63). If, however, the macrophages are preexposed to released VSG, the subsequent IFNγ-induced response, including Stat-1 phosphorylation, is markedly reduced. Infection with *T. gondii* is also characterized by the strong production of proinflammatory cytokines, such as IL-12 and TNFα required for host resistance; however, nuclear translocation of both NF-κB and Stat1 is blocked in infected cells, despite the fact that both transcription factors undergo phosphorylation-dependent activation in infected cells (64). Thus, although both *T. cruzi* and *T. gondii* initiate strong proinflammatory responses in host macrophages, these signaling pathways appear to be subsequently impaired to avoid reaching pathologic levels that may be lethal to the host and/or lethal to the parasite during the adaptive phase of the immune response.

In addition to their suppressive effects on macrophages, parasite products can also negatively regulate dendritic cell function. For example, CCR5-dependent IL-12 production by splenic DCs is rapidly suppressed after initial *in vivo* stimulation with *T. gondii* (STAg) and cannot be restimulated for approximately 1 week thereafter. This inhibition appears to result from the induction by parasite products of lipoxin A4, an arachadonic acid metabolite that downregulates both CCR5 expression on DCs and IL-12 production by the same cells (65). Similarly, in murine malaria infections, the initial burst of inflammatory cytokine production is downregulated as DCs become refractory to further TLR signalling (66). A similar phenomenon is observed with human DCs exposed to *P. falciparum*, in which case it appears to be mediated by direct binding of infected red blood cells to the scavenger receptor CD36 on the DCs (67). Human DCs exposed to *T. cruzi* trypomastigotes also become unresponsive to subsequent LPS-induced activation, a refractory state that can be achieved by the ceramide portion of the parasite-derived GIPL *(68)*. Studies with *Leishmania* suggest a more passive strategy for

avoidance or delayed initiation of immune control mechanisms. In the case of *L. major*, the metacyclic promastigotes that are deposited in the skin by vector sand flies are poorly taken up by DCs, whereas the efficient uptake of amastigotes by DCs *in vitro* and *in vivo* was found to depend on parasite-reactive IgG and involved FcgRI and FcgRIII that primed them for efficient production of IL-12 *(69)*. Furthermore, the initial encounter of other *Leishmania* species associated with more chronic infections fail to activate DCs on their own or to prime them for further maturation and IL-12 p70 secretion in response to endogenous agonists such as IFNγ and CD40L (70). Similarly, DCs exposed to helminths show only minor signs of maturation, and in the case of DCs exposed to schistosome egg antigens (SEA) or to microfilaria, their Th1-inducing capacity in response to TLR ligands or CD40L/IFNγ became severely impaired (71–73).

Mechanisms Underlying Th1/Th2 Response Selection

Because parasites often stimulate CD4$^+$ T cell responses that are highly polarized in either the Th1 or Th2 direction, parasitic infection models have become important tools for studying the cellular basis of Th1/Th2 subset selection. As discussed previously, DCs are believed to be an important source of the signals that determine CD4$^+$ T cell effector choice, and their role is best understood for Th1 responses. *T. gondii, T. cruzi, Plasmodium,* and to a lesser extent *Leishmania* have been shown to activate DCs, resulting in upregulated expression of IL-12 and costimulatory molecules. One of the costimulatory molecules induced on such DCs is CD40. Of interest, when upregulated CD40 on DCs interacts with CD40L on T cells, IL-12 p70 synthesis is enhanced, which in the case of *Leishmania* provides an essential positive feedback loop for Th1 activation and immunity *(74)*. In addition to its role in initiating Th1 differentiation, an unexpected requirement for continuous IL-12 signaling was observed for the maintenance of host resistance to *T. gondii* and *Leishmania* infections even in the chronic state (75,76). Also contrary to accepted dogma, there is the evidence that IL-12 signaling is not obligatory for initial Th1 subset selection. Thus, in studies in which parasite-induced CD4$^+$ T lymphocyte responses were analyzed at a single-cell level, wild-type and IL-12–knockout mice exposed to *T. gondii* developed comparable frequencies of splenic IFNγ^+ CD4$^+$ T cells, despite different levels of IFNγ being detected in the culture supernatants, suggesting that IL-12 may be more important for Th1 effector competence than for Th1 cell priming per se *(77)*. It is likely that in addition to IL-12 there are signals delivered by other cytokines, including IL-18, IFNα, and IL-1, that may be provided by protozoan-conditioned DCs to bias CD4$^+$ T cell priming toward a proinflammatory Th1$^-$ cell fate. For example, intrinsic differences were observed in high

versus low production of IL-1α by DCs from BALB/c susceptible versus resistant strains, respectively, after uptake of *Leishmania* amastigotes, and injection of IL-1α around the time of *L. major* challenge enhanced protective immunity in BALB/c mice *(78)*.

As noted, the first direct demonstrations of the relevance of the Th1/Th2 balance to the regulation of disease outcome *in vivo* were made in studies on the *Leishmania major*/mouse model. The mechanisms controlling the polarized Th2 response in susceptible BALB/c mice have been of enormous interest. A key finding is that much of the early IL-4 derives from an oligoclonal population of CD4 cells with the Vβ4 Vα8 TCR that recognize the *Leishmania* antigen LACK (79). It was initially believed that these cells might represent a unique lineage in BALB/c mice that are precommitted to releasing large amounts of IL-4. Subsequent studies have revealed, however, that the Th2 response in BALB/c mice may reflect an intrinsic defect in their ability to mount or sustain a parasite-driven Th1 response. BALB/c mice appear to have an intrinsically poor Th1-differentiating capacity, because even in the absence of IL-4 or IL-4 receptor signaling, IFNγ responses remain relatively weak *(80,81)*. Of likely relevance is the observation that under conditions of neutral priming, IL-12Rβ2 expression is not maintained during Th development in BALB/c mice *(82)*.

Additional differences in the factors controlling Th1 differentiation that are intrinsic not to CD4$^+$ T cells but to components of the innate response were noted earlier with respect to IL-1 production by DCs after uptake of amastigotes. An additional strain difference that may influence Th-subset development relates to the finding that the dissemination of parasites from the site of inoculation to the draining lymph nodes and spleen occurs early in BALB/c mice, whereas early parasite containment is observed in resistant mice *(83)*. These differences in parasite dissemination raise the possibility that distinct populations of DCs with the capacity to induce preferential priming for either Th1 or Th2 cells become activated in resistant versus susceptible mice. Such populations might not represent distinct APC lineages, but instead they may reflect modulation of APC function by specific tissue environments. That the site of antigen delivery can influence T cell priming has been clearly demonstrated in the *L. major* model; parasites delivered intravenously, intranasally, or even to different skin environments can elicit Th2 responses and nonhealing infections in normally resistant mice *(84,85)*.

Whereas *L. major* infection in BALB/c mice remains an extraordinary tool for investigating the factors controlling Th2 response selection *in vivo*, the fact that the model reflects an aberrant response arising, at least in part, from inherent Th1 developmental defects suggests that these defects might not reflect the mechanisms underlying the Th2 polarization that is a hallmark of helminth infections in virtually all mammalian hosts. Furthermore, whereas the Th2 immune deviation is clearly an inappropriate host response to an intracellular pathogen like *Leishmania*, it is an evolutionarily driven, integral aspect of acquired resistance to parasitic worms. The role of DC in Th2 response selection in helminth infection seems clear because DCs conditioned by exposure to helminth products (*Brugia* or *Schistosoma*) have been shown to polarize naive T cells toward a Th2 phenotype (86,87). In this case, however, activation of DCs as judged by the upregulation of prototypic MHC and costimulatory markers appears to be minimal, as is production of IL-12 or IL-4. Furthermore, Th2 polarization is MyD88 independent, whereas Th1 differentiation is in most instances MyD88 dependent. These observations are consistent with a model of Th2 induction by DCs that occurs via a default pathway, in the absence of Th1 priming signals, especially IL-12. However, such defaulting to Th2 is not observed when IL-12–deficient mice are infected with either *T. gondii* or *Leishmania* (see earlier discussion). Furthermore, in the case of DCs exposed to schistosoma antigens, there is a requirement for expression of signaling (NF-κB) and costimulatory (CD40 and OX40L) molecules for the induction of Th2 responses (88). Notch signaling, initiated by upregulated expression of the Notch ligand Jagged 1 on APCs, has also been implicated in Th2 differentiation, and mice that lacked signaling from all four Notch receptors failed to develop a protective Th2 cell response against the gastrointestinal helminth *Trichuris muris* (89). Therefore, it is more likely that helminth-conditioned DCs, rather than initiating a default differentiation pathway in naive T cells, provide a set of positive signals that result in Th2 priming.

The concept that IL-4 provides an essential instructive signal for Th2 differentiation is also under scrutiny. As noted earlier, helminth-conditioned DCs will polarize a Th2 response *in vitro* in the absence of IL-4, and mice deficient in IL-4, IL-4R, or the Th2-promoting transcription factor STAT-6, when infected with the helminth parasite *Nippostrongylus brasiliensis* or *Schistosoma mansoni*, develop diminished but still physiologically significant Th2 responses. In the case of IL-4–deficient mice, such residual Th2 cytokine secretion was shown to mediate, through the action of IL-13, protective or immunopathologic effects against *N. braziliensis* or *S. mansoni*, respectively (90,91). Although these findings argue that whereas IL-4R/STAT-6 signaling is not essential for priming of IL-4$^+$ CD4$^+$ T lymphocytes, it is clear that IL-4 plays a critical role in the maturation and stabilization of Th2 cells once their phenotype has been decided. For example, STAT-6–deficient animals exposed to a helminth stimulus display not only diminished numbers of Th2, cells but also an expanded population of Th1 cells that appears to be IL-12 independent (92). This observation supports data from other studies arguing that an important function of the IL-4R/STAT-6 pathway may be to silence IFNγ gene expression, a mechanism that

would indirectly lead to elevated Th2 frequencies. Finally, Th2 cells need not be the only source of IL-4 for maturation of the Th2 response; basophils committed to express IL-4 are recruited to the liver and lungs of mice infected with the migrating intestinal helminth *N. brasiliensis* (93,94).

EFFECTOR MECHANISMS OF HOST RESISTANCE

Once parasites have successfully evaded innate host defenses and had their antigens processed by APCs, adaptive cellular and humoral immune responses are invariably induced, usually against a wide array of antigenic constituents of each pathogen. The problem is that because of the nature of the host–parasite adaptation, these responses are rarely orchestrated in a manner that will completely eliminate the parasite or restrict its growth. The design of successful immune intervention strategies depends on the identification of relevant target antigens but even more importantly on an understanding of the type of immune response and protective mechanism that must be induced. These effector mechanisms can be broadly classified based on the type of parasite (intracellular or extracellular) against which they are directed.

Intracellular Parasites

Because of their primary habitat within host cells, intracellular parasites are believed to be susceptible mainly to cell-mediated immune effector mechanisms, often involving a mixture or succession of CD4$^+$ and CD8$^+$ T cell responses. The extent of CD8 involvement appears to be partially related to the degree of class II versus class I MHC expression on the host cells infected. CD8$^+$ T cells are especially critical effector cells for the control of *T. cruzi* or *T. gondii* infections because these parasites can infect many nucleated cell types that express only MHC class I molecules. Nevertheless, even in *Leishmania* infection, in which parasites reside almost exclusively in macrophages, CD8$^+$ T cells can be highly protective against both primary infection and challenge exposure (95,*96*). In addition to their contribution of IFNγ to the effector response, CD8$^+$ T cells might also control intracellular parasitic infection through the lysis of host cells. This would be of particular benefit to the host if the target cells from which viable parasites are released are themselves defective in intracellular killing (e.g., fibroblasts, DCs) and if the parasites are subsequently made available for uptake by cells that are more responsive to activation signals (e.g., macrophages). In every protozoan infection analyzed, however, including *T. gondii (97)*, malaria (98), and *T. cruzi* (99), mice deficient in the lytic molecules perforin or granzyme B show no or minimal loss of host resistance. The foregoing observations suggest that, as already noted for NK cells (see

earlier discussion), the protective functions of CD4$^+$ and CD8$^+$ T cells against intracellular parasites are mediated primarily through lymphokine production rather than target cell lysis.

IFNγ is the key lymphokine involved in control of intracellular protozoan parasites, as demonstrated by the extreme susceptibility of IFNγ-deficient mouse strains to infections with *Leishmania* (100), *T. cruzi* (101), *T. gondii* (102), *Plasmodium (103)*, and even *Cryptosporidium parvum (104)*, which dwells in epithelial cells inside the gut. Its mechanism of action is perhaps clearest in the case of *Leishmania*, which replicate primarily, if not exclusively, in macrophages—a cell type readily activated by this cytokine. The major function of IFNγ in restricting parasite growth appears to be the induction of inducible nitrogen oxide synthase (iNOS) and the subsequent generation of toxic reactive nitrogen intermediates (RNIs) within infected macrophages. Thus, disruption of the iNOS gene in a normally resistant strain leads to a susceptible phenotype, and macrophages from the same knockout strain show defective IFNγ-induced control of parasite growth (105). In addition to IFNγ, optimal production of RNI depends on costimulation with TNF or triggering by alternative signals such as IFNα/β or by CD40L and LFA-1 produced by parasite-induced CD4$^+$ T cells *(106)*. The production of RNI by IFNγ-activated macrophages is inhibited by IL-4, IL-10, IL-13, and TGFβ (107), and this is likely to be a major but not the sole mechanism by which the Th2 response prevents healing in leishmaniasis.

In contrast to *Leishmania*, most intracellular protozoa, including *T. cruzi*, *T. gondii, Cryptosporidium, Eimeria,* and *Plasmodium* spp., preferentially invade cells not traditionally believed to possess microbicidal mechanisms that can be activated by IFNγ. In the case of these pathogens, the role of RNIs or respiratory oxygen intermediates (ROIs) in IFNγ-mediated control of parasite growth is more tissue restricted. A good example is the role of IFNγ in immunity against the exoerythrocytic stages of malaria. IFNγ produced primarily by CD8$^+$ T cells in response to vaccination induces RNIs within hepatocytes invaded early after sporozoite challenge and restricts further pathogen development (108). However, when malaria parasites escape the liver they take up residence in erythrocytes, which, in contrast to hepatocytes, are unable to produce RNIs.

Lymphokine-mediated intracellular control of *T. gondii* infection involves a more complicated mechanism than induction of RNIs. The immunity induced cannot be attributed solely to activated macrophages as originally believed because the parasite infects multiple host cell types and host resistance requires IFNγ signaling in cells of both hemapoietic and nonhemapoietic origin *(109)*. Accordingly, the role of RNIs in resistance has been shown to be limited, functioning predominantly in the chronic stage of infection. An important clue concerning the mechanism controlling acute infection came from studies in

mice deficient for members of the p47GTPase family. These proteins are induced by IFNγ in a variety of hemapoietic as well as nonhemapoietic cell types. Mice deficient in either interferon induced GTPase (IGTP) or a second family member, LRG-47, were found to be highly susceptible to infection with *T. gondii* although they developed a normal IFNγ response (110). On IFNγ stimulation of *T. gondii*–infected cells, IGTP has been shown to traffic from the endoplasmic reticulum to the parasitophorous vacuole, where it participates in a process involving disruption of the vacuole, stripping of the tachyzoite membrane, and autophagic elimination of the parasites in the host cell cytosol (111,*112*). Although LRG-47 is similarly required for effective IFNγ-dependent control of *T. gondii*, it is not recruited to the parasitophorous vacuole and thus must serve a different function. Of interest, LRG-47 also plays a major role in IFNγ-dependent host resistance to *T. cruzi* and, in addition to regulating intracellular killing of the parasite, is required for a normal hematopoietic response to the infection. Thus, *T. cruzi*-infected LRG47$^{-/-}$ mice, although they develop a higher parasitemia, also undergo profound bone marrow failure that is likely to be the direct cause of their early mortality (113). Another IFNγ-dependent mechanism of intracellular parasite killing that limits *T. gondii* replication in human but not mouse nonhemapoietic cells is the induction of indolamine 2,3-dioxygenase, an enzyme that catabolizes tryptophan, an essential amino acid for growth of this protozoan (114). The foregoing examples underscore the complexity of the effector pathways triggered by IFNγ that act against different parasites in different host cells.

Although resistance to the erythrocytic stages of malaria is believed to be mediated primarily by humoral mechanisms, blood-stage immunity develops after infection in B cell–deficient mice and can be transferred with defined CD4$^+$ T cell lines and clones, suggesting that cell-mediated effector mechanisms also exist (115). Direct killing of infected red blood cells by lymphocytes is believed to be unlikely; instead, parasite clearance seems to depend on activation of phagocytosis by Th-1–type cytokines (of which IFNγ is absolutely crucial). Although it is possible to augment this mechanism by vaccination, experimental vaccines relying exclusively on T cell–mediated effector mechanisms have been associated with high mortality. For example, 60% of mice receiving a vaccine designed to induce CD4$^+$ Th1 responses to an immunodominant blood-stage antigen of *P. yoelii* died despite being able very effectively to eliminate infected erythrocytes (116). Even when the role of antibody is clear, as with the passive transfer of immune serum, the extent of protection is reduced by prior splenectomy or T cell depletion. The relevant pathways seem to function through cytokine (e.g., IFNγ, TNFα) activation of macrophages that phagocytose and destroy infected RBCs in spleen. This process is augmented when infected RBCs are opsonized by FcR-binding

antibodies, providing an excellent example of cooperation between cellular and humoral arms of the immune response. In support of this concept, resistance to human malaria has been correlated with T cell production of IFNγ (117) and generation of NO (118) *in vitro* and with FcR-binding antibody subclasses (119).

Intracellular protozoa live briefly in the extracellular milieu during initial host infection and when they invade new cells during their *in vivo* multiplication. During this period they are vulnerable to attack by antibody (Ab). In addition, although they do not directly kill free parasites, Abs can block their invasion of new cells, thereby suppressing infection. These forms of humoral immunity are of special interest in vaccine development. After repeated infection, humans living in areas endemic for *P. falciparum* gradually develop immunity to asexual blood stages, preventing high-density parasitemia and thereby preventing clinical disease. The contribution of Abs to this resistance was demonstrated in experiments in which serum from highly immune adults was transferred to acutely infected children, resulting in a temporary but highly significant reduction in parasitemia (120). The generally accepted explanation for slow acquisition of immunity to malaria is that it is strain specific and that an individual becomes immune only after being exposed to the strains circulating in his or her community. Furthermore, humoral immunity to malaria is likely to depend on an array of Abs of differing antigen specificities and functions, including agglutination of sporozoites, merozoites, or parasitized RBCs, inhibition of parasitized RBC cytoadherence to small blood vessels, and/or blocking of hepatocyte or red cell invasion by sporozoites or free merozoites, respectively (115). For the latter mechanism, the antigenic fine specificity of the Ab is crucial because some Ab specificities are able to block merozoite invasion into erythrocytes, whereas others, with distinct but overlapping specificities, either have no effect or, in the worst case, impede the activity of invasion inhibitory specificities (121). Although many of these mechanisms operate independently of FcR binding, an additional *in vitro* mechanism has been described, Ab-dependent cellular inhibition (ADCI), in which IgG1 and IgG3 in donor serum interact with monocytes or granulocytes via FcR, triggering them to produce TNFα, which is proposed to be inhibitory for parasite development *(122)*.

A well-studied example is the antibody response against the circumsporozoite (CS) protein present on preerythrocytic stages of malaria (123). Monoclonal Abs (mAbs) directed against CS protein prevent the invasion and development of sporozoites in cultured hepatocytes and *in vivo*, in passive transfer studies, confer protective immunity against *Plasmodium berghei, P. yoelii, P. vivax,* or *P. knowlesi* sporozoite challenge *(124)*. With the advent of intravital imaging techniques, it has become apparent that sporozoites are initially inoculated into dermal connective tissues, where they may take up to 30 minutes to

locate and invade a blood vessel. In immunized animals or those that have been passively transfused with anti-CS antibodies, sporozoites become immobilized within minutes and fail to invade blood vessels [see Vanderberg and Frevert (125) for excellent video imaging showing these effects]. Although incomplete sporozoite neutralization or inhibition of hepatocyte invasion allows the development of forms that can infect red cells, reducing the number of developing hepatic schizonts can significantly reduce the size of the blood inoculum and delay the onset of patent parasitemia and may allow the host more time to develop effective anti–blood stage immunity. Sporozoite antigens may therefore prove to be very valuable components of a multivalent vaccine.

Extracellular Parasites

The extracellular parasites are a highly diverse group of pathogens, which include nematoda (round worms), platyhelminthes (flat worms), and a few extracellular protozoa. Because they exhibit variability in size, tissue tropism, and mechanism of immune evasion, it is not surprising that immunity against many of these pathogens often requires more than one immune effector mechanism to mediate resistance. A variety of immune cells and mediators are activated during infection, including T cells, eosinophils, mast cells, basophils, macrophages, and antibodies. Immunity is achieved through a variety of direct and indirect mechanisms that include ADCC, increased mucus production, alterations in gut physiology, and exposure to toxic mediators produced by activated macrophages and eosinophils, which ultimately cooperate to facilitate worm expulsion. Such complex mechanisms are needed against helminths in particular because they live in the gut, blood, lymphatics, and a variety of other host tissues.

Helminth parasites induce highly polarized Th2 responses that contribute to the mast cell, eosinophil, giant cell, IgE/IgA, and mucosal responses that are typically associated with these infections. For the intestinal helminths, it is clear that elements of the type 2-response are crucial for resistance to infection. Several worms have been studied in detail in this regard: *Trichuris muris*, a natural parasite of the mouse and closely related to human whipworm, *Heligomosoides polygyrus*, *Litomosoides sigmodontis*, *Trichinella spiralis*, *Nippostrongylus brasiliensis* (the rat hookworm), and *Strongyloides stercoralis*. Although Th2 cytokines are clearly involved in resistance to many of the intestinal nematodes, the importance of Th2 immunity is less certain with many of the filarial *(Brugia malayi, Wuchereria bancrofti, Litomosoides sigmodontis)* (126–128) and schistosome species *(129)*, as discussed in detail later.

T. muris and *H. polygyrus* are both transmitted by the oral-fecal route independent of an intermediate host, and, in some strains of mice, they can establish chronic infections. In the case of *T. muris*, immunity is strictly dependent on the genetic background of the host, with resistant animals rejecting the parasite soon after exposure and susceptible animals developing long-lived chronic infections *(130)*. In this model, resistant mice develop type 2 responses, whereas susceptible mice mount type 1 responses, with a variety of immunoregulatory cytokines and mediators influencing this decision. For example, in normally susceptible strains, IFNγ, IL-12, MyD88, and Toll-like receptor-4 deficiencies *(130*,131) can promote the expansion of type 2 responses and effective clearance of the parasites.

For both *H. polygyrus* and *T. muris*, primary immunity depends on the development of a parasite-specific CD4$^+$ T cell response *(132)*. Most mouse strains are susceptible to primary *H. polygyrus* infections, but after drug clearance the animals develop strong type 2 responses and are highly resistant to secondary infection. The maintenance of immunity during recall infections is crucially dependent on the presence of memory CD4$^+$ Th2 cells at the site of infection (133). The memory Th2 response also triggers the development of alternatively activated macrophages, which help to clear secondary *H. polygyrus* infections (134). Exogenous IL-4 can cure primary *T. muris* and *H. polygyrus* infections, whereas anti-IL-4R mAb treatment suppresses immunity to both. Of interest, however, the individual roles of IL-4 and IL-13 in these infections appear to depend on the genetic background of the host because C57BL/6 IL-4 knockout mice are susceptible to *T. muris* infection, whereas BALB/c IL-4 knockouts are completely resistant *(135,136)*. These latter studies were the first to suggest an IL-13–independent role for IL-13 in resistance, which was confirmed by treating BALB/c IL-4–deficient mice with a soluble IL-13 inhibitor. IL-13–deficient mice also generate chronic infections despite developing relatively normal IL-4 responses, further emphasizing the important contribution of IL-13 to the mechanism of resistance *(135)*.

Other cytokines, chemokines, and signaling pathways, including TNF, IL-18, IL-1, IL-25, IL-10, IL-27R (WSX-1), CCL2, Notch, and the NF-κB, family were also identified as important regulators of protective IL-13 responses during *T. muris* infection. For example, mice treated with neutralizing antibodies to TNF develop relatively normal Th2 responses after infection with *T. muris*, yet they fail to expel their parasites, illustrating a critical downstream role for TNF in the mechanism of IL-13–mediated immunity *(137)*. IL-1α and IL-1β are also protective, although, unlike TNF deficiency, which does not affect the Th2 response, IL-1 deficiency has a profound inhibitory effect on Th2 cytokine production, thus identifying a unique role for IL-1 signaling in the development of immunity *(138)*. Chronic *T. muris* infections are also established in IL-10 and IL-10/IL-4 double-deficient mice, with IL-10 enhancing type 2–dependent immunity by downregulating the type 1 response (139,140). IL-10–deficient mice also

display marked morbidity and mortality after *T. muris* infection, suggesting a particularly critical role for IL-10 in the development of either immunity or pathology. Mortality is reduced if the animals are treated with a broad-spectrum antibiotic, suggesting that an outgrowth of opportunistic bacteria in the gut contributes to the uncontrolled inflammation and high morbidity of IL-10$^{-/-}$ animals (140). IL-25 was also identified as an important regulator of Th2 responses *(141)*. Studies conducted with IL-25$^{-/-}$ mice showed that IL-25 is required for the rapid development of type 2 immunity during both *T. muris* and *N. brasiliensis* infection (142,143). Like IL-10, IL-25 also limited the development of pathogenic inflammation in the gut. Thus, multiple pathways are involved in the generation of protective IL-4/IL-13 responses during *T. muris* infection.

The normal development of immunity in *N. brasiliensis* infection appears to be almost entirely IL-4 independent, as demonstrated in experiments with IL-4$^{-/-}$ and anti–IL-4 mAb–treated mice (144). The IL-4–independent mechanism is, however, dependent on the IL-4 receptor and Stat6 signaling, suggesting a critical contribution of IL-13, which was confirmed in IL-13 blocking studies. IL-13- and IL-4/IL-13–deficient mice are also more susceptible to *N. brasiliensis* than IL-4$^{-/-}$ mice, further illustrating the critical role of IL-13 in the development of immunity (145). Immunity to *T. spiralis* also requires STAT6 *(146)* and IL-4R signaling but not IL-4 (126), again suggesting a dominant role for IL-13 in the development of antihelminth immunity. The fact that IL-4 and IL-13 are capable of stimulating immunity in immunodeficient hosts suggests that a non–bone marrow–derived cell expressing the IL-4R is being targeted in the gut, which was recently confirmed in elegant experiments using bone marrow chimeras *(147)*.

Notwithstanding the clear results in mice, the relative contribution of type 2 cytokines to the development of immunity in humans is uncertain. The most straightforward hypothesis, and one predicted for many years, that IgE is protective against intestinal helminths, has either been refuted following intensive investigation using mouse models or at least received little direct confirmation (148,*149*). The possibility exists, however, that there are host species differences in this regard because in rats the rapid expulsion of a secondary *T. spiralis* infection is easily transferred to naive animals with IgE *(150)*. IgE$^{-/-}$ mice can expel adult worms but at a slower pace, and they develop nearly twice as many muscle larvae as IgE$^{-/-}$ mice (151). Although type 2 cytokines promote IgE class switching in B cells, the exact mechanism by which IL-4 and IL-13 mediate worm expulsion in the gut is undefined. Nevertheless, many important advances have been made in this area over the last few years. For example, IL-4, IL-13, and *H. polygyrus* infection all have dramatic effects on intestinal physiology, causing decreased peristalsis, increased

mucosal permeability, reduced sodium-linked glucose absorption, and decreased chloride secretion in response to 5-hydroxytryptamine and acetylcholine (152,*153*), which together may facilitate expulsion of enteric nematodes from the gut. Smooth muscle hypercontractility and goblet cell hyperplasia are also induced by type 2 cytokines and inhibited by IL-12 and the IL-13 decoy receptor (140,*154*,155). Intestinal permeability and smooth muscle contractility are also regulated by the actions of mast cell–derived proteases and protease-activated receptors, which are expressed throughout the small intestine. The net effect of these processes is to trap parasites in mucus within the gut lumen, increase intestinal fluid content, and peristalsis, which presumably leads to the expulsion of luminal dwelling parasites. More recently, a Th2-induced protein made by goblet cells (RELMbeta/FIZZ2) was found to inhibit *T. muris* chemotaxis by interacting with the parasite's chemosensory apparatus, suggesting an additional role for Th2-induced effector molecules in resistance to gastrointestinal nematode infection (156).

Eosinophils are also frequently associated with helminth infections. Surprisingly, they do not appear to play a significant role in protective immunity to *T. muris*, *H. polygyrus*, or *N. brasiliensis (149)*. Nevertheless, there is evidence from experiments with anti–IL-5 mAb–treated, IL-5 transgenic, and IL-5Rα-chain knockout mice that eosinophils play a significant role in immunity against tissue-invasive larval forms of *Strongyloides* spp. and *Angiostrongylus cantonensis* (157,*158*,159). Immunity against primary *T. spiralis* infection is also impaired in IL-5–deficient mice and is associated with decreased muscle hypercontractility *(160)*. Because eosinophils can produce significant quantities of IL-4 and/or IL-13 (161,*162*), one of their key functions may be to amplify the effector mechanisms that are controlled by type 2 cytokines (163). There is a large body of literature, primarily from studies in rats and humans, that suggests that eosinophils play a role in protection against (non–gut dwelling) schistosomes (164,165), although anti-IL–5 treated and eosinophil-deficient animals display no changes in susceptibility to these parasites, again suggesting host-species differences (161,164). Overall, despite the prevailing dogma, the majority of studies have failed to support a critical role for eosinophils in immunity to the intestinal helminths.

Mast cells, which have been linked with IL-4–induced changes in intestinal physiology, appear to play an important role in immunity to *T. spiralis*; mice treated with mAbs against stem cell factor (SCF, a non–T cell–derived cytokine) or c-kit (both of which play a central role in mast cell development) are unable to expel their parasites *(166)*. In these experiments, there was no inhibitory effect on the CD4 response, and when the mAb treatment was stopped, the parasites were quickly expelled. These data suggest that the CD4 T cell–dependent response cooperates with SCF to promote the mast cell response, which

ultimately facilitates parasite expulsion. Several cytokines made by CD4 cells, including IL-3, IL-4, IL-9, IL-10, and IL-18, have been implicated in the protective mast cell responses (91,139,*167*). The contribution of IL-9 seems especially convincing because high concentrations of IL-9 accelerate the clearance of *T. spiralis (168)* and *T. muris (169)*, whereas anti–IL-9 mAb treatment inhibits immunity to *T. muris (170)*. IL-9–producing dendritic cells have been used as adjuvants to generate the protective CD4[+] Th2 responses (171), raising the possibility that IL-4 derived from mast cells is feeding back to enhance Th2 cell differentiation *(169)*. A similar Th2-promoting mechanism was proposed for tissue basophils, which have been identified as an important source of IL-4 in schistosome, filarial, and *N. brasiliensis* infections (93,*172*,173). In filariasis patients, the presence of antigen-specific IgE appears to be critical for basophil IL-4 production (173). Thus, CD4[+] Th2 cells, eosinophils, mast cells, and basophils may all contribute to the protective type 2 responses that are induced after infection with helminth parasites.

In addition to playing roles in immunity to gastrointestinal helminths, there is growing epidemiologic evidence that type 2 responses, particularly in the form of antigen-specific IgE, mediate the resistance that develops with age in endemic areas. Although the exact mechanism by which IgE Ab mediates protection is unclear, it is possible that parasite-specific IgE cooperates with eosinophils or macrophages in an ADCC type mechanism (174). Consistent with this hypothesis, carriage of the HLA-DRB1*13 class II allele is associated with increased posttreatment IgE levels against *S. mansoni* antigens and lower long-term reinfection levels (175), whereas field studies in Brazil suggested that resistance is controlled by a major gene that localizes to a region of chromosome 5, which encodes the type 2 cytokines *(176)*. IgE-primed basophils may also enhance immunity by producing Th2 cytokines (93,*172*,173).

Both type 1 and type 2 associated effector mechanisms may be needed for the efficient clearance of lymphatic filariasis *(177)* because the primary immune response to live filarial parasites is dominated by both Th2 cytokines and several proinflammatory mediators, including IFNγ, TNFα, granulocyte-macrophage colony-stimulating factor, IL-1α, and IL-8. In the *Brugia* mouse model of filariasis, B cells are required for the development of immunity (178), with IgM antibodies participating in the clearance of both primary and secondary infections and IgE assisting with primary but not secondary infections (179). Eosinophils are also required for resistance to primary *Brugia pahangi* infection *(180)*, suggesting that an ADCC-type effector mechanism facilitates parasite clearance. In the *L. sigmodontis* model of filariasis, IL-4 blocks nematode development in resistant hosts but not in susceptible strains of mice, suggesting that additional immune effector molecules are required in some hosts *(181)*. Related studies have suggested important synergy between IFNγ

and IL-5 in the development of antifilarial immunity (182), although the role of IFNγ is unclear.

As with many of the extracellular parasites, resistance to protozoan trypanosomes appears to require elements of both cell-mediated and humoral immunity. The African trypanosomes are tsetse-transmitted parasites that inhabit the extracellular compartment of their host's blood and avoid detection by the humoral immune system by switching among antigenically distinct variant surface glycoproteins (VSGs) (see later discussion). Trypanosome-infected hosts typically do not produce antibodies that destroy the parasite other than those that are VSG specific. Parasitemias manifest as recurring waves, with each wave of parasites expressing a different VSG, and are cleared after development of VSG-specific Ab. Before an effective antibody response can be generated, however, the host can develop quite high parasitemias, severe trypanosomiasis-associated pathology, generalized immunosuppression, and, in some circumstances, debilitating secondary infections *(183)*. It is clear that overproduction of IFNγ and nitric oxide appears to be the root cause of these deleterious side effects *(184)* while also contributing to host resistance, because parasite control within the extravascular tissue compartment has been shown to involve a parasite antigen-specific Th1 response, associated with IFNγ-dependent activation of macrophages (*185*,186).

Another important extracellular protozoan, *Giardia,* is a flagellated intestinal parasite that causes both acute and chronic diarrheal disease. Despite its intestinal habitat, *Giardia* appears to be controlled by mechanisms distinct from those mediating resistance to most gastrointestinal nematodes, although recent studies suggest that mast cell–derived IL-6 may be important for the rapid elimination of *Giardia* in mice (187,*188*). Although a T cell–dependent mechanism is also clearly essential for resistance to acute infections, numerous studies have suggested that antibodies, particularly of the IgA isotype, are required to control chronic *G. lamblia* infections (reviewed in ref. *189*). More recently, it was suggested that neuronal NOS (NOS1) might facilitate clearance of *Giardia* from the gut by increasing gastrointestinal motility and parasite-induced diarrhea (190).

The foregoing examples stress that whereas intracellular and extracellular parasites often stimulate distinct immune response profiles, their immune control may involve overlapping immunologic effector arms.

MECHANISMS OF IMMUNE EVASION

Pathogens that rely on an invertebrate vector to complete their life cycle or are only sporadically transmitted from one host to another are under strong evolutionary pressure to prolong their survival within the mammalian host.

Because the adaptive immune response is the principal barrier to the persistence of pathogens in the mammalian host, parasites have evolved diverse strategies to evade immune control mechanisms, either by evading immune recognition or by suppressing the immune response. The former strategy refers to the ability of some parasites to sequester within sites that are inaccessible to immune attack, to mask themselves with host antigens, to shed their own target antigens, or, most notably, to undergo antigenic variation. The later strategy refers to the active suppression of established, ongoing immune responses that may contribute to the state of equilibrium that is established between host and parasite in sites of chronic infection.

Evasion of Immune Recognition

The asexual, blood stage of malaria would seem the most obvious example of a well-hidden parasite. Its ability to invade mature erythrocytes, which lack both class I and class II histocompatibility molecules, in theory at least should protect it from recognition by antibodies or effector T cells. However, because parasitized erythrocytes are efficiently cleared by the spleen, additional immune evasion strategies, that is, antigenic variation, are required (described later). Other intracellular protozoa appear to hide within immunologically privileged sites. The persistence of *T. cruzi* within heart or skeletal muscle, which is believed to underlie the pathogenesis of Chagas' disease, occurs despite the fact that parasites are cleared from most other tissue (191). Infected muscle cells may be only poorly recognized as targets for cytotoxic T lymphocytes (CTLs) or poorly accessible to their homing, or they may have intrinsic defects in immune-mediated killing mechanisms. A similar form of sequestration has been proposed to explain the long-term persistence of *Leishmania* within fibroblasts and dendritic cells following their efficient killing by activated macrophages during the acute stage of infection (192). Although persistent low-level infection of host cells has been proposed as an explanation for latency in *T. gondii* infection, the major parasite reservoir during chronic infection is undoubtedly provided by the tissue cyst, essentially a modified host cell carrying a specialized dormant parasite stage, the bradyzoite. Helminths (with the exception of *Trichinella*) do not invade host cells and therefore cannot use this strategy for evading immune recognition. Furthermore, because most multicellular helminth parasites do not replicate themselves within their mammalian hosts, they are not equipped to evade immune recognition by undergoing antigenic variation. Instead, they employ alternative mechanisms such as disguising their surfaces with host molecules and rapidly shedding membrane (tegument)-bound immune complexes (193). In addition, helminths have evolved a series of elaborate processes for inactivating antibody, complement, and cellular effector elements that threaten the parasite surface (194). Of interest, recent data suggest that helminths may take advantage

of host T lymphocyte and cytokine signals as developmental triggers, and if these signals are in low abundance or lacking *in vivo* parasite growth may be aborted or severely attenuated (195–197). In the case of schistosome parasites, development of female parasites is not directly influenced by the adaptive immune system, whereas male development is *(198)*. In this sequential model, adaptive immune signals trigger development of mature males, which subsequently stimulate development of mature females. Thus, in this example, chronic infection is achieved only when specific features of the host adaptive immune system are successfully exploited.

Antigenic variation is an important mechanism of immune evasion shared by diverse classes of pathogenic protozoa, including African trypanosomes, *Giardia*, and malaria. In each case, the antigens involved are highly immunogenic but poorly cross-reactive and are encoded by large families of nonallelic genes. The best-studied example of antigenic variation in parasites is that of African trypanosomes, the etiologic agents of sleeping sickness (reviewed in ref. 199). As mentioned, these organisms, such as *T. brucei*, produce waves of parasitemia by generating subpopulations that express antigenically different forms of the major surface variant-specific glycoprotein (VSG). This switching occurs independent of antibody and at relatively high frequency. An internal subregion of the VSG appears to be the major epitope driving the Th1 response, and this region is also highly variable.

In the case of *Giardia lamblia*, surface antigenic variation occurs within a family of variant-specific, cysteine-rich, zinc finger proteins (VSPs). After inoculation into mice of a single *G. lamblia* clone, the original VSP is expressed for approximately 2 weeks and then is gradually replaced by other VSPs, coincident with the appearance of variant-specific antibodies (reviewed in ref. 200). Mice that are unable to make antibodies, however, are still able to control acute *G. lamblia* infection, and, even in immunodeficient mice or gerbils, certain clones of *G. lamblia* are selected for or against, depending on the parasite clone and the host species *(201)*. Thus, in addition to immune evasion, antigenic variation may be involved in other aspects of biological selection, such as diversifying the host range of the parasite.

Although the need for antigenic variation might be obvious for extracellular protozoa such as trypanosomes and *Giardia*, it is less obvious why malaria parasites—hiding inside red blood cells—should have evolved a similar strategy of immune evasion (reviewed in ref. 202). The most plausible explanation is as follows. Developing schizonts cause erythrocyte distortion, loss of flexibility, and abnormal surface exposure of various membrane components, all of which make infected erythrocytes vulnerable to clearance from the circulation during passage through the spleen in a manner very similar to that by which normally aged red cells are removed and destroyed. To avoid passage through the spleen, the parasite exports to the red cell

surface a range of molecular anchors—of which the best characterized is *P. falciparum* erythrocyte membrane protein-1 (PfEMP-1)—which bind to endothelial receptors, allowing the parasite to sequester in peripheral tissues. Parasite sequestration contributes to malaria pathology, clogging blood vessels and triggering focal inflammation, giving rise to cerebral, respiratory, and renal symptoms; sequestration in the placenta gives rise to pregnancy-associated malaria. Because these molecular anchors are parasite derived, they are recognized by the immune system; antibodies bind to them, prevent endothelial sequestration (and disease), and allow parasitized RBCs to be cleared in the spleen. Thus, for the parasite to establish a chronic infection, a system of clonal antigenic variation is required. The importance of these molecular anchors as a parasite survival strategy is demonstrated by the fact that there are upward of 50 copies of the gene for PfEMP-1 (*var* genes) per parasite, more than 200 copies of other clonally variant surface protein genes *(203)*, and innumerable allelic variants of each gene in the global parasite population.

Evasion by Immune Suppression

Generalized immunodepression, which is a feature of many chronic parasitic infections, including malaria, African trypanosomiasis, and visceral leishmaniasis, appears in most instances to be secondary to other immune evasion strategies, and results from the need to downregulate inflammation to prevent immune pathology (see next section) or from a variety of immune dysfunctions that high systemic parasite burdens can produce. These dysfunctions include disruption of normal lymphoid architecture, such as occurs in the mouse spleen during chronic infection with *Leishmania donovani,* in which excess TNF production leads to destruction of stromal cells in the periarteriolar lymphoid sheath and the loss of the chemokines that these cells would normally produce to recruit naive T cells and mature DCs (204). The accumulation of parasite-derived metabolic products can also be directly inhibitory to lymphocyte function. Metabolic products of *S. mansoni* adult worms, for example, have also been shown to strongly inhibit lymphocyte proliferation, including primary and secondary Th2 responses (205,*206*).

There is evidence from *in vitro* studies that clonally variant or polymorphic antigens of parasitic protozoa may also promote parasite survival by modulating the immune response. The simultaneous presence of variant CS T cell epitopes (also referred to as altered peptide ligands), as might occur in African children infected with multiple allelic variants of malaria, was found to deliver an altered signal to the responding T cells that induced nonresponsiveness to its target agonist epitope *(207)*. In the case of *T. cruzi,* which can express and secrete multiple members of the highly polymorphic surface sialidase superfamily at one time, epitope-specific T cell responses are suppressed either by altered peptide ligand inhibition or because im-

mune recognition is impeded by a flood of competing targets *(208)*. Some variants of PfEMP-1 appear to mediate binding of malaria-infected erythrocytes to dendritic cells and inhibit their maturation (209), whereas erythrocytes infected with nonbinding parasite lines failed to adhere to dendritic cells or to affect their function. However, whether these phenomena are of any functional immunologic consequence in the infected host is not known. Similarly, lymphocyte polyclonal activation, which can result in depression of antigen-specific responses, is a feature of many parasitic protozoan infections, including blood and tissue trypanosomes, *L. donovani*, *T. gondii*, and rodent malarias, but again, a causal link between polyclonal activation and immune evasion has not been established. The original hypothesis—that these organisms possess mitogenic or superantigenic moieties (210)—has been substantiated in the case of *T. cruzi*, in which the B cell mitogen has been cloned and characterized as a eukaryotic proline racemase *(211)*. For malaria there is evidence that some domains of PfEMP-1 may be mitogenic for human B cells *(212)*.

Regulatory T Cells and Parasite Persistence

The modulation of ongoing immune responses in sites of chronic infection, such as the gut or the skin, may in many instances reflect not only parasite survival strategies, but also normal mechanisms of immune homeostasis that operate to control immunopathology associated with antimicrobial effector mechanisms. Accumulating evidence has implicated a crucial role for regulatory T cells in the dynamic equilibrium that is established between parasites and their hosts. Regulatory T cells is the name given generally to the subsets of CD4$^+$ T cells, and more recently CD8$^+$ T cells, that negatively regulate multiple immune functions. Among the different subsets of CD4$^+$ regulatory T cells that have been described, the best characterized are the so-called naturally occurring CD4$^+$ CD25$^+$ T cells that are present in naive animals. These cells also express CTLA-4 and the transcription factor Foxp3, which are actively involved in their development and suppressive function. T cells with regulatory activity can also be induced from conventional naive cells after encounter with antigen in the periphery (Tr1, Th3, and CD8$^+$ Treg cells). In addition to the critical role that Treg play in suppressing potentially pathogenic T cell responses directed against self-antigens or gut flora, they may also suppress potentially beneficial immune responses, such as those directed against infectious pathogens and tumors. Both natural and inducible Treg can produce downmodulatory cytokines (IL-10 and TGFβ) that switch off inflammatory and protective immune responses and can interfere with effector T cell activation in a contact-dependent manner. The evidence that natural Treg contribute to pathogen persistence was initially demonstrated in the *L. major* mouse model, in which IL-10 produced by CD4$^+$ CD25$^+$ T cells was required for the persistence of amastigotes in the skin

following clinical cure in resistant mice (213). These cells, at least some of which are *Leishmania* specific, were found to accumulate in the dermal lesion and to suppress the frequency of Th1 cells and their ability to mediate parasite killing in the site. Similarly, in a model of mouse malaria characterized by extremely rapid parasite growth (*P. yoelii* YM or 17XL), very early induction of TGFβ and IL-10 appears to inhibit the development of responses that are required for parasite clearance. Neutralization of IL-10 and TGFβ (214)—or, in some studies, depletion of natural regulatory T cells (215)—at the onset of infection allows parasite replication to be contained, and mice are able to resolve their infections and survive. A similar scenario has been observed in experimental human infections within the context of malaria vaccine trials (216).

The ability of natural Treg to suppress Th2 responses has also been demonstrated, such that *L. major*–infected BALB/c mice treated with anti-CD25 antibody developed even more severe disease *(217)*. The persistence of filarial worms as a consequence of Treg-mediated suppression of Th2 responses was shown for *Litomosoides sigmodontis* infection of mice, although in this case the effects were independent of IL-10 (218). The isolation of T cells with regulatory characteristics from humans infected with filarial nematodes and the observation that CTLA-4$^+$ T cells contribute to their suppressed production of IL-5 indicate that regulatory T cells may be involved in suppression of protective immune responses in patients with onchocerciasis or lymphatic filariasis (219,220). The role of natural Treg in modulating immunopathology associated with helminth infections is discussed later.

The role of IL-10 in parasite persistence is especially striking in the case of *Leishmania*, although in some cases this powerful deactivating cytokine was found to be produced by cells other than natural Treg. Of interest, the inability to heal infection with a substrain of *L. major* that induces a polarized Th1 response in C57Bl/6 mice was associated with IL-10 production by CD4$^+$ CD25$^-$ Foxp3$^-$ T cells that also produced IFNγ (221). A similar phenotype is associated with control of Th1-driven immune pathology associated with *T. gondii* infection in mice (discussed later). The data suggest that in sites of strong inflammation, IL-10–producing Th1 cells may be activated as an especially powerful mechanism of feedback control. The *L. major* mouse model has also revealed a potential role for suppression mediated by IL-10 and TGFβ produced by macrophage after uptake of Ig-opsonized parasites (222,223). Thus redundant mechanisms of homeostatic control, including innate cells and natural and adaptive Treg, may be activated to control immune pathology associated with antimicrobial immune responses in tissues that are especially susceptible to injury, for example, the skin and mucosa. The regulatory T cell subsets that have been described in parasitic infections are summarized in Table 35.3.

IMMUNOPATHOLOGIC MECHANISMS AND THEIR REGULATION

If the appropriate adaptive immune mechanisms fail to develop or if they are not able fully to eradicate the infection, then persistent inflammation and other nonspecific responses may be the only way of limiting the infection. This is the situation for many parasitic diseases, and it carries an inevitable risk of pathologic side effects. This does not mean that all infections with the same parasite species lead to the same immune pathology. One of the most striking features of human parasitic disease is the great variability in clinical outcome, ranging from asymptomatic infection to fatal disease. Esophageal disease due to *T. cruzi*, liver fibrosis and portal hypertension due to *S. mansoni*, and cerebral malaria due to *P. falciparum* are a few examples of the many immunopathologic complications that may occur in some individuals but not others. Part of this variability is determined by host genetics, whereas other potential determinants include parasite virulence factors, infection intensity, and the prior level of immunity. The picture may be further complicated by coinfection with other infectious agents: For example, the severity of *P. falciparum* malaria is increased by concomitant bacteremia but reduced by concomitant *P. vivax* infection (224). HIV antiretroviral drugs also impair CD36-mediated cytoadherence and nonopsonic phagocytosis of parasitized erythrocytes by human macrophages, which may lead to altered malaria disease outcomes in treated coinfected individuals (225). The pathology associated with chronic *S. mansoni* infections reduces the CD4$^+$ T cell count, which can exacerbate the effects of HIV-1 in coinfected individuals (226). *S. mansoni* infection has also been shown to increase susceptibility to AIDS virus infection, transmission, and replication in nonhuman primates *(227)*, and similar observations have been made in malaria-infected HIV patients (228). Concomitant exposure to malaria affects the regression of hepatosplenomegaly after treatment for *S. mansoni* infection *(229)*. Coinfections of *T. gondii* and *S. mansoni* are also more lethal *(230)*. Finally, even more surprising was the finding that endosymbiotic *Wolbachia* LPS is the principal cause of river blindness in filariasis (231).

It is impossible to do justice to the remarkably broad range of immunologic mechanisms that contribute to the pathology of parasitic disease. Twenty years ago, much of the research in this field concerned the role of immune complexes, complement, and anaphylaxis. These areas remain important, but the focus has shifted to the molecular basis of cellular processes such as inflammation, granuloma formation, and tissue remodeling. An important issue is how the host maintains the fine balance between a protective immune response and one that is liable to cause pathologic complications. It is becoming increasingly clear that this is one of the most critical determinants

▶ **TABLE 35.3 Regulatory T Cells and Parasitic Infections**

Parasite	Host	Treg Phenotype	Cytokine Secreted	Suppressive Function	Ref.
Leishmania					
L. major	C57Bl/6	CD4+CD25+Foxp3+	IL-10	Suppress Th1 responses and sterile cure in healed mice	213
L. major	BALB/c	CD4+CD25+	nd	Suppress Th2 responses, moderate lesion progression	*217*
L. major	C57Bl/6	CD4+IFNγ+CD25−Foxp3−	IL-10	Suppress Th1 responses and healing	221
L. brasiliensis	Human	CD4+CD25+CTLA+ Foxp3+	IL-10/TGFβ	Treg from lesion suppress proliferative responses *in vitro*	*339*
Malaria					
Plasmodium yoelii	BALB/c	CD4+CD25+	nd	Suppress CD4 response and resistance to lethal infection	215
P. yoelii	C57Bl/6	CD8+	IL-10/ TGFβ	Suppress type 1 cytokine response; inhibit parasite clearance	214
P. chabaudi	C57Bl/6	nd	IL-10/ TGFβ	Suppress immunopathology in nonlethal infection	*245, 246*
P. falciparum	Human	CD4+CD25+Foxp3+	TGFβ	Suppress systemic type 1 response; facilitate parasite growth	216
P. falciparum	Human	CD4+CD25+	L-10	Suppress antigen-specific IFNγ from cord blood lymphocytes	*340*
Toxoplasma	Mouse	CD4+IFNγ+CD25−Foxp3−	IL-10	Suppress Th1-mediated pathology	238
Filaria					
Onchocerca volvulus	Human	Tr1	IL-10	Antigen specific IL-10, suppressive activity not shown	219

		CD4+CD25+Foxp3+	IL-10 indep	Inhibit Th1 and suppress Th2 response	265

IFNγ, interferon-γ; IL, interleukin; indep, independent; nd, not determined; TGFβ, transforming growth factor-β.

of a successful host–parasite relationship, and, as such, it is of considerable importance for vaccinologists. Of interest, in many parasitic infections this balance appears to be regulated by the coordinated actions of a growing list of important immunoregulatory mechanisms.

Achieving Balance Between the Antiinfective Immune Response and Host Pathology

Whereas a proinflammatory Th1 response is usually required to control intracellular infections, there is also a need to balance the response. The potentially harmful ef-

fector molecules induced by Th1 responses include NO, ROIs, and TNF, which often operate in a synergistic fashion. IL-10, TGFβ, and to a lesser extent IL-4 produced by distinct subsets of regulatory cells including Tregs, Th2, Th3, and Tr1 cells appear to be important in preventing the Th1 responses from overshooting during intracellular infections. There are also several examples in which Th2 responses appear to be detrimental. Strong antibody responses may lead to the formation of antigen–antibody complexes or complement activation resulting in bystander lysis *(232)*. Eosinophils, typically associated with the Th2 response, are involved in hypersensitivity reactions to the filarial worm *O. volvulus* and can contribute

to fibrotic tissue remodeling (161). Th2 responses appear to be the primary cause of hepatic fibrosis and chronic morbidity in *S. mansoni*–infected mice *(233)*. The data suggest that a variety of mediators, including IFNγ, IL-12, IL-10, Tregs, and decoy receptors cooperate to keep Th2 responses in check. Finally, a new subset of T helper cells designated Th17 was recently described, which have replaced Th1 cells as the critical pathogenic cells in several autoimmune diseases *(234)*. Although they provide adaptive immunity tailored to specific classes of pathogens, most notably extracellular bacteria, it is unclear whether Th17 cells regulate immunity or immunopathology during parasitic infection (235). In summary, a successful resolution to infection typically requires precise titration of T helper cell responses appropriate to the type of pathogen (Figure 35.2). This is not just in terms of amount, but also of where, when, and for how long polarized responses persist.

Pathogenesis of Chronic Th1 Responses

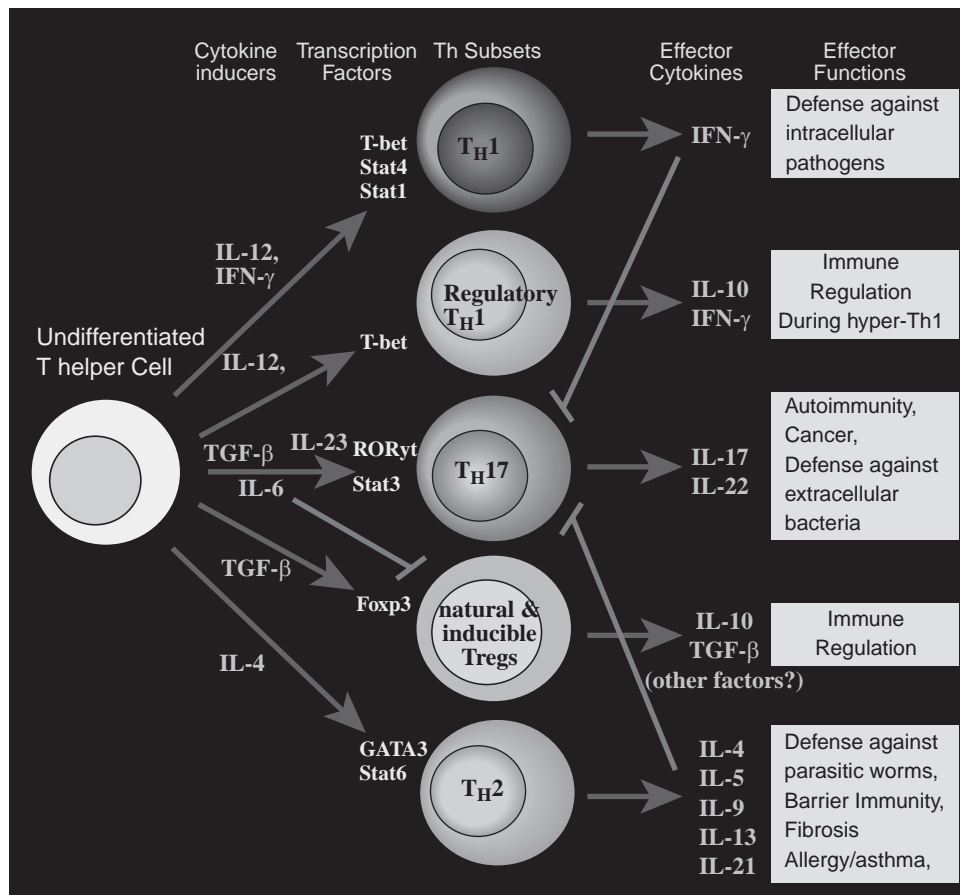
As discussed, control of intracellular pathogens such as *Leishmania* spp., *T. gondii*, and *T. cruzi* requires the coordinated activation of both antigen-specific cells (T lymphocytes) and less specific responses (NK cells, neutrophils, and macrophages), with IFNγ and TNF playing critical roles by upregulating macrophage activation and nitric oxide production. Of interest, IL-10–deficient mice inoculated with a normally avirulent *T. gondii* strain or with a virulent strain of *T. cruzi* succumb to infection within the first 2 weeks of infection (236,237). In both of these infections, animals lacking IL-10 show increased suppression of parasite growth, and, in the case of *T. cruzi*, inflammation and necrosis within the endocardium and interstitium of the myocardium is reduced. The increase in mortality appears to be caused by high systemic levels of IL-12, IFNγ, and TNF produced in large part by activated CD4$^+$ lymphocytes and macrophages. The livers of both *T. gondii*– and *T. cruzi*–infected mice show numerous and prominent necrotic foci together with dramatically increased mononuclear cell infiltration. Similarly, macrophages from the mutant mice activated *in vitro* or *in vivo* with *T. gondii* secrete higher levels of TNF, IL-12, and inducible NO than macrophages from IL-10–sufficient animals. The combined clinical manifestations suggest that the IL-10 knockout mice die in response to an overwhelming systemic immune response, resembling that observed during septic shock. In support of this conclusion, administration of anti-CD4, anti-IL-12, or anti-TNF Abs reduces mortality in IL-10 knockout mice (236,237). Thus in these


FIGURE 35.2 Effector and regulatory CD4$^+$ T cell subsets involved in achieving the balance between the antiinfective immune response and host pathology.

Immunity and immuno-pathogenesis
FIGURE 35.3 Immunopathogenesis of malaria. Infected red blood cells (iRBCs) and parasite products bind to pattern recognition receptors (PRRs, e.g., TLR2 and TLR9) on monocytes and dendritic cells (DCs) and induce a cascade of proinflammatory cytokines (most importantly interleukin-12 [IL-12], interferon-γ [IFNγ], and tumor necrosis factor-α [TNFα]). These inflammatory signals initiate numerous pathologic processes. They cause upregulation of adhesion molecule expression on vascular endothelium, promoting vascular sequestration of iRBCs, which clogs the vessels, reduces blood flow, and simultaneously raises intracranial pressure. iRBC products also bind to PRRs in tissue, initiating local inflammatory loops that amplify iRBC sequestration. Vascular occlusion and subsequent tissue damage contribute to cerebral malaria, respiratory distress, and multiorgan failure. Other cytokines such as IL-1, TNFα, and IL-6 induce the fever response, which includes elevated temperature, nausea, headache, prostration, and muscle pain. The actions of inflammatory cytokines are antagonized by antiinflammatory cytokines, principally IL-10 and TGFβ, which inhibit both production of, and cellular responses to, inflammatory signals.

models, IL-10 plays a major role in protecting the host against an excessive and lethal type 1 cytokine response.

Recent studies in the murine *T. gondii* model have demonstrated that CD4$^+$ T lymphocytes are the major source of the host-protective IL-10 (238). Of interest, CD25$^-$, Foxp3$^-$-producing Th1 cells are the principal CD4$^+$ subpopulation producing the cytokine, and these same cells can trigger macrophages to control the parasite through their simultaneous synthesis of IFNγ. These and other findings suggest that IL-10 is triggered in parasite-induced IFNγ-producing Th1 cells as means of suppressing IL-12 synthesis in APCs and downregulating further Th1 expansion.

Much has been written about the protective versus pathologic consequences of proinflammatory cytokine production in malaria (Figure 35.3) (reviewed in ref. 239). During the preerythrocytic stage in the liver, when parasite burden is relatively low and the infection is clinically asymptomatic, there is evidence that IL-12, IFNγ, and NO each plays an important role in preventing the infection from progressing further *(240)*. Once the parasites invade erythrocytes and grow to large numbers, the risk–benefit equation is less clear. Although TNF, IL-12, and IFNγ can inhibit blood-stage parasites and thereby exert a protective function, at this stage the cytokine response is systemic, and some pathologic side effects are inevitable. The most common clinical consequence in humans is fever, whereas life-threatening complications such as profound anemia and cerebral malaria occur in a proportion of infections due to *P. falciparum* but not other species. Mice

with malaria do not develop fever (instead, systemic inflammation leads to a decrease in core temperature), but, depending on the specific host–parasite combination, they may develop anemia, fatal neurologic symptoms, or multiorgan failure; TNFα and, more recently, lymphotoxin-α have been the cytokines most consistently associated with severe pathology in these models (241,*242*). Moreover, polymorphisms of the promoter regions of the TNF gene (243) have been associated with susceptibility to severe complications of *P. falciparum* malaria in African children. One interpretation of these findings is that a strong early proinflammatory cytokine response is protective, whereas a strong late response is pathologic (244).

Experimental studies suggest that IL-10 and TGFβ cooperate to downregulate potentially pathogenic proinflammatory cytokine responses in malaria *(245)*. IL-10–deficient mice infected with *P. chabaudi chabaudi* showed increased mortality compared with normal wild-type littermates, although peak parasitemias did not differ markedly *(246)*. Instead, acute infection was characterized by an enhanced TNF response, which directly contributed to pathology; neutralization of TGFβ in *P. chabaudi*–infected IL-10–deficient mice was rapidly and universally fatal (247). Thus, susceptibility of IL-10–deficient mice to an otherwise nonlethal infection results not from fulminant parasitemia but from a sustained and enhanced proinflammatory cytokine response. Similarly, treatment of infected mice with a neutralizing antibody to TGFβ exacerbated the virulence of *P. berghei* and caused *P. c. chabaudi* infection, which normally resolves spontaneously, to become lethal; it was concluded that the protective effects of this cytokine are also due to downregulation of inflammatory responses (244). However, as described previously, very early induction of TGFβ and IL-10 can inhibit the effector response that is required for parasite clearance (214,215); thus, the outcome of malaria infections is determined, in part at least, by the sequence and timing of proinflammatory and antiinflammatory (immune regulatory) responses.

Pathogenesis of Chronic Th2 Responses

With many of the nematode infections, the protective Th2 response can cause significant pathologic changes in the gut (inflammation, excess mucus, damage to epithelium, and diarrhea). However, these effects are often transient and quickly resolve after parasite expulsion. If the parasites are not expelled quickly, the immune response typically shifts to a more Th1-polarized reaction (248). Thus, there are only a few examples in which persistent Th2 reactions are established as a result of chronic infection. Perhaps the most widely studied in this regard are the schistosome parasites, which are extremely successful at establishing long-term infections in their definitive hosts. On infection, adult parasites of *S. mansoni* migrate to the

mesenteric veins, where they live up to 10 years or more, laying hundreds of eggs per day. Some of the eggs become entrapped in the microvasculature of the liver, and once there, they induce a granulomatous response (249). Subsequently, fibrosis and portal hypertension may develop, which is the primary cause of morbidity in infected individuals and in some cases may ultimately be lethal. Consequently, much of the symptomatology of schistosomiasis is attributed to the egg-induced granulomatous inflammatory response and associated fibrotic pathology (250).

Granulomas are pathogenic, not because they cause hepatic failure in the short term, but because they precipitate fibrosis, increased portal blood pressure, and development of portal systemic shunts that are prone to bleed *(251)*. CD4$^+$ Th cells are essential for granuloma formation, whereas all other lymphocyte types examined so far (including B cells, CD8 cells, NKT cells, and $\gamma\delta$ T cells) appear less critical. In fact, B cell–deficient (μMT) mice mount an exacerbated granulomatous response, and unlike wild-type animals, they fail to downmodulate pathology late in infection, suggesting that B cells play an important immunomodulatory role, perhaps by producing IL-10 *(252)*. Perinatal exposure to specific anti-SEA idiotypes has also been shown to induce long-term effects on survival, pathology, and immune response patterns in mice subsequently infected with *S. mansoni (253)*. These cross-reactive regulatory idiotypes can also predict clinical outcomes of chronic disease (254).

The critical role of Th2 cells in granulomatous inflammation and fibrosis was confirmed in experiments in which mice vaccinated with egg antigen plus IL-12 to induce an egg-specific Th1 response on subsequent infection developed smaller granulomas and less severe fibrosis than did nonvaccinated infected controls (255). Decreased fibrosis was associated with a diminished Th2 response and increased Th1 cytokine production. Anti–IL-4 mAbs were also shown to reduce granuloma size and fibrosis in infected mice, although the effects of IL-4 deficiency varies in different strains of IL-4$^{-/-}$ mice *(256)*.

Although egg-induced granulomas are widely believed to be detrimental to the infected host, it is clear that the lesions also serve an important host-protective function, particularly in *S. mansoni* infections. In chronically infected hosts, schistosome eggs provide a continuous antigenic stimulus for the immune response. If these antigens are not sequestered or neutralized effectively, they may damage the affected tissues, with the liver being particularly sensitive. Indeed, T-cell–deprived, nude, severe combined immune deficiency (SCID), and egg-tolerized mice infected with *S. mansoni* all die earlier than comparably infected immunologically intact control mice because they are unable to mount a normal granuloma response *(257)*. Widespread microvesicular hepatic damage induced by toxic egg products contributes to the poorer survival of infected immunosuppressed mice. Granuloma formation

therefore seems to be a compromise solution to allow the host to live with the infection.

During granuloma development, the primary CD4$^+$ T cell response switches from a Th1 response of short duration to a persistent Th2 response, which dominates soon after the acute stage of infection. The development of the Th2 response was thought to be highly dependent on IL-4; therefore, it was hypothesized that depleting IL-4 might slow the development of severe hepatosplenic disease. Nevertheless, studies conducted with IL-4–deficient mice demonstrated that IL-4 plays an essential host-protective role during infection with *S. mansoni (256,258)*. Unlike wild-type mice, that develop chronic infections without significant complications, infected IL-4–deficient mice suffer from an acute inflammatory disease, which is characterized by cachexia and significant mortality. Of interest, IL-4R-signaling is required for the efficient passage of eggs through the intestine into the lumen *(257)*. Consequently, the eggs are trapped in the intestinal wall, which causes localized inflammation and ultimately increased systemic exposure to bacterial toxins such as LPS. This, combined with the decreased Th2- and enhanced Th1-type response, results in increased proinflammatory cytokine production that contributes to the weight loss and death of the IL-4–deficient animals.

IL-10 appears to also play a role in inhibiting inflammation during both murine and human *S. mansoni* infections *(233,259)*. In mouse studies, marked increases in IFNγ, TNF, and iNOS expression were detected in infected IL-10–deficient animals, and this correlated with the development of morbidity and mortality. Even more striking effects were observed in mice that are deficient in both IL-4 and IL-10 (DKO mice), which developed the most highly polarized Th1-type response and in which 100% mortality was seen by week 9 postinfection *(233)*. The mice had elevated serum aspartate transaminase levels, suggesting that mortality was likely attributable to uncontrolled proinflammatory cytokine production and acute hepatotoxicity. Other studies suggest that IL-4 and perhaps IL-10 protect the host by downregulating the generation of reactive oxygen and nitrogen intermediates that can damage the liver *(260)*. Regardless of the exact mechanisms involved, IL-4 and IL-10 are both required to prevent the Th1 responses from overshooting and becoming pathogenic. IL-10 has also been implicated in the control of the Th2-driven granulomatous response, the failure of which is thought to be responsible for the development of hepatosplenic disease in some chronically infected individuals. Roles for IL-10 in immune downmodulation have also been documented in *Schistosoma mansoni*– and *S. haematobium*–infected humans *(261,262,*263). Recent studies in mice have focused on defining the cellular sources of IL-10, and although a role for Treg-derived IL-10 has been reported, it is clear that IL-10 derived from a variety of sources, including Th2 cells, macrophages, dendritic cells, and B cells, can help to regulate type 2 responses and perhaps, development of hepatosplenic disease (88,*252,264,265*).

Because fibrosis is driven by the Th2 response, many of the complications associated with chronic infection (portal hypertension, collateral vessel formation, bleeding from esophageal and gastric varices) likely result from the persistent production of type 2 cytokines (266). Although it is clear that intact IL-4 receptor signaling is critical for the development of granulomas and fibrosis, IL-13 was identified as the dominant profibrotic mediator in schistosomiasis (90). Infected IL-13–deficient mice also survive longer than wild-type animals, further highlighting the pathogenic role of IL-13 in chronic infections *(267)*. Thus, IL-4 appears to play a host-protective role, whereas IL-13 is pathogenic during chronic schistosome infections. A valid approach toward immunoprophylaxis of schistosomiasis may be to design a vaccine that minimizes IL-13 activity and egg-induced pathology. In mice, the progression of hepatic fibrosis correlates with the intensity of the type 2 cytokine response, and immunologic interventions that block IL-4 and IL-13 were found to reduce collagen deposition significantly (*268,*269) (Figure 35.4). Fibrosis can also be slowed or prevented in mice that are sensitized with egg antigens and IL-12 or CpG oligonucleotides before infection (255,*270*). Thus, an antipathology vaccine that is based on "immune deviation" could be envisioned for schistosomiasis, and novel immunodominant eggs antigens are being identified with this goal in mind.

Over the last several years, immune deviation has been used extensively as a research tool to study the mechanisms of granuloma formation and fibrosis in detail. Several mediators and cell types that characterize type 1 cytokine responses were shown to inhibit fibrosis, including TNFα, IL-12, and NO *(271,272)*. Because macrophages and dendritic cells are important sources of these mediators, a significant effort has been made to elucidate their roles in the pathogenesis of schistosomiasis. In the case of NO, the protective antifibrotic effects of type 2–to–type 1 immune deviation are completely inhibited in the absence of nitric oxide synthase-2 (NOS-2). Activated macrophages are capable of expressing two cytokine inducible enzymes, NOS-2 and arginase, which share L-arginine as a substrate, and type 1 and type 2 cytokines were shown to induce NOS-2 and arginase-1 (Arg-1) expression, respectively *(273)*. The Th1-associated cytokines IFNγ and TNFα induced NOS-2 in macrophages designated "classically activated," whereas the type 2 cytokines induced Arg-1 activity in cells termed "alternatively activated" (274). Studies conducted in the schistosomiasis model identified IL-13 as the major arginase inducer *(275)*, and arginase activity correlated consistently with the size of granulomas and the severity of fibrosis. In contrast, NOS-2 dominated in Th1-polarized mice, and these animals developed small granulomas with little fibrosis. These data served as a first
FIGURE 35.4 Pivotal role of interleukin-13 (IL-13) in schistosome egg–induced hepatic fibrosis. C57BL/6 mice were infected with *Schistosoma mansoni* cercariae and treated with sIL-13Rα2-Fc or control immunoglobulin (Ig) on weeks 6 through 12 postinfection. Mice were sacrificed, and liver sections were stained with picrosirius red (dark-staining areas around granulomas) to identify collagen and examined at 25× magnification. Note the presence of granulomas in the liver of sIL-13Rα2–treated mice, yet the absence of significant collagen staining. The inset in the second panel shows the relative change in granuloma size in animals deficient in IL-4 or IL-13 or simultaneously deficient in IL-4 and IL-13, relative to wild-type (WT) mice. Note that granuloma size decreases only in mice deficient in both cytokines.

example of the differential regulation of NOS-2/Arg-1 by type 1/type 2 cytokines *in vivo*. More importantly, they clarified how CD4$^+$ Th2 cells and "alternatively activated" cells (macrophages/DCs/fibroblasts) might cooperate to control disease progression in schistosomiasis.

PARASITE VACCINE STRATEGIES

There is no safe, uniformly effective vaccine against any human parasitic infection. The lack of progress in this field is due to many factors, including the low priority that has historically been given to development of vaccines against diseases confined mainly to the developing world. By contrast, the perceived economic benefit to the agricultural industry of vaccines against livestock parasites has led to the licensing of several anthelminthic vaccines for veterinary use (276). The greater impediments, however, may be related to the nature of parasitic infections themselves. In contrast to those bacterial and viral infections for which highly effective vaccines exist and for which there is complete immunity induced by primary infection, most antiparasite vaccines will need to outperform the immune response to natural infection. Furthermore, virtually all bacterial or viral vaccines that are in use mediate their protection by inducing a strong, long-lived humoral response that inhibits attachment or invasion, promotes clearance, or neutralizes released toxins. By contrast, there are no vaccines that are uniformly effective against diseases caused by intracellular pathogens that require cellu-

lar immunity to mediate protection. Thus, the manner in which potentially protective antigens can be administered to generate and maintain appropriate T cell responses has yet to be proven in a clinical setting. Consequently, for the development of vaccines against intracellular protozoa, for example, malaria, *Leishmania*, *T. cruzi*, and *Toxoplasma*, it will not be sufficient simply to identify target antigens; novel and rational approaches to vaccine design and delivery will need to be explored. In fact, from the examples discussed later, it is clear that ample numbers of potentially protective antigens have been identified and cloned from most of the major human parasitic disease agents, and the completion of their genomic sequences has already led to the identification of additional vaccine candidates based on their predicted developmental stage specificity, surface expression, secretion, or virulence associations (277–279). The vaccination strategies that are being explored to meet the challenge of both antigen selection and delivery will be considered in the general context of B and T cell antiparasite vaccines. Note that the examples provided are by no means exhaustive but reflect general principles of vaccination against extracellular and intracellular targets.

B Cell Vaccines

Vaccination Against Intestinal Protozoa

Parasitic protozoa that have an exclusive extracellular lifestyle in their mammalian hosts and are sensitive to antibody-mediated control include the intestinal pathogens

Entamoeba histolytica and *Giardia lamblia*. Most deaths from *E. histolytica* arise from amebic liver abscess, the major extraintestinal manifestation of disease. Clinical studies suggest that the presence of mucosal antibodies to the surface Gal/GalNAc lectin of *E. histolytica* capable of blocking amebic adherence to intestinal epithelial cells correlates with reduced risk of recolonization *(280)*. A recent vaccine study provides direct evidence that vaccination with the Gal/GalNAc lectin can produce IgA antilectin antibodies and provide protection against intestinal amebiasis in a mouse model of disease *(281)*. An amebic serine-rich protein (SREHP) is a highly immunogenic surface antigen of *E. histolytica* containing multiple tandem octapeptide and dodecapeptide repeats. Passive immunization with antibodies to SREHP protects SCID mice from amebic liver abscess. Parenteral immunization with recombinant SREHP or with a SREHP-based DNA vaccine was highly effective in protecting gerbils against amebic liver abscess (282). Specific serum and mucosal antibodies targeting surface antigens are also known to be important in elimination of *Giardia* from the host intestine. *Giardia* vaccines containing whole-trophozoite preparations protected animals even when challenged with heterologous strains (283). Thus an immune response to variant surface antigens that are known to be targets of cytotoxic antibodies appears not to be essential for control of acute infection, and this supports an alternative role for antigenic variation in, for example, diversifying the host range of the parasite *(201)*. The cloning and expression of *Giardia* antigen genes for vaccine testing is in its infancy. Genes coding for cyst wall proteins (CWPs), which could be used for developing a transmission-blocking vaccine, have been cloned, and a recombinant protein induced IgA antibodies such that immunized mice shed fewer cysts after challenge with live cysts *(284)*.

Vaccines Targeting Extracellular Stages of Malaria

Because both preerythrocytic- and erythrocytic-stage malaria parasites are at least transiently exposed to humoral antibody, vaccine strategies based on eliciting high-titered antibodies that can inhibit their invasion of red blood cells or hepatocytes have long been favored (Figure 35.5). As discussed, antibodies to sporozoite surface proteins can immobilize invading parasites, preventing them from reaching or invading hepatocytes; such antibodies can be protective, and the dominant antibody epitope is represented by the CS central repeat sequences (NANPn in *P. falciparum*). These observations have made the CS protein the most extensively studied of all the malaria vaccine candidates (reviewed in ref. *285*). The latest version of the vaccine—RTS,S—comprises a recombinant CS polypeptide fused to the surface protein of hepatitis B virus and administered together with an adjuvant

containing lipopolysaccharide (monophosphoryl lipid A) and a water-soluble glycoside obtained from tree bark (*Quillaja saponaria*) *(286)*. The vaccine has been designed to induce both antibodies and T cell–mediated effector mechanisms, and it is not clear which of these mechanisms is most important in conferring immunity. This vaccine is discussed in more detail later.

Antibodies that inhibit the invasion of erythrocytes by the extracellular merozoite stage of malaria *in vitro* are found in many but not all individuals living in malaria-endemic regions. Although the significance of these inhibitory antibodies to naturally acquired resistance is unclear, their target antigens nonetheless remain prime candidates for asexual malaria vaccines (reviewed in ref. *287*) (Figure 35.5). One of the targets of invasion-inhibitory antibodies is merozoite surface protein (MSP-1), which was the first purified malaria protein to be used as a vaccine *(288)*. The 19-kDa C-terminal fragment of MSP-1 is the only part of the larger molecule to be taken into the red cell during invasion. Although MSP-1 proteins from different isolates of *P. falciparum* show considerable allelic polymorphism, the regions corresponding to the 19-kDa fragment are relatively conserved, and antibodies raised to one version of the protein cross-react with antibodies raised to other variants *(289)*. Native and recombinant forms of *P. falciparum* MSP-1$_{19}$ and a longer fragment, MSP-1$_{42}$, can protect *Aotus* monkeys *(290)*. MSP-1$_{42}$ is in clinical trials *(291)*. Apical membrane antigen-1 (AMA-1) is also the target of efficient invasion inhibitory antibodies and is being developed as a potential vaccine *(292)*, but problems may lie ahead because the target epitopes of invasion inhibitory antibodies appear to be highly polymorphic.

Despite their extreme polymorphism, the variant surface antigens present on infected erythrocytes that mediate adhesion to endothelial cells are potential vaccine candidates. Epidemiologic data suggest that the risk of severe manifestations of the disease is reduced after only a very few clinical episodes *(293)* and that parasites causing severe disease tend to express a subset of variant surface antigens *(294)*. Thus, a finite number of variant antigens might be sufficient to elicit broad immunity against severe disease. Two structural domains, termed DBLα and CIDR1α, which are present in the semiconserved head structure of all PfEMP-1 molecules sequenced to date (295), are attractive candidates for inclusion in such a vaccine. Similarly, relatively few PfEMP-1 variants appear to mediate parasite sequestration in placenta, and a pregnancy malaria vaccine might work by targeting the DBLγ domain that binds to chondroitin sulfate, the major placental ligand for parasitized RBC sequestration (296).

Antimalarial transmission-blocking immunity works primarily by antibody-mediated, complement-dependent lysis of extracellular sexual stages of the parasite within the midgut of a blood-feeding mosquito (reviewed in ref. 297). Transmission-blocking immunity has been induced *in vivo*
STAGES	ANTIGENS [a]	MECHANISM
Sporozoite	**CSP, TRAP/SSP2**, STARP, SALSA	**Anti-infection vaccine.** Antibody binds surface antigens to inhibit hepatocyte invasion
Hepatocyte	**CSP, TRAP/SSP2,** LSA1, EXP1, LSA3, STARP, SALSA	**Anti-infection vaccine.** T-cell recognition of infected hepatocytes; cytokine-mediated inhibition of growth, schizogony
Merozoite	**MSP1**, MSP2, MSP3, MSP4, PfEBA175, PvDABP, **AMA1,** SERA, GLURP, Pf155/RESA, RAP1, RAP2	**Anti-morbidity/mortality vaccine.** Antibody binds to parasite antigens to block erythrocyte invasion
Erythrocyte (asexual)	PfEMP1, rifins, Pf332	**Anti-morbidity/mortality vaccine.** Antibody binds to antigens on infected erythrocyte to inhibit sequestration
	Glycosylphosphatidyl-inositol (GPI) anchors	Antibody binds to GPI to inhibit inflammation and pathology
Mosquito	**Pfs25**, Pfs28, Pfs48/45, Pfs230	**Transmission-blocking vaccine** Antibody binds to parasite antigens to inhibit fertilization, oogenesis

[a] Antigens in **bold type** represent those currently in major clinical trials

FIGURE 35.5 Stage-specific vaccine targets in malaria parasites. **Left:** The life cycle of malaria and the immune effector mechanisms that target the different developmental forms of the parasite. (From Malaria Vaccine Initiative, *What is malaria?*, available at http://www.malariavaccine.org/mal-what_is_malaria.htm, with permission). **Right:** The major candidate vaccine antigens identified on these stages and the proposed mechanism by which immunization would act against each target. (Adapted from Richie TL, Saul A. Progress and challenges for malaria vaccines. *Nature.* 2002;415[6872]:694, with permission.)

by immunization with gametes of avian, rodent, and monkey malarias. Several potential transmission-blocking vaccine candidates have been identified, and the genes encoding these surface proteins have been isolated and sequenced, but their production as recombinant proteins is hampered by failure to recreate the highly complex tertiary structures that are the targets of inhibitory antibodies. Furthermore, for those antigens expressed only by invertebrate stages of the parasite, lack of natural boosting may prevent maintenance of sufficiently high antibody titers.

Clearly, an optimal vaccine against malaria would need to target multiple antigens and induce immunity against all stages. However, by targeting certain antigens confined to asexual blood stages, the induction of an adult-like immune status among high-risk infants in sub-Saharan Africa could greatly diminish severe disease and death caused by *P. falciparum*.

T Cell Vaccines

Vaccination Against Leishmaniasis

Vaccines against intracellular parasites will need to induce long-lived cellular immune responses. As already discussed, for diseases such as malaria, leishmaniasis, Chagas' disease, and toxoplasmosis, Th1 and/or CD8[+] T cell responses are the effector mechanisms required for protective immunity. An inherent problem with most nonliving vaccines is their relative inefficiency in generating these sorts of cellular responses. A major advance in T cell vaccine development was the demonstration that proteins derived from *L. major* could elicit a powerful Th1 response and protective immunity if given with recombinant IL-12 as adjuvant (298). IL-12, or IL-12–inducing adjuvants such as bacillus Calmette-Guérin (BCG), CpG-oligodinucleotides (CpG-ODN), or CD40L have since been

used extensively in animal models to potentiate the efficacy of whole-cell killed vaccines or a diversity of recombinant protein *Leishmania* vaccines (reviewed in ref. 299). A polyprotein containing several *Leishmania* antigens (TSA, LmSTI1, and LeIF), formulated with the TLR4 agonist MPL, a detoxified derivative of 4′-monophosphoryl lipid A of LPS *(300)*, is the only defined, subunit vaccine against leishmaniasis in human trials.

The shortcomings of nonliving vaccines with respect to their potency and durability have been revealed in experimental studies. When mice were challenged with *L. major* 3 months as opposed to 2 weeks after immunization, a protein plus rIL-12 vaccine was no longer effective *(301)*. In contrast, a DNA vaccine encoding the same antigen remained effective, presumably due to more sustained expression of the antigen. Immunization with plasmid DNA is thus an attractive approach because it mimics the persistent antigenic stimulation of subclinical infection, and a large number of DNA vaccines encoding a diversity of *Leishmania* antigens have demonstrated some efficacy in mouse models of cutaneous and visceral leishmaniasis (302). The gold standard of the protection that can be achieved by vaccination protocols, and the only vaccination strategy against leishmaniasis that has worked in humans, is "leishmanization," which is based on the lifelong convalescent immunity that is acquired after induction of a lesion at a selected site with small doses of a cutaneous strain. The requirement for antigen persistence in this live "vaccine" is indicated by the mouse studies in which immunity to rechallenge infection was lost following manipulations that completely cleared the persisting parasites (213,*303*). Thus, whereas nonpersisting antigens delivered with appropriate adjuvants may contribute to vaccine efficacy by generating Th1 central memory cells, the presence at the time of challenge exposure of a population of antigen-dependent, effector memory cells that are tissue seeking and readily secrete cytokine on encounter with antigen in the periphery appears to be critical for the full expression of acquired immunity in the challenge site (304). Such loss of effector memory T cells after antigen clearance might well explain the failures of a whole-cell killed *L. major* vaccine plus BCG significantly to reduce the incidence of cutaneous leishmaniasis in individuals living in areas of relatively low transmission, where natural boosting is unlikely to have occurred *(305)*. The requirement for persistent antigens reinforces the rationale for live, attenuated vaccines. The generation of safe, live attenuated vaccines demonstrating some efficacy in mice has been accomplished by targeted deletion of genes involved in parasite survival or virulence, including mutants lacking dihydrofolate reductase *(306)*, cysteine proteinases *(307)*, or LPG-related molecules *(308)*. However, because live parasite vaccines will be extremely difficult to standardize and to deliver in field settings, there has been considerable interest in developing DNA

vaccination, particularly as a component of herterologous prime/boost strategies involving viral vectors, capable of eliciting longer-lived cellular immune responses *in vivo*.

Another advantage of DNA vaccines is their ability to elicit specific CD8$^+$ T cells. Although CD8$^+$ T cells contribute to *Leishmania* resistance, they are especially important to the control of infections involving *T. cruzi* and *T. gondii*, which require effector CD8$^+$ T cells to kill parasites within cells lacking MHC class II molecules. Furthermore, because *T. cruzi* escapes from the parasitophorous vacuole and becomes cytoplasmic, many of its released antigens have access to the class I processing pathway. Immunization using plasmid DNA or viral vectors expressing the trans-sialidase surface antigen (TSSA) can induce CD8$^+$ T cell–mediated protective immunity against lethal *T. cruzi* infection in mice (309,*310*). Protection was also achieved using DNA encoding the KMP11-HSP70 fusion protein *(311)* and the *T. cruzi* complement regulatory protein *(312)*. Recombinant proteins, including cruzipain, the cysteinyl proteinase of *T. cruzi*, and purified paraflagellar rod proteins derived from the flagellum of *T. cruzi* trypomastigotes and mixed with either CpG-ODN or IL-12 have been used to elicit cellular immune responses in mice and enhanced survival against *T. cruzi* challenge infection *(313,314)*. It is important to note that in no case have these experimental vaccines been capable of achieving sterile immunity, and protection against the chronic phase of Chagas' disease involving myocardial dysfunctions was not evaluated in these models.

Vaccination Against Malaria Liver Stages

Because malaria parasites infect and replicate in hepatocytes, which express MHC class I, infected hepatocytes are potential targets of CD8$^+$ T cell responses. Irradiated *Plasmodium* sporozoites, which can infect hepatocytes but do not progress to a blood-stage infection, have been shown to protect rodents, monkeys, and humans against malaria by inducing IFNγ-producing CD8$^+$ T cells specific for preerythrocytic antigen (reviewed in ref. 315). Overirradiation of sporozoites negates their ability to immunize, suggesting that the targets of protective mechanisms are novel antigens expressed only if sporozoites undergo partial differentiation within hepatocytes. On the other hand, killed sporozoites can efficiently prime long-lived memory T cells, which, although they do not protect against immediate challenge with viable parasites, can protect against secondary infection (316). These observations suggest that live and dead parasites differentially prime T cell responses, although the molecular basis of this has not yet been elucidated. Similar to that described following sterile cure in leishmaniasis, immunity using irradiated sporozoites was lost in rats that were treated with a drug that eliminated parasites in the liver before rechallenge (317).

Efforts to mimic the protection generated by irradiated sporozoites using nonliving protein- and DNA-based vaccines have yielded encouraging results. A synthetic peptide representing the 102–amino acid–long C-terminal region of the *P. falciparum* CS protein and fused to hepatitis B surface antigen elicited strong CD8$^+$ and CD4$^+$ T cells responses, as well as antisporozoite antibodies, in human volunteers, particularly when given with the water-in-oil adjuvant Montanide ISA-720. The vaccine 'RTS,S' induced strong antibody and T cell responses in adults already primed to CS by preexposure to malaria. Most significantly, in this trial, vaccine efficacy during the first 9 weeks of follow-up was 71%, but it decreased to 0% over the next 6 weeks (318). In another trial, despite the apparently short-lived nature of protection, vaccinated children were less likely than those receiving the placebo to develop clinical malaria in a second year of follow-up (319), raising hopes that 'RTS,S' may be the first malaria vaccine to be licensed for use in humans. Nevertheless, the vaccine does not confer sterilizing immunity, and the level of protection is much lower than has been obtained with irradiated sporozoites *(320)*.

Despite initial enthusiasm that DNA vaccination strategies might improve the durability and potency of the cellular response, clinical trials have been disappointing, and the use of sequential immunizations using various heterologous prime/boost protocols is being tested to enhance the effectiveness of preerythrocytic vaccines (reviewed in ref. 123). Priming with plasmid DNA encoding CS and various liver stage–specific proteins and boosting with recombinant adenovirus or pox virus, such as modified vaccinia virus Ankara (MVA) or fowlpox, has induced complete protection and very high levels of IFNγ-secreting CD8$^+$ T cells in mice. Although protection in human trials has been less convincing, delays in time to emergence of blood-stage parasites have been consistently obtained, suggesting that the vaccination substantially reduces, but does not eliminate, liver-stage parasites.

Vaccination to Prevent Pathology

In many parasitic infections, disease is a consequence of the host immune response. Because these pathogens are so well adapted to their hosts, it may therefore be easier and more efficient to design immune interventions that prevent parasite-induced immunopathology rather than eliminate the infection itself. Although this approach will not lead to eradication of the parasite, it would likely reduce or alleviate the health consequences of infection. The feasibility of antipathology vaccines was demonstrated in a murine model of schistosomiasis (255). Because disease in schistosomiasis is largely due to the granulomatous pathology that develops around parasite eggs trapped in target host tissues, a valid approach toward immunoprophylaxis for schistosomiasis is to vaccinate to minimize

granulomatous pathology. In wild-type mice, granuloma size and collagen deposition are correlated with the intensity of the type 2 response, and immunologic interventions, such as the administration of IL-4 and IL-13 antagonists, reduces both the size of granulomas and magnitude of fibrosis (discussed earlier) (269,*321*). In extensions of these studies, mice immunized with parasite egg antigens plus IL-12 *(322)* or CpG oligonucleotides *(270)* to induce an egg-antigen–specific type 1 response, on subsequent infection exhibited far less severe egg-associated liver disease than did infected, nonimmunized controls. Of importance, several immunodominant egg antigens have been described in recent studies *(323,324)*, and thus it may be possible to design recombinant antipathology vaccines that duplicate the promising results produced with these crude parasite extracts.

Parasite-derived GPI has been implicated in much of the pathology of malaria (325), binding to TLRs on dendritic cells and macrophages and inducing release of TNFα and other proinflammatory cytokines. As a proof of principle that GPI might serve as a target of an antidisease vaccine, mice immunized with synthetic GPI were protected against the acute immune pathology associated with *P. berghei* infection; however, because the mice were not immune to the parasite itself, they were unable to control parasite replication and eventually died of overwhelming parasitemia *(326)*. These observations suggest that whereas vaccines that prevent immune pathology might reduce some aspects of morbidity, they are unlikely to be deployed in the absence of vaccine components that also limit parasite burden.

Vaccines Against Helminths

Infection with helminthic parasites remains a significant health problem in many tropical countries. Although control measures are available in some areas, in most cases, patients living in endemic regions are quickly reinfected. Therefore, vaccines that reduce parasite and/or egg burdens would be a valuable tool to complement existing disease-prevention programs and could represent a less costly and more practical approach than repeated chemotherapy. Nevertheless, although many subunit vaccines have been described and tested in various animal models, suboptimal levels of protection have hindered the development of all but a few of these candidate vaccines *(327)*. Significant advances in vaccination technology over the last decade have made it possible to engineer vaccines that elicit strong cellular and humoral immunity. Novel DNA vectors, improved delivery systems, new adjuvants, and immunomodulatory cytokines allow significant augmentation of the immune response to vaccines and preferential induction of specific effector mechanisms, including antibody isotypes, T helper cell subsets, and cytotoxic T cells. However, to effectively harness and implement these

advances, it will be necessary first to better elucidate the immune mechanisms responsible for killing helminth parasites.

The best examples of successful immunization against helminths are provided by vaccine models using radiation-attenuated larval parasites. With the irradiated schistosome vaccine, although complete sterilizing immunity appears to be an unachievable goal, immunity approaching 60% to 80% is clearly possible and has served as the gold standard for schistosome vaccine development *(328)*. The cumulative evidence from vaccine studies conducted in numerous gene knockout mice suggests that irradiated parasites can induce protection via both Th1- and Th2-dependent pathways *(129)* and that humoral and cellular mechanisms are both required for the generation of optimal immunity *(329,330)*.

Although there has been extensive research on defined vaccines against helminth infection [reviewed recently by Maizels et al. (331)], none of the candidate antigens has been shown to be protective in humans. Based on antibody responses in schistosome-vaccinated mice, several vaccine candidate antigens have been put forward for phase I trials, and at least one of the antigens (GST) has completed phase I and is entering phase II trial. These antigens include glutathione-*S*-transferase (P28/GST); paramyosin (Sm97); IrV5 (myosin-like 62-kDa protein); triose phosphate isomerase (TPI); Sm23 and tetraspanin-2, both integral membrane proteins; and Sm14, a fatty acid–binding protein *(332,333)*. With the recent advances in schistosome genomics and proteomics, a new panel of potential vaccine antigens is being identified, and these warrant further investigation (334). A number of filarial vaccine candidates have also been described and are being tested, including chitinase, tropomyosin, paramyosin, and several larval antigens called the "abundant larval transcript family" (ALT) (331). Finally, a novel recombinant larval protein antihookworm vaccine is in clinical trial (335). Although these accomplishments represent a significant advance for the field of helminthology, it is important to note that all of the candidate antischistosome vaccine antigens have, at best, provided only partial immunity, with few consistently reaching a required threshold of 40% protection. It is hoped, however, that ongoing improvements in vaccination technology, combined with greater knowledge of the mechanisms controlling resistance, will allow development of more-efficacious and better-defined vaccines for these complex organisms.

CONCLUSION

The last 4 to 5 years have seen a rapid expansion in research dealing with innate determinants of the immune response to parasites and in innate effector functions. This work has important implications not only for understanding the basis of Th-subset selection by parasites, but also for providing insights useful in the design of new adjuvants and immunomodulators. The studies on helminth infections will in addition provide a unique opportunity to decipher the innate determinants of the Th2 response and should represent an exciting research area in the coming years. The study of immunoregulatory mechanisms in parasitic infection has also seen important progress in recent years, with much of this work testifying to the multilayered complexity and tightly balanced interaction of antiparasitic immune responses. This work has forced us to rethink many of the paradigms concerning polarized effector functions and their regulation in parasitic infection. Thus, it is becoming increasingly evident that rather than being the product of a single arm of the immune response, effective control of parasites involves the coordination of both humoral and cellular elements dependent on both Th1 and Th2 cytokines. Moreover, the simplified notion that Th2 immune polarization underlies susceptibility to intracellular pathogens such as *Leishmania* has had to contend with accumulating evidence in mice and humans that regulatory cells and cytokines (e.g., IL-10 and TGFβ) modulating concurrent Th1 immunity better explain nonhealing and persistent infections. Targeting regulatory T cells or their cytokines, especially in conjunction with antiparasitic drugs, offers the potential for more efficient or even sterile cures.

The last 4 or 5 years has also seen remarkable progress in molecular parasitology that should affect immunologic approaches to disease control. For instance, the ability to target virulence genes for deletion in *Leishmania* and *Toxoplasma* has led to the generation of safe, live attenuated vaccines that promote more durable immunity than nonliving vaccines. The completion of the *L. major*, *T. cruzi*, *T. brucei*, and *P. falciparum* genomes should foster further discoveries of virulence molecules for deletion or drug targeting and identify additional protective antigens for vaccine development. The genomic sequence of an important helminth parasite, *B. malayi*, was recently completed *(343)* although transgenesis for helminths is still in its infancy. Given the overlapping pathways of immune regulatory and effector mechanisms in chronic parasitic infections and the dynamic nature of host responses during different phases of infection and in different tissues, there is clearly a danger in confining immune analyses to selected cells obtained from a fixed place and time. A systems biology approach that employs host–parasite genomic databases along with computer algorithms may be needed to reveal control points in immune networks that are associated with parasite killing, persistence, or pathology. Perhaps the most compelling need is for more human immunology to determine the clinical relevance of the mouse models and as an adjunct to clinical development of particular vaccines or immune-based therapies.

During the period since the publication of the last version of this chapter in the previous edition of this book, public recognition of the importance of malaria as one of three major global infectious diseases (along with AIDS and tuberculosis) has resulted in the expansion of government- and private foundation–supported vaccine programs, in some instances with industrial partners, aimed primarily at moving candidate immunogens into clinical trials. It is to be hoped that the initial encouraging results of the phase II 'RTS,S' vaccine trial in reducing the incidence of clinical malaria and severe disease in Mozambican children will be sustained and will provide a road map as to how public/private partnerships supporting translational research can achieve genuine progress in the control of these significant neglected diseases.

Immunity to Viruses

Hildegund Ertl

INTRODUCTION

Viruses are the simplest of all life forms. They can be viewed as selfish genes with the single-minded purpose to replicate. Viruses are parasites, and their replication depends strictly on the machinery of cellular organisms. They have developed vehicles that allow for efficient transfer of their genes into host cells, supporting their replication. Replication of viruses is rarely subtle; instead it commonly results in damage or even death of the invaded cells. Hosts have in turn developed defense mechanisms against this invasion. Mechanisms used directly by the attacked cells to block virus entry or virus replication have evolved to protect individual cells and are employed by both primitive monocellular organisms such as bacteria and sophisticated mammalian hosts alike. More complex organisms have also developed specific organs and cells to form an immune system to ward off invading pathogens. In turn, viruses, which are much more flexible than their hosts because of their rapid replication allowing for genetic modifications, are constantly mutating to dodge the defense mechanisms of their unwilling production facilities.

Altogether, >400 viruses cause disease in their human hosts. More than 100 of those belong to the *Rhinovirus* genus. Considering the multitude of viruses that are pathogenic in humans, it is not surprising that in spite of advances in modern medicine, viral infections remain one of the leading causes of human morbidity and mortality worldwide. Constant evolution allows more efficient replication of viruses, in part through an increase in host range from animals to humans. Therefore, although not long ago governments of some developed countries declared infectious diseases a problem of the past, the fight against infectious diseases became one of the main topics of the last G-8 summit, the meeting of eight of the world's leading industrialized nations.

One major current threat is a new influenza A virus pandemic of potentially catastrophic outcome. Three influenza A virus pandemics struck in the last century. The influenza pandemic of 1918 killed more young Americans than all of the wars of the twentieth century combined and

claimed an estimated 20 to 50 million human lives globally. Additional pandemics occurred in 1957, which caused approximately 2 million human deaths, and in 1968, which resulted in approximately 1 million human deaths. The currently evolving H5N1 virus, which could be the precursor for the next pandemic, has disturbing similarities to the highly virulent virus of 1918, which was reconstructed through reverse genetics with the help of bits and pieces of viral genome isolated from a human cadaver that had been preserved in the arctic permafrost. H5N1 virus was first detected in Asian poultry in 1997. By July 2006, 229 human cases of H5N1 virus infection had been reported, mainly from Asia, but also from Africa and Europe. These cases resulted in 131 fatalities, which is far in excess of previously observed mortality rates of influenza A virus infections. So far the virus has been transmitted by human contact with infected birds, and only a few isolated cases suggest direct human-to-human transmission. Further mutations of H5N1 virus, either in the form of adaptive point mutations, that is, antigenic drift, or through reassortment in humans concomitantly infected with a different influenza A virus, called antigenic shift, could eventually allow for sustained and efficient human-to-human transmission.

The human immunodeficiency virus (HIV)-1 was first identified in 1981. It evolved from a simian immunodeficiency virus that infects chimpanzees and crossed the species barrier less than 100 years ago. Since then it has gained an irreversible foothold in the human population.

A corona virus that had spilled over for years into humans from a yet-to-be-identified animal reservoir failed to cause serious symptoms, but then suddenly began to result in life-threatening acute respiratory infections in 2003. This change in virulence was the result of a deletion mutation within the viral genome.

Vaccines are currently available for only a fraction of the identified human viral pathogens. Vaccines to viruses that only infect humans, that is, without an animal reservoir, can eradicate a virus, as was shown for smallpoxvirus, which was eliminated through global vaccination campaigns by 1977. Other human viruses for which vaccines are available, such as poliovirus, measles virus, or hepatitis B virus, could potentially be eliminated by global mass vaccination as well.

SOME BASICS IN VIROLOGY

Virus Classification

The International Committee on Taxonomy of Viruses has approved 3 orders, 56 families, 9 subfamilies, 233 genera, and 1,550 virus species. The three orders include DNA viruses, DNA and RNA reverse transcribing viruses, and RNA viruses. DNA viruses are divided into double-stranded (ds) DNA viruses (e.g., poxviruses, herpes viruses, adenoviruses, and papilloma viruses) and single-stranded (ss)

DNA viruses (e.g., parvoviruses). RNA viruses are divided into dsRNA viruses (e.g., reoviruses), negative-sense ssRNA viruses (e.g., influenza virus and rabies virus), and positive-sense ssRNA viruses (e.g., poliovirus and yellow fever virus). The genome can be linear (e.g., poxvirus), circular (e.g., papillomaviruses), or segmented (e.g., influenza virus) and can range in size from 375 kp (poxvirus) to 4 to 6 kb (adeno-associated viruses). Viruses are further classified into enveloped or naked, that is, nonenveloped viruses. Viruses can also be divided according to their morphology, which can be polymorphic or structured. To given an example of the taxonomic division of viruses, measles virus belongs to the genus *Morbillivirus*, the subfamily Paramyxovirinea, and the family Paramyxoviridae. In this chapter, examples of viruses are used to clarify antiviral immunity. A list of these viruses, their classifications, abbreviations, and antigens that are mentioned throughout the text is given in Table 36.1.

Virus Transmission

Viruses are transmitted either through the mucosal surfaces of the airways, the intestinal or genital tract, or the eye, abrasions of the skin, or by directly gaining access to the bloodstream. Mucosal entry is most common. Viruses, such as influenza viruses, parainfluenza viruses, certain types of adenoviruses, or rhinoviruses spread through the airways and are transmitted by droplets that are formed during coughing or sneezing of an infected individual. Such viruses can be extraordinarily contagious, as attested by influenza viruses, which cause periodic pandemics that spread around the globe within less than half a year. Aquatic birds serve as influenza A virus reservoirs. The virus mutates rapidly, and antigenic variations of the two surface proteins, the hemaglutinin (HA) and the neuraminidase (NA), allow for the development of antigenic drift strains that can evade protective humoral immune responses induced by previous infections. Most annual epidemics are caused by antigenic drift variants. Rearrangements of the HA or NA encoding gene segments between viral strains circulating in humans with those endemic in animals result in more dramatic changes, also called antigenic shifts, and the pandemics of 1957 with H2N2 and 1968 with H3N2 were caused by such new strains of influenza virus. Influenza A virus can also gain human-to-human transmissibility through adaptive mutations. This was the case with the H1N1 virus that caused the pandemic of 1918. During this and subsequent pandemics, some countries prohibited public coughing or sneezing, a control measure that was shown to be ineffective. Control measures such as quarantine of infected individuals to stop transmission can be effective, as was shown during the severe acute respiratory symptom (SARS) outbreak caused by a corona virus in 2003–2004, but they will not stop an influenza virus pandemic.

▶ **TABLE 36.1**

Family	Genus	Virus	Abbreviation	Proteins
Poxviridae	Orthopoxvirus	Vaccinia virus	—	B18R, B13R, GIF, C10L, NIL, A46R, A52R, B8R, M104L, E3L, K3L, MT1, T2, crmA-D, VCP
		Ectromelia virus	—	p28
	Leporipoxvirus	Shope fibroma virus	—	N1R
		Myxoma virus		M57, M135R, F2, SEPP-2, M-T2, M-T4, M-T5
	Mulluscipox	Molluscum contagiosum virus	MCV	MC159, MC160, MC066. M11L, MC148
Herpesviridae	Herpesvirus	Human cytomegalovirus	HCMV	US11, US2, UL33, UL78, US27, US28, UL146, UL145, UL147, UL111A, UL144, UL16, US10, US3, US6, US11, UL40, UL35, UL36, UL18
		Mouse cytomegalovirus	MCMV	m157, m144, m152, m6/gp48, m144
		Karposi sarcoma–associated herpesviruses (human herpesvirus-8)	KSHV (HHV-8)	K3, K4, K5, N5, mκ3
		Herpesvirus samiri	—	CCPH
		Epstein–Barr virus	EBV	BHRF1
		Herpes simplex virus	HSV	ICP47, gc
Adenoviridae	Adenovirus	Human serotype adenoviruses	—-	E1B/19K, E1B/55K, E3/10.4K, E3/14.5K, E3/19K
Polyomaviridae	Papillomavirus	Human papillomavirus	HPV	E6, E7
Flaviviridae	Hepacivirus	Hepatitis C virus	HCV	NS3/4, NS5A, E2
Filoviridae	Ebolavirus	—	—	Vp35
Orthomyxoviridae	Influenza virus A	—	—	NS1

Intestinal transmission is caused by virus shedding in feces, from where viruses gain access to oral ingestion. Orally transmitted pathogens are in general remarkable stable. They can pass through the acidic environment of the stomach or survive in water for prolonged times. Infection of aquatic birds with influenza viruses, which are transmitted orally in birds, is linked to contamination of lake water. Outbreaks of rotaviruses have been caused by contaminated water. Poliovirus, which prior to worldwide immunization programs caused devastating infection of children worldwide, was commonly transmitted in public swimming pools. Hepatitis A virus can be transmitted by ingestion of raw oysters that have become infected by viruses in water.

Genital transmission by sexual contact maintains the pandemic of acquired immunodeficiency (AIDS), which is caused by human immunodeficiency virus (HIV). AIDS is by now the leading cause of death in humans aged 18 to 59 worldwide. Between 1981 and 2003, an estimated 20 million humans died of AIDS. By 2005, 40.3 million people were infected with HIV-1. In 2005, it was estimated that an additional 3.1 million humans had died of AIDS, while 4.9 million people became newly infected with HIV-1. Sub-Saharan Africa has by far the highest incidence rates of HIV-1 infections, and in some sub-Saharan nations, such as in Botswana, a staggering 37.3% of the adult population is infected. HIV-1 is starting to spread in other regions, in-cluding highly populated countries of Asia such as India and China. India has a population of 1 billion with an estimated infection rate of 0.9%, China has a population of 1.2 billion with an estimated infection rate of 0.1%, and both countries are at risk for an explosive increase in HIV-1 infection rates. Women are at a higher risk than men to become infected by heterosexual contact, and currently 60% of all HIV-1 infected individuals are women. Infected women in turn can transmit virus to their offspring during pregnancy, birth, or breastfeeding, and it is estimated that more than 2.2 million infants have become infected from their mothers.

Certain types of human papillomaviruses (HPV), such as types 16 and 18, are sexually transmitted. Although these viruses cause benign infections in most men and in the majority of women, who can clear virus-infected cells through adaptive immune responses, oncogenic types of papillomaviruses can persist and cause cervical cancer. Cervical cancer is currently the second most common cause of cancer death in women worldwide, claiming approximately 300,000 to 400,000 lives each year. In the United States, approximately 4,800 women die each year from cervical cancer. Worldwide, cervical cancer affects about 1% of all women and is the most common cause of cancer death in women under the age of 50. A vaccine to HPV-16 and HPV-18 was licensed recently, and it is expected that this vaccine will reduce the incidence of

cervical cancer induced by these two types of HPV. Notwithstanding, over 50 types of HPV are known, and some others besides types 16 and 18 are oncogenic.

A number of viruses can only infect humans if they gain direct access to the bloodstream. These viruses rely on intermediate hosts, which commonly include blood-feeding insects such as mosquitoes, ticks, or flies. Rabies virus can only infect warm-blooded mammals. It causes a fatal encephalitis, and one of the symptoms in rabies virus–infected animals is increased aggressiveness resulting in unprovoked attacks, which in turn allows rabies virus to spread from the saliva of the infected animal into the bite wound of its victim.

Virus Cell Entry

Many viruses enter cells through the use of specific cell surface receptors, which in turn influences the tropism of the virus. Examples of viral receptors include sialic acid for influenza viruses, the coxsackie adenovirus receptor (CAR) for coxsackie virus and most types of adenoviruses (1,2), CD46, a complement component, for adenoviruses of subfamily B2, measles virus, or human herpes virus 6 (3–5), CD4 for HIV-1, CD54, an intercellular adhesion molecule used by 78 of the more than 100 rhinovirus types (6), CD155 used by poliovirus (7), the herpes virus entry mediator (HVEM), a member of the TNF family used by herpes simplex virus (8), or heparan sulfate protoglycan used by some strains of adeno-associated virus (AAV) (9). Many viruses, in addition to their primary binding receptor, use coreceptors for cell entry. For example, the envelope protein of HIV-1, upon binding to CD4, changes its structure and then binds to CCR5 to gain access into the cells. Adenoviruses gain entry into cells after binding of the fiber knob to CAR, followed by interactions between the viral penton and cell surface–expressed integrins. Once viruses bind to cell membranes, they employ a variety of pathways to gain access into the cell. Naked virus particles can cross the cell membrane directly, or they can form a pore within the membrane and inject their genome into the cytoplasm. Other nonenveloped viruses, such as adenoviruses or AAVs, sink into clathrin-coated pits upon binding to cell surface receptors, which invaginate and close off, forming clathrin-coated vesicles within the cytoplasm. There the clathrin dissociates into triskelions, which leave the vesicles. The resulting uncoated vesicles transport the virions to endosomes, from where virus can be released.

Enveloped viruses such as influenza virus enter cells by receptor-mediated endocytosis. The membrane of some enveloped viruses can fuse with cell and the release virus components such as its protein-covered genome into the cytoplasm. Parainfluenza viruses such as Sendai virus or HIV-1 enter cells through direct fusion between the viral and cell membrane, allowing the viral contents access into the cytoplasm. Most but not all viruses replicate in the nucleus. Poxviruses, which are the largest of all viruses and encode several hundred proteins, can transcribe their DNA in the cytoplasm, and the viruses carry the enzymes needed for transcription of the early viral genes. Other viruses have to transport their genome into the nucleus. Some viruses, such as adenoviruses, travel through the cytoplasm to the nuclear pore complex, taking advantage of cellular transport systems such as microtubules. Once the virus reaches the nuclear pores, it uncoates, and the genome, still complexed with some of the viral proteins such as factor VII for adenoviruses, is injected into the nucleus. HIV, an RNA virus, carries a reverse transcriptase that in the cytoplasm converts viral RNA into DNA. The DNA in turn moves into the nucleus through nuclear pores.

Cells have evolved mechanisms to recognize viruses at these early stages while viruses gain access to the host cell replication machinery. Pathogen-recognition receptors such as Toll-like receptors are located at the cell surface or within cells. They recognize patterns, rather than specific sequences, that are not present in normal healthy cells but are associated with pathogens. Such patterns include motifs on viral proteins, DNA, or RNA. Viral RNA can also be sensed by RNA helicases such as RIG-1, resulting in the induction of interferon responses. Within the nucleus, incoming viral DNA can be complexed into so-called nuclear dots, and there is circumstantial evidence that binding of viral genomes to such nuclear dots inhibits their replication and is thus part of the cellular defense machinery.

Virus Replication

Once the virus gains access to the nucleus, virus propagation is initiated. Transcription of the more complex DNA viruses occurs in two stages and starts with transcription of the so-called early genes, which encode proteins needed for transcription and nuclear export of viral RNA, followed by replication of the genome and then transcription of the late genes, which encode the structural proteins.

This process can be exemplified by transcription of the adenovirus genome, a double-stranded DNA virus with a genome of 30 to 35 kb in length that is read in both directions and increases its repertoire of polypeptides through further splicing (10). The E1A proteins are produced first. They modulate the cellular metabolism to make the cell more susceptible to virus replication, primarily by interfering with NF-κB and p53 pathways. The E1B gene products prolong cell survival by inhibiting cell apoptosis. The E2 gene products provide the machinery for replication of virus DNA and, together with cellular factors, promote transcription of late genes. The E3 gene products, which are not essential for adenovirus replication, provide a compendium of proteins that subverts the host defense mechanisms. The E4 gene products facilitate virus messenger RNA metabolism and provide functions to promote virus DNA replication and shutoff of host protein synthesis. They also prevent viral DNA concatemer formation. Adenoviruses also transcribe a set of hairloop-structured RNAs

that are not translated, termed virus-associated (VA)-RNAs, and these play a role in combating cellular defense mechanisms. DNA replication begins from both DNA termini, followed by transcription of the late genes that encode the structural proteins. The encapsidation process of the viral DNA is governed by the presence of a packaging signal at the conventional left end of the virus DNA, which consists of a series of AT-rich sequences. These events are accompanied by major changes in the nuclear infrastructure and the permeabilization of the nuclear membrane of the host cells. This facilitates the egress of the virus into the cytoplasm and is followed by the disintegration of the plasma membrane and the release of infectious virus.

Some RNA viruses, such as influenza A viruses, carry enzymes that are needed to initiate viral transcription. The influenza A virus genome is composed of eight segments of linear negative-sense single-stranded RNA. The genome sequence has terminal repeated sequences at both ends that are 12 to 13 nucleotides long. The viral endonuclease (PB2) cuts terminal nucleotides from the RNA, which are then used as primers for the transcription of the genes. Once the initial proteins have been synthesized, eight complementary positive-sense RNA strands are made from the eight negative-sense RNA segments. From this cRNA, a negative-sense RNA is produced. Assembly of virus particles takes place in the cytoplasm at the plasma membrane.

Upon replication, some viruses exit their host cells by budding through the plasma membrane, in a process of reverse endocytosis. Other viruses are released upon the death of the infected cells. Still other viruses pass from one cell into adjacent cells without exposure to the extracellular environment.

ANTIVIRAL IMMUNE RESPONSES

Immune responses are essential to protect their host from pathogens. Humans with severe immmodeficiencies, whether due to inheritance, infection with HIV-1, or immuno-ablating medical interventions, commonly die as a result of overwhelming viral infections.

Viruses come in different flavors, and the immune system has evolved to respond accordingly. Although all viruses have the ultimate goal of replicating, their approach differs and can roughly be divided into "hit and run" or "hit and hide" varieties. The hit-and-run variety infects an individual, replicates rapidly, and then spreads to the next victim. Such viruses can cause fulminate and fatal infections, because survival of the host is not essential for their continued existence once they have spread to the next organism. Many of the small viruses, but also some of the more complex DNA viruses, take this hit-and-run approach. A typical example is influenza virus, which causes an acute infection and then spreads to the next host. The host either dies or completely clears the infection. The suc-

cess of influenza virus is linked to its ease of transmission, so there is no reason for this virus to rely on continued infection of a given host.

Another example is rabies virus. This virus in interesting because its incubation time varies tremendously; patients can develop symptoms within 2 to 3 weeks, or the infection can stay asymptomatic for decades and then suddenly flare up. It is unknown where the virus hides during this time, and it is also unknown why rabies virus suddenly starts to replicate in the central nervous system years later, causing disease. Humans or animals that develop symptoms of rabies nearly always die, and the very few humans who have survived have severe neurologic deficits. The virus is by no means as contagious as influenza virus but instead requires direct and fairly intimate contact between an infected host's saliva and its next victim. Notwithstanding, the virus is very successful, for it has a broad host range and ensures that infected individuals who become contagious at the end stage of their disease exhibit the aggressive behavior that is needed for rabies virus to spread.

To ward off hit-and-run viruses requires a rapid and robust immune response to blunt viral spread within an individual without causing undue damage to the infected host. Hit-and-hide viruses are usually more complex, because much of their genome is devoted to combating immune responses. These viruses replicate upon infection, but they do not focus on seeking a new host; rather, they focus on extending their survival within an infected host. Examples are herpes viruses, which, upon an acute and lytic cycle, become latent and persist for the lifetime of an infected host. Another example is HIV-1, which initially replicates to high titers, causing influenzalike symptoms. An adaptive immune response is triggered and reduces viral load. Nevertheless, the virus cannot be cleared and persists until the host eventually succumbs to virus-associated complications. HIV-1 is far less contagious than influenza virus and does not have the luxury of the broad host range of rabies virus. Chronic infections thus allow the survival of viruses that are less easily transmitted. Chronic or persistent infections pose different demands on the immune system than transient and acute infections, because viral loads need to be controlled for long periods of time.

VIRUSES AND THE INNATE IMMUNE SYSTEM

The innate immune system has two roles: It provides an early defense system against pathogens; and it alerts and assists in activating the adaptive immune system.

Pathogen Recognition Receptors

The innate immune system lacks the exquisite specificity of the adaptive immune system. Specificity for recognition of foreign antigens is provided by receptors called pattern

recognition receptors (PRRs), which recognize pathogen-associated molecular patterns (PAMP) (11). Toll-like receptors (TLR) serve as PRRs, and 12 TLRs have been identified to date in mammals (12). Of those, TLR-3, -7, -8, and -9 recognize viral genomes (13); TLR-3 recognizes dsRNA, TLR-7 and -8 recognize G/U-rich ssRNA, and TLR-9 recognizes unmethylated CpG motifs on dsDNA present in bacteria or large DNA viruses such as herpes viruses. TLR-2 and TLR-4 recognize mainly bacterial products but can also be activated by viral proteins, such as the hemagglutinin of measles virus (TLR-2) (14) or the fusion protein of respiratory syncytial virus (TLR-4) (15). TLRs that recognize viral genomes are in the endosome, whereas those that bind proteins are on the cell surface. Expression of TLRs in the endosomes ensures access to viral genomes while preventing interaction with host cell–derived RNA. Most of the TLRs use MyD88 as an adaptor molecule (16), which upon binding to TIRAP activates IRAK and TRAF6 and then NF-κB and IRF-3. TLR-3 signals through TRIF (17), which binds to TRAF6 and RIP1, which activate NF-κB. Alternatively, TRIF can bind to TBK1, which activates IRF3 and IRF7. The latter pathway can also be used by TLR-4. Activation of NF-κB followed by its translocation to the nucleus results in production of proinflammatory cytokines such as IL-6, TNF-α, and IL-12; activation of IRF-3 or -7 causes production of type I interferons (IFN).

DsRNA is further recognized by two kinases, protein kinase R (PKR) (18) and RNAseL (19). Upon activation, PKR phosphorylates the eukaryotic initiation factor 2 (eIF-2) α subunit. This inhibits translation in virus-infected cells. PKR thus functions to protect cells against synthesis of viral proteins once the kinase is activated by dsRNA, a common by-product of viral propagation. Activation of PKR furthermore induces production of type I interferons (20). RNAseL affects degradation of RNA and thus also inhibits protein synthesis.

DsRNA can activate two cytoplasmic IFN-inducible DExD/H box RNA helicases termed retinoic acid–inducible protein 1 (RIG-1) and melanoma differentiation–associated gene 5 (mda-5) (21,22). In addition to helicase domains, these proteins contain a tandem caspase recruitment domain, which results in signal transduction cascades that activate NF-κB and IRF-3. The specificity of the helicases is comparable to that of TLR-3, and it is currently unclear how their roles in antiviral defense differ. TLR-3 is localized in intracellular vesicles and may encounter viral RNA upon phagocytosis of viral particles. The helicases as well as PKR are located in the cytoplasm and are likely to react to dsRNA produced during viral replication. TLR-3 is expressed on NK cells and may play an important role in their activation. Binding of West Nile virus to TLR-3 was shown to initiate an inflammatory response that increases the permeability of the blood–brain barrier, thus allowing the virus to enter the brain (23). Overall, TLR3 is the most abundantly expressed TLR in the central nervous system

(24), indicating that this TLR may have a specific and yet-to-be-identified role in the brain.

Early Antiviral Cytokines

Stimulation of NF-κB or the interferon pathways by viral PAMPs results in production of a series of proinflammatory cytokines and chemokines. Some of the cytokines, such as interferons, have direct antiviral activity. Interferons are subdivided into type I interferons (IFN-1), which in humans include one type of IFN-β, IFN-ε, IFN-κ, IFN-ω, and at least 13 variants of IFN-α, type II interferon, also called immune interferon or IFN-γ, and type III interferon, also called IFN-λ or IL-28/29 (25).

All nucleated cells can produce type I IFNs, although during a primary infection most of it originates from dendritic cells (DCs), especially plasmacytoid DCs (pDCs). IFN-γ is produced mainly by T and NK cells. Type III IFN can be produced by a number of cells, including DCs. Both IFN-α and IFN-β use the same receptor and have interchangeable functions. The receptor for type I IFNs consists of two subunits, IFNAR-1 and IFNAR-2. Binding of type I IFN to its receptor leads to phosphorylation of the tyrosine kinase (Tyk)-2 and Janus kinase (Jak)-1 (26). This in turn causes tyrosine phosphorylation of Stat1 and 2 proteins, which upon translocation into the nucleus form a complex with other proteins, leading to activation of interferon-inducible genes (27). Type I IFN acts mainly through Stat1 and Stat2 but can also activate Stat3, Stat4, and Stat5.

Mainly NK cells produce IFN-γ in response to PAMPS or other cytokines such as IL-12 or IL-18. Binding of IFN-γ to its receptor, which contains two chains called IFNGR-1 and IFNGR-2, leads to the phosphorylation of Stat1 via Jak-1 (28,29).

Type III IFN acts through a receptor complex composed of the IL-28 receptor (R) α chain and the IL-10Rβ chain. Binding of IFN-λ to its receptor activates Stat1 and 2 but, similar to type I IFN, can act through Stat3, 4, or 5. Type III IFN can signal through non-Jak-Stat pathways either through the kinase AKT or mitogen-activated kinases (MAPK) JNK and ERK1/2. Although type I IFN can use some of these alternative pathways as well, its action through JNK has not yet been reported. Type I and type III IFNs are commonly produced by the same cells in response to virus infections (25). However, in one study, expression of IFN-λ but not type I IFNs was demonstrated from liver biopsy samples of patients infected with hepatitis C virus (HCV), indicating differential regulation of their expression (25,30).

Type I IFNs are in general 10 to 100 times more potent as antiviral agents compared to IFN-γ. All types of IFNs affect viral multiplication at several levels. They can inhibit entry of the viruses into host cells by reducing expression of the viral receptors. IFN-1 induces production of the Mx protein that inhibits transcription of

influenza viruses through a still ill-defined pathway (31). IFNs downregulate viral promoters. They trigger expression of $2'5'$-oligoadenylsynthase and double-stranded RNA kinase, which inhibits production of viral progeny. For some viruses, IFN-γ can promote transcription. For example, the long terminal repeat of HIV-1 is activated by IFN-γ (32). IFN-γ induces nitric oxide synthases, which converts L-arginine to L-citrulline and NO. The latter has direct effects on poxviruses and herpes viruses by inhibiting DNA replication, synthesis of late viral proteins, and viral assembly (33).

In addition to their antiviral activity, IFNs play a dominant role in other host defense mechanisms. They activate macrophages and NK cells. They promote Th1-type immune responses. They drive maturation of DCs, induce or augment expression of MHC class I and II determinants, costimulatory molecules of the B7 family, and proteins involved in antigen processing. They enhance cross-priming. IFN or IFN-receptor knockout mice show increased susceptibility to some viral infections. IFN-α has been licensed for treatment of chronic infections with hepatitis B (34) and C virus (35) and for treatment of human papilloma virus–associated genital warts (*Condyloma acuminata*) (36).

Activation of Cells of the Innate Immune System

Chemokine-mediated Recruitment of Leukocytes

Most viruses cause an inflammatory reaction through chemokine-mediated recruitment of leukocytes to the site of infection. At least 50 different chemokines have been identified in humans to date (37,38). Most of them can be divided into CXC or CC chemokines, depending on the positioning of their cystein residues. Chemokines are either constitutively expressed to maintain normal trafficking of leukocytes, or they are induced under conditions of inflammation to recruit a cellular infiltrate. The chemokine system is redundant, and receptors and their ligands involved in inflammatory reactions are commonly promiscuous. Chemokines as well as cytokines are induced in response to interactions between PAMPs and PRRs. This affects a local increase of the expression of adherent molecules on blood vessel walls, which causes leukocytes to slow down and to start rolling. This is followed either by detachment of the rolling cells as a result of the shearing forces of the blood flow or by firm adhesion and then extravasation from the blood into the tissue, where leukocytes migrate to the site of infection. The latter two events are controlled by chemokines. Neutrophils are attracted first through CXC chemokines such as CXCL8, CXCL5, and CXCL1. Monocytes and other mononuclear cells that express CCR2, CCR3, or CCR5 are recruited later through CCL2, CCL3, and CCL5 chemokines. The role of

chemokines that recruit different NK cell subsets remains controversial. Resting NK cells express CXCR4, whereas activated NK cells upregulate CCR2, CCR4, CCR7, and CCR8, indicating that they migrate in response to the corresponding chemokines.

Activity of Natural Killer (NK) Cells

NK cells are activated by viruses either directly, upon recognition of viral sequences by TLRs such as TLR-3, or indirectly through IL-12. NK cells contribute to early viral control through direct lysis of virus-infected cells and through the production of IFN-γ (39,40). NK cells carry a multitude of activating as well as inhibitory receptors to ensure selective lysis of infected cells (41,42). The overall balance of signals through both types of receptors determines NK-cell activity. Some of the NK-cell receptors belong to the killer immunoglobulinlike receptors (KIR), which can be activating or inhibitory and which differ in their specificity to HLA. Inhibitory KIRs contain immunotyrosine-based inhibitory motifs in their cytoplasmic tail. Some of the inhibitory KIR receptors recognize MHC class I determinants, and loss of MHC class I molecules upon virus infections activates NK cells, provided that an activating receptor is engaged by a host-cell ligand or a pathogen-derived sequence. Some activating KIRs are sensitive not only to modulation of MHC class I expression, but also to peptides displayed by class I molecules. This specificity for viral peptides displayed by MHC class I is not as exclusive as that of T-cell receptors but rather resembles that of PRRs. The inhibitory KIR receptors include KIR2DL1 specific for HLA-C/C2, KIR2DL2/3 specific for HLA C/C1, KIR3DL1 specific for HLA-B Bw4, and KIR3DL2 specific for HLA-a/A3/A11. The corresponding activating receptors KIR2DS1, KIR2DS2, and KIR3DS1 have the same specificity, whereas KIR2DL4 appears to recognize HLA-G. Of the two lectinlike receptors, CD94/NKG2A is inhibitory whereas CD94/NKG2C is activating. Both recognize HLA-E, which binds the leader sequence of HLA-A, -B, and -C molecules as well as the leader sequence of nonclassical MHC molecules, and thus signals global changes in MHC expression. Additional activating receptors are NKG2D, NKp46, and NKp30, which are constitutively expressed on NK cells, whereas NKp44 is induced upon activation of NK cells. These receptors are termed cytotoxicity receptors because their ligation causes release of perforin or granzyme, which kills the target cells through pore formation in the cell membrane. NKG2D recognizes the stress-induced MHC class I–related MICA and MICB proteins, whereas NKp46 and NKp44 recognize viral hemagglutinins (43). NK cells also express TLRs involved in viral sensing, although the role of such TLRs remains to be established. IL-12 and type I interferon also provide potent activating signals to NK cells. NK cells are linked to the adaptive immune system through their

interactions with immature DCs. Activated NK cells can lyse immature DCs upon ligation of the NKp30 receptor. Upon maturation, DCs upregulate MHC class I molecules and become resistant to NK-cell lysis. NK cells can drive maturation of DCs through production of proinflammatory cytokines such as TNF-α. In turn, mature DCs can activate the CD56^{high} subset of NK cells through IL-12. NK cells are pivotal in providing early control of virus infection, as was shown in animal models, in which lack of NK cells resulted in enhanced susceptibility to infections with a number of different viruses such as sendai virus, influenza virus, or cytomegalovirus, a finding that was confirmed in human patients with NK deficiency (44).

Dendritic Cells

DCs provide a crucial connection between the innate and the adaptive immune system. Two main subsets of DCs have been identified to date, called myeloid DCs (mDCs) (45) and plasmacytoid DCs (pDCs) (46), which differ in morphology, surface marker expression, and function. A third subset, called lymphoid DCs, has also been described (47). mDCs have a typical dendroid morphology. They are CD11b$^+$ and CD11c$^+$. pDCs have a plasma cell-like morphology. They are CD11c^{low} and CD11b$^-$. Human pDCs express CD123, whereas mouse pDCs express Ly6c. Both mDCs and pDCs are bone marrow–derived. They show distinct migration patterns; immature mDCs migrate to peripheral tissues, whereas immature pDCs, which are CD62L^{high}, migrate to lymphatic tissues, where they enter the T-cell zones. Immature mDCs constantly monitor their environment by phagocytosing particles including viruses, but are unsuited to present antigen to naive T cells until they differentiate into mature DCs. Such differentiation signals are provided by cytokines such as TNF-α or type I IFNs and by activation of PRRs such as the TLRs. Interestingly, mDCs express many of the TLRs that recognize bacterial products such as TLR-2, -4, and -5. They also express TLR-3. In contrast, pDCs express TLRs that recognize viral genomes such as TLR-7, -8 (expressed only by mouse pDC, not by human pDCs), and -9, indicating a pivotal role of pDCs in antiviral defense (48). Upon receiving an activation signal, mDCs initially increase phagocytosis and start secreting chemokines that attract an additional inflammatory infiltrate, which includes cells of the innate and adaptive immune system and additional immature mDCs and pDCs. Activated mDCs then cease to take up antigen, rearrange their actin cables, and upregulate CCR7 expression, which drives their migration to draining lymph nodes. Activated DCs furthermore upregulate their antigen-processing machinery as well as expression of MHC class I molecules, and translocate MHC class II determinants from intracellular vesicles to the cell surface. At this stage, MHC molecules are loaded with antigen-derived

peptides. In addition, mature DCs start to express or up-regulate positive costimulatory molecules of the B7 family such as CD80 and CD86 as well as CD40, and secrete cytokines such as IL-12 and type I IFNs. Once mature mDCs reach the lymph nodes, they migrate to the T-cell zones and commence activation of naïve T cells. In contrast, upon activation, pDCs produce type I IFN at levels that are 10 to 100 times higher on a per-cell basis than those produced by mature mDCs. In mDCs, stimulation through a PAMP, through cytokines, or through CD40 ligation activates IRF-3, which leads initially to the production of low amounts of type I IFN. Upon binding to its receptor, type I IFN then increases its own production through a positive feedback mechanism, which requires upregulation of IRF-7. pDCs constitutively express IRF-7, which renders these cells independent of positive feedback, and they can therefore produce large amounts of type I IFN immediately upon activation (49). pDCs can present antigen to naïve T cells; they upregulate MHC determinant and costimulatory molecules upon differentiation into mature pDCs. Nevertheless, levels of these crucial cell surface molecules are lower than those on mature mDCs. Furthermore, pDCs do not phagocytose antigen and are thus poorly suited to present antigen (50). It is unclear whether pDCs indeed present antigen *in vivo* to cells of the adaptive immune system or if their primary role is to produce type I IFNs and to assist maturation of mDCs.

Antigen presentation by DCs can influence the homing behavior of activated T cells. Mucosal surfaces are particularly vulnerable to pathogen invasion. Especially the intestinal mucosal membrane is constantly bombarded with bacteria and food-derived antigens and has thus evolved a distinct immune system. DCs within the intestine have been shown to activate T cells that preferentially home to gut-associated lymphoid tissues. Such homing is mediated by expression of CCR9 and $\alpha4\beta7$ on T cells. Lamina propria–derived DCs, unlike DCs in the spleen or in central lymph nodes, express the integrin chain of CD103, which induces T cells with gut-homing preference (51).

DCs not only activate adaptive immune responses, they also have important regulatory functions. Immature DCs fail to activate T-cell responses but instead cause T-cell anergy once a T cell encounters its cognate antigen on DCs, which lack expression of costimulatory signals. In addition, immature or "semimature" DCs are thought to induce regulatory T cells, which suppress adaptive immune responses (52,53). Mature DCs can also downregulate T-cell activation through the expression of negative costimulatory molecules. CD28 expressed on T cells can bind to CD80 and CD86, which provide positive costimulation. CD80 and CD86 bind with higher affinity to CTLA-4, which is expressed later on activated T cells and delivers a negative signal (54). The ICOS:ICOS ligand pathway has overlapping functions with CD28 and appears to be particularly important for stimulating cytokine production by

effector T cells (55). However, ICOS also has a negative regulatory role, influencing the function of IL-10 production by regulatory T cells (56). Functional studies support both stimulatory and inhibitory roles for B7-H3 (57). The newest member of the B7 family, B7-H4, has a negative regulatory function (58). PD-1 is an inhibitory receptor expressed on T cells and B cells, and it induces cell cycle arrest (59). PD-1 interacts with two receptors, PD-L1 and PD-L2, which exhibit distinct patterns of expression. PD-L1 is expressed more broadly than PD-L2; PD-L1 is expressed on T cells, B cells, macrophages, DCs, endothelium, syncytiotrophoblasts, and other cell types, whereas PD-L2 expression is restricted to macrophages and DCs. Chronic viral infection seems to cause activation of the PD1-PDL1/L2 pathways, potentially resulting in an impairment of T-cell functions (60). The B- and T-lymphocyte attenuator (BTLA) (34) provides inhibitory signals upon binding to the herpes virus entry mediator (HVEM) (61), which is expressed on DCs, and also interacts with gD of herpes virus and with a distinct region with two TNF family members, LIGHT and lymphotoxin-A.

ANTIGEN-SPECIFIC IMMUNE RESPONSES

Activation of the innate immune system is followed by stimulation of adaptive immune responses to viral pathogens. Cells of the adaptive immune system have exquisite specificity to their respective antigen through clonally expressed receptors that maintain a complex repertoire through genetic rearrangement and, in the case of B-cell receptors, through additional somatic hypermutations. To maintain the large repertoire that is needed to mount a response against the multitude of pathogens, cells with a given receptor specificity are present at very low numbers. Upon activation, B and T cells need to undergo extensive proliferation to reach more effective numbers. T and B cells replicate very rapidly, with an approximate doubling time of 6 hours. Notwithstanding, viruses can multiply 1,000 fold during the same period. The 4- to 5-day delay between viral infection and onset of adaptive immunity caused by the initial proliferation of T and B cells with the appropriate receptor specificities leaves the host susceptible to capacious virus replication, which at this stage is controlled mainly by cells and factors of the innate immune system.

The adaptive immune system is composed of B and T cells; T cells are divided into CD4$^+$ and CD8$^+$ T cells. T cells are stimulated by peptides derived from foreign antigens that are displayed by MHC molecules on the surface of mature DCs. CD4$^+$ T cells, which have immunoregulatory functions, are activated by peptides derived from exogenous antigen displayed by MHC class II molecules, whereas CD8$^+$ T cells, which have effector functions and can lyse virus-infected cells directly, are activated by pep-

tides that are in general derived from de novo–synthesized antigens, and that are displayed on MHC class I molecules. B cells are activated by native antigen. Effector T cells have the task of eliminating virus-infected cells preferentially by killing them before new viral progeny have been assembled. Restricting their receptor specificity to virus-derived peptides that are bound to transplantation antigens prevents them from being sidetracked by free virus.

CD8$^+$ T Cells

During a primary virus infection, viral control is achieved predominantly by specific CD8$^+$ T cells that can eliminate virus-infected cells through direct lysis of MHC class I–expressing infected cells, and that can further reduce virus replication through the release of cytokines such as IFN-γ.

Antigen Processing and Presentation for CD8$^+$ T-Cell Activation

CD8$^+$ T cells respond to peptides that are 8 to 10 amino acids long and displayed by MHC class I determinants (62). Such peptides are commonly derived from early viral proteins and allow for early destruction of the infected cells (63). Naïve CD8$^+$ T cells are activated by MHC class I/peptide complexes displayed on mature DCs. Other cells, such as B cells, macrophages, or tissue cells, cannot activate naïve CD8$^+$ T cells (64), although they can trigger a recall response. Minute amounts of MHC class I/peptide complexes suffice to trigger activation of CD8$^+$ T cells, though immunogenic levels most likely vary and depend in part on the affinity between the MHC peptide complex and the T-cell receptor, as well as on the duration of antigen presentation.

Peptide loading of MHC complexes in most cases occurs in the endoplasmic reticulum (ER) although, at least *in vitro*, empty cell surface–expressed MHC class I molecules can bind exogenous peptides. Because empty cell surface–expressed MHC class I molecules are unstable, this process may not play a role *in vivo*. The most common pathway for peptide/MHC class I complex formation involves productive infection of cells followed by synthesis of viral antigens. Proteins that are not translated faithfully or that are folded incorrectly are degraded in the cytoplasm into peptides by proteolytic enzymes that form the proteosome complex (65). Synthesis and posttranslational modifications of this complex are increased by IFN-γ (66). Peptides that are derived upon enzymatic cleavage of proteins are transported into the ER through transporter associated with antigen presentation (TAP) (67,68). TAP shows preference for peptides that are 8 to 13 amino acids in length and, depending on the species of the host cell, for

peptides with certain motifs such as hydrophobic carboxy termini (69).

Newly synthesized MHC class I heavy chains are also transported into the ER, where they bind to calnexin, which promotes appropriate folding of the protein. The folded heavy chain then binds β2 microglobulin. The correct folding of the MHC class I heavy chain is further facilitated by calreticulin. The resulting complex binds to tapasin, providing a link to TAP (70). Upon TAP-facilitated transport into the ER, peptides with the appropriate anchoring residues bind to the groove that is displayed on top of the MHC class I heavy-chain/β2 microglobulin complexes. If necessary, peptides are further clipped by peptidase present in the ER until they reach a size that is optimal for binding to MHC. Some peptides contain signal sequences that allow for TAP-independent transport into the ER. Binding of peptides to MHC class I molecules causes release of calreticulin and tapasin and is followed by transport of the MHC/peptide complex through the Golgi apparatus to the cell surface.

Not all viruses infect DCs directly, so alternative pathways exist to ensure that their antigens are presented to CD8[+] T cells. DCs present exogenous antigen in the context of MHC class I determinant through a process called cross-presentation or cross-priming (71). This process is enhanced by type I IFNs. Cross-priming involves direct uptake of viruses or viral proteins by DCs through phagocytosis or pinocytosis into lysosomes, from where they are transported to early endosomes. Here some of the viral proteins are degraded by enzymes present in these compartments. Viruses and viral degradation products can egress the endosomes and reach the cytoplasm for further degradation by proteasome complexes and TAP-dependent transport of peptides into the ER. Alternatively, phagosomes (the endosomal vehicles that contain material that is phagocytosed by DCs) can fuse directly with the ER, generating compartments that have been dubbed ergosomes (72). Loading of peptides onto MHC class I molecules within ergosomes was shown to be TAP-dependent, suggesting that viruses, proteins, or peptides first have to leave the ergosome and then re-enter the ergosomes with the help of TAP, most likely upon further degradation. Upon association with MHC class I molecules, the peptide/MHC class I complexes within the ergosomes are transported to the cell surface through a process that is not completely inhibited by the drug brefeldin, which blocks transport through the Golgi complex, suggesting that ergosomes can fuse directly with the outer cell membrane like endosomes (73).

A second mechanism of cross-priming has been suggested in which preformed MHC class I/peptide complexes are transferred from cells that are productively infected with a virus to DCs. Direct proof that this pathway is used *in vivo* is missing. A third and related pathway has been suggested in which peptides formed in infected cells

are transported by chaperone proteins to DCs (74). Again, proof that this pathway is used *in vivo* is missing, and current evidence suggests that the chaperone model of cross-presentations is likely to be an *in vitro* artifact, as the efficiency of cross-priming was shown to correlate directly with the stability of the antigen. The model of cross-presentation through chaperones would predict that unstable proteins that are readily degraded into peptides would be more efficiently presented by cross-presentation than antigens that are relatively resistant to proteolysis, but, in contrast, cross-presentation of unstable proteins can be increased through proteasome inhibitors.

Once MHC/peptide complexes reach the cell surface, they are remarkably stable. It has been estimated that each MHC class I molecule has the potential to bind any of 10,000 different peptides. Nevertheless, upon virus infection, CD8[+] T-cell populations that recognize one or two epitopes of a virus commonly dominate the response. This in turn allows viruses to escape immunosurveillance by CD8[+] T cells through mutation of such epitopes (75).

Nonclassical MHC class I molecules such as CD1 (76) can also present antigen, in part nonpeptide antigens such as lipids, to the immune system. The role of these alternative pathways for antiviral defense is not yet understood.

Primary CD8[+] T-Cell Responses

Activation of primary CD8[+] T-cell responses occurs in lymphatic tissues and requires antigen presentation by DCs. Activation occurs rapidly, within hours after peptide-loaded mature DCs reach the T-cell–rich zones of lymphatic tissues. DCs migrate primarily to lymph nodes draining the site of infection, and T cells are stimulated primarily within these draining nodes. Viruses that cause systemic infections are presented in multiple lymph nodes as well as in the spleen. Upon receiving activation signals, CD8[+] T cells proliferate extensively in a 6- to 8-hour cycle. For example, during an experimental infection of mice with lymphocytic choriomeningitis virus (LCMV), 10^2 naive CD8[+] T cells can expand within a few days to 10^7 effector cells. Activation of CD8[+] T cells to some viruses is dependent on help from CD4[+] T cells, whereas other viruses induce CD8[+] T cells in the absence of CD4[+] T cells. It has been suggested that CD4[+] T cells provide additional differentiation signals to DCs, enabling them to prime CD8[+] T cells (77). Some viruses can apparently induce a similar differentiation pathway of DCs, allowing for activation of CD8[+] T cells in the absence of T help. CD8[+] T cells that are deprived of CD4[+] T-cell help are commonly short-lived and fail to establish functional memory (78).

During activation, CD8[+] T cells undergo a number of phenotypic changes (79). They reduce expression of CD62L and CCR7, which allows their egress from

lymphatic tissues. Early during activation, they transiently upregulate expression of CD69 and CD25. The latter is the receptor for IL-2 and may be required for IL-2–driven T-cell proliferation. Upon activation, CD8$^+$ T cells upregulate expression of CD27 and CD44. A subset of CD8$^+$ effector T cells augments expression of the IL-7 receptor α chain (CD127). CD8$^+$ effector T cells express granzyme and perforin, and they produce cytokines and chemokines upon encounter with their cognate antigens, including IFN-γ, TNF-α, IL-2, and MIP-1α/β. A number of parameters during antigen presentation, such as costimulatory signals, type of T-cell help, strength of T-cell–receptor engagement, and duration of presentation, are likely to influence the breadth of CD8$^+$ T-cell functions, which in turn determines their effectiveness in limiting viral spread (80). Once they are fully activated, CD8$^+$ T cells leave the lymph nodes and migrate to sites of infection. Activated T cells express different chemokine receptors and a higher density of certain types of adhesion molecules (LFA-1 or integrin α4) than naïve T cells, which allows them to leave the blood vessels and enter sites of inflammation (81). Once activated T cells reach an area of inflammation, their adhesion molecules interact with P- and E-selectins, ICAM, VCAM, and CD34, which are expressed at increased levels on vascular endothelial cells in the presence of cytokines such as IL-1 or TNF-α. This interaction initially causes a loose attachment of the lymphocytes, followed by their rolling along the vessel walls (82). Chemokines secreted at the site of inflammation carry heparin-binding sites that cause them to be retained in the extracellular matrix close to their site of origin. Once the lymphocytes reach an area that is rich in chemokines corresponding to their receptors, they bind firmly to the vascular endothelial cells and eventually emigrate out of the vessels into the tissue. Recruitment of activated T cells is thus driven by chemokines and not by the antigen specificity of the T-cell receptors (83). Once CD8$^+$ T cells reach infected tissue and re-encounter their antigen on MHC class I–positive cells, they commence effector functions by releasing cytokines and mediating lysis of virus-infected cells. IFN-γ, which is released by most activated antiviral CD8$^+$ T cells, upregulates the antigen-processing machinery and MHC class I expression, thus facilitating interactions between infected cells and activated CD8$^+$ T cells. CD8$^+$ T cells predominantly lyse their target cells through the release of granzyme and perforin, which form pores in target-cell membranes and cause apoptotic cell death. Another lytic pathway involves interactions between Fas ligand (CD95) expressed by activated T cells and Fas expressed by some types of target cells. Interactions between CD95 and Fas trigger activation of caspases and apoptotic cell death of the target cells (84). Although each CD8$^+$ T cell can lyse several target cells, direct lysis appears to be rather inefficient, because it requires direct interactions between CD8$^+$ T cells and each infected cell. Nevertheless, it is crucial for viral clearance. Mice that lack perforin were shown to have an increased susceptibility to a number of viral infections.

CD8$^+$ T-Cell Memory and Recall Responses

Once virus-infected T cells have been eliminated during an acute viral infection, approximately 90% of the activated CD8$^+$ T cells undergo activation-induced cell death. Effector T cells that express high levels of CD127 preferentially survive the contraction phase and differentiate into memory cells (85). During this process they undergo a number of functional and phenotypic changes. At least two types of memory CD8$^+$ T cells have been identified to date, so-called central memory CD8$^+$ T cells (T$_{CM}$) and effector memory CD8$^+$ T cells (T$_{EM}$) (86,87). T$_{CM}$ T cells express CD62L and CCR7 and home to lymphatic tissues, whereas effector memory T cells lack expression of CCR7 and CD62L and remain in peripheral tissues. It was initially argued that upon re-encounter of antigen, T$_{EM}$ can immediately commence effector function such as secretion of cytokines or target cell lysis, whereas T$_{CM}$ initially need to proliferate and hence assume effector functions with a delay (88). Accordingly, it was argued that T$_{EM}$ provide a crucial first barrier against virus infections. Subsequent studies showed that T$_{CM}$ can release cytokines as rapidly as T$_{EM}$ and that they also assume lytic activity quite rapidly, although not as instantaneously as T$_{EM}$. In addition, it was shown that in some virus infections, such as with LCMV, T$_{CM}$ provide superior protection to T$_{EM}$ (89). This may in part reflect that, although both memory CD8$^+$ T cells can proliferate upon re-encounter of their antigen, T$_{CM}$ have a higher proliferative capacity than T$_{EM}$, allowing for a more robust recall response. In other virus infections, such as pulmonary infection with influenza A virus or with sendai virus, T$_{EM}$ rather than T$_{CM}$ were shown to protect from virus-associated disease (90). One would assume that the type of virus and the site of infection in part dictate which subset is needed for efficient early viral clearance, and that in most cases both subsets are beneficial. T$_{EM}$ have the advantage of location, T$_{CM}$ have the advantage of numbers.

Whether T$_{EM}$ and T$_{CM}$ reflect distinct T-cell subsets or rather distinct stages of differentiation remains debated. Overall, numbers of CD8$^+$ memory T cells are maintained at remarkably stable levels during the lifetime of a creature. Each individual memory CD8$^+$ T cell has a finite lifespan of about 2 months and requires IL-7 as a survival factor. At the population level, constant numbers are maintained through homeostatic proliferation, which is dependent on IL-15 and takes place primarily in the bone marrow (91). In the absence of antigen, numbers of T$_{EM}$ gradually decline while numbers of T$_{CM}$ increase. As demonstrated in the LCMV system, this is caused by differentiation of T$_{EM}$ into T$_{CM}$, suggesting a linear relation between these two T-cell populations (92).

Upon repeated re-exposure to antigen, the overall ratio of T_{EM} to T_{CM} increases, with more of the memory CD8+ T cells retaining an activated phenotype (93). CD8+ T cells induced by repeated immunization have a reduced proliferative capacity and accumulate preferentially in nonlymphatic tissues.

Effect of Chronic or Persistent Infections on CD8+ T Cells

During chronic viral infections, CD8+ T cells can become exhausted (94). In mice persistently infected with LCMV, specific CD8+ T cells gradually lose the ability to mediate target cell lysis, secrete TNF-α or IFN-γ. Exhausted CD8+ T cells lose the ability to proliferate to antigen. Exhausted T cells express high levels of PD-1, an inhibitory receptor of the CD28 family. Blockage of PD-1/PD-L1 interaction by monoclonal antibodies was shown to restore T-cell functions and their proliferative capacity (95). Impairments of CD8+ T cells were also observed in humans chronically infected with HIV-1, hepatitis B virus (HBV), or HCV. In HIV-infected patients, CD8+ T-cell functionality rather than frequencies was shown to correlate with progression; compared to patients with HIV-1–specific CD8+ T cells showing a broad range of functions, patients with CD8+ T cells showing limited function progress faster to disease, reflected by increased viral loads, loss of CD4 T cells, and opportunistic infections (80).

Other persistent infections are characterized by periodic virus replication rather than perpetually high levels of replication. For example, certain types of herpes viruses, such as herpes simplex virus (HSV) or cytomegalovirus (CMV), persist in a latent form during which viral protein synthesis is virtually shut off. Upon reactivation of the virus as a result of certain stress factors, viral replication is reinitiated and, in response, specific memory CD8+ T cells expand and in healthy individuals rapidly control the infection. The repeated recall responses result in very high frequencies of specific memory CD8+ T cells over time. In the elderly, who have commonly impaired immune responses, frequencies of CD8+ T cells with a naïve phenotype decline while those with a memory phenotype increase, suggesting exhausting of the repertoire as a result of chronic exposure to antigens. It is not uncommon that in elderly humans up to 30% of peripheral CD8+ T cells show specificity to antigens of herpes viruses. It has been suggested that aging is infectious, as morbidity and mortality of the elderly is linked to the functionality of their immune system (96).

Mucosal CD8+ T Cells

The immune system can be roughly subdivided into two separate, albeit interactive, entities: a central immune system localized in the spleen and lymph nodes, which pa-trols the inner tissues and organs; and a mucosal immune system, which in humans covers a total surface area of approximately 400 m^2 of mucosa of the airways, the intestines, and the urogenital tract, which are the most common ports of entry for pathogens. Mucosal surfaces, such as those of the intestinal tract or the airways, are constantly bombarded with "harmless" antigens that are best ignored. The inner tissues and organs, on the other hand, are in a sterile environment, warranting more stringent control against foreign antigens. The two immune systems that control the central and the mucosal surfaces are faced by different challenges and in consequence have distinct characteristics. The central immune system has been exceedingly well characterized over the last 30 years. Less is known about the mucosal immune system, which provides the first line of defense against most viral infections.

The mucosal immune system consists anatomically of local inductive sites, called organized mucosa-associated lymphoid tissue (O-MALT), such as tonsils, Peyer patches, and the appendix, and effector sites that are present directly in the mucosa, called diffuse mucosa-associated lymphoid tissue (97). In the intestine, T cells can be found within the lamina propria (LP), and these T cells are phenotypically similar to those found in the central immune system. T cells can also be found within the epithelium. The intraepithelial lymphocytes (IELs) are distinct from those that reside in the LP. The epithelium that covers the mucosal surfaces differs depending on the anatomic location; for example, the intestine is covered by a single epithelial layer, whereas the vagina is covered by a multilayered squamous epithelium that varies in thickness with the menstrual cycle. Transport of antigen from the mucosal surface to the O-MALT system or the local lymph nodes is accomplished by M cells in the intestine and the airways, whereas mucosal surfaces covered by a squamous epithelium rely on local DCs for transport of antigen to the inductive sites. Mucosal DCs may differ functionally from those in the central immune system (98). For example, they express CD103, which induces $\alpha 4\beta 7$ expression of CD8+ T cells. This in turn promotes their homing to mucosal sites (31). The best-studied mucosal T-cell populations are the intraepithelial lymphocytes (IELs) of the intestine. They appear relatively late in development (about 2 to 4 weeks after birth in mice) (99) and are initially composed mainly of T cells that express the γ/δ receptor (100). These γ/δ^+ cells are eventually joined by T cells that carry the α/β receptor (100). A portion of α/β T cells is double-positive for CD4 and CD8, in contrast to T cells found in the spleen or lymph nodes. The majority of these double-positive T cells carry homodimers of the CD8α chain. T cells that carry the γ/δ T-cell receptor (TcR) and are single-positive for CD8 also lack CD8β-chain expression (101). A portion of the intraepithelial T cells (both α/β and γ/δ TcR$^+$) develop within the mucosal immune system independent of the thymus (102).

Antigen recognition by double-positive CD8α/β and TcRγ/δ T cells is different from that of single-positive and α/β TcR-expressing T cells. The latter subsets, which are present in the central and the mucosal immune system, recognize antigenic peptides in association with classical MHC class I or II determinants. The double-positive CD8α/βT cells of the mucosal immune system fail to respond to activation with anti-TcR antibodies and furthermore express potentially autoreactive antigen receptors (103). T cells that express the γ/δ receptor have been shown to have effector functions; they conduct antimicrobial activity (104–107) and promote the development of IgA-secreting B cells (108). Many of the γ/δ^+ T cells seem to recognize antigen directly, including nonprotein structures, without the need for presentation by classical MHC determinants (109). T cells that express either the α/β or γ/δ receptor are present in vaginal epithelium. The vaginal γ/δ T cells have a distinctive phenotype that resembles those in the skin: They are CD4$^-$CD8$^-$, CD45$^+$ and express an invariant TcR (110).

Mucosal T cells show an activated phenotype. They can be primed locally within Peyer patches by viruses that target the intestine, such as rotavirus or reovirus. In some instances, CD8$^+$ T cells induced in lymphatic tissues of the central immune system migrate to mucosal sites. This migration is facilitated by expression of $\alpha 4\beta 7$ (111) and certain chemokine receptors such as CCR9 (112). Mucosal homing of effector CD8$^+$ T cells has been observed upon systemic infection of mice with LCMV virus. Other systemic infections fail to trigger CD8$^+$ T cells that migrate efficiently to the mucosa, suggesting that the quality and strength of the activation signal may influence mucosal homing of CD8$^+$ T cells. Mucosal CD8$^+$ T cells have lytic activity and secrete cytokines such as IFN-γ in response to antigen. Memory CD8$^+$ T cells can also be detected at mucosal sites (113). Memory CD8$^+$ T cells within the LP differ from those within the intestinal epithelium, and the presence of such cells in the LP is not indicative of the presence of such cells within the epithelium. Memory CD8$^+$ T cells within the LP resemble T$_{EM}$ cells within other tissues, whereas the phenotype of memory CD8$^+$ T cells within the epithelium differs. Memory CD8$^+$ T cells within the epithelium express granzyme. They express high levels of CD69, CD103, and the integrin chain $\beta 7$. They express only low levels of CD27, CD122, or Ly6C. Levels of CD127 are intermediate. They can proliferate upon re-exposure to antigen, albeit less efficiently than CD8$^+$ T$_{CM}$. They produce IFN-γ and TNF-α but no IL-2. Overall, this phenotype suggests that memory CD8$^+$ T cells within the intestinal epithelium are highly activated. Lack of expression of receptors for memory CD8$^+$ T-cell survival and proliferation factors indicate that either they will decline over time, that homeostatic proliferation within the mucosa is driven by other cytokines than those that operate to maintain central memory CD8$^+$ T cells, or that the mucosal memory CD8$^+$ T cells are constantly being replaced from the pools of memory CD8$^+$ T cells within the central immune system.

Role of CD8$^+$ T Cells in Viral Infections

CD8$^+$ T cells are crucial to control acute viral infections caused by cytopathic viruses that kill the infected cells. Accordingly cytopathic viruses are either cleared successfully by the immune system or they result in the death of the infected individual. Examples of cytopathic viruses include orthomyxoviruses (influenza virus), paramyxoviruses (mumps virus, measles virus, respiratory syncytial virus), reoviruses (rotavirus), picornaviruses (poliovirus, hepatitis A virus, rhinoviruses), Ebola virus, or poxviruses. In mice, clearance of infections with influenza virus, Theiler virus, HSV-1, Ebola virus (114), and Friends retrovirus depends on CD8$^+$ T cell–derived perforin or granzyme rather than IFN-γ. Clearance of neuronal infections such as measles also requires CD8$^+$ T cells, although within the central nervous system IFN-γ production by CD8$^+$ T cells rather than release of toxic granules is needed to resolve viral infections (115). Neurons lack expression of MHC class I determinants, although such molecules are induced by IFN-γ. Neurons have limited capacity for self-renewal, and it is tempting to speculate that viral inhibition by antiviral cytokines is more beneficial to the host than killing irreplaceable neutrons. The relative paucity of MHC class I determinants on neurons may favor cytokine release over directly lytic mechanisms.

Noncytopathic viruses can establish very long-lasting infections and successfully evade complete destruction by immune effector mechanisms. CD8$^+$ T cells are instrumental in controlling such infections. A role for CD8$^+$ T cells in controlling infections with retroviruses was documented in nonhuman primates infected with a chimeric simian/human immunodeficiency virus, which, like HIV-1, infects CD4$^+$ cells and causes their eventual loss (116). Similarly, in human HIV-1 patients, protection against CD4$^+$ T-cell loss and control of viral load is correlated with the functionality of virus-specific CD8$^+$ T cells.

HPVs can cause persistent infections upon integration into the host cells' genome. Most types of HPV cause harmless proliferation of keratinocytes in the skin or the genital mucosa. Skin warts, which are common in children, often regress spontaneously, presumably upon activation of an immune response. Genital warts that are highly infectious can be treated either surgically or by topic application of interferon. Genital infections with oncogenic types of HPV, most notably 16 and 18, are cleared by most patients rapidly as a result of cellular immune responses to the early viral proteins. Some patients develop persistent infections, which after years of latency can lead to cervical cancer. Immunosuppressed women have a significantly higher incidence of cervical cancer, indicating that viral clearance is mediated by cellular immune responses.

HCV, a flavivirus, and HBV, a hepadnavirus, can establish persistent hepatic infections that cause chronic inflammatory liver disease and liver failure or hepatocellular carcinoma. It is currently not clear why a fraction of patients develop persistent infections whereas others clear the viruses completely during the acute infection. Patients chronically infected with HBV have relatively weak CD8$^+$ T-cell responses to this virus, which may contribute to the lack of complete eradication of virus-infected cells. In contrast, carriers of HCV have vigorous CD8$^+$ T-cell responses to multiple viral antigens. HCV mutates more rapidly than HBV, and the resulting viral variants may continuously escape immune-mediated destruction. During chronic infections, CD8$^+$ T cells control the viral load and at the same time contribute to liver injury. Patients with chronic hepatitis virus infections are currently treated with type 1 IFN, which in some but not all patients results in clearance of the virus-infected cells.

Some strains of LCMV can cause chronic infections in mice. In these mice, LCMV-specific CD8$^+$ T cells become exhausted and cease to function. Exhausted T cells express PD-1, and elegant studies by the Ahmed group showed that treatment of mice with monoclonal antibodies that block PD-1/PD-L1 interactions can restore CD8$^+$ T-cell functions, which in turn results in a reduction of virus titers in infected tissue, again proving that CD8$^+$ T cells are required to control chronic infections.

Persistent infections, which are characterized by periodic production of low levels of virus such as seen with most types of herpes virus, do not appear to impair T-cell functions, although they may take a toll on the overall capacity of the immune system as a result of very high frequencies of CD8$^+$ T cells activating over time, thus reducing the number of T cells available for other infections. Chronic infections during which large numbers of virus particles are produced each day, on the other hand, do impair T-cell functions over time, which in the extreme can lead to CD8$^+$ T-cell exhaustion. Attempts to improve the outcome of chronic viral infections through vaccination should take this into account, as immunization with additional antigen without signals that readjust the impairment of the CD8$^+$ T cell responses are unlikely to be of benefit to the host.

The role of memory CD8$^+$ T cells in protecting against reinfection remains debated. Once an individual has cleared an infection, the ensuing immune response in general provides life-long protection against the same virus. This was already appreciated in ancient history. In China, during smallpoxvirus epidemics, patients were inoculated with scab material from infected individuals because it was known that this would provide long-term resistance to a natural infection. Needless to say, this practice killed many and was eventually abandoned. In 1781, a measles epidemic struck the isolated islands of Faeroe off the coast of Scandinavia. Once the epidemic ran its natural course,

Faeroe did not re-encounter this pathogen until 65 years later, when a new epidemic infected nearly every one of its inhabitants except for the elderly population that had been infected more than six decades earlier. Immunologic memory is long-lived and provides protection against some pathogens for life without further encounter of the antigen.

What is not clear is whether and to what degree different adaptive immune mechanisms contribute to this long-lasting protection in humans. In many viral infections, CD8$^+$ T cells do not appear to prevent reinfection, and resistance is linked to virus-neutralizing antibodies. For example, different strains of influenza A viruses show heterogeneity of their surface antigens, which bind neutralizing antibodies. Their internal proteins, which carry T-cell epitopes, are relatively conserved. Humans infected with a given strain of influenza virus are rendered resistant to reinfection with the same virus, but remain susceptible to infection with a serologically distinct influenza A virus even if this virus shares T-cell epitopes with the initially infecting strain. The same applies for infections with adenoviruses. Fifty-six serotypes of adenovirus have been identified in humans to date. They cause a variety of symptoms ranging from mild to deadly respiratory infections, gastroenteritis, or conjunctivitis. Adenoviruses are grouped into six families, and members of each family show extensive sequence homology (>90%). Most of the sequence variability is seen in the viral hexon, which binds neutralizing antibodies. Humans infected with one serotype of adenovirus are rendered resistant to reinfection with the same serotype but remain fully susceptible to infection with a different serotype even if this serotype belongs to the same subfamily. Both of these findings suggest that CD8$^+$ T cells are inefficient to protect against a second infection, although there is some evidence that humans with high frequencies of circulating CD8$^+$ T cells to influenza A virus develop relatively milder forms of disease following infections with a serologically different influenza virus strain (117). Both influenza A viruses and adenoviruses cause infections that are limited to the respiratory tract, the intestinal tract, or the eye. Although this remains to be confirmed experimentally, one could postulate that CD8$^+$ T$_{EM}$ cells that home to these compartments are required for solid protection, and that this subset of T cells is relatively short-lived and differentiates over time into T$_{CM}$, which home to lymph nodes. In other viral infections, when viruses are spread throughout the organism or infect lymphatic tissues, long-lived T$_{CM}$ may provide better protection against infection-associated disease. In one of his articles, Rolf Zinkernagel compared memory CD8$^+$ T cells to an urban police force that tries to protect taxpayers from thieves (118). The police cars mainly cruise on highways, so thieves who target houses in little alleys (the equivalent of tissues) get away, for by the time the victim calls the police and they actually arrive, the deed is done. Police may happen to cruise by a robbery of a store next

to a major highway (the equivalent of viremia, i.e., virus in the bloodstream), notice that something is amiss, and apprehend the culprits. Thieves that are dumb enough to rob the police station (the lymphatic tissues) would most likely be stopped instantly unless the police are totally incompetent (impaired immune system).

Answers to the question of whether and to what degree antigen-specific memory CD8[+] T cells can prevent viral infections are needed in order to develop effective vaccines to viral pathogens that continue to take a major toll on human lives. One example is HIV-1. Currently available vaccines to many other viral agents provide protective immunity mainly through the induction of circulating virus-neutralizing antibodies. Passive transfer studies have indicated that neutralizing antibodies to HIV-1 can protect nonhuman primates from an experimental mucosal infection with a pathogenic chimeric simian/human immunodeficiency virus (119). Unfortunately, attempts to generate vaccines that express the HIV-1 envelope protein in a form able to induce protective titers of broadly cross-reactive HIV-1–neutralizing antibodies have failed thus far (120), and current vaccine efforts are focused mainly on inducing protection through T cells directed against more conserved epitopes of HIV-1 (121). Unfortunately, it is unknown if vaccine-induced T cells can indeed prevent infections, or at least reduce viral setpoint loads and thus lessen progression to disease and further spread of the virus.

Vaccines against influenza A virus used annually against the prevailing human strains are available. They induce protective immunity through the induction of subtype-specific neutralizing antibodies. The most commonly used vaccines are based on whole, subunit, or surface (HA + NA) formulations of influenza virus grown in embryonated chicken eggs. Vaccines are usually trivalent, containing two strains of influenza A and one strain of influenza B virus. As influenza vaccines induce protection through strain-specific neutralizing antibodies, vaccine composition is reviewed annually and updated to incorporate antigenic drift or shift strains. It takes approximately 6 months to develop sufficient stockpiles of an influenza virus vaccine, so new vaccine compositions are designed in spring to have the annual vaccines available to prevent the seasonal influenza virus outbreaks that typically occur in winter.

Influenza virus pandemics are caused by newly evolved strains of influenza A virus. Advanced stockpiling of a pandemic influenza virus vaccine is unrealistic, as the vaccine's antigen composition, especially that of HA and NA, must closely resemble the pandemic strain. Once such a strain has evolved, it is expected to spread throughout the world within less than 6 months, overwhelming production capacity of vaccine manufacturers. Rather that relying on rapid production of traditional vaccines to induce protection through stimulation of type-specific neutralizing antibodies, and for which precise knowledge of the molecular composition of the coming pandemic influenza A virus

strain is a prerequisite, one could develop and stockpile vaccine compositions that induce CD8[+] T cell–mediated cross-reactive protection against heterotypic strains of influenza A virus. Such vaccines provide resistance to heterotypic strains of influenza virus in experimental animals, but it is unknown whether and to what degree such T-cell–inducing vaccines would protect humans against influenza A virus–associated disease.

CD4[+] T Cells

CD4[+] T cells have regulatory functions; CD4[+] T-helper cells promote activation of B and CD8[+] T cells, while CD4[+] regulatory T cells inhibit the induction or the effector functions of such responses.

Antigen Processing and Presentation for CD4[+] T-Cell Activation

CD4[+] T cells recognize peptides displayed by MHC class II molecules (122). Although MHC class I and II molecules are closely related structurally, their peptide-binding grooves are distinct. The MHC class I groove is closed at both ends, which limits access to peptides of 8 to 10 amino acids in length, whereas the MHC class II groove is open at both ends, permitting association with peptides of varied lengths. Unlike MHC class I molecules, which are displayed on nearly all nucleated cells, MHC class II expression is restricted to a small subset of cells such as macrophages, B cells, and DCs. Upon synthesis of the α and β subunits, MHC class II molecules assemble in the ER into a nonameric complex composed of three α chains, three β chains, and three invariant chains. Binding of the invariant chain stabilizes the overall structure of the complex. The invariant chain contains a peptide sequence termed CLIP (Class II–associated invariant peptide) that binds promiscuously to the groove of MHC class II dimmers, thus preventing binding of other peptides within the ER. The MHC class II–invariant chain complexes are translocated to endosomes/lysosomes, where proteins taken up from the extracellular domain are broken down by disulfide reduction and enzymatic proteolysis. Within the endosomes the invariant chain, which blocks access of peptides to the MHC class II groove, is degraded by cathepsin S. Upon dissociation of the invariant chain, an accessory protein termed DM associates with the N-terminal part of the peptide-binding groove. DM is then replaced with an antigenic polypeptide. These polypeptides can be short and fit readily into the groove, or they can be quite large, with long chains extending beyond the groove at either end. The portions of the polypeptides that fit into the groove are protected from proteolysis, while the overhanging parts are removed by cleavage. The MHC class II peptides complexes are then transported to the cell surface. In immature DCs, most MHC class II

molecules are stored within the endosome and are released to the cell surface once DCs receive a maturation signal. Although immature DCs constantly synthesize MHC class II molecules to replace those that are degraded in the endosomes/lysosomes, mature DCs shut off synthesis of MHC class II molecules and rely on the long (>10 hours) half-life of cell surface–expressed and recycled MHC class II molecules to present antigen to CD4+ T cells.

CD4+ T-Cell Responses

Activation of naïve CD4+ T cells requires presentation of antigen by MHC class II molecules in context of the co-stimulatory molecules CD80 and CD86 and the adhesion molecule CD54 (123). Upon antigen recognition, CD4+ T cells proliferate in response to autocrine IL-2. Proliferation of CD4+ T cells is not as extensive as that of CD8+ T cells, and during most infections the frequencies of specific CD8+ effector T cells exceed those of CD4+ T cells. It has been estimated that CD4+ T cells undergo approximately 8 to 10 cycles, whereas CD8+ T cells can cycle 20 times or more, depending on the scope of the infection. Activation and proliferation of CD4+ T cells is augmented by proinflammatory cytokines such as IL-1, IL-6, and TNF-α, which are produced by cells of the innate immune system in response to viral infections. The type of activation determines CD4+ T-helper cell polarization into Th1- or Th2-type cells; Th1 cells are induced in the presence of IFN-γ and IL-12 or agents that block IL-4, whereas Th2 cells develop in the presence of IL-4. Once T cells commit to either pathway, epigenitic imprinting of the chromatin ensures the stability of this phenotype.

Virus infections induce both Th1 and Th2 cells. Th1 cells secrete IL-2, IFN-γ, and TNF-α; Th2 cells produce IL-4, IL-5, IL-10, and IL-13. Some viruses, such as measles virus, induce a non-antigen–specific global shift toward Th2, resulting in transient suppression of Th1-linked immune responses (124). Once CD4+ T cells are activated in the T-cell–rich zones of the lymph nodes, they are ready to commence effector functions. Within the lymph nodes, CD4+ T cells are needed for formation of germinal centers at which CD4+ T cells interact with B cells through CD40–CD40 ligand interactions. CD4+ T-cell–derived cytokines are instrumental for isotype switching of B cells. In mice, Th1-cell–derived IFN-γ promotes switching to IgG2a, whereas Th2-derived IL-4 preferentially induces IgG1 switching. CD4+ T-cell–derived cytokines also drive proliferation of B cells and their differentiation into long-lived antibody-secreting plasma cells. As mentioned previously, some of the cytopathic viruses, such as LCMV, sendai virus, influenza virus, or ectromelia virus (a mouse poxvirus), can induce CD8+ effector T cells without CD4+ T help, although the help is required for efficient memory CD8+ T-cell formation. Other viruses, such as mouse hepatitis virus, HSV, or adenoviruses, only elicit a CD8+ T-cell

response in the presence of functional CD4+ T cells. CD4+ T cells help differentiation of naïve CD8+ T cells into effector cells by providing activation signals to DCs and by secretion of growth factors, most notably IL-2, which promotes CD8+ T-cell proliferation and under certain circumstances CD8+ T-cell survival.

Once they are activated, CD4+ T cells downregulate CCR7 and CD62L, which allows their migration to peripheral tissues. In the periphery, CD4+ T cells can contribute to viral clearance either indirectly, through the release of antiviral cytokines produced in response to viral peptides displayed on MHC class II–positive cells, which are dispersed throughout most tissues and accumulate at sites of inflammation, or directly, by killing infected MHC class II molecule–expressing cells. MHC class II antigens are constitutively expressed on some cells such as B cells, and it has been shown that CD4+ T cells can kill Epstein–Barr virus (EBV)–infected B cells (125). In other cell types that normally fail to express MHC class II, expression can be induced by cytokines such as IFN-γ. Following the effector phase, CD4+ T-cell responses contract, and about 10% of the cells survive to form the memory CD4+ T-cell pool (126). Whereas contraction of CD8+ T cells occurs very rapidly, within a few days, CD4+ T cells undergo activation-induced cell death over a period of several weeks. Similarly to CD8+ T cells, memory CD4+ cells can be grouped into T_{EM} and T_{CM} memory cells, which can be differentiated based on expression levels of CD62L and CCR7. Memory CD4+ T cells are maintained at constant levels through IL-7–regulated homeostatic proliferation. Nevertheless, the longevity of CD4+ T-cell memory and its dependence on antigen remains debated. Upon re-encounter of antigen, memory CD4+ T cells proliferate and differentiate into effector T cells. Memory CD4+ T cells assume effector functions more rapidly than naïve T cells, in part through storage of RNA for key cytokines and chemokines, which are available for immediate translation once the T-cell receptor has been engaged. Reactivation of memory CD4+ T cells is relatively independent of costimulation, allowing for reactivation by antigen-presenting B cells or macrophages. Notwithstanding, costimulation affects the quality of the recall response; CD4+ T cells activated in the absence of costimulation proliferate and produce IL-2 but fail to produce IFN-γ and are poorly suited to assist reactivation of CD8+ T cells.

Role of CD4+ T Cells in Protection against Viral Infections

In adoptive transfer studies in which naïve mice were injected with T-helper cells generated *in vitro*, CD4+ T cells have been shown to protect against a subsequent pulmonary challenge with a lethal dose of influenza A virus. Protection was in part mediated by perforin, suggesting that the T-helper cells eliminated infected cells by direct

killing. Protection was also linked to an accelerated antibody response (127). Earlier studies showed that selective presence of CD4$^+$ T cells in the absence of CD8$^+$ T cells or neutralizing antibodies increases influenza virus–associated immunopathology and thus mouse mortality following infection (128). In other mouse models of viral infections, CD4$^+$ T cells were also shown to contribute to protection, commonly acting in concert with CD8$^+$ T cells. One would expect that because of their restricted recognition of cells that express MHC class II, CD4$^+$ T cells would be poorly suited to single-handedly control virus infections unless such infections are limited to MHC class II–positive cells. Their primary role is indirect; they facilitate stimulation of naive CD8$^+$ T cells, assist in memory CD8$^+$ T-cell development, and promote antibody responses.

Regulatory CD4$^+$ T Cells

The notion of T cells that suppress activation of adaptive T cells was first proposed in the 1970s (129). These cells were supposed to act through complicated idiotypic–anti-idiotypic receptor interactions in which antigen-specific (that is, idiotypic) receptors on effector T cells induced T cells with corresponding anti-idiotypic receptors that then released suppressor factors. The suppressor T cells could never be isolated, and the experimental evidence for their existence was circumstantial. Experiments that were conducted to prove the existence of suppressor T cells were so complex that artifacts were probable. By the late 1970s the majority of immunologists concluded that suppressor T cells were a product of fantasy and poor experimentation, and for two decades manuscripts that described suppressor T cells or grant applications that proposed to study such T cells were viewed with scorn. In the mid-1990s, suppressor T cells were finally isolated. To avoid public ridicule, they were termed regulatory T cells (129,130). A number of cell subsets can have immunomodulatory functions, including NK cells and CD8$^+$ T cells. By far the best-studied populations of regulatory cells are two subsets of CD4$^+$ T cells; one subset is constitutively present and is termed natural Treg, while the other is induced by antigen and is called Tr.

Natural Treg are CD4$^+$CD25$^+$CTLA-4$^+$GITR$^+$ and express the transcription factor forkhead box (Fox)p3 (131,132). They comprise approximately 5% to 10% of the circulating pool of CD4$^+$ T cells. Natural Treg respond to self-antigens and are crucial to maintain tolerance. They play a role in infectious diseases by reducing the magnitude of primary immune responses, by limiting effector T-cell functions, and by reducing secondary immune responses. Treg recognize antigen through polyclonal T-cell receptors, and it is assumed that their receptors that respond primarily to self-antigens cross-react with antigens expressed by pathogens. They control adaptive immune responses through secretion of anti-inflammatory cytokines such as IL-10 or TGF-β, through modulation of DCs, and through direct cell-to-cell contact. Treg express TLRs including TLR-7 and -8 and are activated by infectious agents. After activation, they migrate to the sites of infection. Mice that lack Treg are better able to control viral infections, but they are also prone to more damaging immune responses, indicating that Treg activity reduces immunopathology, which in turn can allow for more extensive and prolonged survival of infectious agents and for the development of persisting infections. This has been documented for a number of bacterial infections and for HCV, for which the degree of liver inflammation in humans correlates inversely with frequencies of circulating Treg. During ocular infections with HSV, CD4$^+$ T cells cause severe blinding infections of the eye in the absence of Treg. That Treg reduce the adaptive immune system's ability to eliminate infected cells and consequently promotes persistence of the pathogen was also shown in mice chronically infected with Friend leukemia virus, in which depletion of Treg restored CD8$^+$ T-cell functions, resulting in a reduction of viral loads.

Antigen-induced suppressor T cells are commonly referred to as Th3 or Tr cells (133). They appear to be triggered preferentially upon mucosal immunization, presumably to prevent induction of immune responses against antigens present in food or inhaled air. Tr cells are induced by DCs and preferentially by mucosal DCs that are not fully matured and secrete IL-10. This immunosuppressive cytokine appears also to favor Tr induction if it is derived from other cell types. For example, nonstructural proteins of HCV induce monocytes to produce IL-10, which in turn promotes Tr activation. Other cytokines, such as IL-4, IL-6, and TGF-β, have been implicated to sponsor Tr differentiation. The role of Tr cells during viral infections appears to be similar to that of CD4$^+$CD25$^+$ Treg. Tr cells inhibit T-cell responses and thus infection-associated immunopathology, which in turn promotes viral persistence.

B Cells

B cells recognize viral antigens through cell surface–expressed receptors, which are membrane-anchored immunoglobulin molecules. Upon virus infection, antigen is translocated by DCs to the T-cell zones of lymph nodes draining the sites of infection. Here they induce antigen-specific CD4$^+$ T cells, which, once activated, migrate to the T/B interphase of the primary B-cell follicles. Naïve B cells can pick up their antigen through specific cell surface–expressed IgM. The antigen is internalized and degraded within the lysosomes/endosomes into peptides that, provided they have suitable anchoring residues, associate with MHC class II molecules. The peptide/MHC complexes are transported back to the cell surface. Once B cells receive activation signals through PAMPs, they move to the T/B border of the follicles, where they interact with

CD4[+] T cells that recognize the MHC/peptide complex on the B cells' surface. T-cell help requires direct interactions between T and B cells in which CD40 expressed on B cells binds to CD40 ligands expressed by T-helper cells. A number of other surface molecules on B cells and their corresponding ligands on T cells participate in forming the synapse between activated T cells and naive B cells. Cytokines secreted by activated CD4[+], such as IL-4 and IL-6, are also required for B-cell proliferation and differentiation. Once B cells are primed, they migrate to the T-cell zones and develop into short-lived plasma cells, or they return to the B-cell zones, where they initiate formation of germinal centers. In either case, isotype switching occurs through genetic rearrangement of the immunoglobulin genes. Hypermutation, on the other hand, happens only in B cells that differentiate into long-lived plasma cells. Short-lived plasma cells start to secrete antibodies within 3 to 5 days but then die rapidly. B cells that return to the B-cell zones undergo more massive proliferation, creating regions that are called secondary follicles, which eventually form the germinal centers. Formation of germinal centers requires T-cell help. Within the germinal centers, B cells undergo affinity maturation through hypermutation of their immunoglobulin (Ig) variable-region genes. B cells with deleterious Ig mutation die by apoptosis, while those that produce antibodies with increased affinity to the antigen continue to proliferate. T-helper cells are present in the germinal center and are thought to deliver signals to promote B-cell memory formation.

Two other B-cell subsets have been described in addition to the B cells that home to the B-cell–rich areas of lymphatic tissues. One subset, which is commonly found in the peritoneal cavity, carries an activated phenotype, presumably due to interactions with self-peptides. These B cells secrete IgM and IgG3 and are the source of naturally occurring antibodies that are found in naïve animals (134). Natural antibodies play a crucial role in inhibiting early viral dissemination. They are able to form complexes with a wide variety of viral pathogens. Such complexes are selectively retained in lymphoid tissues, facilitating induction of adaptive immune responses and reducing the spread of the pathogen to other vital organs. An additional B-cell subset is found in the marginal zone of the spleen at the juncture of white and red pulp (135). This subset, called marginal-zone B cells, also has a preactivated phenotype and is able to respond very rapidly to viral pathogens by secretion of IgM antibodies. This response, which is independent of T-helper cells, peaks after 3 to 4 days and is then followed by antibodies originating from follicular B cells in lymph nodes and spleens. Once peritoneal-cavity B cells or marginal-zone B cells become activated, they terminally differentiate into plasma cells. They do not contribute to the memory response but instead undergo programmed cell death. B cells have thus evolved to respond very rapidly with "unedited" antibodies of low affinity to

an incoming pathogen. These antibodies are secreted without further input from T-helper cells that are not yet fully activated at this early stage after an infection. A T-helper cell–independent B-cell response has an increased risk for cross-reactivity with self-antigen. To lessen the threat of permanent damage due to auto-antibodies, the B cells that provide early antibodies are not destined to become part of the memory B-cell pool.

B-cell effector functions are mediated by secreted antibodies. B cells can produce five different types of antibodies, IgA, IgD, IgE, IgG, and IgM, which can express the same antigen-binding site but differ in the composition of their constant regions. IgA, IgG, and IgM contribute to the control of viral infections. IgM is produced first and is then, over time, replaced by IgG upon isotype switching. IgGs are most commonly found in blood, and they are divided into four subtypes. All IgGs with the appropriate specificity can prevent infection of cells by neutralizing viruses. Antibodies can lyse virus particles directly, or they can activate the complement cascade to disrupt the viral membrane. Human IgG3 is particularly effective at activating complement. IgGs can also facilitate uptake of viruses by Fc receptor–positive phagocytes, which degrade the virus. IgA has similar functions to IgG but can be transported actively across epithelial surfaces, allowing for its secretion at mucosal surfaces. IgA is thus crucial for protection against pathogens that invade through the mucosal epithelium.

B cells terminally differentiate either into antibody-producing plasma cells or into memory B cells (136). Memory B cells are long-lived and persist for many years. It is unknown whether this survival involves homeostatic proliferation or whether individual cells have an extended lifespan. Survival of memory B cells requires expression of the B-cell receptor, which led to the notion that periodic receptor engagement is required through low-affinity interaction with cross-reactive self-proteins or through periodic exposure to antigen. Antigen can form very stable complexes with antibodies, and such complexes can be captured by Fc receptors expressed on follicular DCs within lymphatic tissues, from where they are released slowly over a long period of time. These small amounts of antigen may suffice to maintain memory B cells.

Antibodies have short half-lives. Nevertheless, after viral infections, specific antibodies can commonly be detected years later. This suggested that antibody-producing plasma cells are maintained for a very long time, either through longevity or by periodic activation of memory B cells through exposure to antigen. Plasma cells die rapidly in culture, and it was initially assumed that they were short-lived and that antibody titers were maintained through constant antigen-driven activation by memory B cells. Subsequent studies showed that plasma cells that home to bone marrow are long-lived. Their survival depends on IL-6 and on interactions with bone marrow

stromal cells. An alternative pathway to maintain antibody-producing plasma cells has been proposed; during infections with unrelated pathogens that carry PAMPs, memory B cells receive signals through PRRs such as TLRs, which drives antigen-independent differentiations of memory B cells into antibody-producing plasma cells (137).

Antiviral antibodies play a role in primary infections. Pre-existing natural antibodies provide an immediate layer of defense, which is rapidly joined by antibodies secreted by marginal-zone B cells or B cells that reside outside lymphoid tissues. Peak production of affinity-matured antibodies takes up to 2 weeks, and such antibodies would not be expected to play a dominant role in primary infections, although they are crucial to ward off secondary infections. Most antiviral vaccines are based on the concept that circulating IgG antibodies or IgA antibodies secreted at mucosal surfaces prevent infections by immediately neutralizing viral pathogens. Under ideal conditions such neutralization leads to so-called sterilizing immunity, in which none of the virus particles are able to infect host cells. Protection by neutralizing antibodies has been documented for rabies virus, influenza A virus, poliovirus, human papillomavirus, and many others. Nonneutralizing antibodies also contribute to protection. For example, antibodies to the ectodomain of the matrix protein of influenza A virus lack neutralizing activity but can nevertheless prevent fatal infection with influenza A virus in animal models (138). Sexually transmitted viruses cross the epithelial cell layer of the genital tract by transcytosis. This can be blocked intracellularly by IgA antibodies, as was shown in experimental SIV infections of nonhuman primates (139).

Antibodies of the IgG isotype are transferred from females to their offspring through transport across the placenta. After birth, IgAs and IgGs are secreted in breast milk and are taken up by the infants' intestines, which are highly permeable shortly after birth. The immune system of newborns is relatively incompetent, and during the time needed for the neonatal immune system to mature, maternally transferred antibodies provide protection against common pathogens. R. Zinkernagel has argued that immunologic memory evolved solely to protect newborns through maternal antibodies (140). He argues that anyone who survives a first infection is likely to be of sufficient genetic fitness to survive a second infection with the same pathogen and that therefore immunologic memory does not offer a survival advantage to a species. One could counterargue that most common infections strike in childhood. Individuals who develop protective immunologic memory against common infectious agents have a far better chance to reproduce successfully once they are sexually mature than those who are constantly ill because of crippling infections with viruses, which not only affect the desire of the prospective parents to become parents but are also commonly transmitted across the placenta, causing abortion or malformations of the fetus.

Autoimmunity/Allergies and Viral Infections

Although epidemiologic data implicate pathogens as causative agents for autoimmune diseases, a direct infectious etiology has yet to be proven. Evidence implicating viruses or bacteria in triggering destructive responses against self-antigens remains circumstantial, at least in a clinical setting. Direct evidence has been gained in transgenic mouse models in which T-cell–receptor transgenic mice that express the corresponding antigen in selective tissues were shown to develop autoimmunity upon stimulation of the T cells by external addition of antigen (141).

Several mechanisms can be envisioned for viruses to cause autoimmune responses. Some viruses cause polyclonal activation of adaptive immune responses, which could lead to inadvertent activation of T and/or B cells with self-reactive receptors. Such polyclonal activation signals may be provided by so-called superantigens that are expressed by some bacteria or viruses (142). Superantigens can activate CD4$^+$ T-cell responses without processing and presentation by MHC class II molecules. They bind to MHC II molecules directly, outside the conventional peptide-binding groove, and then interact with the variable region of the β chain of the T-cell receptor. Each superantigen can bind to a number of different Vβ chains and cause activation of the corresponding CD4$^+$ T cells independent of their antigen specificity. A superantigen can thus activate up to 25% of the entire CD4$^+$ T-cell repertoire, resulting in fulminate cytokine release, which can cause toxic shock and death. A number of viral antigens have superantigen activity, such as the nucleoprotein of rabies virus, nef of HIV-1, and a yet-to-be-identified component of EBV. The polyclonal activation of T cells by contact with superantigens is thought to lead to stimulation of self-reactive T cells that are otherwise kept in check through negative immunoregulatory mechanisms.

Antigenic mimicry, in which a viral antigen resembles a self-antigen, could also elicit autoimmune responses (143). Bioinformatic searches for sequence homology between viral proteins and self-proteins show that such homologies are quite common. For example, a sequence in Coxsackie B virus is homologous to one in glutamic acid decarboxylase (GAD), a protein expressed by insulin-producing pancreatic islet cells. Antibodies to GAD are linked to type I diabetes, and Coxsackie B virus has been shown to trigger loss of insulin production in animals. The polymerase of HBV mimics myelin basic protein, and immunization of rabbits with the shared peptide sequence induces pathology that resembles allergic encephalomyelitis. Nevertheless, in humans, neither multiple sclerosis (which is similar to allergic encephalomyelis) nor type I diabetes has been linked

to specific infections, which may in part reflect the long latency between a certain infection and overt symptoms caused by either autoimmune disease.

Organ-specific autoimmunity may be caused by local viral infections in which the strong inflammatory response to viral antigens promotes presentation of self-antigens. For example, upon infection with Theiler virus, mice develop a virus-associated encephalomyelitis in which T cells respond to the antigens of the virus. This is replaced by T cells recognizing myelin basic protein or proteolipid protein, causing continued neurologic damage (144). Infection of mice with Coxsackie B3 viruses causes cardiomyopathy that develops in two stages: at first, virus-specific T cells develop and damage the infected cells; they are then replaced by an even more destructive autoimmune T-cell response (145). In either model, the damage caused by antigen-specific T cells is limited to clearance of infected cells, but the associated inflammation triggers self-reactive T cells, which prolong and exacerbate disease.

Viral and bacterial infections have not only been implicated in causing autoimmunity, they are also thought to protect against autoimmunity and allergy (146). In the last 30 years, developed countries have experienced a steady and alarming increase in autoimmune diseases and allergies. This epidemic is not seen in undeveloped countries, and it is more pronounced in colder countries than in warmer countries. Although these allergies and autoimmunity have opposing underlying mechanisms, with allergies being basically a misguided Th2 response while autoimmunity is associated with Th1 responses, epidemiologic evidence shows that their prevalence is linked to increased hygiene and decreased infections. One could postulate several mechanisms for this linkage. One could argue that adaptive immune responses against strong antigens of pathogens will outcompete the comparatively weaker immune responses to self-antigens or allergens. One could argue that immune responses to infectious agents increase negative regulatory responses that dampen adaptive immunity to strong antigens and abolish weaker responses to self-antigens or allergens.

IMMUNOEVASION BY VIRUSES

Viruses and their hosts coevolved through the millennia. While the hosts developed a more sophisticated immune system to limit damage inflicted by viral infections, viruses changed in tandem and acquired traits that allowed them to dodge destruction by their hosts' immune responses. RNA viruses, which have small genomes, primarily but not exclusively evade by rapid mutations caused by the infidelity of their replication machinery that lacks the proofreading capacity of mammalian polymerases. Although lack of faithful genome replication is costly in that many of the resulting viruses lack the fitness of the par-

ent virus, in the end it serves the virus population, which produces thousands of new infectious viruses from each original virus and can thus afford to lose some to defective genomes. The larger, more complex DNA viruses have the space to devote a significant percentage of their genome to encode polypeptides that allow their evasion from the forces of the hosts' immune systems. Considering the size limitations of the genomes of even the larger viruses, the multitude of genes that serve to subvert immune responses must clearly provide them with an evolutionary advantage. Also, pathways that are targeted by viruses give insight to immunologists to what degree such pathways play a role in the immunologic defense against viruses.

Escape by Hiding

Viruses can hide by changing their molecular shape through mutations that modify sites targeted by antibodies, T-cell receptors, or antiviral cytokines. In the face of neutralizing antibodies, viral variants, also termed quasispecies, are selected for that have lost or modified the neutralizing antibodies' target sites, which are generally located on viral surface proteins (147). Selection of viral variants with mutated internal viral proteins is prompted by the activity of T cells (148). The latter is found during HIV-1 or HCV infections, in which, over time, virus particles are selected for that carry mutations in dominant CD8$^+$ T-cell epitopes. IFNs, which have potent antiviral activity, can drive outgrowth of viral mutants with increased resistance to its activity. This has been observed in chronic infections with HCV, in which lack of a response to IFN therapy can be associated with selection of therapy-resistant viral variants (149).

The central nervous system is an immunologically privileged site where viruses are relatively sheltered from the immune system. A number of viruses take advantage of this and establish neuronal infections. A typical example is rabies virus, which multiplies in neurons. Once the virus is ready to be transmitted to the next host, it spreads via axonal flow to the periphery to infect, for example, cells of the salivary gland. Although effector or memory T lymphocytes can cross the blood–brain barrier, the immune system lacks the needed signals in the periphery to efficiently activate rabies virus-specific T cells and is thus incapable of controlling the infection. Herpes viruses can shut off viral protein synthesis upon infection of cells and enter a state of latency. The immune system remains ignorant of latently infected cells that do not express viral antigens. This allows the virus to evade complete destruction during the height of an acute immune response. Once the immune system assumes a more relaxed stage of memory, the virus can reactivate and replicate unhindered for a few days, until T cells convert from memory cells back to effector cells. These short bursts of viral replication suffice to produce ample amounts of virus to allow its spread to other organisms.

Escape by Destruction of Immune Cells

A number of viruses infect cells of the adaptive immune system, leading to their demise. The best example is HIV-1 virus, which infects and destroys CD4+ T cells (150). This is probably mediated in part by the viral envelope protein, which forms spikes on the surface of the virions that can contribute to killing uninfected CD4+ T cells, susceptible to being killed by cells that express Fas.

Escape from Early Innate Immune Responses

Inhibition of PRR Activation

Innate immune responses are rapidly initiated once a viral PAMP is recognized by a cellular PRR. A number of

viruses, such as poxviruses, HCV, and adenoviruses, have evolved pathways to block activation of cellular inflammatory reactions to their PAMPs (Figure 36.1).

The poxvirus protein N1L interrupts TLR signaling to NF-κB by blocking the TANK-binding kinase (TBK)1, which is part of the TLR–NF-κB and TLR–TRF-3 activation pathways (151). The vaccinia virus A46R protein has a toll-like-interleukin-1 resistance (TIR) domain and inactivates MyD88, a crucial adapter molecule for TLR signaling. In addition, A46R interferes with the activity of TRIF, thus also shutting off MyD88-independent pathways used by TLR-4 and TLR-3. Vaccinia virus protein A52R blocks tumor necrosis–activated factor 6 (TRAF6) and interleukin 1-receptor–associated kinase 2 (IRAK2), inhibiting activation of NF-κB or IRF-3 upon TLR signaling (152).

The single-stranded RNA genome of HCV can form double-stranded hairloops that activate TRL-3 or RIG-1, resulting in activation of NF-κB and IRF-3. The viral protease NS3/4 cleaves the mitrochondrial signaling protein (MAVS), which is downstream of the RIG-1 pathway, thereby blocking interferon induction by its genome. NS3/4 also cleaves TRIF, inhibiting TLR-3 signaling (153).

The A238L protein of African swine fever virus inhibits KF-κB activation by encoding a homolog of IκB (154).

Inhibition of Interferons

Immunosubversion of the interferon pathways by viral proteins is shown in Figure 36.2. Because HCV replication is very sensitive to the antiviral effects of IFNs, the virus developed multiple strategies to interfere with the induction of early proinflammatory cytokine responses, which are induced through several pathways upon HCV infection. The viral NS5A protein induces signaling to activate Stat3, resulting in production of IFN. The viral core protein activates PKR, which shuts off protein synthesis and induces IFN. The genomic PAMP activates TLR-3 and RIG-1. As described previously, the viral protease blocks signaling through either PRR. The HCV core protein inhibits Jak-

Stat signaling by IL-6 (155). The viral NS5A induces IL-8, which through yet-to-be-defined mechanisms inhibits the activity of IFNs (156). In addition, NS5A and E2 inhibit PKR, blocking activation of IFN production through this pathway (157). Furthermore, the HCV genome encodes decoy sequences for RNAseL, protecting its transcript from degradation.

Adenoviruses, which carry a double-stranded DNA genome, encode one or two species of viral-associated RNA that are folded into double-stranded RNA hairloops, which inhibit activation of PKR (158). The ebolavirus VP35 protein prevents production of IFN by blocking phosphorylation of IRF-3 (159). The NS-1 protein of influenza A virus inhibits activation of NF-κB by viral RNA (160). The NSs protein of Bunyamwera virus, which is transmitted by mosquitoes and causes febrile infections in humans, also blocks induction of IFN production through yet-to-be-identified pathways (161).

Viruses of the paramyxovirus family, which is composed of a number of different viruses including sendai virus, human parainfluenza viruses, and mumps virus, have several strategies to abrogate interferon signaling. They can cause proteolytic degradation of Stat-1, thus inhibiting signaling through both type I and type II IFNs. They inhibit
FIGURE 36.2 IFN-regulated genes. IFNAR, interferon α/β receptor; IFNGR, interferon γ receptor 1; IRF, interferon regulatory factor/interferon response factor; JAK, Janus kinase; STAT, signal transducers and activators of transcription; TYK, tyrosine kinase.

formation of transcription complexes essential for IFN signaling or they prevent phosphorylation of serine 727 on Stats, which is needed for their optimal transcriptional activity (162).

HPVs inhibit the activity of interferon through the early proteins E6 and E7 that interfere with cell-cycle regulation in oncogenic types of papillomavirus. The E6 protein binds and inactivates IRF-3 (230). The E7 protein binds to IRF-1 and histone deacetylase, thus silencing the activity of the transactivator on IFN-inducible promoters (163).

IL-18 is a cytokine that, like IL-12, induces IFN-γ production. Molluscum contagiosum virus (MCV) as well as orthopoxviruses secrete IL-18–binding proteins, which prevent the cytokine's interaction with its natural receptor. IL-18 is produced as a precursor molecule that is cleaved by caspase 1 into its active form. The crmA protein of vaccinia virus inhibits the activity of this caspase (164).

Other viral proteins act downstream on the activity of IFN-induced proteins. The M-T7 protein of myxoma virus and the B8R protein of vaccinia virus (both belonging to the poxvirus family) show sequence homology with the IFN-γ receptor (165). Both proteins bind to IFN-γ, inhibiting ligation to its receptor. Vaccinia virus also encodes a type I interferon inhibitor that shows sequence homology with the IFN-1 receptor.

The E3L protein of vaccinia virus inhibits activation of PKR. The K3L protein of vaccinia virus is a homolog of eIF-2, which serves as a decoy for activated PKR (166).

Interference with Other Cytokines/Chemokines

Collectively, herpes and poxviruses encode 40 members of the chemokine receptor family that serve as decoys for chemokines (167). Four proteins of human cytomegalovirus (HCMV), UL33, UL78, US27, and US28, show homology with the CCR1 receptor. UL146 and UL147 of HCMV encode CXC chemokine homologies; mouse CMV (MCMV) encodes a CC chemokine homolog, MC148 protein of Molluscipox virus shows similarity to the CCR8 chemokine receptor. Both leporipox (infectious for rodents) and orthopoxviruses encode secreted proteins (M-T1 and p35, respectively) that have functional homology to chemokine receptors. The M104L protein of poxvirus shows some similarity to MIG, an interferon-induced CXC chemokine. The effect that these different chemokine receptor mimetics have on the innate and adaptive immune responses to pox and herpes viruses remains under investigation. One would assume that sequestration of chemokines will affect leukocyte migration and thus reduce inflammatory reactions to the infections.

Herpes and poxviruses in addition produce proteins that bind or mimic cytokine receptors. The B8R protein of vaccinia virus binds to IFN-γ (168), whereas B18R binds to type I IFN (169). The poxvirus-encoded GIF binds to both GM-CSF and IL-2 (170). Poxviruses encode M135R

(myxoma virus) and B18R (vaccinia virus), two proteins that bind and consequently inhibit IL-1β. The C10L protein of vaccinia virus encodes a protein that blocks the IL-1 receptor. IL-1β is synthesized as a precursor that requires cleavage by caspase 1 to gain functional activity. The same caspase also cleaves the precursor molecule of IL-18. Cowpoxvirus encodes a serine protease inhibitor called crmA that inhibits the function of caspase 1. The activity of crmA is not restricted to caspase 1 but also affects additional caspases involved in apoptosis (171).

Parapoxvirus, which infects sheep and goats, as well as CMV and EBV, encode an IL-10–like protein that inhibits synthesis of IL-12 and thus generation of Th1 immune responses. Similarly, the UL111A open reading frame of HCMV has sequence homology with IL-10 (172). UL146 and 147 of HCMV encode an IL-8–like molecule that may affect lymphocyte trafficking and IFN activity (173). IL-18 mimics are encoded by poxviruses such as molluscum contagiosum, ectromelia, cowpox, or vaccinia viruses (171). Kaposi sarcoma–associated herpes virus (KSHV), also called human herpes virus 8 (HHV-8), encodes an IL-6–like protein (174).

HCMV encodes UL144, which is a homolog of the TNF-receptor (TNFR) supergene family [222]. Its functions are currently unknown. Shope fibroma virus and myxoma virus encode a single TNFR homolog called T2 (223), whereas orthopoxviruses encode one to three different TNFR homologs called crmB, crmC, and crmD (224). T2, crmB, and crmD bind TNFI and lymphotoxin A, whereas crmC associates only with TNFα. T2, crmC, and crmD block TNFα−mediated cell lysis. The T2 protein in addition prevents apoptosis of CD4$^+$ T cells. This activity is independent of TNF-α (175).

Inhibition of NK Cell and Macrophage Activity

Cells infected with some viruses have reduced MHC class I surface expression and become susceptible to lysis by NK cells. In order to avoid this destruction by NK cells, some viruses either selectively spare downregulation of certain types of MHC, they encode MHC class I homologs, they directly inhibit the activating receptors on NK cells, they reduce recruitment of NK cells by interfering with chemokines as described earlier, or they affect NK cells directly (176) (Figure 36.3). MCMV and HCMV encode two proteins, m144 and UL18, which serve as MHC class I decoys. MCMV m157 interacts with inhibitory and activating NK receptors; in MCMV-resistant strains of mice, m157 is a ligand for the NK-activating Ly49H receptor, whereas in susceptible strains of mice it binds the inhibitory Ly491 receptor. HCMV proteins US2, US3, US6, and US11 downregulate the expression of most types of HLA molecules. They do not impair HLA-C and HLA-E expression, which are the dominant ligands for the inhibitory receptors of NK cells. Cell surface expression of HLA-E is generally
FIGURE 36.3 Immunopathogenesis of malaria.

TAP-dependent. In uninfected cells, HLA-E presents a peptide present in the signal sequence of HLA-C. Processing of this peptide, needed for its transport into the endoplasmic reticulum for binding to HLA-E, requires TAP, which is inhibited in HCMV-infected cells. The signal sequence of UL40, another HCMV-encoded protein, carries a sequence with a potential binding motif to HLA-E. It is possible that this peptide associates with HLA-E independently of TAP, thus allowing its translocation to the cell surface. KSHV encodes K3 and K5, which reduce MHC class I expression by causing their rapid endocytosis and degradation in lysosomes. Although K3 reduces expression of all of the HLA class I molecules, K5 selectively downregulates HLA-A and HLA-B but spares HLA-C and HLA-E. The *nef* gene of primate lentiviruses such as HIV-1 or SIV encodes a protein that acts in a similar way; it selectively downregulates expression of HLA-A and HLA-B but not of HLA-C or HLA-E.

Viruses not only increase the strength of inhibitory signals to NK cells but also interfere with activating receptors. HCMV downregulates expression of LFA-3, an adhesion molecule that binds to CD2 on NK cells. MCMV encodes a protein m152 that reduces expression of H60, a ligand for the NK-cell–activating receptor KG2D. N5 of KSHV reduces expression of ICAM-1 and CD86, which can both

serve as ligands for activating NK receptors. NKG2D, one of the activating receptors of NK cells, binds to the UL16-binding protein (ULBP), which triggers the release of toxic granules. HCMV encodes UL16, which can bind ULBP and thus prevent its interaction with NKG2D. The tat protein of HIV binds to a calcium channel on NK cells, which blocks calcium influx and calcium-calmodulin kinase II, which is needed for NK-cell cytotoxicity.

Some viruses, such as HSV and HIV, can infect and kill NK cells directly. The major envelope protein E2 of hepatitis C virus binds to CD81, which in turn inhibits NK-cell activation and effector functions (177).

Activated phagocytes in particular macrophages produce inducible nitric oxide synthase (iNOS), which generates nitric oxide, a compound with antimicrobial functions. Production of iNOS is induced by type I IFNs, and viruses indirectly reduce iNOS production by interfering with the type I IFN pathways.

Inhibition of Complement Activation

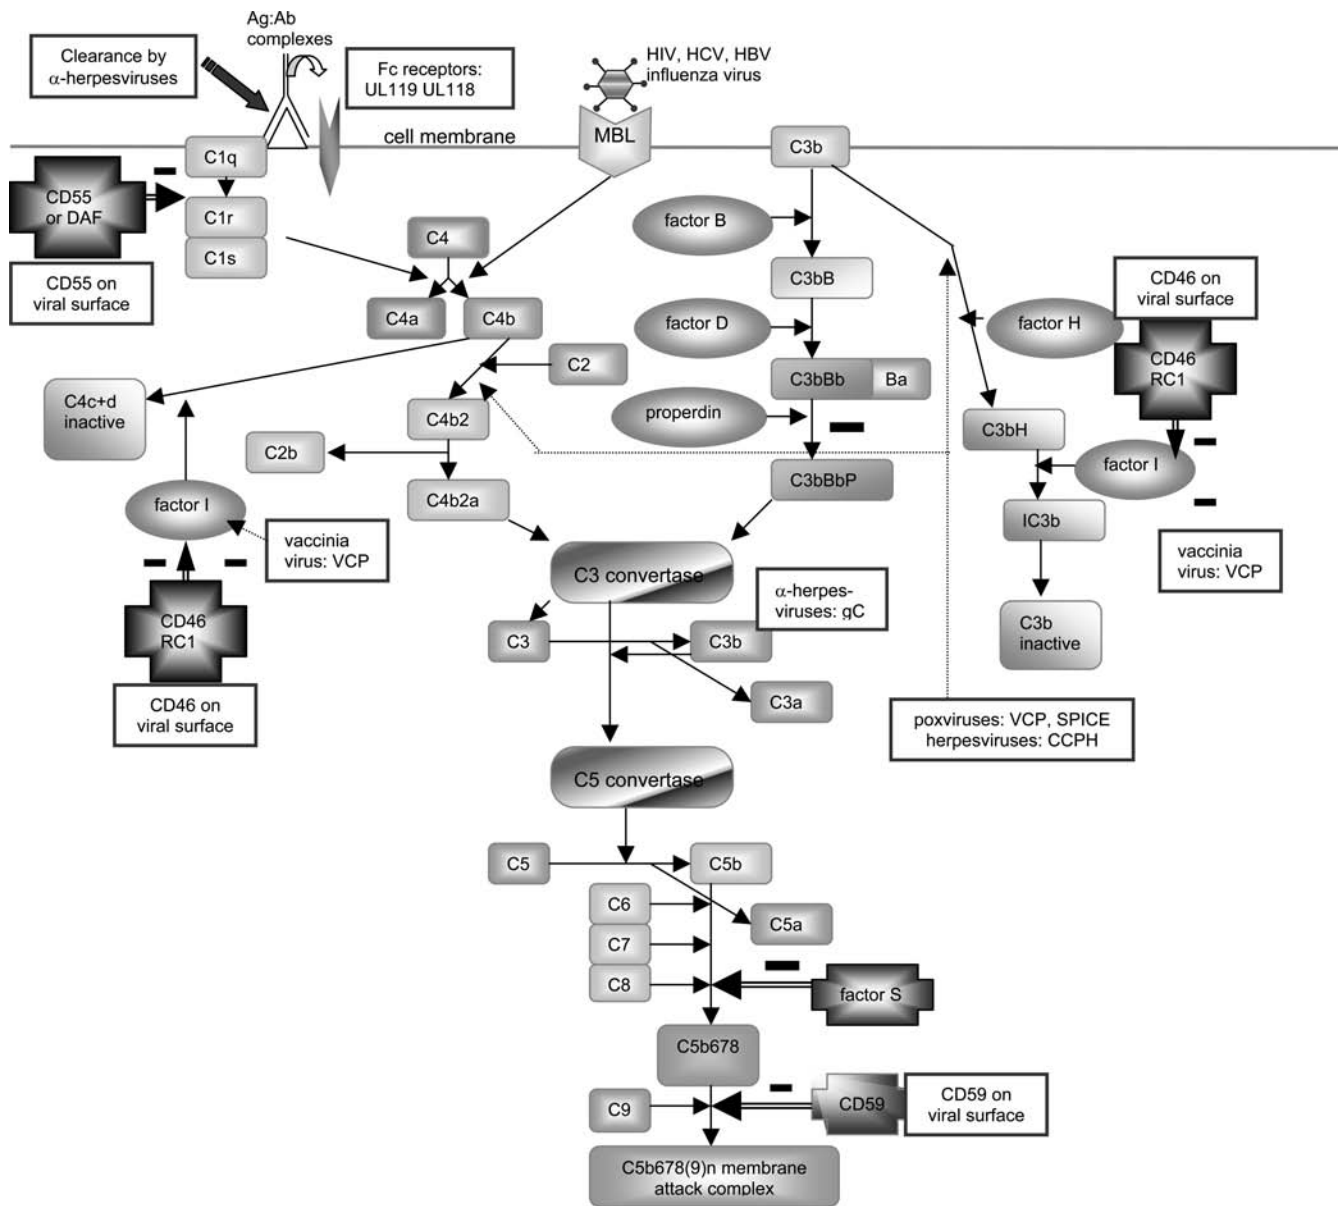
Complement can directly lyse some viruses, promote phagocytosis, or kill virus-infected cells upon binding of antibodies to cell surface–expressed viral antigens. Viruses have thus evolved strategies to subvert activation of


FIGURE 36.4 Interference of activation of the complement cascade pathways. CCPH, complement control protein homolog; CD, cluster of differentiation; HBV, hepatitis B virus; HCV, hepatitis C virus; HIV, human immunodeficiency virus; MBL, mannose-binding lectin; SPICE, smallpox inhibitor of complement enzymes; VCP, vaccinia virus complement control protein.

complement (178) (Figure 36.4). The complement system is composed of dozens of proteins that are sequentially activated through three distinct pathways called the classical, alternative, and lectin pathways. The classical pathway is activated once a virus, such as HIV or HCMV, or an antigen–antibody complex, binds to C1q, which forms a complex with C1r and C1s. Conformational changes of C1q enable the protein to activate C1r, which cleaves C1s into a protease, which in turn cleaves C4. Complement is activated through the alternative pathway as a direct consequence of C3b deposition on the surface of membranes. The mannose-binding lectin (MBL) pathway is induced

through the binding of monosaccharides to MBL, which activates the attached protease and causes cleavage of C4. A number of viruses can bind MBL, such as HIV, HCV, HBV, and influenza virus. All three pathways converge after formation of the C3 complex, and after a few more steps, eventually form a complex that pokes holes into membranes, causing cell or viral death. Complement activation is tightly controlled through inhibitory molecules such as the C1 inhibitor, the decay-accelerating factor (DAF or CD55), the membrane cofactor protein (MCP or CD46), the C4-binding protein, CD59, and factor H. Many of these molecules contain a short 60-amino acid consensus

sequence with four conserved cystein bonds. Viruses have evolved three strategies to a avoid destruction by complement: (a) They can interfere with activation of the classical pathway by shedding antigen–antibody complexes from the surface of infected cells or by expressing Fc receptor–like structures that complex antibodies that are bound to viral surface proteins; (b) they can encode complement inhibitors; and (c) they can incorporate host-derived complement inhibitors into their envelope.

The first mechanism is used by alpha herpesviruses, which rapidly eliminate antigen–antibody complexes from the cell surface. Other herpes viruses and coronaviruses express Fc receptors on infected cells. Binding of these Fc receptors to antibodies can sterically block formation of antigen–antibody complexes, or they may bind to antigen–antibody complexes in such a way as to block complement activation.

The second pathway is used by vaccinia virus, which encodes the vaccinia virus complement control protein (VCP). This protein has the typical consensus sequence of complement inhibitors and binds to C3b and C4b. It also acts as a cofactor to complement-regulating factor I. Variola virus, which causes smallpox in humans, encodes the smallpox inhibitor of complement enzymes (SPICE), which inactivates C3b. Herpes virus saimiri encodes a complement control protein homolog (CCPH), which resembles DAF and inhibits C3 convertase activity. Alpha herpesviruses produce glycoprotein gC, which can bind C3b. EBV can cleave serum C3 into an inactive form, preventing activation of the alternative pathway.

The third pathway is used by enveloped viruses. Budding of such viruses from the cell membrane takes place at lipid rafts that are rich in cholesterol and other lipids and also contain glycosyl phosphatidyl inositol anchored complement control proteins such as CD46, CD55, and CD59, which are incorporated into the membrane of the extracellular enveloped form of poxviruses, herpesviruses, and HIV. Alpha viruses pick up sialic acid residues on their surface during budding, inhibiting C3b deposition on the virus surface, which would initiate the alternative pathway of complement activation.

It should be noted that CD46, one of the inhibitors of complement activation, is used as a receptor by several viruses, such as adenoviruses of subfamily B2 and measles virus. To what degree this affects complement activation is unknown.

Inhibition of Apoptosis

The damage caused by virus infection can induce cells to undergo programmed cell death. Premature cell death is counterproductive for viruses if it occurs before they have successfully completed their replication cycle. Viruses, especially poxviruses, have developed a number of pathways to inhibit apoptosis (179,180) (Figure 36.5).

Apoptosis can be triggered by fas–fas ligand (CD95) interactions. The intracellular domain of CD95 contains a death effector domain (DED), which binds to corresponding DEDs on adaptor proteins such as FADD. Upon ligation of the extracellular part of the receptor, the cytoplasmatic tail binds to the death-inducing signal complex (DISC), which contains the caspase FLICE. This results in activation of caspase 8, which in turn activates caspase 3, which, through cleavage of cellular proteins, induces apoptotic cell death. Activation of caspase 8 is inhibited by cellular FLICE-like inhibitor proteins (cFLIP). Another apoptotic pathway involves mitochondial damage, which, upon permeabilization of the mitrochondrial membrane, causes activation of caspase 9. Apoptosis can also be induced by overexpression of p53, which mediates apoptosis through a pathway involving activation of Bax and its translocation from the cytosol to mitochondrial membranes, cytochrome c release from mitochondria, and caspase 9 activation, followed by the activation of caspase 3, 6, and 7. p53-Mediated apoptosis can be blocked at multiple checkpoints, by inhibiting p53 activity directly, by Bcl-2 family members regulating mitochondrial function, and by caspase inhibitors.

Poxviruses inhibit apoptosis of infected cells through a number of pathways. Molluscum contagiosum virus (MCV) prevents caspase 8 activation through two viral proteins called MC159 and MC160, which bind to FADD and procaspase 8, inhibiting activation of caspase 8. Some poxviruses produce a serine protease inhibitor–like molecule called crmA or SPI-2. CrmA inhibits the activity of caspases such as ICE (IL-1β–converting enzyme) and caspase 8, which are part of the death pathway. In addition, both proteins bind to granzyme B, a serine protease that is part of the lytic granules secreted by cytolytic T cells upon recognition of their target antigen. The SPI-2 family of poxvirus serpins, such as B13R from vaccinia virus, can inhibit fas- or TNF-mediated apoptosis. SERP-2, another serpin expressed by myxoma virus, inhibits caspase 1 and granzyme B protein. PKR not only inhibits translation of proteins, it may also activate caspase 8.

Intracellular reactive oxygen intermediates trigger apoptotic cell death. H_2O_2 can be reduced by cellular enzymes such as glutathione peroxidase, which is a selenocysteine-containing protein. The MC066 of MCV shows 74% sequence homology to this enzyme and was shown to protect cells from death due to reactive oxygen intermediates. MC066 does not interfere with apoptosis induced through fas.

The p28 of ectromeliavirus (mousepox) and the N1R of Shope fibroma virus have a RING finger motif that inhibits apoptosis induced by UV light. Inhibition is upstream of caspase 3. The M11L protein of myxoma virus localizes to mitochondrial membranes and prevents their permeabilization upon cell damage, thus inhibiting activation of caspase 3. The M-T4, M-T2, and M-T5 of
FIGURE 36.5 The pathway to viral apoptosis. Apaf-1, apoptosis protease activating factor-1; Bax, Bcl-2–associated X protein; Bcl-2, B-cell lymphoma 2; CAD, caspase-activated DNase; Cyt-c, cytochrome c; DISC, death-inducing signaling complex; FADD, Fas-associated death-domain protein; FAS, fatty acid synthase; FLICE, Fadd-like ICE (caspace 8); ICAD, inhibitor of CAD; PKR, dsRNA-dependent protein kinase.

myxomaviruses also inhibit apoptosis through as-yet-undefined pathways.

HCMV encodes at least two proteins that interfere directly with pathways that cause programmed cell death. UL35 protein is an inhibitor of caspase 8–induced apoptosis. UL36 binds to pro-caspase 8 and blocks its recruitment to the death-inducing signaling complex (DISC), a step preceding caspase 8 activation. vMIA binds and sequesters Bax at mitochondria, and interferes with BH3-only-death-factor/Bax-complex-mediated permeabilization of mitochondria.

A number of viruses encode antiapoptotic proteins with Bcl2-like activity. Examples include the E1B 19K polypeptide of adenoviruses, BHRF1 of EBV, and A179 of African swine fever. The E1B/55K protein of adenovirus, furthermore, inhibits p53-mediated apoptosis, whereas E3/10.4K and 14.5K proteins accelerate degradation of Fas and TRAIL receptors from the cell surface.

Escape by Subverting Antigen Processing and Antigen Presentation

A number of viruses have devised strategies to impair presentation of their antigens by the MHC class I pathway, thus reducing activation and effector functions of antigen-

specific CD8$^+$ T cells, again stressing the importance of this cell subset for antiviral defense (181,182). Nearly every step of the MHC class I presentation pathway can be interfered with, and some viruses encode multiple proteins that act at different levels of the MHC class I processing pathway. Interference of MHC class II processing is less common but has also been described (Figure 36.6).

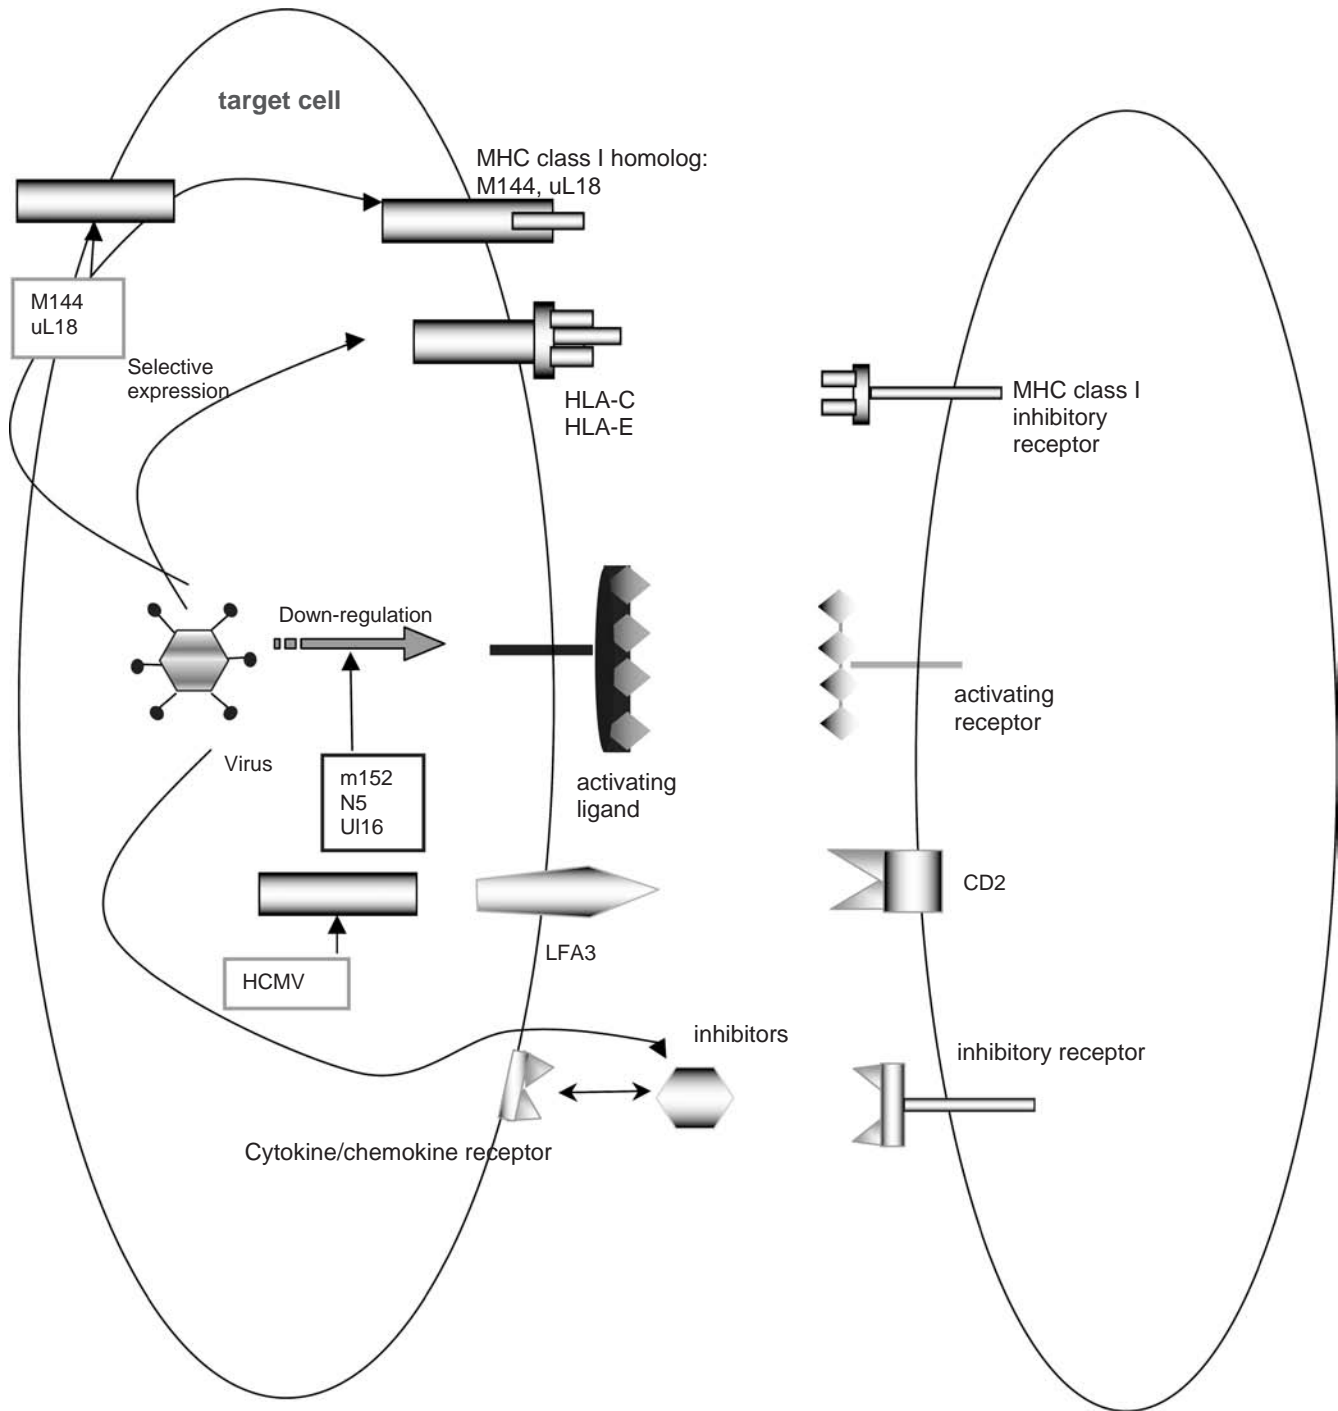
Viruses can escape detection T cells by inhibiting synthesis of MHC molecules. For example, tat of HIV-1 represses the MHC class I promoter. Human cytomegalovirus (HCMV) can impair MHC class II expression through two pathways. MHC class II molecules are expressed on only a subset of cells, and their transcription is tightly regulated, mainly through the class II transactivator (CIITA), a non-DNA–binding protein that interacts with transcription factors that associate with the MHC class II promoter. CIITA is the rate-limiting factor of MHC class II production and thus determines the expression pattern of these molecules. CIITA production is regulated by four promoters, two of which sponsor constitutive expression of CIITA in antigen-presenting cells. One is activated by IFN-γ and causes increased MHC class II expression in the presence of this cytokine. Upon binding of IFN-γ to its receptor, Jak1 and Jak2 thyrosine-phosphorylate the intracellular domain of the receptor, which then recruits Stat1.


FIGURE 36.6 MHC class II processing. CD2, cluster of differentiation 2; HCMV, human cytomegalovirus; HLA, human leukocyte antigen; LFA-3, lymphocyte function–associated antigen type 3; MHC, major histocompatibility complex.

Stat1 phosphorylated by Jak1 and Jak2 forms a homodimer that is translocated to the nucleus. The Stat1 homodimers bind to the IFN-γ activation sequence GAS present in promoters of IFN-γ–inducible genes. This causes production of IRF-1 (interferon regulatory factor-1), a transcription factor that, together with Stat-1 homodimers and

the ubiquitously expressed upstream factor-1 (USF-1), activate the inducible promoter of CIITA. Proteins of HCMV can increase degradation of Jak1 kinase and can further decrease CIITA activity in a Stat1-independent way.

Transport of MHC molecules to the cell membranes requires their binding to peptides, which for loading of MHC

class I molecules depends on active transport of peptides from the cytoplasm to the ER with the help of TAP. The E7 of HPV-18 and the E1A protein of adenovirus human serotype 12 inhibit the promoter controlling TAP production. The mK3 protein of mouse gamma herpesviruses such as HHV-8 binds to TAP and tapasin, resulting in their ubiquination and degradation. The 19K polypeptide encoded by the E3 domain of adenoviruses binds to TAP and prevents association between TAP and tapasin. Other herpesviruses, such as HSV and HCMV, encode proteins that inhibit TAP-mediated peptide transport. US6, a protein encoded by HCMV, binds to TAP and prevents binding of ATP, which is needed for peptide transport. The ICP47 polypeptide from herpes simplex virus (HSV) inhibits TAP by blocking its peptide-binding site, thus preventing its association with other peptides. EBV encodes a protein that weakly binds the IL-10 receptor. Similar to cellular IL-10, the EBV protein reduces expression of TAP.

CD10 and CD13 serve aminopeptidases to trim peptides to a size that allows their binding to the groove of MHC class I or II molecules. Yet-to-be-identified proteins of HCMV block the activity of CD10 and CD13. Although CD10 expression is apparently blocked at the transcriptional or translational level, CD13 seems to be retained within the ER.

Once MHC class I molecules have bound peptides, they are transported to the cell surface to present the peptides to CD8$^+$ T cells. A number of viral products interfere with this transport, by retaining MHC class I molecules within the ER, by affecting their export into the cytoplasm, or by interfering with passage through the Golgi apparatus. The cytosolic tail of the 19K gene product of the E3 domain of adenovirus contains a dilysine motif that inhibits MHC class I trafficking by acting as an ER retrieval motif. The US3 and US10 proteins of HCMV also prevent the exit of MHC class I from the ER through pathways that are still poorly understood. The m152 of murine cytomegalovirus (MCMV), which encodes a 40-kDa glycoprotein, affects retention of peptide-loaded MHC class I molecules in a pre-Golgi compartment.

US11 and US2 of HCMV dislocate the MHC class I molecules from the ER to the cytoplasm, where they are rapidly degraded. In the presence of US2, the intracellular half-life of MHC class I is reduced from about 6 hours to less than 2 minutes, demonstrating that this pathway of MHC class I destruction is highly efficient. US2 binds to MHC class I molecules in the ER while the protein is being glycosylated, causing its incorrect folding. The complex is then transported through Sec61 pores back into the cytoplasm, where, upon deglycosylation, both proteins— i.e., the MHC class I molecule and the viral protein—are degraded. US11 has a similar mode of action, but unlike US2, it does not become demolished upon translocation into the cytoplasm. The m6/gp48 protein of MCMV binds to MHC class I/β2-microglobulin complexes in the ER.

During transport of the complex to the cell surface, the m6/gp48 protein, whose cytoplasmic tail has a dileucin motif, targets the complex to lysosomes where they are proteolytically digested.

The K3 and K4 proteins of HHV8 lower expression of cell surface MHC class I molecules by enhancing their endocytosis into clathrin-coated pits. In addition, K5 down-regulates cell surface expression of the costimulatory molecule CD86. Nef of HIV-1 reduces cell surface expression of MHC class I by redirecting the molecules from the trans-Golgi network to the endosomes. In addition, nef reduces expression of costimulatory molecules of the B7 family.

USE OF VIRAL VECTORS FOR GENE TRANSFER

The ease with which viruses move their genes into mammalian host cells has led scientists to explore their use for gene replacement therapy to correct missing or faulty genes. Needless to say, after millions of years of evolution that empowered complex organisms to fight virus infections, 20 years of viral gene replacement therapy research has thus far met with very little success in humans.

To allow for their use in gene replacement therapy, viruses are typically rendered replication-defective, and part or all of their genome is replaced with the gene that produces the therapeutic protein under the control of regulatory elements. Numerous types of viruses have been explored or are currently under scrutiny. Two of those, replication-defective adenovirus vectors and adeno-associated virus (AAV) vectors, well attest to the vows of viral gene therapy.

Twenty years ago, E1-deleted adenovirus vectors, most commonly based on the human serotype 5, were heralded as the potential solution to all genetic diseases (183). E1-deleted adenovirus vectors, or subsequent second-, third-, and fourth-generation vectors in which more and more of the viral genome had been removed, indeed succeeded in transferring genes into experimental animals (184). In animals that were immunoincompetent, such as SCID mice, expression of the transferred genes was sustained. In immunocompetent animals the transgene product and the antigens of the vector stimulated, as one would expect, potent B- and T-cell responses; CD8$^+$ T cells rapidly eliminated the transduced cells, while neutralizing antibodies to the hexon protein of adenovirus prevented successful reapplication of the vectors. In spite of limited success in experimental animals, human trials were initiated, in which the potent innate immune responses to the adenovirus vectors caused significant morbidity and resulted in the death of one patient (185).

AAVs vectored for use in gene replacement therapy are so-called dependo-viruses of the parvovirinae subfamily

that in nature infect concomitantly with a helper virus such as adenovirus or herpes virus. Helper viruses are needed for multiple steps in the replicative cycle of AAV. So far, six distinct serotypes have been identified in humans, termed AAV-1 through -6. Of those, AAV-2–based vectors have been used most commonly for gene therapy. The AAV-2 genome is composed of a 4.7-kb single-stranded DNA flanked by inverted terminal repeats (ITRs). ITRs initiate DNA replication and are required for encapsidation of the genome. The genome contains two open reading frames (ORFs), one encoding proteins needed for DNA replication and for integration, the other encoding the three capsid proteins, which are generated from a single ORF by alternative splicing and distinct translation-initiation sites. In AAVs used for gene transfer, the ORFs are removed and replaced with the gene of interest, including regulatory elements flanked by the ITRs (186). The resulting vector can be grown in cells that provide the proteins encoded by AAV in trans and that furthermore provide helper virus functions commonly provided through gene products of adenovirus. Humans are naturally exposed to AAV, which they acquire together with a helper virus. The gene therapy literature shows that AAV vectors, depending on the dose, the amount of vector, the type of the transgene product, and the host's genetic makeup, can be poorly immunogenic, allowing for long-term expression of the transferred gene in mice, canines, and nonhuman primates (187). In particular, AAVs appear to escape detection by the innate immune system and thus fail to elicit the inflammatory reactions (188) that are needed to induce adaptive immunity. Nevertheless, in spite of very promising preclinical data, in a clinical trial in which AAV-2 expressing factor IX was transferred to the liver for correction of hemophilia B, patients eliminated the transduced hepatocytes, most likely through $CD8^+$ T cells directed against the capsid proteins of AAV-2 (189). It is likely that in humans during natural infections with AAV together with a helper virus, the innate immune response to the helper virus promotes adaptive immune responses including $CD8^+$ T cells against antigens of AAV. Upon AAV-mediated gene transfer, even if AAV by itself fails to cause a strong inflammatory reaction, pre-existing memory $CD8^+$ T cells would be expected to be reactivated and do what they are supposed to do—eliminate the AAV vector-transduced cells.

It is of interest to note that both E1-deleted adenovirus vectors and AAV vectors that remain favored tools of gene therapists are currently in clinical trials as vaccine carriers (190,191).

CONCLUSION

Our immune system is in constant battle with viruses, which in spite of their puny sizes are formidable opponents. Viruses continue to take a tremendous toll on hu-
