man lives, outpacing wars and natural disasters combined. Although vaccines and antiviral drugs have lessened the impact of some viral infections, new viruses that can cause disease and death in humans are constantly evolving, raising havoc in human societies. Our best defense against viruses remains our immune system, which in most cases can rapidly control acute infections. Adaptive immunity appears to be less suited to eliminate viruses that have mastered the art to establish chronic infections. This results in part from defense mechanisms of those viruses, but it also results from a shortcoming in adaptive immunity, which has to eliminate pathogens without causing undue damage to its own host. During chronic infection, negative immunoregulatory mechanisms hamper the effectiveness of adaptive immune responses. A full understanding of the delicate balance between immunity and persistent viruses is still evolving, and further knowledge may help to devise treatments that lessen the burden of chronic viral infection.

Immune Responses to Intracellular Bacteria

Eric Pamer

INTRODUCTION

Despite the development of new antibiotics and vaccines, bacterial pathogens remain a major cause of human infection. Bacteria are diverse prokaryotic organisms that can be classified according to morphology (rod vs. coccus), staining characteristics (gram-positive vs. gram-negative), oxygen tolerance (anaerobe vs. aerobe), and growth rates (slow vs. rapid grower). Bacterial pathogens—i.e., those organisms that can cause disease in higher forms of life—can also be divided into those that infect the host and remain extracellular and those that invade host cells and become intracellular. Invasion of eukaryotic cells and intracellular survival and replication represent the strategy that a subset of pathogenic bacteria, the intracellular bacteria, have developed in order to survive and replicate within a mammalian host. Intracellular bacteria express factors that circumvent or inactivate microbicidal effector mechanisms that eukaryotic cells have evolved to eliminate invading pathogens. These bacterially expressed factors are referred

to as *virulence factors* because they enable intracellular bacteria to cause disease by invading cells and promoting bacterial survival, replication, and spread. Pathogenic intracellular bacteria that lose these virulence factors, for example, by mutation or loss of a virulence factor-encoding plasmid, generally become avirulent, that is, incapable of causing disease.

In contrast to intracellular bacteria, extracellular bacterial pathogens survive and replicate outside of mammalian cells and have evolved a variety of mechanisms to avoid complement-mediated killing or phagocytic uptake by inflammatory cells. Although extracellular pathogens do not replicate within mammalian cells, some, such as *Staphylococcus aureus,* are capable of surviving within phagocytic cells (1) and others, such as *Neisseria meningitidis,* transiently invade cells to traverse epithelial barriers (2). Some extracellular pathogens, such as *Pseudomonas aerigunosa,* cause disease by injecting microbial proteins into the cytosol of adjacent epithelial cells (3), and in this fashion manipulate host cells using virulence mechanisms that are shared by some intracellular bacteria (4). Thus, the dividing line between intra- and extracellular pathogens is not completely distinct, and the immune mechanisms that are activated in defense against intracellular and extracellular bacteria share many features. Nevertheless, the components of the immune system that provide protection against intracellular and extracellular bacterial pathogens are only partially overlapping. With respect to protection against intracellular bacterial infection, macrophages, T cells and cytokines and accessory cells that facilitate antigen-specific T-cell responses are especially important for immune defense. On the other hand, neutrophils and humoral immunity play a more important role in defense against extracellular bacterial pathogens.

INTERACTIONS BETWEEN INTRACELLULAR BACTERIA AND THE IMMUNE SYSTEM

Intracellular bacterial pathogens differ from one another in a variety of ways that affect the innate and adaptive immune responses induced in the mammalian host. In the following sections, some of the key characteristics of different intracellular bacterial pathogens are described. and their implications for the host immune response are discussed.

Effect of Cell Wall Composition

The bacterial cell wall and outer membrane represent one of the major ligands for innate immune receptors and trigger signals that shape the inflammatory responses. The signal transduction pathways and inflammatory responses triggered by different innate immune receptors and bacterial ligands are diverse. Thus, the composition of the bacte-

rial cell wall and membrane has a direct effect on the innate immune response and indirectly influences adaptive immune responses. A classical method to distinguish different bacterial pathogens, first described in 1884 by the Danish microbiologist Hans Christian Gram, is the Gram stain: Organisms that retain crystal violet dye are termed gram-positive, whereas those that do not are gram-negative. *Listeria monocytogenes,* a rod-shaped bacterium that infects macrophages, hepatocytes, and intestinal epithelial cells, is gram-positive and thus is enveloped by a thick layer of peptidoglycan, lacks lipopolysaccharide (LPS), and expresses lipoteichoic acid (LTA) on its surface (5). Other intracellular bacterial pathogens, such as *Salmonella enterica,* are gram-negative rods and have a cell wall consisting of a relatively thin layer of peptidoglycan surrounded by lipopolysaccharide (4). The distinct cell wall composition of *S. enterica* and *L. monocytogenes* has implications for the inflammatory response induced within the mammalian host. A third group of intracellular bacterial pathogens, which includes *Mycobacterium tuberculosis,* contains yet a different outer surface that consists of a complex array of glycolipids that include mycolic acids and lipoarabinomannans (6). These components induce inflammatory responses that are distinct from those elicited by peptidoglycan, LPS, and LTA. It is interesting that apparently minor modifications in surface molecules of microbial pathogens can affect the inflammatory responses induced in the infected host. For example, lipid chains of mycolic acids are modified by specific cyclopropane synthetases, which are encoded by a family of *M. tuberculosis* genes. Each cyclopropane synthetase generates a specific cyclopropane ring that structurally modifies the mycolic acid side chain, thereby altering the virulence and pathogenicity of *M. tuberculosis* (7,8). Thus, *M. tuberculosis* has evolved a mechanism to subtly modify the surface lipids that interface with the mammalian host (9,10). These modifications modify the host's innate inflammatory response and thus alter *in vivo* mycobacterial growth and survival.

Effect of Bacterial Growth Rate

In addition to the molecular composition of intracellular bacterial pathogens, other microbial characteristics also influence immune responses. The rate of bacterial replication is a factor that has significant consequences for innate and adaptive immune responses. Some intracellular bacteria, such as *Salmonella enterica* or *Listeria monocytogenes,* can divide every 30 to 40 minutes in the mammalian host. In this setting, the tempo of the disease can be very rapid and the amount of antigen can be quite large. In contrast, *Mycobacterium tuberculosis,* even under optimal growth conditions, divides only once every 24 hours. In this setting, particularly when the inoculum of a slow-growing pathogen is small, the threshold for activating the adaptive immune response may not be met for many weeks

following infection. Thus, the *in vivo* kinetics of microbial growth, the production of ligands for innate immune receptors, and the generation of antigens that can be detected by T lymphocytes are quite variable following infection with different intracellular bacterial pathogens. Rapid bacterial growth, with resultant production of microbial products that trigger innate immune receptors and the production of large amounts of antigen, can increase the tempo and magnitude of innate inflammatory and adaptive immune responses. On the other hand, slow *in vivo* bacterial growth with attenuated innate inflammatory responses and potentially subthreshold levels of antigen may result in suboptimal immune responses that are incapable of clearing the pathogen.

Targeting Different Host Cells

Although a range of mammalian cells can be infected by intracellular bacterial pathogens, most intracellular bacteria are only capable of infecting and replicating within a limited subset of cell types. For example, *Mycobacterium tuberculosis* and *Salmonella enterica* survive and replicate predominantly within macrophages (11,12), whereas *Listeria monocytogenes* infects macrophages and hepatocytes (13,14). The type of cell that bacteria infect has implications for the immune response. Epithelial cells, for example, are not efficient at presenting antigens via the MHC class II pathway and have a limited capacity to kill intracellular bacteria. Macrophages, on the other hand, are efficient antigen-presenting cells and, upon activation, are highly effective at bacterial killing. Natural infections with *Salmonella enterica* and *Listeria monocytogenes* are acquired by oral ingestion, and thus, both of these pathogens encounter, invade, and traverse intestinal epithelial cells before gaining access to macrophages.

Traversing Epithelial Barriers

Intestinal epithelial cells form a defensive barrier against microbes, and pathogens that are acquired by the intestinal route infect intestinal epithelial cells in order to establish systemic infections in the mammalian host. In the case of *Listeria monocytogenes,* E-cadherin is postulated to be a receptor for the bacterial surface protein internalin-A and mediates bacterial entry into the intestinal epithelial cell (15). *Salmonella enterica,* on the other hand, traverses the intestinal epithelial barrier by entering M cells, which overlay Peyer patches in the gut (16). *Salmonella enterica* can also traverse the intestinal epithelial barrier by invading CD18-expressing phagocytes (17).

Bacterial entry into epithelial cells is a complex process because, unlike macrophages, epithelial cells are not phagocytic. Thus, in order to enter intestinal epithelial cells, intracellular bacterial pathogens have evolved complex pathogenesis strategies to induce their uptake

(4). *Salmonella enterica,* for example, upon contacting the surface of intestinal epithelial cells, induces membrane ruffling at the site of contact that results from actin polymerization and other cytoskeletal changes (18). This process, which is essential for *S. enterica* virulence following oral ingestion, involves a multicomponent virulence complex referred to as the type III secretion system (TTSS) (19). TTSSs enable gram-negative bacteria to secrete proteins across their membranes and cell wall and into the cytosol of adjacent mammalian cells. This remarkable feat is accomplished by the highly organized assembly of a bacterially encoded multicomponent needle complex, which, by spanning all bacterial and eukaryotic membrane and cell wall barriers, provides a narrow channel that connects the bacterial cytosol with the cytosol of the mammalian cell. The *S. enterica* chromosome contains two "pathogenicity islands" that encode two distinct TTSSs on its chromosome, SPI-1 and SPI-2, which each contain roughly 20 genes that confer bacterial virulence (4). Inactivation of SPI-1 results in bacteria that are unable to infect intestinal epithelial cells, rendering the pathogen incapable of causing infection following oral ingestion (19). SPI-1 encodes the structural components of the needle complex and also effector proteins that are injected into the epithelial cell. Three *S. enterica* proteins, SopE, SopE2, and SopB, interact with CDC42 and Rac1 of the epithelial cell to induce actin polymerization that ultimately leads to the internalization of the bacterium (20). Other proteins, such as SptP, are secreted by the TTSS into the epithelial cell cytosol in order to revert the cytoskeletal changes induced by invasion (21). Expression of virulence factors is highly regulated, and different factors are secreted at distinct times and in different locations during cellular infection. For example, the SPI-2-encoded TTSS is not expressed by *S. enterica* until the bacteria have entered a host cell (22,23). Proteins secreted by the SPI-2–encoded complex appear to be essential for the modification of the macrophage phagosome, specifically, evasion of phagocyte NADPH oxidase–mediated killing (24).

Effect of Subcellular Localization

Different intracellular bacterial pathogens inhabit distinct compartments within mammalian host cells (Table 37.1). Most intracellular bacteria remain within vacuoles and thus are separated from the cytosol by a host cell–derived membrane. *Salmonella typhimurium, Mycobacterium tuberculosis,* an*d Legionella pneumophila,* the cause of Legionaire's disease, reside and replicate within macrophage vacuoles or phagosomes. The nature of the vacuole varies with the pathogen, with some intracellular bacteria, such as *Legionella pneumophila,* residing within vacuoles that resemble the endoplasmic reticulum (25,26) while others, such as *Mycobacterium tuberculosis,* reside within vacuoles with endosomal characteristics (27). *M. tuberculosis*

▌**TABLE 37.1 Intracellular Bacteria**

Bacterial Species	Cell Type Infected	Subcellular Localization
Anaplasma phagocytophilum	Neutrophil	Vacuole
Brucella abortus	Macrophage	Vacuole
Bartonella bacilliformis	Erythrocyte/endothelial cell	Vacuole
Burkholderia pseudomallei	Macrophage	Vacuole
Calymmatobacterium granulomatosis	Monocyte	Vacuole
Chlamydia trachomatis	Mucosal epithelial cell	Vacuole
Chlamydia psittaci	Macrophage	Vacuole
Coxiella burnettii	Macrophage	Vacuole
Ehrlichia canis	Neutrophil/monocyte	Vacuole
Franciscella tularensis	Macrophage	Vacuole
Legionella pneumophila	Macrophage	Vacuole
Listeria monocytogenes	Macrophages/hepatocyte	Cytoplasm
Mycobacterium tuberculosis	Macrophage	Vacuole
Mycobacterium leprae	Macrophage/Schwann cell	Vacuole
Rickettsia rickettsii	Endothelial cell	Cytoplasm/nucleus
Rickettsia prowazekii	Endothelial cell	Cytoplasm
Salmonella enterica	Intestinal epithelial cell/macrophage	Vacuole
Shigella flexneri	Epithelial cell	Cytoplasm

impairs vacuolar acidification and the acquisition of lysosomal hydrolases and thus, to prevent destruction, arrests endosomal maturation (28). The MHC class II antigen–processing pathway intersects with endosomal compartments to present antigens to CD4 T cells and some pathogens, such as *Mycobacterium tuberculosis,* segregate their vacuoles from the MHC class II molecules (29).

In contrast to bacteria that remain within phagosomes, some intracellular bacterial pathogens escape vacuoles and enter the cytosol of infected cells. *Listeria monocytogenes* accomplishes this feat by secreting a membranolytic protein, listeriolysin, which ruptures the phagocytic membrane and enables bacterial entry into the cytosol (30). *L. monocytogenes* replicates rapidly in the host cell cytosol and moves by polymerizing actin on one pole, a process that pushes bacteria throughout the infected host cell and also into neighboring cells (31). Upon invading the neighboring cell, *L. monocytogenes* again produces listeriolysin, which lyses the phagosome, thus allowing bacteria to enter the next cell without an intervening extracellular phase. Vacuolar escape is essential for the virulence of *L. monocytogenes,* and deletion of listeriolysin O renders bacteria completely avirulent (32).

Several other intracellular bacterial pathogens also escape the vacuole, such as *Shigella flexneri* and *Rickettsia rickettsiae*. In the case of *Shigella flexneri* infections, although bacteria escape the vacuole and enter the host-cell cytoplasm in cell culture (33), it is unclear whether this process is a component of *in vivo* virulence. Entry into the host-cell cytoplasm and nucleus is also a feature of infections with *Rickettsia rickettsii,* a tick borne pathogen that infects endothelial cells and vascular smooth muscle cells and causes Rocky Mountain spotted fever (34).

As might be expected, cytosolic localization has important implications for both the innate and adaptive immune response to intracellular bacterial pathogens. For one, antigens secreted by cytosolic bacteria have direct access to the MHC class I antigen–processing pathway and thus prime CD8 T-cell populations that often play a substantial role in bacterial clearance and long-term protective immunity. On another level, innate immune receptors that associate with microbial molecules are present in the cytosol and result in the activation of inflammatory processes (35).

ROUTE OF ACQUISITION: IMPLICATIONS FOR SYSTEMIC AND MUCOSAL IMMUNITY

Intracellular bacterial pathogens can be acquired by inhalation, oral ingestion, or through the epidermis. Some bacterial pathogens, such as *Mycobacterium tuberculosis* and *Legionella pneumophila,* are acquired by the respiratory route and thus their initial interactions are with phagocytic cells of the lungs, most likely alveolar macrophages and dendritic cells. Other intracellular bacterial pathogens, such as *Salmonella typhimurium* and *Listeria monocytogenes,* enter the mammalian host via the intestinal tract and thus their initial encounters are with intestinal epithelial cells and M cells of the gut and also CX3CR1-expressing dendritic cells that extend dendrites into the gut lumen (36,37). Other intracellular bacterial pathogens, such as the *Rickettsia rickettsii* or *Anaplasma phagocytophilum,* are transmitted to the mammalian host by bites of the lone star tick or the deer tick, respectively (34,38). In these circumstances, the pathogens bypass the mammalian epidermis and enter the bloodstream,

presumably after interacting with phagocytic cells in subcutaneous tissues. The lung, gut, and skin have associated lymphoid tissues that are distinct in terms of cellular composition, chemokine and integrin expression, and cytokine production. In the lung, macrophages and dendritic cells deliver microbes, such as the respiratory intracellular bacterial pathogens *M. tuberculosis* and *Legionella pneumophila,* to draining lymph nodes in the peribronchial and mediastinal region. During inflammation, lymphoid tissues can develop in the lungs and serve as auxiliary sites for T-cell priming (39). Gut-associated lymphoid tissues, which initiate immune responses against enteric intracellular pathogens such as *Salmonella enterica* and *Listeria monocytogenes,* are also complex. Peyer patches, which occur in the small intestine, consist of B cells and dendritic cells and lie beneath a layer of M cells, which transport antigens, including bacteria, from the intestinal lumen to the underlying lymphoid tissues. The intestinal epithelium also contains a variety of T cells, referred to as intraepithelial lymphocytes (IELs), which express either the $\alpha\beta$ or $\gamma\delta$ T-cell receptor (40). The lamina propria of the gut contains a large number of T cells that are predominantly of the memory phenotype (41,42). Although these immune cells very likely play a key role in immunity to intestinal intracellular bacterial pathogens, very little is known about their precise contributions to antimicrobial defense.

INNATE IMMUNE RESPONSES TO INTRACELLULAR BACTERIA

Mammalian cells express a range of innate immune receptors that bind to different microbial molecules and transmit signals that activate antimicrobial defense mechanisms (43). Innate immune receptors are present on the cell surface, within the vacuolar compartments of mammalian cells, and also in the cytoplasm. These receptors contain sequences that associate with microbial molecules and either contain domains that directly signal or that associate with adaptor molecules that initiate a signaling cascade that culminates in the expression of genes that provide antimicrobial defense. The following sections outline the recently defined innate immune signaling pathways that are involved in the recognition of intracellular bacterial pathogens. Many of these pathways are also involved in defense against extracellular bacterial pathogens and pathogenic viruses, fungi, and protozoa.

Toll-like Receptors (TLRs) in Defense against Intracellular Bacteria

The most completely characterized interactions between microbial molecules and innate immune receptors involve the members of the Toll-like receptor (TLR) family (44). Mammalian genomes contain up to 12 distinct TLR genes that encode transmembrane proteins that bind distinct microbial molecules, such as LPS (TLR-4), CpG (TLR-9), LTA (TLR-2), and flagellin (TLR-5 and TLR-11). MyD88 is an intracellular adaptor protein that mediates many, but not all, TLR signals, and mice that lack MyD88 are highly susceptible to infection with *Listeria monocytogenes* and *Mycobacterium tuberculosis* (45–47). MyD88-deficient macrophages are less effective at killing *Salmonella enterica* because of decreased phagocyte oxidase activation (48). Although the absence of MyD88 markedly increases susceptibility to a number of bacterial infections, the absence of individual TLR genes often does not noticeably affect susceptibility to infections, most likely reflecting the redundancy of these innate immune receptors. Thus, although TLR-2 recognizes and signals in response to components of *L. monocytogenes,* mice that lack this receptor have normal resistance to infection (46). Remarkably, although TLR-5 is expressed on lamina propria dendritic cells and responds to flagellin derived from *Salmonella enterica,* TLR-5–deficient mice are more resistant to infection with *S. enterica,* presumably because of diminished transport of bacteria from the lamina propria to mesenteric lymph nodes (49).

In contrast to the proposed detrimental effect of TLR-5 on murine *Salmonella* infections, in humans TLR-5 appears to play a protective role in defense against *Legionella pneumophila* infection. Genetic analysis of humans that became infected at a tulip festival in the Netherlands revealed a greater incidence of a TLR-5 mutation that results in a nonfunctional receptor in infected patients than in uninfected controls (50). Because TLR-5 is stimulated by bacterial flagellins, this result suggests that detection of *L. pneumophila* flagellin contributes to defense against infection.

Expression of TLRs is regulated and cell type-specific and thus, different cell types express different combinations of TLRs. TLRs are also targeted to different cellular compartments, with some TLRs residing on the plasma membrane (TLR-2 and TLR-4) and others residing within membrane-bound compartments of the cell (TLR-3, -7, and -9) (51). Thus, in the setting of intracellular bacterial infection, TLR signaling differs depending on the compartment occupied by the microbial pathogen and the TLR ligands that are available for association with their respective receptor. Parallel innate immune signaling pathways mediated by the ITAM-containing DAP12 adaptor molecule appear to inhibit TLR signaling, and mice that lack DAP12 are more resistant to *L. monocytogenes* infection (52).

Nod Signaling in Defense against Intracellular Bacterial Infection

Innate immune recognition of microbial molecules also occurs in the cytosol of mammalian cells. The most completely characterized cytoplasmic innate immune receptors are the Nod proteins, Nod1 and Nod2, which

contain leucine-rich CARD and nucleotide-binding domains (53). These proteins recognize fragments of peptidoglycan in the cytosol and induce NFκB signaling and innate immune activation via the adaptor molecule RIP2. Mice that lack RIP2 are more susceptible to *Listeria monocytogenes* infection (54), and mice that lack Nod2 are defective in clearing *L. monocytogenes* upon enteric challenge (55). Thus, the Nod recognition pathway contributes to defense against infection with this gram-positive intracellular pathogen. Although CpG motifs within bacterial DNA are detected by TLR-9, bacterial DNA is also detected in the cytosol by non–Toll-like receptors, and triggers innate immune activation and secretion of type I interferons. These signaling pathways play a role in defense against *L. monocytogenes* and *L. pneumophila* infections (56).

Inflammasome-mediated Defense against Intracellular Bacteria

Recognition of microbial molecules in the cytosol of mammalian cells is mediated in part by the inflammasome, a roughly 700-kDa complex of proteins that includes apoptosis-associated specklike protein (ASC), Ipaf, and cryopyrin (also known as Nalp-3), which, upon stimulation, result in the activation of caspase-1 and the secretion of IL-1 and IL-18 (57). Inflammasome components are also involved in bacterially induced apoptosis of infected macrophages, a process that contributes to pathogenesis by some intracellular bacterial pathogens, including *S. enterica*. Genetic deletion of individual inflammasome components in mice has revealed their contribution to defense against a number of intracellular bacterial infections. Caspase-1–deficient mice, for example, are more susceptible to infection by *L. monocytogenes* (58) and *Salmonella enterica* (59). Macrophages derived from mice with a genetic deletion of ASC do not activate caspase-1 and are resistant to bacterially induced apoptosis (60), suggesting that macrophage apoptosis may enhance *in vivo* bacterial clearance. ASC-deficient macrophages also produce diminished amounts of IL-1 and IL-18 upon cytosolic invasion by *L. monocytogenes* (61). Along similar lines, macrophages that lack Ipaf, another component of inflammasomes, do not activate caspase-1 in response to intracellular infection with *Salmonella enterica* (60), and cells that lack Ipaf are resistant to *S. enterica*–induced apoptosis. On the other hand, macrophages that lack cryopyrin, a component of inflammasomes also referred to as NALP-3, produce IL-1 and IL-18 in response to *S. enterica* infection but do not undergo bacterially induced apoptosis (62,63). In contrast to *S. enterica* infection, NALP-3–deficient macrophages infected with *L. monocytogenes* do not produce IL-1β or IL-18. These studies indicate that inflammasomes interact with different intracellular bacterial pathogens distinctly. Although most studies have characterized the response of inflammasome-deficient macrophages to bacterial infection, characterization of the *in vivo* response of deficient mice to infection are fewer but demonstrate that mice that lack caspase-1 are more susceptible to infection with *Salmonella typhimurium*, whereas mice that lack Ipaf, ASC, or NALP-3 are not (59).

In the case of *Legionella pneumophila* infection of macrophages, bacterial flagellin plays a particularly important role in the induction of innate immune responses. Studies of human populations indicate that TLR-5 plays a role in defense against *L. pneumophila* by recognizing bacterial flagellin (50), but experiments with mouse macrophages have identified another receptor that detects *L. pneumophila* flagellin. Although most commonly used laboratory mouse strains are innately resistant to *L. pneumophila* infection, the A/J mouse strain is highly susceptible to infection with *L. pneumophila*. The susceptibility of A/J mice was traced to mutations within a gene encoding Naip-5 or Birc1e (64,65). Naip-5 is structurally similar to Nod proteins, containing a nucleotide-binding domain and a leucine-rich region. Naip-5 activation in *L. pneumophila*–infected macrophages results in caspase-1–mediated apoptosis and IL-1β production. *L. pneumophila* that lack the Dot/Icm type IV secretion system do not activate macrophage apoptosis, are less virulent, and do not activate Naip-5. Caspase-1–deficient mice are similar to mice with deficient Naip-5, indicating that caspase-1 is the mediator of the Naip-5 effect. Naip-5 also interacts with inflammasome components. For example, Ipaf-deficient macrophages, similar to caspase-1– or Naip-5–deficient cells, do not restrict *L. pneumophila* growth (66). In contrast, ASC-deficient macrophages do not produce IL-1β but effectively restrict *L. pneumophila* growth (67). Thus, IL-1β production, in response to Naip-5/caspase-1 activation, does not play a role in restricting *L. pneumophila* growth, but other caspase-1– and Ipaf-dependent processes restrict of bacterial growth (67).

Mutants of *L. pneumophila* that lack flagellin do not induce caspase-1 activation, do not induce macrophage apoptosis, and escape macrophage-mediated innate immune defense (68). Thus, innate immune defenses mediated by Naip-5 (also called Birc1e) respond to bacterial flagellin in a process that is independent of TLR-5 and MyD88. Flagellar assembly or motility are not required for innate immune activation, and introduction of purified fagellin into the cytosol induces caspase-1 activation and macrophage apoptosis (69).

NEUTROPHILS AND DEFENSE AGAINST INTRACELLULAR BACTERIA

From the perspective of a bacterial pathogen, one of the major benefits of intercellular survival is avoiding contact with neutrophils. Nevertheless, neutrophils can play an important role in defense against intracellular pathogens.

In the case of *S. enterica* infections, neutrophils play a particularly important role in the gut and a less important role in systemic sites of infection (70). In the mouse model of *L. monocytogenes* infection, antibody-mediated depletion of neutrophils greatly exacerbates infection, implicating neutrophils in the *in vivo* clearance of bacteria (71). How neutrophils detect and kill bacteria that are within hepatocytes, for example, remains unclear (72). It is likely, however, that neutrophils are recruited to sites of bacterial infection by the localized induction of the CXC-chemokines Mip-2 and KC (in humans, IL-8). Release of formyl-methionine–containing peptide, which can bind to formyl-peptide receptors on neutrophils and induce chemotaxis and degranulation, may also contribute to neutrophil recruitment and clearance of intracellular bacteria. Although neutrophils are highly bacteriocidal, one pathogen, *Anaplasma phagocytophylum,* infects and survives within granulocytes by preventing fusion with cytochrome b_{558}–containing vesicles and by diminishing transcription of gp91^{phox} (38).

MONOCYTE-MEDIATED DEFENSE AGAINST INTRACELLULAR BACTERIA

Mammalian monocytes can differentiate into tissue macrophages and dendritic cells and mediate immune defense against a broad range of pathogens, including intracellular bacteria. Monocytes derive from progenitors in the bone marrow and enter the bloodstream and then peripheral tissues. In the setting of *L. monocytogenes* infection, monocytes enter infected tissues such as the liver in a CD11b-mediated fashion, and blocking CD11b with a specific antibody results in uncontrolled bacterial growth in infected organs and death (14). CCR2 is a chemokine receptor that is expressed on a subset of monocytes that contributes to inflammatory responses, and mice with genetic deletions of CCR2 have increased susceptibility to infection with several intracellular bacterial pathogens (73). For example, CCR2-deficient mice succumb to infection with small doses of *L. monocytogenes* because monocytes are not recruited to bacterially infected tissues (73,74). MCP-1, a CC-chemokine that is a ligand for CCR2, is induced by *L. monocytogenes* infection and promotes the recruitment of monocytes (75). The first step in monocyte recruitment is emigration from the bone marrow into the bloodstream, and this step is mediated by MCP-1 and requires CCR-2–mediated signals (76). Thus, in mice that lack either CCR2 or MCP-1, inflammatory monocytes are retained in the bone marrow upon infection with *L. monocytogenes*. CCR2-mediated recruitment of monocytes is also required for effective control of pulmonary infection with *Mycobacterium tuberculosis* (77).

TNF and iNOS are essential for the efficient clearance of *L. monocytogenes* from infected mice (78,79), and mono-cytes are the major source of these proteins in infected tissues. Thus, in spleens of CCR2-deficient mice infected with *L. monocytogenes,* TNF and iNOS levels are markedly reduced (74). Although recruitment of monocytes does not require TLR-mediated signals, induction of TNF at the sites of infection is TLR-driven (75).

CYTOKINES MEDIATING DEFENSE AGAINST INTRACELLULAR BACTERIAL INFECTION

IFN-γ plays a central role in defense against intracellular bacterial pathogens (80). Genetic analysis of humans with an increased incidence of mycobacterial and *Salmonella* infections uncovered mutations in the IFN-γ receptor (IFNGR1) that in some cases abolished and in other cases diminished transduction of IFN-γ–mediated signals (81–83). Additional individuals with increased susceptibility to mycobacterial and *Salmonella* infections were identified with mutations in the genes that encode IL-12 p40, a subunit shared by IL-12 and IL-23 (84). These individuals, as well as individuals with mutations in the IL-12-receptor, produced less IFN-γ in response to stimulation with mycobacterial extracts. Mutations in the gene that encodes STAT-1, which in the homodimeric form mediates IFN-γ signaling, also predispose individuals to mycobacterial and *Salmonella* infections, again demonstrating the importance of IFN-γ in defense against these pathogens (85). An X-linked form of increased susceptibility to mycobacterial infections has been attributed to mutations in the gene that encodes NF-κB essential modulator (NEMO) (86). In these individuals, monocytes produce less IL-12 in response to stimulation with activated T cells, a result of decreased responsiveness to CD40 triggering (86).

Studies performed in mice with genetic deletions of IFN-γ also demonstrate the important role of this cytokine in defense against infections with intracellular bacteria. IFN-γ–deficient mice are highly susceptible to infection with *Mycobacterium tuberculosis* (87,88), *Listeria monocytogenes* (89), and also attenuated strains of *Salmonella typhimurium* (90). In the murine model of *M. tuberculosis* infection, IFN-γ promotes the expression of inducible nitric oxide synthase, an enzyme that produces NO, an essential participant in *in vivo* mycobacterial killing (91). As in humans, murine deficiency of IL-12 p40 is also associated with increased susceptibility to *M. tuberculosis* infection. Comparison of mice that lack p40 (common to IL-12 and IL-23), p30 (IL-12), and p19 (IL-23) revealed that IL-12 is essential for optimal IFN-γ–mediated immune defense against *M. tuberculosis*, whereas an effect of IL-23 on antimycobacterial defense was detectable only if IL-12 was concurrently absent (92). IL-12 probably makes its most important contribution to antimicrobial immune defense by enhancing the induction of Th1 CD4 T-cell–mediated

immunity, but IL-12–mediated signals also enhance the migration of pulmonary dendritic cells from the lung to draining lymph nodes following intrapulmonary challenge with *M. tuberculosis* (93).

Tumor necrosis factor (TNF) is a pleuripotent cytokine that contributes to monocyte and granulocyte activation, enhances inflammatory cell migration, induces the production of other inflammatory cytokines, and increases the permeability of endothelial cells. Monoclonal antibodies or soluble receptors that block TNF receptor–mediated signaling are used clinically to ameliorate autoimmune inflammatory diseases such as rheumatoid arthritis and are very effective. Blocking TNF signaling, however, also increases susceptibility to a range of infectious pathogens, most prominently intracellular bacterial pathogens such as *M. tuberculosis* (94) and *L. monocytogenes* (95). The increased incidence of infections caused by these pathogens was not entirely surprising, because studies in mice, using either TNF- or TNF receptor–deficient mice, demonstrated their marked susceptibility to infection with these pathogens (79,96). TNF is synthesized as a membrane-bound protein that is cleaved from the cell surface by a metalloprotease, TNF-α–converting enzyme (TACE). Mice that lack this enzyme or that lack the metalloprotease cleavage site produce only membrane-bound TNF but are resistant to low-dose *L. monocytogenes* infection, suggesting that soluble TNF is not required for T-cell–mediated antimicrobial defense (97). Instead, it is likely that the TNF-mediated signals that are essential for microbial clearance are mediated by direct cell–cell contact. The nature of this interaction and the cellular participants remain incompletely defined.

In contrast to TNF and IFN-γ, type I interferons (IFN-α and IFN-β) are principally involved in defense against viral infections. Infection with some bacterial pathogens, however, also induces type I interferon production. *L. monocytogenes* infection of macrophages induces IFN-β, for example, in a process that requires bacterial invasion of the cytosol (98). However, in contrast to TNF and IFN-γ, type I interferons play a detrimental role in defense against *L. monocytogenes* infection. Mice that lack the receptor for type I interferons are more resistant to *L. monocytogenes*, with decreased numbers of bacteria in the spleen and liver after intravenous inoculation of bacteria (99–101). Some studies indicate that the recruitment and survival of monocytes is enhanced in the absence of type I interferon signaling, but another, potentially more important, mechanism may involve the effect of type I interferon on T-cell survival. *L. monocytogenes* infection, specifically LLO production by virulent bacteria, induces T-cell apoptosis, but this process is markedly attenuated in mice that lack the type I interferon receptor (102). The immunosuppressive effect of bacterially induced, type I interferon–mediated T-cell apoptosis is most clearly demonstrated by the finding that Rag$^{-/-}$ mice, which lack T cells, are re-

markably resistant to *L. monocytogenes* at early time points following infection. Reconstitution of Rag$^{-/-}$ mice with wild-type T cells, but not with T cells lacking the type I interferon receptor, renders them more susceptible to *L. monocytogenes* infection (102). The immunosuppression induced by T-cell apoptosis in this setting is partially the result of IL-10 production by phagocytic cells internalizing apoptotic cells.

T-CELL RESPONSES TO INTRACELLULAR BACTERIA

In contrast to extracellular bacterial pathogens, which are eliminated by antibody-, complement-, and phagocyte-mediated mechanisms, clearance of intracellular bacterial pathogens is generally dependent on the activation and expansion of pathogen-specific T lymphocytes. The T-cell subsets that are involved and the mechanisms of microbial clearance differ for different bacterial pathogens, to a large extent reflecting the subcellular localization of the bacterium within the host cell. To activate CD4 and CD8 T cells, bacterial antigens must intersect the MHC class II and MHC class I antigen-processing pathways, respectively. Dendritic cells, although not a major reservoir of infection with intracellular bacterial pathogens, play a predominant role in priming naïve T cells. In some cases, dendritic cells are infected with bacteria directly, in others dendritic cells acquire apoptotic fragments of infected cells and cross-present antigens to naïve T cells (103).

Interactions of Intracellular Bacteria with Dendritic Cells

A subset of intracellular bacterial pathogens causes disease by traversing the intestinal epithelium and disseminating throughout the body. *Salmonella enterica* is one such organism, and its interaction with the intestinal epithelium has been well characterized. *S. enterica* contains several virulence regions in its genome that enable invasion and intracellular survival. The SP1 locus, which encodes the components of the type III secretion system, enables *S. typhimurium* to invade the intestinal epithelium via M cells in follicle-associated epithelial areas and to enter Peyer patches. Dendritic cells in Peyer patches respond to bacterial infection in a CCR6-dependent manner and rapidly prime CD4 T cells specific for *S. typhimurium* (104). Invasion via M cells, however, appears to be only one of several ways that *S. typhimurium* can dive below the intestinal epithelial surface. SP1-deficient *S. typhimurium* can disseminate from the gut without traversing M cells and are taken up by CD18-expressing cells (17), which carry them to the spleen. Remarkably, dendritic cells in the lamina propria of the gut extend dendrites into the gut lumen by disrupting tight junctions between intestinal

epithelial cells and, in this process, capture luminal bacteria and transport them to mesenteric lymph nodes (36). Indeed, the lamina propria has an extensive network of dendritic cells that depends on the expression of CX3CR1 to enable dendrite extension into the gut lumen (37).

Intracellular bacteria also interact with dendritic cells following systemic infection, an interaction that is essential for effective priming of T lymphocytes. Experiments using a mouse strain in which dendritic cells can be selectively deleted by administration of a toxin demonstrated that CD8 T-cell priming following *L. monocytogenes* infection is entirely dependent on the presence of dendritic cells (105). Dendritic cells in spleen are directly infected by *L. monocytogenes* following intravenous inoculation, and toxin-mediated depletion of dendritic cells diminishes the number of bacteria that localize to the spleen (106).

CD4 T-Cell Responses to Intracellular Bacteria

T lymphocytes play a key role in the immune response to intracellular bacterial pathogens. In the case of bacteria residing in phagosomes, MHC class II–restricted CD4 T cells play a particularly important role in immune defense. Mice that lack MHC class II molecules, and consequently that also lack CD4 T cells, have markedly enhanced susceptibility to infection with *Mycobacterium tuberculosis* and *Salmonella enterica* (107,108). Along similar lines, patients infected with the human immunodeficiency virus (HIV) who have low CD4 counts are also more susceptible to infection with *M. tuberculosis*, *M. avium complex,* and several species of *Salmonella* (109). It is believed that IFN-γ production by pathogen-specific CD4 T cells is essential for activation of macrophages that harbor intracellular bacteria. IFN-γ induces the expression of iNOS by macrophages and thus contributes to bacterial killing.

In the setting of *M. tuberculosis* infection, clinical findings in patients and experimental results using murine models indicate that CD4 T cells, though essential for preventing progressive disease, fail to mediate complete bacterial clearance (110). Immunocompetent individuals can harbor viable *M. tuberculosis* for decades after initial exposure, and despite detectable CD4 T-cell responses, the pathogen persists, presumably in a latent state within macrophages. In mouse models of *M. tuberculosis* infection, vaccines that prime *M. tuberculosis*–specific CD4 T cells enhance resistance to challenge infection, diminishing *in vivo* mycobacterial growth in the immunized host by a factor of 10 to 100. No vaccine, however, has been able to prevent infection upon challenge with live, virulent *M. tuberculosis* (111). Along similar lines, immunization with *Mycobacterium bovis* BCG, a TB-preventive vaccine that has been administered extensively outside the United States, also provides only partial protection against infection (111).

The kinetics and differentiation of *M. tuberculosis*–specific CD4 T cells has been investigated in the mouse model. In mice, ESAT-6 is an immunodominant *M. tuberculosis* antigen detected by CD4 T cells, and the magnitude of the immune response to this antigen can be measured by intracellular staining of IFN-γ. Kinetic analysis of the CD4 T-cell response demonstrated that, in contrast to viral infections, such as influenza virus infection of the lung where CD4 T-cell responses are maximal 6 to 8 days following viral inoculation, CD4 T-cell responses to inhaled *M. tuberculosis* are delayed and do not peak until 21 to 28 days after exposure (112). This expansion of IFN-γ–producing CD4 T cells coincides with the inhibition of further increases in the number of viable bacteria in the lungs of infected mice.

CD4 T cell responses to *Salmonella enterica* have been investigated using T-cell receptor transgenic mice specific for an epitope derived from the bacterial flagellin. Following intestinal infection, flagellin-specific T cells are primed within 3 hours and undergo extensive proliferation in Peyer patches and mesenteric lymph nodes (113). In this system, the inoculum of *S. enterica* must be quite high to obtain T-cell priming, and at lower inocula, flagellin-specific CD4 T cells do not undergo proliferation (114). T-bet expression is required for Th1 differentiation of *S. enterica*–specific CD4 T cells (115).

Listeria monocytogenes infection of mice also induces CD4 T-cell responses, with peak responses occurring about 1 week after bacterial inoculation (116). The tissue distribution of pathogen-specific CD4 T cells differs, depending on the route of initial infection, with greater numbers of memory CD4 T cells in liver and intestinal epithelium following oral infection (116). CD4 T cells primed by *L. monocytogenes* infection produce IFN-γ and can mediate protective immunity. In contrast to CD8 T cells (see below), *L. monocytogenes*–specific CD4 T cells must produce IFN-γ in order to mediate protective immunity and thus, it is believed that CD4 T cells activate and enhance the bacteriocidal capacity of macrophages harboring intracellular bacteria (117). In contrast to *Salmonella* infections, T-bet is not required for IFN-γ production following *L. monocytogenes* infection (118). In addition to mediating bacterial clearance, *L. monocytogenes*–specific CD4 T cells have also been implicated in the generation of long-term CD8 T-cell memory against this pathogen (119,120). This role for CD4 T cells will be discussed in greater detail in the following section.

T-Regulatory Cells in Defense against Intracellular Bacteria

T-regulatory cells prevent the development of autoimmunity and also temper adaptive T-cell responses to microbial pathogens. Depletion of T-regulatory cells therefore enhances T-cell responses to *L. monocytogenes* (121) and also

increases the immunigency of killed bacterial pathogens (122), which usually do not induce substantial CD8 T-cell populations (123). In protozoal infections, such as that caused by *Leishmania,* T-regulatory cells prevent the complete clearance of the pathogen from the site of infection and thereby enhance the maintenance of long-term CD4 T–cell–mediated memory (124). It is likely that T-regulatory cells also influence the clearance and persistence of intracellular bacterial pathogens.

MHC Class I–Restricted T-Cell Responses

The MHC class I antigen-processing pathway and CD8 T lymphocytes are primarily involved in the recognition and eradication of viral infections. Viral antigens are synthesized in the host cytosol and thus have direct access to the MHC class I antigen-processing pathway. Many intracellular bacteria, however, also introduce protein antigens into the host-cell cytosol, either by invading the cytosol directly or by injecting proteins across plasma or vacuolar membranes into the cytosol.

Listeria monocytogenes has been used extensively to characterize CD8 T-cell responses to bacterial infection (35). Early studies of T-cell responses to this pathogen revealed that CD8 T cells are primed and that adoptive transfer of *L. monocytogenes*–specific CD8 T cells into naïve mice conferred protective immunity (125). As noted previously, *L. monocytogenes* escape killing in the macrophage vacuole by secreting listeriolysin O, a pore-forming toxin that perforates the vacuolar membrane and enables bacterial access to the cytosol (32). In the cytosol, *L. monocytogenes* secretes a number of proteins that are rapidly degraded by cytosolic proteasomes (126), in a manner that conforms to the N-end rule of protein degradation (127), and peptide fragments are transported into the ER and bound by newly synthesized MHC class I molecules. Studies in cell cultures demonstrated that the efficiency of epitope production is quite high, with one bound epitope requiring the degradation of 10 to 35 whole protein molecules (126,128). As might be expected, the quantities of different bacterially derived epitopes varied, with those derived from highly secreted proteins being more prevalent and those derived from scarce proteins being less prevalent. Quantitation of CD8 T-cell responses to these different epitopes, however, revealed little correlation between the frequency of epitopes and the magnitude of the CD8 T-cell responses (129,130). Indeed, the dominant response, which is specific for a peptide derived from listeriolysin O, recognizes a peptide that is presented in only small amounts on the cell surface. Comparison of CD8 T-cell responses to different MHC class Ia–restricted epitopes demonstrated similar expansion and contraction kinetics, suggesting that the duration of T-cell proliferation is not determined by the amount of

antigen that is presented (130). Interestingly, inhibiting bacterial growth by administering antibiotics to infected mice has little effect on T-cell expansion or contraction but does limit CD8 memory T-cell development (131,132). Studies characterizing the duration of *in vivo* T-cell priming demonstrated that T-cell priming is restricted to a relatively narrow period of time during the first 72 hours of infection, suggesting that a negative feedback mechanism downregulates T-cell priming at later time points (133).

Adoptive transfer of *L. monocytogenes*–specific CD8 T cells into naïve mice protects these mice from bacterial challenge (134). How CD8 T cells mediate protection against *L. monocytogenes* infection remains incompletely understood, however. Surprisingly, CD8 T cells that lack IFN-γ, TNF, or perforin can still mediate protective immunity upon transfer into recipient mice (89,135,136). CD8 T-cell effector functions likely make distinct contributions to bacterial clearance in different tissues, as indicated by the finding that CD8 T cells lacking perforin and TNF can mediate protection in the liver but not the spleen of *L. monocytogenes*–infected mice (136).

As noted in the previous section, *L. monocytogenes* infection also induces CD4 T-cell responses that can mediate protective immunity (134). In addition to cytokine-mediated effects of CD4 T cells on bacterial clearance, CD4 T cells also provide stimuli that enhance the long-term survival of *L. monocytogenes*–specific memory CD8 T cells (119,120). Initial studies of *L. monocytogenes* infection of mice lacking CD4 T cells demonstrated normal primary CD8 T-cell responses, but careful, longer-term follow-up studies demonstrated that the frequency of memory CD8 T cells gradually diminished in the absence of CD4 T cells. This gradual loss of CD8 T-cell memory results from events that occur during the priming of CD8 T cells and can be attributed, at least in part, to the production of IL-2 by responding CD4 T cells (137).

Oral infection with *L. monocytogenes* induces robust antigen-specific CD8 T-cell responses in the intestinal lamina propria and in the intestinal epithelial layer (41,42). CD8 T cells in the gut undergo expansion with kinetics that are similar to those in the spleen and liver, but their frequency remains higher following clearance of the pathogen. It remains unclear whether intestinal CD8 T cells play a role in protection from subsequent re-exposure to *L. monocytogenes*.

In contrast to *L. monocytogenes*, which enters and secretes proteins into the cytosol, *S. enterica* remains within a vacuole. Nevertheless, in order for *S. enterica* to survive within the host cell, it injects bacterial proteins into the cytosol of the infected cells using the type III secretion system, an essential process for *S. enterica* virulence. Experimental studies have demonstrated that recombinant *S. enterica* engineered to secrete known antigens into the cytosol of infected cells via the type III secretion system

can prime antigen-specific CD8 T-cell responses (138), albeit with delayed kinetics compared to responses induced by either viral or *L. monocytogenes* infection (139). Recombinant *S. enterica* expressing viral antigens are being investigated as potential vaccine candidates (140,141).

CD8 T cells are also postulated to contribute to defense against *M. tuberculosis* infection. Initial studies demonstrated that mice lacking β2-microglobulin are more susceptible to *M. tuberculosis* infection, suggesting that CD8 T cells promote mycobacterial clearance (142). Analysis of T cells in lungs of mice cured of *M. tuberculosis* and then reinfected demonstrated the activation and expansion of memory CD8 T cells (143). Other studies, however, using mice lacking CD8α or mice depleted of CD8 T cells by antibody administration, suggest that expression of MHC class I molecules may contribute more to mycobacterial clearance than CD8 T cells, leading to the hypothesis that other MHC class I–binding receptors, such as the NK receptors, may contribute to the control of mycobacterial infections (144). Thus, the precise contribution of MHC class I molecules and CD8 T cells in defense against *M. tuberculosis* infection remains incompletely defined.

MHC Class Ib–Restricted T-Cell Responses

Conventional MHC molecules, also referred to as MHC class Ia molecules, are highly polymorphic and are responsible for allogeneic graft rejection and graft-versus-host disease. In addition to MHC class Ia molecules, the major histocompatibility complex of mice and humans encodes additional MHC class I molecules that are far less polymorphic. These molecules, referred to as MHC class Ib molecules, are structurally very similar to MHC class Ia molecules in terms of containing peptide-binding grooves and associating with β2-microglobulin. Two MHC class Ib molecules, murine H2-M3 and human HLA-E, have been implicated in defense against intracellular bacterial infections.

H2-M3 is an MHC class Ib molecule that binds endogenous peptide of mitochondrial origin, specifically selecting peptides that contain the N-formylated amino terminus of mitochondrially encoded proteins (145). Structural analysis of the H2-M3 protein revealed that H2-M3 contains a peptide-binding groove with a binding pocket specific for N-formyl-methionine (146). Because bacterial and mitochondrial ribosomes initiate protein synthesis with N-formyl methionine, while eukaryotic ribosomes do not, H2-M3 was suspected to play a role in defense against bacterial infection (147). Characterization of the CD8 T cell response to *L. monocytogenes* infection revealed that a substantial fraction of responding T cells were restricted by H2-M3 and specific for bacterially secreted N-formyl methionine containing peptides (148,149). Mice with genetic deletion of H2-M3 are more susceptible to *L. mono-*

cytogenes infection, clearly establishing the role of H2-M3–restricted CD8 T cells in antimicrobial defense (150). N-formyl methionine–containing peptides from *M. tuberculosis* (151) and *S. enterica* (152) are also presented by H2-M3 to CD8 T cells following murine infection with these pathogens. In the case of murine *S. enterica* infection, Qa-1, another MHC class Ib molecule, has also been implicated in peptide presentation and CD8 T-cell activation (153).

Although CD8 T cells restricted by H2-M3 and MHC class Ia molecules following *L. monocytogenes* infection are phenotypically similar, their relative expansion kinetics following primary and secondary infection are distinct. H2-M3–restricted T cells expand more rapidly during primary infection than MHC class Ia–restricted T cells, and, in marked contrast to "conventionally" restricted T cells, H2-M3–restricted T cells undergo little expansion after secondary exposure to *L. monocytogenes* (154,155). Although the mechanisms responsible for this disparity remain undefined, these findings suggest that MHC class Ib–restricted T-cell responses may play a more prominent role during primary infection while making only minor contributions to memory responses.

HLA-E is a human MHC class Ib molecule that contains a binding groove that binds peptides derived from signal sequences of MHC class Ia molecules. Consistent with other MHC class Ib molecules, HLA-E is highly conserved between different individuals, that is, it lacks the polymorphism typical of MHC class Ia molecules. Characterization of T lymphocytes from individuals with a history of exposure to tuberculosis revealed that many CD8 T-cell clones that are specific for *M. tuberculosis* are restricted by HLA-E (156). Along similar lines, a subset of CD8 T cells specific for *Salmonella typhi* following immunization with the Ty21a typhoid vaccine were also found to be HLA-E–restricted (157). Although the contribution of HLA-E–restricted CD8 T cells to antimicrobial defense remains unclear, HLA-E–presented antigens are exciting vaccine candidates because they, unlike MHC class Ia–presented antigens, are likely to be immunogenic in HLA-disparate individuals.

CD1 MOLECULES AND PRESENTATION OF MYCOBACTERIAL LIPIDS

CD1 molecules are structurally similar to MHC class I molecules, associate with β2-microglobulin, and present antigens to T lymphocytes (158). In contrast to conventional MHC class I molecules, CD1 molecules have a deeper groove that, instead of binding peptides, accommodates hydrocarbon chains of lipids. Humans express four different CD1 molecules, CD1a, CD1b, CD1c, and CD1d, which differ in terms of intracellular trafficking, antigen presentation, and the T-cell populations that they stimulate (158).

CD1d molecules, for example, present lipid antigens to NK T cells in humans and mice. Mice do not express CD1a, CD1b, or CD1c, but in humans these molecules have been shown to present lipids derived from mycobacteria to T-cell populations. Mycolic acid, one of the major components of the mycobacterial outer surface, is a microbial antigen that is presented by CD1b (159). Subsequent studies demonstrated that lipoarabinomannan, phosphatidyl inositol mannoside, glucose monomycolate, and isoprenoid glycolipids are also bound by CD1 molecules and presented to T cells (160,161). The mechanism by which these highly hydrophobic hydrocarbons are inserted into the groove of the CD1 molecule remains unclear, but saposins, lysosomal lipid-binding proteins, have been implicated in lipid loading of CD1 molecules (162,163). Because CD1-restricted T cells can produce IFN-γ upon stimulation with mycobacterial lipids presented by CD1-expressing antigen-presenting cells, CD1-restricted T cells are believed to play a role in immune defense against *M. tuberculosis*. A particularly interesting feature of antigen presentation by CD1 molecules is their distinct subcellular localization, which allows them to present antigens from different endosomal compartments (158). Thus, CD1a traffics to early endosomes, CD11c to intermediate endosomes, and CD1d and CD1b traffic and derive antigens from late endosomes, lysosomes, and MHC class II compartments of antigen-presenting cells (158).

KILLING OF INTRACELLULAR BACTERIAL PATHOGENS

Although microbial killing is arguably the most important outcome of immune activation during infection, the molecular mechanisms that result in killing of intracellular bacterial pathogens are only partially understood. Killing of *S. enterica* in macrophages is mediated by NADPH phagocyte oxidase and inducible nitric oxide synthase. The oxidative burst, mediated by NADPH oxidase, kills bacteria in the first few hours following cellular infection, and nitric oxide–derived products synergize with oxidative products, in the form of superoxide anion, hydrogen peroxide, and peroxynitrite, to enhance early killing (164). At later time points following cellular infection, NO-mediated inhibition of bacterial growth predominates (164). Cytokines such as IFN-γ enhance NO-mediated bacterial killing by inducing nitric oxide synthase, while TNF enhances collocalization of NADPH phagocyte oxidase–containing vesicles with *Salmonella*-containing vacuoles (165). At another level, MyD88-dependent TLR-mediated signals activates p38 MAPK, which phosphorylates p47^{phox}, thereby enhancing NADPH oxidase assembly (48).

In addition to enhancing NADPH oxidase– and iNOS-mediated intracellular bacterial killing, IFN-γ also induces LRG-47, a 47-kDa GTPase that associates with vac-

uolar membranes. Mice that lack LRG-47 are markedly more susceptible to infection with *M. tuberculosis*, *S. enterica,* and *L. monocytogenes* (166). In fact, mice that lack LRG-47 are essentially comparable to IFN-γ–deficient mice in terms of susceptibility to infection by these intracellular bacterial pathogens. Initial studies indicated that LRG-47–deficient, *M. tuberculosis*–containing vacuoles did not acidify normally, thereby enhancing intracellular mycobacterial growth (167). More recent experiments demonstrate that autophagy is a major mechanism by which IFN-γ induces macrophage-mediated killing of *M. tuberculosis* (168,169) and that LRG-47 is essential for this process. Although *L. monocytogenes,* in contrast to *M. tuberculosis*, does not reside in a vacuole, LRG-47 is also essential for *in vivo* control of *L. monocytogenes* infection (170). Although autophagic elimination of intracellular bacteria may also play a role in this setting, it remains unclear how LRG-47 enhances killing of intracellular *L. monocytogenes*.

Although IFN-γ plays an essential role in defense against *M. tuberculosis* infection, the long-term persistence of mycobacteria in humans indicates that IFN-γ–mediated immune defense is not completely effective. Studies in murine and human macrophages demonstrated that *M. tuberculosis* infection reduces their responsiveness to IFN-γ (171). Inhibited responsiveness to IFN-γ is not general but specific for a subset of IFN-γ–induced effects, such as activation of the class II transactivator, but iNOS induction is maintained (172). Inhibition of INF-γ signaling is not the result from interference with STAT-1 phosphorylation or targeting to promoters and has both MyD88/TLR2-dependent and -independent components (173). Inhibition of IFN-γ signaling in part results from IL-6 production by *M. tuberculosis*–infected macrophages. Although the mechanism by which *M. tuberculosis* infection impairs macrophage responsiveness to IFN-γ remains incompletely defined, incomplete cytokine-mediated macrophage activation provides a plausible explanation for the inability of infected macrophages to eliminate *M. tuberculosis*.

T lymphocytes, by virtue of their MHC restriction, interact principally with other mammalian cells and do not recognize or respond to microbes directly. Microbial killing, therefore, is largely the purview of inflammatory cells such as macrophages, monocytes, dendritic cells, and neutrophils, which take their cues either directly or indirectly from T lymphocytes. Human T lymphocytes, however, release a protein, granulysin, which can directly kill microbes such as *L. monocytogenes* and *M. tuberculosis* (174). In patients with leprosy, caused by *Mycobacterium leprae,* higher frequencies of CD4 T cells expressing granulysin in infected cutaneous tissues correlated with fewer mycobacteria, suggesting that granulysin mediates microbial killing *in vivo* (175). Granulysin kills bacteria by altering their membrane permeability (176).

BACTERIAL MECHANISMS TO SUBVERT HOST IMMUNE RESPONSES

Intracellular bacteria have evolved complex strategies to invade cells, localize to distinct intracellular compartments, and spread to other cells. Mammalian cells, on the other hand, have evolved complex mechanisms to detect intracellular bacteria and activate antimicrobial effector processes. Some microbial pathogenesis strategies, in addition to enabling intracellular survival, also can be viewed as subverting immune recognition by the host. For example, *M. tuberculosis*, by avoiding intracellular compartments containing MHC class II molecules, may limit detection by pathogen-specific CD4 T cells (29). Along similar lines, by preventing the acidification of phagosomes, *M. tuberculosis* may inhibit the proteolytic generation of peptides that can associate with MHC class II molecules (177).

At the level of cytokine-mediated immune defenses, infection with *L. monocytogenes* induces IL-10 production, which attenuates both innate and adaptive immune responses. IL-10–deficient mice clear *L. monocytogenes* infections more rapidly (178). As described previously, virulent *L. monocytogenes* also induces type I interferon production, and mice that lack the receptor for type I interferon clear *L. monocytogenes* infections more rapidly (99–101). It has been postulated that *L. monocytogenes* induces type I interferon production in order to enhance its *in vivo* survival, a notion that remains speculative at this time.

CONCLUSION

Intracellular bacteria remain a major cause of human disease, and the generation of effective vaccines has been frustratingly difficult. The last decade has seen remarkable progress in defining the mechanisms that important pathogens such as *Mycobacterium tuberculosis, Salmonella enterica, Listeria monocytogenes,* and *Legionella pneumophila* use to invade cells and survive. Mechanisms by which host cells recognize intracellular bacteria are increasingly being identified and characterized and, importantly, their effects on adaptive immunity and their potential for enhancing long-term T-cell–mediated immunity determined.

Immunity to Extracellular Bacteria

Jeffrey N. Weiser and Moon H. Nahm

INTRODUCTION

Human interactions with bacteria are complex. A consortial relationship has developed between humans and microbes. We are composed of 10^{12} human cells and are inhabited by 10^{14} bacteria composed of innumerable species (1). More than 500 distinct species are estimated to reside in the human oropharynx alone (2). Relatively few of these bacteria are harmful to us in any way. We know little about the innate or acquired immune mechanisms that maintain this equilibrium. In large part, many diseases caused by bacteria are mistakes in which this consortial relationship breaks down and lines are crossed. The innate and adaptive responses to these transgressions can in themselves lead to dire consequences. In *Lives of the Cell*, Lewis Thomas points out

> The microorganisms that seem to have it in for us in the worst way—the ones that really appear to wish us ill—turn out on close examination to be rather more like bystanders, strays, strangers in from the cold. They will invade and replicate if they get the chance, and some of them will get into our deepest tissues and set forth in the blood, but it is our response to their presence that makes the disease. Our arsenals for fighting off bacteria

are so powerful, and involve so many different defense mechanisms, that we are in more danger from them than from the invaders. We live in the midst of explosive devices; we are mined (3).

Although certain bacterial species are classified as pathogens, they can live in harmony on our surfaces for long periods and never cause disease. The bacteria that can cause human disease are quite diverse. Based on the pathogenesis of infection and the resulting immune response, these bacteria can be categorized into two general types: those causing intracellular infections and those causing extracellular infections. Most bacteria causing intracellular infections avoid being killed after phagocytosis by either interfering with phagosome-lysosome fusion or escaping from the phagosome and into the cytoplasm. Cellular immunity is critical against bacteria that reside mainly within an intracellular milieu, as is described in Chapter 37. In contrast, the bacteria causing extracellular infections survive in the host by avoiding engulfment by professional phagocytic cells such as neutrophils and macrophages. They do this by presenting a surface that minimizes the opsonic and lytic effects of antibody and complement. Although extracellular bacteria have the ability to enter and pass through cells as a means of moving from one *in vivo*

environment to another, they are readily killed once captured by phagocytes. Accordingly, the host defense against extracellular bacteria is critically dependent on humoral immunity complement and the production of specific antibody. Table 38.1 lists many of the important bacteria that can cause extracellular infections in humans, together with the diseases they cause and some of their major virulence factors. In this chapter, we describe the surface structures of many of these bacteria and provide examples of how they are able to infect their hosts and cause disease. We also describe the salient aspects of the innate immunity and antigen-induced immunity important in the host's defense against these bacteria.

SURFACE STRUCTURE OF GRAM-POSITIVE AND GRAM-NEGATIVE BACTERIA

Differences among bacteria contribute to their specific adaptation to either a particular host species or to microenvironments within their host. In general, our current understanding of the limitations of nutrients and the specificity of enzymes and bacterial adhesins, or host receptors, that account for these highly specific microbial tropisms is limited. The diversity of bacterial structures encountered by the host offers a major challenge to immune detection of potential pathogens. There are no structural features that reliably differentiate pathogens from nonpathogens. Moreover, many important extracellular pathogens exist mainly as commensals, only causing damage when the balance between host and microbe is perturbed (opportunistic pathogens). Thus, their diversity requires that initial recognition through innate immunity be focused on the more conserved structural features or "molecular patterns" of bacteria. These molecular patterns are, in general, structures such as peptidoglycan, lipoteichoic acid (LTA), and lipopolysaccharide (LPS) that are also essential for bacterial viability and are thus unlikely to be modified so as to evade innate immunity. A further consideration is that these structural differences among types of bacteria may dictate differences in host responses and contribute to distinct patterns of disease. That said, different types of bacteria may also give rise to remarkably similar host responses. The syndrome of sepsis, for instance, looks very similar regardless of whether it is caused by a gram-positive or a gram-negative organism, although there may be little overlap in the specific bacterial mediators involved.

Most extracellular, as well as intracellular, pathogenic bacteria can be divided into two major groups (gram-negative and gram-positive) based on their response to staining with Gram's stain. To illustrate the surface of the bacteria in the two groups, the surface structures of *Streptococcus pneumoniae* and *Neisseria meningitidis* are shown in Figure 38.1A and B, respectively. Three layers are commonly recognized: cytoplasmic membrane, cell wall, and

outer layer. Although these layers are described later in detail, it is important to note that these definitions are operational and that, in reality, the layers are not entirely distinct. For instance, molecules anchored in the cytoplasmic membrane or cell wall may extend into or through other layers. It is also important to note that the capsule, O antigens, and cell wall are not contiguous shields; rather, they are permeable enough to allow through secreted products and nutrients, as well as some immunologic factors (e.g., antibodies and complement).

All bacteria have a cytoplasmic membrane, a non–sterol-containing phospholipid bilayer. This membrane is an osmotic barrier and also forms a barrier for most molecules. The cytoplasmic membrane encompasses various proteins, many of which function in transport. Some of these proteins, referred to as lipoproteins (e.g., pneumococcal surface adhesion A [PsaA], which is a manganese permease in *S. pneumoniae*), are noncovalently anchored to the membrane through lipid modifications and are especially common among some bacteria (e.g., *Borrelia burgdorferi* and *Mycobacterium tuberculosis*). Proteins not exposed on the surface generally display a greater degree of structural and functional conservation compared with those exposed to the selective pressure of host immunity.

A cell wall is found in all of the pathogenic bacteria of both groups, with the exception of mollicutes (which include the genus *Mycoplasma*). The cell wall surrounds the cytoplasmic membrane and is made of peptidoglycan, which is a polymer of alternating sugars *N*-acetyl glucosamine and muramic acid, the latter being connected to a stem peptide. The stem peptides include four to five D- and L-amino acids that are extensively cross-linked by bridges that provide rigidity to the cell wall and protect it from environmental extremes (especially differences in osmolarity). These cell wall peptides include atypical amino acids and are highly conserved within a species and relatively conserved across gram-negative species. Peptidoglycan polymerization is carried out by enzymes, many of which are the target of β-lactam antibiotics and are referred to as penicillin-binding proteins. Compared with gram-negative bacteria, gram-positive organisms may have different stem peptides and cross-linking, as well as a thicker (20 to 30 nm compared with 2 to 4 nm) cell wall layer that can retain the Gram's stain better. The thick cell wall of the gram-positive bacteria may be responsible for their greater resistance to complement-mediated lysis. Other features of the cell wall, such as O-acetylation of muramic acid found in some species, mediate resistance to lysozyme, an enzyme that lyses bacteria by cleavage of the peptidoglycan backbone (4).

In addition to peptidoglycan, many gram-positive bacteria have polysaccharide (PS) associated with their cell walls, with this cell wall PS often extending into the outer layer. The structure of the cell wall PS of gram-positive bacteria varies among species but is relatively invariant within

▶ **TABLE 38.1 Extracellular Bacteria Commonly Associated with Diseases**

Species	Disease	Important Virulence Structures/Molecules	Special Adaptations Critical to Host Infection
Neisseria gonorrhoeae	Urethritis, cervicitis, salpingitis, endometritis, prostatitis, arthritis, proctitis, pharyngitis	Lipopolysaccharide, fimbria, peptidoglycan, Opa protein adhesin, IgA1 protease	Phase and antigenic variation, molecular mimicry of human antigens
Neisseria meningitidis	Bacteremia, meningitis, septic arthritis	Capsule, lipopolysaccharide, fimbria, IgA1 protease	Phase and antigenic variation, molecular mimicry of human antigens, asymptomatic carriage common
Haemophilus influenzae	Otitis media bronchitis, pneumonia, sepsis, meningitis (encapsulated strains)	Lipopolysaccharide with phosphorylcholine, fimbria, high–molecular weight adhesions, IgA1 protease	Phase and antigenic variation, molecular mimicry of human antigens
Bordetella pertussis	Whooping cough in children, chronic cough syndrome in adults	Pertussis toxin, pertactin, filamentous hemagglutinin, fimbria	Coordinate regulation of multiple virulence factors upon exposure to the host environment
Pseudomonas aeruginosa	Infections in compromised hosts, pneumonia, sepsis	Lipopolysaccharide, proteases, lipases, lecithinases, exotoxin A, elastase, flagella	Relatively large genomic size (~6 megabases) allows considerable adaptability to changes in environmental conditions, biofilms
Escherichia coli	Urinary tract infection, sepsis, traveler's diarrhea, dysentery, neonatal meningitis, hemolytic-uremic syndrome	Capsular polysaccharide, lipopolysaccharide, fimbria, toxins, siderophores	Antigenic heterogeneity of capsule and lipopolysaccharide
Vibrio cholerae	Diarrhea	Cholera toxin, fimbria	Bacterial dispersal via cholera toxin, which induces copious watery diarrhea
Helicobacter pylori	Peptic ulcer disease	Urease, flagella, CagA	Ability to survive at low pH provides a niche lacking bacterial competition or efficient immune surveillance
Streptococcus pneumoniae	Pneumonia, otitis media, meningitis, sinusitis	Capsule, PspA and C, pneumolysin, neuraminidase, hyaluronidase, teichoic acids with phosphorylcholine, IgA1 protease	Asymptomatic colonization, genetic transformation permitting continual generation of new genotypes
Streptococcus pyogenes (group A Streptococcus)	Acute pharyngitis, scarlet fever, necrotizing fasciitis, streptococcal toxic shock syndrome, rheumatic fever, glomerulonephritis	Hyaluronic acid capsule, M protein, streptococcal pyrogenic exotoxins, streptolysin O, streptolysin S, NAD-glycohydrolase, C5a peptidase	Molecular mimicry of human antigens, high diversity of M proteins
Streptococcus agalactiae (group B Streptococcus)	Bacteremia, neonatal pneumonia and meningitis	Capsule, β-hemolysin, hyaluronidase, C5a peptidase	Asymptomatic colonization, acquisition by infants during parturition
Staphylococcus aureus	Impetigo, folliculitis, boils, cellulitis, wound infections, toxic shock, osteomyelitis, endocarditis, bacteremia, pneumonia, food poisoning	Tissue-degrading enzymes, alpha toxin and other membrane-damaging toxins, epidermolytic toxins, enterotoxins, capsule, protein A, TSST1, pigment	Resistant to dehydration, asymptomatic colonization
Bacillus anthracis	Cutaneous infection, inhalation anthrax	Capsule, lethal and edema factors	Opportunistic infection by a spore-forming soil organism
Corynebacterium diphtheria	Diphtheria (pharyngitis/tonsillitis)	Diphtheria toxin	Toxin gene contained in temperate phage and expression regulated by iron concentration
Clostridium tetani	Tetanus (spastic paralysis)	Tetanus toxin (blocks inhibitory neurotransmitters)	Opportunistic infection by a spore-forming soil anaerobe
Clostridium perfringens	Gas gangrene, anaerobic cellulitis, endometritis, food poisoning	More than 10 exotoxins	Opportunistic infection of wounds
Clostridium botulinum	Flaccid paralysis: cutaneous, infant, ingestion forms	Botulism toxin blocks acetylcholine release at synapses	Opportunistic infection by a spore-forming anaerobe

Ig, immunoglobulin; TSST1, toxic shock syndrome toxin-1.
FIGURE 38.1 Schematic representation of the surfaces of **(A)** *Streptococcus pneumoniae* and **(B)** *Neisseria meningitidis* as examples of gram-positive and gram-negative bacteria, respectively. The cell wall polysaccharide of *S. pneumoniae* is often called C-polysaccharide (C-PS). The inset in panel B shows lipopolysaccharide (LPS) anchored to the outer leaflet of the outer membrane.

a species. Differences in the antigenicity of the cell wall PS have been used to distinguish species (e.g., separate streptococci into groups A, B, C, etc.) (5). Cell wall PS often has phosphate group(s) in repeating units of glycerol or ribitol in a structure known as teichoic acid. Teichoic acid may also be linked to lipid molecules, when it is then called lipoteichoic acid (LTA), which is anchored to the cytoplasmic membrane and extends out through the cell wall (6). In pneumococci, the overall PS structures of LTA and cell wall teichoic acid (also referred to as C-polysaccharide) are very similar, with the difference being their mode of attachment to the bacterial surface (7).

Another major difference in surface structure between gram-negative and gram-positive bacteria is the presence of an outer membrane on gram-negative bacteria. The outer membrane is an asymmetric bilayer. The inner leaflet is comprised primarily of phospholipids, whereas the outer leaflet contains lipid A, the hydrophobic component of LPS. LPS, also called endotoxin, is an amphipathic glycolipid with four distinct regions: lipid A, the inner core, the outer core, and, in some species, the O antigen. Lipid A is composed of a dihexosamine backbone to which between four and seven saturated (12- to 16-carbon) fatty acids are attached through amide and ester linkages. Lipid A is the principal "toxin" associated with most gram-negative bacteria, although it is now clear that lipid A is not a true toxin. Instead, its ability to induce cytokines accounts for its potentially detrimental effects. The carbohydrate portion of the LPS, which makes a minimal contribution to its endotoxin activity, is attached to lipid

A through a molecule unique to gram-negative bacteria called keto-deoxyoctanoate. Together with heptose moieties, this molecule forms the inner core of the LPS.

The outer core is composed of 7 to 10 monosaccharide units whose arrangement is relatively conserved among gram-negative species (8). In many gram-negative bacteria, the outer core of LPS is connected to a repeating series of carbohydrates called the O antigen. The O antigen forms a hydrophilic shield around the bacterium that provides a barrier to complement deposition on the bacterial cell surface. The O antigen is variable in length, is antigenically diverse, and confers serotypic specificity. The O antigens of *Escherichia coli*, *Klebsiella*, and *Salmonella* have as many as 30 repeating units composed of four to six sugars each (8). Members of the genera *Neisseria* and *Haemophilus*, on the other hand, lack O antigens, and the size of their carbohydrate regions, also called lipooligosaccharides (LOSs), does not exceed 7,000 daltons. Proteins, including channel-forming porins, are also found in their outer membrane.

For many pathogenic extracellular bacteria, PS components dominate the outer layer. In addition to the PS on LPS (gram-negative) and teichoic acid (gram-positive), there is often another thick layer of carbohydrate referred to as "capsule" that may account for more than half of the bacterial mass. An exception to this general rule is *Bacillus anthracis*, whose capsule is made of poly-D-glutamic acid rather than a polysaccharide (9). *S. pneumoniae* has capsular PS that is covalently attached to the cell wall in most (but not all) serotypes (10). In contrast, the capsule PS is anchored to the outer membrane by acyl chains in *N. meningitidis* (11) and *Haemophilus influenzae* type b (12). Capsular PSs may be highly diverse both within and between species. In the case of *S. pneumoniae*, each strain expresses a single type of capsular PS, with members of this species being capable of synthesizing at least 90 structurally distinct types (13). This diversity limits immune recognition until antibody is generated to the capsular PS of the infecting strain (antigenic variation).

The outer layer is well developed in bacteria that cause extracellular infections and has many features that help the bacteria circumvent the host immune system. First, the outer layer has properties that reduce the attachment of extracellular bacteria to eukaryotic surfaces, including those of phagocytes. Generally, the PS capsules render the bacteria hydrophilic and negatively charged like eukaryotic cell surfaces, which are rich in sialic acid. The negatively charged surface makes the bacteria partly resistant to the deposition of complement by the alternative pathway by enhancing the degradation of C3b (14) (Chapter 33). Second, in some cases, elicitation of antibody is minimized because the capsular PS or LPS mimics host antigens, as is more fully described later in this chapter (page 1193). Third, the outer layer can physically mask most of the other bacterial surface components and thus minimize the number of exposed epitopes that can be recognized

by the antibody and complement. Although the capsule is porous to antibodies and complement, the binding of antibodies and the fixation of complement beneath the capsule surface are relatively ineffective in promoting opsonophagocytosis and clearance (15).

BACTERIAL VIRULENCE FACTORS

Extracellular bacteria often elaborate molecules called "virulence factors" that are useful to their survival and proliferation in the host. For example, the shielding function of the outer layer is further augmented by the presence of surface proteins that can interfere with host clearance mechanisms. Proteins inhibiting effective complement deposition include pneumococcal surface protein A (PspA); pneumococcal surface protein C (PspC), alternatively called choline-binding protein A (CbpA); and the C3-binding protein in *S. pneumoniae* (16,17) or M protein in *Streptococcus pyogenes* (18). An example of a protein that interferes with antibody is protein A, which is expressed on the surface of *Staphylococcus aureus* and binds immunoglobulin in a manner that precludes recognition of its target antigen (19). In addition, many successful mucosal pathogens, including members of the *Neisseria*, *Haemophilus*, and *Streptococcus* genera, express proteases with specificity for the hinge region of human immunoglobulin A1 (IgA1) (20). These IgA1 proteases remove the Fc_α component required to promote the inflammatory process, leaving the organisms' antigens obscured by the binding of inert Fab_α fragments. By inhibiting the deposition of complement or antibody, many of these proteins act to diminish phagocytosis.

The best-known virulence factors are toxins, which interrupt specific host functions. These proteinaceous molecules (also referred to as exotoxins to differentiate them from endotoxin) can be grouped on the basis of their molecular structure and their mechanism of action (21). The largest group is called A-B toxins, which are comprised of two subunits, each with a different function. The A subunit has enzymatic activity, and the B subunit targets the A subunit to the host cells. This group includes diphtheria toxin, cholera toxin, pertussis toxin, and two anthrax toxins (lethal factor and edema factor). For instance, lethal factor of *B. anthracis* behaves as the A subunit and requires a B subunit protein named "protective antigen" to enter into target cells. In some cases, the toxin alone is sufficient to account for the detrimental symptoms of its respective infection. Cholera toxin causes ADP ribosylation of G proteins, which stimulates adenylate cyclase and increases cAMP in cells lining the gut. This results in secretion of electrolytes and is responsible for a severe diarrhea, promoting transmission but often causing dehydration that, if not treated, may be fatal. Uptake of botulism toxin by nerve endings leads to

retrograde transport that interrupts synaptic transmission and causes a flaccid paralysis (22). Staphylococcal enterotoxin A (a toxin that acts from the gut lumen), which is one of five membrane-damaging toxins produced by staphylococci, is the primary cause of staphylococcal food poisoning and plays a major role in invasive infections (23). Some strains of *Escherichia coli* produce a protein-synthesis-inhibiting verotoxin, which may damage the microvasculature of the kidney and cause hemolytic uremic syndrome (24). Another group of proteins secreted by *S. aureus* and *S. pyogenes* have toxin-like effects but lack any enzymatic activity. These "superantigens" cause a nonclonal stimulation of T cells by bridging major histocompatibility complex (MHC) class II molecules (outside the antigen-binding site) on antigen-presenting cells and the Vβ region of the T cell receptor on T cells. The ensuing massive release of cytokines by localized release of a superantigen, such as the toxic shock syndrome toxin-1 (TSST1) expressed by some strains of *S. aureus*, results in systemic symptoms that are collectively known as toxic shock syndrome (25).

Another class of virulence factors neutralizes host defenses. Pneumolysin from *S. pneumoniae* is a member of a large class of cholesterol-dependent cytotoxins that oligomerize to form large pores, which interfere with a number of host cell functions or induce cell death when present at higher concentrations (26). Pneumolysin also depletes complement at a distance from the pneumococci and interferes with both the function of phagocytes and the development of protective immunity (27). *S. pyogenes* and group B streptococci produce a C5a peptidase that inhibits the chemotaxic effects (recruitment of host phagocytes to the sites of infections) of C5a, a product of complement activation (28). *Helicobacter pylori* produces urease, which can generate ammonia that can neutralize acid in the stomach and thereby promotes its survival. *S. aureus* produces a pigment that makes the bacterium more resistant to oxidative stress and killing by neutrophils (29).

Whereas evasion of professional phagocytes is critical for extracellular pathogens, the ability to attach to other cell types, including both mucosal and nonmucosal surfaces, is important for their persistence. Many bacterial surface proteins have an adhesive function that confers a high affinity for binding to specific host cell receptors. Nasopharyngeal carriage of pneumococci is mediated largely by adherence to the host molecule *N*-acetyl-D-glucosamine $\beta1\rightarrow3$ galactose or *N*-acetyl-D-glucosamine $\beta1\rightarrow4$ galactose (30). Bacteria often mimic host ligands to coopt their receptors for their own purposes. Many pathogens of the airway express phosphorylcholine (phosphocholine [PC]) on their surfaces (31). This molecule, which is otherwise unusual in bacteria, is found on platelet-activating factor and allows bacterial binding to its receptor (rPAF) (32). To facilitate their attachment to host cells, many bacteria use a pilus (fimbria)—a long filamentous structure extending from the organism. The Pap pilus of *E. coli* binds the Gal$\alpha1\rightarrow4$Gal unit of cell surface globoside in urethral epithelial cells (33). The *Vibrio cholerae* pilus allows the bacterium to attach to the enterocyte for more efficient toxin delivery (34,35). *Bordetella pertussis* has three adherence factors—a filamentous hemagglutinin, pertactin, and a pilus—which allow it to attach to ciliated respiratory epithelial cells in the trachea and bronchi and thus resist the cleansing action of mucus flow (36,37).

Another group of virulence factors helps bacteria acquire essential nutrients. Motile bacteria (e.g., *Pseudomonas aeruginosa*) express flagellin, a complex motor apparatus that allows the bacterial cell to transit along a concentration gradient of nutrients (38). Although in some cases the host and microbe provide nutrients for one another, for some nutrients there is fierce competition. Mucosal fluid and blood are low in free ferric iron due to the presence of iron-binding proteins such as lactoferrin and transferrin. To successfully compete with the host for this vital metabolite, *N. meningitidis*, *Neisseria gonorrhoeae*, and *H. influenzae* have complex surface transport systems that can obtain iron from human transferrin, lactoferrin, and hemoglobin (39). Other bacteria, such as *E. coli* and *Salmonella*, use a different mechanism to acquire iron; they secrete small, high-affinity iron chelators called siderophores that remove iron from human proteins in the environment surrounding the bacteria. The iron–siderophore complex is then taken up by the bacterium, and the siderophore is degraded so that the iron can be freed for use (40).

Production of virulence factors is often highly regulated by bacteria to accommodate changes in environmental stimuli. In staphylococci, it has been shown that the amount of capsule is regulated in response to environmental stimuli (41). One of the best studied of such regulatory systems is the BvgAS, a two-component regulatory system in *B. pertussis* (42). This system, which regulates the expression of adhesins, toxins, and other virulence factors, is controlled by external signals including Mg^{2+}, temperature, and nicotinic acid. Two proteins are involved in this regulatory system, BvgS and BvgA. BvgS, the sensor, is a kinase and is able to autophosphorylate itself in response to the environmental signal. BvgA, the response regulator, is in turn phosphorylated by BvgS. Phosphorylated BvgA is able to activate transcription of virulence genes through a change in its interaction with a 70-bp consensus sequence repeated in Bvg-regulated promoters (42). Analogous two-component regulatory systems in other pathogens are frequently used to regulate the expression of genes associated with virulence (43).

A common theme among extracellular bacteria is the ability rapidly to modify their cell surfaces to adapt to different host environments, such as the natural environment outside of a host, the mucosa of a host, or more invasive

sites within a host. For some pathogens, these modifications occur through sensing signals in their environment followed by programmed alterations in gene expression as described for the *Bordetella*.

Another strategy used by extracellular pathogens depends on selection among a heterogeneous population for those members with permissive characteristics. This heterogeneity in a population is commonly generated through genomic rearrangements, such as recombinational events or slip-stranded mispairing in highly repetitive DNA sequences (44). This latter mechanism allows for reversible on–off switching (phase variation) and is especially prevalent in genes encoding cell surface structures subject to immune pressure. For instance, the capsular PS on *N. meningitidis* is needed to protect the organism during invasive infection but inhibits adherence on the mucosal surface, where complement is less abundant. Phase variation of a gene required for capsule synthesis allows for selection of organisms without capsule (phase-off) (45). This change facilitates the bacterial adhesion to the epithelial cells, perhaps by exposing the bacterial adhesins. Alternatively, by decreasing capsule production, the bacteria become less hydrophilic and less negatively charged. This change facilitates their entry into the epithelial cells and their subsequent invasion into deeper tissues. On the emergence of the bacteria from the epithelial cells in the submucosa, capsule synthesis is restored (phase-on) because of the selective pressure of complement-mediated clearance and the requirement for the capsule to survive where the concentration of complement is higher. The flexibility to express different surface properties helps bacteria successfully evade the host immune system and survive in many niches within the host.

Bacteria-to-bacteria signaling is another important mechanism for the control of virulence factors. This phenomenon, called "quorum sensing" (46), has been shown to be operative in a large number of gram-negative and gram-positive species. The signal transmitted between the bacteria can be an acylated lipid (e.g., homoserine lactone) in gram-negative bacteria (e.g., vibrios) or a peptide in gram-positive bacteria (e.g., *S. aureus*). Quorum sensing has been shown to be important in biofilm formation in a number of bacterial species, in the expression of "competence" for the uptake and incorporation of exogenous DNA (transformation), and for the regulation of a number of virulence factors (47). Biofilms are communities of one or multiple bacterial species that adhere both to each other and to a target surface. These extensive aggregates are particularly resistant to many host clearance mechanisms and to antibiotics that are effective against free-living (planktonic) bacteria. Biofilms, therefore, are often a contributing factor in more-chronic bacterial infections such as those involving foreign bodies.

An important characteristic of virulence factors is their structural polymorphism. For instance, there are at least 100 different serologic types of M proteins of *S. pyogenes* (48). Similarly, pneumococci have 90 serologically distinct capsular PSs (13). The polymorphism in the structure of many virulence factors allows the bacteria making them to avoid antigen-specific host immunity. For example, antibodies to the immunodominant region on one serotype of M protein do not cross-react with M proteins of other serotypes and thus do not provide protection against strains expressing other serotypes. Similarly, newly acquired pneumococci can escape recognition by anticapsular antibodies produced in response to previous pneumococcal infections with other serotypes.

The polymorphism in virulence factors is achieved by various genetic mechanisms. Variation in M proteins is the result of sequence differences in the N-terminal (but not C-terminal) half of M proteins (49). *S. pneumoniae* has the genes for synthesizing capsular PS as a "genetic cassette" that can be exchanged among different strains (50) and may result in the shift in the serotype distribution after the use of vaccines designed to elicit serotype-specific protection (13). *Neisseria* has genetic machinery for rapid gene rearrangement (51) through gene conversion using the multiple "silent" pili genes with different sequences. This process, similar to gene rearrangements that generate specific immunoglobulins, permits an individual bacterium quickly to produce progeny expressing pili with different characteristics. The number of potential pilus–antigen variants within the progeny of a single organism is estimated to be greater than 100,000 (52). In addition, *Neisseria* contain large numbers of genes with tandem repeats that undergo phase variation through slip-stranded mispairing of these sequences. Based on predictions from whole-genome sequencing, through this mechanism alone the organism may be able to generate more than 2^{65} different phenotypic variants (53).

Sequencing of the entire genomes of bacteria has shown that the genes for virulence factors have generally originated from other organisms and exist as a part of large blocks of DNA containing multiple genes. These DNA blocks are called "pathogenicity islands" (PAIs). For instance, strains of "enteropathogenic" *E. coli* (EPEC) contain a PAI encompassing about 41 genes encoding a surface ligand required for intimate association of the bacterial and host cell and a bacterial secretion apparatus (54). This system (type IV secretion system) allows for delivery of the receptor for its own adhesin, encoded on the same PAI, into host cells. Elaborate secretion mechanisms (types III and IV) and pore-forming toxins are mechanisms whereby extracellular organisms gain access to the host cell cytoplasm to modify its activity to suit the needs of the extracellular pathogen. Another example is *H. pylori,* which injects cytotoxin-associated gene A (CagA) molecules directly into host cells using a syringe-like type IV secretory apparatus. CagA is then phosphorylated by the host cells, and the phosphorylated CagA alters host cell function, with

the *H. pylori* strains producing the CagA molecules being more likely to cause ulcers (55). In the case of *S. pyogenes*, its pore-forming toxin, streptolysin O, allows for translocation of an enzyme (NAD-glycohydrolase) that is capable of producing the potent cytoplasmic second messenger cyclic ADP-ribose (56).

BACTERIAL INVASION OF THE HOST

Both keratinized skin and mucosal surfaces have inherent nonimmune defense mechanisms that modulate bacterial growth and minimize the risk of invasion. Healthy human skin is an effective physical barrier to infection by most human extracellular and intracellular pathogens. The keratinization of fully differentiated skin epithelium results in a relatively impermeable surface. In addition, lysozymes, toxic lipids, and hydrogen ions secreted by cutaneous glands offer bacteriostatic protection for cutaneous pores and hair follicles. Occasionally, this defense can be breached by extracellular bacteria such as *S. pyogenes* or *S. aureus,* causing cellulitis and abscess. More commonly, bacterial invasion through intact skin requires physical damage, such as abrasions, burns, or other trauma. For instance, cutaneous anthrax develops when *B. anthracis* enters the body through a break in the skin. *Staphylococcus epidermidis*, a member of the commensal skin flora, can infect indwelling catheters by spreading through the puncture site in the skin and may lead to bacteremia or colonization of prosthetic devices, including artificial heart valves and shunts. A major factor allowing these bacteria to cause disease is their ability to elaborate within the bacterial population a biofilm (see prior discussion) that facilitates their adhesion, is antiphagocytic, and acts as a barrier to antibiotic penetration (57).

Unlike the skin, the mucosal epithelium is not keratinized. Instead, mucosal areas, such as the gastrointestinal tract, nasopharynx, upper airway, and vagina, are moist and nutritionally rich. Thus, it is not surprising that mucosal areas contain a large number of bacteria. In oral secretions and gastrointestinal products, 10^8 and 10^{11} bacteria/mL may be found, respectively. To ensure their survival in the mucosal environment, extracellular bacteria elaborate many virulence factors required for the acquisition of essential nutrients or for their adherence to the host cells. In some cases, bacteria may subvert the host inflammatory response. *Salmonella* species can block the activation of NF-κB and the subsequent activation of the inflammatory response. They achieve this by preventing the degradation of IκB, which is essential for the translocation of NF-κB from the cytoplasm to the nucleus (58). In some cases, pathogens locate in a less well-protected microenvironment within the mucosal areas. *H. pylori* survives in the very acidic stomach by burying itself in the mucus, which protects it from direct exposure to the acid

and from phagocytes. There are also few other species for *H. pylori* to compete with in this more hostile environment.

Mucosal sites have an especially diverse array of bacterial species. Most of the bacteria species found at the mucosal sites are harmless. In addition, polymerase chain reaction analysis of 16S ribosomal RNA sequences suggests the presence of many additional unidentified (and so far unculturable) bacterial species on the mucosal surface (59). Many potentially pathogenic bacterial strains are also often found in the mucosal areas of healthy individuals without causing symptoms. *S. pneumoniae*, *N. meningitidis*, *H. influenzae*, and *S. aureus* are examples of pathogenic extracellular bacteria that are frequently carried in the nasopharynx of healthy individuals. The carriage rate of pathogenic bacteria can be relatively high, as shown by the fact that 50% to 60% of healthy young children may carry *S. pneumoniae* in their throats (60). Maintenance of species diversity is dynamic. In some situations, collaboration among bacteria is essential for their successful colonization, as seen among the complex hierarchical communities adhering to tooth surfaces. In other situations, bacterial species compete and regulate diversity among themselves (31). Many bacterial species produce molecules that suppress the growth of other bacterial species. These molecules may include bacteriocins, small molecules that target members of the same or different species that do not express its cognate immunity protein (61). Some species can take advantage of host responses to which they are resistant to outcompete another member of the same niche that is less resistant (31). The host may also control the diversity of colonizing bacteria by modifying the pH or other environmental conditions in the mucosal area. Interference with these homeostatic mechanisms as occurs with antibiotic therapy may alter the flora and predispose the host to disease. As noted, stomach acid is an effective barrier to reaching the nutrient-rich environment of the gut. When stomach acid is pharmacologically reduced, the inoculum of organisms like *V. cholerae* required to infect the intestines is greatly diminished.

Several explanations have been advanced to explain why many pathogens do not cause disease when resident at mucosal sites during colonization. One explanation is that the maintenance of diverse bacterial population is responsible for the prevention of the disease. For instance, the destruction of the normal gastrointestinal bacterial flora with some antibiotics can be associated with a selective expansion of *Clostridium difficile* and the development of pseudomembranous colitis (62). Another explanation may be that the pathogenic bacteria carried in healthy persons are different from those isolated in the setting of disease. For instance, during nonepidemic periods, approximately 5% to 10% of the population carries *N. meningitidis,* which are mostly nonencapsulated (63). During epidemics, 30% to 60% of the population may carry meningococci, which

are mostly encapsulated, and the majority of which are of the same capsular type as the case strain causing the epidemic (64). A third explanation is that the pathogenic bacteria are effectively confined to the mucosal surface, where they do not cause damage or induce inflammation. Group B streptococci are carried asymptomatically in the lower intestine and the female genital tract. In the same host, in the setting of parturition, group B streptococci may access the bloodstream and cause septic infection. A fourth explanation is centered on the differences among hosts. Group B streptococci that colonize the mother may cause life-threatening infection when the same strain is passed to the neonate at or before birth (65).

Although pathogenic extracellular bacteria can exist asymptomatically in the mucosa, they can passively enter into less defended sites and cause focal infections. For instance, *E. coli*, which is normally present in the gut, may enter the normally sterile urogenital tract and cause urinary tract infections. *S. pneumoniae* and *H. influenzae* are often carried in the nasopharyngeal space, but they can invade nearby, normally sterile cavities (e.g., lungs, sinuses, and middle ear) and cause focal infections. Aspiration of bacteria from the nasopharynx into the lung most likely occurs frequently with no ill effects; however, aspiration may lead to an infection when there is damage to the epithelial surface, particularly when the protective effects of mucociliary activity are lost, as often occurs in a smoker or during recent viral infection (respiratory syncytial virus or influenza) (5). Some bacteria produce enzymes such as hyaluronidase (66), which may aid in their passage though tissue barriers.

Bacteria can actively invade deeper tissues by multiple pathways. They can enter through specialized cells. *Shigella*, for example, can breach the gut mucosa by transcytosing through the M cells in the gut (67). Alternatively, extracellular bacteria can breach a cellular barrier (epithelium or endothelium) by going through (transcytosis) or between (paracellular pathway) the cells (67). *Porphyromonas gingivalis*, an organism associated with adult periodontitis, may breach the epithelial layer by the paracellular pathway through the production of enzymes useful in digesting the tight junction (68). Two different mechanisms of transcytosis have been described for pneumococci. In one, pneumococci may cross the bronchial epithelial cells by binding the polymeric Ig receptor of the epithelial cells and traveling in a retrograde manner by the IgA secretory pathway (69). In the other, pneumococci may use PC to bind to rPAF, which is abundant on activated endothelial cells, epithelial cells, or pneumocytes (30,70). In many cases, bacterial adhesion triggers changes in the host cell function, and these changes can assist transcytosis. For instance, nontypeable *H. influenzae* with LPS glycoform-containing PC can bind to rPAF on endothelial cells and initiate signaling through this receptor (71).

ANTIGEN-NONSPECIFIC HOST DEFENSE RESPONSE

To protect from infections caused by highly adaptable bacteria, the host uses a multilayered defense. This includes the mechanical barriers and iron sequestration described previously, as well as phagocytes, complement fixation, lysozyme, and (cytokine-induced) local inflammation. In addition, the host is protected with antigen-specific antibody (see later discussion) and T cell–mediated cellular immunity. Antigen-specific immunity, although exquisitely protective, takes from several days to weeks to develop after exposure to a pathogen. Because many extracellular pathogens are capable of causing overwhelming infection in periods of hours to days, other, more rapidly acting forms of protection are needed. Consequently, the primary defense against bacteria during the early phase of infection remains antigen-nonspecific host immunity. The importance and significance of nonspecific immunity is readily demonstrated by the relative ease with which colonies of severe combined immunodeficiency (SCID) mice, which lack antigen-specific immunity, can be maintained (72). This section describes several antigen-nonspecific host defense mechanisms; for additional information, see the chapter on innate immunity (Chapter 14).

Mucosal Defense

Although mucosal areas are rich with nutrients for bacteria, uncontrolled local proliferation of bacteria is held in check by mechanical cleansing actions and the lack of available iron. In the gastrointestinal tract, normal peristaltic motility, the secretion of mucus, and the detergent action of bile limit the number of bacteria. The normally sterile lower respiratory tract is protected by the movement of mucus by cilia lining the airway, which continually remove aspirated bacteria. Normal epithelial and tissue architecture is essential for drainage and expulsion of bacteria, and disruption of this mechanism by smoking, viral infections (e.g., influenza), or bacterial infection (e.g., pertussis) makes the host markedly susceptible to infection by bacteria that otherwise only exist as commensals of the upper airway. The increased frequency of lower respiratory tract infections in the elderly is due, in large part, to the loss of function of the mucociliary elevator and the increased aspiration from the upper respiratory tract of secretions containing bacteria (73,74).

In addition to the removal of bacteria by mucus flow, mucosal fluid contains many antibacterial products such as lactoferrin, lactoperoxidase, mucin, lysozyme, and defensins (75). Lactoferrin, which is found in various body fluids such as milk, saliva, and tears, binds iron and lowers the level of available iron (especially in areas with a low pH) (76). Mucin traps microbes and facilitates their removal. IgA antibodies in mucosal fluid may inhibit

colonization by interfering with microbial adherence or by inactivating toxins (77). In addition, the polymeric structure of secretory IgA promotes agglutination, which in turn facilitates removal by mucus. Lysozyme reduces the bacterial load by cleaving the 1→4 linkage of *N*-acetylmuramic acid in the bacterial peptidoglycan. A number of antimicrobial peptides, including defensins, disrupt bacterial membranes (78). In the intestine, Paneth cells at the base of intestinal crypts produce defensins that are important in defense against intestinal infections (79). In the lung, collectin-like surfactant proteins, such as SP-A and SP-D, may be important in host defense by opsonizing bacteria for alveolar macrophages (80). SP-A–deficient mice, for example, are more susceptible to group B streptococcal infection of the lung (81). Epithelial cells that interface with the microbial world must exist in a quiescent state in response to colonizing organisms. If not, chronic inflammation may result in a disease (e.g., chronic inflammatory bowel disease). When the epithelial barrier is breached, these cells are able to elaborate cytokines and chemokine as an early trigger to the inflammatory response.

Local Response to Bacterial Invasion (Acute Inflammation)

On entry into the host, many bacterial products initiate local inflammatory processes. The list of the bacterial products initiating these processes includes peptidoglycan, LPS, lipoteichoic acid, exotoxins, lipoproteins, and glycolipids (82). Antibiotics used for treatment may make bacteria produce additional inflammatory products. Most of these molecules (pathogen-associated molecular patterns [PAMPs]) trigger responses through interaction with pathogen pattern recognition molecules, including Toll-like receptors (TLRs) (see Chapter 14). Of the 13 described TLRs, those anchored on the cell surface and recognizing bacterial PAMPs appear to be most important in responses to extracellular bacteria, although, in some cases, direct binding of the PAMPs has yet to be demonstrated. Cellular amounts of TLRs may also be an important factor in controlling inflammatory responses because TLRs are generally most abundant on inflammatory cells but are in lower levels in the epithelial barrier continuously exposed to microbial products (83). Lipoproteins and lipoteichoic acid are detected by TLR2. TLR2 requires a binding partner (TLR1 or 6) to transmit signals leading to cytokine production (84). Mice lacking the TLR2 gene are more susceptible to mucosal and systemic infection with staphylococci and streptococci (85,86). Although LPS binds to CD14 and lipid-binding proteins, it requires binding to TLR4 for cell signaling, because mice without functional TLR4 are unresponsive to LPS. Bacterial flagellin signals through TLR5 (87). Bacterial DNA, rich in unmethylated CpG motif, is a potent inducer of inflammation through its binding to

TLR9. However, the importance of TLR9, an intracellular signaling receptor, in bacterial infection is unclear.

There are a number of TLR-independent mechanisms for the recognition of bacterial products. Many components of bacteria (e.g., peptidoglycan) can enhance the inflammatory process by activating complement through the alternative pathway (88) via the generation of chemoattractant fragments (e.g., C5a). The Nod family of cytosolic molecules transmits proinflammatory signals in response to peptidoglycan fragments and may contribute to the response of phagocytes to typical extracellular pathogens (89). In addition, several mechanisms have been described whereby penetration of the cytoplasmic membrane by extracellular bacteria allows access to the Nod proteins in nonphagocticic cells (90). Protein A on *S. aureus* binds to the tissue necrosis factor-α (TNFα) receptor (TNFR1), and this interaction reproduces the inflammatory effects of its natural ligand (91). Bacteria produce formyl-methionyl peptides (e.g., f-Met-Ile-Leu-Phe), which are potent chemoattractants for neutrophils and macrophages (92).

During the initial phase of inflammation after a bacterial invasion, many cell types residing in the mucosa or skin (e.g., keratinocytes) may produce molecules important in controlling infections. Several studies revealed that mast cells are among the important resident host cells. Mast cells, classically known for their stores of histamine and serotonin (93), are abundant along the bronchial tree and epidermis of the skin. They are now known to contain preformed TNFα as well as to be a major source of various cytokines. Mast cells account for 90% of IL-4– and IL-6–producing cells in the nasal cavity (94). On exposure to various bacterial products (e.g., LPS), mast cells release these cytokines, which are essential for the recruitment of neutrophils to the site of inflammation. The absence of mast cells can increase the susceptibility of animals to bacterial infections in the peritoneum or the lung; their absence can be partially compensated for by administration of TNFα (95).

As the inflammatory process persists, additional cell types come to the site of inflammation. In the case of experimental pneumococcal pneumonia, neutrophils come to the lung in 12 to 24 hours, followed by the appearance of monocytes and macrophages in 48 hours (96). Few lymphocytes are observed in the lung during this time period. Neutrophils and macrophages become activated by the bacterial products (e.g., LPS) and chemokines (e.g., IL-8) on their arrival at the site of infection. Neutrophils and macrophages can rapidly phagocytize and kill the bacteria. (See Chapter 18 for a detailed description of phagocytosis.) Phagocytosis can occur when phagocytic cells recognize certain native molecular structures of the bacteria such as lectins, PS, and peptides (RGD sequence) (97) or, aided by their CR3 and Fc receptors, recognize the host opsonins on the bacterial surface.

Inflammatory processes trigger the cascade of chemokine and cytokine release at the site of inflammation. Sequential appearance of chemokines has been noted in the pneumonia model (96). The peak levels of chemokines macrophage inflammatory protein-2 (MIP-2) and KC are achieved in the lung less than 6 hours after infection. The peak levels of MIP-1α and monocyte chemotactic protein-1 (MCP-1) are observed in 12 to 24 hours. Neutralizing MIP-1α and MCP-1 along with RANTES (regulated on activation, normal T cell expressed and secreted) reduces macrophage recruitment. The cytokines produced during acute inflammation can be divided into two groups: proinflammatory cytokines (e.g., IL-1 and TNFα) and antiinflammatory cytokines (e.g., IL-4). The molecules produced during inflammation can induce the expression of endothelial leukocyte adhesion molecule (ELAM), intercellular adhesion molecule (ICAM), and vascular cell adhesion molecule (VCAM) on endothelial cells and selectins and integrins on leukocytes, thereby modifying the properties of the cells at the site of inflammation (cell adhesion, vascular permeability, etc.).

Systemic Response to Bacterial Invasion

Once extracellular bacteria enter the systemic circulation, they are rapidly removed by the spleen or the liver (15,92). Persons lacking splenic function (due to sickle cell disease or splenectomy) are at an increased risk of overwhelming sepsis from encapsulated pathogens (e.g., *S. pneumoniae*) (98). Clearance of bacteria from the blood by these organs is facilitated because phagocytes are abundant and blood circulates slowly in these organs, preexisting cross-reactive antibodies can fix complement (99), and the alternative pathway or mannose-binding lectin can fix complement nonspecifically. The bacteria release many inflammatory bacterial products into the systemic circulation and trigger many systemic changes, such as fever and accumulation of leukocytes at the sites of infection.

Cytokines (e.g., IL-6, IL-1) and glucocorticoids trigger the acute-phase response by stimulating hepatocytes to produce and secrete a variety of molecules that are termed acute-phase reactants, such as coagulation factors, serum amyloid A protein, C-reactive protein (CRP), TREM-1 (100), and collectins (101). Collectin molecules, which have a C-type lectin motif and a collagen-like motif, can bind to the surface of bacteria, activate complement along the classic pathway, and opsonize bacteria. For instance, mannose-binding lectin, a collectin, binds bacterial surface glycoproteins that contain mannose and *N*-acetyl glucosamine. Increased incidence of infection has been associated with low serum levels of mannose-binding lectin in individuals (102).

CRP, named for its ability to bind to pneumococcal C-polysaccharide, is found in highest concentrations in serum. Transgenic mice expressing human CRP are more resistant to systemic pneumococcal infection (98). After CRP binds to PC, which is expressed on many respiratory tract pathogens, it activates complement or functions like anti-PC antibody by engaging FcR. Indeed, CRP can kill PC-expressing *H. influenzae in vitro* in the presence of complement. Because many pathogens use phosphorylcholine to bind to the host cells via rPAF, CRP also blocks bacterial adhesion that involves this receptor (103).

One systemic response to infection is to lower the serum concentration of iron. This is achieved by an increase in the transferrin concentration in serum and by an increase in iron storage by tissues. Iron at the site of inflammation may be reduced by neutrophil-secreted lactoferrin. The reduction in the amount of iron available to bacteria can be a significant defensive measure (104). Moreover, even a moderate reduction in iron intake (105) and the use of an iron chelator have been shown to be beneficial against infections by extracellular bacteria. In contrast, an excess of iron may predispose an individual to infections (106).

In the past, the study of the role of molecules in host defense *in vivo* was limited by the availability of a few natural mutations (or alleles). With the widespread use of targeted gene-deletion and transgenic technology, many new molecules have now been investigated for their *in vivo* role. Some of these studies that are relevant to extracellular bacterial infections are listed in Table 38.2. Although the story is evolving, these studies have begun to show the complexity of the host defense in molecular detail. For instance, studies have revealed the unexpected relevance of some molecules to protection against bacterial infections. Lipoproteins are relevant to bacterial infections because lipoproteins can bind and neutralize LPS (107). Surfactant molecules are also important, and their mechanisms are under investigation. These studies further illustrate the differences in the protective mechanisms used against different groups of bacteria. C9 deficiency predisposes one to infection by gram-negative organisms such as *N. meningitidis* but not to infection by gram-positive bacteria. This information has supported our understanding that serum bactericidal activity is not the major protective mechanism for gram-positive bacteria.

Several additional mutations are found to affect predominantly the defense against gram-negative organisms (108). The *IL-1B* gene is allelic at various locations, but only the allelic homozygosity at position –511 of the IL-1B gene is associated with an increased fatal outcome to *N. meningitidis* infections in humans compared with heterozygosity at that position (109). The fact that heterozygous individuals are more protected than homozygotes also complicates the potential explanations. In addition, *in vivo* manifestations of the same genetic defect can be different in different genetic backgrounds. The effect of the *btk* mutation is largely limited to production of antibodies to PS antigens in mice (110), but the same mutation produces agammaglobulinemia in humans (111). Of

◗ **TABLE 38.2 Examples of Genes Associated with Changes in the Susceptibility to Extracellular Bacterial Infections**

Gene	Susceptible	Reference
Low-density-lipoprotein receptor	Gram-negative bacteria (lipopolysaccharide)	241

Nod1	*H. pylori*	90
IL-1 receptor associated kinase IRAK-4	*S. pneumoniae*	254

interest, an immunodeficient human patient with the inability to produce antibodies to PS (but not protein) antigens was found to have a mutation at *btk* (112), further emphasizing that background genes can have a profound effect on the *in vivo* role of one mutation. Finally, phenotypic changes are complex. IL-10 gene deletion results in fewer bacteria but more tissue damage after an infection (113). Mrp-1 gene deletion results in an increased resistance to pneumococcal infections (114). As additional information becomes available, a more comprehensive picture will emerge. This should help us to expand the use of immunoregulators (e.g., TNFα antagonist) for treating autoimmune diseases (115) without compromising the patient's ability to combat infections.

ANTIGEN-SPECIFIC HOST DEFENSE RESPONSE

Accompanying antigen-nonspecific responses, the host also mounts an adaptive, antigen-specific immune response. For protective responses to extracellular bacteria, B cell–mediated (but not T cell–mediated) immune responses are critical, as shown by clinical observations

of patients with Bruton's agammaglobulinemia. These patients, who have relatively normal T cell function but lack B cells, suffer primarily from infections caused by extracellular bacteria, which can be very successfully treated with the passive administration of pooled γ-globulin (116). Consequently, protective B cell responses are described in detail in what follows.

Responses of the Host (B Cell) Immune System to Bacteria

After an asymptomatic exposure or an infection, the host develops antibodies to many different bacterial antigens. For instance, the level of antibodies to various pneumococcal antigens increases in young children as they age, even if they never have clinical infections (117). However, the antibody levels remain low in those young children without evidence of asymptomatic nasopharyngeal carriage of pneumococci. This finding suggests that asymptomatic carriage of pneumococci is sufficient to raise antibody levels (117).

When an infection occurs, it presents the host with a large load of free antigens released from bacteria such as capsular PSs and proteins (e.g., toxins). Bacterial proteins induce strong immune responses in a conventional

T cell–dependent manner; indeed, the antibody response induced by bacterial proteins has been used to diagnose infections (118). In addition, the released PSs that are readily detectable in the urine of many patients (119) are used to diagnose pneumococcal pneumonia (120). The released PSs may neutralize the anti-PS antibodies in the host. For example, vaccination with hemophilus vaccines may neutralize preexisting anti-PS antibody and briefly increase disease susceptibility immediately after the vaccination (121).

In contrast to proteins, bacterial PSs generally elicit antibody responses with minimal help from T cells (122). Because bacterial PSs usually have many repeating units and multiple epitopes, they can efficiently cross-link BCR and stimulate B cells. The PSs primarily stimulate two subsets of B cells: B1 B cells (123) and marginal zone (MZ) B cells (124,125). These two types of B cells along with follicular B cells are the three recognized subsets of mature B cells with preferential anatomic locations. B1 B cells are associated with the peritoneum, MZ B cells are found in the splenic marginal zone, and follicular B cells are in splenic follicles. In mice, the subsets can be distinguished by their surface phenotypes. Follicular B cells are IgM^{low}, IgD^{high}, CD23^{+}, CD21^{int}, and CD1d^{low}, whereas MZ B cells are IgM^{high}, IgD^{low}, CD23^{low}, CD21^{high}, and CD1d^{high} (126). B1 B cells express CD11b and B220, with CD5 expression being used to divide them into B1a (CD5^{+}) and B1b (CD5^{-}) subsets (123). Furthermore, these subsets have distinct developmental requirements. MZ B cells require a proline-rich tyrosine kinase (Pyk-2) (124), Aiolos, and Notch2 (126). B1 B cell deficiency was noted in mice without the regulatory B1 subunit of calcineurin (127). B1a B cells are absent in CD19-deficient mice (128), and the development of B1 and follicular B cells requires BTK (129).

Several observations support the contention that the antibody response to PS antigens is largely independent of T cells. Athymic mice can produce antibodies to PS antigens. PS antigens do not bind class II molecules as protein antigens do (130) and may actually interfere with the presentation of protein antigens (131). In addition, they do not usually induce the formation of germinal centers (132), elicit poor immune memory (133), and easily tolerize B cells (134). Nonetheless, there have been past reports of T cell involvement in the antibody response to PS antigens (135), and recent studies suggest that CD40 is involved in this response (136). Because the PS antigens used for the studies may have had contaminants that affected their immune properties (137) and zwitterionic PSs may behave differently from other PSs (138), additional studies with pure PSs would be needed to define the role of non-B cells in the antibody response to PS antigens.

Polysaccharide antigens commonly elicit oligoclonal antibodies, which use a restricted number of V region genes (139,140) even among genetically unrelated humans (141). In addition, the antibodies to PS exhibit few somatic mutations (141,142) and generally have a low affinity to the antigen (143). However, because the capsular PS and LPS O antigens present repeating epitopes, even low-affinity antibodies can bind with enough avidity to fix complement and cause opsonization and/or bacteriolysis.

Capsular PSs have been used as vaccines because their antibodies are protective. Young children, however, do not produce antibodies to most PS antigens until they are several years old (144), and they are particularly susceptible to infections by encapsulated bacteria during their first few years of life (145). However, young children readily produce antibodies to PS when it is conjugated to a protein carrier. The clinical use of "conjugate" vaccines to induce antibodies to *H. influenzae* type b (Hib)-PS in young children has virtually eliminated Hib meningitis as well as oropharyngeal colonization by Hib (146). Similar "conjugate" vaccine approaches have been used to produce 7-valent pneumococcal and 4-valent meningococcal conjugate vaccines (147,148). The pneumococcal conjugate vaccine has been used for young children since 2000 and has markedly reduced the incidence of invasive pneumococcal infections in both young children and older adults (149).

The immunobiology of conjugate vaccines can differ based on the protein carriers used. Among hemophilus conjugate vaccines, Hib-PS conjugated to the meningococcal outer membrane protein complex (OMPC) can elicit antibody responses after only one immunization (150), presumably because, unlike other protein molecules used as carriers, OMPC stimulates TLR2 (151).

Not all bacterial antigens are presented to the host as free molecules, and some antigens remain associated with the bacteria. When the bacteria enter the blood circulation, they preferentially localize at the marginal zone of the spleen. The marginal zone has features useful in capturing particles in the blood: the zone is where the terminal arteriole ends and empties into sinuses and has several characteristic macrophages and dendritic cells (DCs) (126). After the localization of the bacteria at the marginal zone of the spleen, even without T cells, within 2 to 3 days MZ B cells can be activated and become plasma cells secreting antibodies to bacterial PSs (125). Marginal zone B cells have additional unique characteristics. They are rapidly stimulated by LPS (152), and their maturation may be facilitated by other bacterial molecules as well. MZ B cells may facilitate the activation of follicular B cells because they can capture IgM immune complex and transport it to follicular dendritic cells (153,154).

Although MZ B cells can mature and differentiate independent of T cells (125), other cells, including T cells, may help their maturation and antibody responses to various bacterial antigens. MZ B cells can present bacterial (protein) antigens to naive T cells (153). In addition to protein antigens, antibody responses to bacterial PSs require cofactors such as B7-2 (155) and CD40 (155,156) and can be

reduced with simultaneous injection of anti-CD4 and CD8 antibodies (157,158). Indeed, studies have shown antibody responses to PSs attached to bacteria to be T cell dependent (159). MZ B cell response may depend on DCs as well. On taking up dead bacteria, CD11c^low, CD11b^high DCs in the blood locate to the spleen and may provide TACI ligand(s) helpful in MZ B cell survival (160). Adoptive transfer of live dendritic cells after an *in vitro* exposure to dead pneumococci can transfer antibody responses to pneumococcal proteins and PS antigens (161). NK T cells may be involved in MZ B cell maturation, because MZ B cells express CD1 and may activate NK T cells (153).

Preimmune animals have antibodies that cross-react with many structurally unrelated antigens. These antibodies are often labeled as "natural antibodies." The majority of these antibodies are of the IgM isotype, and they frequently bind autologous antigens. Anti-PC antibodies may be examples of natural antibodies. Recent studies suggest that these natural antibodies are important in the early phase of bacterial and viral infections (162). For instance, anti-PC antibodies react with a PC epitope found on *S. pneumoniae*, *H. influenzae*, and *Wuchereria bancrofti* (a tissue nematode) (163–165). Anti-PC antibodies can reduce the susceptibility of mice to pneumococcal infections (164). A recent study suggested that the natural antibodies are from B1a B cells. CD19-deficient mice lack B1a B cells and have a reduced number of MZ B cells. These mice also lack anti-PC antibodies and are susceptible to pneumococcal infections (128). In contrast, another mouse strain that exhibits both a reduced number of MZ B cells and a deficiency of B1b cells can produce anti-PC antibodies and is as resistant to pneumococcal infections as are normal mice (128).

In addition to natural antibodies, animals often have preexisting antibodies to a PS that cross-react with structurally similar PSs (166–168), probably because many PS molecules have very similar structures. Sometimes it is difficult to distinguish usual "anti-PS antibodies" from "natural antibodies." Cross-reactions may play an important role in protecting the host against its first exposure to a bacterial species. For instance, human adults carry detectable amounts of antibodies to the *H. influenzae* type b PS (Hib-PS)—even in the absence of vaccination—and are thus relatively resistant to *H. influenzae* infections (145). Although some of the antibodies may be the result of immunization by subclinical infections, the majority of human preimmune (but not postimmune) anti-Hib PS antibodies cross-react with *E. coli* K100, the PS capsule of which is an isopolymer of Hib PS (169). Experimental colonization of rats with *E. coli* K100 can protect them against Hib (170). About 1% of human IgG binds a carbohydrate epitope [gal(1→3)gal] (171), and this antibody can kill *Trypanosoma* and *Leishmania in vitro* (172). Cross-reactive antibodies binding the LPS core components are thought to be responsible for the protection from bacteremic dis-

semination of gonococci in nonimmune patients (99), although they cannot prevent infection of the genital tract (99).

Normal gut flora may be the antigenic stimulus for many of the cross-reactive anti-PS antibodies. About 1% of the human population carries *E. coli* K100 in its gut at any moment (173). Antibodies to gal(1→3)gal are found to bind many species of bacteria isolated from normal stool specimens (171). The gut flora may have additional interesting effects on the immune system. For example, in some transgenic mice, inflammatory bowel diseases develop in the presence of normal intestinal flora but not in the absence of gut flora. In addition, in some animals, such as chickens and rabbits, microbial colonization of the gut appears to be necessary for the normal development of antibody V region repertoires (174). Bacteria should therefore be considered as active participants in shaping the host immune system.

Protective Mechanisms of Antibodies

Antibodies to virulence factors may act by neutralizing the function of those factors. Antitoxin antibodies can protect a host by blocking the action of the toxins or by increasing the removal rate of the toxins (e.g., blocking the binding of the toxins to the host cell receptors). Antibodies to superantigens or tetanus toxin can inactivate them and thereby provide protection to the host. Antibodies to an *E. coli* adhesin can prevent experimental infections of *E. coli* (175). Antibodies to M protein neutralize its ability to interfere with complement and provide protection against *S. pyogenes* infections. Antibodies to LPS (176,177), or perhaps to LTA (178), can be protective. Antibodies to PspA, pneumolysin, autolysin, or PspC (CbpA) can protect animals from fatal pneumococcal sepsis. Although these antigens are being investigated as potential replacements for the expensive pneumococcal conjugate vaccines, the protective mechanisms that they use are unclear. The most recent hypothesis suggests that antibodies to PspA may alter the complement fixation on pneumococci (27,179). Antibodies to IgA1 protease or iron-transport systems (180,181) can also protect against bacterial infections, most likely by neutralizing the normal functions of the target antigens. Finally, in the presence of antibodies and complement, the ability of the liver to remove bacteria increases significantly (15). Thus, another protection mechanism provided by antibodies may be to facilitate the *in vivo* removal of bacteria from circulation by enhancing the ability of the reticuloendothelial system to clear bacteria.

Antibodies to capsule PS can provide protection by fixing complement on the surface of bacteria and by inducing bacteriolysis or opsonization. The bacteriolysis pathway can provide significant *in vivo* in protection against gram-negative bacteria, as is illustrated by the susceptibility to *N. meningitidis* infections of persons with

deficiencies of C5-9 components (182). In contrast, antibodies and complement do not lyse gram-positive bacteria but opsonize them for phagocytic killing, as explained later (88). Host phagocytes cannot readily recognize and kill the intact encapsulated gram-positive bacteria. However, once they are coated with antibodies and complement fragments, the host phagocytes can readily recognize the bacteria with various recognition receptors and engulf the bacteria for intracellular killing. An Fc receptor (CD16b) and a complement receptor (CR3) are among the important recognition receptors. CR3, an integrin molecule, is a heterodimer of CD11b and CD18. Protection mediated by this antibody/complement-mediated opsonization is probably very important *in vivo*, because both complement deficiency and agammaglobulinemia predispose individuals to infections by many different extracellular bacteria (116,182). To be effective for opsonization, the epitope of the surface antigens must be exposed on the surface of the bacteria. Effective antibodies to the porins of *N. meningitidis* recognize the surface loop of the molecule (183). In most pneumococci, C-polysaccharide (C-PS) is mostly buried underneath the PS capsule. Although antibodies to the C-PS can fix complement (15), anti–C-PS antibodies were ineffective in protecting mice against most *S. pneumoniae*, unlike antibodies to capsular PS, which are protective (184). However, a recent study found that purified human anti–C-PS antibodies can opsonize pneumococci (185); thus, additional studies are needed.

Because antibody-mediated opsonization and bacteriolysis depend on the complement-fixing properties of the Fc region, the relative efficacies of antibodies of different immunoglobulin isotypes have been compared. IgM antibodies are produced early in the course of infections and should be important in the early phase of infections because they fix complement very efficiently and can opsonize bacteria. Selective deficiency of IgM antibodies was found to increase susceptibility to bacterial infections (186). Studies found that specific IgM antibodies agglutinate erythrocytes, fix complement, and lyse erythrocytes more readily than IgG antibodies (187), and IgM antibodies are more effective in complement-mediated bacteriolysis (188); however, IgG antibodies are more effective than IgM antibodies in preventing pneumococci infections of mice (189) or in opsonizing Hib *in vitro* (190). Moreover, antibodies to some IgG subclasses have been reported to be more protective against specific viral (191) and fungal (192) infections than antibodies to other subclasses. These results suggest that optimal opsonization requires not only complement receptors but also Fc receptors for IgG. In the absence of inflammation, IgM antibodies are confined to the intravascular space, whereas IgG antibodies can enter the extracellular space. However, inflammation can make the vessels at the infection site permeable, at which point antibodies of all isotypes may enter the infection site. Com-

pared with IgM antibodies, IgG antibodies may be especially efficient at neutralizing toxins because they have a longer half-life, generally have a higher affinity, and are already present in extravascular spaces prior to infection (193).

IgG subclasses differ in their ability to fix complement and to bind Fc receptors (194,195). It was also reported that IgG1 mouse monoclonal antibody is protective against *Cryptococcus neoformans* but that IgG3 mouse antibody is not (192). Consequently, the the fact that antibodies to bacterial PS are found to be largely restricted to a single IgG subclass (IgG2 in humans and IgG3 in mice) has led to many studies of the differences in the protective properties of antipolysaccharide antibodies of different isotypes. Mouse IgG3 antibodies (but not antibodies of other IgG subclasses) can associate with each other through their Fc regions (196). This feature may make the IgG3 antibodies with a low affinity to PS more effective in binding the antigen than antibodies of other isotypes of the same affinity. Although the foregoing observations provide a theoretical advantage for mouse IgG3 antibodies, this same aggregation phenomenon has not been observed for human IgG2 antibodies, even though some human IgG2 can form covalently joined dimers (197). The full significance of IgG3 aggregation is not clear, however, because antipolysaccharide antibodies of the IgG3 isotype have not been observed to be any more efficacious against pneumococcal infections than antibodies of other isotypes (198). IgG2 antibody levels can be significant, however. People expressing the Gm23$^-$ IgG2 allele have higher IgG2 antibody levels than people with the Gm23$^+$ allele. Among C2-deficient persons, Gm23$^-$ persons are more susceptible to bacterial infections than Gm23$^+$ individuals (199).

Moreover, in contrast to expectations, many studies found that human IgG1 antibodies are slightly more effective at opsonization and bacteriolysis than are human IgG2 antibodies (195,200). Neither of these isotypes appears to be essential, however, because individuals lacking IgG1 and IgG2 subclass genes are healthy (201). Furthermore, human IgG2 antibodies bind less strongly to CD16, CD32, and CD64 than do IgG1 or IgG3 antibodies (202) and may not be effective for neutrophil opsonization in individuals homozygous for a specific CD32 allele (200). These observations, taken together, strongly suggest that the human IgG2 (or mouse IgG3) subclass may not provide any unique advantage in defense against bacteria.

IgA is highly heterogeneous in structure: It can exist as a monomer, a polymer, or in secretory forms. However, its function is unclear. Although it has been reported that IgA can opsonize (203), fix complement (204), and facilitate the lysis of *N. meningitidis* (205), other studies have found that IgA does not fix complement *in vitro* (206) and may even inhibit the IgG-mediated complement-dependent killing (207). The ability of IgA to fix complement may also depend

on its denaturation or its glycosylation status (208,209). Nevertheless, other studies indicate that IgA antibodies may fix complement by the mannose-binding lectin pathway (210) and that human IgA antibodies against pneumococcal capsular PS can opsonize pneumococci for killing by neutrophils (211).

Bacteria that commonly colonize or infect mucosal areas often produce IgA1 protease, and IgA antibody has been found to provide protection in at least some of these cases (212). These findings suggest that IgA may play an important role as a part of the complex mucosal immune defense. IgA antibodies may be important in reducing nasopharyngeal colonization by bacteria, inasmuch as the mice deficient in IgA or polymeric immunoglobulin receptor can carry pneumococci in the nasopharynx even after an immunization against pneumococci (213). IgA may function by aggregating the bacteria and facilitating their expulsion from mucosal areas. IgA may also block the invasion of bacteria through the mucosal epithelial cells, because endocytosed IgA has been found to block the transport of virus through epithelial cells (214). However, IgA-deficient persons or mice are relatively healthy, and IgA-deficient mice can elicit normal protective immunity to experimental infections with influenza virus. IgM antibodies may function as secretory antibodies in IgA-deficient individuals (215).

Responses by T Cell Immune System to the Extracellular Bacteria

Although immune responses to toxins from extracellular bacteria are T cell dependent, antibodies to the toxins mediate protection; therefore, the protective immunity against extracellular bacteria is clearly centered on the B cell responses. However, recent studies suggest additional roles for T cells in responses to extracellular bacteria and their products. PS associated with lipid can stimulate T cells in association with CD1 molecules (216). In addition, studies of abscess formation in response to *Bacteroides fragilis* infection showed that its zwitterionic capsular PS can be taken up by antigen-presenting cells, which can process the PS with a nitric oxide–dependent mechanism and present it in association with MHC class II molecules (138) to stimulate $CD4^+$ T cells to produce IL-17 (217). T cell stimulation also requires participation of cofactors CD86 and CD40L (218). IL-17 is an important part of the host response to *B. fragilis,* because antibody to IL-17 can block the *B. fragilis*–induced abscess formation (219). Recently, Th17 T cells were defined as a distinct $CD4^+$ T cell subset that secretes IL-17 and requires a novel set of cytokines for Th17 lineage commitment (TGFβ and IL-6) and stabilization (IL-23) (220). Although the role of Th17 T cells in immune responses to extracellular bacteria is being investigated, IL-17 receptor deficiency or deficiency of IL-23

has been associated with increased susceptibility to extracellular bacterial infections (221,222).

DELETERIOUS HOST RESPONSES

Inflammatory response by the host inevitably causes some tissue damage. In some bacterial infections such as pneumonia and meningitis, this damage plays a significant role in disease pathology and symptoms. For instance, animal models of meningitis have shown that inflammation associated with bacterial products (primarily cell walls) is the primary cause of neurologic damage. Treatment of animals with antibiotics alone can eradicate the bacteria, but it does not prevent neurologic damage. In contrast, when inflammation was controlled by steroids administered along with the antibiotics, the amount of neurologic damage was considerably reduced (223).

Antigen-nonspecific Deleterious Response

Uncontrolled inflammation at the systemic level can produce septic shock, which can be triggered by several factors, including exotoxins (e.g., staphylococcal enterotoxin B) of gram-positive bacteria, the combination of LTA and peptidoglycan from gram-positive bacteria (224), or LPS from gram-negative bacteria. The staphylococcal enterotoxin B superantigen binds the host's class II molecules of the MHC region and can stimulate large numbers of helper T cells to release cytokines. Septic shock can also be initiated when LPS from gram-negative bacteria binds CD14 and a TLR and stimulates macrophages or monocytes to secrete inflammatory cytokines. (See Chapter 14.) In addition to cytokines, the stimulation of host cells by bacterial products leads to the release of other mediators of inflammation, such as arachidonic acid metabolites; activation of the complement cascade; and activation of the coagulation cascade. Excess release of the mediators leads to the failure of the vascular system and, finally, the failure of multiple organ systems. Studies using transgenic mice with defective genes have identified several molecules critical in developing septic shock, such as TNFα, one of its receptors TNFRI, IL-1–converting enzyme, and ICAM-1 (225). This approach also showed that CD14 and TLR4 are critical for LPS-induced septic shock and that CD28, a T cell costimulation molecule, is necessary for superantigen-induced septic shock (225).

Anthrax infections provide another example of uncontrolled host response. "Lethal factor" binds the "protective antigen" immobilized on the macrophages and then stimulates the cells to secrete cytokines and reactive oxygen intermediates. These macrophage products are believed to kill the host, because the host dies even when the proliferation of the bacteria is controlled. When macrophage cells are removed from animals, the animals are resistant

to anthrax toxins (226). This suggests that the macrophage response to the toxins is actually responsible for the death of the host.

Although inflammation is a significant cause of morbidity and mortality, it must also be regarded as the host's primary protection from bacterial infections. Evidence for this hypothesis comes from studies with TLR4-deficient mice, which, although they are nonreactive to LPS and are completely resistant to LPS shock, are more susceptible to infection with gram-negative bacteria than are normal mice (227,228). Perhaps LPS is "toxic" because the host has evolved to use this common bacterial component as a trigger for host responses.

Antigen-specific Deleterious Response

Many bacterial antigens express the epitopes cross-reactive with host antigens and thus have the potential to elicit antibodies during infections that cross-react with host tissue. For instance, the PS capsule of *N. meningitidis* group B mimics epitopes expressed in the central nervous system (229), such as the *N*-acetylneuramic acid epitope in the embryonic N-CAM (230). The LPS of many strains of *N. meningitidis*, *N. gonorrhoeae*, *H. influenzae*, and *H. ducreyi* expresses the epitope of blood group antigen pK (231). The LPS of *Campylobacter jejuni* and *Helicobacter pylori* expresses epitopes mimicking other host antigens, such as ganglioside and Lewis X, respectively (231). Epidemiologic studies associated *C. jejuni* infections with the development of an autoimmune disease—Guillain-Barré syndrome (232).

Although the association between the abovementioned examples of cross-reacting bacterial antigens and autoimmunity is unclear, *S. pyogenes* infection is associated with rheumatic fever and acute glomerulonephritis. Studies found that *S. pyogenes* can be divided into two classes with a monoclonal antibody to M protein (233) and that rheumatic fever develops only after an infection of *S. pyogenes* with class I strains (233). Class I and class II strains of *S. pyogenes* can also be readily distinguished by the linkage relationship of the M protein genes with the genes encoding related surface proteins (233,234). M proteins from some class I *S. pyogenes* express epitopes highly cross-reactive with epitopes of cardiac myosin, tropomyosin, vimentin, laminin, and keratin (235–237). An antibody molecule may bind to all of these protein molecules because a major portion of these proteins are coiled-coil α-helix (237). The polyreactive antibodies to M protein may directly damage myocardial and endothelial cells (238). In addition to antibodies, CD4$^+$ and CD8$^+$ T cells are found at rheumatic heart valves (239), and the T cells proliferate to M protein peptides and heart proteins (240). These observations suggest that the T cells with cross-reactivity between M protein and myosin may be involved in the pathogenesis of rheumatic fever as well.

CONCLUSION

Because extracellular bacteria can grow rapidly and produce toxins, some are potent pathogens. To combat these bacteria, higher organisms primarily depend on two arms of the immune system: innate immunity and adaptive immunity centered on antibody molecules. The two arms of the immune system comprise of multiple layers of protection. In the early stage of an infection, innate immunity involving pattern recognition receptors, complement, phagocytes, and natural antibodies cross-reacting with many antigens is important in host defense. During the late stage of an infection, pathogen-specific antibodies appear. These antibodies generally mediate the ultimate protection against extracellular bacteria by triggering the protective effects of complement and phagocytes. Nevertheless, innate and adaptive immune responses may cause damage instead of protection. A better understanding of how our immune system protects against each pathogen will aid in the development of more effective preventive and therapeutic measures against these pathogens.

Immunology of HIV Infection

Norman L. Letvin

INTRODUCTION

Acquired immunodeficiency syndrome (AIDS) has rapidly emerged as a devastating worldwide medical problem. Although the first cases of AIDS were described as recently as 1981 and its etiologic agent human immunodeficiency virus type 1 (HIV-1) was only isolated in 1983, the rapid pandemic spread of HIV-1/AIDS has changed the world in which we live. Five million new HIV-1 infections occur each year (1). HIV-1 has ravaged sub-Saharan Africa, where more than 25% of adults are infected by HIV-1 in such countries as Botswana and Zimbabwe (Figure 39.1). At the present time the virus is spreading most rapidly in India, Central Asia, and Eastern Europe. It continues to be a serious problem in the West, with more than 1 million HIV-1 infections diagnosed to date in the United States. Twenty million people have died from AIDS, and 40 million are currently living with HIV-1 infections.

Although antiretroviral drug treatment is available for infected individuals, these therapies are not curative. Moreover, antiretroviral drugs are prohibitively expensive for most people in the developing world. Thus, the conse-

quences of this infection at both an individual and societal level make the development of strategies for the control of HIV-1 an absolute priority.

The immunopathogenesis of AIDS is unique among human viral diseases. Although humans mount a vigorous immune response against HIV-1, containment of replicating virus is incomplete. This incomplete immune control of the virus can be explained, at least in part, by the ability of the virus to persist in nonreplicating forms, by its propensity to mutate, and by its ability to destroy the cellular elements of the immune system. The immunobiology of the virus–host interactions of HIV-1 must be understood if we are to succeed in generating new drug therapies or in harnessing the immune response to create a vaccine to contain viral replication in infected individuals.

This chapter will provide an overview of our current understanding of the immunopathogenesis of AIDS. The overview will include a description of HIV-1 and other closely related primate lentiviruses. The mechanisms of HIV-1 spread from one infected individual to another will be examined. The immunologic dysfunction that occurs as a consequence of persistent HIV-1 infection will be
FIGURE 39.1 Prevalence of HIV-1 infections in different geographical regions worldwide. HIV-1 is a worldwide epidemic, and sub-Saharan Africa, the Indian subcontinent, and Southeast Asia are the areas most affected. Estimates of the number of infections are shown in the boxes. Adapted from (1) and (189).

detailed, and the factors that contribute to the extreme variability of the clinical course in infected individuals will be explored. The humoral and cellular immune responses induced by HIV-1 will be described, with an exploration of the ramifications of the incomplete immune control of the virus. Finally, we will examine the progress made to date and the obstacles we are still facing in the creation of an effective HIV-1 vaccine.

THE HIV-1 VIRUS

HIV-1 is a retrovirus and a member of a family of primate lentiviruses (2). An infectious HIV-1 virion contains two copies of a 9.2 kb single-stranded viral RNA genome (Figure 39.2). Once the virus enters the cell, the RNA is converted to double-stranded DNA by a virus-encoded enzyme, reverse transcriptase. This double-stranded DNA enters the cell nucleus and integrates into the host cell genome to generate a provirus using the virally encoded enzyme integrase. The integrated provirus becomes the primary template for the subsequent transcription of the virus' structural, regulatory, and accessory genes.

HIV-1 encodes three structural gene products (Figure 39.3). The *gag* gene encodes precursors for the virion capsid proteins (capsid, nucleocapsid, and matrix) that package genomic viral RNA into virions and participate in viral uncoating. The *pol* gene encodes precursors for several virion enzymes required for viral replication (protease, reverse transcriptase, RNase, and integrase). The *env* gene
FIGURE 39.2 HIV-1 virion structure. Lentivirus particles are spherical and consist of a lipid bilayer surrounding a conical nucleocapsid. Adapted from (190).
FIGURE 39.3 Genomic organization of HIV-1. The genomic organization of the linear double-stranded proviral DNA form of the virus is shown. The presumed function of each of the viral gene products is shown in the associated table.

encodes precursors for the envelope glycoproteins gp41 and gp120, which form the envelope protein gp160. The HIV envelope protein binds to CD4 and to chemokine receptors to facilitate entry into and infection of CD4$^+$ T cells or macrophages as will be discussed later.

The virus also encodes a series of small regulatory gene products, *tat* and *rev,* that are both essential for *in vitro* and *in vivo* virus replication. While the basal transcription of integrated HIV-1 is very low, the *tat* gene product dramatically augments this RNA synthesis. It does this by binding to an RNA stem-loop structure that is present on the 5′-terminus of viral mRNAs and thus acts to enhance transcriptional elongation. The *rev* gene product binds to a particular sequence present in unspliced viral transcripts, targeting them for nuclear export. This allows the unspliced viral transcripts, which encode the Gag and GagPol proteins, to enter the cytoplasm of the infected cell, be translated, and subsequently be cleaved by the viral protease.

The viral accessory genes *vpu, vpr, nef,* and *vif* are dispensible for *in vitro* replication but are required for *in vivo* replication and viral pathogenicity. *vpu* encodes a protein that enhances the release of viral particles and promotes the degradation of CD4 in an infected cell. In the host cell, vpu catalyzes gp160 liberation from CD4 in the endoplasmic reticulum, resulting in both an increase in Env transport to the cell surface and CD4 degradation via the ubiquitin/proteosome pathway. The functions of the *vpr* gene product include stimulation of gene expression from the HIV-1 LTR, induction of arrest in the G2 phase of the cell cycle in the host cell, and facilitation of transport of double-stranded viral DNA, produced by reverse transcription in the cytoplasm, to the nucleus in the infected cell. The functions associated with the *nef* gene product include down-regulation of both CD4 and major histocompatibility complex (MHC) class I on the surface of the infected cell, stimulation of virus infectivity, and modulation of cellular activation pathways. Finally, as described in more detail later, the *vif* gene product allows the virus to circumvent the potent antiviral activity of the host cell protein APOBEC3G.

Viral entry into cells usually requires an interaction of the envelope glycoprotein of the virus with the CD4 molecule (3) (Figure 39.4). Since CD4 is a cell signaling molecule and CD4$^+$ T lymphocyte dysfunction is a clinical hallmark of HIV-1 infection, considerable experimental work has been invested in determining whether an interaction between CD4 and gp120 is responsible for immune abnormalities in AIDS. While recombinant gp120 added to CD4$^+$ T lymphocytes *in vitro* has been shown to induce T lymphocyte abnormalities, there has never been conclusive evidence to suggest that viral gp120, either virion-associated or shed, can trigger T cell abnormalities *in vivo*.
FIGURE 39.4 HIV-1 binding and entry into a cell. HIV-1 envelope binding to CD4 expressed on a cell surface results in conformational changes in the envelope that facilitate coreceptor binding. These events lead first to the insertion of the fusion peptide into the cell membrane and then membrane fusion. Adapted from (191).

It has also been demonstrated that HIV-1 makes use of other co-receptors for cell entry after binding to CD4 in a two-step binding mechanism (4–6). Those molecules are chemokine receptors and members of the seven transmembrane G-protein–coupled receptor family. The chemokine receptor used by a particular HIV-1 isolate has important ramifications for the cellular tropism of that isolate. It has been shown that infection of a transformed T cell line *in vitro* can only occur with viral isolates that employ the CXCR4 molecule as their second receptor. Infection of primary macrophage populations occurs with isolates that employ the CCR5 molecule as a second receptor. Entry of viruses into primary human T cells can occur through either the CXCR4 or the CCR5 receptor.

The demonstration that these seven transmembrane G-protein–coupled receptors are important for HIV-1 entry into cells provided an explanation for some previously puzzling biologic properties of HIV-1 isolates. This finding provided a rationale for how CD4$^-$ cells, such as endothelial cells, can be infected *in vivo* (7). It explained why HIV-1 replication in lymphocytes can be inhibited *in vitro* by a number of beta chemokines, including MIP-1α, MIP-1β, and RANTES, since these molecules are ligands for viral coreceptors (8).

This viral requirement for second receptors also explained some of the well-described idiosyncratic biologic events in the viral transmission process and in clinical progression to AIDS in those who are infected. It has been known for some time that only a subpopulation of HIV-1 isolates appears to be transmitted by sexual contact. Those viral isolates are almost universally macrophage-tropic (9). It is now clear that the isolates of HIV-1 that are most likely to be transmitted are macrophage-tropic because

they are CCR5-tropic. It has also been known for some time that clinical conversion from an asymptomatic infection to AIDS in chronically infected individuals is associated with a phenotypic change in the infecting viral isolates (10). It is now appreciated that this phenotypic change is associated with a change of second receptor use by the virus from CCR5 to CXCR4. HIV-1 replication increases substantially in the infected individual as that individual progresses clinically to symptomatic AIDS. It is unclear whether the associated conversion from CCR5-tropic to CXCR4-tropic virus in these individuals results in a virus with particularly high replication potential, or rather that high levels of replicating virus select for CXCR4-tropic viruses.

An understanding of the immunobiology of AIDS must be built upon an appreciation that HIV-1 represents an extraordinarily diverse population of antigenically distinct viruses, both at a population level and at an individual level. This diversity is a result of a continuous process of mutation that occurs during HIV-1 replication. One of every 10,000 nucleotides of the replicating virus mutates because the HIV-1 reverse transcriptase lacks 3′ exonuclease proofreading activity.

The virus therefore rapidly becomes an antigenically heterogeneous swarm of viral quasispecies, even in a single infected individual. With more than 1 billion new viral particles created daily during the period of peak viral replication in an infected individual early after infection, there is reason to assume that virtually any mutation that the virus can tolerate will be generated. To contain HIV-1 replication, the immune system must therefore deal with a diverse population of viruses in an infected individual. The HIV-1 virus is also heterogenous at a population level. Analysis of viral sequences from HIV-1 has shown that the
FIGURE 39.5 Genetic diversity of HIV-1 isolates. This figure depicts a neighbor-joining tree, based on a full genome sequence alignment with a few representatives of each of the M group major HIV-1 clades. The tree was drawn using the Treemaker tool at the Los Alamos HIV-1 database. Adapted from (189).

viruses cluster into distinct groups that are referred to as *subtypes* or *clades* (Figure 39.5). Most HIV-1 isolates that are found in the Western hemisphere and Europe are clade B viruses, whereas those in India are clade C viruses.

INTRINSIC MECHANISMS OF ANTIVIRAL DEFENSE

Recent work has defined a number of intracellular proteins that have anti–HIV-1 activity. The most intensively studied of these proteins is APOBEC3G (11). APOBEC3G is incorporated into budding HIV-1 virions and causes extensive deamination of dC to dU on the minus single-stranded viral DNA as it is being synthesized during reverse transcription in the target cell. This causes an accumulation of dG to dA mutations in the subsequently synthesized plus-strand DNA of the virus. This phenomenon is termed *hypermutation* because the deamination can occur in greater than 10% of all viral C residues, a level of mutation that is not tolerable to the virus. APOBEC3G is a member of a family of closely related cytidine deaminases that includes APOBEC1 and activation induced deaminase (AID), which deaminate the apolipoprotein B mRNA in gastrointestinal tissue and antibody genes in B cells, respectively.

The HIV-1 auxiliary protein Vif allows the virus to circumvent the potent antiviral activity of APOBEC3G through at least two complementing mechanisms. Vif recruits a ubiquitin ligase complex that mediates the polyubiquitylation of APOBEC3G, targeting this protein for destruction by the 26S proteasome. Moreover, Vif also impairs de novo APOBEC3G synthesis. Thus, Vif blocks the incorporation of APOBEC3G into HIV-1 virions.

Trim5α is another recently described intrinsic mediator of potent defense against primate lentiviruses (12). It is a member of the tripartite motif family of molecules and is composed of RING, B-box 2, and coiled-coil domains, as well as a C-terminal B30.2 (SPRY) domain. By directly recognizing the viral capsid of select primate lentiviruses, it accelerates uncoating of the capsid of viral particles

following their entry into cells. By disrupting the ordered process of viral uncoating and reverse transcription, this protein acts to block cross-species transmission of certain immunodeficiency viruses.

In further studies to define genetic restriction factors for HIV-1, Murr1 has been shown to inhibit HIV-1 replication in unstimulated CD4$^+$ T lymphocytes (13). This gene product, previously implicated in copper regulation, appears to mediate this inhibition by stimulating basal and cytokine-mediated nuclear factor (NF)–κB activity. With considerable research activity ongoing at the present time in the area of host genetic restriction factors for HIV-1 replication, there is reason to believe that more of these molecules will be characterized in the near future.

ANIMAL MODELS OF AIDS

Animal models have proven of central importance in elucidating aspects of HIV-1 pathogenesis and evaluating AIDS vaccine strategies. Because HIV-1 is a member of a family of primate lentiviruses that are species-restricted in their ability to replicate, HIV-1 does not infect small laboratory animals. Mice therefore cannot be used to assess the immunobiology of HIV-1 infections. Nevertheless, several small laboratory animal models have been developed with the hope of applying them to studying HIV-1 biology. These models have relied on the tactic of reconstituting the immune systems of immune-incompetent mice with human lymphoid tissue. However, the use of these models has been limited because the complex biology associated with the dissemination of HIV-1 in humans is not reproduced in these mice.

Much of our current understanding of AIDS immunobiology has come from studies of nonhuman primates infected with primate immunodeficiency viruses. Many African nonhuman primate species are infected with lentivirus isolates that are closely related to HIV-1. These viruses are referred to as *simian immunodeficiency viruses,* or *SIVs*. It is, in fact, the transmission of selected SIVs

across primate species barriers that led to the AIDS epidemic in human populations. HIV-2, the virus responsible for much of the AIDS in humans in West Central Africa, is indistinguishable at the genomic level from the SIV that endemically infects the West Central African monkey the sooty mangabey (14). Thus, a cross-species transmission of SIVsm from the sooty mangabey introduced this virus into humans.

Similarly, an SIV referred to as *SIVcpz* has been found endemically in chimpanzees living in the wild in West Central and East Africa. This virus arose as a result of cross-species transmissions and subsequent recombinations of two distinct SIVs that endemically infect nonhuman primate species on which chimpanzees prey. In fact, SIVcpz is so similar at the genomic level to HIV-1, it has been suggested that HIV-1 first entered humans in West Central Africa through blood–blood contact as humans were hunting SIVcpz-infected chimpanzees for food (15).

Interestingly, the various SIV isolates have dramatically different levels of pathogenicity in different primate species. The diverse SIVs that endemically infect various monkey species in Africa have little or no pathogenicity in their natural host species. SIVagm isolates that infect African Green monkeys replicate to only very low levels in this species and have not been reported to induce an AIDS-like illness. Studies of large numbers of sooty mangabeys that are naturally infected with their own SIVsm isolates have shown that this virus replicates at a very high level, comparable to the level of replication seen in HIV-1–infected humans. However, only a single case of AIDS has been reported in a sooty mangabey, and that occurred in a monkey infected for greater than 19 years.

The pathogenicity of the virus isolates that are responsible for AIDS in humans is quite variable. SIVsm/HIV-2, a virus that has very little pathogenic potential in its natural host species, causes AIDS in humans, although it appears to be less pathogenic in humans than SIVcpz/HIV-1. While the pathogenicity of SIVcpz in chimpanzees remains unknown, there is reason to think that the virus may have a low pathogenic potential in this species. This thinking derives from the observation that many HIV-1 isolates obtained from humans have been inoculated into chimpanzees, and only one of these isolates has been shown to induce AIDS in this species of great apes.

Importantly, selected SIV isolates induce an AIDS-like illness when inoculated under experimental conditions into certain Asian macaque species. The best studied of these is the infection of rhesus monkeys with SIVsm. SIVsm is also referred to in the literature as SIVmac because it was first isolated from macaques inadvertently infected with this sooty mangabey virus. Rhesus monkeys infected with SIVsm/SIVmac develop peak and set-point plasma virus RNA levels that are even higher than those observed in HIV-1–infected humans. The virus is R5-tropic and accordingly causes profound depletion of the CCR5-expressing memory CD4$^+$ T lymphocytes in rhesus monkeys. Infected monkeys develop wasting, and a spectrum of opportunistic infections and tumors indistinguishable from that seen in HIV-1–infected humans (16).

Chimeric viruses that express HIV-1 envelopes on an SIV backbone can be constructed in the laboratory. These viruses are known as *simian human immunodeficiency viruses* or *SHIVs*. A variety of HIV-1 envelopes have been incorporated into SHIVs, resulting in viruses with distinctive pathogenic profiles. SHIVs expressing R5-tropic envelopes have been able to replicate in macaques, but only to low levels, and have not proven consistently pathogenic. Selected SHIV isolates constructed with X4- or dual-tropic envelopes induce profound CD4$^+$ T lymphocyte loss, immunodeficiency, and an AIDS-like illness in macaques (17). However, this SHIV-induced clinical syndrome differs from HIV-1–induced disease in humans because the X4-tropic SHIVs selectively eliminate the naïve rather than the memory CD4$^+$ T lymphocyte populations targeted by the R5-tropic HIV-1 isolates in humans.

In spite of the distinct pathogenic profiles of these different primate immunodeficiency viruses in Asian monkeys, both the SIV- and SHIV-infected macaques have proven enormously powerful models for exploring mechanisms of AIDS immunopathogenesis and approaches to HIV-1 vaccination. They have been particularly useful in characterizing virologic and immunologic events that occur during the initial days following infection, a period of time during which HIV-1–infected humans are rarely recognized by clinical investigators. These models have also proven invaluable for evaluating a diversity of strategies for HIV-1 vaccination.

HIV-1 TRANSMISSION

HIV-1 is transmitted primarily by sexual exposure. It is also spread by needle sharing among intravenous drug users. Transfusion of virus-contaminated blood products occurred quite frequently before blood screening procedures were developed in the mid-1980s. However, with the introduction first of antibody testing and later of nucleic acid testing by blood banks, transfusion-associated transmission of HIV-1 has been nearly eliminated. Mother-to-infant spread of the virus also occurs and remains a serious problem worldwide (18). Testing for HIV-1 and treatment of infected women with a short course of antiretroviral drugs can reduce the frequency of intrapartem and peripartem transmission from as many as 30% to less than 2% of newborn infants. However, HIV-1 transmission from mother-to-infant during breastfeeding remains a major problem in the developing world.

Although we understand the epidemiology of HIV transmission in human populations, its transmission at the cellular level is not well defined. It is well established that

HIV is transmitted in genital secretions and blood products, with most transmission occurring across a mucosal surface during sexual contact (19). However, the extent to which HIV associates with cells during the process of transmission remains poorly understood. In infected individuals, viable virus exists both in a cell-free state and within cells. While viral transmission can presumably occur through exposure to either cell-free or cell-associated virus, the form in which the virus is usually transmitted during sexual contact remains unknown.

Studies in the SIV/macaque model of AIDS initially suggested that the first infected cell is of the dendritic or monocyte/macrophage lineage (20). That observation led to the hypothesis that virus in a dendritic cell (DC) or macrophage travels from the mucosal site of initial infection to local draining lymph nodes and then replicates in those lymph nodes (21). This scenario would explain why there appears to be selectivity for macrophage-tropic viruses at the time of viral transmission. While that paradigm is certainly intuitively attractive, recent studies in the SIV/macaque model have raised questions concerning its validity. In experiments in which SIV was applied to the tonsils or vaginal mucosa and local mucosal tissue was then evaluated, viral RNA was found only in T lymphocytes and not in DCs or macrophages (22,23). These studies suggest that viral infection might occur in T lymphocytes in addition to the previously defined DC/macrophage infection early after viral exposure.

HIV IMMUNOBIOLOGY AND CLINICAL CONSEQUENCES OF HIV-1 INFECTION

Following transmission across a mucosal barrier, HIV-1 is thought to begin replicating in subsets of T lymphocytes, monocyte/macrophages, and DCs that express CD4

and CCR5. Virus is presumed to spread from the mucosal area to local draining lymph nodes, and then disseminate rapidly via the blood stream to lymphatic tissue and other anatomic compartments throughout the body. Peak viral replication occurs 2 to 4 weeks after the transmission event, at a time before the virus-specific cellular and humoral immune responses are fully mobilized. Levels of virus in the blood can exceed 10^7 copies of viral RNA/mL plasma at this time.

Systemic viral replication, however, is quickly dampened in association with the emergence of virus-specific immune responses. Thus, by 9 to 12 weeks following initial infection, systemic viral loads usually reach a relatively consistent, low steady-state level. The steady-state level, referred to as *set-point*, is approximately 30,000 to 50,000 copies of viral RNA/mL plasma in untreated individuals. Clinical prognosis of HIV-1–infected individuals has been tied to the set-point viral load, with lower levels associated with better prognosis (24).

Because memory CD4$^+$ T cells express CCR5, the usual coreceptor for transmitted HIV-1, and activated cells are particularly susceptible to HIV-1 replication, there is a rapid and dramatic loss of activated, memory CD4$^+$ T cells during the first days following HIV infection (25). A very large number of lymphocytes are found in the gut-associated lymphatic tissue, including the majority of CCR5-expressing memory CD4$^+$ T cells. Therefore, the gastrointestinal tract is a site of extensive CD4$^+$ T lymphocyte loss in the early days following infection with HIV-1. Activated, memory CD4$^+$ T lymphocytes are, however, destroyed in all anatomic compartments of infected individuals.

The eventual pathogenic consequences of HIV-1 infection reflect the close association of viral replication and CD4$^+$ T lymphocyte destruction (Figure 39.6). Normal CD4$^+$ T lymphocyte counts are 800 to 1,050/mm^3, with a range (2 standard deviations) of 500 to 1,400/mm^3.
FIGURE 39.6 Usual clinical course of the untreated HIV-1–infected individual. A burst of viral replication with an associated loss of CD4$^+$ T lymphocytes occurs during the first weeks following viral infection. Partial control of the virus then occurs, with a slowing of CD4$^+$ T lymphocyte loss. When the CD4$^+$ T lymphocyte count eventually decreases to below 200 cells/mm^3, opportunistic diseases occur that lead to death. Adapted from (192).

T lymphocyte decline from this normal level is directly correlated with viral load. A CD4$^+$ T lymphocyte decline of approximately 4% per year occurs for every $\log_{10}$ HIV-1 RNA copies/mL plasma in an infected individual. The rate of CD4$^+$ T lymphocyte decline, in turn, is correlated with the rate of disease progression in the HIV-1–infected person.

A clinical condition referred to as an *acute retroviral syndrome* occurs in association with the intense viral replication during the first days following HIV-1 infection. This syndrome is characterized by the sudden onset of a fever with associated lymph node enlargement, sore throat, muscle pain, weight loss, and a skin rash. This self-limited syndrome is often not recognized by infected individuals. When it is recognized, the infected person often simply dismisses the condition as a "flu" because the symptoms are indistinguishable from those associated with many other acute viral infections. Evidence suggests that individuals with more severe symptoms during primary infection have a more rapid progression to clinical AIDS than those who are relatively asymptomatic.

Even without the introduction of therapy, the acute retroviral syndrome is followed by a prolonged asymptomatic period. During this time, on average a period of 8 years, the individual is most often unaware that he or she is infected with HIV-1. Nevertheless, ongoing viral replication during this asymptomatic period leads to inexorable CD4$^+$ T lymphocyte loss (26).

The diagnosis of AIDS is eventually made when the HIV-1–infected individual develops an opportunistic infection or tumor. Some of these medical complications, including tuberculosis, pneumococcal pneumonia, shingles, and thrush, can become manifest when the CD4$^+$ T lymphocyte count is >200/mm^3. However, most of the medical problems, referred to as *AIDS defining clinical events,* occur when the CD4$^+$ T lymphocyte count is <200/mm^3. The usual AIDS defining infections include *Pneumocystis carinii* pneumonia, toxoplasmosis, cryptococcal meningitis, *Candida* esophagitis, disseminated cytomegalovirus infection, and disseminated *Mycobacterium avium* infection. AIDS defining opportunistic tumors include Kaposi's sarcoma and non-Hodgkin's lymphoma.

The same pathogenic process underlies this diversity of clinical diseases. All are caused by microorganisms that commonly infect healthy individuals. In the setting of intact immune function, the spread of these microorganisms is held in check and they cause no disease. However, as the immune system is destroyed in the HIV-1–infected individual, these microorganisms are no longer contained and they cause diseases that can be fatal.

ANTIRETROVIRAL THERAPY

Without specific therapy, the average life expectancy following clinical recognition of an AIDS-defining opportunistic infection or tumor is 1.3 years. However, thera-

pies to provide prophylaxis against the development of opportunistic infections and, more important, the use of antiretroviral drugs to contain HIV-1 replication have dramatically altered the natural history of HIV-1 infections (27). AZT, the first drug found to have activity against HIV-1, was introduced in 1987. This drug is a member of a family of drugs known as *nucleoside analogue reverse transcriptase inhibitors*. These nucleoside analogues are incorporated into viral RNA and lead to termination of the nucleotide chain being synthesized, blocking reverse transcriptase activity and the generation of proviral DNA. Other nucleoside analogue reverse transcriptase inhibitors have been introduced into clinical use since 1987. However, the use of these drugs as stand alone therapeutic agents was associated with only a modest prolongation of life in infected individuals.

A number of new classes of anti-HIV-1 drugs have been developed since the mid-1990s. The first of these new classes of drugs to be introduced into clinical use, the protease inhibitors, acts by inhibiting the activity of protease, the viral enzyme that cleaves developing viral proteins. The non–nucleoside analogue reverse transcriptase inhibitors, introduced soon after the protease inhibitors, affect the activity of the reverse transcriptase enzyme. Further, the first drug that acts by blocking the ability of the virus to fuse to a cell membrane was introduced as a clinical agent in 2003. Drugs that block the activity of the viral integrase or virus-CCR5 binding are currently undergoing clinical evaluation.

The use of representative drugs from these different classes in combination with one anther has revolutionized the care of the HIV-1–infected patient. A combination of these drugs has substantially more antiviral activity than a single drug used alone. Moreover, HIV-1 can rapidly develop mutations that allow the virus to escape from the activity of one of these drugs if that drug is used as a single therapeutic agent. The simultaneous use of combinations of drugs from these different classes of therapeutic agents dramatically slows the emergence of drug-resistant mutant viruses. By the late 1990s, there was a 60% to 80% decrease in mortality from HIV-1 infections in populations receiving these new combination therapies (28). These combination therapies are often referred to as *highly active antiretroviral therapy* (HAART).

In spite of these considerable advances in the treatment of HIV-1 infections, there is a growing realization that drug therapies will, in the end, not solve the problem posed by the worldwide AIDS epidemic. While these therapies clearly decrease viral replication, they do not eradicate HIV-1 from infected individuals. Antiretroviral drug treated patients who have undetectable plasma viral RNA levels still harbor replicating virus. This ongoing viral replication has been demonstrated in a number of ways. The virus in treated individuals continues to accumulate mutations, a phenomenon that can only occur in the

setting of continuing viral replication (29). Moreover, interruption of antiretroviral therapy in individuals with undetectable plasma viral RNA can result in a dramatic rebound of viral replication (30). In fact, plasma viral RNA levels often reach pretreatment levels in these individuals.

A number of reservoirs of replicating or replication competent HIV-1 have been described in individuals who have been successfully treated with antiretroviral drugs (31). These sites include lymphoid tissue, where virus has been demonstrated in CD4$^+$ T lymphocytes in the germinal centers of lymphoid tissue and trapped on follicular DCs. Other reservoirs of virus include resting CD4$^+$ T lymphocytes in the peripheral blood, monocytes/macrophages, DCs, the central nervous system (CNS), and the reproductive tract.

Other factors also limit the impact of drugs on the AIDS epidemic. The antiretroviral therapies are often associated with toxicities that limit the ability of patients to use the drugs. The emergence of mutant HIV-1 isolates in treated individuals that are resistant to the activity of available drugs and the transmission of these mutant viruses to uninfected individuals may also limit the ultimate efficacy of these therapies. Finally, the populations in the developing world most severely affected by the AIDS epidemic cannot bear the economic burden of the costs of these therapies. Moreover, developing nations often do not have the medical infrastructure needed to use the therapies optimally.

VARIATION IN CLINICAL COURSE OF HIV INFECTION

Investigators have devoted considerable attention to studying infected individuals who are particularly successful in containing HIV-1 replication to help define the immunologic and virologic factors that may contribute to the control of HIV-1 spread in the infected individual. The rate of disease progression can vary dramatically among those infected with HIV-1. A small number of infected individuals, referred to as *long-term nonprogressors* (LTNP) or *elite controllers,* maintain relatively normal CD4$^+$ T lymphocyte counts and have unmeasurable plasma viral RNA levels for years or even decades following infection, even without antiretroviral therapy (32,33). While some of these individuals have eventually developed progressive disease, a very small percentage of them have shown no evidence of replicating virus as determined by usual assays and have remained free of clinical disease. A number of immunologic, virologic, and host genetic factors have been implicated in this rare but potentially important cohort of HIV-1–infected individuals.

Most LTNPs demonstrate preserved immune function; however, it is not clear whether this accounts for control of HIV-1 replication or is a consequence of that control. These patients have been shown to have persisting neutralizing antibody responses, preserved lymphoid architecture, and preserved virus-specific T cells (34,35). The preserved antibody responses may, however, simply be a consequence of their preserved helper CD4$^+$ T responses rather than the explanation for their benign clinical status. Similarly, while the usual HIV-1–infected individuals have dramatic lymphoid hyperplasia with destruction of the normal architecture of their lymph nodes, there is evidence of only mild follicular hyperplasia in the lymph nodes of these rare patients. This observation may, however, simply be a consequence of the low level of viral replication that occurs in these individuals rather than an etiologic explanation for the limited virus replication. Finally, reports indicate that HIV-1–specific CD8$^+$ T lymphocyte populations are present at only very low frequencies in these individuals. This finding would be expected in the setting of low levels of viral replication where there is little viral antigen being produced to stimulate the expansion of effector lymphocytes. Thus, the immunologic correlates of the extraordinary virologic control in these patients may be consequences rather than causes of their effective viral containment.

Occasional individuals have a benign clinical course and are found to be infected with an HIV-1 isolate with a mutation that attenuates the pathogenicity of the virus. The most dramatic of these reported cases was a cluster of transfusion-associated infections in Australia where the mutant virus originated from a single blood donor (36). This virus contained deletions in the *nef* gene, the *nef*/U3 LTR overlap region and rearrangements of the NFκB/SP-1 sites in the viral LTR. Importantly, long-term follow-up of the clinical status of this cluster of infected individuals demonstrated that they went on to develop AIDS, albeit with a delayed time course (37). However, while infection with mutant viruses can certainly result in disease with a relatively benign or delayed clinical course, such cases constitute a very small percentage of the reported long-term nonprogressors.

Host genetic factors appear to account for the majority of cases of elite control of HIV-1 infection. One of the most intensively studied of these host factors is the relationship of particular MHC class I alleles with slow clinical progression (38). Heterozygosity at MHC class I loci is associated with slow clinical progression, while homozygosity at these loci is associated with more rapid progression (39). The presumptive explanation for this phenomenon is that heterozygosity facilitates CTL responses to a greater breadth of HIV-1 epitopes than is seen in individuals who are homozygous for particular MHC class I alleles. Broad CTL responses presumably mediate more effective control of HIV-1 replication than do more focused responses.

In addition to the impact of MHC class I heterozygosity, a number of particular MHC class I alleles have been associated with slow clinical progression in HIV-1–infected

individuals. This relationship is most marked in infected individuals expressing HLA B57*01 or HLA B27 (40). Since MHC class I alleles play a central role in the CD8$^+$ T lymphocyte response to a virus and HLA B57*01-restricted CD8$^+$ T lymphocytes dominate the HIV-1–specific cytotoxic T lymphocyte (CTL) response in B57*01$^+$ infected individuals, it is likely that this MHC class I association with long-term nonprogression reflects a particularly effective B57*01-restricted CD8$^+$ T lymphocyte response to the virus. Other MHC class I alleles have also been associated with slow clinical progression, including HLA B14 and C8.

Interestingly, expression of the HLA Bw4–80I allele in association with the activating killer immunoglobulin-like receptor (KIR) allele KIR3DS1 has also been shown to be associated with slow clinical progression following HIV-1 infection (41). Since KIR molecules are expressed on the surface of natural killer (NK) cells, this provocative finding suggests a possible contribution of innate immunity to the control of HIV-1 replication.

Among genetic host factors involved in HIV-1 resistance, the allelic form of the CCR5 molecule expressed by the infected individual has been shown to contribute most profoundly. CCR5, the second receptor for most of the transmitted isolates of HIV-1, can exist in Caucasian populations either as an intact molecule or with a 32 base-pair deletion. The so-called *delta 32* form of CCR5 has a deletion in the portion of the gene that encodes the third extracellular domain of the molecule, resulting in a frame shift and premature stop codon in the fifth transmembrane domain of the molecule. Homozygosity for this delta 32 allelic form of CCR5, which occurs in 1% of Caucasians, confers almost absolute protection against acquisition of the virus (42). Thus, only a handful of CCR5-delta 32 homozygotes have been reported that are infected with HIV-1. This protection is evidence that the virus cannot infect cells that do not express an intact second receptor.

Importantly, while heterozygosity for the delta 32 form of the CCR5 molecule does not confer absolute protection against HIV-1 infection, it is associated with slower progression to AIDS and death in infected individuals (43). When compared to infected individuals expressing CCR5 alleles coding for full-length CCR5, HIV-1–infected CCR5 delta 32 heterozygotes have lower plasma viral RNA levels, slower rates of CD4$^+$ T lymphocyte decline, and a 2- to 4-year delay in time-to-death following seroconversion. These findings are likely a consequence of the fact that heterozygotes have a reduced expression of full-length CCR5 on the surface of their CD4$^+$ T lymphocytes, which likely decreases the efficiency of HIV-1 infection of those cells.

A number of other chemokine receptor allelic polymorphisms have also been associated with delayed progression to AIDS following HIV-1 infection. CCR2, a molecule with 82% sequence homology to CCR5, is only rarely a second receptor for *in vitro* HIV-1 infection. Nevertheless,

homozygous or heterozygous expression of a CCR2 protein that contains a single valine to isoleucine substitution at position 64 of the first transmembrane domain CCR2-64I, is associated with a slowing by 2 years of progression to AIDS following infection (44). Finally, allelic forms of the ligands for various other chemokine receptors, including SDF and RANTES, have been assessed for their contributions to the rate of AIDS progression; some studies have suggested associations between particular allelic forms and progression while other studies have not shown such associations.

Polymorphisms in genes associated with molecules that participate in immune cell interactions have also been evaluated for their contribution to AIDS progression in HIV-1–infected individuals. Polymorphisms in the IL-10 promoter, a regulatory region associated with IL-4 production, the tumor necrosis factor (TNF) promoter, and the mannose-binding lectin promoter have all been implicated in influencing the rate of AIDS progression (45). This complex network of associations between allelic forms of molecules and the rate of AIDS clinical progression underscore the importance of both virus–cell interactions and immune activation in the pathogenesis of this disease.

An even more extreme of protection against HIV-1–induced disease has also been described. An extensive but controversial literature has appeared in recent years describing rare cohorts of individuals who are repeatedly exposed to HIV-1 but never convert to virus seropositivity (46). These subjects have been identified both in serodiscordant couples and also among commercial sex workers. Determining immune correlates of protection in such individuals could prove extremely valuable for developing novel strategies for HIV-1 vaccination. These individuals develop virus-specific peripheral blood CD4$^+$ and CD8$^+$ T lymphocyte responses. Mucosal virus–specific T lymphocytes and antibodies have also been described in exposed, uninfected subjects. However, studies have also been published suggesting that these claims of virus-specific immunity in the absence of detectable infection are based on experimental artifact rather than reliable data (47). Interesting studies have also been published suggesting that at least a subpopulation of multiply exposed but seronegative individuals harbor replicating virus at a level that cannot be detected with usual assays (48). Thus, levels of replicating virus in these individuals may be high enough to drive cellular and humoral immune responses, but too low to be detected by usual laboratory assays.

There remains considerable skepticism of these claims because of the low level and inconsistency of the measured immune responses in these exposed, uninfected subjects. Very low responses have been reported in these subjects, considerably lower than are seen in normally infected individuals. Moreover, these responses may be present at the time of one blood sampling and absent at the time of the next sampling. The ultimate importance of these cohorts

of subjects for elucidating the basis of sterile protection remains to be determined.

CD4+ T LYMPHOCYTE LOSS FOLLOWING HIV-1 INFECTION

While HIV-1 replication is controlled by the immune response in the early weeks following infection, the containment of the virus is not complete. The incomplete nature of containment of viral replication eventually results in viral destruction of the immune system. The immunologic hallmark of persistent replication of HIV-1 in humans is a gradual loss of CD4+ T lymphocytes, most of which occurs during the period of clinical latency following primary infection.

The mechanism by which CD4+ T lymphocytes are lost in the HIV-1–infected individual has remained an issue of considerable controversy. Early in the AIDS epidemic, at a time when the assays for measuring cell-associated virus were quite insensitive, it was assumed that only approximately 1 in 10^7 peripheral blood CD4+ T cells were infected with HIV-1. Explanations were, therefore, sought to account for the occurrence of profound CD4+ T cell loss in the absence of viral infection of CD4+ T cells. The presumption that there were insufficient numbers of cells infected to account for CD4+ T cell killing led to the suggestion that CD4+ T cells were dying through a secondary apoptotic process (49). However, as assays for cell-associated virus improved in sensitivity, it became clear that large numbers of CD4+ T cells harbored replicating virus in the infected individual. These observations led some to conclude that the CD4+ T cell loss in HIV-1–infected individuals occurs solely as a result of virus replicating in and killing individual cells (50). Others have implicated CD8+ T lymphocytes or general chronic immune activation in the killing of infected CD4+ T helper cells. A number of studies have been done in recent years to characterize the mechanism and dynamics of CD4+ T lymphocyte loss in AIDS and the interpretations of these studies have generated conflicting explanations for CD4+ T cell decline.

With the advent of highly active antiretroviral therapy, it became clear that an early and rapid reconstitution of some of the lost peripheral blood CD4+ T cell population occurred in HIV-1–infected individuals upon initiation of treatment (51–53). In fact, carefully observed clinical responses to HAART in HIV-1–infected subjects have been used to draw conclusions concerning AIDS immunopathogenesis. Thus, the rapid repopulation of CD4+ T lymphocytes following the initiation of HAART has led to the proposal that there is a continuous, high rate of CD4+ T cell turnover in HIV-1–infected individuals and that the decline in CD4+ T cells in infected individuals occurs as a result of exhaustion of the capacity to replenish this rapidly turning-over CD4+ T cell population. The data generated in these studies allowed a calculation of the life span of a CD4+ T cell following infection with HIV-1: a $t_{1/2}$ of 1.6 days. While this explanation for CD4+ T cell loss in HIV-1–infected individuals was attractive, further studies have not substantiated this model.

The first study to raise doubts about the validity of the exhaustion model previously discussed was an experiment done to assess telomere length in CD4+ and CD8+ T cells in HIV-1–infected subjects (54). Telomeres shorten in length as cells divide. Therefore, one can approximate the relative past proliferation of a lymphocyte by measuring the length of its telomeres. When peripheral blood T cells from HIV-1–infected individuals were assessed for their rate of turnover on the basis of telomere length, it was demonstrated that CD4+ T lymphocytes turn over in these individuals at a rate no different than those in uninfected individuals. Interestingly, these studies showed that CD8+ T cell populations in infected individuals have an increased rate of turnover. Studies were also done to assess the dynamics of CD4+ T cell loss and repopulation in AIDS in the SIV/macaque model (55,56). BrdU labeling was employed to measure lymphocyte turnover in both infected and uninfected animals. These studies showed some increase in the rate of CD4+ T cell turnover in infected as compared to uninfected monkeys. However, consistent with the studies of T lymphocyte telomere length, the rate of CD8+ T cell turnover in these infected animals was greater than that of CD4+ T cells. Finally, in studies performed using deuterium-labeled lymphocytes in humans, no evidence of an increased rate of CD4+ T cell turnover could be documented in HIV-1–infected subjects (57). In fact, in those studies decreased numbers of circulating CD4+ T cells in HIV-1–infected individuals appeared to be attributable to a decrease in the production of those lymphocytes.

The demonstration that HIV-1 infection can only occur in a subset of CD4+ T lymphocytes has considerably clarified the longstanding puzzle of how CD4+ T lymphocytes are destroyed. It is now apparent that HIV-1 infects the subset of CD4+ T lymphocytes that express a chemokine receptor, usually CCR5, and that these cells support viral replication more readily if they are activated (25). The gastrointestinal tract is therefore an important site of CD4+ T lymphocyte loss early following infection, since CCR5-expressing, activated CD4+ T lymphocytes are found in large numbers in this anatomic compartment (58). Moreover, since CCR5 is selectively expressed on the memory subset of CD4+ T lymphocytes, these important immune cells are preferentially lost following infection (59). These data suggest that immune cell loss in AIDS occurs in a subpopulation of CD4+ T lymphocytes, and this cell loss occurs as a result of direct killing by replicating virus.

Other facets of the biology of CD4+ T lymphocytes in HIV-1–infected individuals have also been explored. Attempts have been made to characterize the CD4+

T lymphocytes that repopulate infected individuals after the initiation of highly active antiretroviral therapy (60). Early after the start of therapy, a rise in the memory (CD45RO$^+$) CD4$^+$ T cell pool is seen. Later, a reduction in the activation status of all T cells can be demonstrated. Finally, there is a rise in CD4$^+$ T lymphocytes with a naïve phenotype (CD45RA$^+$CD62L$^+$). The early rise in circulating memory CD4$^+$ T cells probably reflects the peripheral expansion of preexisting, mature T lymphocytes. The reduction of T cell activation likely occurs as a consequence of the sustained decrease in production of infecting virus in those individuals. Therefore, immune reactivity and the associated T cell activation is no longer being driven by the virus. Finally, the late increase in circulating naïve CD4$^+$ T cells probably reflects repopulation of the periphery with immature, uncommitted lymphocytes from bone marrow and thymus. These events suggest that some reconstitution of the pool of helper T lymphocytes can occur with the institution of HAART.

OTHER IMMUNOLOGIC DYSFUNCTION IN AIDS

While CD4$^+$ T lymphocyte loss is the best-studied immunologic abnormality seen in those infected with HIV-1, other evidence of immunologic dysfunction is clearly observed in these individuals. Perhaps the most striking of these abnormalities is the destruction of the lymphoid microenvironment (61). As HIV-1–induced disease progresses clinically, there is an inexorable destruction of lymph node germinal centers. Although the etiology of this germinal center destruction has not been fully explained, the loss of follicular DCs (FDCs) is prominently seen. FDCs do not express CD4, and there is no evidence that these cells

themselves become infected with HIV-1 (62). FDCs trap viral particles in germinal centers during the course of infection. This contact with the virus, or local cytokine production that occurs as a consequence of infection, may contribute to the degeneration of these cells. CD8$^+$ T lymphocyte populations also migrate into the germinal centers of lymph nodes during the course of HIV-1 infection. These cell populations may secrete cytokines or lytic granules that mediate destruction of FDCs. Whatever the etiology of FDC loss proves to be, the destruction of the infrastructure upon which the germinal center is built contributes to germinal center dysfunction and eventual disintegration.

Chronic HIV-1 infection also destroys the thymus (63) (Figure 39.7). Thymic tissue loss is so marked that it can be demonstrated radiographically (64). The loss of thymic function in AIDS is also apparent at a molecular level. Genetic rearrangements of the antigen recognition domains of the T cell receptor (TCR) alpha and beta chains of maturing T lymphocytes occur in the thymus as T lymphocytes become committed to a single antigen recognition specificity. These rearrangements include a deletion of TCR delta genetic material, resulting in the generation of so-called *TCR excision circles* (TRECs) that can be detected in developing T lymphocyte populations. High levels of circulating T lymphocytes containing these excision circles is an indication of ongoing thymic maturation of T lymphocytes. As AIDS progresses clinically, the proportion of circulating T lymphocytes that contain these TRECs decreases (65). This suggests a waning of thymic function. The etiology of thymic loss and dysfunction in AIDS remains unclear. Importantly, however, both the radiographic evidence of thymus loss and molecular evidence of thymic dysfunction have been shown to reverse in HIV-1–infected individuals receiving antiretroviral therapy. These observations suggest that thymic dysfunction is
FIGURE 39.7 Immunohistochemical analysis of a thymus from an HIV-1–infected adult. Anti-CD1a staining of a thymus from a normal individual (**A**) is shown with the medulla (M) and cortex (C) noted. A similarly stained thymus from an HIV-1–infected adult (**B**) is also shown with arrows pointing to thymopoietic areas, consistent with persistent thymic function in chronically infected individuals. Adapted from (193).

indeed reversible in individuals who respond to antiviral therapy.

Evidence continues to accrue indicating that the bone marrow is also abnormal in HIV-1–infected individuals. It has been clear since the earliest clinical descriptions of AIDS that all bone marrow–derived cell populations are abnormal in infected individuals (66). Abnormalities are apparent in their number, morphology, and function (67). Anemia, thrombocytopenia, and neutropenia are quite commonly seen as clinical manifestations of AIDS. Assays of bone marrow progenitors that assess their potential to generate mature, functional cells invariably show diminished activity in infected subjects. Since the major constituent cell populations that comprise the immune system are generated in the bone marrow, there is reason to presume that these cell populations are not produced normally in HIV-1–infected individuals. In fact, studies suggest that at least a small component CD4$^+$ T cell loss in AIDS may be attributable to decreased production of these cells, presumably in the bone marrow (57). The etiology of this bone marrow dysfunction remains poorly understood. However, studies have shown that viral infection of bone marrow macrophage populations may contribute to an abnormal microenvironment that is responsible for at least some of this dysfunction (68).

HIV-1 infection also leads to profound cytokine dysregulation. Endogenous cytokines, including TNF alpha, GM-CSF, IL-6, and IFN gamma, have been shown to increase HIV-1 replication in various cell populations *in vitro* (69–71). The mechanisms by which this cytokine-induced up-regulation of viral replication occurs can differ and sometimes be complementary. For example, TNF alpha is a transcriptional activator of HIV-1 via NF kappa B, while IL-6 induces HIV-1 replication by a posttranscriptional mechanism. It is assumed that immune cells in the infected individual produce increased quantities of many of these cytokines, which, in turn, increase viral replication *in vivo*. It has, however, also been shown that other immunologically active cytokines, such as IFN alpha and IFN beta, can suppress HIV-1 replication *in vitro*. Therefore, the sum effect of cytokine dysregulation on HIV-1 replication *in vivo* is difficult to gauge.

Although B lymphocytes have never been shown to harbor replicating HIV-1 *in vivo* in infected individuals, B lymphocyte abnormalities have been described in individuals infected with HIV-1. An increase in circulating B lymphocytes has been described during primary HIV-1 infection as well as during primary infection of macaques with SIV (72). Cytokine production by B lymphocytes in infected individuals has also been shown to be abnormal, with increased levels of TNF alpha and IL-6 spontaneously produced by these cells (73,74). In fact, it has been suggested that these B lymphocyte-produced cytokines may actually upregulate HIV-1 replication in CD4$^+$ T lymphocytes and macrophages. It is likely that the B lymphocyte activation

that occurs in HIV-1–infected individuals contributes to the striking incidence of AIDS-related B cell malignancies (75).

Finally, HIV-1 infects CD4-expressing antigen presenting cell populations, including monocytes, macrophages, and DCs. Very few circulating cells of these lineages are actually infected by the virus, and this infection does not appear to mediate the obligatory death of these cells. Rather, these infected cells are felt to represent an important reservoir of virus that will probably prove difficult to eradicate by antiviral therapies. Relevant to this postulated role as a reservoir, the infected DC has been shown to mediate an extremely efficient transfer of virus to normal T lymphocyte populations, at least under *in vitro* culture conditions (76). In fact, the DC-specific C-type lectin DC-SIGN has been shown to bind HIV-1 envelope, perhaps promoting capture of virus by DCs and facilitating infection of CD4$^+$ T lymphocytes (77). While very few infected monocyte/macrophages have been documented in the circulation, large numbers of resident macrophages have been shown to be infected in various organs, including the lungs and the brain.

In light of the infectability of cells of the monocyte/macrophage lineage, it is not surprising that these cells do not function normally in infected individuals. The abnormalities of these cells include problems with oxidative burst response, C3 receptor–mediated clearance, Fc receptor function, and chemotaxis (78). These cells in HIV-1–infected individuals also have been shown to have a decreased ability to mediate antibody-dependent cell-mediated cytotoxicity and microbicidal activity (79). Infection of resident brain macrophages probably initiates a cascade of cytokine abnormalities that change the milieu of the CNS, leading to neuronal damage and AIDS dementia (80).

IMMUNE CONTROL OF HIV-1

While the containment of HIV-1 spread is incomplete in the infected individual, the substantial damping of viral replication that occurs during primary infection in humans suggests that immune mechanisms are contributing to viral control. Considerable work has been done to define the contribution of innate, humoral, and cellular immune responses to this partial control of HIV-1 replication. These studies are reviewed later in this chapter.

Although there is circumstantial evidence to suggest that innate immune mechanisms contribute to early HIV-1 containment in infected individuals, it has proven difficult to demonstrate this unequivocally. An NK cell contribution to viral clearance is suggested by the genetic correlative data showing that the expression of the HLA Bw4-80I allele in association with the activating KIR allele KIR3DS1 is associated with slow clinical progression following HIV-1 infection (41). NK cells have been shown

in vitro to mediate killing of HIV-1–infected cells (81). However, NK cell–mediated control of the virus has never been directly demonstrated. Studies in the SIV/macaque model in which cobra venom toxin was administered to monkeys prior to infection to eliminate the activity of specific limbs of the complement cascade failed to demonstrate a definitive role for complement in early viral control (82). Some have suggested that the resistance to HIV-1 infection in cohorts of exposed, uninfected individuals could be most readily explained by innate immune mechanisms. Yet, no such innate immune-mediated protection has been demonstrated to date.

ANTIBODY RESPONSE TO HIV-1

Since the immune control of many viruses depends on antibody-mediated virus neutralization, considerable effort has been invested in characterizing the mechanisms by which HIV-1 may be neutralized by antibody. Virus is neutralized when antibody binds to virions and blocks the ability of those virions to enter their target cells. HIV-1 engages both the CD4 molecule and the virus coreceptor, either CCR5 or CXCR4, on the cell surface. This engagement triggers HIV-1 fusion with its target cell mediated by a trimeric envelope complex that includes three molecules of gp160. A neutralizing antibody must therefore block the series of events that begins with HIV-1–coreceptor binding and ends with HIV-1 fusion.

Current models suggest that neutralizing antibodies block HIV-1 infection by binding to the mature trimer on the virion surface and blocking the events associated with initial receptor engagement or by binding after virion-target cell attachment and inhibiting the fusion process (83). Blocking of virion–cell engagement presumably occurs when a threshold number of envelope glycoprotein spikes are occupied by antibody. If the antibody blocks the fusion process that occurs after virion–cell engagement, the antibody presumably binds to domains of the virus that are exposed as a result of this process of engagement.

Progress in the elucidation of antibody-mediated neutralization of HIV-1 has been slowed by a lack of comparability of neutralization data generated in different laboratories. Until recently, HIV-1 neutralization assays were performed in different laboratories using different target cells, different techniques for detecting virus replication, and different types of indicator viruses. This has made it impossible to compare experimental results from different laboratories. However, recent technological advances have provided an approach that will finally allow standardization of these assays (84). Engineered cell lines can be generated that express high levels of the receptors for HIV-1, and neutralization can be assessed using these cells as targets. Moreover, pseudotyped viruses can be generated *in vitro* by cotransfecting cells with both an *env*-deficient

HIV-1 and any selected *env* gene. The pseudovirions created by these cotransfections can initiate a single round infection that can be assessed by monitoring expression of a reporter gene carried either by the virus or the engineered cell line. By assessing an antibody's ability to block the single round infection of a panel of pseudovirions expressing different Envs, the potency and breadth of that antibody's neutralizing ability can be ascertained.

It was assumed at the outset of the AIDS epidemic that a neutralizing antibody response to HIV-1 would play a crucial role in containing the replication of this virus. However, a number of observations have raised doubts about that assumption. It has been clear for some time that the HIV-1 neutralizing antibody response in patient sera against primary patient isolates of HIV-1 is quite weak (85,86). Moreover, the burst of HIV-1 replication that occurs during the period of primary infection is contained well before the emergence of a neutralizing antibody response in infected individuals (87–89). Monkeys depleted of B lymphocytes by infusion of an anti-CD20 antibody and then infected with SIV show normal early virus clearance. Interestingly, recent evidence does suggest that immune pressure mediated by antibodies results in the selection of HIV-1 mutants that are not susceptible to antibody neutralization (90,91). Although this process of autologous neutralization escape by virus occurs, it does not appear to be associated with clinical deterioration in the infected individual. Hence, treatment of chronically infected humans with monoclonal antibodies that have *in vitro* HIV-1 neutralizing activity has very little impact on viral replication *in vivo*. These observations suggest that the antibody response may not be of central importance in controlling HIV-1 replication in the setting of infection.

In fact, a number of unique characteristics of HIV-1 appear to protect the virus from antibody-mediated neutralization (92). The envelope of HIV-1 is heavily glycosylated, and these sugars can shield the underlying viral protein structures from access by antibodies. Neutralization-sensitive domains of the envelope appear to be hidden from antibodies due to steric hindrance caused by this glycosylation, steric hindrance caused by adjacent protein domains, or the fact that these domains are only exposed upon ligand binding. While the loops of the virus envelope appear to be particularly good targets for neutralizing antibodies, the high rate of mutation within these regions and their resulting extreme sequence variability preclude the possibility of a single antibody specificity that will neutralize a diversity of HIV-1 isolates.

In spite of the aforementioned limitations in forming an effective neutralizing antibody response to HIV-1, there is a limited amount of data suggesting that antibodies play a role in HIV-1 containment. Considerable attention has been focused on characterizing neutralizing HIV-1–specific antibody responses since these may be of central importance in the creation of an HIV-1 vaccine. Much of
FIGURE 39.8 Tomographic reconstruction of an HIV-1 envelope glycoprotein trimer. A side view **(A, C)** and top view **(B)** of an envelope spike are shown. Structure modeling indicates the positions of the V1/V2 loops, the CD4 binding sites, and the V3 loop. The membrane proximal envelope region is shown **(C)** with the positions of two highly conserved neutralizing epitopes (the 4E10 and 2F5 epitopes). Adapted from (194).

the work in this area has been driven by a limited number of characterized monoclonal antibodies that are able to neutralize a diversity of HIV-1 isolates. Antibodies against three different neutralizing determinants of HIV-1 envelope have been studied in some depth: the third hypervariable loop of the envelope glycoproteins, the CD4-binding site of envelope, and the transmembrane envelope gp41 protein (Figure 39.8).

The third hypervariable domains of the HIV-1 envelope glycoproteins create a loop structure as a result of the formation of disulfide bonds (93). This so-called *V3 loop* has been implicated in the interactions of HIV-1 envelope glycoproteins with chemokine receptors (94). It is, therefore, reasonable that an antibody binding to this loop may interfere with the ability of the virus to bind to and enter a cell. In fact, the earliest antibodies that arise after an infection capable of neutralizing HIV-1 appear to recognize this V3 loop sequence (95,96). Considerable experimental work was done early in the AIDS epidemic in an attempt to develop the V3 loop as an immunogen for eliciting protective immune responses against HIV-1. However, a number of observations dampened enthusiasm for this approach. Extreme sequence variability exists among diverse HIV-1 isolates (97). Therefore, V3 loop–specific antibodies for the most part mediate type-specific neutralization. Moreover, it has become clear that in primary HIV-1 isolates, the V3 loop on the intact virion is not exposed to neutralizing antibodies (98). Thus, while antibodies do arise to the V3 loop, the antibodies are ultimately unable to access it and neutralize virions. At the time, these observations convinced investigators interested in vaccine development to shift their attention to the evaluation of more highly conserved sequences of the virus that might serve as targets for neutralization.

However, recently generated data has renewed interest in the V3 loop as a target for neutralizing antibodies. A limited number of monoclonal anti-V3 loop antibodies have been described that bind and neutralize a diversity of primary HIV-1 isolates (99). One such antibody, 447–52D, recognizes the GPGR motif at the tip of the V3 loop and neutralizes 47% of clade B HIV-1 isolates. Another antibody, 58.2, recognizes an epitope overlapping the tip of the loop and neutralizes a third of clade B isolates. Further, a homology between the V3 loop and the 40s loop of the CC chemokines has been described, suggesting that the V3 loop structure may have evolved to mimic a chemokine when the virus interacts with the cell-surface chemokine receptors CCR5 or CXCR4 (100). These findings have motivated continuing work to determine the ramifications of antibody–V3 loop interactions.

The CD4 binding sites of envelope represent another potential neutralizing determinant of HIV-1. Because the CD4 molecule is nonpolymorphic, the domains of HIV-1 that bind to CD4 must be relatively conserved among diverse isolates to maintain the viability of the virus. In fact, selected monoclonal antibodies specific for the CD4 binding domains of gp120 can be broadly neutralizing, recognizing and blocking a diversity of HIV-1 isolates from infecting cell populations *in vitro* (101,102). The best studied of these CD4 binding domain-specific neutralizing monoclonal antibodies is b12, an antibody that has been shown to occlude the CD4 binding site on gp120. The crystal structure of this monoclonal antibody has demonstrated a unique, long protruding CDR3 loop that may facilitate its ability to gain access to the deeply recessed CD4 binding pocket of the virus envelope (103). Importantly, however, the CD4 binding site–specific antibodies that have been assessed *in vivo* for their ability to protect chimpanzees from

HIV-1 challenge have not been protective. This observation has led to the suggestion that the CD4 binding site–specific antibodies, as a group, may not ultimately prove to be particularly potent as neutralizing antibodies.

The extraordinary degree of sequence conservation in the transmembrane gp41 protein of the envelope between various HIV-1 isolates makes it an attractive target for eliciting broadly neutralizing antibodies through vaccination. In fact, monoclonal antibodies have been developed that bind to the gp41 of a diversity of HIV-1 isolates and neutralize the virus *in vitro* (104). The most intensively studied of these monoclonal antibodies, 2F5 and 4E10, recognize distinct domains of the membrane proximal region of the ectodomain of gp41. Since these antibodies do not block receptor attachment, they are thought to inhibit the fusion process. While 2F5 binding is readily demonstrated to a linear peptide derived from this region of gp41, vaccination with this linear peptide cannot induce a neutralizing 2F5-like antibody. 4E10 has been shown to recognize an ordered helical peptide structure of gp41. No success has yet been achieved in attempts to elicit 2F5- or 4E10-like antibodies through subunit vaccination.

Several domains of HIV-1 only become exposed after CD4 binding of the envelope trimer. Coreceptor binding by gp120 triggers a change in the conformation of gp41 that exposes its hydrophobic fusion domain, facilitating the insertion of the N-terminal peptide of gp41 into the cytoplasmic membrane of the target cell. A peptide mimetic of a domain of gp41 has been shown to intercalate into the fusion apparatus and block the conformational changes required for viral fusion. This finding argues that it may be possible to generate antibodies that can similarly interfere with gp41-mediated fusion events. In fact, the well-defined series of molecular events leading to HIV-1 entry suggest that highly conserved amino acid sequences of both the C and N terminal regions of gp41 may prove useful targets for vaccine-induced neutralizing antibody responses (105,106).

Recent studies have shown convincing evidence that the envelope glycoproteins of HIV-1 undergo a continuous process of mutation that allow the virus to escape from neutralization by antibody (90,91). Pseudovirions created with envelopes of the HIV-1 isolated from chronically infected individuals cannot be neutralized by the antibody in the serum of those individuals at the time the envelopes were obtained. Since a selection process must be driving this viral evolution, this observation makes a strong argument for transient viral control by neutralizing antibodies in the setting of chronic infection.

Evidence in mouse models and in man suggests that neutralizing antibodies in individuals with established HIV-1 infections have little effect on ongoing viral replication. Immunodeficient mice reconstituted with human lymphoid tissue have been infected with HIV-1 and then infused with neutralizing anti–HIV-1 antibodies. These antibody treatments have little effect on HIV-1 replication (107). Intravenous administration of hyperimmune globulin with high titers of anti–HIV-1 antibodies in HIV-1–infected humans, similarly, has little effect on viral load or disease progression.

Thus, while antibodies may contribute to shaping the course of early viral infection, they ultimately do not appear to play a role in controlling viremia. Neutralizing monoclonal antibodies have been defined, yet they are difficult to elicit, and their antiviral activity can be readily circumvented as HIV-1 mutates to evade their binding. Importantly, however, preexisting circulating antibodies specific for HIV-1 envelope will likely be able to alter the clinical consequences of *de novo* HIV-1 infections. This is most convincingly demonstrated in nonhuman primate studies. The infusion of IgG derived from serum of an SIV-infected monkey into a naïve rhesus monkey caused a damping of viral replication and an attenuation of the pathogenicity of subsequent SIV infection (108). Moreover, the infusion of HIV-1–neutralizing monoclonal antibodies in macaques prior to their exposure to a highly pathogenic SHIV dramatically altered the consequences of both intravenous and mucosally initiated infections (109,110). In monkeys in which very high serum concentrations of neutralizing monoclonal antibodies are achieved, SHIV infections can be blocked or the pathogenic consequences of the infections can be significantly attenuated. These observations suggest that neutralizing antibodies specific for HIV-1 may have utility in the setting of vaccination to prevent HIV-1 infection.

CD8$^+$ T LYMPHOCYTE RESPONSE TO HIV-1

While little data have been generated to suggest that anti–HIV-1 antibodies play a role in containing replication of the virus in infected individuals, a number of studies have implicated HIV-1–specific CD8$^+$ CTL in controlling HIV-1 replication. This evidence comes from both *in vitro* and *in vivo* studies. HIV-1–specific CTLs have been found in large numbers in a variety of anatomic compartments in both HIV-1–infected humans and SIV-infected macaques: in peripheral blood lymphocytes, bronchoalveolar lavage lymphocytes, lymph nodes, spleen, skin, cerebrospinal fluid, and vaginal mucosal tissue (111). CD8$^+$ T lymphocytes have been shown to inhibit HIV-1 replication *in vitro* (112,113). A number of mechanisms have been implicated for this inhibition. Direct CTL lysis of HIV-1–infected cells *in vitro* can block the propagation of an *in vitro* infection. Soluble factors produced by CD8$^+$ T lymphocytes are also able to mediate this inhibition of virus replication. The beta chemokines MIP-1α, MIP-1β, and RANTES have been shown to inhibit HIV-1 replication *in vitro* (114). Other soluble factors most likely also play a role in this CD8$^+$ T lymphocyte–mediated inhibition of HIV-1 spread.

Further evidence demonstrates that clearance of the intense viral replication occurring during early days following infection correlates with the emergence of the HIV-1–specific CD8+ CTL response (115). A correlation also has been described between this early viral clearance and the appearance of an *in vivo* expansion of a clonal or oligoclonal population of CD8+ T lymphocytes as measured by their use of the same TCR V beta or V alpha gene family. Oligoclonal populations of T lymphocytes expressing TCR genes of the same family have been shown to emerge coincident with HIV-1 clearance during primary infection (116), suggesting that an HIV-specific CD8+ T lymphocyte population may be responsible for viral clearance. Temporal correlations between the emergence of oligoclonal populations of CD8+ CTL and viral clearance are particularly well delineated in the SIV/macaque model of AIDS. Using chromium release-type assays, Vß repertoire analyses, and tetramer assays, a tight correlation has been demonstrated between early viral clearance and the emergence of SIV-specific CTL responses (117–119) (Figure 39.9). The clinical status of HIV-1–infected individuals has also been shown to correlate with the strength of their virus-specific CTL responses. In chronically infected individuals, the HIV-1–specific CTL response, as measured with both precursor frequency CTL assays and tetramer binding assays, has been shown to be associated with clinical status and clinical prognosis (120,121).

Perhaps the most compelling evidence for the importance of CD8+ T cells in containing HIV-1 replication comes from studies in SIV-infected rhesus monkeys. In these studies, *in vivo* depletion of CD8+ cells in the monkeys, achieved by infusion of monoclonal anti-CD8 antibody, had profound effects on the replication of SIV (122) (Figure 39.10). When CD8 depletion lasted fewer than 21 days, the clearance of virus during primary infection was delayed by a full week as compared to control antibody treated monkeys. When the duration of depletion was greater than 28 days, primary viremia was never cleared following infection. The infected monkeys depleted of CD8+ T lymphocytes for more than 28 days during the period of primary infection died with a rapidly progressive AIDS-like syndrome. Moreover, the transient CD8+ T lymphocyte depletion of chronically SIV-infected rhesus monkeys was associated with a substantial rise in viral replication that returned to baseline levels with the reemergence of the CD8+ T cell population. These observations illustrate the central role played by CD8+ T lymphocytes in the control of HIV-1 replication.

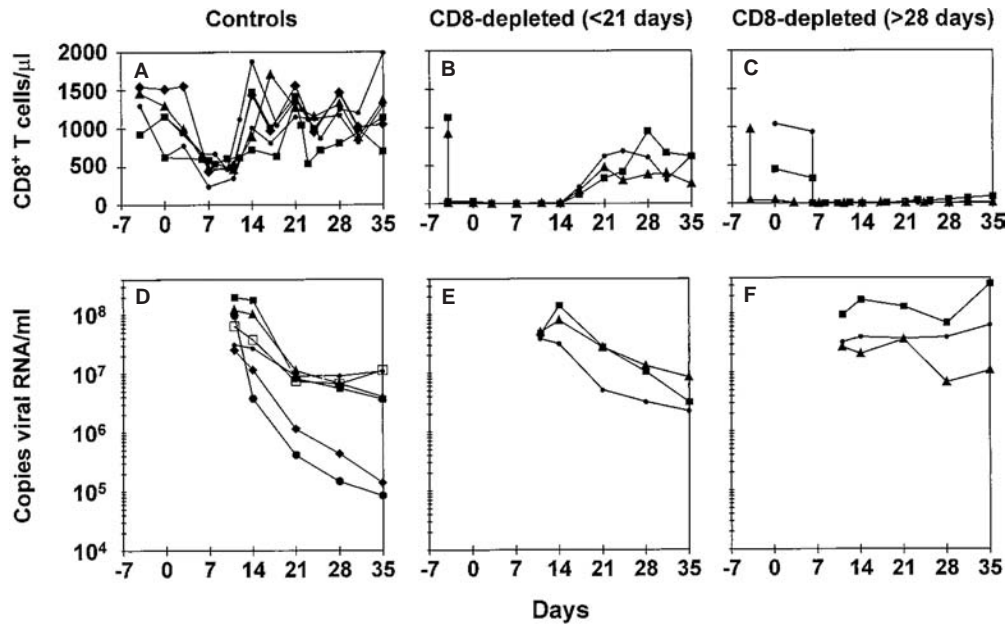
CTL responses to HIV-1, like responses to many other pathogens, are specific for only a limited number of dominant epitopes. This extreme focusing of the immune response places extreme selection pressure on HIV-1 to mutate at these few dominant epitopes. Because of the high mutation rate of HIV-1, it was reasonable to postulate that HIV-1 would be particularly adept at this mechanism of immune evasion. In fact, studies in HIV-1–infected humans as well as SIV- and SHIV-infected rhesus monkeys have shown that viral mutational escape from CTL pressure does occur (123). This viral mutational escape was dramatically illustrated when a clonal population of Nef-specific CTL was infused into a chronically HIV-1–infected patient to evaluate the utility of adoptive immunotherapy
FIGURE 39.9 Temporal coincidence of early primate immunodeficiency virus control and the emergence of a virus-specific CD8+ T lymphocyte response. SIV replication, as measured by plasma viral antigen level, is partially controlled as the SIV-specific CD8+ T lymphocyte response emerges during the period of primary infection in six previously naïve rhesus monkeys. Adapted from (118).


FIGURE 39.10 CD8+ lymphocyte depletion is associated with loss of immune control of primate immunodeficiency virus replication in rhesus monkeys. Rhesus monkey CD8+ lymphocytes were eliminated by monoclonal anti-CD8 antibody infusion for less than 21 days (B) or longer than 28 days (C). SIV containment to setpoint levels was delayed from 1 week in monkeys depleted of CD8+ lymphocytes for less than 21 days (E), and SIV replication was never contained in monkeys depleted of CD8+ lymphocytes for greater than 28 days (F). Adapted from (122).

for AIDS (124). An amino acid substitution in the patient's HIV-1 quasispecies in the epitope recognized by the Nef-specific CTL clone rapidly appeared, allowing the virus to escape from CTL recognition. As the phenomenon of viral escape from CTL pressure has been studied in greater depth, it has become clear that the virus quasispecies is shaped, on one hand, by viral avoidance of cellular immune pressure, and, on the other hand, by viral maintenance of optimal replication competency. This pressure to mutate away from CTL recognition underscores the importance of CTL in the control of HIV-1 infection.

The virus can employ a variety of mutational strategies to escape from CTL pressure (124). Most commonly, amino acid substitutions are selected for in the CTL epitopes of the virus that interfere with the binding of those CTL epitope peptides to MHC class I molecules. However, it has also been shown that extra-epitopic amino acid substitutions can be generated that interfere with the intracellular processing of the viral proteins, blocking the ability of epitope peptides to enter the MHC class I processing pathway. It has also been suggested that epitope mutations can occur that result in loss of TCR recognition of the epitope peptide/MHC class I complex without interfering with epitope peptide binding to MHC class I.

While a change in amino acid sequence may allow for viral escape from CTL, it is often associated with a conformational change in the protein containing the dominant epitope. CTL escape mutations that occur soon after infec-

tion are often those that do not exact a fitness cost on the virus. Some mutations in HIV-1, SIV, and SHIV have been reported to emerge in the viral quasispecies within a few weeks of infection, and viruses with these mutations can rapidly predominate in a population of replicating viruses (125). Such mutations appear to occur in regions of viral proteins that can tolerate the structural changes that are associated with those particular amino acid substitutions without impacting the function of those proteins. When these variant viruses are transmitted to MHC class I disparate individuals, individuals in whom there should be no CTL pressure on that particular region of the virus, the virus may not revert to its wild-type sequence, demonstrating that there is little fitness cost associated with the change.

Other mutations that facilitate viral escape from CTL recognition occur only after the virus has been replicating in an individual for a prolonged period of time. There is evidence that some of these epitope mutations can exact such a profound fitness cost on the virus that they are only tolerated if additional amino acid substitutions are incorporated into the virus as well. Thus, an HLA-B27–restricted CTL epitope mutation in HIV-1 has been described in which a position 2 epitope substitution that eliminates the anchor residue of the epitope can only be tolerated by the virus if an associated residue 6 epitope mutation is also present (126). Moreover, a dominant Gag epitope mutation is only tolerated by SIV/SHIV if a

particular mutation upstream or downstream of the epitope is also present (127). In the latter example, these associated flanking compensatory amino acid substitutions are needed for normal capsid assembly.

If the fitness cost associated with viral CTL escape mutations is substantial, the amino acid substitutions will usually revert to the wild-type sequences when viruses are subsequently transmitted to individuals who do not carry MHC class I alleles that allow the generation of CTL responses specific for those particular epitopes. When an HIV-1 isolate containing an epitope mutation that allowed for escape from HLA-B57/58*01$^+$ restricted CTL was transmitted to HLA-B57/58*01$^-$ individuals, the epitope mutation reverted to the wild-type sequence (128). Interestingly, a study in SIV-infected monkeys demonstrated that episodic reversion to wild-type virus regularly occurred in monkeys in which viral mutational escape had previously occurred, but this reversion was rapidly reversed by the reemergence of epitope-specific CTL (129). This finding suggests that the maintenance of a CTL escape variant is a dynamic process in which there can be continuous change in the virus, reflecting the conflicting pressures of immune pressure and replication fitness. Moreover, the phenomenon of transmission-associated viral sequence reversion likely contributes to the relatively consistent pathogenicity of HIV-1 over extended periods of time in human populations.

The importance of CTL in containing viral replication in HIV-1–infected humans and SIV- and SHIV-infected monkeys is underscored by reports of dramatic clinical deterioration associated with single amino acid substitutions in dominant viral CTL epitopes that allow the infecting virus to escape from CTL recognition. The aforementioned chronically HIV-1–infected patient, who received infusions of a clonal population of Nef-specific CTL and developed a Nef escape viral variant that could not be recognized by CTL, demonstrated an abrupt rise in HIV-1 replication and a consequent loss of viral control associated with those CTL infusions (124). Similarly, a chronically SHIV-infected monkey that was successfully controlling viral replication to a very low level developed a CTL-escape virus and thereafter evidenced a rapid and profound clinical deterioration (130). These types of findings illustrate the role of CTL in controlling HIV-1 replication, the importance of CTL escape in AIDS immunopathogenesis, and finally the extent to which immune control of HIV-1 can depend on CTL recognition of a single dominant viral epitope.

Finally, studies have suggested that HIV-1–specific CD8$^+$ T lymphocytes do not function normally in infected individuals. When compared with cytomegalovirus-specific CD8$^+$ T lymphocytes, HIV-1–specific CD8$^+$ T lymphocytes in infected individuals express lower levels of perforin and higher levels of surface CD27 (131). There is also a skewing of these CD8$^+$ T lymphocytes toward a CD45RA$^-$CCR7$^-$ phenotype, consistent with a preterminally differentiated state (132). Further, the molecule PD-1, a negative regulator of activated T cells, is significantly up-regulated on these cells (133). These studies indicate that HIV-1–specific CD8$^+$ T lymphocytes are impaired in both their maturation and function. The etiology of these abnormalities remains unknown.

CD4$^+$ T CELL RESPONSE TO HIV-1

Determining the effects of helper T cell cytokine production on clinical AIDS progression has been an active and sometimes controversial area of investigation. A number of years ago, it was proposed that a bias of immune cells toward the production of specific networks of cytokines might either improve or impede immune control of HIV-1 (134). Work in murine models of the immune control of parasitic infections indicated that a bias toward production of TH1 cytokines interfered with parasite control, while a bias toward the production of TH2 cytokines improved containment of those pathogens. Since CD8$^+$ T lymphocytes have been shown to be of central importance in containing HIV-1 spread, and TH1 cytokines are known to support effector T lymphocyte responses *in vivo*, it was suggested that a bias toward production of TH1 cytokines may be beneficial for controlling HIV-1 replication. Moreover, it was proposed that a bias toward production of TH2 cytokines may interfere with immune containment of HIV-1 replication. Some even suggested that a vaccine-elicited immune response that was TH2 biased may accelerate disease progression in vaccinated individuals who subsequently become infected with HIV-1. While this hypothesis generated a substantial amount of investigative work, the general consensus of those working in the field has been that there is no evidence to support this paradigm of AIDS pathogenesis (135).

Since virus-specific CD4$^+$ T lymphocytes generated following infection with some viruses can have effector cytotoxic function, effort has gone into evaluating HIV-1–specific CD4$^+$ T lymphocytes for cytolytic capacity. However, no CD4$^+$ T lymphocyte-mediated killing activity has been observed. Therefore, the consensus in the field now is that CD4$^+$ T lymphocytes contribute to HIV-1 containment through providing help for the generation of virus-specific antibody and CD8$^+$ T lymphocyte responses.

Considerable attention has been focused on characterizing the functional capacity of CD4$^+$ T cells in HIV-1–infected individuals. T lymphocytes are functionally abnormal in those infected with the virus. In studies of peripheral blood lymphocytes of subjects with variable degrees of CD4$^+$ T lymphocyte loss, it was demonstrated that T lymphocyte responsiveness to soluble protein antigen is lost remarkably early after infection, earlier than responsiveness to alloantigen or mitogen (136). In fact, an inverse correlation exists in chronically infected individuals

between virus load and HIV-1–specific CD4$^+$ T cell function as measured by viral protein driven proliferative responses (137). Moreover, early institution of highly active antiretroviral therapy during the period of primary infection can result in the preservation of considerable HIV-1–specific CD4$^+$ T cell function. These observations have led to the suggestion that the preservation of memory HIV-1–specific CD4$^+$ T cells as well as the cytokine production capacity of these cells may be crucial for the containment of HIV-1 in those individuals infected with the virus.

CHALLENGES IN THE CREATION OF AN HIV-1 VACCINE

Creation of an HIV-1 vaccine represents an unprecedented scientific challenge. The traditional approaches for creating effective antiviral vaccines have proven inadequate for making one against HIV-1. For example, vaccines based on live attenuated HIV-1 might mutate and regain their pathogenicity following inoculation into humans. Inactivated virus and protein-based vaccines have not generated antibodies that neutralize the genetically diverse viruses that are currently infecting human populations throughout the world. Moreover, these types of vaccines would not induce the cell-mediated immune responses that are needed to control the spread of HIV-1 in exposed individuals. A totally novel vaccine approach will therefore ultimately be required to stop the spread of this virus.

Despite the considerable efforts that have gone into developing an HIV-1 vaccine, few prototype immunogens have been evaluated for protective efficacy in human clinical trials. One of these vaccines, a recombinant form of the envelope glycoprotein gp120 administered with the adjuvant alum, was shown to confer protection against challenge by a highly attenuated HIV-1 isolate in chimpanzees (138). However, the vaccine had no protective efficacy in humans (139). In fact, most investigators involved in HIV-1 vaccine development were not surprised by the outcome of this trial. The vaccine elicited a gp120-specific antibody response, but the antibody did not neutralize HIV-1 isolates that were recently obtained from the blood of infected individuals (140–142). Moreover, because a vaccine antigen of this type does not enter the MHC class I pathway following administration, it cannot efficiently induce a CTL response. Since this subunit immunogen did not elicit neutralizing antibodies or CTL, there was little reason to suppose that it would confer protective immunity.

Another HIV-1 vaccine efficacy trial is currently underway to evaluate this same subunit immunogen in combination with a live recombinant viral vector using a prime-boost regimen. The vector being assessed in this clinical trial is a canary pox virus expressing HIV-1 genes. Although the canary pox virus has been shown to express genes

in vitro in human cells, it does not replicate efficiently in these cells. It is hoped that this vector will express HIV-1 transgenes at a high enough level *in vivo* in humans to elicit a CTL response but will have no associated toxicity because it does not replicate. There is, however, also little optimism associated with this trial because of the low level of immunogenicity of the vector in humans observed in earlier clinical studies (143).

Although these advanced-phase human clinical trials for candidate vaccines have aroused little optimism, studies in nonhuman primates suggest that it should be possible to create an effective HIV-1 vaccine. Pretreatment of rhesus monkeys with SIV-specific immunoglobulin results in a reduction of viral replication following challenge with SIV (108). Infusion into rhesus monkeys of monoclonal antibodies that neutralize HIV-1 isolates *in vitro* has blocked the subsequent acquisition of primate immunodeficiency virus infection that is initiated by either intravenous or mucosal exposure to virus (109,110). Confidence that these findings might be translated into an effective antibody-based vaccine for HIV-1 is tempered by the observation that protection against infection in this experimental model has required levels of circulating antibody that are too high to be induced by routine vaccination strategies (144,145). Moreover, investigators remain unable to create a subunit immunogen that elicits broadly neutralizing antibodies. It is possible, however, that the rapid mobilization of a memory B cell population soon after exposure to HIV-1 might result in an early, robust antibody response that could eliminate or partially contain the replicating virus.

Studies in nonhuman primates have also shown that vaccine-elicited cellular immune responses, even in the absence of neutralizing antibodies, can confer significant protection against the clinical consequences of an immunodeficiency virus infection. Monkeys immunized with plasmid DNA, a live recombinant viral vector, or a combination of these vaccine modalities develop cellular immune responses that do not protect against the acquisition of infection, but do slow the rate of clinical disease progression that occurs following infection (146–148) (Figure 39.11). In comparison with control vaccinated animals, such vaccinated monkeys show a more rapid expansion of memory CTLs, a consequent reduction in peak and chronic levels of viral replication, a delay in the loss of CD4$^+$ T cells, and a delay in time to death.

Recent studies have begun to delineate the mechanisms underlying this prolonged survival of vaccinated, challenged monkeys. Because memory CD4$^+$ T cells express CCR5, the coreceptor for transmitted HIV-1 and SIV isolates, there is a rapid and dramatic loss of this lymphocyte subpopulation during the first days following infection as the virus targets these cells for destruction (25,58,149). By contributing to the control of early replication, vaccine-induced CD8$^+$ and CD4$^+$ T cell responses in rhesus monkeys provide some degree of protection against the
FIGURE 39.11 Vaccine-elicited cellular immunity confers partial protection against early primate immunodeficiency virus replication and an associated prolongation of survival in rhesus monkeys. Monkeys were vaccinated to induce a cell-mediated immune response and then infected with a highly pathogenic SIV. As shown in panel A, the vaccinated monkeys had lower levels of viral replication (blue lines) than did the control monkeys (red lines) through the first 120 days following infection. As shown in panel B, this blunting of viral replication in the vaccinated monkeys (blue line) was associated with a prolongation of survival. Adapted from (150).

destruction of these memory CD4$^+$ T cells (150,151). The protection of these cells confers a survival advantage, as the immune systems of the monkeys are better able to deal with potential opportunistic infections and malignancies.

Although the level of protection afforded by a CTL-based vaccine is certainly not ideal, the use of such a vaccine in human populations could have several important benefits. The prolonged survival of vaccinated individuals who subsequently become infected with HIV-1 would be an enormous advantage, particularly in resource-poor areas of the world where access to antiretroviral drugs remains limited. Further, if vaccinated individuals who become infected with HIV-1 maintain low levels of viral replication, the rapidity of viral spread from infected to uninfected people may slow (152). This is because low levels of HIV-1 replication in an individual should be associated with low levels of virus in their secretions, which in turn should be associated with the inefficient transmission of virus. In fact, levels of HIV-1 viremia in an infected individual have been shown to predict the likelihood of that individual transmitting virus (153). Therefore, a vaccine of this type could have benefits both for the individual and the population as a whole.

Nevertheless, accumulating evidence from nonhuman primate studies indicates that the duration of protection afforded by a CTL-based vaccine may ultimately be limited. Vaccine-related containment of primate immunodeficiency virus replication can be abruptly lost in monkeys following viral challenge, with a consequent dramatic clinical deterioration (130,154). In these monkeys, the change in clinical status was associated with viral acquisition of a mutation in a dominant CTL epitope that allowed the virus to escape from control by CTLs. The mutant viruses

rapidly became the predominant viral quasispecies in the infected monkeys. These findings suggest that vaccine-elicited dominant-epitope–specific CTLs contain primate immunodeficiency virus replication, and that the immune pressure on the virus that is mediated by these CTLs selects for mutations that allow the virus to escape from recognition by this cellular immune response.

However, although it is reasonable to assume that virus will eventually escape from CTL control in this setting, protection may last for a relatively long period of time following infection. If viral replication is initially contained at a very low level, it may take a long time for escape variant viruses to be generated, as mutations will emerge in a population of viruses at a rate proportional to the rate of ongoing viral replication. Moreover, if CTLs are generated to multiple virus epitopes, escape of the virus at all of those epitopes may be required for the virus to evade T cell recognition and effective immune control. A CTL-based vaccine strategy may therefore be a viable approach to vaccine control of HIV-1 despite the phenomenon of viral escape from CTL recognition (155).

Bolstered by these rationales, two major CTL-based vaccines recently entered advanced-phase clinical testing: a recombinant adenovirus-based vaccine, and a plasmid DNA prime and recombinant adenovirus boost-based vaccine. However, the efficacy trials of the recombinant adenovirus-based vaccine as a sole immunogen were stopped early when an enterim analysis of the emerging results demonstrated on evidence of efficacy. Moreover, this analysis also raised the possibility that vaccinated men who were uncircumsized or vaccinees with serologic evidence of prior exposure to the vector may have had an increased rate of acquisition of HIV-1 infection. The impact

of circumcision in this vaccine setting is consistent with the emerging evidence for the contribution of the foreskin in male acquisition of HIV-1. One theory that has been proposed to explain the impact of prior exposure to adenovirus is that exposure of adenovirus primed individuals to repeated administrations of an adenovirus vector may expand and activate adenovirus-specific $CD4^+$ T cells, increasing the number of activated $CD4^+CCR5^+$ T cells that can be infected by HIV-1. While these findings are discouraging, they do not indicate that an effective HIV-1 vaccine cannot be created. Rather, they suggest that other strategies are needed for generating protective immunity.

Although neutralizing antibodies do not play a pivotal role in early HIV-1 clearance, a vaccine-elicited neutralizing antibody response may confer substantial protection. For a vaccine to prevent infection by a diverse range of HIV-1 isolates, it must induce antibodies that neutralize genetically disparate HIV-1 isolates. However, the creation of a subunit immunogen that can elicit such an immune response has proven elusive. Some of the subunit envelope immunogens evaluated to date generate antibodies that block infection of HIV-1 isolates that have envelope proteins similar in sequence to those used in the vaccine. They also induce antibodies that have activity against a small subset of HIV-1 isolates that are particularly sensitive to neutralization. However, these vaccine-elicited antibodies do not neutralize most circulating HIV-1 strains (156–158). Nevertheless, it should be possible to configure an immunogen that will elicit a broadly neutralizing antibody response. This possibility is illustrated by the demonstration that monoclonal antibodies can be generated that neutralize diverse HIV-1 isolates (159,160).

Several strategies are currently being explored to create an effective subunit envelope immunogen. One of these approaches involves generating novel envelope-specific monoclonal antibodies that can neutralize a diverse range of HIV-1 isolates (161). By mapping the recognition specificities of these antibodies, domains of the virus will be identified that can serve as targets for broadly neutralizing antibodies. The underlying assumption in this strategy is that if a monoclonal antibody can be generated that neutralizes the virus, an immunogen can be configured to elicit an antibody with the same specificity and activity. However, it was recently reported that at least some of the monoclonal antibodies with broad neutralizing activity have polyspecific reactivity with autoantigens, and the production of these antibodies may be regulated by tolerance mechanisms (162). In fact, two of the most broadly reactive HIV-1 envelope-specific monoclonal antibodies are polyspecific autoantibodies that are reactive with the host phospholipid cardiolipin. It should be noted, however, that some investigators feel that this apparent cross-reactivity may reflect the hydrophobicity of the combining sites of these antibodies (163). This observation raises questions concerning the feasibility of generating antibodies in healthy individuals with these envelope specificities.

Another approach being explored to solve the difficult problem of inducing broadly neutralizing HIV-1–specific antibodies is to develop a more in-depth understanding of the structure of the HIV-1 envelope. It is hoped that this will suggest approaches for creating immunogens that approximate the native envelope glycoprotein in its biologically relevant three-dimensional conformations. Progress in this area has been slow because of the technical difficulties associated with determining the structure of the flexible, heavily glycosylated envelope protein. To date, structures of monomeric HIV-1 gp120 bound to CD4 and unbound monomeric SIV gp120 have been determined (164,165). However, the envelope glycoprotein of HIV-1 is comprised of two components, gp120 and the transmembrane part gp41. Moreover, it exists on the virus as a trimeric molecule and undergoes conformational changes as the virus fuses to the outer membrane of a cell during the process of infection. The structures of biologically relevant HIV-1 envelopes remain to be elucidated.

Although considerable effort is being expended to define conserved neutralizing epitopes of the HIV-1 envelope and to determine the structure of the prefusion envelope trimer, novel envelope immunogens continue to be created and evaluated as potential vaccine immunogens. These include baculovirus-expressed particles that express the envelope glycoprotein on their surface, chemically stabilized envelope trimers, and domains of the membrane-proximal region of the envelope expressed in membrane fragments.

Since much of the HIV-1 epidemic is fueled by sexual transmission of the virus, most investigators assume that an effective vaccine must elicit a mucosal immune response that will block the transmission of the virus at a mucosal surface. It is important to recognize that there are caveats associated with this assumption. First, it is still not proven that HIV-1 crosses an intact mucosal surface to initiate an infection. Epidemiological studies have clearly shown that the likelihood of HIV-1 acquisition is increased in individuals with genital ulcers, suggesting that sexual transmission of the virus may occur by hematogenous seeding (166–168). Moreover, it remains possible that many HIV-1 transmission events occur through microvascular tears in mucosal tissue rather across intact mucosa. It is, therefore, not proven beyond a doubt that sexual transmission of HIV-1 occurs across an intact mucosal surface.

Second, it is well-established that vaccine-induced systemic immune responses can confer effective protection against mucosally transmitted viruses. A clear example of this phenomenon is seen with the protection provided by the Salk polio vaccine (169). This inactivated-virus vaccine induces a systemic antibody response that does not block the transmission of the virus. Rather, it diminishes poliovirus replication systemically after mucosal

transmission has occurred, blocking seeding of the CNS with the virus. This highly effective vaccine, therefore, aborts the natural course of a mucosally transmitted poliovirus infection without acting at the site of transmission.

Accepting these possible caveats, considerable effort is being focused on inducing both cellular and antibody responses that might contribute to containing the virus at a mucosal surface. At least some parenterally administered live recombinant vectors have been shown to elicit cellular immune responses at mucosal surfaces in nonhuman primates (170). Studies are being pursued to determine whether mucosal delivery of vectors, such as the gene-deleted adenoviruses, can actually enhance the mucosal cellular and humoral immune responses elicited by those vaccines. Novel live vector systems are also being explored that are specifically designed to induce mucosal immunity. Foremost among these strategies is the use of live recombinant Mycobacteria spp. and enteric bacteria such as Salmonella spp. These are nonpathogenic recombinant microorganisms that can be administered at a mucosal surface and should specifically elicit local cellular and humoral immune responses. Whether strategies specifically designed to generate potent mucosal immune responses can confer protection against sexually transmitted HIV-1 remains an open question.

Mutations rapidly accumulate in HIV-1 as it replicates, such that circulating strains of the virus can differ from one another by 20% in the more conserved proteins and by as much as 35% in the highly variable envelope proteins (171,172). Moreover, primary HIV-1 isolates have no principal neutralizing determinants, and each of these isolates can have a distinct target for the neutralizing antibody response. The implications of the sequence diversity of HIV-1 are also problematic for virus-specific $CD8^+$ T cell responses. Certainly there can be some antigenic cross-reactivity between isolates of HIV-1 in the cellular immune response, but single amino-acid substitutions can sometimes abrogate $CD8^+$ T cell recognition of a dominant epitope of the virus (173–175). HIV-1 vaccines that are based on a single sequence of the virus may therefore elicit immune responses that are too focused and type-specific to provide effective protection against the quasispecies of genetically diverse HIV-1 isolates that exist in a human population. A vaccine strategy for HIV-1 must therefore take into account the extreme sequence diversity of this virus.

One vaccine strategy being developed to deal with HIV-1 genetic variation involves the use of immunogens that incorporate a combination of variant genes or proteins from representative viruses. The rationale behind this approach is that immune responses to a particular portion of the virus may diversify following exposure to many related variant proteins, leading to the generation of memory T and B cells that can recognize sequences related to but distinct from those used to elicit the memory cell populations. In fact, a vaccine that includes three distinct enve-

lope genes, encoding proteins from representative clade A, B, and C viruses, is moving forward into advanced-phase human clinical testing (176). Preliminary immunological evaluation of immune responses induced by this vaccination regimen suggests that the cellular and humoral immune responses to these distinct envelope proteins do not interfere with one another (177). However, although these vaccine-elicited immune responses have greater breadth than those elicited by envelope immunogens that employ a single gene sequence, the breadth of these responses has not proven to be greater than would be expected based on the additive properties of the immunogens.

Other approaches to dealing with the immunological problems created by the genetic diversity of HIV-1 isolates are also being evaluated. Several of these approaches make use of hypothetical viral gene sequences that are generated by phylogenetic reconstruction. These reconstructions are based on the data that have been accumulated to document the diversity of HIV-1 gene sequences that exist worldwide. Consensus sequences for each HIV-1 gene have been designed that encode the most common amino acid at each position of each viral protein. Ancestral sequences have also been constructed to approximate progenitor viral gene sequences (178). In both of these approaches, the sequences of these hypothetical genes are closer to the sequences of currently circulating viruses than most currently circulating viruses are to each other. Importantly, envelope proteins that have been constructed based on these types of hypothetical sequence have proven functional in several *in vitro* assay systems (172). These envelopes have been shown to bind to both CD4 and chemokine receptors and to bind several of the monoclonal antibodies that recognize conserved neutralizing determinants of HIV-1. It remains to be determined whether vaccines that are based on these hypothetical genes elicit immune responses with greater breadth than vaccines that incorporate single, naturally occurring viral genes.

Should it prove possible to create immunogens that induce both broadly neutralizing antibodies and broadly reactive CTLs, the magnitude, durability, and quality of the immune responses that can be generated with currently available technologies may still not be adequate for providing effective protection against HIV-1. In fact, studies have suggested that the level of circulating neutralizing antibody needed to prevent infection of macaques with a primate immunodeficiency virus are much higher than can be induced with traditional vaccine modalities (109,110). Moreover, the magnitude of the CTL responses that have been generated in human volunteers so far is not nearly as great as the vaccine-elicited responses in macaques that have controlled primate immunodeficiency virus spread (179,180).

Although live recombinant virus vectors continue to show promise as a viable approach for eliciting cellular immune responses to HIV-1, the magnitude of the

responses in human volunteers immunized with such vaccines has been substantially lower than that seen in nonhuman primates. This reduced immunogenicity may be a consequence of preexisting vector-specific immunity. For example, adenovirus serotype 5 (Ad5)–specific immunity induced by naturally occurring adenovirus infections may reduce the immunogenicity of immunogens based on gene-deleted Ad5 vectors (181). Ad5-directed immunity does not, however, interfere with the immunogenicity of the Ad5-based vectors in macaques because nonhuman primates are infected with distinct families of adenoviruses with serological profiles that differ from human adenoviruses. To circumvent the problem of preexisting Ad5-specific immunity, novel adenovirus vectors are being developed for which there should be no preexisting immunity in human vaccine recipients. These novel vectors include selected human adenoviruses, such as adenovirus serotype 35, that rarely cause natural infections in humans (182). Adenoviruses that infect nonhuman primate species, including selected chimpanzee adenovirus isolates, are also being developed as potential vaccine vectors (183). Finally, chimeric adenovirus vectors are also being constructed that circumvent susceptibility to preexisting neutralizing antibodies against the vector but maintain high levels of immunogenicity (184).

In light of the concern that the durability of vaccine-elicited cellular immune responses will be important for an HIV-1 vaccine, several vectors are being explored that should persist in vaccinees. The assumption underlying this approach is that microorganisms that are never fully cleared in infected individuals should continue to make protein and therefore perpetuate an immune response. The most promising of the persisting vectors are those constructed with mycobacteria, including Mycobacterium bovis bacillus Calmette–Guérin (BCG). It should be noted, however, that emerging data indicate that the maximal generation of memory T cells might occur when antigen does not persist.

Plasmid DNA constructs have proven to be effective immunogens in mice for eliciting cellular immune responses and for priming antibody responses. It is now clear, however, that DNA vaccines are less immunogenic in nonhuman primates than they are in mice, and even less immunogenic in humans than in nonhuman primates. Therefore, strategies are being aggressively pursued to improve the immunogenicity of plasmid DNA vaccines. These strategies include formulating the plasmid DNAs with liposomes or polymers to increase their *in vivo* expression as well as protect them from rapid degradation (185). Novel delivery technologies are also being explored, including the use of *in vivo* electroporation to increase the efficiency of cellular transfection with DNA (186). In addition, studies have been done showing that coadministration of plasmid DNA immunogens with plasmids encoding cytokines has the potential to increase vaccine-elicited cellular immune responses (187). The best-studied of these approaches includes the use of cytokines that increase the clonal expansion of antigen-specific T cells, such as interleukin (IL)-2 and IL-15, and cytokines that attract and induce the maturation of antigen presenting cells, including granulocyte/macrophage colony-stimulating factor and β-chemokines.

It remains unclear whether qualitative aspects of vaccine-elicited cellular immune responses or particular viral protein specificities of those cellular responses will prove important in protecting against viral replication and disease progression. The increasingly sophisticated use of polychromatic flow cytometry will allow the assessment of the functional capabilities of vaccine-induced T cell populations. It will be important to determine whether the production of certain cytokines or cytotoxic mediators by vaccine-elicited T cells is associated with particularly effective control of virus replication. Further, although there is a general consensus that it will be desirable to generate immune responses to several viral structural gene products, it is not yet clear whether cellular immune responses to some of the early viral regulatory proteins such as Tat and Nef will confer a substantial additional benefit to vaccines.

Finally, effort is being focused on developing technologies that will augment humoral immune responses to subunit HIV-1 envelope immunogens. This is a particularly daunting challenge, as it will be important to deliver such immunogens in a manner that will not alter their natural structural conformations. The technologies receiving the most attention at the present time include oil and water emulsions and CpG motif-containing adjuvants that signal through Toll-like receptor 9.

Data from nonhuman primate studies indicate that existing technologies should allow for the creation of HIV-1 vaccines that preserve memory CD4$^+$ T cell populations and, as a result, attenuate the clinical course of infection. Importantly, several recent advances promise to improve the protection conferred by immunization. The magnitude and durability of vaccine-elicited immune responses should be dramatically improved by increasing the immunogenicity of plasmid DNA immunogens as well as the development of new generations of viral vectors that can escape recognition by preexisting vector-specific immunity. A greater breadth of immune recognition should be achieved using consensus gene sequences in these novel vectors. Moreover, investigations into the strategies for eliciting broadly neutralizing antibodies and mucosal immune responses should create strategies for further improving the effectiveness of HIV-1 vaccines. While the creation of an effective HIV-1 vaccine remains an enormous challenge, continuing progress in all of these areas provides reason for optimism about ultimately controlling the spread of AIDS.

Vaccines

G.J.V. Nossal

INTRODUCTION

"Among the many pursuits of mankind, none can be more rewarding than that of preventing diseases by procedures which derive from the practice of vaccinology. Vaccines, together with sanitation and nutrition, have served as principal tools employed in public health to increase the health and life span of human beings. Vaccinology is a field in which dreams may be turned into realities."

Thus wrote one of the pioneering giants of 20th century vaccine development, Maurice Hilleman, in 2003 (1). Vaccine research is once again very much in the public eye. Fields as diverse as HIV-AIDS, pandemic bird influenza, severe acute respiratory syndrome, and defense against bioterrorism attacks ensure that possible new vaccines remain in the spotlight. Vaccinology is poised at the interface of medical microbiology and immunology on the one hand, and of health policy and sociology on the other, and it has become a robust discipline in its own right. However, not every aspect of the scene is rosy. In the industrialized countries, the reduced prevalence of many infections has engendered a dangerous complacency. In the developing countries, resource constraints continue to loom large. In both situations, the activities of passionate but misguided antivaccine activists exert an influence disproportionate to their small numbers. Given the importance of the field, it is essential that all immunologists gain a good working knowledge of vaccinology.

This chapter describes how greatly knowledge of immune regulation in general, and of the relationship between innate and adaptive immunity in particular, contributes to vaccine research and design. Much technical material needs to be covered concerning adjuvants, choice of antigens, new routes of administration, and experimental vaccine design principles. At the same time, this chapter also addresses practical issues such as how to avoid a plethora of injections for our infants; how to reach those global citizens who most need vaccines, namely those in the poorer countries; and how to determine priorities to ensure that scarce health resources are deployed in the most efficient way.

The chief focus of the chapter naturally is on prevention of infection, although the possibility of vaccines playing a role in the control of established chronic infections such as HIV/AIDS or hepatitis C must also be explored. Beyond communicable diseases, there is a vast potential terrain, including vaccines to fight cancer, immunization approaches to autoimmunity or allergy, vaccination to prevent hemolytic disease of the newborn, or contraceptive vaccines. The cancer vaccine question is covered in Chapter 46, and the other issues are touched in Chapters 42 to 44. Here we can only cover the key concepts involved.

The world is waiting so eagerly for effective vaccines against the "big three" diseases—AIDS, tuberculosis and malaria—that it would be easy to lose sight of the devastating impact of diarrheal diseases, acute respiratory diseases, and largely nonfatal diseases such as schistosomiasis or hookworm, which cause extensive morbidity and loss of productivity. This chapter is not meant as a compendium of all new generation vaccines (2), which would require a work almost as long as the present book, but rather as an outline of the principles of vaccinology illustrated by specific examples of established or experimental vaccines. Many diseases are covered because of the protean nature and rich promise of the field.

HISTORICAL PERSPECTIVES

People who yearn for a simpler, Arcadian life less dominated by science and technology tend to forget that before the Industrial Revolution, life really was nasty, brutish, and short. Not only the great figures of music and literature, but also ordinary men, women, and children frequently died of infections easily prevented or cured today. It would be tempting to ascribe the improved situation only to medical science, particularly vaccines and antibiotics, but in fact the progressive lengthening of the average human lifespan much antedated these developments. Less grinding poverty, better sanitation, reduced overcrowding, and

▶ **TABLE 40.1 Chief Landmarks in the History of Vaccinology**

1796	Edward Jenner introduces vaccination against smallpox
1880	Louis Pasteur develops attenuated fowl cholera vaccine, and soon after vaccines against anthrax and rabies.
1896	Robert Koch discovers the cholera vibrio. Killed, whole-cell bacterial vaccines against cholera, typhoid, plague, and other bacteria follow. They are very reactogenic.
1924	Bacille Calmette-Guerin (BCG) is introduced as a live attenuated tuberculosis vaccine.
Late 1920s, early 1930s	Progressively better diphtheria and tetanus vaccines are introduced based on toxins and then toxoids.
1935	17D strain of live attenuated yellow fever vaccine is introduced.
1945	Chick embryo allantoic fluid-derived killed influenza vaccine is developed.
1949	John Enders cultivates the poliomyelitis virus in tissue culture.
1955	Jonas Salk introduces the killed injectable poliomyelitis vaccine (IPV).
1961	Albert Sabin develops the live oral poliomyelitis vaccine (IPV).
1960–1969	Progressively improved live attenuated measles, mumps, and rubella vaccines are developed.
1974–1984	Polysaccharide vaccines against encapsulated gram-positive bacteria are introduced and progressively improved—Meningococcus, Pneumococcus, Hemophilus.
1981	Hepatitis B vaccine is licensed using surface antigen from human carrier plasma.
1983	*Hemophilus influenzae* carbohydrate-protein conjugate is developed as an effective vaccine for infants.
1986	Yeast-derived recombinant hepatitis B vaccine is licensed. This first vaccine derived thorough genetic engineering effectively begins a new paradigm that will dominate the next 20 years.

improved nutrition all played their part. But vaccines do have a proud place and count among the most cost-effective of all health interventions. Yet, the history of vaccines is not without its false starts and misadventures. The emergence of vaccines into the medical mainstream was in fact quite slow (Table 40.1).

Early civilizations that left written records, such as those of Egypt, India, Greece, and China, make reference to infectious diseases, but the accuracy of diagnosis is frequently questionable. It has been argued that the "leprosy" referred to in the Bible may well have represented a dermatological condition, such as psoriasis. Nevertheless, the fact that immunity was specific—that is, that one rarely contracted a given disease twice—was known to the ancient Greeks. The word *immunity* was first used in the 14th century for the example of plague. One disease that was particularly feared was smallpox, clearly described for the first time in China in the 4th century A.D. This was first because of its great prevalence, second because of the high case fatality rate (usually 20% to 30%), and third because when the pustules heal, they leave deep scars, therefore, recovering patients are disfigured for life. The history of vaccines begins with smallpox (3).

The Jennerian Era and Its Aftermath

Given that the microbial origin of infectious diseases was not discovered until the 19th century, it is hard to know what working hypothesis lay behind the first attempts to prevent smallpox. As early as the 10th century AD, the pus-

tular fluid from smallpox lesions or the dried scabs from healing sores were given to susceptible individuals in an attempt to make them immune. This practice, known as *variolation,* involved inoculation into the skin in India, but into the nose in China. Surprisingly, variolation usually resulted in a much less severe disease than natural infection. There was a nasty lesion at the inoculation site, some satellite blisters, frequently a mild rash, and some constitutional symptoms of fever, myalgia, and lethargy, but mortality appeared to have been only 1% to 2%, and generalized scarring was also rare. One wonders what society thought about the fact that contacts of variolated individuals not infrequently developed the full, natural infection. Despite this, fear of smallpox epidemics was so great that even the august Royal Society of London debated the merits of variolation in the early 18th century. Clearly variolation worked, but the disadvantages were such that the medical profession as a whole remained skeptical.

Lady Mary Montague was the wife of the British ambassador in Constantinople and had her own 6-year-old son variolated in 1718. Returning to London, she interested several prominent members of the Royal College of Physicians in the practice as they struggled with the terrible smallpox epidemic of 1721. The president of the college, Sir Hans Sloane, became a convert following some experiments on convicted felons (no institutional ethics committees then!) and arranged the variolation of two royal princesses. Despite this, and perhaps fortunately, variolation did not become widespread in Britain or Europe.

Edward Jenner and the Rapid Spread of Smallpox Vaccination

Cows develop a smallpoxlike disease, cowpox, and lesions can appear on the udder and teats. Milkmaids can catch a mild version of cowpox, involving sores on the fingers and hand. In the 1760s and 1770s, several physicians drew attention to the fact that milkmaids were rarely pock-marked and that many could not be variolated. Several people—for example, farmer Benjamin Justy—claimed to have inoculated cowpox material into their children based on these observations. Be that as it may, it was the Gloucestershire general practitioner Edward Jenner who not only published first (4), but who was also actually intrepid enough to test the putative immunity by a challenge variation. On May 17, 1796, milkmaid Sarah Nelmes donated a little fluid from her cowpox-affected hands, and Jenner forthwith inoculated James Phipps who promptly developed a lesion at the inoculation site. Jenner recorded (4):

> "*Notwithstanding the resemblance which the pustule thus excited on the boy's arm bore to variolous inoculation, yet as the indisposition attending to it was barely perceptible, I could scarcely persuade myself the patient was secure from the smallpox. However, on his being inoculated some months afterwards, it proved that he was secure.*"

A further variation five years later confirmed the maintenance of immunity.

Jenner's paper was rejected by the *Transactions of The Royal Society,* so he published his "Inquiry" privately. He must have derived great satisfaction from the speed with which vaccination, as the practice was termed, spread. In Europe, it became compulsory in several European countries early in the 19th century, and with stunning results. For example in Sweden, there were 5,126 smallpox deaths per 1 million population in 1800, but only 50 in 1821. Soon vaccination became popular in the United States and only slightly later throughout the world. In the second half of the 19th century, calf-derived fluid replaced the human source, and periodic revaccination was introduced. Jenner became famous in his own lifetime, but not nearly as revered as later. For example, in 1896 Britain extensively celebrated the centenary of the James Phipps experiment, secure in the knowledge that vaccination had proven brilliantly successful. Jenner has been recognized in memorials in many places, the statue in Kensington Gardens, London, among them, which represented the focal point for the great bicentenary events of 1996. Its plaque refers simply to "the country doctor who benefited mankind."

Who would have guessed that 181 years had to elapse between James Phipps' vaccination and the last case of naturally occurring smallpox? This is a reflection on the kind of world we inhabit. That said, smallpox eradication represented a signal public health achievement, which we shall now briefly summarize.

Global Eradication of Smallpox

Edward Jenner had speculated on the possibility that his vaccine could wipe out smallpox. It eventually became apparent that there was no animal reservoir of the smallpox virus and that it could live for only short periods outside the human body, so logically eradication was a possibility. North and Central America beat the scourge by 1951, Europe by 1953, and many countries in Asia by 1960, but at that time smallpox was still an enormous problem in Sub-Saharan Africa and most of the Indian sub-continent.

The World Health Assembly, the governing body of the World Health Organization (WHO), took a heady decision during its twelfth meeting in May 1959. As 977 million people still lived in smallpox endemic areas, global eradication was set as a new WHO goal. The preamble to the 1959 resolution mentioned a wildly optimistic timetable of 4 to 5 years for eradication. Given the huge scope of its mission, WHO has always been seriously under-resourced, and in fact little happened until 1966 when at last a significant budgetary allocation was made. Dr. Donald A. Henderson was appointed as head of the Smallpox Eradication Unit and Dr. Isao Arita as his medical officer. The 1967 plan called for 220 million people to be vaccinated that year. While Henderson set himself a 10-year target, he soon realized that immunizing all susceptible citizens was simply not feasible. He also recognized the challenge of quality control for the large number of vaccine doses required, as some suppliers proved thoroughly unreliable. Among the many other practical problems were data collection and handling, training of vaccinators and their supervisors, and certification of reference laboratories. The decision was taken to concentrate immunization efforts on known or possible contacts of actual cases. This put an enormous premium on a good surveillance strategy. The invention of a simple bifurcated needle to at once draw up and dispense vaccine fluid minimized wastage and improved vaccine take.

By 1971, such sufficient progress had been made toward global eradication that both the United States and the United Kingdom ceased their routine vaccination programs. In the early to mid 1970s, intense effort went into India and the Horn of Africa, but war between Ethiopia and Somalia certainly did not help. However, a large-scale emergency effort got on top of the disease, and the last case of naturally occurring smallpox was recorded in Merca, Somalia, on October 26, 1977.

Tragically, the story does not quite end there. A few laboratories continued their research on smallpox, and in 1978 a medical photographer at the University of Birmingham died from the disease, which she somehow caught from

the smallpox laboratory one floor below her in the medical school. The small outbreak was soon controlled, but the 49-year-old head of the smallpox laboratory, Professor HS Bedson, felt so responsible that he committed suicide. The event highlights the dangers of variola virus stocks in laboratories, but both the United States and the former USSR refused to agree to the WHO's suggestion that all such stocks be destroyed. It well may be that further stocks are being held for biological warfare or bioterrorism purposes, although Iraq's "weapons of mass destruction" could never be found. The current major efforts that have gone into stockpiling smallpox vaccine, including improved vaccinia variants, just in case evil forces unleash secret sources of virulent variola virus is somewhat ironic.

On December 9, 1979—more than 4,000 years after the disease's first appearance and 183 years after young Master Phipps' adventure—the Global Commission on Smallpox Eradication certified that global eradication had been achieved. The campaign has rightly been hailed as the world's greatest public health triumph (Figure 40.1). Dr. Henderson is a revered figure and still a senior U.S. gov-

ernment advisor on control of epidemics and related matters. His self-imposed deadline slipped by only one year. The total cost of the WHO's program was $300 million, compared with an estimated cost burden of the disease of $1,350 million per annum prior to control.

The Dawn of Immunological Science (1875 to 1910): Pasteur, Koch, von Behring, Ehrlich

Jenner had no overarching theory for how vaccination provided immunity to smallpox. Two great giants, Louis Pasteur (1822 to 1895) and Robert Koch (1843 to 1910), established the true etiologic cause of infectious diseases and thus set the scene for a better understanding of the specificity of immunity. Pasteur (5) destroyed the spontaneous generation theory of bacteria, and Koch, his archrival and debating opponent, enunciated his famous postulates that, if fulfilled, established an agent as the cause of a disease. Pasteur made the critically important observation that bacteria grown for substantial periods in artificial

FIGURE 40.1 The parchment certifying global eradication of smallpox, 1979.

media lost their virulence. For example, *Pasteurella septica,* the cause of fowl cholera, when attenuated *in vitro* no longer caused disease. Rather, injection of such attenuated bacteria protected chickens from the effects of fresh, virulent cultures (6). With surprising speed, this idea was tested in a real-life setting. In 1881, the first tests of an attenuated anthrax vaccine were run, and in 1882, 85,000 sheep were immunized. Pasteur coined the word *vaccine* as a general term for immunizing preparations in homage to Edward Jenner and his use of vaccinia virus. Even though Pasteur did not know that rabies was caused by a virus rather than a bacterium and had to attenuate it in rabbit spinal cord rather than through culture, his introduction of rabies immunization on little Jacob Meister had a galvanic effect and was soon widely practiced. Crowned heads from all over the world came to pay honor to Pasteur, and he was able to build the Pasteur Institute in Paris entirely from benefactions. Founded in 1888, this Institute is of huge historic significance, as it was the first human institution entirely devoted to biomedical research.

Pasteur originally believed that microbes had to be alive to engender immunity, but following Koch's discovery of the cholera vibrio, killed whole-cell bacterial vaccines were introduced as early as 1896. Essentially similar, very reactogenic vaccines against typhoid fever and plague were shown to be at least partially effective. It is amazing to think that it took a further 60 years for controlled trials to show that this type of vaccine could confer significant short-term protection. But immunity research soon took quite a different direction. Roux and Yersin discovered that certain bacteria, notably diphtheria and tetanus bacilli, produced powerful soluble exotoxins, and von Behring and Kitasato discovered antibodies in 1890 and had some success in the passive immunotherapy of diphtheria, with antidiphtheria toxin antibodies from horses. This resulted in the first ever Nobel Prize in Medicine. Antitoxin could be mixed with the relatively crude toxin preparations available from culture supernatants, and the first active immunization against diphtheria or tetanus involved toxin-antitoxin mixtures. However, quantitation was poor and results variable. It took the genius and tenacity of Paul Ehrlich to bring rigor to the field. His development of quantitative methods for the measurement of antibody levels made von Behring's passive immunotherapy workable, and his theories on the cellular and molecular basis of immune phenomena gave the field tremendous intellectual thrust.

It could be argued that the first golden age of immunology (around 1880 to 1910) was accompanied by a certain degree of hubris. There was a time when it almost appeared that all that was needed to conquer communicable diseases was to isolate the causative agent, establish Koch's postulates, attenuate or kill the agent, and immunize. Yet from the earliest trials—for example, those of Pasteur on rabies—there was controversy. Several of the early preparations were neither as safe nor as protective as their protagonists claimed. Remember that neither production

facilities nor regulatory agencies were well developed at this time, and the design of many of the clinical trials left much to be desired. Particular triumphs notwithstanding, broadly, the early promise of vaccines was not fully realized in the first golden age. There were significant professional reservations about vaccines and, in certain quarters, a distinctly antagonistic community reaction. The author was born in 1931, and it is quite clear that at that time, educated parents were by no means convinced about the advantages of immunization as a whole. Thus, the author had a good struggle with both diphtheria and whooping cough.

Early Bacterial Vaccines, Toxins, and Toxoids (1910 to 1930)

The flame of the live attenuated vaccine never died in the Pasteur Institute, and following Koch's isolation of the tubercle bacillus, the search for a tuberculosis (TB) vaccine began. Calmette and Guerin (7) started with an isolate of TB from a cow. After an amazing series of 213 subcultures over a period of 13 years, they intrepidly tried the culture orally in a newborn infant. Thus, Bacille Calmette-Guerin (BCG) was born. It was soon given intradermally rather than orally and was clearly effective in infants for the prevention of miliary TB and tuberculous meningitis, although its capacity to prevent adult pulmonary TB, the real killer in TB, is much more controversial.

World War I gave increased opportunity for the whole cell–killed bacterial vaccines to make their mark, especially in the case of typhoid, where systematic use seemed to control the disease despite the absence of a formal clinical trial. Another killed bacterial vaccine used fairly widely in the 1920s was that against *Bordetella pertussis*.

In 1923, Glenny discovered that formalin treatment of diphtheria toxin could render it harmless while preserving its immunogenic potential (8). At the Pasteur Institute, Ramon conducted similar studies. It was soon realized that these so-called toxoids were much more satisfactory as vaccines than the chancy toxin-antitoxin mixture, and their progressive introduction into the industrialized countries from about 1930 markedly lowered the impact of both diphtheria and tetanus. The decrease in the United States is over 99%.

Early Viral Vaccines: Yellow Fever and Influenza (1930 to 1950)

The 1920s saw the differences between viruses and bacteria becoming clear, and the 1930s was a heady period for isolation of disease-causing viruses, but tissue culture was still the realm of a few practitioners. An important development was Goodpasture's discovery of, and Burnet's improvement of, techniques for growing viruses and *Rickettsiae* in embryonated hen's eggs. Theiler's safe and effective live attenuated yellow fever vaccine, 17D, hails

from this period, as do first-generation killed whole virus influenza vaccines and vaccines against typhus that were important for troops in World War II. Formalin-killed mouse brain–derived Japanese B encephalitis vaccine was also effective.

The Tissue Culture Revolution: Poliomyelitis, Measles, Mumps, Rubella (1950 to 1970)

The revolution in antiviral vaccines really began with the development of tissue culture as a way of growing viruses. The paper by Enders' group on the cultivation of the Lansing strain of the poliomyelitis virus in 1949 really was a watershed (9). It is difficult now to reconstruct the fear that surrounded poliomyelitis before 1955. Although the disease was epidemic in nature, waxing and waning with the summer seasons of maximum spread, it never went away. During a high incidence year, parents feared to send their children to the cinema or the swimming pool. Polio was a dreaded enemy. In the United States, for example, there were typically 20,000 or more cases of paralytic poliomyelitis per year. On April 12, 1955, the 10th anniversary of the death of Franklin D. Roosevelt, perhaps the most famous polio victim, a press conference at the University of Michigan revealed to the world that Dr. Jonas Salk's formalin-treated whole virus vaccine provided protection. Between 1955 and 1961, 300 million doses of the vaccine were administered, and polio declined dramatically. A major setback was the infamous Cutter Incident in which faulty production techniques allowed two lots of vaccine to slip through with inadequate formalin inactivation, resulting in 149 cases of polio, a disaster that lent impetus to the development of the live attenuated oral poliomyelitis vaccine of Sabin, first introduced in 1961. By 1965, this latter vaccine had essentially replaced the Salk vaccine in the United States, and soon after in most countries, although not in the Netherlands, Iceland, and Sweden. Being orally active, it was more convenient to use, and containing far fewer virions it was also much cheaper (Figure 40.2). Very rare reversions to neurovirulence, particularly in poliomyelitis virus type 3, (estimated at one case of acute flaccid paralysis per 2.7 million doses of oral poliomyelitis vaccine administered) have occasioned a rethink in the industrialized countries. Most now recommend injectable poliomyelitis vaccine again to obviate this very rare but extremely serious problem. The late Jonas Salk campaigned tirelessly for this reversion, the rivalry between him and Albert Sabin being legendary.

The great adventure of polio eradication is not quite finished, but there is no doubt that the dramatic success of polio immunization paved the way for a number of other live attenuated virus vaccines, again dependant on the principle of attenuation in tissue culture. Enders' original Edmondston strain of measles vaccine, first in-
FIGURE 40.2 William H. Gates administering the Sabin oral poliomyelitis vaccine to an Indian child.

troduced in 1963, was a little bit "hot." When the author's younger son was born in 1964, the recommendation was to use this vaccine but to coadminister gamma globulin containing antimeasles antibodies! The problem was solved through the introduction of the more attenuated Moraten and Schwartz derivatives of the original Enders strain. This excellent measles vaccine was followed by a mumps vaccine first introduced in 1967 and a live attenuated rubella vaccine in 1968. Hilleman (10) records that a combined measles-mumps-rubella vaccine was the realization of a long-term dream achieved in 1969 and licensed in 1971. Now some firms have introduced a tetravalent measles-mumps-rubella-varicella vaccine. The potential to eliminate all four diseases from the industrialized countries is real. In several European countries, measles, mumps, and rubella transmission appears to have ceased, with the exception of imported cases.

Dawn of the Molecular Era: Hepatitis B, Pneumococcus, *Hemophilus Influenzae B* (1970 to 1990)

Hepatitis B vaccine represented a watershed from several points of view. Although the toxoids and polysaccharide

meningococcal vaccines are molecular or subunit vaccines from one point of view, use of the surface antigen of the hepatitis B virus (HBsAg) represented a new degree of purity of a single protein as a vaccine. It was also the first vaccine manufactured through recombinant DNA technology. It was the first example of a protein the tendency of which for self-assembly into 22nM virion-like particles greatly aided immunogenicity. Less obviously, it was the first time that a vaccine was introduced to the market as an expensive "boutique" vaccine for special risk groups such as doctors, nurses, and blood-bank workers, later to become a much cheaper public health tool of immense significance for developing countries. Given that there are 350 million carriers of hepatitis B worldwide and that 20% to 25% of carriers develop chronic liver disease, and a substantial proportion of these go on to primary hepatocellular carcinoma, the hepatitis B vaccine is the first anticancer vaccine in history. It is also unique in that the relevant antigen was originally thought to represent a protein polymorphism (Australia antigen) (11) and only later recognized as a viral component (12).

The great success of the hepatitis B vaccine has stilled many of society's fears about the use of recombinant DNA products and has certainly helped usher in the new era in which genetic engineering approaches have become the norm in vaccine research and development. It is to be hoped that the 18-year gap between Blumberg's discovery of Australia antigen and the development of the first generation blood-derived vaccine will not be repeated. Indeed, the time gap between cloning HBsAg and the yeast-derived vaccine was much shorter (13), and expression systems have improved enormously since that time.

Molecular vaccines of a different character were the subunit capsular polysaccharide vaccines against *Streptococcus pneumoniae, Neisseria meningitidis,* and *Hemophilus influenzae B* (Hib). These were licensed in the 1970s and early 1980s. Unfortunately, these vaccines do not work well in young infants, so another major molecular breakthrough was the conjugation of the carbohydrate antigens to a protein carrier, usually diphtheria or tetanus toxoid. This allowed effective T cell help and immunologic memory to develop. Various Hib conjugates were licensed in the late 1980s, effectively bringing us to the modern era. This progress will be summarized in the section on bacterial, viral, and parasitic vaccines.

KEY PRINCIPLES OF VACCINOLOGY

In the search for new vaccines, much effort is directed at identifying, isolating, and eventually manufacturing antigens from pathogens that are key to the pathogen's survival and multiplication within the host. These may be surface molecules, the neutralization of which may prevent infection; toxins that the invader uses for tissue destruction to provide a nidus for growth; or internal antigens, which can be processed and presented on infected cells provoking T cell–based destruction. It is important to realize that such pure antigens, when introduced into the body, do not necessarily induce an immune response. Indeed, pure, deaggregated proteins are more likely to induce immunologic tolerance. The first key principle in vaccinology, therefore, is to ensure immunogenicity of the material used.

Immunogenicity

To be immunogenic, a candidate vaccine generally has to reach an antigen presenting cell (APC), usually a dendritic cell. Furthermore, the APC, in its resting state, is not ready to initiate the immunoproliferative cascade; it must first be activated. In the past several years, our knowledge of these first important steps in the adoptive immune response has been greatly enhanced by analysis of innate immune responses used by invertebrate species against infection. The innate immune system is evolutionarily as old as multicellular life itself, namely around 2 billion years, but details of its molecular basis have only recently become apparent.

Janeway (14) first suggested the importance of "receptors that recognize patterns of microbial structure" and claimed a dual type of self/nonself discrimination, one among lymphocytes but the other based on APCs. It gradually became clear (15) that the innate immune system recognizes microorganisms via a limited number of germline-encoded pattern-recognition receptors (PRRs), whereas microbes possess pathogen-associated molecular patterns (PAMPs) that are integral to their structure and function. Different PRRs recognize different PAMPs, and although this limited germline-encoded and constitutively expressed repertoire of PRRs contrasts with the huge repertoire of rearranged T and B cell receptors, it nevertheless represents a valid and effective defense system. Amazingly, Janeway (14) foresaw in 1989 that the PRR–PAMP union would generate a stimulatory signal. The matter developed a new impetus with the strange saga of the Toll-like receptors (TLRs).

The Toll-like Receptors

Interleukin 1 (IL-1) is a key cytokine, and when it unites with the IL-1 receptor, a cascade of cellular signals is initiated that leads to activation of the NFκB transcription factor pathway and of MAP kinases. This in turn regulates the expression of genes involved in inflammation, immunity, and tissue repair. When it was found that a gene known as Toll, involved in dorsal-ventral polarization of the *Drosophila* embryo, was homologous to the cytoplasmic domain of the IL-1 receptor (16), insect scientists began to look for possible defense functions of the Toll gene. It was found that Toll was essential for protection against fungal infections (17). Toll was behaving like a PRR.

The search for mammalian homologues of Toll has been fruitful. To date, 12 members of the TLR family have been defined (15). All the TLRs are type 1 integral membrane glycoproteins with an extracellular domain containing leucine-rich repeats and an intracellular domain containing the IL-1-R homology. A given TLR can recognize two or more PAMPs that may not even be structurally related. Taken as an ensemble, the TLRs can recognize PAMPs of bacteria, viruses, parasites, fungi, and even some components of dead or dying cells. A partial list of TLR-PAMP interactions is given in Table 40.2 (modified from [15]). Note that TLRs can function as homodimers or heterodimers.

TLRs are expressed on dendritic cells (DCs) and macrophages, as well as on B and T cells, and nonimmunologic cells such as fibroblasts. Moreover, expression can be strongly upregulated—for example, by pathogens or cytokines. Some TLRs are expressed on the cell surface while others are found intracellularly—for example, in endosomes, in which case their ligands have to be internalized before TLR signaling can occur.

The complex signaling cascades that follow PAMP binding are gradually being unraveled. After ligand binding, TLRs dimerize and recruit adaptor molecules. Five have so far been identified (18), and it is likely that the differential responses mediated by different TLRs involve selective use of these adaptors. For example, the adaptor MyD88 (which is also used by the IL-1 receptor) initiates a cascade finally leading to the production of pro-inflammatory cytokines, whereas the adaptor TRIF sends the cascade in a direction ending with manufacture of type 1 interferons. In general terms, TLR stimulation leads to Th1 rather than Th2

▌ **TABLE 40.2 TLR Recognition of PAMPs**

TLR	*PAMP*	*Bacterial Species*
TLR4	Lipopolysaccharide	Gram-negative bacteria
TLR2/TLR6	Diacyl lipopeptides	Mycoplasma
TLR1/TLR2	Triacyl lipopeptides	Mycobacteria and others
TLR2/TLR6	Lipoteichoic acid	Group B Streptococcus
TLR2	Peptidoglycan	Gram-positive bacteria
TLR2	Lipoarabinomannan	Mycobacteria
TLR5	Flagellin	Flagellated bacteria
TLR9	Unmethylated CpG motifs in DNA	Bacteria including mycobacteria
TLR11	Structure not determined	Uropathogenic bacteria

TLR	*PAMP*	*Viral Species*
TLR9	Unmethylated CpG motifs in DNA	DNA viruses (e.g., HSV-1 and 2
TLR3	Double-stranded RNA	RNA viruses-dsRNA as a replication intermediate
TLR7 and TLR8	Uridine or uridine/guaranosine rich single-stranded RNA	RNA viruses
TLR2 and TLR4	Various viral envelope glycoproteins	Various viruses such as measles, CMV and respiratory syncitial virus

TLR	*PAMP*	*Parasite Species*
TLR9	Hemozoin	*Plasmodium falciparum*
TLR2	Glycosylphosphatidyl isosital mucin	Trypanosomes
TLR4	Glycosylinositoll phospholipids	Trypanosomes
TLR11	Profilins	Toxoplasma

TLR	*PAMP*	*Fungal Species*
TLR6/TLR2	Zymosan	*Saccharomyces cerevisiae*
TLR2	Phospholipomannan	*Candida albicans*
TLR4	Mannan	*Candida albicans*
TLR2 and TLR4	Glucuronoxylomannan	*Cryptococcus neoformans*

TLR	*PAMPs That Are Host Components*	
TLR4	Heat shock proteins 60 and 70	
TLR4	Fibrinogen	
TLR12	So far an "orphan" TLR with PAMP not identified	

differentiation. However, some TLR-2 ligands can induce a Th2-bias (19), probably through the phosphorylation of ERK MAP kinase and induction of c-FOS, whereas other TLR-2 ligands such as zymosan can suppress T cell responses via a mechanism dependent on the anti-inflammatory cytokines IL-10 and TGF-β (20).

There are multiple subsets of DCs in both humans and mice. This raises the question of whether TLRs are differentially expressed within them and thus whether different DC subsets modulate immune responses (e.g., via Th1/Th2 balance) (21). For example, plasmacytoid DC in humans preferentially express TLR7 and TLR9 and also preferentially produce interferon-γ (22). At the same time activation of a given DC subset via distinct PRRs can differentially stimulate distinct types of T cell responses (23), illustrating the functional plasticity of DC. There is clearly a large amount of work that needs to be done before we can harness all this new knowledge for vaccine design. Nevertheless, in the section about adjuvants, we shall encounter examples of strategies critically involving TLRs.

Other PRRs in Innate Immunity

The avalanche of research on TLRs should not obscure the fact that there are other families of PRRs. Many pathogens activate complement via either the classical or alternative pathway, and complement fixation can be destructive. Pentraxins are a complex superfamily of multimeric (usually pentameric) proteins of which the best known are C-reactive protein, serum amyloid P component, and pentraxin 3 (PTX3). PTX3 is a key element of the humoral arm of innate immunity (24), and PTX3-deficient mice are highly susceptible to various bacterial and fungal infections. PTX3 activates complement and is an opsonin. It is evolutionarily conserved and has other functions in assembly of extracellular matrix and in fertility.

The mannose-binding lectin (MBL) is an evolutionarily conserved, circulating host defense protein with broad spectrum recognition capability against a wide variety of pathogens (25). It recognizes carbohydrate moieties such as D-mannose, L-fucose, and N-acetylglucosamine. MBL is synthesized predominantly in the liver and circulates as a multimer of homotrimers with the carbohydrate recognition domain attached via an α-helical coil to a collagen helix. MBL belongs to the collectin family of which four other members are known. There are endogenous as well as infectious ligands of MBL, including components of dying or of transformed cells. MBL is able to activate complement and act as an opsonin, and low levels of MBL can worsen susceptibility to infections in immunocompromised individuals. Interestingly, low levels of MBL render humans more susceptible to the SARS corona virus (26).

A second category of carbohydrate-binding lectins is the family of type II transmembrane proteins DC-SIGN, L-SIGN, SIGN-R1, and langerin (27). These molecules also have carbohydrate recognition domains, but this time associated with the surface of specific cells. As the name implies, DC-SIGN is specific for DCs and can recognize glycoproteins from several viruses and bacteria. Its homologues L-SIGN and (murine) SIGN-R1 show subtly different carbohydrate recognition profiles. Langerin is specific for Langerhans cells and plays an interesting role in presenting a nonpeptide (lipid) mycobacterial antigen to T cells (28). DC-SIGN can cluster into domains of 100 nm to 200 nm to help binding and internalization of virus particles (29) to increase the affinity for specific ligands. Finally, there is likely to be significant cross-talk between signaling through C-type lectins and through TLRs (27), indicating that the innate immune system is quite complex and sophisticated.

In the plant kingdom, there is a family of proteins, the plant R proteins, which are involved in resistance to pathogens (30). These exist both on the surface of plant cells and in the cytoplasm. The R proteins contain multiple leucine-rich repeats, a motif also found in the TLRs. It can be argued that all the surface R proteins resemble TLRs. What, then, might be the animal equivalent of the cytoplasmic R proteins? The best candidates are two closely related proteins, NOD1 and NOD2, which are capable of sensing bacterial lipopolysaccharide and bacterial muramyl dipeptide respectively (31). There is some evidence of synergy between NOD and TLR activation. An intriguing observation is that some familial cases of Crohn's disease have a partial loss of function mutation in the gene encoding NOD2. This raises the possibility that incorrect sensing of gut bacteria contributes to the intestinal inflammation, although NOD-"knockout" mice show no intestinal pathology. A number of other cytoplasmic pathogen recognition systems have recently been reviewed (15).

A further set of recognition phenomena relates to signals that warn an animal of "danger." Matzinger's original danger hypothesis suggested that the key signal came from stressed or damaged tissue (32), and this received support when necrotic, but not apoptotic, cells were shown to be capable of stimulating APC via TLR-2 (33). However, the notion can also be broadened to include danger signaled by pathogens. Both tissue injury and micro-organismal invasion provoke the rapid release of diverse host proteins that are potent immunostimulants and for which the novel term *alarmins* has been proposed (34). These mediators include defensins, cathelicidin, eosinophil-derived neurotoxin, and high-mobility group box protein 1. Members of the cationic host defense (antimicrobial) peptide family are found in every complex species (35). These amphipathic molecules are 12 to 50 amino acids long, are rich in arginine and lysine, and have up to 50% hydrophobic residues. Defensins and cathelicidins have direct antimicrobial activity against bacteria, viruses, parasites, and fungi, but also act as immune system modulators (36), stimulating immune activation but also defending the host

against excessive inflammation. Therapeutic potential is being explored (e.g., for prevention of catheter-associated infections [37] or as adjuvants). Oppenhein and Yang believe many more alarmins remain to be identified (34). They cite recent evidence showing the DC-activating potential of several chemokines and granulysin and express the hope that further research on alarmins will lead to less toxic adjuvants.

Intensive though the work of the past decade has been on the interface between innate and adaptive immunity, the impression remains that we are really only at the beginning of this field. When we understand it more completely, we shall have powerful means of ensuring greater and safer immunogenicity of our vaccines.

REACTOGENICITY

Long before we knew about all the danger signals discussed in this chapter thus far, it was realized that effective vaccines often produced mild side-reactions. We shall consider serious adverse effects of vaccines in a later section, but the mild reactions fall under two headings. Live attenuated vaccines, such as those against smallpox or measles, involve the replication of the altered microorganism in the host, and in a proportion of cases a very minor version of the disease to be prevented can occur (e.g., with vaccinia, a nasty sore at the scarification site and local lymphadenopathy; with measles, a very mild rash and transient fever). Vaccines consisting of killed microbes or materials from them can cause local redness, swelling, and pain at the injection site and some mild systemic reactions such as transient fever, irritability, anorexia, headache, and general malaise. It must be stressed that in the vast majority of cases these reactions are mild, of short duration, and easily controlled by an antipyretic such as paracetamol.

These symptoms arise because immunogenic vaccines cause some inflammation and cytokine induction. Together they reflect the *reactogenicity* of a vaccine. Given that there is a great deal of individual variation, it is nevertheless the case that some vaccines are more reactogenic than others. Remembering that vaccines are given to healthy rather than sick individuals, and frequently to infants, a balance needs to be struck between acceptable reactogenicity and the seriousness of the disease to be prevented. A medical officer sent to control an outbreak of bubonic plague will accept greater reactogenicity than the mother of an infant needing protection against whooping cough. For the established vaccines, experience and progressive modification of formulations have provided the requisite balance. For vaccines still in the research phase, such as an anti-malaria vaccine, the equation is still being worked out. Paradoxically but fortunately, reactogenicity tends to be less in very young infants. On the other hand, it can be a real problem in immunocompromised individuals where the risk:benefit equation needs to be evaluated on a case-by-case basis.

Age at Immunization

A further key principle is that particular vaccines have to be given at the appropriate age. For example, hepatitis B can be acquired during the birth process, and immunization within the first 12 hours of life is recommended, followed by two later doses. However, the live attenuated measles vaccine is strongly inhibited by the presence of antibodies coming from the mother, so it is only given at 12 months of age in industrialized countries and at 9 months in developing countries. The standard "platform" of diphtheria-pertussis-tetanus vaccination consists of injections at 2, 4, and 6 months of age, with a booster at 15 to 18 months. In recent years, other vaccines have been added to this platform, as we shall see later in this chapter, while still others are not recommended before 12 months. Certain vaccines (e.g., against the pneumococcus or the influenza virus) are particularly relevant to saving lives among the aged, although progressively being recommended at younger ages. Some vaccines have their maximum value when given around the time of puberty (e.g., the human papilloma virus ([HPV] vaccine to prevent cervical cancer or the rubella vaccine for the prevention of intrauterine rubella, though the latter is now given earlier as part of a combination vaccine).

Vaccines for travelers represent a special case, particularly as some, such as those against cholera and typhoid fever, tend to protect for relatively short periods.

An area as yet insufficiently studied is that of booster-immunization in adolescence or adult life. We are all familiar with the tetanus "shots" given when we are injured to boost our childhood immunity. Recent epidemics of diphtheria have suggested that adults lose their immunity rather easily, so boosters every 10 years are recommended, but this is more honored in the breach than the observance. It is also likely that pertussis is a more common cause of severe respiratory disease in adults than is generally realized, so pertussis boosters could be useful.

Disease Burden and Cost-benefit Considerations

In the United States, there are new vaccines licensed against about 30 diseases, and the research pipeline shows that about 75 more diseases are being targeted for future prevention (38). In many cases, several different approaches are being taken to a particular disease. This illustrates the scope of the priority-setting exercise facing the world. In the industrialized countries, the key question is how many injections will the mothers of our infants tolerate, thus there is a big premium on the preparation of combinations of vaccines, where the large pharmaceutical

firms are doing well, and on oral and other mucosal or transdermal delivery methods, where progress is slower. In the developing countries, cost is a major consideration, and a great deal of effort is going into the analysis of disease burden and cost-benefit considerations. This is no easy task as in many developing countries microbial diagnostic facilities are limited, so exact causation of pneumonia, meningitis or diarrhea is hard to establish. Furthermore, a surprising degree of variation in disease incidence between neighboring countries or different regions within a single country has been noted. This suggests that disease burden may have to be established in many places where the case for universal immunization is not self-evident. Of course there are diseases of such huge importance, such as HIV/AIDS, malaria, tuberculosis, or invasive pneumococcal disease, where a vaccine would clearly be a breakthrough product, but there are other examples, such as *Hemophilus influenzae B* in Asia, where some doubt remains. Dr. John Clemens, the director of the International Vaccine Institute in Seoul, Korea, believes there are examples where only an intervention trial involving vaccination and examining mortality statistics will provide reliable answers.

Societal Acceptance and Cultural Considerations

Vaccinology must also accommodate variations in societal acceptance of vaccines. There are some paradoxes here. In industrialized nations, the very success of immunization has made epidemics (e.g., of diphtheria, poliomyelitis, or measles) essentially things of the past. This gives anti-vaccine activists an advantage, but it is still the case that when immunization coverage rates fall below a threshold, typically around 80% of the population, a disease may become resurgent. As a further paradox, in developing countries where overall educational standards are low, an anti-vaccine rumor can gain extraordinarily wide acceptance. A recent case in point involved Nigeria, where the belief that the poliomyelitis vaccine represented a plot to render female Muslim babies sterile gained such currency that in mid-2003 immunization was essentially suspended. As a result, the resurgent virus caused disease not only in Nigeria but also through importation in many other countries.

The key to societal acceptance of vaccines is education. Well-planned and executed educational campaigns, especially involving the mass media, can have a major effect. Paradoxes remain, however. In the United Kingdom, a cleverly targeted campaign preceded the introduction of universal vaccination against *Neisseria meningitidis* serogroup C, including alerting people to the fact that only *some* forms of meningitis could be prevented. Immunization proved hugely successful. Yet a community of such sophistication was sufficiently scared by claims that the measles-mumps-rubella vaccine caused autism and Crohn's disease that a measles eradication campaign that had been going well was effectively derailed. It took some years for common sense to return.

A final reflection is that the proportion of people who strongly and consistently harbor anti-vaccine sentiments is actually quite small, perhaps 2%. The last paradox is that their refusal to have infants immunized does not matter as much as it might, because herd immunity will look after their children.

ADJUVANTS

The term *adjuvant* is a wide one and refers to the broad spectrum of substances or stratagems that are able to increase the immunogenicity of antigens incorporated into or coadministered with the adjuvant in question. O'Hagan and Valiente (39) have recently proposed a classification of adjuvants into immune potentiators on the one hand (e.g., TLR agonists), or antigen delivery systems on the other (e.g., emulsions or microparticles attractive to APC). The trouble with this otherwise useful suggestion is that many adjuvants represent a combination of these two principles. Pearse and Drane (40) have proposed the term *integrated adjuvants* for such cases.

One reflection of the difficulty of this field is that, despite the enormous amount of work that has been done, particularly in recent years, there are only two licensed adjuvant approaches. Overwhelmingly, the more common is alum, comprising aluminium phosphate and aluminium hydroxide, which we shall describe. Also, an emulsion adjuvant known as MF59 is licensed in Italy (41). Of course, some vaccines have their own "built in" adjuvanticity, such as BCG, a live attenuated tubercle bacillus, or the vaccinia virus for smallpox prevention. The difficulty in finding an ideal adjuvant rests in retaining adjuvant properties but avoiding worrying reactogenicity. We know from experimental animal work that different adjuvants bias the immune response toward antibody formation or cell-mediated immunity, and further toward particular antibody isotypes or certain T cell subsets. Now that pathogen genome mining as well as conventional vaccine research have yielded such a wealth of candidate antigens, the search for the right adjuvant for each vaccine has become somewhat of a "Holy Grail" in vaccinology.

To set the stage for a description of the more promising modern candidate adjuvants, we begin with a brief historical survey of the field.

Empirical Approaches to the Design of Adjuvants

Long before the TLRs were recognized, a great deal of empirical research had resulted in a variety of adjuvants that

are now understood a little better. For example, it was realized that particulate antigens, readily scavenged by APCs, were much more immunogenic than soluble antigens. As early as 1926, Glenny et al. (42) noted that alum precipitation of diphtheria toxoid, creating a microparticulate antigen, considerably increased immunogenicity. It was found that killed bacteria could nonspecifically raise immune responsiveness, and *Mycobacterium tuberculosis* was very effective. Jules Freund combined killed tubercle bacteria with the absorption-delaying effects of mineral oil, creating the strong and widely used Freund's adjuvant (43). This caused far too serious local and systemic reactions for human use, and in many countries, is now no longer deemed appropriate for experimental animals either, prompting a search for less toxic bacteria-derived products retaining adjuvant properties. It was realized even in Freund's day, however, that the adjuvant could guide the direction of the immune response. Freund's adjuvant promotes both antibody formation and delayed-type hypersensitivity reactions, but when the mycobacteria are omitted, as in Freund's incomplete adjuvant, only antibody formation results.

In experimental immunology, various bacteria other than killed *M. tuberculosis* are used as adjuvants. It appears that if a killed bacterial preparation is itself highly antigenic, the adjuvant power spills over to the response to an antigen coadministered with it. Some guidance may also be given to the response. Killed *Bordetella pertussis* organisms are a strong Th2/antibody formation adjuvant for pure protein antigens. *Corynebacterium parvum* is more of a Th1 adjuvant. Turning to a parasite, *Nippostrongylus brasiliensis,* has long been used if one wishes to elicit powerful immunoglobulin E (IgE) responses.

Aluminum Compounds as Adjuvants

Aluminum hydroxide and aluminum phosphate are the two most commonly used adjuvants. Two chief methods underlie alum adjuvants: either *in situ* precipitation of aluminum compounds in the presence of antigen, or adsorption of antigen onto preformed aluminum gel. The latter is now more commonly used, as alum precipitation is quite demanding and batch-to-batch variation is a significant problem. The insoluble particles that result are less than 10 μM in diameter and may be as small as 0.1 μM. Alum adjuvants promote good antibody formation but little or no DTH or CD8$^+$ T cell–mediated cytotoxicity. They can lead to significant IgE responses, which on the one hand may be advantageous for anti-parasite vaccines, but on the other hand, can lead to hypersensitivity to the antigen in question. Overall, the safety record of alum is good, but occasionally local reactions can be troublesome. Properly formulated alum adjuvants are thus very satis-

factory for diseases that can be prevented by serum IgG antibodies.

Emulsions as Adjuvants

Emulsions and emulsifying reagents have been central to adjuvant research. Incomplete Freund's adjuvant was used in the 1950s for the human influenza vaccine but never passed the regulatory hurdles. Companies have continued to improve their formulations, which may also contain one or more chemical promoters of immunogenicity. Both water-in-oil and oil-in-water emulsions can be used, and the oil can be of mineral, vegetable, animal, or synthetic origin. Stabilization by a surfactant is important, as is the nature of the emulsifying agent.

The firm SEPPIC has been promoting water-in-oil emulsions for human use, namely Montanide ISA51 and Montanide ISA720, which have been used in numerous phase I and II trials. Montanide ISA720 is of special interest because it has been used in HIV, malaria, and cytomegalovirus (CMV) vaccine trials. The adjuvant contains a natural, metabolizable oil and a highly refined mannide oleate emulsifier. Seventy parts of adjuvant are mixed with 30 parts of the aqueous, antigen-containing medium and homogenized, yielding watery droplets 0.3 to 3 μM in diameter, the emulsion being stable at 4°C for at least 2 years. The adjuvant promotes antibody formation and significant cytotoxic T cell activity.

The firm Chiron (now Novartis) has clinical experience going back 15 years with an oil-in-water emulsion known as MF59. This is now registered in Italy for use with an influenza vaccine (Fluad) and has been used in millions of doses. It has been found to be very safe and effective. The droplets of the metabolizable oil squalene are about 0.15 μM in diameter, and the other components are polysorbate 80, sorbitan trioleate, trisodium citrate dihydrate, and citric acid monohydrate. The preparation is surprisingly nonviscous, and thus easy to use and minimally reactogenic. The emulsion is stable at 2°C to 8°C for at least 3 years. MF59 is a good promoter of antibody formation and of Th2 type CD4$^+$ T cell responses but not of cytotoxic T cells in subhuman primates or human subjects.

The Syntex adjuvant formulation (SAF) is another oil-in-water emulsion, but it is noteworthy for also containing the immunostimulatory compound threonyl-muramyl dipeptide (threonyl-MDP) (44). This agent has an interesting history, going back to the early days of the search for the immunopotentiating chemicals in bacteria. Ellouz et al. (45), searching for the minimal structural requirements needed for the adjuvant properties of bacterial peptidoglycans, found that *N*-actetyl-muramyl- *L*-analyl- *D*-isoglutamine, or MDP, powerfully promoted both antibody formation and cell-mediated immunity. There have been variations on the theme; Allison and Byars (44) claimed

that the threonyl derivative is less toxic and more powerful. The SAF emulsion vehicle also contains the nonionic block polymer surfactant poloxamer 401, which has adjuvant properties in its own right. The metabolizable oil is squalene, and the emulsifier is polysorbate 80. The adjuvant has elicited both cell-mediated and humoral immune responses with a variety of antigens. However, it does not appear to be progressing rapidly to clinical use, perhaps because the MDP component is, after all, too reactogenic.

Modern "Designer" Adjuvants

The major pharmaceutical companies involved in vaccine research have rapidly applied modern principles to rational adjuvant design. Up till now, each company has gone more or less its own way, and "head to head" comparisons of adjuvants are rare. This may soon change, as the Bill & Melinda Gates Foundation's Global HIV/AIDS Enterprise is funding research with precisely this aim. Some prominent examples of modern adjuvants follow.

AS02, GlaxoSmithKline Biologicals

AS02 is an integrated adjuvant comprising an oil-in-water emulsion to which two separate chemical immunostimulants have been added. These are 3D-MPL and QS21. Monophosphoryl lipid A (MPL) is the best product remaining from an important line of work. This sought to take the LPS endotoxins of gram-negative bacteria such as *Escherichia, Pseudomonas,* or *Salmonella* (now known to be strong TLR agonists) and to extract from them less toxic adjuvants. MPL is modified from lipid A and is much less toxic (46) but powerfully immunostimulatory; 3D-MPL is a further derivative. QS21 is an adjuvant derived from the bark of the South American tree *Quillaja saponaria*. Crude extracts consisting of a mixture of tannins, polyphenolics, and triterpene glycoside saponins were found to be immunostimulatory. A saponin mixture known as Quill A was a somewhat purer preparation, and when it was fractionated by high-performance liquid chromatography into at least 23 components, QS21 emerged as the saponin with the most power and least toxicity (47). QS21 strongly stimulates both T cell–dependent and T cell–independent antibody formation as well as cell-mediated immunity, including CD8$^+$ T cell cytotoxicity.

Not surprisingly, therefore, AS02 proved to be a powerful adjuvant in rodents, subhuman primates, and humans. In human malaria vaccine trials (see later discussion), it caused rapid and strong antibody formation, Th1 T cell proliferation with IFN-γ production, and CD8$^+$ cytotoxic T lymphocytes (CTL) responses (48). In HIV vaccine studies in Rhesus monkeys, the same results were obtained, and T cell immunity was impressive with two *M. tuberculosis* antigens in the same species. Given that antibody and T cell responses were both strong, GlaxoSmithKline saw

this adjuvant as holding promise for HIV/AIDS, malaria, tuberculosis and cancer, obviously all in the long term.

Iscomatrix^{TM}, CSL Limited

Early immunologists were quick to realize that poorly immunogenic proteins could become more stimulatory as microparticles or microaggregates, such as through mild heat aggregation of serum proteins. Similarly, the property of physiological self-assembly can increase immunogenicity, as when the soluble hepatitis B protein self-assembles into virus-like particles. ISCOMs, or immunostimulating complexes, are a variation on this theme. Initially (49) these were microparticles consisting of lipids, saponins, and antigens (typically membrane proteins from enveloped viruses) that form spontaneously under the correct conditions. They are hollow, spherical particles of approximately 40nM diameter with a characteristic cage-like morphology when examined electron microscopically using negative staining techniques. The immunostimulatory properties of saponin derived from the bark of the *Quillaja saponaria* tree have long been known, but associated toxicity is considerable. Early ISCOM preparations used the purer forms Quil A and QS21, but reactogenicity was still observed, probably due to the hemolytic nature of the free saponin. ISCOMATRIX^{TM} is a further development of the technology (40) that appears to be suitable for human use. The saponin used is known as ISCOPREP and is a well-defined, extensively characterized fraction. The lipids used are Di-palmytoil phosphatidyl choline and cholesterol. These are chemically defined and synthetic. Saponin and lipid in the nonionic detergent Decanoyl-N-methylglucamide are incubated with a buffer and the ISCOMATRIX preparation forms. The incorporation of the saponin into the nanostructures removes the hemolytic activity and severe reactogenicity. At this stage, unlike the original ISCOMs, ISCOMATRIX has no antigen within it, which must now be added. If the protein is positively charged, electrostatic interactions with the negatively charged adjuvant will ensure tight association. Procedures for modifying either the protein or the adjuvant to maximize association have been developed, and a range of more specific coupling procedures has also been developed (50). Correctly formulated, these vaccines induce antibodies of all IgG isotypes, even in the presence of preexisting or passively acquired antibody. As well, strong CD8$^+$ T cell responses ensue.

Clinical experience with this adjuvant is now substantial. Two studies with an *E. coli* expressed, purified HPV16 E6E7 fusion protein in 60 women and men showed the vaccine to be safe and well tolerated, inducing humoral immune responses at all doses and cellular immune responses at the highest dose (51). Effective responses were also obtained in 55 people receiving intramuscular and 24 people receiving intranasal trivalent split virion

influenza vaccine. A promising study has been conducted with the hepatitis C virus (HCV) core protein. Thirty male subjects received three immunizations of vaccine or placebo on days 0, 28, and 56. Antibody responses resulted in all but one of the HCV-immunized subjects, and specific T cell responses in subjects given the highest dose. A phase II study is underway in the hope that a therapeutic vaccine for chronic HCV infection might emerge.

Oligodeoxyribonucleotides Containing CpG motifs (CpG ODN)

There is a long history of attempting to use nucleic acids as adjuvants. In the 1960s, there was quite a vogue for using the polynucleotides polyI:C and polyA:U, known stimulators of interferon production, as experimental immunostimulators. The field took on an altogether different and more promising dynamic as a result of the work of Tokunaga et al. (52). These investigators were interested in the antitumor potential of BCG, noted that much of it was in the DNA fraction, and drew attention to particular sequences of oligodeoxyribonucleotides (ODN). Subsequently, using shorter ODN, they discovered that palindromic hexamers, each of which contains nonmethylated CpG dinucleotides, are responsible for immune activation, measured in their case by induction of interferon production by natural killer (NK) cells. Krieg et al. (53) established that the minimal immunostimulatory sequence was unmethylated 5′-Pur-Pur-CpG Pyr-Pyr-3′. Methylation of the cytosine was found to reduce activity. Because mammalian DNA contains fourfold fewer CpG dinucleotides than mammalian genomic DNA, and because 70% of these are methylated whereas bacterial cytosines rarely are, there arose the speculation that the mammalian innate immune system evolved to recognize the bacteria-specific pattern (54). This was well before the recognition of the TLR-9 receptor as the relevant PRR for CpG motifs as PAMPs.

Krieg and Davis of Coley Pharmaceuticals (55) have argued that CpG ODN is the strongest Th1-inducing adjuvant yet discovered. In humans, its PRR, TLR-9 is found only on B cells and plasmcytoid DC. Through its action on these cells, CpG ODN causes improved antigen presentation and the production of high levels of Th1 cytokines. Three main families of CpG ODN, termed *A, B,* and *C,* have been identified (56). The A class is a powerful activator of NK cells and DC but a poor stimulator of B lymphocytes. The B class, most frequently used in studies published to date, is a strong stimulator of B cells and DC but weaker for induction of NK cells or IFN-γ. The most recently discovered C class combines both sets of properties and also induces strong CD8$^+$ CTL responses. Species differences in effectiveness have been most extensively studies for the B class. The CpG that works best for mice is the hexamer GACGTT,

but for humans GTCGTT is preferred. Two to three hexamers are optimal, best separated by at least two intervening bases, preferably Ts. The presence of poly-G flanking sequences is helpful as is a phosphorothioate backbone. The immune stimulatory effects are enhanced by a TpC dinucleotide on the 5′ end and by being pyrimidine rich on the 3′ side.

CpG ODN has been validated as a strong adjuvant in many studies (55). Model pure protein antigens, important pathogen-derived antigens such as hepatitis B surface antigen, hepatitis C envelope protein, influenza virus, and HIV gp160 have all been used, as well as many others. Further, CpG ODN can synergize with other adjuvants, such as alum, QS21, or MPL. Human studies have included trials with a commercial hepatitis B vaccine where, remarkably, a single dose induced sero-protection in 75% of subjects. In another trial involving 60 healthy volunteers, the B class ODN CPG7909, a 24-mer, was given with the influenza vaccine Fluarix^R and although the results were not dramatic, the suggestion was that lower vaccine doses could be used if the adjuvant was present (57).

Another company, Dynavax Technologies, terms its products *immunostimulatory sequences*, or ISS. Apart from infectious diseases, where targets include hepatitis B, hepatitis C, and HIV, Dynavax is especially interested in allergy, with ISS covalently linked to allergens being seen as a possible treatment. The motif AACGTTCG is considered superior to the hexamer AACGTT, and Dynavax has published extensively on the compound 1018, which is 5′-TGACTGTGAACGTTCGAGATGA-3′, but has also used other oligonucleotides. When 1018 was covalently coupled to the ragweed pollen antigen Amb a 1, the conjugate included a strong Th1-type response in mice, in contrast to Amb a 1 alone, which led to a Th2 response (58). Moreover, when peripheral blood mononuclear cell cultures from ragweed-allergic subjects were stimulated *in vitro* with the conjugate, the resulting cytokine profile was IFNγ dominated, and even when the cells had been pre-stimulated with Amb a 1 (leading to a Th2 response), the conjugate induced IFNγ production and partially inhibited IL-4 and IL-5 production.

Given these promising results, Dynavax went on to a phase II clinical trial in 27 hay fever sufferers, achieving good allergen-specific IgG levels. Randomized, placebo-controlled phase III trials have started. A phase I/II clinical trial of HBsAg linked to the ISS molecule has also begun.

It therefore appears that the CpG oligonucleotides have a promising future in both immunoprophylaxis and immunotherapy of various kinds. Further aspects of interest are that they can be used as mucosal adjuvants; that, in mice, they stimulate immune responses at a very young age; and that they allow immunogenicity even in the presence of preexisting antibody. Given this information, it is perhaps a matter of some concern that the clinical

development of these adjuvants does not appear to have moved much further since the last edition of this textbook.

A further elaboration of the CpG ODN story comes from the work of Adamsson et al. (59). The ODN, in this case CpG ODN 2006, a 24-mer containing four CpGs, was chemically conjugated to the nontoxic B subunit of cholera toxin (CTB). Simple admixture of CTB (a well-known mucosal adjuvant) and ODN had no enhancing effect, but chemical linkage resulted in marked potentiation of cytokine and chemokine responses in human peripheral blood mononuclear cells or murine splenocytes. Mice immunized with tetanus toxoid and the conjugate showed much greater antibody responses and a tilting toward Th1 isotypes and IFNγ production. The effects were mediated through the expected TLR9/MyD88 and NFκB–dependant pathway.

Lipidated, T Cell-Helped, TLR2-Targeted Peptide Vaccines

Jackson's group (60) has come up with an interesting simple generic peptide-based vaccine structure that they term *self-adjuvating* and that promotes both antibody and cytotoxic T cell responses. The vaccines are totally synthetic and essentially consist of three components, namely a single helper T cell epitope, a target epitope of interest (which may concern either antibody or T cell receptors), and a TLR2-targeting lipid moiety with strong adjuvant properties. The T helper epitope is generic for different vaccines. The target epitope is specific for each particular vaccine and can be either a class I major histocompatibility complex (MHC)–restricted epitope for cytotoxic T cell responses or an epitope recognized by antibody where a humoral response is desired. The T helper epitope is contiguous with and N-terminal to the target epitope. In most cases the Th epitope was KLIPNASLIENC-TKAEL from the canine distemper virus, but in some cases GALNNRFQIKGVELKS from influenza virus hemagglutinin. The Th epitope and the target epitope were separated by a single lysine residue. The lipid was Pam2Cys, a TLR2-targeting ligand closely related to the well-known Pam3Cys (N-palmytoil-S-[2,3bis (palmytoyloxy) propy]-cysteine), which has long been known as a strong adjuvant. Pam2Cys (Dipalmytoil-S-glycerylcysteine) is the lipid component of the macrophage-activating lipopeptide-2 isolated from mycoplasma and can readily be synthesized. It was attached to the lysine separating the two peptides through two serine residues. The use of a branched geometry in the construction of these vaccines is based on Jackson's previous work showing that a branched structure is significantly more immunogenic than the same epitopes in a tandem linear array, as well as more soluble.

In the mouse, the lipopeptides were effective experimental vaccines in diverse disease models requiring CD8$^+$ T cell immunity including two tumor models, live *Listeria monocytogenes* challenge, or influenza virus recovery. Anti-

body responses to peptides from model hormone antigens were also markedly enhanced, the efficacy equaling that of complete Freund's adjuvant. The lipopeptides also work in dogs, and early clinical trials are being planned.

Inulin-derived Adjuvants

Inulin is a simple inert plant-derived polysaccharide consisting of a family of linear β-D-(2$\rightarrow$1) polyfructofuranosyl α-D-glucoses. A particulate form, known as gamma inulin (γ-IN) is a powerful complement activator and is an effective adjuvant capable of boosting both cell-mediated and humoral immunity (61). It appears to be remarkably nontoxic and has proven to be superior to alum in many animal models, on occasion outperforming Freund's complete adjuvant. A very small human study showed it to be effective in stimulating T cell responses to the ET protein of HPV16 in cervical cancer cases. More extensive human trials are now planned.

Liposomes, Virosomes, and Virus-like Particles

Liposomes have some but not all of the features of ISCOMs. Alving's group has obtained a good adjuvant effect using liposomes with cholera and malaria antigens. They have also obtained quite promising results using envelope protein peptides in a simian immunodeficiency virus (SIV) trial with macaque monkeys (62). The liposomes contain dimyristoyl phosphatidyl choline, dimyristoyl phosphatidyl glycerol, cholesterol, and monophosphoryl lipid A. In some experiments liposomes were alum adsorbed. Liposomes have also acted as adjuvants for diphtheria toxoid, tetanus toxoid, and a variety of hepatitis antigens. There is a great capacity to vary the particle size of liposomes, from approximately c.20 nM up to more than 10 μm in diameter. In general, liposomes are best used together with some other adjuvant.

Virosomes are multimeric aggregates of virus-derived transmembrane proteins (e.g., influenza hemagglutinin), and proteosomes are similar multimers of bacterial transmembrane proteins. They consist of 60 nM to 100 nM vesicles or membrane vesicle fragments. Amphipathic immunogens can be incorporated into these structures. These agents do not induce cell-mediated immunity unless an appropriate further adjuvant is added. Glück, of the Swiss Serum and Vaccine Institute, has been a strong proponent of the virosome approach. He has used influenza virus virosomes as a delivery system for, for example, hepatitis A and B or diphtheria and tetanus antigens (63), or as a mucosal vaccination strategy against influenza itself (64). In the latter case, hemagglutinin and neuraminidase were extracted from influenza virus, and phosphatidylcholine liposomes also containing the mucosal adjuvant *E. coli* heat-labile toxin at 1 μg per dose were prepared. Two nasal spray

immunizations induced good humoral responses in adult human volunteers, with significant salivary IgA. Elderly subjects also tolerated the vaccine well.

Virus-like particles (VLPs) are the results of self-assembly of virus capsid proteins. The considerable success of the hepatitis B vaccine owes much to the strong immunogenicity of the HBsAg particles. Similarly, the major capsid protein of the HPV is strongly immunogenic as a VLP. It has also been possible to incorporate other proteins into HBsAg VLPs and thus to enhance their immunogenicity.

Other Methods of Rendering Antigens Particulate

There are other ways of effecting a polymerization of antigens such as association with polymers. Nonionic block copolymers, usually used as additives to adjuvants employing an emulsion, are polymers of polyoxypropylene and polyoxyethylene, with which antigen can be associated. They have been used as components of complex adjuvant formulations by both Syntex and Ribi Chemical Co. These formulations induce a good Th1 response.

Carbohydrate polymers of mannose (e.g., mannan) or of β1-3 glucose (e.g., glucan) have been used in a similar manner. It is possible to conjugate peptides to mannan via an aminocaproic spacer and thereby produce a good antibody response. Mannan can also enhance the adjuvant properties of LPS. Part of the action may result from the stimulation of macrophages, which have a mannan-binding receptor.

Other surface active agents include dimethyl dioctadecyl ammonium bromide, avridine, and polyphosphazenes. Carbohydrate polymers with adjuvant properties include mannans as noted earlier, glucans, and dextrans. An interesting parasite-derived adjuvant is the *Leishmania* protein LeIF. This list is by no means exhaustive.

Microencapsulation of Antigens

This idea combines several desirable principles for adjuvants. Biodegradable microcapsules are particulate. They can enclose immunostimulatory molecules as well as antigen. They delay absorption of antigen and act as long-term depots. Best of all, they offer the hope that different chemical compositions will create particles that release their antigen as a pulse at various defined times after injection. Variables that affect the timing of release include particle size and the composition of the polymer. An ideal preparation would be a mixture of particles dissolving at intervals to mimic a primary dose and two booster doses.

Several laboratories share the credit for the development of controlled-release vaccine through encapsulation. The idea of biodegradable microcapsules containing antigens was promoted by Chang (65) and put into practice by Langer (66). The currently most popular material, the polymer poly(lactide-co-glycolide) (PLG), was first used by O'Hagan et al. (67) and by Eldridge et al. (68). This material was a happy choice because PLG has been used for many years as a biodegradable suture material. In that context, it has shown itself to be safe and nonreactogenic. PLG degrades by hydrolysis. How long this takes is determined both by chain length and by the ratio of lactide to glycolide in the polymer. The WHO has sponsored a considerable amount of work on PLG in the hope of coming up with a "one shot" formulation, which in the first instance could be applied to the problem of neonatal tetanus in developing countries. As infant immunization rates were low for women now of childbearing age, the WHO programs aim to immunize pregnant women with tetanus toxoid so that the newborn infants would be protected by antibodies crossing the placenta. However, it is difficult to persuade these women to make three trips to their local health center, which may require hours of walking. Once the controlled-release strategy has been perfected for this purpose, it could be adapted to other vaccines, such as hepatitis B or Hib.

Many frustrating problems have been encountered in this endeavor, but they are gradually being overcome one by one. The most important problem relates to stability of antigens in microparticles, both during the manufacturing process and *in vivo*. Further, although the lactide-to-glycolide ratio in PLG affects degradation rate, it was found in practice that a mixture of two different sets of microcapsules resulted not in sharp peaks of antigen release but rather in continuous release over a period. This seems to produce satisfactory antibody responses. It is now clear that, in preclinical studies, one injection of antigen in microcapsules can lead to higher and more sustained antibody formation than can two injections of antigen adsorbed onto alum.

Cyanoacrylates are another form of biodegradable polymer. For example, poly(butyl-2-cyanoacrylate) has been used as an adjuvant for oral immunization. Poly(methylmethacrylate) nanoparticles constitute another biodegradable adjuvant. The antigen can be either incorporated into the nanoparticles or adsorbed onto previously formed particles.

The use of PLG and other microparticles is under extensive investigation for the mucosal administration of vaccines. Particles of very small size (nanoparticles) may be even more suitable. Digestion in the stomach needs to be combated, perhaps by enteric-coated polymers, and coating with substances that increase intestinal absorption may be necessary. Delivery via the respiratory tract—for example, via intranasal immunization or aerosol administration—is a good possibility for respiratory pathogens. Rectal and vaginal delivery is also possible. Because there is a great deal of "cross-talk" between the various components of the mucosal immune system,

and because oral delivery is by far the most practical, this deserves full experimental exploration in the first instance.

Biodegradable microparticles can induce T cell immunity, including CD8[+] CTLs, as well as just antibody formation. For example, HIV envelope proteins contained in PLG particles induced HIV-specific CD4[+] and CD8[+] T cell responses in mice. Similarly, microparticles outperformed incomplete Freund's adjuvant in promoting Th1 CD4[+] T cell responses with a subunit antigen from *M. tuberculosis* (69). The addition of cytokines or chemical adjuvants to further enhance these T cell effects remains to be explored.

Cytokines as Adjuvants

Cytokines have profound regulatory effects on all three cell types involved in immune responses (APCs, T cells, and B cells), so it is natural to ask whether they might find a use in adjuvant preparations, particularly inasmuch as some cytokines are noteworthy for guiding the immune response down particular pathways. This being so, it is interesting to note that the field of cytokines as adjuvants has not yet made much progress. Of course, cytokines are quite expensive and can exhibit marked, albeit dose-dependent, toxic effects. A variation on the theme explored in a later discussion is cytokine gene constructs as components of vectored or DNA vaccines, an approach that would have the advantage that the cytokine is delivered to the same milieu as the antigen, as opposed to systemically administered cytokines.

Several cytokines act on APCs. IFN-γ and TNF-α recruit and activate macrophages and help T cells develop antiviral effector functions, and IL-1α and IL-1β are also strongly pro-inflammatory. These cytokines have been assessed for their capacity to improve the response of mice to an inactivated rabies vaccine. All of them increased virus-specific IgG responses, IFN-γ raised resistance to challenge infection, and IFN-γ and IL-2 acted synergistically. Limited clinical trials have shown IFN-γ to accelerate the response of humans to hepatitis B vaccines. Granulocyte-macrophage colony-stimulating factor (GM-CSF) and FLT-3 ligand are strong stimulators of DCs; each has been claimed to have adjuvant properties in soluble form, and each has been used to stimulate DCs in various approaches to cell-based anticancer vaccines (70). The FLT-3 ligand stimulates both CD8α^+ (lymphoid type) and CD8α^- (myeloid type) DCs in the mouse and both CD11c$^+$ (monocytoid) and CD11c$^-$ (plasmacytoid) DCs in the human, whereas GM-CSF stimulates only the latter in each case. The former DC type tends to produce Th1-stimulating cytokines and the latter a Th2 bias. The differential mobilization of distinct DC subsets may have some potential in guiding immune responses. An early trial of FLT-3 ligand as an adjuvant in combination with alum failed to show an increase in the already strong immune response.

IL-2 has been explored most extensively (71). It can be highly effective in restoring immune responsiveness in mice with a deficient T cell system or in overcoming immune response gene-mediated low titers. Its effects in healthy animals are less impressive, although some enhanced protection in a variety of infectious disease models has been noted. IL-2 can improve survival in a variety of cancer immunotherapeutic models. One noteworthy clinical effect is its capacity to convert lepromatous leprosy into tuberculoid leprosy when injected directly into the lesions of patients. IL-4 and IL-10 have received some attention through their capacity to send the immune response veering into a Th2 direction, but currently the focus is on IL-10 as a possible therapy in autoimmunity rather than as an adjuvant. IL-12 can promote Th1 development, an effect that has been beneficial in a trial *Leishmania* vaccine. IL-23 has also been proposed for this purpose. One does not detect a great thirst within pharmaceutical industry to use soluble cytokines as adjuvants. In the longer term, it is conceivable that one or more could find a place in either vectored or DNA vaccines, as a gene construct rather than a finished product.

Molecular Targeting of Antigens

Antigens have to be brought to APCs, which in turn have to be activated to begin the adaptive immune response. Getting antigens to APC by linking them to ligands for which the APC have a counter-structure is a good first step. For example, fusing a protein antigen with C3d can increase murine anti–hen egg lysozyme responses by up to 10,000-fold (72), yielding responses much higher than with Freund's complete adjuvant. In mucosal immunity, coupling antigens covalently to a mucosal adjuvant can have profound effects, as discussed earlier. Now that the TLRs are being rapidly unraveled, one can anticipate more experimentation on antigens coupled to their various ligands. One novel development is the chemical conjugation of CpG ODN with the nontoxic CTB to create a highly immunostimulatory adjuvant (59). The rationale was to utilize the TLR-9 ligating properties of CpG ODN as well as the efficient ability of CTB to bind to immune cells, especially APC, and to transport the linked agent into endosomes and further to the trans-Golgi network and the endoplasmic reticulum. Using tetanus toxoid as an antigen, the conjugated molecule markedly enhanced IgG antibody formation and tilted the isotype pattern toward a Th1 response. Further, there was powerful *in vitro* stimulation of pro-inflammatory cytokines and chemokines by human peripheral blood mononuclear cells.

The reader by now has gathered that the field of adjuvants is not too rich in simplifying or overarching paradigms. It seems likely that empirical research will continue to dominate for some time. It may be well to end on a positive note. Combinations of the principles

discussed here seem to be the way of the future. There have been any number of disappointing clinical trials of a malaria vaccine based on the *Plasmodium falciparum* circumsporozoite protein (CSP). Recently, when and only when three separate principles of adjuvanticity were combined did a vaccine capable of moderate protection against malaria result (73). The principles were incorporation of the malarial antigen into a virus-like particle, use of an oil-in-water emulsion, and addition of the chemical immunostimulants monophosphoryl lipid A and QS21. The Bill & Melinda Gates Foundation has recently supported head-to-head comparisons of various adjuvants for experimental HIV/AIDS vaccines, and this should promote progress in what is clearly a difficult area.

Viruses Can Activate Multiple TLRs

It may be that certain viruses have built in adjuvanticity through their capacity to engage multiple TLRs. Querec et al. (74) found that the live attenuated yellow fever vaccine 17D can activate multiple subsets of human and mouse DCs *in vitro*. It did so via no fewer than four TLRs, namely TLRs 2, 7, 8, and 9. As a result, the immune response is a mixed one of Th1 and Th2 helper cell induction as well as antigen-specific CD8$^+$ cytotoxic T cells. The Th1 responses are mediated by the adaptor protein MyD88, which is present downstream of most TLRs, but the Th2 responses require TLR-2 signaling, mediated by the adaptor protein TIRAP. Thus distinct TLRs might differentially regulate the Th1/Th2 balance. Incorporating different combinations of TLR ligands into vaccine candidates could therefore lead to immune responses appropriate to the disease in question. Yellow fever vaccine 17D is currently being manipulated to act as a carrier for a number of other antigens.

Yellow fever is not the only virus to activate TLRs. Measles and HCV appear to signal through TLR2 and Newcastle disease virus activates DCs through both TLR7 and TLR9, while Cocksackie virus B triggers TLR8.

Viruses and other pathogens can also signal via other PRRs, such as C-type lectins and mannose receptors (23). An intriguing possibility is that some of these interactions—for example, via DC-specific, ICAM-3 grabbing nonintegrin (DC-SIGN)—could actually induce regulatory T cells, thus suppressing the immune response and DC function (75). In this case the pathogen may in fact be manipulating the immune response to favor its own persistence, and, if so, learning more about the various PRRs and their functions could lead to novel strategies to treat chronic infections.

Mucosal Adjuvants

While conventional adjuvants can be considered for mucosally delivered vaccine preparations, there is a special class of lectin-like molecules endowed with immunostim-

ulatory properties that are uniquely involved in enhancing mucosal responses. Cholera toxin (CT) is the most powerful mucosal adjuvant yet developed. The CTB retains much of the adjuvant property but not the toxicity. *E. coli* heat-stable enterotoxin (LT) is active, and fragment C of tetanus toxin has similar effects.

Obviously, the toxicity of CT and LT limits their usefulness as adjuvants. Pizza et al. (76) developed a clever strategy involving genetic modification of CT and LT resulting in derivatives that are still able to assemble into a holotoxin but have greatly diminished toxicity. These mutants act not only as mucosal immunogens, but also as adjuvants for coadministered bystander antigens. Recently, two equivalent derivatives of CT and LT, known as CTK63 and LTK63, have been prepared by substitution of a single, identical amino acid. The substitution is near the nicotinamide adenine dinucleotide (NAD) binding cleft. Interestingly, LTK63 worked much better than CTK63 both for the facilitation of serum antibody and as a coinducer of IgA in nasal or lung lavages of mice, being only slightly inferior to CT itself (77). The reasons for this difference are currently entirely obscure. Indeed, the mechanisms whereby the toxins mediate immunity are poorly understood.

Interestingly, when CT-B is covalently coupled to an antigen and is then given by a mucosal route, CT-B induces a strong mucosal IgA response to itself and, frequently, the conjugated antigen, but it actually causes systemic or peripheral immunological tolerance (78). Moreover, far less antigen is required than for normal mucosal immunity or tolerance induction. Further, the strategy works even in the presence of an already established state of systemic immunity. Impressive results have been obtained in animal models of autoimmune disease, including autoimmune encephalomyelitis, collagen-induced arthritis, and insulin-dependent diabetes mellitus. One possible mechanism may be the induction of T cells producing immunosuppressive cytokines such as transforming growth factor (TGF-β) and IL-10. Interestingly, even trace amounts of coadministered CT prevent tolerance induction.

Table 40.3 enunciates some of the principles underlying the design of adjuvants. Hopefully, some of these will lead to clinically successful new adjuvants after a disappointingly long waiting period.

CLASSIFICATION OF ESTABLISHED VACCINES

Dealing as it does with the administration of powerful biologicals to normal individuals, the vaccine community, including industry, is understandably conservative. Vaccines take time to establish themselves in the public consciousness, and then to change these vaccines for improved versions again takes time and effort. The world is facing some awkward decisions in the years immediately ahead as a

▌**TABLE 40.3 Some Principles Underlying the Design of Adjuvants**

- Uptake of antigens by APC is vital, hence rendering antigens polymeric or particulate helps.
- Activation of APC is essential; hence agents that engage TLR work well.
- Depot effects and delayed absorption can enhance immunity; hence emulsions and biodegradable microparticles underlie many adjuvant approaches.
- Bacteria and bacterial products were found early to stimulate immunity; many pure derivatives have resulted.
- A heterogeneous collection of natural or synthetic chemicals has been found empirically to enhance immunity.
- Many cytokines increase immune responses.
- Molecular targeting of antigens to APC through conjugation of ligands can enhance immune responses.
- Viruses and other pathogens may stimulate multiple TLRs and therefore possess built-in immunogenicity.
- Adjuvants are essential for good mucosal vaccine results, but much remains to be done in this field.

number of new vaccines have emerged from the research and development pipeline.

The purpose of a vaccine is to stimulate the immune response without subjecting an individual to the risk of actual infection. An ideal vaccine would confer the same degree of immunity as natural infection for diseases against which immunity is solid, or it would do better than nature for diseases in which immunity is not solid. Because most vaccines fall short of this ideal, it is frequently necessary to give vaccines more than once, making use of the phenomenon of immunological memory—namely, the capacity to respond more strongly to an antigen on re-exposure to it. Vaccines can elicit every kind of immune response, including antibody formation, Th1 and Th2–type CD4$^+$ T cell responses and CD8$^+$ T-cell responses, but most vaccine development programs for currently licensed vaccines have relied on the vaccine's capacity to evoke antibody formation. This will change as more ambitious targets are set and as capacity to guide immune responses down particular pathways improves. In particular, much more interest is being taken in whether a vaccine can lead to Th1-type and cytotoxic CD8$^+$ T cell responses.

Vaccines are designed primarily to prevent infection, although one of the first vaccines, the vaccine against rabies, was given after infection had been initiated. There is now increasing research on therapeutic vaccines—that is, vaccines administered after infection has been established. Such vaccines are designed to strengthen an immune response that is inadequate, particularly in cases of chronic or recurrent disease.

Obviously, microorganisms possess thousands of molecules that are foreign to a host animal or person and that are thus antigenic. Immune responses against the majority of these are entirely irrelevant to the prevention of infection. Therefore, increasing attention is being given to the identification, purification, and, frequently, molecular cloning of the antigens that evoke host-protective responses. With more complex pathogens such as parasites, it is not immediately apparent which antigens these are, and detective work needs to be done to establish correlates of immunity. The full genome sequence of many pathogens has been determined, and a new strategy is to search for likely transmembrane proteins or molecules involved in virulence, and then to conduct trials of these in mice for possible vaccine efficacy. This process is termed *genome mining*. Identification of the correct antigens is not the end of the story, however, because many pure, soluble proteins are poorly immunogenic. In fact, there is the need to balance the greater immunogenicity of whole microorganisms against the lower reactogenicity and greater conceptual elegance of molecular vaccines. This situation needs to be dissected on a case-by-case basis, although with more recent vaccines, such as Hib and acellular pertussis, the balance appears to be swinging in the latter direction.

Vaccines have potential usefulness beyond communicable diseases, such as anticancer vaccines, birth control vaccines, and vaccines aimed at lowering immune responses, such as in autoimmunity or allergy. These uses fall outside the scope of this chapter.

A classification of established vaccines is presented in Table 40.4.

Live Attenuated Vaccines

Ever since Jenner's smallpox vaccine, live attenuated vaccines have occupied a special place in the pantheon of vaccinology. Many viral vaccines of this type have an efficacy of >90%, and protection frequently lasts for many years. This is perhaps not surprising, because the multiplication of the pathogen in the host creates an antigenic stimulus not unlike that of a natural infection in terms of antigen amount, character, and location. This key advantage is also the source of potential disadvantage, as the "miniversion" of the relevant disease can assume dangerous proportions—for example, generalized vaccinia or BCG spread in immunodeficient or immunosuppressed children. In some vaccines, the mutations causing loss of virulence are not known. Further, mutations can restore virulence, as in the case of poliomyelitis. Much recent research has centered on more rationally planned attenuation based on an understanding of the molecular determinants of virulence. Relevant genetic engineering can result in improved vaccines in which reversion to virulence is impossible.

It must be recognized that the success of live attenuated vaccines poses some problems as to correct maintenance of immune status. For example, in many countries, measles vaccine is given only once, and nowhere is it mandated more than twice. Will this confer the same

▌**TABLE 40.4 Classification of Licensed Vaccines**

Types of Vaccine	Examples
Live attenuated viral	Poliomyelitis (OPV Sabin), measles, mumps, rubella, rabies, varicella, vaccinia, yellow fever, rotavirus, influenza (intranasal)
Live attenuated bacterial	BCG for tuberculosis or leprosy, Ty21a for typhoid fever
Killed whole virus	Poliomyelitis (IPV-Salk), influenza, hepatitis A, rabies
Killed whole-cell bacterial	Pertussis, cholera, anthrax, plague
Toxoids	Diphtheria, tetanus
Molecular vaccines—proteins	Acellular pertussis, subunit influenza, hepatitis B
Molecular vaccines—carbohydrate	Hib, Vi typhoid, meningococci, pneumococci
Molecular vaccines—carbohydrate-protein conjugate	Hib, meningococci, pneumococci
Combination vaccines	DPT, MMRV, DPT-Hib, DPT-Hib-IPV-hep B.

life-long immunity as an attack of measles? We cannot be sure and thus must maintain a level of alertness about booster doses in adult life. This has not been a priority area for live attenuated or any other kind of vaccine but is currently the subject of much debate. There are instances in which public health regulations mandate regular boosters—for example, the yellow fever vaccine for travelers to affected countries. Another vexing question is whether repeated environmental exposure to a common microbe provides a kind of natural booster. If so, problems may arise as a disease becomes uncommon in a community.

Surprisingly, giving a number of live attenuated vaccines together appears to cause no problems.

Vaccines Consisting of Killed Microorganisms

Because vaccines consisting of killed microorganisms are nonreplicating antigens, booster doses are essential. Some are excellent vaccines with high efficacy and safety, such as the Salk injectable poliomyelitis vaccine (IPV) or the hepatitis A vaccine. Others are of poor efficacy and short duration, such as the whole cell–killed injectable cholera vaccine, which has been all but abandoned. Others are partially effective but require improvement in terms of percentage of protection or duration of immunity. These include the older killed influenza and typhoid vaccines. Many of these vaccines have already been overtaken by new and improved versions, including subunit vaccines and orally active preparations.

Toxoids

When disease pathological processes are caused predominantly by a powerful exotoxin or enterotoxin, vaccines provoking antitoxin antibodies make good sense. In some cases, an exotoxin is a bacterium's device for creating sufficient tissue destruction to permit a rich growth medium to develop. That is the case in tetanus, diphtheria, and gas gangrene. For these cases, the relevant toxoids make good vaccines. Toxoids from enterotoxins have, in general, been less successful. However, a genetically detoxified derivative of the heat-labile enterotoxin (LT) of enterotoxigenic *Escherichia coli* is showing promise as a possible vaccine against traveler's diarrhea. This has been achieved through site-directed mutagenesis to inactivate the adenosine diphosphate–ribosyltransferase activity of the A subunit of LT. Equivalent mutants of CT may eventually prove important.

The current conventional diphtheria and tetanus vaccines contain many impurities; further, the formaldehyde treatment needed to turn the toxins into toxoids also causes cross-linkage of beef peptides present in the culture medium, resulting in the presence of unnecessary antigens in the final preparation. Scientifically, one could mount an argument for a mutant, nontoxic pure molecule, such as CRM197, as a new vaccine. CRM197 is a material cross-reacting to diphtheria toxin and containing a single glycine to glutamic acid substitution at position 52 rendering the toxin inactive. Despite scientific attractiveness, there is not much commercial pressure for changing vaccines that are working well. Doubtless, if the acellular pertussis component of diphtheria toxoid, whole-cell pertussis, and tetanus toxoid (DPT) vaccine continues to impress with their lack of reactogenicity, more pressure may build for the diphtheria and tetanus components to be free of side effects, and so ongoing research should be encouraged.

Molecular Vaccines: Protein

The recombinant DNA era has yielded a plethora of antigenic molecules that are pure and have been chosen in animal models through their capacity to provoke an immune response that is host protective. Some subunit vaccines, such as Hib and acellular pertussis, result from extremely elegant research that warrants description in its own right. Whereas some subunit vaccines, such as HBsAg, are highly immunogenic at low doses, others have been of disappointing strength and require adjuvants more

powerful than the aluminum salts currently used to adsorb pure proteins onto small particles. As a group, subunit vaccines have been more expensive than older vaccines. This major barrier to developing country use can be partially countered by programs such as the Global Alliance for Vaccines and Immunization (discussed later) that create a large demand, whereby high volumes drive down costs of production.

Molecular Vaccines: Carbohydrate and Conjugate

The capsular polysaccharides of encapsulated bacteria are powerfully immunogenic and can make good vaccines. However, they suffer from three drawbacks. The carbohydrates are serotype specific—that is, they cover one variant of the pathogen only. Therefore, an effective vaccine may have to be a "cocktail" of many different carbohydrate molecules. Thus, the Merck pneumococcal vaccine has 23 separate components. Second, these vaccines work poorly or not at all in young infants. For a disease such as meningitis, in which the greatest rate of mortality is among children younger than 1 year, this represents a serious limitation. Third, being T-independent antigens, the vaccines engender suboptimal immunological memory. Therefore, the conjugation of these carbohydrates to protein carriers that engender T cell help represented a major step forward, which is described in detail in a later section.

Combination Vaccines

As more effective vaccines are developed, the question of the number of needle pricks to which young infants are subjected becomes an urgent one. Among the traditional vaccines, the DPT combination was standard for a long time, and whole-cell pertussis has been replaced by the subunit acellular pertussis in industrialized countries. As already mentioned, MMR is an extremely successful combination, and recently varicella has been successfully

added to this, thus MMR-V. Considering DPT as a "platform," one can see logical additions to this, such as the addition of one or more of Hib, injectable killed polio (Salk) vaccine, and hepatitis B. In fact, such pentavalent and hexavalent formulations are now available. Antigenic competition has not yet become manifest, although the addition of Hib to DPT has caused problems for some manufacturers in the levels of antibodies reached. As successful vaccines for other types of meningitis become more popular (e.g., against *N. meningitidis* type C), the question of whether to add these or whether to create a second "meningitis/pneumonia" package will have to be faced. At least two companies are considering the possibility of heptavalent combinations, such as DPT–HiB–hepatitis B–meningitis A/C. Of course, the pneumococcal vaccine currently licensed (Prevnar from Wyeth) is already a 7-valent mixture, and more serotypes will soon be added. Consideration is also being given to a multiserotype meningococcus "cocktail," discussed in more detail later.

NEW APPROACHES TO VACCINE DESIGN

Table 40.5 outlines the main new approaches to vaccine design. In thinking about these approaches, it is important to remember that established public health practice is not easy to change, and it appears likely that the newer approaches will find more favor with regard to diseases for which no vaccine currently exists, such as HIV/AIDS or malaria, than in situations in which current vaccines are reasonably satisfactory.

Vectored Vaccines

Bernard Moss and Enzo Paoletti independently opened up a major chapter in vaccinology when they demonstrated that genes for important antigens could be introduced into the vaccinia virus without perturbing its replication and could be expressed in host cells in which the virus was

▌ **TABLE 40.5 Newer Approaches to Vaccine Design**

Approach	*Purpose*
Vectored vaccines	To employ an attenuated virus or bacterium with limited replication potential to carry a gene or genes for antigens from a pathogen into the body
Nucleic acid vaccines	To use a plasmid containing genes coding for one or more antigens from a pathogen so the body itself becomes a factory for the antigen(s) in question; there are variations on the theme
Peptide vaccines	To construct a polymer out of a number of peptides, frequently T cell epitopes, creating an immunogen
Mucosal vaccines	To administer an antigen not by injection but via a mucosal surface (e.g., orally or intranasally) so as to engage the mucosal immune system in protection
Transdermal vaccines	To administer the antigen via the skin
Edible vaccines	To genetically engineer a plant such that it comes to contain antigen(s) in a form that is immunogenic when eaten
Prime-boost strategies	To administer two separate versions of a vaccine sequentially, typically a DNA vaccine followed by a vectored vaccine or either of these followed by a protein vaccine

dividing (79,80). This "Trojan Horse" concept, whereby harmless microorganisms act as vectors for antigen genes, has been extended in innumerable directions. Among other important vectors in use experimentally are vaccinia variants; avipoxviruses; adenoviruses; polioviruses; herpesviruses; crippled HIV, *Salmonella, Shigella,* and BCG bacterial species; and many more. The power of the concept is that it combines the best of two worlds: the force of a live attenuated vaccine, and the scientific precision of the rational subunit vaccine approach. Further, given the large size of the vaccinia genome or the genomes of some of the other vectors, it is feasible to consider the insertion of quite a few antigen genes, thus covering several diseases at once. It is also straightforward to incorporate one or more cytokine genes in the construct, should this be desirable for either the strength of the immune response or the direction it should take.

Although the concept was first introduced in the early 1980s, no relevant vaccine has yet come on the market. Clinical investigation has been somewhat limited so far, but, as discussed later, it has accelerated in the context of the so-called "prime-boost" strategy. There are understandable reservations about the use of unmodified vaccinia, particularly at a time when HIV is rife, because it can be dangerous in people with an ineffective T cell system, a reservation that could be partially countered by the inclusion of the IL-2 gene in the construct, which prevents athymic nude mice from succumbing to vaccinia (81). A number of vaccinia strains lacking genes that contribute to virulence have been prepared and are in clinical trial—for example, modified vaccinia Ankara (MVA). Also, nonreplicating viral vectors, such as canarypox or fowlpox in humans, can be considered. The field has doubtless been slowed somewhat by poor responses in early clinical trials of experimental HIV and malaria vaccines. Nevertheless, the overwhelming weight of preclinical data, with disease protection against at least 20 pathogens in at least 15 species, suggests that further research must eventually be crowned with success. It should be noted that the approach is designed to induce excellent T cell, including cytotoxic T cell, immunity.

Experimentation with bacterial vectors is not yet as far advanced, but examples are taken up when enteric and intracellular pathogens are discussed.

Nucleic Acid Vaccines

Few areas of experimental vaccinology have emerged as surprisingly and developed as explosively as that of nucleic acid vaccines. Two preludes to the actual discovery warrant mention. Wolff et al. (82), using plasmid DNA coding for a reporter gene, found that DNA injected as a saline solution and without the adjunct agents normally used for transfection could cause synthesis of the reporter protein in the recipient animal. This surprising finding came from a control group in which the real hope for the experimental group was uptake of liposomes containing DNA. Of various injection sites tested, intramuscular injection worked best. The total number of myotubes transfected within the injection region is 1% to 5%. The second prelude relates to a DNA delivery system, originally developed by an agricultural firm, Agrecetus, and first used as a means of transfecting plant cells. This Accell gene delivery system, also termed the *gene gun,* consists of a helium gas pressure–driven device capable of delivering into very superficial layers of tissue tiny gold particles coated with plasmid DNA. These DNA-coated microprojectiles could, for example, be delivered to the skin of mice, resulting in the synthesis of the relevant protein (83). It was not long before each of these two approaches was used to elicit immune responses in the mouse. The gene gun approach induced antibody formation against human growth hormone and human α-1 antitrypsin in the first demonstration that DNA immunization could work (84). Further, the prolonged persistence of encoded protein in the serum signaled the probability of continued antigenic stimulation. The first demonstration of a host-protective immune response came from the intramuscular injection approach (85). Mice were injected with plasmids encoding the nucleoprotein of influenza A virus. They developed both antibodies and class I MHC)-restricted CTLs. Upon challenge with a virulent influenza A strain, PR/8, 100% of treated mice survived, whereas 100% of controls were dead by day 9. Almost simultaneously, Fynan et al. (86) also protected mice against PR/8 by using the gene gun and DNA encoding the relevant hemagglutinin as the antigen. After these two striking results, the field really took off. A scant 4 years later, Donnelly et al. (87) were able to review an extraordinary range of preclinical studies showing humoral and T cell responses protective against a wide range of viruses, bacteria, and parasites, as well as various tumor models.

What are the essential features of nucleic acid vaccines? The key difference from the live vector approach is that the DNA encoding the antigen of interest cannot replicate in the human or animal body. The plasmids concerned are usually grown in *E. coli.* Their origin of replication is not suitable for mammalian cells. It is important to include a strong promoter element suitable for high-level gene expression in mammalian cells; for example, the immediate/early promoter of the human CMV works well. The construct should also have an appropriate messenger ribonucleic acid (RNA) transcript termination/polyadenylation sequence. After intramuscular injection, the DNA enters the cytoplasm and then the nucleus of the myocyte, but it is not integrated into the genome. Neither muscle cells nor the DCs, which are the targets of the gene gun approach, have a high rate of division, nor do they show extensive homology with the plasmid, and so homologous recombination is highly unlikely. Random integration remains a formal possibility, but, so far, no

adverse effects have been noted. Gene expression is not at a high level. Antigen leaks out of myocytes for a considerable period, and, in the case of the gene gun, the gold particles deposited in the epidermis soon find their way into Langerhans cells, which then make their way to local lymph nodes. In the case of intramuscular injection, it is clear that the myocyte itself is not the inducer of immune responses. This was approached by Fu et al. (88) in an ingenious experiment. Parental into F1 bone marrow chimeric mice were prepared in such a way that the myocytes carried both parental MHC haplocytes but the professional APCs such as DCs, being (after an appropriate period) bone marrow derived, carried only the bone marrow donor parental haplotype. After reconstitution, the chimeric mice were given plasmid DNA coding for influenza virus nucleoprotein to generate CTLs. According to the rules of MHC restriction, because the mice possessed the thymic epithelial framework of the F1, their peripheral T cells, although of parental genotype, should be capable of recognizing antigen in the context of *both* parental haplotypes. However, when the CTLs were tested *in vitro,* they were clearly restricted only by the MHC alleles of the bone marrow donor. Had myocytes been the APCs creating the CTLs *in vivo,* this would not have been the case. In further chimeras, transplantation studies were done with an NP gene–transfected myoblast cell line. With appropriate choice of strains, it could be shown that H2-incompatible myoblasts could induce CTL responses, but these, when analyzed, were restricted to the MHC haplocyte not of the myoblast donor but of the bone marrow donor. This clearly showed that the myoblasts acted as a source of antigen that was somehow transferred to APCs in a way that allowed processing for the class I MHC pathway. This apparent exception to the dual pathway rules is an example of "cross-priming," which has also been noted in other systems. The efficacy of DNA vaccines in generating CTLs has been a common feature of most examples so far studied in mice.

The potential advantages of nucleic acid vaccines are numerous. The subunit approach to pure molecular vaccines can be seriously hampered by incorrect folding or glycosylation of antigens, which can present formidable problems and add to the cost of such vaccines. This should be largely obviated in DNA vaccines. Once an appropriate DNA vaccine has been engineered, it should be stable and batch variation should be minimal, facilitating quality control procedures. In terms of actual manufacturing procedure, nucleic acid vaccines should be relatively cheap. Multivalency could be achieved either by coinjection of a mixture of plasmids or by constructing complex plasmids.

A variation on the theme is the use of positive-strand RNA viruses such as alpha viruses that self-replicate within nondividing host cells and can be engineered to deliver inserted RNA coding for the antigen in question. It is also possible to engineer replicons in which the antigen-encoding RNA is substituted for viral structural genes and replicons can be packaged into infectious particles with helper viruses or split-genome packaging cell lines. DNA/RNA replicons can also be engineered and in some circumstances are more immunogenic than plasmid-based DNA vaccines.

Despite the justifiable excitement about nucleic acid vaccines, it has become clear that the responses achieved in subhuman primates and in humans are much lower than those in mice. In part, this may be a dosage question, because a human weighs 3,000 times more than a mouse, and it has not been practical to increase dosage commensurately. Considerable effort has therefore gone into enhancing the efficacy of DNA vaccines. Uptake of DNA has been enhanced by *in vivo* electroporation. DNA has been incorporated into microparticles or liposomes or has been given with an oil-in-water emulsion. Coinjection of cytokines or engineering the DNA to encode for a cytokine represents another approach. Of particular interest is the concept of encoding together with the DNA for the antigen DNA for a ligand that can target the fusion protein to an appropriate site. Boyle et al. (89) used L-selectin to target the antigen to high endothelial venule receptors, thus enhancing the amount going to lymphoid tissue, or CTL-associated antigen 4 to target the antigen to the counterstructures CD80 and CD86 on the surface of APCs. This strategy greatly increased antibody responses and improved protective efficacy in an influenza virus model. Moreover, the approach worked in a large animal—the sheep. Pig skin is believed to be a reasonable model for human skin, and when CTL-associated antigen 4–antigen fusion constructs were delivered into pig skin by the gene gun, the targeting strategy markedly enhanced the speed and magnitude of the antibody response.

Further aspects of nucleic acid vaccines are discussed later in the section on prime-boost strategies and in the specific context of HIV/AIDS and malaria vaccines.

It is clear that something as novel as nucleic vaccines will present substantial problems for the regulatory agencies. In addition to the carcinogenicity/insertional mutagenesis possibility, the conjectural hazards include autoimmunity to DNA or as a result of immune-mediated destruction of antigen-expressing cells. The latter could lead to direct damage or could occasion the release of intracellular antigens that would then provoke autoimmunity. In practice, however, induction of autoimmunity to autologous constituents is quite difficult and proceeds only with the use of strong adjuvants such as Freund's complete adjuvant. Another objection that has been raised is the possibility that a constant leak of small quantities of antigen over a prolonged period of time could lead to immunological tolerance, thus making the recipient incapable of responding to the antigen in question. This has not been encountered in any situation so far.

Peptide Vaccines

Peptide vaccines can be either synthetically prepared or encoded by DNA. Frequently, the plan is to include a multiplicity of epitopes, particularly T cell epitopes—for example, from several different antigens of a pathogen. The approach can also deal with serotype variation of antigens, epitopes being chosen from multiple strains. Peptide vaccines suffer from the constraint that many antibodies are directed to conformational determinants. The most interesting peptide vaccine research is in HIV, malaria, and tumor immunology.

An interesting variant involving highly polymerized peptides linked to a built-in adjuvant has already been considered earlier in this chapter.

Mucosal Vaccines

It has been estimated that the combined surface area of the mucosae of the gastrointestinal, respiratory, and urogenital tracts is 400 m^2. The total lymphocyte complement of the mucosal immune system is greater than that of the lymph nodes and spleen. In fact, the mucosa-associated lymphoid tissues (MALT) contribute three quarters of all immunocytes. The mucosal immune system includes organized collections of lymphoid tissue, such as the tonsils, adenoids, Peyer's patches, and appendix, and also single lymphoid follicles. These collections contain macrophages and DCs, sample antigens, and generate both T and B cell responses, including germinal center formation. There is a high proportion of immunoglobulin A (IgA) in the antibody formed. There is also extensive infiltration of epithelia and the lamina propria with lymphocytes and plasma cells. It is believed that these represent effector cells and that there is no immune induction within these latter sites. There are also large numbers of lymphoid cells in the parenchyma of exocrine glands.

Two types of antigen-capturing cells are of importance in mucosal immunity: the intraepithelial DCs and M cells. In stratified or pseudostratified epithelia, the DCs serve much the same function as skin Langerhans cells and extend right to the surface. In tracheal epithelium, for example, there are up to 700 such cells per mm^2 forming an almost contiguous network (90). As in the case of Langerhans cells, these DCs take antigens to draining lymph nodes for immune induction. The M cells are unique features of the mucosal immune system. They exist in the epithelium overlying organized collections such as Peyer's patches. Their job is to take up antigens from the mucosa and deliver them to the mucosal lymphoid tissue via a specialized pocket in the epithelium. M cells are active in taking up both macromolecular antigens and particulate antigens such as bacteria and essentially serve to channel them to professional APCs in the lymphoid collections beneath. M cell membranes contain the glycolipid GM1, to which

CT can bind, and a variety of other carbohydrate structures with selective binding activity. Bacteria and viruses can also exploit this capacity of M cells to take them up efficiently to infect mucosae. This exploitation probably includes sexual transmission of HIV.

The lymphocyte traffic pattern differs for the mucosal immune system and the conventional immune system (91). There is a distinct tendency for mucosa-associated cells to home back to mucosal tissue but not necessarily to the same mucosa. The possibility therefore exists that immunization could occur via one mucosal surface, but an unrelated one could be protected. Nevertheless, the common mucosal immune system is more restricted than previously thought. In humans, studies with CTB administered by various mucosal routes have shown that the strongest response occurs at the directly exposed mucosa and the second strongest at adjacent mucosae (92). An exception is intranasal immunization that, apart from stimulating the respiratory tract, also induces a strong vaginal-genital tract immune response. As well as activating T and B cells, antigens delivered mucosally can also induce CD4$^+$ CD25$^+$ regulatory cells and therefore have strong suppressor activity.

Stimulation of immune responses via mucosal surfaces, leading to local IgA production and a variety of systemic B and T cell effects, suffers from two difficulties: Most nonreplicating antigens lead to immune responses only after large and multiple antigen doses, and these responses are of short duration. Even natural infection of mucus membranes leads to shorter-lived immunity than in the case of a systemic infection. This is why the field of mucosal adjuvants is particularly important.

Mucosal adjuvants include any substance or process that enhances uptake of antigen by mucosal lymphoid tissue. For example, bacteria are capable of recruiting large numbers of DCs into tracheal epithelium, and these DCs are critical to the induction of an immune response (93). Similarly, viruses can bring DCs into epithelia and can stimulate subsequent migration to draining lymph nodes. It has been argued that the increased susceptibility of neonates to respiratory infections results from the hyporesponsiveness of their immature DCs to such signals. In more mature individuals, the inherent immunogenicity of microorganisms suggests that the use of live vectors, be they bacterial or viral, engineered to express the antigen of interest, may in itself provide sufficient adjuvanticity, albeit perhaps with a limited duration of immunity.

Apart from specifically mucosal adjuvants, many adjuvant processes applicable to injectable vaccines have been used in experimental mucosal vaccines (reviewed in [92]). These include CpG ODN, VLPs, ISCOMs, liposomes, biodegradable particles, and bacterial spores.

Enteric and acute respiratory infections represent major public health problems, and HIV infection is frequently acquired through mucosal routes; therefore, vaccines

protecting mucosal surfaces are highly desirable. With regard to their construction, it must be noted that mucosal surfaces are normally colonized by a rich flora of commensal bacteria. Remarkably little is known about what permits these commensals to remain but not to overgrow. There may well be some degree of immunological tolerance at work, and oral tolerance is a well-established phenomenon. At the same time, overgrowth and invasion would appear likely were there not some level of immune response. For the intelligent design of mucosal vaccines, better understanding of this balanced situation is required. Tolerance-including strategies may be valuable as well—for example, in autoimmune situations.

Cell-mediated immune responses within mucosal tissue must also be considered. These doubtless contribute to clearance of both bacteria and viruses from mucosal areas after infection: Holmgren makes the point that with some infections, such as *V. cholerae* or enterotoxigenic *E. coli*, the infection is so superficial that neither the bacteria nor their toxins penetrate into the epithelial cells, and in that case, antibodies alone (ideally mucosal IgA) are required for protection, whereas other pathogens, such as *Salmonella* and *Shigella* infections, penetrate deeper, where IgA but also systemic immunoglobulins M and G (IgM and IgG) antibodies may be important, as may the T cell component (94). Ideally, a mucosal vaccine should protect both against toxins produced by pathogens and against antigens involved in adhesion to epithelial cells (e.g., fimbriae) or invasion of tissue. In the case of viruses, CD8$^+$ $\alpha\beta$ TCR$^+$ cytotoxic T cells that are present intraepithelially clearly contribute to protection.

Vaccines that can be considered mucosal vaccines against five diseases have been licensed (although not in all countries). These are the oral Sabin-type polio vaccine; cholera vaccine, including killed bacteria, given with CTB or live attenuated bacteria; oral live attenuated typhoid vaccine; two different oral live attenuated rotavirus vaccines; and an intranasal influenza vaccine. In view of the power of the approach, it is hoped that more mucosal vaccines will follow. Much effort is going into the use of live recombinant microorganisms as mucosal delivery systems, such as live attenuated *Salmonella* bacteria given orally or adenoviruses given intranasally, but none of these have progressed very far.

Further aspects of the mucosal approach will be raised in the section on HIV/AIDS vaccines.

Transdermal Vaccines

It has been known for decades that antigens applied directly to the skin can cause an immune response, for that is exactly what contact sensitization represents. However, the realization that direct topical application of vaccines to the skin can cause systemic T and B cell responses is relatively novel (95). It is noteworthy that the Langerhans type of DC is really quite superficial in the epidermis, and once antigen has reached the cells, the question of their activation and consequent migration to the draining lymph node depends very much on the type of stimulus. For example, if the vaccine in question is administered together with an adjuvant such as CT, the immune cascade is initiated. Simple admixture with, for example, influenza virus hemagglutinin, suffices to initiate a boostable immune response involving both the systemic and mucosal compartments. Other exotoxins, including detoxified mutants, also work well. Simple skin manipulation, such as cleansing with alcohol or hydration of the skin, may enhance responses, and patches, gels, creams, and ointments are also under investigation.

Another concept being explored for transdermal administration of vaccines is a patch consisting essentially of extremely fine needles which would minimally abrade the skin but still target antigens within the patch to superficial Langerhans cells.

Edible Vaccines

Mason et al. (96) were stimulated by the call at the 1990 World Summit for Children for a radical new approach to vaccines for developing nations, so they set about creating transgenic plants that expressed putative vaccine antigens. The long-range idea was the possibility that a readily available food, such as bananas, might come to constitute a cheap source of edible vaccines. Apart from the considerable technical hurdles involved in expression of genes for antigens in edible portions of plants, a series of immunological questions needed to be addressed. These included the avoidance of oral tolerance, ensuring sufficient oral immunogenicity, ensuring some degree of protection against enzymic degradation of vaccines, and determining adequate dosage. Despite these constraints, progress has actually been remarkably rapid. A start was made with hepatitis B surface antigen in tobacco plants. Successful engineering resulted in the accumulation of VLPs in the tobacco leaf. Similar success was achieved with VLPs of Norwalk virus capsid protein. Next, potato plants were engineered to express the B subunit of heat-labile *E. coli* enterotoxin (LT-B), in the hope that a cheap source of a mucosal adjuvant would eventually result. Mice fed 5-g samples of raw potatoes on four occasions developed serum IgG and mucosal IgA specific for LT-B. The author had the pleasure of being a visiting professor in Dr. Myron Levine's laboratory in the University of Maryland on the very day that the first clinical trial of feeding raw, engineered potatoes to human volunteers was initiated. Both mucosal and systemic antitoxin immune responses were induced. Of course, it is not anticipated that potatoes will be used in the long run, because they need to be cooked. Rather, the aim is to engineer fruit that can be fed raw to infants and small children. To that end, a transformation system for bananas

has been developed. Active research is being pursued on edible vaccines against hepatitis B, cholera, measles, and HPV.

It is envisaged that edible vaccines either will contain a mucosal adjuvant or will consist of VLPs. Either of these strategies should militate against oral tolerance. Coexpression of cytokine genes could also be envisaged. It is hoped that the plant cell wall, consisting of cellulose, pectins, and proteins, will be a partial barrier to enzymatic degradation of the enclosed antigen, allowing some to reach the small intestine, a major inductive site of mucosal immunity. Clearly, dosage for infants of various ages will have to be the subject of extensive research.

There is another and perhaps more practical dimension to the field of edible vaccines. This is to regard the transgenic plant itself not as the vaccine but rather as a factory for pharmaceutical proteins that are then extracted and processed much as they would have been from transformed bacteria or yeasts. It has been estimated that protein production costs from plants might be up to 1,000-fold cheaper than present fermentation methods (97). Three major strategies for antigens from pathogens have been developed: stable transformation of the nuclear genome, stable transformation of the chloroplast genome, and transient expression in plants using viral vectors (98). There is considerable interest in using such approaches for monoclonal antibody production as well. Of course, costs of the raw material represent only a fraction of the final vaccine cost. Field production costs have been computed for large batches of hepatitis B virus (HBV) grown in potato, tomato, corn, or tobacco leaf, and they varied from 1.36 U.S. cents to 7.11 U.S. cents per dose. Greenhouse production costs are somewhat higher. Contemplating plants as factories for pharmaceuticals obviously raises regulatory and environmental issues of an entirely new order. Yet one senses considerable excitement about the long-range possibilities.

Prime-boost Strategies

Most vaccines have to be administered on more than one occasion to achieve a satisfactory level of disease prophylaxis. Normally, booster vaccines are identical to the priming vaccines except that one or more components of a combination may be dropped. The initial impetus for a different approach came because of early disappointments with HIV envelope protein–based vaccines, which failed to produce antibodies capable of neutralizing primary isolates of HIV and failed to induce significant levels of HIV-specific CD8$^+$ CTLs. This prompted a search for alternative approaches. First, recombinant vaccinia virus engineered to express *env* was given as a primary dose to mice, followed by a booster dose of recombinant glycoprotein (gp) 160 (99). This endeavor was soon broad-

ened to include priming with other vectored vaccines and boosting with either pure protein or VLPs. Viral vectors have included various modified vaccinia variants of diminished virulence and poxviruses of birds such as canarypox and fowlpox (which do not complete their replication cycle in mammalian hosts and yet express inserted genes) as well as various adenoviruses. Less commonly, alphaviruses, polio viruses, and crippled HIV have been suggested.

Prime-boost strategies can markedly enhance antibody formation but, more important, can engender strong CD8$^+$ and CD4$^+$ T lymphocyte responses. Just why the mixed-modality approach works so well is not entirely clear. "Focused priming" of T cells by naked DNA has been invoked, a CD8$^+$ T-cell response to one or a few immunodominant epitopes then being strongly amplified by, for example, a poxvirus boost. Certainly if the only antigen shared between the priming entity and the boosting entity is the antigen of interest, it seems logical that the immune system would react in a secondary manner to only that antigen. With DNA priming and protein boosting, it has been postulated that the low doses of protein associated with priming engender a high-affinity antibody response. Different mechanisms probably underlie the different regimens. There is, however, no doubt that the prime-boost approach has conferred excellent protection in animal models of various diseases, though early clinical trials have been less impressive. The matter is examined in more detail in the sections dealing with HIV/AIDS and malaria. A useful review of prime-boost strategies was published by Ramshaw and Ramsay (81).

BACTERIAL VACCINES

Diphtheria, Acellular Pertussis, and Tetanus

Historically, the diphtheria-pertussis-tetanus combination has come to be well accepted; only about 2% of the population harbor serious reservations. In view of its importance in a developing nation and the fact that health systems are geared to it, DPT has been regarded as a "platform" on which further vaccines, such as hepatitis B, Hib, and injectable poliomyelitis vaccines (IPV), and others, such as conjugate meningococcal or pneumococcal vaccines, could be placed. Different countries follow different schedules for a primary course of DPT, such as at 2, 3, or 4 months of age; 2, 4, and 6 months of age; or, in the setting of a developing country, 6, 10, and 14 weeks of age. It is generally agreed that three doses should be administered by 6 months of age. There is also variability between countries on the timing of a booster dose, such as DPT at 18 months or diphtheria toxoid only at 3 to 5 years. Tetanus toxoid plus a low dose of diphtheria toxoid is advised again at

school-leaving age, and, ideally, a further booster should be given if a person suffers a penetrating wound (for tetanus) or travels to an epidemic or endemic area (for diphtheria). For tetanus, five doses are regarded as conferring life-long immunity, but this may not be correct. For diphtheria, a major epidemic in the countries of the former USSR, including many cases among adults, has shown that initial immunization had been inadequate, that immunity does wane with time, or both. In the United Kingdom, 25% of blood donors aged 20 to 29, but 53% of those aged 50 to 59, were found to have inadequate antibodies to diphtheria toxin. Relatively little attention has been given to adult reimmunization, but a movement for more aggressive immunization of older persons has begun. Boosters of diphtheria and tetanus every 10 years would be a very good idea.

It has already been mentioned that genetic detoxification of diphtheria and tetanus toxins is possible but that there has been little pressure to modify the traditional toxoid vaccines. Nevertheless, the mutant diphtheria protein CRM197 has been popular as the protein component of conjugate vaccines. Pertussis, however, has a reputation for being reactogenic and perhaps for causing rare more serious side effects.

For these reasons, there has been wide acceptance of a subunit (acellular pertussis, or aP) vaccine containing not killed bacteria but pure antigens derived from the bacteria. In fact, acellular pertussis vaccines have been in routine use in Japan since 1981. Renewed interest in the United States and in Europe has resulted in the testing of no fewer than 13 acellular pertussis vaccines. The key antigen is pertussis toxoid (PT), and other important antigens for protection are filamentous hemagglutinin and pertactin. Typical of the extensive clinical research that has been done on acellular pertussis vaccines is a trial in Italy, where immunization rates are relatively low and in which two acellular vaccines from SmithKlineBeecham and Chiron Biocine (renamed Chiron Vaccines in 1996) were compared with a whole-cell vaccine from Connaught Laboratories. The double-blind, randomized controlled trial involved 14,751 infants enrolled over a 1-year period in 1992 to 1993 (100). It involved 62 public health clinics and follow-up for an average of 17 months. Pertussis infection was confirmed by culture and quantitative serological tests. Unfortunately, the Connaught vaccine behaved quite atypically, giving only 36% protection. The two acellular vaccines behaved equivalently, giving 84% protection. Local and systemic adverse events were significantly less frequent with the two acellular vaccines, and their incidences were similar to those of a diphtheria toxoid vaccine without the pertussis component.

The chief difference between these two vaccines was that in the SmithKlineBeecham vaccine, the PT was detoxified by chemical treatment, whereas the Chiron Biocine vaccine contained a mutated, nontoxic form of PT that had been genetically detoxified. Site-directed mutagenesis introduced two point mutations (Arg 9→Lys and Glu 129→Gly) in the enzymic site of the PT. This vaccine caused a higher anti-PT response than that containing chemically inactivated PT, and continued blinded observation for a further year revealed significantly fewer pertussis cases in the Chiron Biocine group. A brief review by Rappuoli (101) gives a sobering insight into what is involved in bringing a new vaccine to the market. The project started in 1984. The cloning and sequencing of the PT gene was achieved in 1985; the amino acids that needed to be changed to remove toxicity were identified in 1987; the filamentous hemagglutinin was cloned in 1988 and the *B. pertussis* strain producing the nontoxic PT was constructed in 1989. Phased clinical trials were started as follows: phase I, 1989; phase II, 1990; phase III, 1992; end of phase III, 1995; filing of worldwide product license application worldwide, 1996. Introduction of new and improved vaccines is not for the faint-hearted!

An analysis of six acellular pertussis vaccines from nine trials was presented by Klein (102). In three of the trials, the acellular vaccine was about 10% less protective (84% versus 93%, 89% versus 98%, 85% versus 96%), but the differences did not reach statistical significance. The author is not aware of any meta-analysis of these data. However, an interesting review of all available clinical trial data was presented by Miller (103), reaching the tentative conclusion that a five-component vaccine—including not only pertussis toxin, filamentous hemagglutinin, and pertactin, but also fimbrial antigens 2 and 3—gave the greatest protection. These last two proteins are not the primary adhesins for the target cell surface but rather may serve to sustain attachment. Among other questions, it remains to be determined how long protection lasts with these newer vaccines. At the moment, there is no major push to switch over to these more expensive vaccines in developing countries, but the trend to the less reactogenic preparations is marked in the industrialized world and probably will prove irresistible globally.

Pertussis affects all ages, although morbidity and mortality rates are highest among children younger than 1 year. Because antibiotics appear to be of little use when symptoms are fully established, the intravenous administration of high-titered anti-pertussis immune globulin must be considered.

There are some doubts about the duration of immunity to pertussis, even with regard to the natural disease itself, and there is increasing evidence of this organism as a cause of prolonged cough illnesses in adolescents and adults. This raises the issues of regular booster immunization, not currently practiced, and of the highest possible infant coverage to achieve eventual herd immunity. There have been recent calls for tetanus-diphtheria-acellular pertussis (Tdap) boosters to replace Td boosters, especially for nurses and other healthcare workers.

Diarrheal Disease Vaccines: Typhoid, Cholera, Enterotoxigenic *E. coli,* and Shigellosis

Vaccines consisting of killed whole typhoid or cholera bacilli were among the earliest developed. However, efficacy was distinctly suboptimal, and local reactions at the injection site and within draining lymph nodes were marked. This approach has been virtually abandoned, and much progress has been made toward newer vaccines.

Typhoid Vaccines

Typhoid fever, which is far more than a diarrheal disease because *Salmonella typhi* is an invasive organism that causes severe parenteral toxicity, remains a serious public health problem. The disease is both waterborne and foodborne in countries with poor sanitation, but it is now quite rare in industrialized countries. There are an estimated 16 million to 33 million cases annually, with 500,000 to 700,000 deaths. In endemic countries, the majority of patients are between ages 5 and 19, which makes school-based immunization an attractive possibility. Unfortunately, routine immunization is not yet occurring, and the effective present-day vaccines are almost entirely confined to use by travelers and armed services personnel. This is a pity, as a study in Egypt concluded there were 59 cases per 100,000 population per year, of which 20% were multidrug resistant.

The live attenuated orally administered *S. typhi* strain Ty21a has been licensed in the United States since 1991. This was derived from the wild-type strain Ty2, which has been maintained in the laboratory since 1918, and the vaccine strain was developed in the early 1970s by chemical mutagenesis. The vaccine can be given orally as enteric-coated capsules. Tests on 200,000 children in Chile showed a protective efficacy of 62% for up to 7 years. Alternatively, a liquid formulation is now available that seems to be more effective, yielding 79% efficacy among 36,000 children aged 5 to 19 (104).

The second typhoid vaccine is an injectable form consisting of the Vi antigen. This is a linear homopolymer of galacturonic acid and forms a part of the capsular polysaccharide of the organism. A single dose of carbohydrate only is 55% effective, protecting for two but not three years. At the International Vaccine Institute in Korea, Clemens' group is coordinating a program known as DOMI (diseases of the most impoverished) funded by the Bill & Melinda Gates Foundation. They have tested a Chinese Vi antigen produced locally. A study of 118,588 persons aged 5 to 60 undertaken in southeast China (105) achieved vaccination coverage of 78% and showed mass immunization to be feasible and safe. The same vaccine had proven 71% effective during a 1999 outbreak. A Vi conjugate vaccine has been prepared in the hope that, like other conjugate vaccines,

it might prove more effective and work at younger ages. A landmark study by Lin et al. (106) used the Vi polysaccharide conjugated to recombinant *Pseudomonas aeruginosa* exoprotein A in a double-blind, randomized, placebo-controlled trial on 11,091 Vietnamese children aged 2 to 5. Two doses were given, 6 weeks apart, and a 27-month follow-up study (including blood culture) showed a remarkable 91% to 95% efficacy (4 cases among 5,525 vaccinees and 47 among 5,566 controls). Even one injection caused good protection. This vaccine is clearly the best currently available.

Robbins' group at the National Institutes of Health have come up with an original idea that might materially cut costs. They have initiated a trial (not fully recruited in 2006) of a di-O-acetyl derivative of fruit pectin as a mimic resembling the Vi antigen. This carbohydrate is abundant, cheap, and contains no LPS, and the chemical conversion is straightforward (107). O-acetyl pectin has also been conjugated to *P. aeruginosa* exoprotein A.

Cholera Vaccines

Cholera is a much-feared disease caused by the waterborne and highly infectious bacterium *V. cholerae,* which has caused devastating epidemics in many parts of the world. Although oral rehydration represented a real breakthrough, case-fatality rates can still reach 20%; the very young and the very old are most susceptible. Through the decades, there has been much strain variation. Since 1961, the biotype El Tor of serogroup 01 has been dominant, and since 1992, the new and more virulent variant 0139 has been a threat (see later discussion). Cholera accounts for an estimated 120,000 deaths each year.

Humans are the only known natural host for *V. cholerae,* although it is also known to be able to survive in water for very long periods. Transmission is due to fecal contamination of water or food, and direct transmission from person to person is thought to be rare. Invasion does not occur, and pathological processes are caused by the toxin and the profuse watery diarrhea that it induces. Protection is through mucosal antibodies.

In a troubled world, a cholera vaccine would take on new significance. Refugee camps represent populations at special risk. In this situation, vaccination should be undertaken preemptively. Once an epidemic is under way, it is probably too late.

More than 100 years after Koch's discovery of the cholera bacterium, we still do not have wide use of a vaccine, although good candidates have been licensed. This is a pity, as a natural infection can produce fairly solid immunity of substantial duration. However, progress has been heartening, including some third-world production.

Extensive work has been done on a Swedish oral vaccine (108) consisting of a mixture of the CTB and killed whole bacteria. The rationale for recombinant CTB is that

it, a nontoxic component of cholera toxin, can give rise to toxin-neutralizing antibodies that can fully protect animals not only after toxin administration, but also after challenge with virulent *Vibrio cholerae*. Further, CTB is stable in the intestinal milieu and binds with high affinity to M cells, thus initiating the immune cascade. This anti-toxic immunity synergizes with antibacterial intestinal immunity conferred by the killed whole-cell vibrios. As currently formulated, each dose of the vaccine Dukoral contains 1 mg of recombinant CTB and 10^{11} vibrios including inactivated Inaba, El Tor, and Ogawa strains.

A large clinical trial in Bangladesh conducted among 62,285 children and women showed good but transient vaccine efficacy (109). For the first 5 to 6 months, protection was 85% (100% in children aged 2 to 5), but this had fallen to 64% by 1 year, 52% at 2 years, and only 19% at 3 years. Adults showed 78% and 63% protection for the first or second year. It appeared important to establish the safety and efficacy of the vaccine in a region with high HIV/AIDS prevalence. Accordingly, the vaccine was used in a mass oral immunization program in Beira, Mozambique, where seropositivity to HIV is 20% to 30% in adults (110). The vaccine in two doses yielded 78% protection and was equally effective in young children and adults. Of the estimated 19,550 persons in the target population, 72% received the first dose and 57% both doses. Although cholera victims were not tested for HIV, the absence of serious side effects suggests that the vaccine is safe to use in seropositive individuals. The trial represents a significant step in validating oral cholera immunization where it is needed most.

A further variant of cholera has emerged in Madras, India. This variant, *V. cholerae* serogroup 0139, has spread rapidly in India, Bangladesh, and adjacent countries and has reached as far as Malaysia, Thailand, and China. Accordingly, formalin-killed 0139 *Vibrio* organisms were added to the existing 01 vaccine, and intestinal and systemic immune responses against both strains were elicited in a majority of human volunteers. This suggests that the development of a bivalent vaccine will be relatively straightforward.

Beautiful work has been done under difficult circumstances in Vietnam. Trach et al. (111) recently reported on an oral killed whole-cell *V. cholerae* vaccine without CTB, consisting of two doses of a mixture of Inaba and Ogawa strains, that was subjected to trials in 134,453 people in Vietnam. This vaccine was locally produced in Hanoi and was inexpensive at about U.S. 10 cents per dose. During an epidemic about 8 months after immunization, it proved 66% protective. Despite some admitted limitations in the trial protocol, the results are promising. Recently a bivalent vaccine containing also serogroup 0139 has been prepared and is undergoing trial.

Several live attenuated strains of *V. cholerae* have reached clinical trial. All these have been constructed to possess known genetic deletions to reduce virulence. The most advanced strain is CVD103-HgR, a live oral cholera vaccine strain constructed by recombinant DNA methods from a classical Inaba strain in which the A subunit of CT has been deleted. This was safe and immunogenic in North American volunteers, provides significant protection against experimental challenge (112), and in 1993 a large-scale, randomized, placebo-controlled field trial was initiated in North Jakarta involving a single oral dose of vaccine. About 67,000 subjects aged 2 to 42 were involved. Unfortunately, in a 4-year follow-up, the vaccine could not be shown to be efficacious. The results were somewhat confounded by an unexpectedly low incidence of cholera during the first year of the trial. Although the results showed 60% protection over the first 6 months and 24% protection during the first year, the low numbers make these results uncertain. Some good results did come out of this trial, however. The vaccine was well tolerated, even in infants as young as 3 months, and it did not interfere with the oral typhoid vaccine Ty21a. Further work on CVD103-HgR is in progress. It is reasonable to conclude that it is a good vaccine for travelers, because protection is evident already 7 days after a single dose and the product (Orochol) is licensed in several countries. Convincing protection in field situations remains to be demonstrated. An attenuated 0139 live oral vaccine, known as CD112, has also been prepared and confers good protection against challenge with wild-type 0139.

Pearson et al. (113) constructed a new series of live attenuated oral cholera vaccines that are based on the deletion of a whole "virulence cassette." Instead of deleting just the CT gene, additional associated virulence factors are deleted. These include the genes for zona occludens toxin, auxiliary cholera enterotoxin, and core-encoded pilus. Certain sequences encouraging recombination were also deleted to prevent the strain from regaining CT genes. Further, mobility-deficient variants were found to be less reactogenic. Volunteer studies with two of these, Peru-15 for *V. cholerae* 01 and Bengal-15 for *V. cholerae* 0139, look promising for a one-dose oral vaccine.

Vaccines Against Enterotoxigenic Escheria coli (ETEC)

Enterotoxigenic *E. coli* is a major cause of traveler's diarrhea and also causes illness ranging from mild to very severe in young children in developing countries. The pathogenesis of the disease is either heat-labile enterotoxin (LT), heat-stable enterotoxin (ST), or both. LT cross-reacts with CTB and so the oral CTB-whole cholera vaccine is partially protective against it. A specific ETEC vaccine should contain both an LT toxoid (as the ST toxin appears to be poorly immunogenic) and antigens from the fimbrial proteins, which help to attach the *E. coli* to the small intestinal mucosa. These attachment proteins or

colonization factors (CFs) are strain specific, and the most prevalent ones would have to be included. In the meantime, an ETEC vaccine consisting of recombinant CTB and formalin-inactivated whole-cell ETEC bacteria expressing five CFs has been in clinical trial (114). In travelers, it has 77% to 82% protective efficacy against severe diarrhea, but protection against mild diarrhea was less impressive. In children in rural Egypt the vaccine failed to protect except in a subset with high immune responses. This argues that CFs plus LT toxoid should be tried.

Another strategy of some promise is to use attenuated *Shigella* bacteria as a vector in which both CFs and detoxified LT are expressed. In guinea pigs, this approach engenders good mucosal immunity (115). However, this is no guarantee that the approach would work in the real-life setting of the intestinal tract of third-world infants. The latest developments concerning this Shigella-ETEC approach are considered in the next section.

Shigella Vaccines

The author was probably among the majority of medical graduates to express surprise when he learned that shigellosis or bacillary dysentery was a bigger public health problem than either typhoid or cholera. It is one of the most serious diarrheal diseases in the world, with an estimated 175 million episodes per annum and 800,000 deaths (116). Both case numbers and estimates of mortality need to be reestimated, because diarrheal disease mortality as a whole is clearly falling. The most important organisms are *Shigella flexneri, Shigella sonnei, Shigella boydii,* and *Shigella dysenteriae. S. flexneri* predominates in developing countries, and *S. sonnei* in industrialized countries, the latter type of country accounting for fewer than 1% of episodes. Each species has multiple serotypes; there are about 30 serotypes altogether, a frustrating fact for the vaccine developer. Usually, a given serotype predominates in a given area at a given time.

Clinical findings of shigellosis include diarrhea, which can vary from mild to extremely severe with ulcerative lesions of the colon and significant blood in the motions. Fever, dehydration, and metabolic disturbances are common, and hemolytic uremic syndrome is a serious complication.

Shigella is, in fact, a facultative intracellular parasite that invades the colonic and rectal mucosa. Invasion of M cells and other APCs occurs, and lymphoid collections can be rapidly destroyed. Systemic and mucosal humoral immune responses are elicited by an infection, and the LPS of the organism is of great importance, because antibodies to it can protect against bacterial challenge. In fact, the two most advanced lines of research into a vaccine involve parenteral O-specific polysaccharide-protein conjugates and live attenuated mutant shigella organisms given

orally. Further approaches include an intranasal proteosome vaccine, a ribosomal vaccine, and vectored vaccines.

Among the live attenuated orally active vaccines, much work has been done by Sansonetti and Phalipon (117) on a deletion mutant of *S. flexneri* serotype 2a strain SC602. This carries both an auxotrophic mutation (deletion of *ivcA*) and one diminishing virulence (deletion of *icsA,* also known as *virG*). An attractive feature of this vaccine is that oral administration of as few as 10^3 to 10^4 live organisms elicits a good local IgA response. In a series of clinical trials, a total of 58 North American volunteers experienced significant reactogenicity in 30% of cases, but interestingly this was not the case in an adult phase I trial in Bangladesh (120) in either adults or children. Unfortunately, these volunteers did not mount an antibody response, so for them at least SC602 appears to have been over-attenuated. Nevertheless, trials of higher doses are planned. This group has also developed a live attenuated *Shigella dysenteriae 1* vaccine strain SC599. The Pasteur Institute is currently (October 2006) recruiting for a phase II immunogenicity and safety clinical trial of two oral doses of this candidate.

Kotloff et al. (118) have developed the CVD series of attenuated vaccine candidates. CVD 1203 is an attenuated *S. flexneri 2a* with deletions in *aroA* and *icsA*, escalating doses showing increasing immunogenicity but also increasing reactogenitity. CVD 1207, with deletions that prevent enterotoxin formation, was less reactogenic but also less immunogenic. CVD 1208, with deletions in *guaBA, set,* and *sen,* was satisfactorily immunogenic with little reactogenicity. The University of Maryland group believes (119) that a multivalent *Shigella* vaccine providing broad coverage against disease will have to include *S. flexneri 2a, S. flexneri 3a, S. flexneri 6, S. sonnei,* and *S. dynenteriae 1*. Attenuated forms of *S. sonnei* (CVD1233) and *S. dysenteriae* (CVD1252) have been prepared. These strains are also being evaluated for use as live vectors for ETEC antigens including fimbrial and LT components. In a similar effort, SC608, a derivative of SC602, engineered to express ETEC fimbrial and enterotoxin antigens, performed well when given intranasally to guinea pigs as a combined Shigella-ETEC vaccine (120).

A further attenuated vaccine is the *S. sonnei* strain WRSS1 that contains an *icsA* deletion. Tested in Israeli army volunteers, it proved to be reasonably immunogenic and well tolerated.

As a final live attenuated approach, the typhoid vaccine strain Ty21a was engineered to carry *Shigella* LPS antigens. Early results look promising in both mice and a small number of human volunteers.

Parenteral vaccination represents a complete alternative and has been pioneered by Robbins and Schneerson (121), rightly honored for their role in the invention of the *Hemophilus influenzae B* conjugate vaccine. As the O-specific polysaccharide domain of the LPS of *Shigella* is essential for its virulence, this antigen conjugated to

protein should make a good, T cell–dependent vaccine. In a small-scale efficacy trial, such a conjugate from *S. sonnei* conferred 74% protection to Israeli military recruits who suffered from a high rate of shigellosis during their basic training. Synthetic tetrasaccharides of increasing length corresponding to the O antigen of *S. dysenteriae* have also been prepared and conjugated, the optimal synthetic configuration proving to be significantly more immunogenic than the natural product. Altogether, this approach looks very promising.

Other inactivated vaccines under investigation include 3 to 5 oral doses of whole killed bacteria; an intranasal proteosome vaccine consisting of 1 mg of LPS noncovalently complexed with outer membrane proteins from *Neisseria meningitidis*, which proved reasonably protective in volunteers; purified ribosomes from *Shigella* bacteria, which have O antigen covalently bound and can be given parenterally; and 34kDa outer membrane protein from *Shigella flexneri* 2a, which, when injected, elicits a good protective response in animals (122).

So the research scene bristles with promising candidate *Shigella* vaccines, but clinical trials in developing country settings are now urgently required.

Helicobacter pylori Vaccines

In 1983, one of those rare true breakthroughs in medicine occurred. Peptic ulcer, a classical and common disease, had been thought to be caused by stress and hyperacidity. Instead, Marshall and Warren (123) attributed it to a spiral bacterium, soon identified as *Helicobacter pylori*. This discovery from Australia was greeted with great skepticism but was supported by Marshall's brave attempt to fulfill Koch's postulates through infecting himself, which resulted in gastritis and re-isolation of the organism, after which he cured himself with antibiotics. It is now generally accepted that *H. pylori* accounts not only for the majority of gastric and duodenal ulcers, but also for acute gastritis, chronic active gastritis, a significant proportion of gastric adenocarcinomas, and essentially 100% of B cell lymphomas of gastric MALT. Marshall and Warren's 2005 Nobel Prize was thoroughly well deserved.

Although the WHO had classified *H. pylori* as a class I carcinogen in 1994, it was only in 2001 that Uemura et al. (124) put the issue beyond doubt with a long-term prospective study of 1,526 Japanese patients with dyspepsia who were monitored for a mean period of 7.8 years. Of these, 1,246 had *H. pylori* infection and 280 did not. Within the study period, 36 gastric cancers developed, of which 23 were intestinal-type cancers and 13 were diffuse-type cancers. Every single cancer occurred among the infected patients ($p < 0.001$). Kaplan-Meier analysis showed the gastric cancer risk to be 5% in the infected group at 10 years.

Infection is acquired mostly during childhood and persists chronically if not treated, but it is reasonably easily cured by so-called "triple therapy" consisting of a proton-pump inhibitor and two antibiotics (e.g., metronidazole and ampicillin).

Many aspects of the epidemiology of *H. pylori* remain mysterious. Transmission is believed to be oral, through vomitus or diarrheal feces. Infection may result in a brief period of acute gastritis, after which the carrier has few or no symptoms for years or even decades. Infection is incredibly common, typically 40% in industrialized countries and up to 90% in some developing countries. However, of these infected people, only 15% to 20% eventually develop severe gastric or duodenal disease. The degree to which these bacteria represent a public health problem is still not generally appreciated. In the United States, it has been estimated that up to 25 million persons are ill with this infection at some stage of their lives. In these cases, re-infection after cure is rare, perhaps 1% per year, but in developing countries, it could be expected to be much higher. In such settings, a prophylactic vaccine would be especially desirable.

H. pylori is a gram-negative spiral, microaerophilic, flagellated bacterium that produces an amazing amount of the enzyme urease, which can make up 5% to 10% of the bacterium's protein. This converts gastric fluid urea to ammonia and carbon dioxide, a very efficient buffering system against stomach acid. Urease-negative *H. pylori* strains appear unable to colonize the stomach. We know much too little about why only some infected people develop chronic gastric disease. The best hint (125) comes from strain variation in the bacteria. Specifically, strains of type I possess a 40-kb fragment of DNA that comprises 31 genes and constitutes a pathogenicity island. Important within this area are the antigen CagA and genes that encode a secretion machinery that allows the active transfer of molecules from the bacterium to the gastric epithelial cell on which the bacteria reside. So-called type I strains express CagA (and appear to be more virulent), whereas type II strains do not. Further, type II strains are sometimes low expressers of another gene, that for the vacuolating cytotoxin VacA, which is thought to be important in pathogenesis. More work needs to be done on strain subtyping.

Neutrophil infiltration is a prominent feature in biopsy specimens from *H. pylori*–infected stomachs. An *H. pylori* 15-kDa protein that is chemotactic for neutrophils and monocytes and is a strong inducer of the production of reactive oxygen intermediates in neutrophils has been identified. This has been termed *neutrophil-activating protein* (NAP). Other possible candidate vaccine antigens of *H. pylori* include flagellin, various adhesins, heat-shock proteins, and LPS.

Animal models have provided proof of principle that both prophylactic and therapeutic *H. pylori* vaccines are feasible. Lee et al. (126) isolated a gastric spiral bacterium

from cats, and this organism, *Helicobacter felis,* can colonize the mouse stomach and cause gastritis and even lymphoma. With this model in place, it was soon shown that a sonicate of *H. felis* was a protective vaccine in mice, providing 96% protection against oral challenge. A further important development was that of adapting fresh clinical isolates of *H. pylori* to grow in the mouse stomach by biweekly serial passage through specific pathogen-free mice. This resulted in the development of (a) one strain, derived from a type I clinical isolate, that caused gastric pathological processes mimicking those in the human, and (b) of another strain, derived from a type II clinical isolate, that caused only a mild inflammatory infiltrate without erosive lesions.

These considerations naturally led to the possibility of subunit vaccines. *H. pylori* urease was the first antigen in clinical trial, because it confers protection in animal models. The results of the first studies were not too impressive, although there was some reduction in the bacterial load. Both CagA and VacA are being assessed as possible oral immunogens in the *H. pylori* mouse model, with the addition of the genetically detoxified *E. coli* heat-labile enterotoxin, LTK63, as a mucosal adjuvant. Early results appear encouraging, as do those with CagA, VacA, and NAP in combination.

What about therapeutic intervention? Doidge et al. (127) achieved eradication of *H. felis* in infected mice with an oral administration of *H. felis* sonicate and CT as a mucosal adjuvant. Similarly, Corthesy-Theulaz et al. (128) successfully used the *H. pylori* urease B subunit as an oral treatment in mice. These results give encouragement for clinical therapeutic vaccine trials. It is probable that Th1 T cells are responsible for much of the inflammatory damage in the stomach, and a change in the balance toward a greater proportion of Th2 cells may be helpful. This accentuates the importance of a safe and effective adjuvant suitable for human use.

A beagle dog model of *H. pylori* infection has been developed, enabling serial gastric biopsies and thus dynamic evaluation of progressive pathological processes (129). In this model, encouraging results have been obtained with systemic immunization with a variety of recombinant proteins, including VacA, CagA, and NAP, simply adsorbed onto alum. A phase I human study validated the safety and immunogenicity of this combination. In view of the relatively low rate of acquisition of infection in industrialized countries, it is likely that any subunit combination vaccine arising from this research will have to be tested in areas with high transmission rates, such as in less developed countries or high-susceptibility ethnic minorities. However, this has not occurred, and one senses a degree of frustration from Doidge at the slow rate of progress (130). He considers the current generation of vaccines as insufficiently successful and pleads for new targets and adjuvants. The Chinese University of Military Medical Science

is recruiting a phase III clinical trial of an oral *H. pylori* vaccine involving 10,000 volunteers, but no details of this vaccine are available.

If a safe, effective vaccine conferring a substantial period of protection can be developed, the approximately 1% lifetime risk of gastric cancer would, by itself, justify universal use; in view of the additional severe morbidity arising from chronic gastritis, gastric dysplasia, and peptic ulcer disease, the case becomes very strong indeed.

Vaccines Against Encapsulated Organisms

Haemophilus Influenzae B

Vaccines traditionally available for encapsulated organisms such as those just described have been prepared from purified capsular polysaccharide antigen. These vaccines suffer from two major disadvantages. First, being polysaccharide in nature, they do not engage the T cell limb of the immune response. This means that the antibodies are chiefly IgM, affinity maturation does not occur, and, most important, young infants do not respond well. Because the incidence of Hib meningitis peaks at around 10 to 11 months of age, a vaccine that is not really effective before the ages of 18 to 24 months is far from ideal.

The first-generation Hib vaccine, based on the polyribosylribitol phosphate (PRP) capsule, was developed almost simultaneously by Anderson et al. (131) and Rodrigues et al. (132). An extensive clinical trial involving 130,178 Finnish children was performed by Peltala et al. (133). No protection was noted in children younger than 18 months, even in those given a booster dose, but just a single dose in children aged 18 months to 5 years of age gave good protection against invasive Hib disease.

The second problem for these vaccines is that, in each case, there are multiple serotypes. With Hib, six capsular serotypes, a to f, are capable of causing disease in humans; fortunately, 99% of typeable strains causing invasive disease are type b. As we shall see, the problem is much worse for meningococci and pneumococci.

The same groups that pioneered the carbohydrate vaccine were involved in the breakthrough that yielded the extremely effective Hib conjugate vaccine (134,135). These researchers made use of the principle of conjugating antigenic Hib PRP saccharides to protein carriers to induce a T cell–dependent response, which matures much earlier in the human than does the T cell–independent response to saccharides alone. Different-length saccharides and different carriers were used by different companies; small, medium, and large polysaccharides were attached, with or without linkers, to diphtheria toxoid, the diphtheria toxin variant CRM_{197}, tetanus toxoid, or the group B meningococcal outer membrane complex. Eskola et al. (136) led the way with a clinical trial in Finland in 1986 to 1987 in which the vaccine was 83% effective and also eliminated

oropharyngeal carriage. A further trial with an improved vaccine in 1988 to 1990 showed higher, more persistent antibody levels and better efficacy. From about 1990 on, there has been an increasing number of countries with national vaccination programs, and the result has been a dramatic decline in invasive Hib disease because of immunity, herd immunity, and lowered pathogen carriage rates. Already by 1991, meningitis incidence had decreased by 82% in the United States. In many countries, Hib meningitis is simply not seen anymore. It may not be too early to hope for the eventual control and near-eradication of this pathogen. Particularly encouraging is the fact that the conjugate vaccine works well in the setting of a developing country. Mulholland et al. (137) performed a double-blind randomized trial in The Gambia involving 42,848 infants who were given either DPT alone at 2, 3, and 4 months or DPT mixed with Hib polysaccharide-tetanus protein (PRP-T). Hib meningitis, Hib pneumonia, and five other forms of invasive Hib disease were evaluated over a 3-year period. Among the children (83%) who received all three doses, the efficacy of the vaccine for the prevention of all invasive Hib disease was 95%; for the prevention of Hib pneumonia, 100%; and of meningitis, 92%. Further, there was a 21.1% reduction of *all* cases of radiologically defined pneumonia.

Given the importance of acute respiratory disease as a killer of infants in developing countries, the Hib vaccine is progressively being added to routine infant immunization programs. Manufacturers are making vaccine available to poor countries at reasonable prices and combinations (e.g., DPT-hepatitis B-Hib) are helpful in reducing the number of injections required. There is evidence that Hib may be somewhat less of a problem in Asia than in Africa, and this is patiently being explored country by country. The conjugate vaccine is being widely used in Latin America.

Neisseria meningitidis

Neisseria meningitidis or the meningococcus causes a frightening disease with sudden onset and severe complications. Further, survivors may suffer lasting damage such as epilepsy, mental retardation or hearing loss. In contrast to Hib, which mainly strikes infants, meningococcal disease can occur at any age, with peak incidences in young children and adolescents and young adults. There are 13 identified serogroups based on the chemical structures of their capsular polysaccharide coats, of which the most important are A, B, C, Y, and W135. Most outbreaks in the industrialized world are serogroup B or C, whereas the commonest epidemic strain in Africa is A. There are also rare nontypeable strains, some of which have been proven to be serogroup B with poor expression of the capsular polysaccharide.

Two recent meningococcal public health measures are of particular interest. The first concerns control of African meningitis epidemics. These occur from December to June in the dry season in the countries of the so-called "meningitis belt" of Sub-Saharan Africa stretching from The Gambia and Senegal in the west to Ethiopia and Somalia in the east. The population at risk numbers 430 million people. A bad epidemic may result in 200,000 cases, with a 10% case fatality and 10% to 15% serious sequelae. Outbreak control previously depended on deployment of the meningococcal polysaccharide vaccine. In 2001, the Bill & Melinda Gates Foundation provided $70 million for the Meningitis Vaccine Project, a partnership between WHO and the Program for Appropriate Technology in Health (PATH). This called for expressions of interest in the development of a conjugate vaccine for *N. meningitidis* serogroup A, and eventually the Serum Institute of India in Pune was chosen as the commercial partner, with a view to providing 25 million doses annually at a cost of 40 U.S. cents per dose. The strategy called for industrialized country producers to supply both the serogroup A polysaccharide and the carrier tetanus toxoid, and for an experienced contract research organization to transfer the conjugation technology to India. In the event, all these steps were successfully completed and in March 2006 a successful phase I clinical study on 74 subjects found the vaccine to be safe and immunogenic. Phase II studies in The Gambia and Mali are commenced in late 2006. If all goes well, the vaccine will be through all testing and widely deployed in 1 to 29 year olds in 2009. Eventually infants will be immunized as well. As an epidemic of W135 meningitis has occurred in Burkina Faso, careful sero-surveillance will be required and a bi- or multivalent vaccine may eventually be needed.

The second series of programs relate to industrialized countries and the control of meningococcus C. A major campaign in the United Kingdom beginning in November 1999 introduced the conjugate vaccine into their routine 2, 3, and 4 months-of-age program. In addition, vaccine was offered to all persons under 18 in a catch-up campaign. The program was highly successful in virtually eliminating this form of meningitis (138), and follow-up studies have shown vaccine effectiveness to remain high 4 years later in those immunized from 5 months to 18 years of age, but less so in those immunized earlier (139). This suggests a booster in the second year of life might be wise. Herd immunity certainly played its part in the success. Successful programs have also been reported from Spain and Scotland, whereas in the Netherlands a single dose of vaccine at 14 months appears to be satisfactory.

A serious problem remains with meningococcus B, which causes 32% of meningococcal disease in the United States and more than 45% in Europe. The group B polysaccharide is composed of a homolinear polymer of (α2.3-8) N-acetyl neuraminic acid. Not only is this poorly immunogenic even when conjugated to protein, probably for reasons of immunologic tolerance, but also long-chain polysialated glycoproteins are abundant in immature brains, raising the specter of neurological damage if

ways were found to break the tolerance. Attempts have been made to replace the native N-acetyl groups with N-propionyl groups, with some success. Alternatively and preferably, protein-based vaccines are being developed. Outer membrane vesicles can be prepared by detergent extraction from bacterial cells. These contain the major porin proteins as well as lipopolysaccharide and have had some success in outbreak control, but not in infants or young children (140). Further, the porins are subtype specific. A much more modern approach involves the technique of "genome mining" (141). In this project, the whole genome of the group B meningococcus MC58 was sequenced and 2,158 open reading frames were identified. Algorithms were used to identify proteins that might be exposed on the surface. Further, emphasis was placed on sequences homologous to group A meningococci and a *N. gonorrhea* strain. A total of 344 probably surface-exposed and conserved sequences were cloned, expressed in *E. coli* and injected into mice. Among these, 28 novel proteins that elicited antibodies that bound to the bacterial surface and had bactericidal activity were identified. A few elicited bactericidal titers comparable to those obtained by the outer membrane vesicle vaccine. From this group, five antigens were selected as inferred by high bactericidal activity or passive protection of mice or rats (142). These were combined into a multicomponent vaccine that was found to produce broad-based immunity. With alum as an adjuvant, mice made antibodies capable of killing 70% of a panel of 85 meningococcal strains from recent clinical isolates representative of global population diversity. When either CpG-ODN or MF59 was used as an adjuvant, this figure increased to 90%. Clinical trials are now planned. The genome mining "reverse vaccinology" approach involving isolation of new antigens and testing of resultant antisera against large collections of pathogen isolates holds promise for other protein-based vaccines.

In the meantime, a combined A, C, Y, W135 conjugate has been successfully trialed, and it remains to be seen where this will fit into the marketplace given that B and C are the dominant strains in the industrialized world. For the author, who feared missing the diagnosis of a meningitis case more than almost anything else during his hospital resident days, the thought of a "meningitis package" vaccine, including Hib and perhaps nontypable *Hemophilus,* would be like a dream come true.

Streptococcus pneumoniae

Streptococcus pneumoniae, the pneumococcus, is the leading cause of severe pneumonia in children and can also cause meningitis and septicemia, as well as less severe respiratory infections and otitis media. It also affects adults, particularly the elderly. It causes 800,000 to 1 million child deaths each year and an additional 800,000 deaths in adults. More than 90% of pneumococcal pneumonia

deaths in children occur in developing countries, and children with HIV/AIDS are 20 to 40 times more likely to get invasive pneumococcal disease than other children. An effective vaccine is thus a tool of immense public health importance. There are more than 80 pneumococcus serotypes based on the polysaccharide capsule, but Merck's 23-valent carbohydrate vaccine, which has been available since 1983, covers most of the pathogenic isolates. This vaccine works well in children over 2 years and in adults, but for infants, a carbohydrate-protein conjugate is required. Several large firms have prepared and tested conjugate vaccines of 7 to 11 serotypes, but only one vaccine has been licensed, Wyeth's 7-valent Prevnar. A phase III clinical trial involving 37,000 Californian infants resulted in 22 observed cases of invasive pneumococcal disease caused by organisms of one of the 7 serotypes in the control group but zero cases in the immunized group ($p < 0.0001$). This 100% efficacy raises the question of whether any further controlled trials would be ethical. However, conditions in developing countries are different, so results of a large trial in The Gambia were greeted with great interest (143). A 9-valent conjugate vaccine containing 8 serotype-specific polysaccharides and one oligosaccharide conjugated to the diphtheria toxoid CRM-17 was used. The randomized, placebo-controlled, double-blind trial involved 8,718 vaccinees aged 6 to 51 weeks and 8,719 controls. Three doses were given at least 25 days apart, and over 95% of the children actually got all 3. The primary endpoint was radiologically proven pneumonia, and the vaccine efficacy was 37% against all causes of pneumonia. Secondary endpoints included invasive pneumococcal disease caused by vaccine serotypes, with 77% efficacy, and mortality from any cause at all, with a heartening 16% reduction. These results demonstrate that a pneumococcal conjugate vaccine would be a real boon in a developing country setting.

GlaxoSmithKline is developing an 11-valent pneumococcal vccine where the polysaccharides are conjugated to *Hemophilus influenzae* protein D as a carrier protein. An interesting large study conducted in the Czech Republic and Slovakia looked at the effects of this vaccine on otitis media, a very common childhood infection accounting for more than 20 million visits to a pediatrician each year in the United States (144). The two leading bacterial pathogens are *S. pneumoniae* and nontypable *H. influenzae*. The vaccine design was such as to kill two birds with one stone. In the randomized trial involving 4,968 infants, subjects received either this conjugate vaccine or hepatitis A vaccine as a control, and four doses were given at 3, 4, 5, and 12 to 15 months of age. Children were followed until the end of the second year of life. The vaccine was 34% effective against all otitis media, 58% effective against otitis media caused by pneumococcal serotypes included in the vaccine, and 35% effective against otitis caused by nontypable *H. influenzae*. The vaccine also

reduced nasopharyngeal carriage of both pathogens. The efficacy against serotype-caused otitis was similar to that in prior Finnish studies. While pneumonia as such was not studied in this case, the combined vaccine must be considered quite promising. It is now being studied in a global clinical program but will not be available for several years.

Obviously, the more serotypes need to be included, the more expensive the conjugate vaccine will be. Therefore, it is a pleasure to record that in 2006 the Bill & Melinda Gates Foundation initiated a large granting program to speed the search for a common protein-based pneumococcal vaccine.

Intracellular Pathogens, Especially Tuberculosis and Leprosy

Bacteria that exploit the scavenger cell system and successfully learn to live inside cells present special challenges to the vaccine developer. Organisms of this sort include *Mycobacterium tuberculosis, Mycobacterium leprae,* and *Listeria monocytogenes.* Robust T-cell responses are the key to immune protection in these cases, involving Th1-type CD4$^+$ cells and CD8$^+$ CTLs, as well as γ/δ T cells and NK cells, each of which has been shown to be of importance. Induction of γ-interferon positive T cells is a central theme in the search for new vaccines (145). Because of its great public health importance, we shall consider mainly TB.

TB is one of the greatest communicable disease killers in the world. An astonishing 2 billion people harbor the bacterium in latent form; of these people, fewer than 10% develop active disease. However, there are about 9 million new active cases each year and about 2 million annual deaths. Unless something is done, between 2000 and 2020 there will be 1 billion people newly infected with TB, 200 million active cases, and 35 million deaths. Two huge threats are (a) combined infection with HIV and TB, in which death can occur within weeks of infection, and (b) the increased prevalence of strains of *M. tuberculosis* that are resistant to one or more antimicrobial agents. For example, in the United States, 13% of new TB cases are resistant to at least one first-line drug, and 3% are resistant to both isoniazid and rifampycin, the two most important drugs.

BCG was developed by serial passage of *Mycobacterium bovis* on media for an incredible 13 years, and it was introduced in 1921. It is the most widely used vaccine in the world, total usage having been over 3 billion doses. It is clearly effective in preventing severe childhood forms of TB, such as TB meningitis and military TB, estimates of efficacy varying from 50% to 80%, and in a developing country setting its broad immunostimulatory action may lower overall infant mortality in the first 6 months, although these studies are controversial. However, BCG is unreliable against adult TB. Early controlled trials suggested good efficacy, but half a dozen later trials, including one very large one in India, proved equivocal or negative. A general consensus today would be that the efficacy of BCG wanes after 10 to 15 years, and, curiously, booster doses do not seem to help, although they may (through cross-reaction) be partially effective for leprosy. The need for a more effective vaccine with a longer-lasting effect is clear. One possible reason for poor apparent efficacy in developing country trials is that prior exposure to environmental mycobacteria may either reduce or mask the protective effect of BCG. A hopeful vista for the longer-term future is that anti-microbial therapy and immunization will interact beneficially. Where it is assiduously pursued, "DOTS"—directly observed therapy, short course—is already having an effect, and DOTS is becoming more widely available through the WHO's Stop TB Partnership and the Global Fund to Fight AIDS, TB, and Malaria.

Attempts to develop a better TB vaccine fall under three broad headings (146), namely new and more planned attenuation of *M. tuberculosis,* restoring to BCG genes for important antigens that had been lost, and a subunit approach using antigens plus an adjuvant shown to be effective through animal models. Of course, such antigens could be coded for by DNA, either "naked" or via a vector, and "prime-boost" strategies could also be entertained.

All three approaches have been helped by the fact that the genome of *M. tuberculosis* has been sequenced (147), as have those of *M. bovis* and of BCG. This has helped the identification of genes deleted during the attenuation process and, through "reverse genetics," in the search for proteins that might represent credible vaccine candidates. Even before this analysis, more empirical research had thrown up at least 20 molecules capable of conferring protection.

Britton and Palendira (146) have summarized the single and double auxotrophic mutants of *M. tuberculosis* capable of protecting mice or guinea pigs. Some of these provide greater immunity than BCG—for example, a mutant unable to export the complex lipid phthiocerol dimycocerosate (148). Studies in immunodeficient mice have shown some of these mutants to be more virulent than BCG, and with the great prevalence of HIV in many countries with high TB incidence, this could constitute a grave problem. Risk of reversion to virulence is ever present, although less in doubly mutated strains. Finally, regulatory bodies may find it difficult to approve any *M. tuberculosis* derived strain.

Improving the current BCG essentially means adding genes that had been deleted and that code for credible candidate antigens. BCG has 14 regions of deletion and is missing 129 genes. Two recombinant BCG strains have entered phase I clinical trials, one over-expressing an antigen known as 85B and the other a urease-deficient strain expressing listeriolysin from *Listeria monocytogenes* (summarized in [145]).

With respect to the subunit approach, literally hundreds of proteins have been screened in experimental animal models (149), including systematic functional genomic antigen discovery and prioritization (150). Prominent targets include antigens secreted into bacterial culture filtrates such as the antigen 85 complex, a family of three closely related mycolyl transferases with homologues in all mycobacterial species, and ESAT-6, a protein restricted to *M. tuberculosis*. Ag85A, Ag85B, and ESAT-6 together represent a powerful combination (summarized in [151]). Mtb72f is a fusion protein derived from two cytoplasmic proteins mtb32 and mtb39 and has passed a phase I clinical trial promoted by GlaxoSmithKline and Corixa (150). The functional genomic approach including the use of human sera to identify proteins immunogenic for humans produced this promising candidate, which with the use of the ASO2A adjuvant induces a strong Th1 response. The final subunit vaccine already in clinical trial is a fusion protein of Ag85B and ESAT-6 given with an adjuvant IC31 from Intercell that contains CpG oligodeoxy-nucleotides and polycationic amino acids (Table 40.6).

Various alternative strategies are using these antigens as well. McShane et al. (152), trialing BCG vaccination followed by a boost with MVA containing Ag85A, are obtaining strong IFN-γ responses in trials both in the United Kingdom and The Gambia. Phase II human studies have commenced with this candidate. Preclinical studies have shown that combinations of multiple antigens as a DNA construct work well—for example, Ag85B plus ESAT-6 plus Ag64; further, the use of plasmid cytokines IL-12 or IL-23 increases T cell responses and vaccine efficacy using subunit DNA vaccines (153). A fuller list of the 20 or so DNA constructs that have shown efficacy in mice can be found in reference (148). Priming with Ag85B DNA and boosting with BCG gave good CD4$^+$ and CD8$^+$ T cell responses and better protection than BCG alone. Boosting with Ag85B as protein or priming with BCG and boosting with Ag85B DNA did not do as well. Recombinant adenovirus vectors represent an attractive alternative to MVA.

Any TB vaccine could be used in one of three ways: pre-exposure to prevent infection, post-exposure to prevent disease, or therapeutically to help to control established disease. Obviously in the third case the vaccine would be adjunct to a drug treatment program. Given the widespread use of BCG in developing countries, it is likely that any new vaccine would, in the first instance, be given to individuals who had already received BCG. Modeling the possible effects of a vaccine highlights that it would act synergistically with chemotherapy. A scenario that many favor is periodic mass vaccination and very intense search for active cases then promptly treated with chemotherapy.

Obviously clinical trials in a disease with such a long latent period will be lengthy, arduous, and expensive. Fortunately, the Bill & Melinda Gates Foundation, the European Commission, and the U.S. National Institutes of Health are all aware of this, and global collaboration toward a licensed vaccine by 2015 is impressive (151).

Leprosy

M. leprae has many similarities to *M. tuberculosis*. Some of the urgency has gone out of the search for a leprosy vaccine because of the remarkable success of multidrug therapy. There is good evidence that BCG itself is a moderately protective vaccine against leprosy, and Convit's vaccine, consisting of killed, armadillo-derived *M. leprae* plus live BCG, appears to be better. Other mycobacteria such as killed *Mycobacterium w* appear to be modestly effective. The subunit vaccine approach is not being actively pursued. One candidate is a 35-kDa protein that is a major target of the human T cell response to *M. leprae*. Sequencing of the *M. leprae* genome is now complete and may in time provide further candidate molecules.

Vaccines Against Group A Streptococci

Somewhat amazingly, since the development of penicillin during World War II, rheumatic fever and rheumatic heart disease nevertheless remain common in many developing countries, the prevalence being up to 20 per 1,000. *Streptococcus pyogenes* infections can also be followed by acute and chronic glomerulonephritis and otitis media. A good vaccine candidate would be the M protein, a coiled-coil alpha helical surface protein of the bacterium. However, the vaccine developer faces two major hurdles. First, there are more than 100 serotypes of group A streptococci, and

▌ **TABLE 40.6 Most Advanced Tuberculosis Vaccine Candidates (From 147,148,152,153)**

Category	Candidate	Key Investigator	Trial Phase
Genetically engineered BCG	BCG overexpressing Ag85B	Horowitz, UCLA	I
	Urease-deficient BCG expressing listeriolysin	Kaufmann, Berlin	I
Subunit vaccines	Fusion protein of Ag85B and ESAT-6 with IC31 adjuvant	Anderson, Copenhagen	I
	Fusion protein of two secreted proteins, Mtb32 and Mtb39	Reed, Seattle	I
Vectored vaccine	MVA, a replication-deficient vaccinia virus, epxressing Ag85A boosts BCG-primed or naturally acquired TB immunity	McShane and Hill, Oxford	II

much of the variation is in the immunity-inducing but highly variable N-terminal portion of the M protein. Second, the major complications are almost certainly autoimmune in nature, and it would be a disaster if immunization triggered the very events that the vaccine is supposed to prevent. Brandt et al. (154) first identified a conserved, non–host cross-reactive peptide from the C-terminal half of the M protein and then linked this (in a manner that maintained the peptide's helical conformation) with a multiepitopic peptide consisting of seven N-terminal portions from seven different, relatively common serotypes, targeting northern Australian aboriginal isolates. The polymer technology, already described in the section on adjuvants, ensured full immunogenicity of all components. The vaccine was strongly immunogenic and protective in mice against a wide variety of strains and was not cross-reactive with any of many host self-proteins. The nature of the polymer backbone would allow peptides from other, non–M protein–derived vaccine candidates to be added as well. Such candidates include C5a peptidase, cysteine protease, and other streptococcal pyrogenic exotoxins. Some of these toxins can be rendered harmless through mutagenesis of the relevant genes. Another candidate is the major streptococcal adhesin, a protein known as sfbl.

Various formulations of these candidates, including parenteral injection, intranasal inoculation, and expression on the surface of *Streptococcus gordonii*, a commensal organism of the oral cavity, are in preclinical research. As antibiotic resistance becomes more of a problem, the pressure will build to take some of these candidates to the clinic.

VIRAL VACCINES

Viral vaccine research has produced both triumphs and tribulations. The triumphs include success against poliomyelitis, measles, mumps, rubella, varicella, hepatitis B, and, to a lesser extent, hepatitis A. The tribulations include struggles with HIV/AIDS, dengue, Epstein-Barr virus, and hepatitis C. Influenza and rotavirus are poised in between. It is not possible to run through the whole gamut of viral vaccines. Rather, the author wishes to highlight some of the complexities and remaining challenges and draw some lessons from them.

Hepatitis A, B, and C

These three viruses show an interesting spectrum of solved and unsolved problems that confront the vaccinologist. Hilleman (155) cited literature suggesting that contagious jaundice has been known to occur since the 5th century B.C. It became clear in the 1950s that "infectious hepatitis" and "homologous serum jaundice" had differing features, and this difference was cemented in the 1960s. Since the

isolation of hepatitis A and B viruses and good serological tests for their recent presence, other forms of fecal-oral and of blood transmission of hepatitis have been discovered, of which the most important enterically transmitted agent is hepatitis E, and the most important parenterally transmitted is hepatitis C.

Hepatitis A is one of a group of diseases that also includes infectious mononucleosis, which is mild or entirely asymptomatic if contracted by young children but more severe if contracted in adolescents and adults. In rare cases, it causes fulminant hepatitis but is usually less severe, although it causes illness for up to several months. It is now only moderately common in industrialized countries, but very common in many developing countries. Immunization is a good idea for travelers, and both active immunization, giving long protection, and passive immunization with immune serum globulin, giving 3 months' protection, work well.

The virus initially proved very difficult to grow, and early studies depended on its identification by electron microscopy in fecal extracts. It was eventually grown in marmoset liver cells and a human hepatoma cell line, after which many types of cells were successfully infected. Growth of the virus in LLC-MK2 cells and availability of a marmoset model for vaccine testing led to a formalin-inactivated killed whole-virus vaccine, which, however, was not acceptable at that time because malignant cells were involved in growing the virus. Two groups eventually succeeded in obtaining growth in human diploid lung fibroblasts, and the resultant vaccines from (then) Smith KlineBeecham and Merck Sharp & Dohme work well. However, because virus yields are not enormous, hepatitis A is an expensive vaccine, and a live attenuated vaccine would be most beneficial in a developing nation. Several candidate vaccines exist; one has been extensively tested in China and found to be highly effective, but none has yet made it through to full registration.

Hepatitis B carrier rates vary from less than 0.1% to 15% of the population in different countries. Altogether, 2 billion people have serological evidence of past infection, and 350 million people are chronically infected. One million people die each year of cirrhosis or hepatocellular carcinoma. The acute attack is mild or insignificant. Hepatitis B virus does not grow in tissue culture, and there are two sources of vaccine: HBsAg isolated from chronic carriers of the virus, and the same material molecularly cloned in yeast or Chinese hamster ovary cells. The carrier-derived vaccine was, for a long time, far cheaper and has been widely used in developing countries. Now the recombinant vaccine has become much cheaper. Some recent tenders for the public sector in developing countries have come in at around 30 U.S. cents per dose, so recombinant vaccine has essentially replaced the human-derived material. Both vaccines are about equally effective; response rates to protective levels of antibody vary from 85% to 95%

in different studies. Protection may be achieved with lower levels of antibody than those generally believed to be protective, perhaps because of CD8$^+$ T cell effects. One worry is that some vaccinated people become carriers of what have been called "escape mutants," which persist despite the presence of good antibody levels to the native virus. The most common change is an arginine-for-glycine substitution in the *a* loop, against which antibodies are usually directed. Although it is not yet certain that the mutation changes the virus to one of lower infectivity, M. H. Kane (personal communication) pointed out that there is no evidence yet of escape mutants having spread from one person to another. There is therefore no need yet to worry about the univalency of the current vaccine. Presumably, if escape mutants become a problem but if the number of different serotypes is limited, the variants could be included in a recombinant vaccine. It is encouraging to note that universal infant immunization is now being widely adopted. Further, the vaccine is frequently given in combination with others.

The hepatitis C virus was the first of the non-A, non-B viruses identified. Hepatitis C is transmitted in the same way as hepatitis B but is an even nastier disease, inasmuch as about 80% of people who contract the infection become chronic carriers, and many of these go on to develop chronic liver disease. Further, a significant proportion develop hepatocellular carcinoma; in Japan, where about 2% of people are carriers, hepatitis C is a more common cause of liver cancer than is hepatitis B.

Research on hepatitis C has been severely hampered by the fact that attempts to culture the virus in standard tissue culture have failed. In view of this, the cloning of the virus by Choo et al. (156) was considered a major triumph, particularly because it soon led to the development of an assay for antibodies useful in screening blood donations. However, development of a vaccine against hepatitis C faces difficulties. The virus is a rapidly mutating RNA virus with a single open reading frame encoding a polyprotein of about 3,000 amino acids. There are two envelope proteins, E1 and E2, identified by analogy with other flaviviruses, which are produced by proteolytic cleavage. Study of these by genomic analysis of hepatitis C cloned from patients in different parts of the world shows a great degree of structural (and therefore antigenic) diversity. Further, experimentation on vaccine candidates is rendered difficult by the fact that the only animal model is the chimpanzee. This makes it hard to characterize and quantitate neutralizing antibodies, although it is known that plasma from a chronic carrier can protect chimpanzees from infection.

Recently, the cloned viral genome has been used to produce infectious hepatitis C virus in tissue culture (157), and a number of different replicon systems have been developed (reviewed in [158]). Further, the functional hepatitis C virus replication complex has been directly visualized by green fluorescent protein insertion or by immunogold

staining. This has revealed many of the details of the infectious process.

The primary event in the virus entering a liver cell is high-affinity binding of HCV E2 protein to a large external loop of the cell surface molecule CD81, a tetraspannin molecule present on several cell types. However, cofactors are certainly required, and both high- and low-density lipoproteins have been implicated. Binding of E2 to CD81 can be inhibited by neutralizing antibodies, and there was a surprising degree of cross-neutralization between greatly disparate virus isolates. This raises the hope that binding may be at least partly independent of E2 sequence variation. Clinical trials of an E1/E2 vaccine are in progress.

Another approach to immunization involves raising CD8$^+$ T lymphocytes to nonenvelope glycoproteins. A variety of these have been tested, particularly the core antigen. A collaboration between Chiron (now Novartis) and CSL Ltd has shown that the use of ISCOMs promotes good CD8$^+$ CTL development in both monkeys and human volunteers. The hope, in the first instance, is for a therapeutic vaccine in chronic carriers, used in combination with antiviral chemotherapy.

Rotavirus Vaccines

In 1973, Bishop and Holmes in Australia discovered 70-nM virus particles possessing a distinctive double-shelled outer capsid in duodenal epithelium and stool filtrates from children with acute gastroenteritis. These so-called *rotaviruses* turned out to be an extremely important cause of diarrheal illness. In industrialized countries, rotavirus accounts for about one third of the hospitalizations of infants and young children for diarrhea. Although the mortality rate is quite low because of intravenous rehydration, both the cost and distress are high. It has been estimated that 2 million to 7 million children in the United States suffer rotavirus diarrhea each year, which results in 500,000 physician visits, 50,000 hospitalizations, and $274 million in direct medical costs. In developing countries, rotavirus is devastating, causing over 600,000 deaths per year. In a developing country like Bangladesh, it has been estimated that up to 1% of all children die of rotavirus diarrhea. The disease is widespread around the world, infection being via the fecal-oral route. By the age of 5 years, 95% of children have encountered the virus. Natural immunity develops (159). Severe diarrhea is rare on second infection. This is interesting, because there are four commonly encountered strains, so some degree of cross-protection is likely. The virus has 11 segments of double-stranded RNA, each of which encodes a protein. The outer capsid (against which protection is required) consists of G and P proteins, both of which induce neutralizing antibodies. The 10 known G proteins and the 8 known P proteins of the human virus could theoretically reassort into 80 different serotypes, but only four strains—P8G1, P8G3, P8G4, and

P4G2—are globally important. For the future, two non-structural proteins could emerge as vaccine candidates: a putative enterotoxin NSP4, and the inner capsid protein VP6. Rarer serotypes are not to be entirely neglected and crop up in some surveys.

Early vaccine trials were with a live attenuated bovine rotavirus and were predicated on the view that animal and human rotaviruses shared a common group antigen. Next, a Rhesus rotavirus was tested. These early vaccines gave variable results. Then a Rhesus–human reassortant vaccine was generated by coinfecting cell cultures with a Rhesus rotavirus possessing G serotype 3 and three different human rotaviruses of G serotypes 1, 2, and 4. The three reassortants possessing a Rhesus genetic background but the human capsid protein 1, 2, or 4 were combined with the G3 Rhesus strain to create a tetravalent vaccine. Each of the four viruses was tested at 10^4 and later 10^5 plaque forming units (PFU), vaccine being administered in three oral doses, and the final vaccine submitted for licensure contained 10^5 PFU of each virus, thus 4×10^5 PFU per dose, all told. In clinical trials involving about 10,000 infants, no major adverse events were noted, except one to be discussed. Vaccine efficacy was 48% to 60% in terms of all disease but 61% to 100% against severe disease. In the United States, 80% of very severe episodes and 100% of dehydrating rotavirus illnesses were prevented. The vaccine, produced by Wyeth-Lederle, was duly licensed in August 1998. It was recommended for all children in the United States, to be given orally at 2, 4, and 6 months. By July 1999, 1.5 million doses had been given to 800,000 children.

In the 27 prelicensing trials of candidate rotavirus vaccines, five cases of a rare form of bowel obstruction were noted. In this syndrome, known as intussusception, a portion of bowel prolapses into a more distal portion, and peristalsis propels it further, causing a painful and potentially fatal blockage. The incidence was 0.05%, in comparison with a 0.02% incidence in the placebo control group; this difference did not reach statistical significance but was sufficient to warrant listing in the manufacturer's product insert. In any event, 15 cases of intussusception were reported between September 1998 and July 1999. As a result, this vaccine (RotaShield) was voluntarily withdrawn from the market in October 1999, a distressing and expensive event.

Notwithstanding this setback, Merck Inc. continued with the development of an oral, live, pentavalent human-bovine reassortant rotavirus vaccine, Rotateq, with activity against G1, G2, G3, G4, and P[8] serotypes. A phase III trial in 68,000 healthy infants aged 6 to 12 weeks involved vaccine or placebo, with two further doses at 4 to 10 week intervals (160). Intussusception occurred in 12 recipients of the vaccine and 15 recipients of placebo within 1 year after the first dose, including 6 and 5 respectively within the first 6 weeks. Full vaccination reduced gastroenteritis severe enough for an emergency department visit of hospi-talization by 94.5%, clinic visits by 86% and any rotavirus gastroenteritis by 74%. This vaccine was licensed in 2006.

A different approach was taken by GlaxoSmithKline. Its vaccine Rotarix is a live attenuated monovalent G1P[8] human rotavirus strain, relying on cross-reactivity to give broad protection. A phase III study was conducted on 63,225 healthy infants from 11 Latin American countries and Finland who received two oral doses at approximately 2 and 4 months of age. Only 13 children developed intussusception during a 31-day window after each dose, 6 vaccine recipients and 7 in the placebo group. The vaccine was 85% effective against severe rotavirus gastroenteritis and actually reduced hospitalization from *all* causes of diarrhea by 42% (161).

Yet another strategy exploits the fact that some strains of rotavirus, so-called *nursery strains,* seem to cause asymptomatic infection in neonates but protect against later rotavirus infection. One of these, RV3, is a G3P[6] virus, which has been in a phase II trial (162) and is now being further developed in association with BioFarma in Indonesia. Another nursery strain is being progressed in India and is in phase II trial. One obvious advantage of having a vaccine of just one strain is lower cost.

Further ideas being explored are parenteral injection of baculovirus-expressed VLPs containing structural rotavirus proteins from multiple serotypes; DNA vaccines; or incorporating rotavirus into microspheres for use as an oral mucosal vaccine. Rotavirus genes have also been inserted into Sabin poliovirus or vaccinia.

The intussusception saga illustrates some of the very real problems in vaccine development. Rare complications can be quite significant when a whole population is the object of study. The more clinical prelicensure work needs to be done, the greater the research and development costs for the manufacturer and the more the pressure to charge a high price. The higher the price, the lower is the likelihood of extensive use in developing nations. Clearly, risk–benefit and cost–benefit analyses will need to form a prominent part of the landscape for the vaccines of the future.

Influenza Vaccines

Influenza is by no means a trivial disease. In industrialized countries, the regular winter attacks provoke a usually self-limited febrile illness that causes many lost hours of work. Further, flu can be the prelude to fatal pneumonia in the elderly. Annual vaccination is widely recommended for this age group, and in many countries is becoming common for children and younger adults as well. About three times per century, much more serious pandemics of influenza have occurred, which we shall consider in detail.

The influenza virus is an RNA virus; the genome consists of eight segments of single-strand RNA. The most important antigen for neutralization is the hemagglutinin (HA), one of two dominant surface proteins; antibodies to the

other, the neuraminidase, can also be neutralizing. The big problem in influenza immunization is the virus' capacity to change its antigenic type. This happens in two ways. Point mutations in the HA occur with a frequency of $10^{-5.5}$ per generation. These lead to subtle but important changes in HA epitopes. This tendency to mutate away from antibody attack is referred to as *drift*. It means that the antibodies made one winter may not be as effective against the next winter's flu. Accordingly, an elaborate system of monitoring and nomenclature has arisen around the world; several WHO Collaborating Centers are responsible for providing seed lots of vaccine twice a year that reflect the most recent and dominant antigenic types. Influenza viruses also infect animals, such as pigs and horses; birds, such as geese, ducks, and chickens; and marine mammals. There are 15 distinct HA types in influenza A, and only some are infectious for humans. There are nine distinct neuraminidase types, only some of which occur in humans. Thus, influenza A viruses are frequently referred to by their serotype (e.g., H3N1). Influenza B virus is also highly adapted to humans. This virus has no subtypes, and the infections on the whole tend to be less severe.

The segmented nature of the viral genome and the existence of a variety of animal hosts makes for the possibility of coinfection of cells with human-adapted and animal-adapted strains, a reassortment of genes and the emergence of novel strains with the sudden appearance of a new antigenic subtype. Such a major change is referred to as *antigenic shift*. There may be little or no cross-reactivity with antibody provoked by previously circulating strains. The stage is then set for a major pandemic. In the 20th century, there were three such pandemics: the so-called swine flu of 1918 to 1919, the "Asian" flu of 1957, and the "Hong Kong" flu of 1969. The swine flu (which was in fact a bird flu) killed 20 million to 40 million people, while the latter two pandemics killed an estimated 1 million people each, older adults accounting for the great majority of deaths. It would appear that the risk for such reassortants is greatest in areas where humans and animals such as chickens or pigs live in close contact.

In 1997, a virus highly virulent in birds was isolated in Hong Kong. This H5N1 strain had been carried to chickens by infected migratory waterfowl and is nearly 100% fatal in chickens. Since then, this virus has spread rapidly throughout Southeast Asia and onward to Central Asia, Europe, the Middle East, Northern and Western Africa, and even West Papua. About 200 million birds have died from the virus or have been killed to prevent its spread. Humans in close contact with chickens are at risk of catching the virus. So far (September 2006) 246 people in 10 countries have fallen ill, with 144 deaths, a far greater case fatality rate than any influenza virus previously reported. Fortunately, human to human transmission rarely occurs. In May 2006, there were two instances in Indonesia where very close contact (e.g., nursing a patient for

6 days) might have caused infection. However, mutation or reassortment with a human strain for easier transmissibility is an ever-present risk. There is already evidence of more than one clade showing the virus is mutating. Accordingly, most industrialized countries have emergency plans that include stockpiling of antiviral drugs, development of point-of-care diagnostic tests, quarantine plans, public health measures, and development of suitable vaccines. A second bird flu, H9N2, has also been encountered and appears to be less virulent.

The standard influenza vaccine consists of formalin-inactivated whole virus, still grown in fertile hen's eggs and frequently rendered less reactogenic by "splitting" through ether or detergent treatment. Tissue cultured variants are in development. In Italy, a vaccine incorporating MF59 adjuvant is registered. The standard vaccine is reasonably effective, but protection is of short duration. Typically, the killed vaccine is 60% to 70% effective. Helpful though such a vaccine is, the search for better vaccines is lively.

Obvious areas to explore are live attenuated vaccines and mucosal administration. These are combined in the efforts of Aviron (now MedImmune) with their preparation FluMist. Cold-adapted viruses, initially developed at the University of Michigan, are produced in specific pathogen-free eggs, and a trivalent preparation consisting of two A and one B strains is given via a nasal spray–syringe delivery system. A single dose is safe and effective. The largest trial achieved 93% efficacy in the first year and in the second, 100% efficacy against strains included in the vaccine, and 86% against the emergent mismatched strain A/Sydney/05/97 (H3N2). This new vaccine was licensed in 2003 for administration to 5 to 49 year-old subjects. Prelicensure studies showed results to be significantly superior to those of the inactivated injectable vaccine. Glück's intranasal virosome-based vaccine, already mentioned, appeared to significantly increase the risk of Bell's palsy, so is not being further marketed. By 2006, FulMist had been administered to more than 4 million individuals with a total of only 5 Bell's palsy cases reported, a causal association not being established, and thus represents a safe, effective and probably superior addition to the armamentarium.

Bird Flu Vaccines

As there is no preexisting immunity, conventional influenza vaccines containing the H5N1 virus do not perform particularly well in humans. For example, Treanor et al. (163) found that 2 doses of 90 mg of influenza virus (3 to 6 times the normal dose) raised a neutralizing antibody titer of 1:40 (the theoretically protective level) in only 54% of adult subjects, with lower doses giving lower responses. This can certainly be improved with either alum or MF59 adjuvant. As quantity of vaccine would be a real issue early in a pandemic, other approaches must be explored. An adenovirus vector genetically engineered to

express H5 hemagglutinin on its surface was 100% effective in protecting mice and also very potent in chickens against authentic H5N1 virus (164). Curiously, subcutaneous injection worked much better than intranasal vaccine in the latter case. This vaccine causes both B and T cell immunity. Other possibilities include live attenuated cold-adapted intranasal vaccine—MedImmune has been given a large contract to develop such a variant—and a platform or backbone vaccine against all 15 variations of the H antigen, with the hope of one generic influenza vaccine stockpile. DNA vaccines, of course, would avoid the need for eggs. There is also rapid development of mammalian cell culture methods for the virus. Plant-made vaccines are another possibility. If and when a shift variant with global pandemic potential emerges, it will be important to ramp up production as rapidly as possible, as well as to prioritize those recipients (e.g., doctors, nurses, quarantine officers) needing the vaccine first.

Antibody-based Vaccines Against Human Immunodeficiency Virus

The human immunodeficiency virus 1 (HIV-1) has developed some devilishly clever strategies to foil the human immune response. It exhibits an astonishing rate of mutation, particularly in the portion of its envelope protein that is involved in infectivity, allowing the virus to escape the antibody response. It finds several levels of "safe haven" refuges unreachable by antibodies—for example, persistence within macrophages and DCs, or penetration into the brain. Further, integration of provirus DNA into the host cell genome, with no external evidence of the virus's presence, represents an escape resistant to CTL attack. It targets the first lymphocyte in the immune cascade, the $CD4^+$ T cell, which may delay an effective immune response and will certainly facilitate the disastrous upsurge in viral load late in the disease, because T cell levels fall so low that resistance essentially disappears. It has an extraordinarily high rate of replication. We now know that the immune system is a pitched battleground from the first entry of the virus.

The most common mode of transmission of HIV is sexual intercourse. The virus infects $CD4^+$ T cells and spreads within this population and also in DCs. By about 1 week, virus can be detected in local lymph nodes and soon in the blood. Seeding to gut-associated lymphoid tissue is particularly extensive. Viremia reaches a peak around 3 weeks with $\sim 10^7$ virus particles per ml of blood, or more. But then $CD8^+$ cytotoxic T cells help to control the early infection (165), HIV-specific cells comprising 10% of the circulating $CD8^+$ pool. The virus load falls up to a 100-fold to reach a relatively stable level (the "set point") by 2 to 6 months after infection. The set point has prognostic significance: The lower it is, the slower the rate of progression to AIDS. But sooner or later the $CD4^+$ T cell count falls, and

when it reaches 200/ml to 400/ml, virus levels rise and AIDS supervenes.

Two to three months after primary infection, neutralizing antibodies appear, but escape mutant viruses immediately become manifest, so the natural antibody response (166) is always faced with persisting, fast-changing virus. The question then is: Could a vaccine elicit an antibody response that prevents the virus from gaining a foothold in the first place?

Early attempts to develop an AIDS vaccine followed the classical path of seeking to induce antibodies to the most prominent antigens on the viral surface: namely, the envelope (*env*) glycoproteins gp160 or the products it yields, the exterior viral protein gp120, and the transmembrane glycoprotein gp41. Two unfortunate findings from phase II trials of recombinant *env* antigens caused early disappointment. First, the data showed a small number of "breakthrough" infections despite immunization; second, antibodies engendered by immunization, although capable of neutralizing HIV grown in transformed T cell lines, were much less effective against freshly isolated virus grown in peripheral blood mononuclear cells. Since those early days, we have learned much about how HIV infects its target cells (reviewed in [166]). Gp120 and noncovalently associated gp41 exist as homodimers on the viral surface. So from the beginning much of gp120 is hidden, while its exposed surface is heavily glycosylated, handicapping a putative neutralizing antibody seeking access. The CD4-binding site is deeply recessed and "guarded" by the V1/V2 loops so the virus can vary extensively. When gp120 binds to CD4, the envelope protein undergoes a conformational change that exposes a high-affinity binding site for one of two coreceptors, CCR5 and CXCR-4, members of the chemokine receptor family. After this second binding event, gp41 in turn changes shape, leading to the insertion of a hydrophobic amino-terminal fusion peptide into the target cell membrane to mediate membrane fusion and viral entry. Much of the current effort in HIV vaccine research seeks to "freeze" these various highly transitory structures. The well-hidden binding sites are relatively conserved compared with the rest of the envelope protein. Be that as it may, the use of recombinant envelope proteins as vaccines has not been successful so far. The firm VaxGen took its recombinant gp120 vaccine AIDSVAX^{TM} to two sizable phase III trials without obtaining significant protection.

Before looking at other antibody-evoking vaccine strategies, we must recall the great heterogeneity of this virus. There are three main types of HIV-1, which probably represent three separate infections of humans from chimpanzees, namely M, N, and O. Both N and O strains are quite rare and are very close to simian immunodeficiency virus. The main M type can be broken in to subtypes or clades of which the most important are A, B, C, D (which may be part of B), E, and G. All clades are present in central Africa. The most important clade in the Americas,

Europe, and Australia is B; in South and East Asia it is C; and in Southeast Asia it is E. Vaccines will probably have to be clade specific. To complicate matters further, inter-subtype recombination is frequent, and the recombinant forms AD, AE, AG, and BC are readily recognized. Clade classification is on the basis of genotype, and the correlation between genotype and immunotype is by no means clear-cut. There is a complex matrix of cross-reactivities in both humoral and cellular responses that will have to be sorted out antigen by antigen when particular antigens are chosen for an eventual vaccine.

There are two reasons why it is too early to give up on antibody production as a key to HIV prophylaxis: First, passively administered antibody can prevent infection of macaque monkeys with SIV–HIV hybrid virus (SHIV), a widely used model for HIV (167). Second, there are five monoclonal antibodies that have the capacity to neutralize a broad variety of freshly isolated HIV subtypes (reviewed in [166]). One is against conserved elements of the CD4 binding site; one sees the coreceptor binding site; one is directed against mannans linked to *env*; and two bind to the membrane-proximal region of gp41. These last two resemble certain auto-antibodies in that they are broadly cross-reactive and bind with high affinity to cardiolipin (168). It has been suggested that these antibodies are rare because of self-tolerance, and if a way could be found to evoke plentiful anti-*env* antibodies of this character, a vaccine against HIV might ensue.

There is no shortage of good ideas for novel antibody-inducing vaccines. Conformationally altered gp120 to which CD4 has been bound represents one possibility, and the most promising variant of this idea is a single-chain gp120-CD4 fusion protein (169) that fortunately does not appear to elicit anti-CD4 antibodies. There are also attempts to create synthetic mimotopes of the suddenly exposed binding structure, utilizing the extensive three-dimensional information that has become available, as well as epitopes exposed during HIV-mediated cell fusion. One proposal seeks to use computational methods to identify those pieces of HIV that are targets for neutralization and to synthesize hundreds of these to create antigens, antibodies against which could be broadly neutralizing. In another endeavor, it is proposed to screen very large numbers of human or experimental animal antibodies for broad neutralization potential and then work backward from the antibodies to the appropriate HIV epitopes. A somewhat similar concept is that of the firm Maxygen, where chimaeric or "shuffled" *env* genes from several different HIV isolates are expressed and tested for reactivity with powerfully neutralizing antibodies, positive proteins then being used to immunize mice to determine whether they generate the requisite antibodies (170). These newer ideas have not yet reached the clinical trial stage. Some of them, as well as projects discussed in the next section, will be supported by a $287 million initiative from the Bill &

Melinda Gates Foundation announced in July 2006 as part of the Global HIV/AIDS Vaccine Enterprise, which gave 16 grants to 165 researchers from 19 countries to support collaborative research. By October, 2006, Gates Foundation grants for AIDS vaccine research had totaled $528 million.

T Cell–Based Vaccines Against HIV

All over the world, great effort is being put into attempts to create an AIDS vaccine based on the induction of powerful T cell immunity, particularly the induction of cytotoxic CD8$^+$ T cells active against virus-infected cells. There are good reasons to believe that CD8$^+$ T cells play a critical role in the control of HIV. Relevant findings include a close correlation between CTL appearance and a fall in virus levels in SHIV-1–infected Rhesus macaque monkeys and the detection of significant numbers of HIV-specific CTLs in a variety of seronegative individuals at high risk, such as babies born to HIV-positive mothers, a small proportion of female African professional sex workers, and a proportion of subjects with needlestick injuries. Among seropositive individuals, those who do not progress or progress slowly to AIDS have robust CTL responses. In view of this evidence, it is important to include in a vaccine virally encoded proteins produced in the cytosol of the infected cell, so that peptide fragments of such proteins could be presented at the surface of the infected cell in association with class I MHC molecules. Further, it would be advantageous to use adjuvants or other techniques known to favor CD8$^+$ T cell production. Use of a multiplicity of antigens might counteract mutations occurring in any single component within the virus-infected cells that should be eliminated. Finally, a procedure evoking mucosal as well as lymph node and splenic CTLs would be ideal.

In a resurgent and now well-financed AIDS vaccine effort, a large number of antigens or genes for antigens have been the subject of intensive research. These include *env, gag, pol, nef, rev, tat,* and HIV protease. Further, an incredible variety of vector systems has been included in preclinical research. Among these are vaccinia; vaccinia modified to be less aggressive (e.g., modified vaccinia Ankara); adenoviruses; avipox viruses, including canarypox and fowlpox; and (although less frequently) other viruses, including recombinant avirulent poliovirus, mengovirus, herpesvirus, Venezuelan equine encephalitis virus, vesicular stomatitis virus, Semliki Forest virus and influenza virus. Possible bacterial vectors include *Salmonella,* BCG, *Shigella, Listeria,* and *Lactobacillus.* Many of these have been through a variety of animal models of protection with a measure of success.

Among the 100 or so vaccine candidates, there is no doubt that the prime-boost strategies described earlier hold pride of place (171–173). Increasing use is being made

of the SHIV virus (HIV envelope and SIV core) model in macaques.

There is by now substantial literature on virtually every conceivable variation on this prime-boost scheme, with many preclinical successes. A constant undercurrent in the literature is strong CD8$^+$ CTLs as a signpost of promise. Among the many additions to prime-boost strategies, a recurring theme is either strong adjuvants accompanying particularly a protein boost or coadministration of cytokine gene expression cassettes with DNA immunogens.

A mucosal approach is also being pursued in a variety of ways. Mucosal surfaces are a major natural route of HIV entry, and protection through the mucosal immune system would therefore be valuable. Berzofsky et al. (174) have long been championing the idea of a multideterminant peptide vaccine comprising epitopes for both T helper cells and CTLs. The mucosal study (175) focused on the antigens *env, pol,* and *gag,* using *env* from HIV and *pol* and *gag* from SIV. The study design involved macaque monkeys and a challenge with virulent SHIV intrarectally. The investigators compared two vaccine approaches: a subcutaneous injection with Montanide ISA51 as an adjuvant, versus intrarectal inoculation of the vaccine with a mutant heat-labile *E. coli* toxin as a mucosal adjuvant. The latter provided significantly better protection, because (at least in part) of a strong intestinal mucosal CTL response. This group is also exploring the concept of epitope enhancement—that is, slightly modifying T helper cell epitope sequences to increase epitope affinity for class II MHC. This results in more effective helper T cells and also more CTLs (176). It must be remembered, however, that appropriate systemic immunization can also raise enough CTLs to protect against rectal challenge. For example, a prime-boost regimen consisting of priming with a cytokine-augmented DNA vaccine and boosting with a recombinant MVA construct, each vaccine containing multiple viral antigens, completely protected against intrarectal SHIV challenge in the same macaque model. But what is the situation in the human?

There have been at least 40 clinical trials of HIV vaccines, most of them phase I but about a quarter of them having progressed to phase II. The harvest has been disappointing. CD8$^+$ T cell responses have usually fallen below those in macaques to SHIV models, and responses in mice have been of poor predictive value. DNA vaccines have been poor performers, and while DNA priming with an MVA-HIV boost is more immunogenic, it is mainly a CD4$^+$ T cell response (177). Prime-boost works better than two injections of MVA. Recombinant replication-defective adenovirus-5 gives one of the best CD8$^+$ responses to *gag* peptides, but preexistent antibodies reduce immunogencity. However, MVA-HIV markedly amplified both CD4$^+$ and CD8$^+$ vaccine-specific T cell responses in HIV-infected individuals undergoing highly active antiretroviral therapy for chronic HIV infection (178). One

prime-boost protocol has reached phase III trial, namely recombinant canarypox priming with *env, gag, pol, nef,* and protease, followed by a gp120 protein boost. Results are not yet available.

The reader wishing to learn more about the many clinical trials should consult www.iavireport.org/trialsdb.

One very positive development in this rather gloomy scene is that recent efforts, particularly by the Bill & Melida Gates Foundation, the National Institutes of Health, and the European Union, have prompted a great deal more coordination and collaboration among the global AIDS vaccine research community. No one expects a licensed AIDS vaccine within the next 10 years, but the author confidently predicts that by the 7th edition of this book a number of credible candidates will have reached "proof of principle" stage. The distance then left to travel should not be underestimated. Perhaps the greatest practical problem in HIV vaccine research is where to go after encouraging phase I and II studies. Large prophylactic studies are horrendously expensive. Results would be most rapidly obtained in developing countries because of the high rate of carriage, but such trials are beset with practical and ethical problems. Practically, will it be possible to conduct trials whose results will meet U.S. Food and Drug Administration standards? Ethically, will it be possible to give trial participants sufficient safe sex education? Will it be possible to guarantee to developing country governments that, if the trial in which their citizens have taken part is successful, the relevant vaccine will be made available to the population at an affordable price? Clearly, the eventual development of a successful vaccine remains an immense scientific and humanitarian challenge.

Dengue Vaccines

Dengue is a mosquitoborne flavivirus infection caused by four dengue virus (DEN) serotypes, DEN-1, 2, 3, and 4. It is found in tropical and subtropical regions around the world, being endemic in more than 100 countries. The problem is worst in Southeast Asia, but recent spread to the Middle East and even to the U.S. states of Texas and Hawaii has caused great concern. Classical dengue fever is a serious but self-limited infection with fever, headache, myalgia, arthralgia, and rashes. The worst problem is a curious and potentially lethal complication, the dengue hemorrhagic fever-dengue shock syndrome (DHF/DSS). This still incompletely understood syndrome usually arises when a person who has been infected with one DEN serotype contracts another. Similarly, an infant possessing maternal antibodies against one strain is susceptible when infected with another. There is some kind of antibody-dependent enhancement of pathology. This increased susceptibility of the partially immune certainly introduced a note of caution into the development of a vaccine.

Much effort has gone into conventional serially tissue-culture passaged tetravalent live attenuated vaccines (reviewed in [179]). GlaxoSmithKline is working with the Walter Reed Army Institute of Research and started a phase II trial in March 2006. This research involves 132 adults aged 18 to 45 years and 51 infants aged 12 to 15 months. Follow-up will be for at least 4 years. Unfortunately, some "interference" between the serotypes has been encountered, and two injections do not elicit neutralizing levels of antibodies in all vaccinees. Sanofi-Aventis has the license to develop a tetravalent vaccine originating from Mahidol University in Thailand. Again, two doses appeared to be followed by breakthrough infections and three doses were needed for consistent neutralizing antibody responses.

Sanofi-Aventis has a second string to its bow because it has licensed a product from Acambis that is a chimaeric yellow fever-dengue virus tetravalent formulation in which pre-membrane and envelope genes from DEN serotypes 1 to 4 were substituted for the same genes of yellow fever (180). This worked well in monkeys, and human studies are in train involving two injections 5 to 9 months apart. No significant adverse reactions have been reported.

Blaney et al. (181) are developing a live attenuated tetravalent dengue vaccine using reverse genetics. The strategy involves attenuating deletions and chimaerization of C, M, and e genes to create a virus with tetravalent specificity. Preliminary clinical studies indicate that the vaccine was well tolerated and immunogenic. Maxygen, in collaboration with the U.S. Naval Medical Research Center, is thrusting in the same direction, but via a DNA vaccine created by DNA shuffling of envelope genes to create a tetravalent construct (182). This vaccine is still at the preclinical stage.

We can anticipate with some confidence that one or more of these approaches will have led to a licensed vaccine by the time of the next edition of this book or soon thereafter.

VACCINES AGAINST PARASITIC DISEASES

If viruses and bacteria have evolved elaborate strategies to defeat the vertebrate immune system, parasites, with their much larger complement of DNA, possess an even wider and more diverse range. Although no vaccine against any human parasitic disease has been licensed, the feasibility of such vaccines has been demonstrated in the veterinary field, where several successful vaccines are in use to deal with both protozoan and metazoan infestations. The difficulty of overcoming all the necessary hurdles for human vaccines is evidenced by the fact that over the past 30 years, some of the best minds in vaccinology have applied themselves to the problem, but only in malaria have vaccines moved to the stage of phase IIb trials, with moderate suc-

cess. Nevertheless, parasitism is so important from a public health viewpoint and the progress in understanding of parasite molecular biology and genetics so significant that the research effort must continue. Moreover, the progressive resistance of some parasites to chemotherapy and of vectors to insecticides highlights the importance of vaccines for disease control.

Malaria Vaccines

Malaria is the most prevalent vectorborne disease in the world. It is caused by protozoa of four species of *Plasmodium*. It threatens 2 billion people in 90 countries and causes approximately 500 million to 600 million clinical cases and 1 million to 2 million deaths per year. Overwhelmingly, the worst continent for malaria is Africa, where 90% of the deaths occur, chiefly in children younger than 5 years. *P. falciparum* is by far the most dangerous of the four species that affect humans, and cerebral malaria, in which parasitized erythrocytes develop cytoadherence antigens and block up cerebral arterioles, is the most prominent cause of death. It is known that antibodies can be therapeutic, and the hope that a vaccine will eventually be developed is sustained by the observation that inhabitants of endemic areas eventually become relatively immune to attacks, although this immunity is not sterilizing, as small quantities of parasites are left in the host.

The next most important species is *P. vivax,* famous for attacks that can recur long after exposure. From a practical point of view, a vaccine that could protect against both *P. falciparum* and *P. vivax* would have much to commend it. Industry could then charge high prices for a traveler's vaccine in industrialized countries. However, the preclinical research is being pursued separately for the two species with a heavy concentration on the bigger killer.

In view of the considerable amount of research that has been done, it is legitimate to ask why no effective malaria vaccine yet exists. This involves both theoretical and practical considerations. The best vaccines are for diseases in which nature provides solid immunity if an individual survives a first attack. This is not the case in malaria, in which immunity in endemic areas is tenuous at best and easily lost if the individual leaves to live in a malaria-free country. Clearly, the parasite has evolved powerful strategies to evade the host immune response. From a practical viewpoint, the parasite is difficult to grow; *P. falciparum* requires human blood, and *P. vivax* does not even replicate *in vitro* in red blood cells. Investigators are thus driven to recombinant DNA technology with all of the difficulties of choice of antigen among hundreds of candidates and correct refolding of every candidate. Add to this the fact that no animal model is a good imitation of the human disease, and the difficulties for the investigator mount.

Among the evolutionary strategies of the parasite, two stand out. The first is high mutability in most of the

antigens that have been studied, resulting in extensive allelic polymorphism, so that multiple forms of the antigen exist in the parasite population as a whole, which presumably reflects selection of mutants because parental forms are eliminated by antibody. Second, a very key antigen of *P. falciparum*, the so-called *P. falciparum* erythrocyte membrane protein 1 (PfEMP1), which is prominent on the surface of infected red blood cells, is represented in the genome by approximately 50 variant copies (183). As a clone of parasites emerges and reaches a sufficient size to strongly signal the immune system, eliminating most parasites, a variant expressing a different PfEMP1 arises, grows, reaches a critical size, and in turn is eliminated by antibody, and so the cycle repeats itself until, eventually, immunity to all the forms of PfEMP1 is achieved.

Life Cycle of Plasmodium falciparum

With these preliminary considerations out of the way, we should now look at the parasite's life cycle (with *P. falciparum* as the model) to determine where the different points of attack might be. Figure 40.3 shows this schemat-
FIGURE 40.3 Life cycle of *Plasmodium falciparum*. Note particularly four life-cycle stages that could be vaccine targets: the sporozoites, the infected liver cell, the merozoites, and the gametocytes.

ically. Invasion of the human is initiated when the female anopheline mosquito bites the human subject, thereby injecting a mobile form known as a sporozoite into the skin. The dominant surface antigen of the sporozoite is the circumsporozoite antigen or CSP, first identified by the Nussenzweigs (184) in the early 1980s and cloned soon thereafter. This candidate vaccine antigen has been the subject of intensive research. The sporozoite rapidly and efficiently invades hepatocytes. Two to 10 sporozoites can initiate infection within 5 to 30 minutes, probably involving an interaction between CSP and the glycosaminoglycan chains of heparin sulfate proteoglycans. A second sporozoite surface protein, the thrombospondin-related adhesion protein (TRAP), has a region highly homologous to a part of CSP and is probably also involved in binding to hepatocyte heparin sulfate proteoglycans. TRAP is required for sporozoite mobility and infectivity.

Within the hepatocyte, each sporozoite develops into a schizont containing 10,000 to 30,000 merozoites. Over this period, the hepatocyte presents on its surface peptides from a number of preerythrocytic stage proteins. A CD8$^+$ cytotoxic T cell attack on infected liver cells could materially lower the number of merozoites formed and thus lessen the attack on erythrocytes. As long as the parasite is confined to the liver, there are no clinical symptoms of malaria. Within 10 days or less, the liver schizont ruptures, and the merozoites are released and begin to invade erythrocytes, there to undergo another asexual amplification. The erythrocytic cycle is responsible for disease manifestation, inasmuch as development, rupture, and reinvasion initiate a vicious cycle.

Merozoite invasion of erythrocytes is a complex process involving multiple steps. The merozoite attaches to the erythrocyte, reorients itself so that its apical end faces the red blood cell, after which a tight junction develops, and parasite organelles known as rhoptries discharge their contents onto the red blood cell membrane. A progressively deeper vacuole forms and eventually closes to surround the engulfed parasite. The best-studied erythrocyte surface receptor for a parasite ligand is the Duffy blood group antigen for *P. vivax*. In contrast, *P. falciparum* seems capable of using multiple pathways for invasion, including sialic acids on glycophorins A, B, and C, as well as peptide sequences on glycophorins. As for the parasite ligands, a Duffy binding-like (DBL) superfamily has been defined. For *P. vivax*, the most important member is a 140-kDa Duffy-binding protein (PvDBP) (185), and for *P. falciparum*, EBA-175 appears to be the prototype. But additional merozoite proteins play a role in invasion, inasmuch as quite a number of monoclonal antibodies against them can block invasion *in vitro*. These include various merozoite surface proteins (MSPs) and proteins translocated from the apical organelles, the rhoptries and the micronemes, to the surface before invasion.

An important event in clinical malaria is the adherence of infected erythrocytes to vascular endothelium. When

this occurs in small vessels in the brain, blockage can follow, resulting in cerebral malaria and death. The chief molecular mediator of cytoadherence is the variant surface antigen PfEMP1, as already mentioned (183). The receptors for adherence are various and include CD36, intracellular adhesion molecule 1, vascular cell adhesion molecule 1, E-selectin, and chondroitin sulfate A.

In addition to producing merozoites, the erythrocytic cycle is also responsible for the production of the sexual forms known as gametocytes. These are taken up by the mosquito and mature into gametes. A vaccine capable of producing antigametocyte antibodies could destroy them in the blood of the vaccinee or could interfere with their maturation in the mosquito, or both. The life cycle of the parasite is, of course, completed in the mosquito, in which sexual union occurs, sporozoites emerge from mature oocysts 10 to 14 days after an infective blood meal, and invasion of salivary glands occurs soon thereafter.

Possible Vaccine Approaches

Given the complexity of this life cycle, many observers believe that a final malaria vaccine will contain key molecules from various and perhaps all stages. However, it is necessary to consider the best candidates from each stage in turn. Much knowledge has accumulated over the past 25 years (reviewed in [186,187]).

The sporozoite stage is an attractive target, inasmuch as a 100% effective vaccine would prevent infection completely and a partially effective one would lower the eventual invasive merozoite burden. Like most malarial antigens, the CSP presents as a dominant antigen multiple tandem repeats, in this case of the sequence NANP, which can absorb a large proportion of the anti-CSP antibodies both of the serum of patients and of CSP (or irradiated sporozoite) immunized persons. Promising results have been obtained with GlaxoSmithKline's vaccine known as RTS,S, given with the adjuvant AS02. RTS,S is a fusion protein of the carboxy-terminal half of CSP (which includes both part of the tandem repeat, thus R, and also important T cell epitopes, thus T) fused to the HBsAg. This is coexpressed in yeast with (nonfused) HBsAg (thus, S), which self-assembles into virion-like structures, aiding immunogenicity. The adjuvant AS02, already described, has strong T and B cell–stimulatory properties. In a human challenge model, this significantly protected malaria-naïve volunteers, although immunity was of short duration. In a field study in a rural area of The Gambia involving 306 men aged 18 to 45 years, the vaccine was safe and well-tolerated although fairly reactogenic, evoked strong anti-CSP antibody and T cell responses, and clearly gave partial protection in that it significantly delayed *P. falciparum* infection and reduced symptomatic malaria (188). Again, immunity waned rather quickly, but some immunological memory resulted, inasmuch as a booster dose given the following year reduced the incidences of infection and of symptomatic malaria. A phase IIb study in 1- to 4-year-old children in Mozambique also gave some protection (73), which appeared to be maintained for 18 months (189). There is also considerable research interest in vaccines consisting of whole irradiated sporozoites or live attenuated sporozoites (reviewed in [187]).

Anti–Liver-stage Vaccine

T cell immunity clearly plays a role in malaria and the most clear-cut example is in relation to parasite T cell epitopes on the surface of the infected liver cell. The most extensively investigated antigen is TRAP (thrombospondin-related adhesion protein), and it has been used alone or combined with a string of up to 15 epitopes from various parasite life stages. There have been multiple small clinical trials of the "prime-boost" approach, using the vectors naked DNA, MVA, an attenuated strain of fowlpox virus, FP9, or other vectors. Some of these have clearly reduced the liver-stage parasite load (reviewed in [187]). Priming with FP9 followed by boosting with MVA presently appears the best combination. An argument can be mounted for combined immunization with RTS,S and TRAP.

Blood-stage Antigens and Vaccines

There is a plethora of blood stage antigens at various stages of testing. The subject of the largest amount of work has been the protein MSP-1, a 195-kDa major merozoite protein, and various fragments of it. Considerable protective efficacy has been shown in murine and simian vaccine trials, although in the human, the highly polymorphic nature of this antigen may prove problematic. Efforts are being directed toward defining conserved protective epitopes of MSP-1. Other significant merozoite surface candidates are MSP-2, MSP-3, MSP-4, and MSP-5. The combination 4/5 looks attractive because it is relatively less polymorphic.

As noted, rhoptry-associated proteins (RAPs) perform as yet ill-defined tasks in merozoite invasion of erythrocytes. The antigens RAP-1 and RAP-2 show less polymorphism and have been partially successful in a Saimiri monkey model. The apical merozoite antigen 1 (AMA-1) is strongly protective in murine and simian trials, has been in phase I human trials, and is in continuing clinical development (190). Because this antigen has 16 conserved cysteine residues and exhibits a three-domain structure, correct refolding after expression is essential and presents a challenge.

In view of the importance of the initial docking events involving PvDBP for *P. vivax* and EBA-175 for *P. falciparum,* these represent further interesting candidates. For PvDBP, the cysteine-rich amino-terminal region II is conserved and constitutes the receptor-binding domain. This fragment, PvRII, when correctly refolded, represents an interesting *P. vivax* candidate. The same may be true for a homologous region of EBA-175.

Although the highly variant surface antigen family PfEMP1, which mediates cytoadherence, also exhibits DBL domains, it remains to be determined whether there is enough conservation in the RII domain for a polypeptide vaccine to hold promise.

Transmission Blocking Vaccines

Vaccines directed against the sexual stages of the parasite would not protect the vaccinee but could have profound effects at the community level if widely deployed. Antibodies made by the vaccinee would be taken up by the biting mosquito in its blood meal and could hamper the complex parasite life cycle within the vector. To date, studies have focused on the gametocyte-specific surface antigens Pfs48/45 and pfs230, the ookinete-specific surface molecules P25 and P28, and a variety of secreted ookinete proteins (reviewed in [186]). Phase I human trials have begun.

Antidisease Vaccines: Glycophosphatidylinositol Toxin of Malaria as a New Candidate Vaccine Molecule

An imaginative new approach to malaria immunization is being investigated by Schofield (reviewed in [191]). This is predicated on the idea that much of the pathological processes in malaria result from an inflammatory cascade initiated by a malarial toxin. GPI of parasite origin is the candidate and an oligosaccharide of the *P. falciparum* GPI glycan was synthesized, conjugated to a protein carrier, and injected into mice. Following challenge with *P. berghei,* the vaccine substantially reduced severe pathology, cerebral malaria, and mortality, but with no effect on parasite growth rate. There was also protection against blood acidosis, pulmonary edema, and vascular occlusion. It is hoped to take this approach into the clinic in the near future.

The Gates Malaria Vaccine Initiative

The analysis just described, which is by no means exhaustive, shows that the malaria vaccine field fairly bristles with promise. A critical block has been the capacity to take candidate molecules that look interesting on the basis of preclinical research to phase I and phase II clinical trials. Therefore, the Malaria Vaccine Initiative funded by the Bill & Melinda Gates Foundation is highly welcome. It will fund the preparation of vaccine pilot lots in accordance with Good Manufacturing Practice criteria, improve facilities for clinical and field trials, and provide coordination and cooperation between various major groups, thus optimizing their potential. However, this is not to deny the many hurdles that must still be overcome before this badly needed vaccine emerges.

Regretfully, vaccines against other human parasitic diseases have not progressed as far. There is considerable preclinical research in schistosomiasis, leishmaniasis, toxoplasmosis, amoebiasis, hookworm, hydatid disease, try-

panosomiasis, and many other parasites. Let us hope that future editions of this book may see at least some of these progress to phase III trials in humans.

ADVERSE EFFECTS OF VACCINES

Three considerations dictate that adverse effects of vaccines must be taken very seriously. First, vaccines are normally given to healthy individuals, as opposed to most other biopharmaceuticals, which are given to the sick. Second, most vaccines are given to infants and young children, deemed to be both very precious and very vulnerable. Third, in the industrialized countries, the very success of immunization programs, combined with good personal hygiene, environmental sanitation, and improved living conditions, has made epidemic disease seem like something unfamiliar and perhaps something with which antibiotics and other medical treatments can cope. In other words, opponents of immunization can be excused for not understanding the risk-benefit equation of vaccines because of a lack of personal experience. This has to be countered by good education.

Fortunately, serious adverse events are very rare with currently used vaccines. This creates what at first seems a curious problem. Because nearly all children get quite a few vaccine injections in the first year of life, a reasonable proportion of all infants coming down with some rare complaint, such as encephalitis, will have had an immunization within, for example, a week of that illness. The assumption of a causative rather than coincidental relationship is quite human and can be contested only by statistical arguments, which are unfamiliar to most people. The more serious claimed side effects are considered first.

The most controversial vaccine from the viewpoint of side effects has been DPT, containing whole killed pertussis bacteria. Reactions such as fever, irritability, local redness, swelling and pain, anorexia, and drowsiness are quite common, although of short duration and easily ameliorated by a drug such as paracetamol. Febrile convulsions occur in about 1 case in 2,000 to 3,000 and cause no long-term harm. Follow-up study has shown no evidence of neurological damage or intellectual impairment. The question of serious acute neurological illness, such as encephalopathy, has caused the most concern. The incidence was put at 1 case per 330,000 vaccine doses in the United Kingdom in 1981, but reanalysis of the data, coupled with a large study in the United States by the Institute of Medicine, challenged this conclusion. The American Academy of Pediatrics found that, although "the data accumulated to date may not prove that pertussis vaccine can never cause brain damage, they indicate that if it does so, such occurrences must be exceedingly rare" (192). The Institute of Medicine concluded that the risk of serious neurological complications was somewhere between 0 and 1 per 200,000. Because the number of cases of whooping cough

has fallen by a factor of 50 in the United States since the introduction of the vaccine, and because the disease is accompanied by permanent brain damage in about 1% of cases and by death in 0.1% to 4% of cases, depending on the study, the risk-benefit equation is still enormously on the side of vaccination, even with the worst assumptions about brain damage from vaccination. The acellular pertussis vaccine has effectively terminated this debt.

The next important area of concern is poliomyelitis. Adverse reactions to this vaccine are of particular importance because there have been no cases of wild poliomyelitis in the industrialized countries for many years. In fact, poliomyelitis transmission ceased in the western hemisphere in 1991. Thus, even a single case of vaccine-associated poliomyelitis is a real tragedy. Unfortunately, a reversion to neurovirulence of the Sabin poliovirus, although excessively rare, is not absolutely unknown. It appears that for approximately 2.7 million doses of the oral poliovirus vaccine, there is one case of paralytic polio, most commonly of Sabin type 3. On average, there have been about five such cases in the United States per year. Some have been in vaccinees and some in their contacts.

A major survey of paralytic poliomyelitis in England and Wales between 1985 and 1991 was reported by Joce et al. (193). In total, 21 confirmed cases were found. Thirteen were vaccine-associated, nine being in vaccinees and four in contacts. Five were imported cases, and three were cases whose source of infection was unknown. The estimated risk of vaccine-associated paralysis was 1.46 per million for the first dose but 0.49 per 10^6 for the second and 0 for the third and fourth. In all, nine cases of paralysis arose from 18.4 million doses of vaccine administered over 7 years, with a risk of paralysis of 0.49% per 10^6 immunizations, which is remarkably similar to the U.S. figure of 1 per 2.7 million. Two vaccine-associated cases occurred in immunodeficient children, for whom inactivated poliomyelitis vaccine should have been offered.

Whereas the risks of oral polio vaccine are truly minuscule, the industrialized world has largely gone back to the injectable, Salk-type vaccine (IPV).

One can draw up a panoply of other "accusations" against vaccines. Live attenuated virus vaccines can certainly cause damage in immunodeficient or immunosuppressed children; generalized vaccinia was probably the worst example. Now that smallpox has been eradicated, this risk has disappeared. If a vaccinia variant is rescued as a vaccine vector, it will be one of lessened virulence.

One can examine the existing vaccines one by one and identify claims for side reactions. Mild measles rash can follow the measles vaccine. Certainly, measles is a nasty disease for the unimmunized, with a case-fatality rate in developing nations of about 2% to 3% in unimmunized infants. In the industrialized world, the measles case-fatality rate is vastly lower, at 0.01% to 0.02%. However, nonfatal complications are common, including otitis media, pneumonia, and subacute sclerosing pan-encephalitis. As far as

the live attenuated vaccine is concerned, encephalitis and similar problems are very occasionally reported, but their origins have been hard to pin down, and the feasibility of reducing these rare, conjectural complications, as well as the acknowledged commoner ones (e.g., febrile convulsions), remains problematic at this stage.

Both the measles vaccine and its companions (mumps, rubella, and soon, perhaps, varicella) have good track records in *not* causing serious complications. Suffice it to say that these are live attenuated vaccines, which can cause problems in particular patients. Reactions are mild and include malaise, fever, mild rash, and (rarely) febrile convulsions. One report (194) surveyed the incidence of thrombocytopenic purpura after MMR vaccination. The incidence was 1 per 500,000 for measles or rubella alone, 1 per 120,000 for measles and rubella, and 1 per 105,000 for the combined MMR vaccine. The syndrome resembled the purpura that can occur after natural measles or rubella infections. Complete recovery occurred in 89.5% of cases; normalization followed by relapse was noted in 7%. No deaths have been reported. This French study accords with conclusions reached in several other countries. Although a plausible causal relationship can be argued, the usually favorable outcome ensures that this rare complication does not modify the risk-benefit equation significantly. The mumps vaccine occasionally causes aseptic meningitis.

From time to time, somewhat exotic claims of adverse events are made. For example, measles vaccination was claimed to cause autism and Crohn's disease. Nine studies have now refuted this. The hepatitis B vaccine was supposed to cause multiple sclerosis; exhaustive analysis has failed to support the association. No matter how bizarre, each claim must be examined carefully.

Excipients in the vaccine or adjuvant substances can occasion side reactions varying from inflammation to abscess formation. More seriously, vaccines can occasionally cause anaphylaxis, thrombocytopenia, or acute arthritis. These serious complications occur in fewer than 1 case in 100,000.

In summary, vaccines that have been through the current stringent regulatory process are incredibly safe. This fact deserves to be widely promulgated, and the media in particular need to be educated through a consistent and nonconfrontational effort.

RECOMMENDED IMMUNIZATION SCHEDULE

In the United States, routine immunization is recommended against 14 diseases, and this is likely to rise quite soon with the recent development of rotavirus and HPV vaccines. The schedule has become quite complex, and pharmaceutical companies are working hard to develop new combinations. Table 40.7 gives the current recommendations for children and adolescents in the

TABLE 40.7

Recommended Immunization Schedule for Persons Aged 0–6 Years—UNITED STATES • 2007

Vaccine ▼ Age ▶	Birth	1 month	2 months	4 months	6 months	12 months	15 months	18 months	19–23 months	2–3 years	4–6 years
Hepatitis B[1]	HepB	HepB		see footnote 1		HepB				HepB Series

☐ Range of recommended ages

☐ Catch-up immunization

☐ Certain high-risk groups

This schedule indicates the recommended ages for routine administration of currently licensed childhood vaccines, as of December 1, 2006, for children aged 0–6 years. Additional information is available at http://www.cdc.gov/nip/recs/child-schedule.htm. Any dose not administered at the recommended age should be administered at any subsequent visit, when indicated and feasible. Additional vaccines may be licensed and recommended during the year. Licensed combination vaccines may be used whenever any components of the combination are indicated and other components of the vaccine are not contraindicated and if approved by the Food and Drug Administration for that dose of the series. Providers should consult the respective Advisory Committee on Immunization Practices statement for detailed recommendations. Clinically significant adverse events that follow immunization should be reported to the Vaccine Adverse Event Reporting System (VAERS). Guidance about how to obtain and complete a VAERS form is available at **http://www.vaers, hhs.gov** or by telephone, **800-822-7967**.

1. Hepatitis B vaccine (HepB). *(Minimum age: birth)*
At birth:
- Administer monovalent HepB to all newborns before hospital discharge.
- If mother is hepatitis surface antigen (HBsAg)-positive, administer HepB and 0.5 mL of hepatitis B immune globulin (HBIG) within 12 hours of birth.
- If mother's HBsAg status is unknown, administer HepB within 12 hours of birth. Determine the HBsAg status as soon as possible and if HBsAg-positive, administer HBIG (no later than age 1 week).
- If mother is HBsAg-negative, the birth dose can only be delayed with physician's order and mother's negative HBsAg laboratory report documented in the infant's medical record.

After the birth dose:
- The HepB series should be completed with either monovalent HepB or a combination vaccine containing HepB. The second dose should be administered at age 1–2 months. The final dose should be administered at age ≥24 weeks. Infants born to HBsAg-positive mothers should be tested for HBsAg and antibody to HBsAg after completion of ≥3 doses of a licensed HepB series, at age 9–18 months (generally at the next well-child visit).

4-month dose:
- It is permissible to administer 4 doses of HepB when combination vaccines are administered after the birth dose. If monovalent HepB is used for doses after the birth dose, a dose at age 4 months is not needed.

2. Rotavirus vaccine (Rota). *(Minimum age: 6 weeks)*
- Administer the first dose at age 6–12 weeks. Do not start the series later than age 12 weeks.
- Administer the final dose in the series by age 32 weeks. Do not administer a dose later than age 32 weeks.
- Data on safety and efficacy outside of these age ranges are insufficient.

3. Diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP). *(Minimum age: 6 weeks)*
- The fourth dose of DTaP may be administered as early as age 12 months, provided 6 months have elapsed since the third dose.
- Administer the final dose in the series at age 4–6 years.

4. *Haemophilus influenzae* type b conjugate vaccine (Hib). *(Minimum age: 6 weeks)*
- If PRP-OMP (PedvaxHIB® or ComVax® [Merck]) is administered at ages 2 and 4 months, a dose at age 6 months is not required.
- TriHiBit® (DTaP/Hib) combination products should not be used for primary immunization but can be used as boosters following any Hib vaccine in children aged ≥12 months.

5. Pneumococcal vaccine. *(Minimum age: 6 weeks for pneumococcal conjugate vaccine [PCV]; 2 years for pneumococcal polysaccharide vaccine [PPV])*
- Administer PCV at ages 24–59 months in certain high-risk groups. Administer PPV to children aged ≥2 years in certain high-risk groups. See *MMWR* 2000;49(No. RR-9):1–35.

6. Influenza vaccine. *(Minimum age: 6 months for trivalent inactivated influenza vaccine [TIV]; 5 years for live, attenuated influenza vaccine [LAIV])*
- All children aged 6–59 months and close contacts of all children aged 0–59 months are recommended to receive influenza vaccine.
- Influenza vaccine is recommended annually for children aged ≥59 months with certain risk factors, health-care workers, and other persons (including household members) in close contact with persons in groups at high risk. See *MMWR* 2006;55(No. RR-10):1–41.
- For healthy persons aged 5–49 years, LAIV may be used as an alternative to TIV.
- Children receiving TIV should receive 0.25 mL if aged 6–35 months or 0.5 mL if aged ≥3 years.
- Children aged <9 years who are receiving influenza vaccine for the first time should receive 2 doses (separated by ≥4 weeks for TIV and ≥6 weeks for LAIV).

7. Measles, mumps, and rubella vaccine (MMR). *(Minimum age: 12 months)*
- Administer the second dose of MMR at age 4–6 years. MMR may be administered before age 4–6 years, provided ≥4 weeks have elapsed since the first dose and both doses are administered at age ≥12 months.

8. Varicella vaccine. *(Minimum age: 12 months)*
- Administer the second dose of varicella vaccine at age 4–6 years. Varicella vaccine may be administered before age 4–6 years, provided that ≥3 months have elapsed since the first dose and both doses are administered at age ≥12 months. If second dose was administered ≥28 days following the first dose, the second dose does not need to be repeated.

9. Hepatitis A vaccine (HepA). *(Minimum age: 12 months)*
- HepA is recommended for all children aged 1 year (i.e., aged 12–23 months). The 2 doses in the series should be administered at least 6 months apart.
- Children not fully vaccinated by age 2 years can be vaccinated at subsequent visits.
- HepA is recommended for certain other groups of children, including in areas where vaccination programs target older children. See *MMWR* 2006;55(No. RR-7):1–23.

10. Meningococcal polysaccharide vaccine (MPSV4). *(Minimum age: 2 years)*
- Administer MPSV4 to children aged 2–10 years with terminal complement deficiencies or anatomic or functional asplenia and certain other high-risk groups. See *MMWR* 2005;54(No. RR-7):1–21.

The Recommended Immunization Schedules for Persons Aged 0–18 Years are approved by the Advisory Committee on Immunization Practices (http://www.cdc.gov/nip/acip), the American Academy of Pediatrics (http://www.aap.org), and the American Academy of Family Physicians (http://www.aafp.org).

☐ Range of recommended ages

☐ Catch-up immunization

☐ Certain high-risk groups

This schedule indicates the recommended ages for routine administration of currently licensed childhood vaccines, as of December 1, 2006, for children aged 7–18 years. Additional information is available at **http://www.cdc.gov/nip/recs/child-schedule.htm.** Any dose not administered at the recommended age should be administered at any subsequent visit, when indicated and feasible. Additional vaccines may be licensed and recommended during the year. Licensed combination vaccines may be used whenever any components of the combination are indicated and other components of the vaccine are not contraindicated and if approved by the Food and Drug Administration for that dose of the series. Providers should consult the respective Advisory Committee on Immunization Practices statement for detailed recommendations. Clinically significant adverse events that follow immunization should be reported to the Vaccine Adverse Event Reporting System (VAERS). Guidance about how to obtain and complete a VAERS form is available at **http://www.vaers.hhs.gov** or by telephone, **800-822-7967.**

1. **Tetanus and diphtheria toxoids and acellular pertussis vaccine (Tdap).**
   (Minimum age: 10 years for BOOSTRIX® and 11 years for ADACEL™)
   • Administer at age 11–12 years for those who have completed the recommended childhood DTP/DTaP vaccination series and have not received a tetanus and diphtheria toxoids vaccine (Td) booster dose.
   • Adolescents aged 13–18 years who missed the 11–12 year Td/Tdap booster dose should also receive a single dose of Tdap if they have completed the recommended childhood DTP/DTaP vaccination series.

2. **Human papillomavirus vaccine (HPV).** *(Minimum age: 9 years)*
   • Administer the first dose of the HPV vaccine series to females at age 11–12 years.
   • Administer the second dose 2 months after the first dose and the third dose 6 months after the first dose.
   • Administer the HPV vaccine series to females at age 13–18 years if not previously vaccinated.

3. **Meningococcal vaccine.** *(Minimum age: 11 years for meningococcal conjugate vaccine [MCV4]; 2 years for meningococcal polysaccharide vaccine [MPSV4])*
   • Administer MCV4 at age 11–12 years and to previously unvaccinated adolescents at high school entry (at approximately age 15 years).
   • Administer MCV4 to previously unvaccinated college freshmen living in dormitories; MPSV4 is an acceptable alternative.
   • Vaccination against invasive meningococcal disease is recommended for children and adolescents aged ≥2 years with terminal complement deficiencies or anatomic or functional asplenia and certain other high-risk groups. See *MMWR* 2005;54(No. RR-7):1–21. Use MPSV4 for children aged 2–10 years and MCV4 or MPSV4 for older children.

4. **Pneumococcal polysaccharide vaccine (PPV).** *(Minimum age: 2 years)*
   • Administer for certain high-risk groups. See *MMWR* 1997;46(No. RR-8):1–24, and *MMWR* 2000;49(No. RR-9):1–35.

5. **Influenza vaccine.** *(Minimum age: 6 months for trivalent inactivated influenza vaccine [TIV]; 5 years for live, attenuated influenza vaccine [LAIV])*
   • Influenza vaccine is recommended annually for persons with certain risk factors, health-care workers, and other persons (including household members) in close contact with persons in groups at high risk. See *MMWR* 2006;55 (No. RR-10):1–41.
   • For healthy persons aged 5–49 years, LAIV may be used as an alternative to TIV.
   • Children aged <9 years who are receiving influenza vaccine for the first time should receive 2 doses (separated by ≥4 weeks for TIV and ≥6 weeks for LAIV).

6. **Hepatitis A vaccine (HepA).** *(Minimum age: 12 months)*
   • The 2 doses in the series should be administered at least 6 months apart.
   • HepA is recommended for certain other groups of children, including in areas where vaccination programs target older children. See *MMWR* 2006;55 (No. RR-7):1–23.

7. **Hepatitis B vaccine (HepB).** *(Minimum age: birth)*
   • Administer the 3-dose series to those who were not previously vaccinated.
   • A 2-dose series of Recombivax HB® is licensed for children aged 11–15 years.

8. **Inactivated poliovirus vaccine (IPV).** *(Minimum age: 6 weeks)*
   • For children who received an all-IPV or all-oral poliovirus (OPV) series, a fourth dose is not necessary if the third dose was administered at age ≥4 years.
   • If both OPV and IPV were administered as part of a series, a total of 4 doses should be administered, regardless of the child's current age.

9. **Measles, mumps, and rubella vaccine (MMR).** *(Minimum age: 12 months)*
   • If not previously vaccinated, administer 2 doses of MMR during any visit, with ≥4 weeks between the doses.

10. **Varicella vaccine.** *(Minimum age: 12 months)*
   • Administer 2 doses of varicella vaccine to persons without evidence of immunity.
   • Administer 2 doses of varicella vaccine to persons aged <13 years at least 3 months apart. Do not repeat the second dose, if administered ≥28 days after the first dose.
   • Administer 2 doses of varicella vaccine to persons aged ≥13 years at least 4 weeks apart.

The Recommended Immunization Schedules for Persons Aged 0–18 Years are approved by the Advisory Committee on Immunization Practices (http://www.cdc.gov/nip/acip), the American Academy of Pediatrics (http://www.aap.org), and the American Academy of Family Physicians (http://www.aafp.org).

(Continued)

TABLE 40.7 (continued)

Catch-up Immunization Schedule
for Persons Aged 4 Months–18 Years Who Start Late or Who Are More Than 1 Month Behind

The table below provides catch-up schedules and minimum intervals between doses for children whose vaccinations have been delayed. A vaccine series does not need to be restarted, regardless of the time that has elapsed between doses. Use the section appropriate for the child's age.

Vaccine	Minimum Age for Dose 1	Minimum Interval Between Doses			
		Dose 1 to Dose 2	**Dose 2 to Dose 3**	**Dose 3 to Dose 4**	**Dose 4 to Dose 5**
CATCH-UP SCHEDULE FOR PERSONS AGED 4 MONTHS–6 YEARS					
Hepatitis B[1]	**Birth**	**4 weeks**	**8 weeks** (and 16 weeks after first dose)		
Rotavirus[2]	**6 wks**	**4 weeks**	**4 weeks**		
Diphtheria, Tetanus, Pertussis[3]	**6 wks**	**4 weeks**	**4 weeks**	**6 months**	**6 months[3]**
***Haemophilus influenzae* type b[4]**	**6 wks**	**4 weeks** if first dose administered at age <12 months **8 weeks (as final dose)** if first dose administered at age 12-14 months **No further doses needed** if first dose administered at age ≥15 months	**4 weeks[4]** if current age <12 months **8 weeks (as final dose)[4]** if current age ≥12 months and second dose administered at age <15 months **No further doses needed** if previous dose administered at age ≥15 months	**8 weeks (as final dose)** This dose only necessary for children aged 12 months–5 years who received 3 doses before age 12 months	
Pneumococcal[5]	**6 wks**	**4 weeks** if first dose administered at age <12 months and current age <24 months **8 weeks (as final dose)** if first dose administered at age ≥12 months or current age 24–59 months **No further doses needed** for healthy children if first dose administered at age ≥24 months	**4 weeks** if current age <12 months **8 weeks (as final dose)** if current age ≥12 months **No further doses needed** for healthy children if previous dose administered at age ≥24 months	**8 weeks (as final dose)** This dose only necessary for children aged 12 months–5 years who received 3 doses before age 12 months	
Inactivated Poliovirus[6]	**6 wks**	**4 weeks**	**4 weeks**	**4 weeks[6]**	
Measles, Mumps, Rubella[7]	**12 mos**	**4 weeks**			
Varicella[8]	**12 mos**	**3 months**			
Hepatitis A[9]	**12 mos**	**6 months**			
CATCH-UP SCHEDULE FOR PERSONS AGED 7–18 YEARS					
Tetanus, Diphtheria/ Tetanus, Diphtheria, Pertussis[10]	**7 yrs[10]**	**4 weeks**	**8 weeks** if first dose administered at age <12 months **6 months** if first dose administered at age ≥12 months	**6 months** if first dose administered at age <12 months	
Human Papillomavirus[11]	**9 yrs**	**4 weeks**	**12 weeks**		
Hepatitis A[9]	**12 mos**	**6 months**			
Hepatitis B[1]	**Birth**	**4 weeks**	**8 weeks** (and 16 weeks after first dose)		
Inactivated Poliovirus[6]	**6 wks**	**4 weeks**	**4 weeks**	**4 weeks[6]**	
Measles, Mumps, Rubella[7]	**12 mos**	**4 weeks**			
Varicella[8]	**12 mos**	**4 weeks** if first dose administered at age ≥13 years **3 months** if first dose administered at age <13 years			

1. **Hepatitis B vaccine (HepB).** *(Minimum age: birth)*
   - Administer the 3-dose series to those who were not previously vaccinated.
   - A 2-dose series of Recombivax HB® is licensed for children aged 11–15 years.

2. **Rotavirus vaccine (Rota).** *(Minimum age: 6 weeks)*
   - Do not start the series later than age 12 weeks.
   - Administer the final dose in the series by age 32 weeks. Do not administer a dose later than age 32 weeks.
   - Data on safety and efficacy outside of these age ranges are insufficient.

3. **Diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP).** *(Minimum age: 6 weeks)*
   - The fifth dose is not necessary if the fourth dose was administered at age ≥4 years.
   - DTaP is not indicated for persons aged ≥7 years.

4. ***Haemophilus influenzae* type b conjugate vaccine (Hib).** *(Minimum age: 6 weeks)*
   - Vaccine is not generally recommended for children aged ≥5 years.
   - If current age <12 months and the first 2 doses were PRP-OMP (PedvaxHIB® or ComVax® [Merck]), the third (and final) dose should be administered at age 12– 15 months and at least 8 weeks after the second dose.
   - If first dose was administered at age 7–11 months, administer 2 doses separated by 4 weeks plus a booster at age 12–15 months.

5. **Pneumococcal conjugate vaccine (PCV).** *(Minimum age: 6 weeks)*
   - Vaccine is not generally recommended for children aged ≥5 years.

6. **Inactivated poliovirus vaccine (IPV).** *(Minimum age: 6 weeks)*
   - For children who received an all-IPV or all-oral poliovirus (OPV) series, a fourth dose is not necessary if third dose was administered at age ≥4 years.
   - If both OPV and IPV were administered as part of a series, a total of 4 doses should be administered, regardless of the child's current age.

7. **Measles, mumps, and rubella vaccine (MMR).** *(Minimum age: 12 months)*
   - The second dose of MMR is recommended routinely at age 4–6 years but may be administered earlier if desired.
   - If not previously vaccinated, administer 2 doses of MMR during any visit with ≥4 weeks between the doses.

8. **Varicella vaccine.** *(Minimum age: 12 months)*
   - The second dose of varicella vaccine is recommended routinely at age 4–6 years but may be administered earlier if desired.
   - Do not repeat the second dose in persons aged <13 years if administered ≥28 days after the first dose.

9. **Hepatitis A vaccine (HepA).** *(Minimum age: 12 months)*
   - HepA is recommended for certain groups of children, including in areas where vaccination programs target older children. See *MMWR* 2006;55(No. RR-7):1–23.

10. **Tetanus and diphtheria toxoids vaccine (Td) and tetanus and diphtheria toxoids and acellular pertussis vaccine (Tdap).** *(Minimum ages: 7 years for Td, 10 years for BOOSTRIX®, and 11 years for ADACEL™)*
    - Tdap should be substituted for a single dose of Td in the primary catch-up series or as a booster if age appropriate; use Td for other doses.
    - A 5-year interval from the last Td dose is encouraged when Tdap is used as a booster dose. A booster (fourth) dose is needed if any of the previous doses were administered at age <12 months. Refer to ACIP recommendations for further information. See *MMWR* 2006;55(No. RR-3).

11. **Human papillomavirus vaccine (HPV).** *(Minimum age: 9 years)*
    - Administer the HPV vaccine series to females at age 13–18 years if not previously vaccinated.

Information about reporting reactions after immunization is available online at **http://www.vaers.hhs.gov** or by telephone via the 24-hour national toll-free information line 800-822-7967. Suspected cases of vaccine-preventable diseases should be reported to the state or local health department. Additional information, including precautions and contraindications for immunization, is available from the National Center for Immunization and Respiratory Diseases at **http://www.cdc.gov/nip/default.htm** or telephone, **800-CDC-INFO (800-232-4636)**.

United States. Schedules will vary somewhat from country to country.

ACCELERATED EFFORTS IN GLOBAL IMMUNIZATION

In recent years, markedly greater effort is going into the attempt to bring the benefits of vaccines to all the world's children. The Global Alliance for Vaccines and Immunization (GAVI), generously funded by the Bill & Melinda Gates Foundation, Norway, and several other donors, is making a big impact (195). Its focus is on a country-driven approach and high accountability, with concrete rewards for good results. In 2005, the G8 group of countries pledged to double aid to Africa, and planning is at an advanced stage for a new and innovative method of financing known as the International Finance Facility for Immunization (IFFIm). The idea is to raise $4 billion through the issue of bonds to be redeemed via unbreakable pledges by the donor countries. Spent over 10 years, it is estimated that this extra money for GAVI would prevent an additional 5 million child deaths by 2015 and more than 5 million future adult deaths from liver cirrhosis and cancer due to hepatitis B (196). In due time, when vaccines become available, the various sizeable bodies devoted to HIV/AIDS, malaria, and TB, such as the Global Fund to Fight AIDS, Tuberculosis, and Malaria, will ensure wide distribution. On the research side, most major donors are getting behind the Global HIV/AIDS Vaccine Enterprise (GHAVE), which seeks to harmonize and coordinate HIV vaccine research around the world.

It is to be hoped that the large polio eradication effort is crowned with success in the next several years. If so, the question will have to be asked whether there should be further eradication attempts. Measles would be a real possibility, but it must be admitted that total eradication is quite an expensive effort. The polio example has shown us that cessation of infant immunization while there is still polio in another country is dangerous. Some argue that control as a public health threat is a more sensible goal to set than elimination of the last virus from the planet. Still, what a magnificent argument to be able to have! Over time, the argument will recur for every organism for which we have an excellent vaccine and no animal or environmental reservoir.

VACCINATION OF THE VERY YOUNG AND THE OLD

Both extremes of age offer special challenges for the designer of new and improved vaccines. Some vaccines should be delivered very early in life, such as at birth, to be maximally useful. These include vaccines for diseases carried by the mother, such as hepatitis B, hepatitis C, HIV, or CMV. Early infant immunization is also good for encapsulated bacteria and rotavirus. Traditionally, BCG has also been given within a few days of birth in developing countries. Other vaccines are recommended for the elderly, including (in many countries) influenza and pneumococcal vaccines. There has been an up-surge of interest in protecting the elderly.

Although much more mature than that of the newborn mouse, the newborn infant's immune system is not yet hugely responsive, and neonatal immunization does not generally lead to extensive antibody formation. However, neonatal immunization can lead to useful priming of both B and T cell memory responses and thus serves a useful purpose (197). Preclinical studies suggest that the immaturity is not so much in $CD4^+$ or $CD8^+$ T cells themselves but rather in APCs and the APC–T cell interaction. This suggests that suitable adjuvant formulations could overcome the problem. Another feature of neonates is that they appear deficient in the capacity to form long-lived, bone marrow–seeking, antibody-forming plasma cells.

Maternally acquired antibodies can interfere with primary active immune responses. This is a serious point for many infant vaccines, including live and nonlive preparations, although it appears not to be an issue for hepatitis B. Inhibition is highly epitope specific and is much more important for B cell than for T cell responses. From a practical viewpoint, each case must be investigated specifically. For the most important vaccines of the future, maternal antibodies should not be a problem for HIV or TB, but for malaria, in which antibodies are of at least equal importance to T cells, the matter may be more germane. In the important example of measles, an aerosolized vaccine may overcome the problem.

At the other end of life, several factors militate against robust immune responses. The thymic cortex is largely replaced by fat, and few or no new T cells are exported from there. Thus, T cell immunity to new antigens must depend on cross-reactions with previously encountered ones. Similarly, the number of progenitors of B cells in the bone marrow is also reduced, although not as markedly. Interestingly, DCs from the peripheral blood of individuals older than 65 years are present in somewhat *increased* numbers, normal in appearance and surface markers, and unimpaired in antigen-presenting function. This may partly militate against the reduced proliferative capacity of aged T cells. While the capacity to mount a serum antibody response may be reduced, some vaccine boosters work well (e.g., tetanus and influenza).

A curious phenomenon in old age is the progressive accumulation of a differentiated $CD8^+$ T cell population specific for CMV, which may leave the rest of the

repertoire depleted (198). Yet the elderly do not have too much trouble mounting a CD4$^+$ T cell response to vaccines such as rabies or tickborne encephalitis (199). Overall, the elderly may require higher antigen doses or more frequent boosters than young adults. An interesting example is Merck's recently introduced vaccine for the prevention of herpes zoster and post–herpetic neuralgia in the ageing. It works well but requires 14 times the dose of live attenuated varicella virus than the formulation for infant immunization.

As more vaccines become available, and as the lowered impact of epidemic diseases prompts complacency in the minds of many, health authorities will have to give much more thought to the whole question of booster immunizations in adult life. In terms of policy, this area is currently a bit of a mess. It should not be left to the vagaries of choices by travelers.

CONCLUSION

There is no doubting the current renaissance in vaccinology. The field veritably bristles with new and exciting possibilities, and although the commercial potential is not as great as for prescription drugs, the healthy percentage sales growth of the sector has not gone unnoticed in the boardrooms of the big pharmaceutical companies. Of the new vaccination approaches discussed, mucosal delivery systems, new adjuvant formulations, and extensive combinations are the most promising. DNA vaccines, viral vectors, and prime-boost approaches are intellectually exciting but some distance away. Transdermal delivery systems, methods to circumvent the need for a cold chain, plant production systems for antigens, and microencapsulation technologies are fertile research areas. Despite his enthusiasm for such novel developments, the author is also aware of the fact that changes to national immunization programs can be made only after extensive clinical research, particularly in cases in which an effective vaccine already exists. The future, therefore, represents a judicious balance between conservatism in a measure already regarded skeptically by a minority and cautious activism as thorough research documents the value of each new and improved vaccine. Nor should a healthy pluralism be opposed. Some countries will move faster on some vaccines because of their particular perspectives and problems. All of this means that the widespread introduction of the rich panoply of vaccines coming from the research sector will probably be slower than the scientific community would like. In the long run, however, the approach to many communicable diseases will be revolutionized by the new vaccinology. Further, the thrusting programs bringing vaccines to the developing countries need to be strongly applauded. The legacy of Jenner and Pasteur is in good hands.

Immunologic Mechanisms in Disease

▌ Systemic Autoimmunity

Betty Diamond

INTRODUCTION

Our understanding of basic immunology has grown immensely over the last decades, leading to a new appreciation of autoimmunity and autoimmune disease. This chapter will provide a re-evaluation of systemic autoimmune disease focusing on general principles that will then be reviewed in the context of some selected diseases, systemic lupus erythematosus (SLE), inflammatory arthritis, scleroderma, vasculitis, and autoimmune muscle disease.

Conceptual Framework

There are several major concepts to be presented:

1. Autoreactivity can be beneficial as well as harmful.
2. Clinical disease depends on an infelicitous interplay of genes and environment.
3. Antigen is important in the maintenance of autoreactivity.
4. Pathologic autoreactivity or autoimmune disease is often accompanied by reduced immunocompetence, with an increased susceptibility to both infection and malignancy.
5. Different cellular and molecular processes characterize the inductive phase of autoimmune disease, the early effector phase of target organ inflammation, and the late phase of irreversible tissue damage.
6. Tissue injury in autoimmune disease involves the recruitment of resident cells within the target organ into the inflammatory process, as well as the infiltration of blood-borne inflammatory cells.
7. Optimal treatment strategies for these diseases should restore immune homeostasis rather than solely diminish immune activation.

These concepts arise from studies of murine models of disease and studies of patients. Increasingly, studies demonstrate the multiple potential pathoetiologies of each autoimmune disease and suggest an as-yet-unclassified heterogeneity of disease. As clearer phenotypic analyses of patient subsets develop, it will be possible to design better therapies for these diseases, and even prevention strategies.

GENERAL PRINCIPLES

Defining Autoimmune Disease

It is important to note that the list of systemic autoimmune diseases is not fixed. There is no definition of autoimmune disease that meets with universal approval. There are a number of inflammatory diseases mediated by cells and effector mechanisms of the innate immune system, without evidence of activation of the adaptive immune response and without evidence of an inciting exposure to foreign antigen. These diseases, familial Mediterranean fever and other autoinflammatory diseases caused by mutations in molecules of the innate immune system such as pyrin, cryopyrin, and NOD2 (1), Behcet disease, perhaps even atherosclerosis, are not classified as systemic autoimmune diseases, despite immune activation and multiple organ involvement. Rather, in the clinical setting, an operational definition of a systemic autoimmune disease is a disease in which tissue damage is mediated by T cells and antibodies, most often displaying autoreactivity (2). Despite defining autoimmune diseases as the consequence of a dysregulated adaptive immune system, it is clear that the innate and the adaptive immune responses are both involved in systemic autoimmune diseases. The innate immune system may contribute to the initial induction of antigen-specific autoreactivity and may also participate in the effector mechanisms responsible for tissue damage, but activated T cells, antibodies, or both, must be present in lesional tissue.

The immune activation present in patients with systemic autoimmune diseases must occur in the absence of any detectable ongoing infection (2). This definition allows for the possibility that many autoimmune diseases may be the late sequelae of infection by either a particular microbial pathogen or a range of different microbial pathogens. It also means that some diseases currently referred to as autoimmune may in the future be diagnosed as an immune response to an ongoing infection or an ongoing exposure to an environmental toxin. Thus, the immunosuppressive or immunomodulatory therapies currently in use or under investigation for autoimmune disease may give way, in some clinical contexts, to antibiotic therapy or to behavioral modification to avoid toxic exposures.

In animal models, the operative definition of an autoimmune disease is more straightforward; whether or not defects in the innate immune system and dendritic cell function are involved, an autoimmune disease can be replicated in a syngeneic host by adoptive transfer of T cells or B cells, or both, and does not occur in the absence of T cells or B cells, or both. Because these diseases, whether in humans or mice, require, by definition, the activation of T cells and B cells, there is a presumption of antigenic specificity in the immune response, although the full range of the targeted autoantigens is not known for most autoimmune diseases. It is also important to be aware that the autospecificities of either disease-associated T cells or antibodies that have been recognized thus far may not be the autospecificities important in eliciting the pathogenic response or the autospecificities leading to target organ injury. New autoantigens and new cross-reactivities continue to be identified; some of these provide novel and important insights into pathogenesis.

Prevalence of Disease

When autoimmune diseases were first described, it was apparent that each disease was relatively uncommon. Increasingly, a relationship among apparently distinct autoimmune diseases is being recognized. This re-evaluation began with epidemiologic studies showing that multiple autoimmune diseases can cluster within a single family and has progressed to the identification of genes that function as susceptibility factors for a number of different autoimmune diseases (3). The close relationship among these diseases is further supported by clinical trials showing that the same therapeutic intervention can provide clinical benefit in multiple distinct diseases. When autoimmune diseases are considered together, they are present in 5% to 7% of the population and constitute a major cause of morbidity and early mortality. There is also some evidence that the incidence of some diseases may be increasing. A recent report suggested a rise, for unknown reasons, in the incidence of systemic lupus (4). As most autoimmune diseases are multigenic in origin and require some environmental trigger, it is possible that genetic admixture, changes in diet, and environmental exposures, as well as changes in microbial exposures, may affect both the incidence and phenotypic characteristics of autoimmune disease.

Normal Self-tolerance

Immune tolerance is discussed in detail in Chapter 29, and is reviewed here only briefly to highlight aspects of immune regulation that may be disturbed in systemic autoimmune diseases. Immune homeostasis depends on the appropriate function of multiple intercellular and intracellular pathways. The innate immune system requires an appropriate threshold for activation and balanced effector functions. The B- and T-cell repertoires must display sufficient autoreactivity for self-regulation but lack pathogenic autoreactivity. Thresholds for activation, survival, and downregulation of the adaptive immune response must permit memory formation, but preclude a chronic inflammatory state. Finally, self-antigens must be effectively sequestered from immune recognition or presented through a tolerogenic pathway. Exactly where normal tolerance mechanisms fail in individuals with systemic autoimmune diseases is a matter of some debate, but increasingly, studies in mice suggest that intrinsic abnormalities in the innate immune system and dendritic cell function, a failure of central and peripheral tolerance checkpoints for T and B cells, and abnormal exposure to self-antigen can all predispose to systemic autoimmunity, and usually more than one defect in homeostatic regulation is present.

T-Cell Tolerance

It is clear that the random V (D) J and VJ gene rearrangements necessary to generate the diversity of T-cell receptors (TCRs) and B-cell receptors (BCRs) that characterize the normal T- and B-cell repertoire give rise to a high percentage of autoreactive antigen receptors. The elimination or regulation of self-reactive T cells begins in the thymus with the deletion of T cells that have high affinity for self-peptide/self-MHC complexes and with the generation of self-reactive regulatory T cells (5). Studies of T-cell selection have focused on transgene-encoded TCRs present in mice with organ-specific autoimmunity or on artificial model systems. With few exceptions, the actual antigens recognized by T cells in systemic autoimmune diseases are unknown. Histone-reactive T cells can be identified in both murine (6) and human lupus (7), and T-cell reactivity to collagen can be identified in mice with collagen-induced arthritis (8) and in rheumatoid arthritis (RA) in humans (9). However, T-cell specificities in myositis, scleroderma, Sjogren syndrome, and vasculitis are unknown, and it can be presumed that the antigenic specificities of most disease-enhancing T cells in lupus and rheumatoid arthritis are also unknown. Studies in mice suggest that even nonautoreactive activated T cells can sustain autoantibody production and autoimmune disease.

Although deficiency of the transcriptional regulator, AIRE, causes a failure to delete autoreactive T cells in the thymus and leads to generalized autoreactivity in mice, especially in endocrine organs (10), there are surprisingly few models of systemic autoimmune disease with an identified defect in thymic selection. The MRL mouse strain displays reduced stringency in central tolerance, but autoimmune disease occurs only late in life in MRL mice, unless there is an impairment in Fas or Fas ligand expression (11). There is, however, evidence that negative selection of autoreactive T cells is critical to the prevention

of systemic autoimmune disease. Mice that lack class II expression on bone marrow–derived cells display thymic maturation of autoreactive T cells. When T cells from these mice are transferred into syngeneic hosts that exhibit normal peripheral expression of class II molecules, systemic autoimmunity ensues (12). Thus, the thymus plays a role in the elimination of T cells reactive with nuclear antigens.

Peripheral T-cell tolerance is maintained, in part, by tolerogenic dendritic cells, and dysregulation of these cells can lead to autoimmunity (13). This may be genetically determined; alternatively, dendritic cell dysfunction may be a consequence of environment, such as vitamin D deficiency (14) or continuous exposure to Toll-like receptor (TLR) agonists (15). Once an inflammatory milieu has been established, dendritic cell activation can lead to the activation of autoreactive T cells that rely on peripheral tolerance mechanisms for their control.

Regulatory T cells are among the enforcers of peripheral tolerance. In organ-specific autoimmunity in mice, these regulatory cells have been clearly demonstrated to be important in containing autoreactivity. In systemic autoimmunity, there is increasing evidence for a decreased number of some regulatory T-cell subsets, but restoration of self-tolerance through the administration of additional regulatory T cells has not yet been achieved.

B-Cell Tolerance

The failure of B-cell tolerance is a major feature of most systemic autoimmune diseases. B-cell tolerance begins in the bone marrow, where antigen engagement of the BCR triggers deletion, anergy, or receptor editing (16). Evidence continues to accumulate that receptor editing or the replacement of a light chain that associates with the heavy chain to form an autoantibody with a novel light chain that does not produce autoreactivity is the first line of defense against autoimmunity; impaired tolerance has been seen both with a deficiency of receptor editing and with indiscriminate receptor editing that leads to novel light chains conferring autoreactivity. Thus far, defects in receptor editing have not been identified in individuals with autoimmune disease. There is some evidence that receptor editing can occur in the rheumatoid synovium, but this appears to be a pathogenic rather than a protective process (17).

BCR signaling thresholds are critical to the maintenance of B-cell tolerance, as all mechanisms of B-cell tolerance depend, at least in part, on BCR engagement. Overexpression of CD19, mutations of CD45, and deletion of CD22 or SHP-1 all enhance BCR signaling and lead to systemic autoimmunity (18), yet inhibition of BCR signaling through enhanced activity of CD22 or Ly108 also leads to autoreactivity because the attenuated signal fails to activate early tolerance mechanisms (19). Because inhibitors of molecules in the BCR signaling pathway are available, understanding the critical balance between overexuberant

B-cell activation (strong BCR signaling) and deficient B-cell tolerance induction (weak BCR signaling) is crucial for proper therapeutic targeting of the BCR signaling pathways.

The study of mice with transgene-encoded BCRs has provided much information about normal tolerance mechanisms and has identified a role for all the above-mentioned tolerance mechanisms as well as developmental arrest and active tolerance that occurs when B cells are chronically exposed to self-antigen and IL-6 (20). There are also data showing that regulatory checkpoints exist for B cells not just during the maturation to immunocompetence but even after exposure to antigen, in the germinal center and in the late stages of B-cell differentiation to memory or long-lived plasma cells (21,22). For example, anti-Sm B cells fail to become plasma cells upon exposure to antigen in a nonautoimmune host, but will mature to a plasma cell phenotype in MRL/lpr autoimmune mice (23). Similarly, a deficiency of the inhibitory Fc receptor, FcRIIb, permits plasma-cell differentiation of autoreactive B cells (24). Finally, B-cell tolerance depends on normal cell death pathways; there is abundant evidence that autoreactive B cells fail to die when there is an excess of antiapoptotic or a deficit in proapoptotic molecules within the cell (25). B-cell tolerance can be broken both by intrinsic defects in B-cell function as mentioned in this section and by the extrinsic provision of excess growth and survival factors such as CD40, BAFF, and cytokines within the B-cell microenvironment (26).

Healthy Autoreactivity

Early immunologists recognized that a major challenge to the immune system is to distinguish self- from foreign antigen. Because they recognized that pathogenic autoreactivity is usually avoided, they inferred a global prohibition on the survival of autoreactive lymphocytes. Since the early days of the "horror autotoxicus" of Ehrlich and the clonal selection theory of Burnet, awareness has grown that autoreactivity is an intrinsic and necessary feature of the healthy immune system, and that the selection against autoreactive cells is not absolute. Most important, there is now an understanding that the immune system responds to antigen, whether it is self- or foreign, only when certain conditions are met. Exquisite regulation of immune activation at multiple levels prevents pathogenic autoreactivity and also ensures an appropriate response to non–self-antigens.

It is now abundantly clear that the repertoire of naïve, immunocompetent T and B cells is shaped by self-antigen. Selection of the T-cell repertoire occurs within the thymus as T cells mature to immunocompetence and continues in the periphery as T cells recognize self-peptide/self-MHC complexes on tolerogenic dendritic cells. Mature immunocompetent T cells are positively selected on the basis of

displaying some degree of reactivity with self-peptide/self-MHC complexes on epithelial cells in the thymic cortex and are negatively selected when the interaction with peptide/MHC complexes on thymic medullary epithelial cells or dendritic cells is overly strong (5). Thus, all T cells that mature to immunocompetence display autoreactivity. The autoantigenic epitopes will vary depending on MHC haplotype and on the degree of TCR engagement required to mediate negative selection. Because the genes encoding the molecules that transduce the TCR signal and control MHC expression display functional polymorphisms that affect either their activity or their level of expression, a different degree of receptor engagement may be required to transduce a survival or a death signal in different individuals (27). Similarly, polymorphisms exist in genes encoding molecules that govern apoptotic pathways, also leading to differences in stringency of negative selection (28,29). Finally, polymorphisms in self-antigens may affect their ability to mediate either positive or negative selection (30). Thus, each individual has a unique spectrum of autoreactive T cells that exit the thymus. Further negative selection occurs in the periphery when these cells either encounter self-antigens presented in a non-inflammatory setting in the absence of costimulatory signals or are suppressed by regulatory T cells. The presence of multiple subsets of regulatory cells in the periphery attests to the importance of these cells in maintaining immune homeostasis (31). Autoreactive T cells, or T cells that were not appropriately subjected to tolerance mechanisms, are present in all systemic autoimmune diseases, yet little is known of the nature of the tolerance defect. In animal models of these diseases, a small amount of evidence exists suggesting a defect in thymic selection, but the major problem(s) is believed to be in peripheral tolerance.

It is not yet clear whether there is a requirement that B cells display some degree of autoreactivity for maturation to immunocompetence, but there is a growing body of data to suggest that positive selection of B cells also occurs. Recent studies show that in healthy individuals a very high percentage of the unselected immature B-cell repertoire in the bone marrow is reactive with nuclear antigens. These studies further show that autoreactive cells are routinely eliminated in both the bone marrow and the spleen but that significant autoreactivity remains in the naïve repertoire, with approximately 10% of naïve B cells displaying reactivity with a small panel of autoantigens (32). This observation perhaps provides a clue to the high percentage of nonautoimmune individuals who have antibody reactivity to nuclear antigens and the frequency of this autospecificity in individuals with systemic autoimmune diseases.

Two populations of B lymphocytes straddle the innate and the adaptive immune system, marginal-zone B cells and B1 cells. Both these populations display limited antigen-receptor heterogeneity, both are skewed to autoreactivity, and both perform protective functions in the immune system (33). B1 cells, in particular, have been studied in some detail. They arise in the fetal liver and are a self-regenerating population thereafter. They express a limited repertoire of immunoglobulin-variable (V) region genes; because they do not express terminal deoxynucleoside transferase, they display limited junctional diversity as well. It is now well appreciated that these cells make antibodies with specificity for phosphatidylserine that bind to apoptotic cells and apoptotic debris (34). Opsonization by antibody enhances macrophage phagocytosis and degradation of apoptotic debris. In the absence of the "natural autoantibodies" made by B1 cells, apoptotic material can be ingested by dendritic cells (35). The ingested DNA and RNA bind to TLRs, activate the dendritic cells, and create an immunogenic environment for the presentation of self-antigen (36). These antibodies are but one of a host of substances, including SAP, C1q, mannose-binding lectin, and C-reactive protein, that coat apoptotic cells to direct them to degradative pathways (37). Apoptotic cells activate lipases that convert phosphatidylcholine to lysophosphatidylcholine (LPC) (35). Natural autoantibodies also bind LPC; interestingly, antibodies to phosphatidylserine and lysophosphatidylcholine are present even in mice raised in a germ-free environment, suggesting that self-antigen may be responsible for triggering antibody secretion (38). These antibodies also cross-react with oxidized low-density lipoproteins (LDLs) and may be protective against atherosclerosis.

Consistent with the hypothesis that natural IgM autoantibodies protect against the development of pathogenic autoimmunity is a study showing that nonspontaneously autoimmune mice will develop anti-DNA antibodies and a consequent lupu-like renal disease when they have no circulating IgM (39). Furthermore, when mice with a genetic deficiency of secreted IgM were challenged with lupospolysaccharide (LPS), they developed increased titers of IgG anti-DNA antibodies. Another study suggesting the beneficial effect of IgM autoantibodies demonstrates that NZB/W lupus-prone mice develop less disease when given IgM anti-DNA antibody. In this study, however, the effect of the IgM autoantibody appeared to relate more to renal protection than to a decrease in activation of IgG-producing DNA-reactive B cells (40). Thus, natural autoantibodies may both impede activation of pathogenic autoreactive B cells and prevent pathogenic antibodies from binding their target autoantigens.

It has been suggested that rheumatoid factor (RF), antibody to the constant region of the IgG heavy chain, also exerts a protective effect. RF is among the natural autoantibodies that are present in nonautoimmune individuals. Titers of RF increase in individuals with chronic infections. Nonpathogenic RF is exclusively IgM, whereas pathogenic, rheumatoid arthritis-related RF may be IgG as well (41). In healthy individuals, RF is thought to serve two important functions. By binding preferentially to antigen-aggregated

IgG, it assists in the removal of immune complexes, thus hastening the degradation of antigens that may be toxins. RF is also thought to assist in the presentation of microbial antigen to the immune system, because immune complexes are more immunogenic than soluble antigen (42). In normal individuals, once the antigen has been cleared and immune complexes are no longer present, the RF B cells are tolerized by soluble IgG and do not enter the memory or plasma cell compartments (43).

Relationship between Healthy and Pathogenic Autoreactivity

A major unsolved question is the relationship between natural autoantibodies and the autoantibodies of autoimmune disease. To date, there is little evidence in humans that natural autoantibodies contribute to autoimmune disease or that B1 cells are the sources of pathogenic autoreactivity, although there are murine models of systemic lupus in which B1 cells or marginal-zone B cells are the source of pathogenic autoantibodies. It is clear from studies of mice expressing transgene-encoded natural autoantibodies that B cells expressing these antibodies are not routinely subject to tolerance induction, even in nonspontaneously autoimmune strains; however, they rarely become memory cells or long-lived plasma cells (33). Thus, these B cells do not inevitably lead to autoimmune disease. Studies of B cells producing transgene-encoded RF have shown that these cells can be activated by immune complexes and T-cell help to secrete low-affinity RF, but that B cells producing high-affinity antibody are deleted (44). Furthermore, in human disease and many mouse models of disease, pathogenic autoantibodies are not derived from B cells making natural autoantibodies but are produced by B2 cells that have undergone extensive somatic mutation (45). Some studies of murine B-cell genealogies demonstrate low-affinity autoreactivity in the precursor B cell, but similar studies of human autoantibodies are scarce and fail to reveal this phenomenon.

It is important to note that autoreactive B cells are routinely activated following exposure to microbial antigen, but the response resolves after the microbial antigen is eradicated. Yet the induction of autoreactivity or failure to control the autoreactivity that routinely arises during the response to microbial antigen is usually not sufficient to cause autoimmune disease. Whether the transition to frank disease requires an increased array of autospecificities, particular pathogenic subsets of autoantibodies, concomitant defects of innate immunity or T-cell tolerance, or vulnerable target organs is not known. Whether systemic autoimmune disease begins with a failure to downregulate the autoreactivity that is activated by infection remains uncertain, but the autoantibodies that characterize autoimmune disease differ significantly from those that are part of a healthy immune response (21,41).

Unifying Features of Systemic Autoimmune Diseases

The general theories or observations regarding autoimmunity that are discussed in this chapter will not apply to all systemic autoimmune diseases. Although it is reasonable to think of these diseases together, it is important to recognize that each disease has unique features. It is also important to note that although it has been a convention to define autoimmune diseases as systemic or organ-specific, this dichotomy is somewhat artificial. Organ-specific and systemic diseases may share susceptibility genes and can coexist within a family and, indeed, within an individual. Organ-specific autoimmune disease as well as systemic autoimmune disease may target autoantigens that are ubiquitously expressed.

Antinuclear Antibodies

A unifying feature of most systemic autoimmune diseases is the presence of autoantibodies to nuclear antigens. It is interesting to note that autoantibodies are made to these same autoantigens in approximately 5% to 10% of a healthy population, with a greater incidence in women and older individuals (46). Antinuclear antibodies are also present in 20% of individuals receiving IFN therapy or TNFα blockade. Only a small percent of these individuals will progress from autoimmunity to autoimmune disease (47). The frequency of elevated titers of antinuclear antibodies (ANAs) in systemic autoimmunity may reflect the autoreactivity present in the unselected B-cell repertoire. Studies documenting an early dysregulation of B-cell selection in systemic lupus and RA support the notion that B-cell dysfunction is a key component of these diseases (48). A study of factors that predispose to ANA reactivity may reveal aspects of the genetic basis for autoreactivity and may illuminate pathways that are dysregulated in systemic autoimmune disease.

Female Predisposition

Another feature of many autoimmune diseases is an increased incidence in women. Overall, there is a threefold greater incidence of autoimmune disease in women, but for some diseases the female predominance is much stronger. This occurs in both systemic and organ-specific diseases. Interestingly, autoantibodies to nuclear antigens are more common in women than in men. These antibodies are present in many autoimmune diseases and, as stated earlier, appear to represent a substrate on which clinical autoimmune disease develops. It is not yet established how much this reflects a sex-determined difference and how much it reflects hormonal influences. Most systemic autoimmune diseases have an age of onset after puberty. For example, in systemic lupus, the female:male

incidence is 3:1 for disease onset prior to puberty, 9:1 after puberty, and reverts to 2:1 after menopause (49). However, several studies now show that autoantibodies can be present years before onset of clinical disease; thus, preclinical disease may precede puberty more frequently than previously recognized (50). It is important to note, however, that not all autoimmune diseases appear to be exacerbated by female hormones. Rheumatoid arthritis, for example, is less frequent in women on oral contraceptive therapy and often improves during pregnancy (51).

Hormones can affect the function of all cells in the immune system. Estradiol can promote the survival of high-affinity autoreactive B cells at both the immature and the transitional stages of development, in part by decreasing the strength of BCR signaling (49). Some studies suggest that there are polymorphisms of estrogen receptor α (ERα) that predispose to autoimmunity and some studies suggest a preferential metabolism of estradiol in autoimmune individuals to its more estrogenic metabolites, but the role of estrogen in systemic autoimmunity remains controversial (52). Prolactin also has been shown to rescue autoreactive B cells from negative selection, but prolactin appears to operate through enhancing the T-cell–mediated rescue of B cells destined for apoptosis.

Recent data suggest that sex-determined differences may also contribute to the female predisposition to disease. The Yaa gene, which accelerates autoimmune disease in men, is present in a region of the Y chromosome that represents a translocation of a portion of the X chromosome; this locus contains the gene encoding TLR 7, for which the natural ligand is RNA (53). Although it is not yet known whether one TLR7 allele is routinely silenced in women, a possible implication is that women routinely express more TLR7, thereby permitting more immune activation by microbial or self-RNA. Finally, it is worth remembering that the effect of sex hormones may not be on immune activation, but may in fact be on target-organ display of autoantigen or target-organ response to the production of inflammatory mediators. Thus, the effects of sex hormones on kidney, joint, muscle, and other targeted organs need to be more fully investigated.

Flares and Remissions

A characteristic of autoimmune diseases is their waxing and waning activity. Most individuals with autoimmune disease experience a succession of exacerbations and remissions; however, some individuals can experience a chronic, smoldering course of disease, whereas others can experience a self-limited disease. In systemic lupus and scleroderma, flares can be accompanied by inflammation and damage in previously unaffected organs. In RA and myositis, flares can involve previously unaffected joints or muscles, respectively. Novel autoreactivities may account for novel organ involvement in some diseases, but

this explanation is inadequate to explain the changes in affected joints in RA, muscles in myositis, or skin regions in scleroderma that occur during disease flares. However, the remission of RA in the joints of a limb that is immobilized, while disease is sustained in a mobile limb, suggests that activation or injury of resident cells as a result of joint motion may be required to sustain target-organ inflammation (54).

Although flares and remissions are typical in autoimmune disease, it is still not established whether flares are secondary to the activation of memory cells or result from a new wave of activation of naïve cells. It is also not clear whether the defects in central and peripheral tolerance that are permissive for disease are always present, or whether normal or near-normal immune homeostasis may characterize periods of remission. Recent studies of systemic lupus suggest the presence of a defect in early B-cell selection and in memory-cell repertoire even in a time of drug-free clinical remission (32). Finally, the mechanisms responsible for naturally occurring remissions have not been identified in systemic autoimmune diseases. Whether regulatory T cells play a role in these remissions is a question of intense current interest.

There are several reasons that such seemingly obvious and critical questions remain unanswered. First, most spontaneous animal models of systemic autoimmunity are characterized by a persistent progression of immune activation and tissue injury. Some induced models exhibit remissions, but rarely do they exhibit subsequent flares. Thus, the animal models for these diseases have not been extremely informative regarding fluctuations in disease activity. Second, the only routinely available tissue to sample from patients is blood, and the cells present in blood may not fully reflect those involved in disease pathogenesis. Furthermore, especially, in the case of B cells and dendritic cells, the number of cells that can be analyzed may be limiting. Currently, it is also difficult to study disease in individuals who are not receiving some form of immunomodulatory therapy. Thus, there are few spontaneous remissions available for study in most patient cohorts.

Genetic Susceptibility

Clinically, it has been known for decades that autoimmune diseases have a genetic component. Children and siblings of individuals with an autoimmune disease have an increased risk of developing that disease. Concordance rates for autoimmune diseases are approximately 5% in dizygotic twins and approximately 30% in monozygotic twins (55). It is also clear that different autoimmune diseases may be present within a single family and that an individual may exhibit more than one autoimmune disease. These observations led to the recognition that these diseases share susceptibility genes even before those genes

were identified. Now it is clear from genetic studies that several genes, CTLA-4, PTPN22, and CARD15 (NOD-2), for example, predispose to more than one autoimmune disease (3).

Monogenic Diseases

Although there is a genetic component to essentially every autoimmune disease, only a few diseases appear to be monogenic. The human disease, APECED, a disease of inflammation in multiple endocrine organs, results from a deletion of the AIRE gene (56). The AIRE gene encodes a molecule that causes tissue-specific proteins to be expressed in medullary epithelial cells in the thymus. The consequence of this ectopic protein expression is the deletion of many developing thymocytes with specificity for peptides from tissue-specific proteins (57). In hosts with a deletion of the AIRE gene, autoreactive thymocytes develop to immunocompetence and initiate an immune attack primarily on endocrine organs. It is clear from both murine and human studies that even in this disease, phenotypic features of disease are determined by genetic background (58). It is also clear that regulatory T cells develop normally in AIRE-deficient mice (59), thus suggesting that regulatory T-cell function is insufficient for the prevention of autoimmune disease when there is a significant failure of central T-cell tolerance.

IPEX, immune dysregulation, polyendocrinopathy, enteropathy, X-linked, is caused by a mutation in the gene encoding Foxp3, a forkhead transcription factor that is critical for function of regulatory T cells. Infants with this disease develop diarrhea, diabetes, hypothyroidism, cytopenias, and an eczema that is apparently related to high IgE levels, although predisposing allergens have not been identified (60). The antigenic specificities of the overexuberant T-effector cells have not yet been determined. Just as the antigenic specificities of autoreactive T cells in patients with APECED will identify autoantigens for which there is central tolerance, the identification of the antigenic specificities of autoreactive T cells in IPEX may provide insight into autospecificities that are routinely regulated in the periphery by regulatory cells.

Deficiency of the gene encoding either Fas or Fas ligand also leads to a systemic autoimmune disease. The Fas protein interacts with Fas ligand to mediate activation-induced cell death in a number of cell lineages within the immune system. In mice, Fas or Fas ligand deficiency confers features of systemic lupus, with production of antinuclear antibodies and glomerulonephritis. In contrast, Fas deficiency in humans causes a disease called autoimmune lymphoproliferative syndrome (ALPS), characterized by generalized lymphadenopathy and hypergammaglobulinemia. In general, these patients produce antibodies to red blood cells or platelets, resulting in anemia or thrombocytopenia, respectively (61). Interest-

ingly, there is an increased incidence of malignancy in these patients, suggesting that a common mechanism of immune dysregulation may be responsible for both autoimmunity and malignancy. However, not all individuals with deficient Fas expression have a disease phenotype; thus, other genes modulate the phenotypic expression of Fas deficiency (62).

Recently, it has been appreciated that mutations in the gene encoding TACI, a receptor for BAFF and APRIL, can lead to both immunodeficiency and the subsequent development of autoantibodies (63). Mice deficient in TACI similarly develop antinuclear antibodies and a lupos-like glomerulonephritis that appears to reflect a release from TACI-mediated B-cell apoptosis and inhibition of B-cell activation, and perhaps a loss of protective IgM autoantibodies (63).

Polygenic Diseases

Most autoimmune diseases are multigenic, with three or more genetic loci involved in disease expression. Each locus represents a chromosomal region that has been mapped by linkage analysis with a particular disease phenotype. It is now becoming clear that a susceptibility locus may identify not merely a susceptibility gene but rather a susceptibility haplotype, as each locus often includes more than one susceptibility gene. This is perhaps best exemplified in the genetic dissection of the NZM 2410 lupus-prone mouse, in which three susceptibility loci were initially described. Subsequent analysis has shown that there are multiple genes within each locus that contribute to disease susceptibility. For example, within the SLE 1 locus on chromosome 1, genes encoding Fc receptors, the complement receptor CR2, and Ly108, the SLAM family member, have all been implicated in disease pathogenesis (64). The analysis of this mouse strain also exemplifies another general principle: There are resistance loci that prevent autoimmunity as well as susceptibility loci that facilitate autoimmunity (64). Thus, an individual's genetic risk is the summation of susceptibility and resistance loci. Yet another principle is embedded within this observation. In general, each susceptibility gene or locus is compatible with normal immune homeostasis. Only when a number of susceptibility loci coexist is normal self-tolerance abrogated. Thus, it may be possible to develop the same disease phenotype from entirely distinct combinations of susceptibility loci. Indeed, it is increasingly clear that the critical susceptibility loci may differ in ethnically or racially different populations. This is perhaps most apparent in RA. In Caucasians and Asians, homozygosity of a DR4 allele with a sequence termed the "shared epitope" (Q/R/D R/K RAA at positions 70 to 74 of HLADRβ1) increases the risk of developing disease from 1 in 100 to 1 in 7 (65); however, in individuals of African descent with RA, the shared epitope is rarely present (66).

Multiple Immune Pathways Contribute to the Genetic Risk for Systemic Autoimmunity

Most genes associated with systemic autoimmunity have been identified in studies of patients with lupus or rheumatoid arthritis. Much less is understood of genetic risk for other systemic autoimmune diseases. It may be helpful to identify four areas of immune cell function that have been genetically implicated in the induction of autoimmunity (a) lymphocyte selection and antigen-receptor signaling, (b) lymphocyte activation and costimulatory molecules, (c) lymphocyte survival and pro- and antiapoptotic pathways, and (d) antigen accessibility.

Lymphocyte Selection

HLA haplotype represents a susceptibility factor in almost all autoimmune diseases. As stated earlier, in rheumatoid arthritis, particular alleles of DR4 represent a strong susceptibility factor only in some populations, yet patients of all ethnic and racial backgrounds respond equally well to current treatment modalities, suggesting a similar pathogenetic mechanism to this disease even in individuals who differ in MHC haplotype

In SLE, class II alleles do not determine disease predisposition so much as autoantibody specificity, with anti-Ro antibodies occurring in DR3 individuals and anti-DNA antibodies in DR2 individuals (67). Interestingly, and in contrast to the response to therapy in rheumatoid arthritis, there are some recent data suggesting that patients who differ with respect to these antigenic specificities also differ with respect to response to B-cell ablation therapy (68). While most autoimmune diseases are associated with particular class II alleles, some are associated with class I alleles. Ankylosing spondylitis and reactive arthritis are associated with HLA B27, and to a lesser degree, B7 (67).

It has long been assumed that the HLA association reflects the importance of HLA molecules in determining T-cell repertoire, but this has not been proven for any autoimmune disease. Many genes besides those encoding class I and class II molecules reside within the MHC locus and may contribute to or be responsible for disease susceptibility. For example, genes encoding TNFα and complement components reside within the MHC locus, and polymorphisms or deletions of these genes can predispose to particular autoimmune diseases (69).

Genes that modulate antigen receptor (TCR or BCR) signaling are associated with lupus and RA in murine models and in the human population (48,64). Some of these genes may alter the threshold for negative selection and tolerance induction early in lymphocyte development, whereas others may alter thresholds for the activation of immunocompetent lymphocytes. Both decreased and increased BCR signaling can predispose to autoimmunity. Although this might seem paradoxical, there is accumulating evidence that signaling pathways and the signaling thresholds that govern cell-fate decisions may differ in immature and mature lymphocytes. Thus, a diminished signal during B-cell development will increase the survival and maturation of autoreactive cells, whereas an enhanced signal after the achievement of immunocompetence may increase B-cell activation. Most disease-susceptibility genes that alter BCR signaling affect the naïve B-cell repertoire. However, some modulators of BCR signaling, such as FcRIIB, a downregulator of BCR signaling, appear to affect antigen-activated cells.

Modulators of TCR signaling can also lead to autoreactivity. In mice, deletion of the gene encoding IBP (IRF4-binding protein), an activator of Rho GTPases, leads to altered TCR signaling and antinuclear antibody production (18). Similarly, deletion of Rasgrp1 leads to a lupus-like disease in mice (18). Whether these signaling defects alter T-cell repertoire or thresholds for activation by cross-reactive antigen or self-antigen is not yet known.

Lymphocyte Activation and Costimulation

Cytokines and costimulatory molecules, including classic costimulatory pathways and those mediated through engagement of toll-like receptors and cytokines, can alter lymphocyte selection, resulting in the rescue of immature autoreactive B cells from negative selection or modulating thresholds for peripheral activation of lymphocytes. Several alterations in costimulatory pathways may be most important after antigen activation. For example, deletion of the roquin gene leads to increased inducible costimulator (ICOS) expression on T cells within the germinal center reaction and enhanced autoantibody production (70). CTLA-4 is a molecule involved in downregulation of activated T cells and in the initial activation of regulatory T cells. Deletion of CTLA-4 in mice is associated with a fulminant inflammatory disease (71). A polymorphism of CTLA-4 in humans that leads to a decrease in soluble CTLA-4 is associated with several autoimmune diseases (72). Soluble CTLA-4 may act as an endogenous inhibitor of CD28-B7 interactions or may induce indoleamine 2,3-deoxygenase (IDO), an enzyme involved in tryptophan metabolism, resulting in local immunosuppression (73). Similarly, PD-1 is an inhibitory receptor on both T and B cells; polymorphisms or deletion of PD-1 may function both in the selection of the naïve repertoire or after the initial encounter with antigen (74).

Inappropriate cytokine production may also predispose to autoimmunity. For example, a polymorphism of osteopontin is associated with autoimmunity in humans (75). Increased osteopontin protects murine T cells from activation-induced death and may assist in the inappropriate survival of antigen-activated autoreactive T cells. In

mice, deficiency of TNFα can predispose to the development of SLE (76). Similarly, TNFα blockade in humans has been associated with the development of SLE in a small percentage of treated patients (77).

Lymphocyte Survival

It is now clear that many genes involved in cell survival constitute susceptibility factors for autoimmune disease, most notably, members of the Bcl-2 family. Increased expression or functional polymorphisms of Bcl-2 can induce a lupos-like disease (78). Recent data suggest cross-talk between apoptotic and antigen-receptor pathways. Interestingly, the combined presence of a lupus-susceptibility allele of Bcl-2 and a lupus-susceptibility allele of IL-10 leads to a 40-fold increased risk of disease (79). Whether the IL-10 allele cooperates with Bcl-2 to decrease stringency of negative selection in the immature B-cell compartment or functions independently of Bcl-2 to alter lymphocyte function later in disease, or both, is not known.

Antigen

Antigen accessibility or antigen load may influence autoimmunity. Murine models clearly demonstrate that an increase in apoptotic debris or defective clearance of apoptotic debris results in a lupos-like phenotype (18). Individuals who are deficient in C1q or DNase demonstrate impaired clearance of apoptotic material and a predisposition to lupus (80). Whether deficiencies in C2 and C4 contribute to lupus because they also lead to reduced clearance of apoptotic cells or whether they lead to reduced BCR signaling and a reduced stringency of negative selection is not known.

Induction of potentially pathogenic autoreactivity is insufficient for autoimmune disease. It is clear that inflammatory effector mechanisms must be activated in target organs, because damage to these organs is usually the result of infiltration by inflammatory cells and release of soluble inflammatory mediators. Thus, genes that govern cell trafficking help modulate the inflammatory response in target organs. In addition, target organs must be vulnerable to autoimmune attack. This vulnerability may be genetically determined, as in rodent models of rheumatic carditis, tubular nephritis, and lupos-like glomerulonephritis, but it can also be altered by nongenetic or environmental factors.

Other Genes of Clinical Significance

There are some genes that are known to be involved in predisposition to autoimmune disease, with an as-yet-undetermined effect on either immune activation or target-organ vulnerability. Estrogen-receptor α alleles associate with both lupus and RA (81). Paradoxically, the effect of estrogen on these two diseases, while still a matter of some uncertainty, seems to be contradictory. Exogenous estrogen appears to increase risk and exacerbate lupus in at least some individuals, while it protects against RA (82). Polymorphisms of the vitamin D receptor and the hydroxylase gene involved in vitamin D metabolism have been implicated as risk factors in several autoimmune diseases. Vitamin D helps maintain dendritic cells in a tolerogenic state, facilitating peripheral tolerance mechanisms. Thus, adequate vitamin D levels may be important in the proper presentation of self-antigen and immune homeostasis, and several studies now suggest that vitamin D deficiency may predispose to both organ-specific and systemic autoimmunity (83).

Antigens in Systemic Autoimmune Disease

B-Cell Antigens

The major evidence for a role for antigen in spontaneous autoimmunity is the observation that increasing antigen exposure in animal models leads to increased B-cell autoreactivity.

Self-antigen

The frequent observation that autoimmune disease may be triggered or exacerbated by exposure to UV light suggests that self-antigen can drive autoimmunity, because UV light clearly induces cell death and alters vascular permeability, thus exposing cells of the immune system to an array of tissue antigens (84). This observation is entirely consistent with the fact that a lupos-like phenotype develops in many murine models characterized by an increase in apoptotic debris, most commonly consequent to impaired clearance. Furthermore, administration of apoptotic cells to certain mouse strains results in the production of antinuclear antibodies (85). Interestingly, many autoantibodies bind to neoantigenic determinants that are exposed on molecules following cleavage by granzyme B, a protease present in cytolytic T cells (86). The implication is that the immune system is tolerant to the peptides derived from self-proteins that are generated by caspase cleavage but not to the peptides generated by granzyme cleavage. A further implication is a potential viral etiology to autoimmune disease, as cytolytic T cells are activated in response to viral infection. Both autoantibodies and autoreactive B cells may then lead to epitope spreading and drive pathogenic inflammation independent of the initial viral insult. Thus, viral infection may initiate autoimmunity but may not be required to perpetuate disease. This suggestion is consistent with the clinical observation that new autoantibody specificities arise over time in individuals with an existing autoimmune disease or progressing toward autoimmune disease (50). As autoreactive B cells become activated, they may present novel (cryptic) peptides of autoantigen to T cells (87). Because these peptides are not routinely presented on thymic dendritic cells, thymic epithelial cells,

or peripheral dendritic cells, there may have been no deletions of T cells specific for these self-peptides.

Although genetic differences can modulate antigen load, environmental influences can also affect exposure to autoantigen. UV light induces cellular apoptosis. Smoking increases the citrullination of proteins in the respiratory epithelium; smoking is a known risk factor for RA, a disease in which antibodies to citrullinated peptides are both diagnostic and pathogenic. The recent recognition of the pathogenicity of antibodies to citrullinated proteins in RA has led to studies showing that mice unable to reverse the citrullination of proteins develop autoimmunity (88). Studies in a murine model for induction of RF have shown that activation of autoreactive B cells requires an adequate exposure to autoantigen. Similarly, administering the Sm antigen, a targeted autoantigen in lupus, to autoimmune mice increases titers of anti-Sm antibody (89). Furthermore, certain immune complexes, such as those containing DNA, RNA, phospholipids, or other ligands for pattern recognition and Toll-like receptors, once formed, can activate dendritic cells and can create a proinflammatory milieu that promotes and perpetuates autoreactivity by converting tolerogenic into immunogenic dendritic cells (90).

Just as apoptotic cells can provide a source of targeted autoantigen in systemic autoimmune diseases, so can the regenerating cells in damaged tissues, which have been shown in some diseases, most notably myositis, to express high levels of targeted autoantigens (91). Thus, the very process of repair of tissue injury may fuel established autoimmunity. In organ-specific autoimmune disease, the removal of the autoantigen can lead to the diminution in number and activation of autoreactive lymphocytes (92); in systemic autoimmune diseases, the targeted autoantigens tend to be ubiquitous, precluding their removal.

Idiotype Networks

Several models suggest that idiotype–anti-idiotype networks can drive B-cell autoreactivity. This phenomenon has been demonstrated in murine models for the induction of anti-DNA and anti-cardiolipin antibodies (93). Although anti-idiotypes to autoantibodies have been found in patients with autoimmune disease, their role in either the induction or the regulation of autoreactivity remains speculative.

Microbial Antigen

Molecular mimicry may operate to permit foreign antigen to initiate autoimmune responses. Autoantibodies have frequently been shown to cross-react with microbial antigen. Some of the more intriguing instances of molecular mimicry are the cross-reactivity of anti-DNA antibodies with bacterial antigens and with the EBNA protein of Epstein–Barr virus (EBV) (94). In lupus, there are reports of high titers of antibody to EBV, consistent with, but not

proof of, the hypothesis that EBV may be a causative agent (95). It is also possible that microbial antigens trigger T-cell dependent B-cell responses, with the consequent somatic hypermutation of immunoglobulin-variable region genes leading to the acquisition of autoreactivity. Clearly, somatic mutation in B cells responding to non–self-antigens can generate autoreactivity. Interestingly, the experimental back-mutation of a very few anti-DNA antibodies derived from lupus patients to their germline configuration has demonstrated an apparent lack of autoreactivity in the precursor B cells (96). This observation is consistent with the argument that pathogenic autoantibodies may be generated in response to microbial antigen. Furthermore, this hypothesis is consistent with the observation that the somatically mutated V-region genes that encode pathogenic autoantibodies are distinct from those that encode natural autoantibodies.

It is interesting to speculate that the mild immunodeficiency that accompanies many systemic autoimmune diseases permits more prolonged microbial infections, fueling the production of autoantibodies. Because autoantibodies induced perhaps by molecular mimicry, perhaps by exposure of usually sequestered self-antigen to B or T cells, or perhaps as a result of bystander B-cell activation, are normally generated in the course of a response to any microbial antigen, it is important to determine when such a response is aberrant and may lead to autoimmune disease. Persistence of autoantibody production is clearly abnormal. Usually, autoantibody titers in nonautoimmune individuals decrease as microbial antigen is eradicated. Epitope spreading is a critical phenomenon in protective immunity, but epitope spreading to autoantigens is not present in the routine autoreactivity seen in response to infectious agents. In autoimmune disease, epitope spreading to an increased number of autoantigenic epitopes occurs, leading ultimately to an expansion in the number of targeted autoantigens (97). Both retrospective and prospective studies now show that there is a slow but steady increase in the number of self-antigens bound by autoantibodies in individuals with clinical disease (50). Indeed, the progression from autoreactivity to autoimmune disease may take several years. Whether this progressive increase is necessary because a particular pathogenic autoantibody must arise, or because multiple autospecificities are necessary for adequate recruitment of inflammatory cells by immune complexes, or because multiple autoreactive B cells are needed to present cryptic peptides of self-antigens to T cells and provide a diverse autoreactive T-cell response is not known.

T-Cell Antigens

T-cell autoreactivity in systemic autoimmune disease is harder to identify than B-cell autoreactivity. In systemic lupus, T cells to histone epitopes have been identified in both

mice and humans (98). T cells infiltrate muscle tissue in polymyositis and dermatomyositis, joints in RA, and salivary glands in Sjogren syndrome, but their target antigens have not been determined. Often the T cells in systemic autoimmune disease appear to recognize posttranslational modulations of self-proteins (88,99). For example, T cells in rodent models of RA induced by collagen immunization recognize glycosylated collagen (100). T cells in murine models of SLE recognize iso-aspartyl–modified peptides; mice deficient in the protein L-isoaspartate O-methyl transferase, which cannot repair isoaspartyl modifications, develop antinuclear antibodies and glomerulonephritis (101). Whatever the important antigenic specificities, T cells are critical effectors in these diseases, because preventing their function ameliorates disease. Furthermore, the antibodies present in these diseases have features characteristic of T-cell–dependent responses, including heavy-chain class switching and somatic mutation. In RA and Sjogren syndrome, ectopic germinal centers can sometimes be seen in target organs (102). It is highly probable that multiple autoantigens are targeted, as the T-cell-receptor repertoire of organ-infiltrating T cells is polyclonal (102), and in murine models, a diverse T-cell repertoire is needed for the development of lupus nephritis (103).

Environmental Antigens

In additional to microbial antigens, drugs or antigens in the environment are potential triggers of disease. Drug-induced lupus can occur following exposure to hydralazine, procainamide, chlorpromazine, diphenylhydantoin, and other agents (104). It is not clear if any of these drugs binds to self-antigen to generate a neoantigen. Some clearly cause hypomethylation of DNA, leading to increased expression of adhesion molecules on T cells and a lower threshold for T-cell activation. When this occurs, even non-autoreactive T cells can activate autoreactive B cells. Although procainamide has been demonstrated to alter T-cell selection in the thymus in mice (105), it is unlikely that this is a major mechanism for disease induction in humans, as thymic maturation of new T cells is minimal in most individuals receiving these drugs and developing lupuslike autoreactivity.

Mercuric chloride induces a lupuslike phenotype with antinuclear antibodies and nephritis (106). Scleroderma, in particular, has been linked to toxin exposure (107). Polyvinylchloride, L-tryptophan, rapeseed oil, gadolinium, and bleomycin have all been associated with the development of a progressive fibrosis; all but gadolinium- and bleomycin-induced disease are characterized by the presence of many eosinophils in lesional tissue. The presence of eosinophils may be a unique feature of exposure to an external agent, as these cells are not routinely present in primary scleroderma.

Much controversy surrounds the potential role of silica as a trigger for autoimmune disease. It has been linked to both systemic lupus and scleroderma. Recent epidemiologic studies have suggested that silica exposure may be a surrogate marker for exposure to bacterial lipopolysaccharide (LPS), as both these exposures occur primarily in individuals who work in proximity to the soil (108). In animal models, repeated exposure to LPS can induce lupuslike autoreactivity but has not been shown to induce a sclerodermalike phenotype (109). At one time there was a concern that silicon breast implants might precipitate autoimmune disease in women, but a number of impartial reviews of the epidemiologic, clinical, and animal data failed to confirm an association.

Mechanisms of Tissue Damage

It is important to consider mechanisms of tissue damage in autoimmune diseases, as these can differ significantly from mechanisms of immune activation. The clear implication of this observation is that whereas some therapeutic interventions may lessen both the inductive and effector phases of autoimmunity, others may be therapeutic with respect to one phase, but not both. The concept that the profile of cytokines and soluble mediators produced by cells in lymphoid organs may differ from those of cells involved in tissue inflammation is now well established. This observation further suggests that it is no longer useful to consider certain mediators to be strictly proinflammatory or anti-inflammatory. For example, TNFα protects against the development of autoantibodies, but contributes to tissue destruction (110). Similarly, TGFβ may limit the inductive phase of autoimmunity, but it causes fibrosis in tissues, leading to irreversible damage. IL-10 may also play a dual role in disease, inhibiting antigen presentation initially but driving T-cell proliferation, antibody class switching, and autoantibody production as disease progresses (111). IFNγ also has been suggested to have dualistic properties, as an enhanced level of IFNγ following treatment of MRL/Ipr mice with an agonistic antibody to CD137 is associated with disease prevention, but is later associated with augmenting the production of pathogenic autoantibodies and exacerbating tissue injury (112). Recently, it has become apparent that a newly described subset of effector T cells, T_H17 cells, induced by IL6, IL23, and TGFβ and producing large amounts of IL-17, is crucial in the collagen-induced model of RA. TGFβ, paradoxically, is responsible for induction of both T_H17 cells and regulatory T cells; these T-cell subsets are likely to establish an important counterpoint in systemic autoimmune disease. Thus, it is clear that disease stages include initiation, progression, and tissue destruction, that the critical pathways for disease exacerbation or remission can differ in each stage, and that particular signaling pathways may be operative in both the activation and the regulation of pathogenic

autoimmunity. In murine models, the disease is largely synchronized, but in human disease, all three stages may exist simultaneously. Studies of therapeutic interventions in animal models and human disease have shown that it is possible to prevent tissue damage while immune activation continues uninterrupted (113), and conversely, one can perform immunoablation in animals and humans and tissue damage may continue unabated (114).

Therapeutic Considerations

For many decades, the therapy for systemic autoimmune disease was based on a strategy of global immunosuppression. Corticosteroids are cytotoxic to plasma cells (they are a major component of the therapy for multiple myeloma), suppress many of the effector mechanisms of inflammation, and are used in many autoimmune diseases. Interestingly, they may, in fact, exacerbate scleroderma, perhaps because the disease is characterized more by fibrosis and less by inflammation. In addition, a number of cytotoxic agents have been used in all systemic autoimmune diseases. These include cyclophosphamide, azathioprine, and, more recently, methotrexate and mycophenolate mofetil. These therapies are designed for use during major flares, and are generally continued in lower dose for maintenance of remission. Recently, a large number of new therapies have been attempted or are under design. The reason for the extraordinary increase in interest in designing therapeutics for autoimmune disease reflects, at least in part, the recognition that these diseases may share common pathogenetic mechanisms.

A major triumph of rational drug design and immunomodulatory therapy has been the success of TNFα blockade in the treatment of RA. This approach targets the effector phase of pathogenesis. Both soluble TNFα receptor and anti-TNFα antibody display equivalent efficacy in the treatment of RA, even though only anti-TNFα antibody blocks membrane-bound as well as soluble TNFα (115) and appears to carry a greater risk of activating latent tuberculosis and other opportunistic infections (116).

The experience with TNFα blockade is also a cautionary tale. Effector pathways and inductive pathways differ in autoimmune diseases, and interfering with one may exacerbate the other. TNFα blockade with either soluble receptor or with anti-TNFα antibody leads to a 20% frequency of ANA positivity. Of these ANA-positive individuals, 10% display anti-DNA antibodies and approximately 1% develop frank lupus (115). The data suggest that withdrawal of TNFα blockade leads to a loss of anti-DNA antibodies and a return to ANA negativity in almost all cases. This observation is consistent with the demonstration of reduced TNFα expression in lupus-prone NZB/W mice and the demonstration of a therapeutic effect of administration of exogenous TNFα in this strain (117). The toler-

ance checkpoint(s) that is compromised is not known, and whether the primary effect is on the T- or B-cell repertoire remains uncertain.

Two other therapies have recently received U.S. Food and Drug Administration (FDA) approval for the treatment of RA and have potential efficacy in other autoimmune diseases as well. These are both designed to target the inductive phase of autoimmunity. CTLA-4Ig blocks T-cell activation by interfering with the interaction of B7 molecules on antigen-presenting cells with CD28 on naïve T cells. In addition, the binding of CTLA-4Ig to B7 induces expression of IDO in antigen-presenting cells, which degrades tryptophan, thereby limiting T-cell proliferation (73). This therapy appears as effective as TNFα blockade in reducing joint pain and inflammation. There are, as yet, no data on the incidence of bone erosions or cardiovascular disease in patients receiving CTLA-4Ig. Inhibition of both the inductive and the effector of the immune system may lead to unacceptable immunosuppression; the combination of TNFα blockade and CTLA-4Ig was more immunosuppressive than either agent alone, as evidenced by a higher rate of infection (118).

Antibody to CD20, rituximab, is a B-cell–depleting agent that has also recently received FDA approval for the treatment of RA. The success of this therapeutic agent suggests the importance of B cells as antigen-presenting cells in RA. It is important to state, however, that B-cell depletion may also work by reducing the titer of pathogenic antibodies. The clinical studies of rituximab therapy show a nonimmediate reduction in titer of IgG RF and antibodies to citrulinated cyclic peptides (anti-CCP antibodies, another antibody specific to patients with RA), but no change in titer of IgM RF (119). Different antibody specificities respond differently to B-cell depletion, almost certainly depending on the B-cell subset responsible for antibody production. In general, a decrease in IgG autoantibodies in the systemic autoimmune diseases is more likely to be beneficial than a decrease in IgM autoantibody titers, as IgG antibodies are more closely linked to disease pathogenesis. Based on a strategy of targeting the B cell in autoimmune disease, antibody to BAFF, a B-cell survival factor, is also being tested in RA and in lupus.

Thus far, no therapeutic agent has been able to induce a long-term drug-free remission, suggesting either a strong genetic component to disease or the persistence of pathogenic cells after cessation of therapy. It is highly likely that different therapeutic agents will be needed to block the inductive and the effector phases of disease, and that it will be necessary to treat patients indefinitely with agents that maintain a clinical remission once the disease phenotype has become manifest. Most important, effective therapy may well require targeting more than one pathway in disease pathogenesis; agents that alone exert a small effect on disease, may, in combination, demonstrate a very significant effect.

SYSTEMIC AUTOIMMUNE DISEASES

The remainder of this chapter will address specific diseases, focusing on human disease, relationships to the proposed concepts of autoimmunity, and supporting evidence from animal models. Critical aspects of each disease that are shared or are distinct will be identified.

SYSTEMIC LUPUS ERYTHEMATOSUS

SLE in humans is characterized by antinuclear antibody production and pathologic findings of inflammation, vasculitis, vasculopathy, and immune-complex deposition in multiple target organs. Susceptibility to SLE is clearly modulated by ethnicity and gender. Although it affects both males and females of all age groups, it most commonly presents in women during their child-bearing years, with a striking female-to-male ratio of 9:1. This ratio is approximately 3:1 in younger and older populations, supporting a role for hormonal factors in the induction of disease. Incidence rates reported during the last 25 years in North America vary from 2 to 7 per 100,000, with rates in African-American, Afro-Caribbean, Hispanic, and Asian populations approximately three times greater than in Caucasian populations. The worldwide prevalence of lupus ranges from 17 to 48 per 100,000, but has been reported as high as 207/100,000 in an Afro-Caribbean population in the United Kingdom. While a precise etiology of SLE is not known, serendipitous combinations of genetic, hormonal, and environmental factors are thought to contribute to the loss of self-tolerance.

Clinical Manifestations

The diversity of disease manifestations and severity in SLE is quite striking and includes constitutional complaints as well as the involvement of every organ system. Given the protean manifestations of disease, the American College of Rheumatology (ACR) criteria for diagnosis of SLE were developed for the purpose of allowing comparisons across studies (Table 41.1) (120). Meeting four of the 11 criteria establishes disease with approximately 95% certainty. There are, however, many patients with SLE who display only two or three criteria; this syndrome is termed incomplete lupus.

The production of autoantibodies is a unifying feature for all SLE patients. Antinuclear antibodies (ANAs) are present in 98% of SLE patients; a positive ANA test is very sensitive for SLE, although not specific, as ANA positivity is a feature of 5% to 30% of a healthy population, most of whom will never develop an autoimmune disease (121). Individual autoantibody specificities to nuclear and intracellular components, such as double-stranded (ds) DNA and Sm, are more specific but occur with lower frequency

TABLE 41.1 Classification Based on the Criteria of the American College of Rheumatology (ACR) for the Diagnosis of Systemic Lupus Erythematosus[a]

ACR criteria 1982 (updated 1997) description

Malar rash	Fixed erythema, flat or raised, over the malar eminences, sparing the nasolabial folds
Discoid rash	Erythematous raised patches with adherent keratotic scaling and follicular plugging
Photosensitivity	Reaction to sunlight, resulting in the development of or increase in skin rash
Oral ulcers	Oral or nasopharyngial ulceration, usually painless
Arthritis	Nonerosive arthritis involving two or more peripheral joints
Serositis	Pleuritis or pericarditis
Renal disorder	Proteinuria >0.5 g/day and/or cellular casts
Neurologic disorder	Seizures and/or psychosis in the absence of drug toxicity or metabolic disturbances
Hematologic disorder	Hemolytic anemia, leukopenia, lymphopenia, or thrombocytopenia
ANA	Positive test for antinuclear antibodies in the absence of drugs known to induce it
Immunologic disorder	Elevated serum antibody titers to dsDNA, Sm, phospholipids, or false positive VDRL

[a]These criteria were developed for the purpose of allowing comparison of patients from different centers enrolled in clinical studies. Patients meeting at least four of the 11 criteria may be diagnosed with 95% certainty, but individual patients with systemic lupus erythematosus may exhit fewer than four criteria.

(Table 41.2). Most autoantibody levels do not correlate with disease activity; antibodies to dsDNA, in contrast, often rise in flare and subside in remission. Individual autoantibodies have been shown to associate with specific disease manifestations. These associations include anti-dsDNA antibodies with lupus nephritis, anti-Ro antibodies

TABLE 41.2 Autoantibodies in Systemic Lupus Erythematosus (SLE)

Autoantibody	Frequency (% positive at any time)	Clinical Association
Anti-dsDNA	50–70	Nephritis
Anti-Sm	5–30	Pathognomonic for SLE
Anti-SSA/Ro	40–50	Dry eyes and mouth, SCLE, neonatal lupus, cytopenias, photosensitivity
Anti-SSB/La	10–15	
Anti-RNP	40–60	MCTD, myositis, Raynauds
Anti-NMDAR	40–50	Cognitive dysfunction, depression
Antiphospholipid	15–50	Thrombosis, pregnancy loss, cutaneous ulcers
Anti-ribosomal P	10–20	Psychosis, depression

SCLE, subacute cutaneous lupus; MCTD, mixed connective tissue disease

with SICCA syndrome (dry eyes and dry mouth) as well as subacute cutaneous lupus and neonatal lupus, anti-RNP antibodies with Raynaud phenomenon, arthritis, myositis, and lung disease (122), and anti-NMDA receptor antibodies with depression and possibly cognitive impairment in SLE (123,124). The recent finding that autoantibodies may precede the clinical diagnosis of SLE by many years suggests that progression to pathologic autoimmunity in SLE need not be an acute process (50). Increases in autoantibody titer and antigenic diversity up to the time of diagnosis suggest that pathologic autoimmunity evolves over time and that the inductive phase may precede the effector phase of disease by many years. Whether a tissue-specific trigger is needed to initiate target-organ inflammation is not known but is highly probable.

Pathogenesis and Genetic Susceptibility

Familial disease clustering and a higher disease concordance in monozygotic than dizygotic twins support an underlying genetic susceptibility. Increasingly, it is recognized that multiple genetic polymorphisms and specific HLA haplotypes contribute to disease susceptibility. Most SLE-associated alleles are present in healthy individuals in the population. The presence of a single SLE-associated allele is insufficient to cause disease; generation of a lupuslike phenotype requires the presence of combinations of several SLE-associated alleles. Many SLE-associated alleles have also been implicated in other autoimmune diseases (e.g., CTLA-4 polymorphisms associated with Graves disease and type 1 diabetes, PTPN22 polymorphisms associated with RA and type 1 diabetes), suggesting that specific patterns of autoimmunity are determined by particular combinations of autoimmune-associated alleles, some of which govern target vulnerability, and environmental stimuli (3). The evidence for a common set of susceptibility genes in multiple autoimmune diseases also helps to explain familial clustering of diverse autoimmune diseases.

At least eight genetic loci with significant linkage to SLE have been identified (Table 41.3) (125). Associations between HLA alleles and specific autoantibodies appear to be modulated by ethnicity (Table 41.4). Presumed susceptibility genes from human studies in SLE include those affecting selection and survival of B cells, T-lymphocyte activation and survival, cytokine production, antigen presentation, and clearance of apoptotic debris (126).

Failure of B-Cell Tolerance

Recent analyses of antibodies cloned from circulating B cells in SLE patients demonstrate a failure to establish self-tolerance during B-cell development and are consistent with an intrinsic B-cell defect at this stage of differentiation (127). Repertoire analyses of antibodies cloned

▌ **TABLE 41.3 Chromosomal Regions with Confirmed Linkage to Systemic Lupus Erythematosus**

Chromosome	Cytogenic Location	Locus Name	Candidate Genes
1	1q23		CRP

12	12q24	SLEB4	
16	16q12		NOD2
			OAZ

CRP, C-reactive protein; Fcγ R, IgG Fc gamma receptor; *PARP*, poly(ADP-ribose) polymerase; TLR5, Toll-like receptor 5; *PDCD1*, programmed cell death 1; MHC, major histocompatibility complex; *TNF*, tumor necrosis factor; *NOD2*, nucleotide oligomerization domain 2; *OAZ*, OLF1/EBF-associated zinc finger protein.

from B cells derived from bone marrow and peripheral blood of healthy donors provide evidence for both a central tolerance checkpoint in the bone marrow and a second peripheral checkpoint, as evidenced by a decrease in the frequency of autoreactive antibodies from 75% in the bone marrow to 20% in the circulating naïve compartment (128). The low-affinity, self-reactive, polyclonal IgM antibodies produced by circulating mature naïve B cells in healthy individuals are thought to facilitate clearance of apoptotic cells, thereby decreasing the development of a potentially pathogenic T- and B-cell response to self-antigen (129). Virtually none of these antibodies binds dsDNA. Although the checkpoint between immature B cells in the bone marrow and newly emigrated cells in blood appears to be intact in the small number of SLE patients studied, the mature naïve B-cell compartment in

▌ **TABLE 41.4 MHC Class II Autoantibody Associations in Systemic Lupus Erythematosus**

Autoantibody	HLA-DRB1	HLA-DQA1	HLA-DQB1	Ethnic Association
Anti-Sm			*0602	Caucasian,
			*0601	African-American
Anti-Ro	*0301	*0501	*0201	Caucasian
	*0803	*0103	*0601	Japanese
Anti-RNP	*04		*0302	Caucasian
		*0101	*0501	African-American

SLE is enriched for autoreactive clones (40% to 50% in SLE, 20% in controls). Mechanisms responsible for this implied failure of the peripheral checkpoint have not been clearly elucidated.

Because signaling through the BCR is a primary mechanism for triggering deletion, anergy, or receptor editing, abnormal BCR signaling is likely to play a role in the breakdown of tolerance (130). As discussed previously, both decreased and increased signaling through the BCR may predispose to an increased risk of autoantibody production. Mouse models support a paradigm of decreased BCR signaling leading to laxity in B-cell negative selection, increased autoreactivity in the naïve B-cell population, and increased risk of autoantibody production. Although the enhanced autoreactivity of the naïve repertoire appears to be a permissive substrate for the development of SLE, back-mutation of two mutated anti-DNA antibodies to their germline-encoded precursors demonstrates a lack of autospecificity in the original antibody.

Circulating mature B cells from SLE patients demonstrate a heightened response to BCR crosslinking, demonstrated by increased levels of intracellular calcium and increased tyrosine phosphorylation. Several mechanisms for enhanced BCR signaling in mature B cells have been identified. Lyn is an intracellular protein tyrosine kinase that can diminish BCR signaling through phosphorylation of CD22, FcRIIb, and other ITIM-containing inhibitory receptors (131). Studies of SLE patients show that Lyn expression may be decreased by 50% or more in resting and activated B cells, with a positive correlation between reduced levels of Lyn and the production of anti-DNA antibodies (132). FcRIIb is an inhibitory receptor that downregulates the BCR when both receptors are co-ligated. Increased intracellular Ca^{2+} flux noted in SLE B cells may be due to defective upregulation of FcRIIb on memory B cells (133), decreased availability of the intracellular SHIP protein that is part of the FcRIIb signaling cascade (134), or an FcRIIb polymorphism (Ile 232 Thr) that prevents partitioning of the receptor into lipid rafts (135), where it must reside to associate with the BCR.

In addition, costimulatory molecules and cytokines whose expression is dysregulated in SLE can rescue autoreactive B cells from BCR-mediated deletion. Expression of some of these molecules, for example, BAFF, CD40, CD40L, IL-10, correlates with disease activity and increased anti-DNA antibody titers (136). BAFF, in particular, is implicated in the pathogenesis of SLE, because mice that overexpress BAFF have a lupuslike disease, NZB/NZW and MRL-*lpr* mice have elevated levels of BAFF, and treatment with anti-BLyS antibody ameliorates progression of disease in these lupus-prone mice (137). The elevated serum levels of BAFF reported in SLE patients may be secondary to the lymphopenia often seen in SLE or may result from exposure of plasmacytoid dendritic cells to DNA or RNA containing immune complexes (138). Marginal-zone B cells in mice (IgM memory cells in humans) are easily stimulated by BAFF to exhibit enhanced function as antigen-presenting cells, potentially activating autoreactive T cells (139).

The presence of extensive somatic mutation seen in autoantibodies derived from SLE patients strongly supports germinal-center maturation of pathogenic, autoreactive B cells. Somatic hypermutation with random point mutations gives rise to self-reactive clones at high frequency, but in nonautoimmune individuals these rarely exit from the germinal center. In SLE, checkpoints at the germinal-center response have been studied through an analysis of antibodies expressing the 9G4 idiotype, which is encoded by the VH 4.34 heavy-chain variable-region gene (129). These antibodies bind N-acetyl-lactosamine (NAL) determinants on blood-group antigens, gangliosides, gastrointestinal mucins, glycolipids, and CD45 on B lymphocytes. Though virtually undetectable in normal sera, 9G4 IgM antibody titers are greatly increased in response to mycoplasma, Epstein–Barr virus, and cytomegalovirus infections. 9G4 B cells constitute 5% to 10% of the naïve and IgM memory B-cell populations in healthy donors; they are, however, excluded from IgG memory B-cell and plasma-cell compartments and are not seen within normal tonsillar germinal centers, suggesting the presence of a tolerance checkpoint at germinal-center entry. Evaluation of lymphoid tissue from tonsillar biopsies and spleens of SLE patients reveals that the frequency of germinal-center 9G4 B cells is 15% to 20%, thereby identifying another failed tolerance checkpoint in SLE (21). The suggestion that transition to the IgM+ memory B-cell compartment is another checkpoint for selection against autoreactive cells is supported by data showing a decrease in frequency of autoreactive IgM+ memory B cells to 2% from 20% in the mature naïve B-cell population in healthy individuals; whether this checkpoint is abrogated in SLE is not yet determined (140).

These data are consistent with data from murine studies identifying multiple tolerance checkpoints during B-cell development and activation. B-cell autonomous properties can alter these checkpoints, as can interactions with other cell types or soluble mediators. The loss of B-cell tolerance in SLE is critical to the initiation of target-organ injury but also has implications beyond autoantibody formation. B cells are essential for antigen presentation and cytokine production (141). B cells with self-reactive specificity are likely to present self-peptides to autoreactive T cells (141); this pathway provides a rationale for B-cell depletion therapy even in autoimmune diseases in which T cells are the critical effectors (142).

Lymphocyte Activation

The presence of class-switched, high-affinity, somatically mutated autoantibodies in SLE patients suggests that cognate B-cell/T-cell interactions and antigen-specific T-cell activation have occurred. Specific HLA DR haplotypes (DR2, DR3) have been associated with a two- to threefold

increased susceptibility for SLE and with particular autoantibody specificities, consistent with the model of an antigen-driven process involving antigen-specific T-cell activation.

By providing help to autoreactive B cells, T cells in lupus contribute to the abrogation of self-tolerance. Lupus T cells display increased expression of activation markers. Some studies show that stimulation of the TCR on SLE T cells leads to an abnormally high increase in intracellular Ca^{tt}. This appears to be a consequence of a decreased association of the ζ chain and an increased association of the γ chain of the Fc receptor with the TCR (143). Although there is a heightened Ca^{tt} influx after TCR stimulation, IL 2 production is decreased. Lupus T cells display increased expression of Crem α, which is perhaps responsible for the reduced IL-2 production, and for their decreased susceptibility to activation-induced cell death (AICD) (144).

Several polymorphisms of genes involved in T-cell regulation have been reported in SLE. The protein tyrosine phosphatase N22 (PTPN22) contributes to the downregulation of T-cell–receptor activation. Polymorphisms in PTPN22 associated with overexuberant T-cell activation have been reported in Caucasian and Spanish SLE populations (145). A polymorphism of the gene encoding PD-1, a receptor in the TNF superfamily that has an ITIM motif in its cytoplasmic tail and is involved in downregulation of activated T and B cells, has been associated with SLE susceptibility in Mexican and European populations (146).

Self-tolerance is maintained, in part, by the suppressive actions of regulatory T cells (Treg). CD4+CD25+ Treg suppress proliferation and effector functions of CD4+CD25− T cells. Studies of Treg in patients with SLE have demonstrated reduced numbers of peripheral CD4+CD25+ cells in patients with active disease (147). The basis for this has not yet been ascertained, but IL 2 is critically important for maintenance and survival of Treg cells; decreased expression may contribute to the abnormalities in Treg function noted in SLE (147).

The Innate Immune Response

It has become increasingly apparent that upregulation of the type I interferon pathways plays an important role in the pathogenesis of SLE (148). Elevated levels of IFNα, correlating with disease activity, severity, and titers of anti-DNA antibodies, were originally reported three decades ago. Causality was demonstrated in the 1990s with the use of recombinant IFNα for treatment of hepatitis C and the subsequent reports of IFNα-induced autoantibody production and the development of a lupuslike syndrome. Several studies have demonstrated the upregulation of a set of IFN-inducible genes in the peripheral blood mononuclear cells of SLE patients (148). The expression of this "interferon signature" has been shown to correlate with disease activity and with the presence of antibodies to RNA containing antigens.

Plasmacytoid dendritic cells have been identified as the major producers of IFNα. These cells are identified by surface expression of blood dendritic cell antigens (BDCA) 2 and 4 and CD123 and intracellular expression of both TLR7 and TLR9. SLE serum has been shown to induce IFNα production in normal peripheral blood mononuclear cells in culture; the IFN-inducing factor in SLE serum is DNA- or RNA-containing immune complexes (148). Chromatin-containing immune complexes are internalized by plasmacytoid dendritic cells through binding of nucleic acid–containing immune complexes to an activating Fc receptor. After internalization, chromatin is delivered to TLR9 or TLR7 located in an intracellular lysosomal compartment. Ligation of TLR9 by DNA or TLR7 by RNA triggers a signaling cascade resulting in transcription of several proinflammatory molecules including IFNα, IL-6, -8, -18, MIP-1α and MIP-1β, RANTES, and BAFF (149). FcR engagement alone by immune complexes is insufficient to promote dendritic cell activation and blockade of TLR7 and 9 with hydroxychloroquine and of TLR9 with inhibitory oligonucleotides will abrogate IFNα production. The proinflammatory effects of IFNα include dendritic cell activation and promotion of B-cell differentiation and Ig isotype switching. By promoting dendritic cell maturation, IFNα also increases the potential for activation of autoreactive T cells. Polymorphisms in the tyrosine kinase 2 (tyk2) gene have been associated with increased expression of type I interferon in SLE (150). Recently, a polymorphism of IRF-5, a transcription factor involved in TLR signaling pathways that regulates the expression of inflammatory cytokines including type 1 IFN and IL-6, IL-12, and TNFα, has been associated with SLE in several patient cohorts (3). It is important to note, however, that in some of the lupus-prone mouse models, decreases in type 1 interferon unexpectedly lead to a worsening of disease, suggesting that the effect of IFNα on autoimmunity is more complex than is currently appreciated (151). Whether there are patients whose disease might also be exacerbated by a reduction in type 1 interferon is unknown.

The anti-inflammatory effects of IL-10 include diminished antigen presentation by dendritic cells and decreased macrophage activation, leading to decreased T-cell activation overall and a reduced Th1 response. In NZB/W lupus-prone mice, IL-10 paradoxically increases disease severity. Correspondingly, treatment of a small number of lupus patients with anti-IL-10 antibody resulted in clinical improvement (152), and promoter polymorphisms in the IL-10 gene leading to enhanced production have been reported to associate with SLE (126).

Tissue Injury

Although the presence of autoantibodies is essential for a diagnosis of SLE, it is recognized that antibodies are not responsible for all of the tissue damage and organ destruction seen in clinical disease. Although specific

autoantibodies have been identified in affected organs in SLE patients (anti-dsDNA antibodies in the kidney, anti-Ro antibodies in skin and fetal heart conducting systems, anti-NMDA receptor antibodies in brain), autoantibodies have also been found in nonlesional tissue, demonstrating that antibody deposition alone is insufficient for inflammation and tissue damage. It has become increasingly apparent that much of the tissue destruction appears to be cytokine-mediated. IFNγ, IL-Iβ, TNFα, TGFβ, IL-18, and IL-6 are all expressed at high levels in kidney biopsy tissue from SLE patients with active glomerulonephritis (153), and skin biopsies from SLE patients have shown increased expression of IFNα and IL-6 in lesional sites (154).

TNFα is a pleiotropic cytokine with well-known proinflammatory effects, including T-cell and macrophage activation and release of other proinflammatory cytokines such as IL-1, -6, -18 and IFNγ (153). Although TNFα blockade has proved to be enormously successful in RA and Crohn's disease, the role of TNFα in SLE is more complex. Low TNFα levels in mice are associated with autoantibody production, and TNFα blockade leads to antinuclear antibody production in 20% of treated individuals. TNFα blockade may be used successfully in active SLE to modulate effector mechanisms of renal injury, but it leads to increased titers of anti-DNA and anticardiolipin autoantibodies. Several polymorphisms for genes encoding TNFα and TNFβ (lymphotoxin-α) have been associated with SLE; their functional effects are not fully determined.

Monocyte chemoattractant protein (MCP-1) is a potent chemoattractant for monocytes, memory T cells, and natural-killer T cells. Expression of this protein is increased in renal tubular cells and glomeruli in lupus nephritis, and urinary levels of MCP-1 are increased in patients with active nephritis (155). A functional MCP-1 polymorphism resulting in increased production of MCP-1 has been associated with SLE nephritis (126), providing evidence that there are genetic determinants of target-organ susceptibility to immune attack.

Antigen Exposure

Reduced uptake of apoptotic cells leads to initiation of disease in murine models of SLE and has been identified histopathologically in lymph nodes of lupus patients (156). Complement components, mannose-binding lectin (MBL), and C-reactive protein (CRP) are all acute-phase reactant proteins that contribute to the opsonization of apoptotic debris, thereby facilitating clearance and reducing the likelihood that apoptotic debris will become immunogenic. Homozygous deficiencies of early complement components C2, C4, and C1q are rare but confer substantial risk for SLE (126). Polymorphisms of both MBL and CRP genes have also been associated with SLE susceptibility;

MBL-susceptibility alleles appear to be more important in Chinese and Spanish populations than in Northern European populations (126).

Efficient uptake of immune complexes and opsonized debris is mediated by Fc receptors expressed predominantly on hematopoietic cells (B cells, neutrophils, macrophages, and dendritic cells). FcRI, IIa, IIIa, and IIIb all contain immunoreceptor tyrosine-based activation motifs (ITAMs) in their cytoplasmic tails. Crosslinking of these receptors by IgG immune complexes results in mast-cell and neutrophil degranulation, phagocytosis, antibody-dependent cellular cytotoxicity, upregulation of cytokine gene transcription, and release of inflammatory mediators (157). These activating receptors also enhance dendritic cell maturation (157). Single-nucleotide substitutions in the activating FcR genes result in molecules with altered binding to IgG immune complexes. Associations between the FcRIIA R131H low-affinity allele and disease susceptibility or nephritis have been reported in Brazilian, Thai, Korean, German, and African-American populations (158). FcRIIIA F158V and FcγRIIIB NA2/NA2 polymorphisms are reported to associate with disease susceptibility in Dutch, Korean, Thai, and Caucasian populations (158). The recent finding that FcRIIa R131 is a significant predictor of the efficacy of B-cell depletion in SLE patients treated with anti-CD20 antibody suggests that identification of FcR polymorphisms may also be useful in predicting response to some therapeutic agents.

DNase I is an endonuclease that creates single-stranded nicks in DNA (159). DNase I–deficient mice develop a lupuslike illness characterized by autoantibodies, nephritis, and early death, and in NZB/W lupus-prone mice, low serum DNase 1 activity is detectable before the onset of renal disease. A small number of patients with SLE have a mutation in DNase 1 leading to low serum DNase activity and markedly elevated IgG titers against nucleosomal antigens, including dsDNA. Several studies of lupus patients have demonstrated low serum DNase 1 activity; low DNase I activity is not associated with coding-region polymorphisms, but could potentially be associated with polymorphisms in noncoding regions that regulate gene expression. It was initially speculated that reduced DNase 1 activity might reflect a loss of serum DNase through damaged kidneys, but low DNase 1 activity has been detected even in patients without kidney disease.

Cell Survival

Polymorphisms in Bcl-2, an antiapoptotic molecule that defines the threshold for cell death and survival, have been implicated in susceptibility to SLE in Chinese and Mexican populations (160). Importantly, the combination of a Bcl-2–susceptibility allele and an IL-10–susceptibility allele has been reported to confer a 40-fold increased risk of

SLE, buttressing the theory that combinations of susceptibility alleles markedly increase risk. Although SLE patients do not have mutations leading to Fas or FasL deficiency, elevated serum levels of soluble Fas have been reported in SLE, and lymphopenia in SLE has been associated with increased Fas expression on circulating lymphocytes.

Hormonal Influences

The greater frequency of lupus in women has fueled the hypothesis that sex hormones play a role in disease pathogenesis (49). Recently, three randomized, placebo-controlled trials of the use of estrogen in SLE patients determined the existence of a subset of patients whose disease is exacerbated by hormone. All three studies concluded that exogenous estrogens were well tolerated in patients with stable disease and lacking in antiphospholipid antibodies, but mild to moderate flare rates were significantly increased in postmenopausal women treated with hormone replacement (161–163). The response to estrogen is mediated by two intracellular receptors, ERα and ERβ, and polymorphisms of the ERα gene have been associated with age of disease onset and disease severity in some human SLE populations.

Twenty percent of SLE patients are reported to have elevated prolactin levels; nonetheless, treatment with bromocriptine, a blocker of prolactin secretion, has displayed equivocal benefit. Prolactin receptors are found on a variety of cells including T and B, and ligation of these transmembrane receptors results in upregulation of CD40, CD40L, and Bcl-2, all of which might facilitate the survival of autoreactive B cells.

New Therapeutic Approaches

For many years, there were few clinical trials on systemic lupus and no new therapeutic options. Therapy consisted of corticosteroids to decrease immune activation and inflammation. Azathioprine was recommended as a steroid-sparing agent, and cyclophosphamide was given to patients with aggressive disease. Hydroxychloroquine was also recommended for most patients and was thought to decrease antigen presentation by interfering with phagolysomal fusion; it is now believed to function by preventing the activation of TLR7 and TLR9 that reside in a lysosomal compartment, thereby blocking DC activation by DNA-containing immune complexes.

Recently, many new therapeutic options have been proposed, and many are currently in clinical trial. First, mycophenolate mofetil was shown to be as efficacious as cyclophosphamide in the treatment of acute lupus nephritis. Trials to determine if mycophenolate is as effective as cyclophosphamide in maintenance of renal remission are underway. Mycophenolate may have a better toxicity profile, as it does not cause ovarian failure and infertility.

High-dose cyclophosphamide treatment followed by autologous stem-cell reconstitution has been performed in lupus patients; a randomized study is now in process. With increasing interest in the potential role of the B cell as the antigen-presenting cell for self-antigen, B-cell–depletion strategies are being explored with antibodies to CD20 and to CD22. A related approach targets BAFF and its three receptors (BAFF-R, TACI, and BCMA). An initial study of anti-BAFF antibody failed to show clinical efficacy, although it did lead to a modest reduction in anti-DNA antibodies.

Costimulatory blockade using an antibody to CD40 ligand (CD40L) to prevent the CD40L interaction with CD40 on B cells and antigen-presenting cells was attempted in lupus patients. The suggestion of clinical efficacy in a few patients, however, was tempered by an unanticipated increase in the incidence of thrombotic events. Subsequent studies have now shown that human platelets, unlike murine platelets, also express CD40L. Antagonistic antibodies to CD40 are now under development to attempt again to target this pathway.

A clinical study of CTLA-4Ig in lupus is currently underway. Interestingly, a therapeutic effect of CTLA-4Ig on established kidney disease in NZB/W mice is seen even though autoantibody titers do not decrease; thus, CTLA-4Ig may have a direct effect on renal pathology. Engagement of CD28 may be required for expression of chemokine and chemokine receptors that allow extravasation of activated cells into tissue. CTLA-4Ig may block this phase of disease pathogenesis or may work directly on renal cells expressing B7 molecules. Studies of ICOS blockade are in development, as are studies of agents that block type I interferon. The murine models show that the efficacy of these interventions are strain-specific and depend on the mechanism for autoantibody production. It is highly likely, therefore, that each of these interventions will be effective in only a subset of patients; identifying each subset in advance of treatment initiation remains a challenge.

Most therapies focus on the inductive phase of autoimmune disease, however, the therapeutic benefits of uncoupling links in the inflammatory cascade and targeting molecules that mediate end-organ damage are increasingly recognized. A small number of patients with refractory lupus nephritis have been treated with TNFα blockade with marked decreases in proteinuria despite an increase in autoantibody production. TNFα-receptor expression on renal epithelial cells appears to be crucial for induction of antibody-mediated glomerulonephritis, although it remains uncertain whether TNFR1 or TNFR2 or both must be present. Thus, the effect of TNFα blockade on renal nephritis is likely to be an effect on resident renal cells.

Studies of antigen-specific therapies are in their infancy. LJP 394 is a multimeric DNA compound that has been demonstrated to reduce anti-DNA antibody titer and to

reduce numbers of DNA-reactive B cells in the BXSB murine lupus model. In clinical trials in lupus patients, it has been shown to reduce titers of high-affinity anti-DNA antibodies, but it has a modest effect, if any, on reduction of renal flares. It may be that LJP394 fails to induce tolerance in the proinflammatory milieu of lupus patients, it may not have been used at an adequate dose, or there may be too many nephritogenic antibodies in lupus patients that are not bound by LJP394.

Mouse Models of SLE

Systemic lupus is a disease that has attracted much attention from immunologists, in part because a very large number of genetic manipulations in mice give rise to a lupus-like disease. Indeed, susceptibility loci have been identified on every murine chromosome, and >30 susceptibility loci have been reported (18). Initial studies of lupus focused on spontaneously arising strains that displayed serum titers of anti-DNA antibodies and glomerulonephritis.

NZB/W Mouse

The NZB/W mouse develops high-affinity anti-DNA antibodies and a proliferative glomerulonephritis. Of interest, female mice develop earlier and more aggressive disease. The disease is hormonally responsive; estrogen exacerbates disease and androgen protects against disease, and studies demonstrate a defect in central tolerance, with high-affinity autoreactive immature B cells maturing to immunocompetence. The mice are characterized by hyperreactivity of naïve B cells with an early spontaneous increase in IgG-producing B cells. The pathogenic anti-DNA antibodies in this strain are IgG, predominantly IgG2a and IgG2b, and many display extensive somatic mutation with some evidence for affinity maturation to DNA, suggesting a requirement for T-cell help and a defect in selection of germinal-center B cells. A B-cell autonomous defect has been shown in adoptive transfer studies, but full disease expression requires the presence of NZB/W T cells as well.

The genetic analysis of the NZB/W strain has revealed a locus on chromosome 1 to be critical in autoreactivity. This same region is a susceptibility locus in the related NZM2410 strain, and an orthologous region of chromosome 1 in humans is also a lupus-susceptibility locus. The locus includes the genes encoding Fc receptors. The NZB/W mouse has been demonstrated to have low-level expression of the inhibitory FcRIIB and, similar to human patients, a failure to upregulate expression of this receptor on memory B cells. Interestingly, a forced increase in expression of FcRIIB in B cells in this strain markedly reduces autoantibody production and renal disease (164). There are, however, many candidate genes in this locus besides FcγRIIB. The IFNγ-inducible gene Ifi202 has also

been implicated in disease susceptibility; the susceptibility allele is linked to increased resistance to p53-mediated apoptosis of B cells (165). Consistent with the hypothesis that an IFNγ-inducible gene is involved in disease pathogenesis, IFNγ itself contributes to disease severity (166).

IFNγ blockade reduces IgG anti-DNA antibody production and glomerular immunoglobulin deposition, in part by preventing class switching to IgG2b and IgG2a; the recent identification of FcR IV with high-affinity binding to IgG2a has led to the speculation that the absence of activation of this receptor may be responsible for reduced renal inflammation when IgG2a antibodies are reduced (167). It has, in fact, been demonstrated in this strain that the deletion of the γ chain of activating Fc receptors leads to a marked reduction in renal inflammation, although it causes no diminution in autoantibody production (168). Several other loci have also been suggested to play a role in autoimmune disease in this strain (18). Of note, the putative susceptibility loci derive from both the NZB and the NZW parental strains. A promoter polymorphism in the gene encoding TNFα leading to decreased expression of TNFα associates with disease; administration of exogenous TNFα reduces autoantibody production in this strain (117). Paradoxically, TNFα contributes to kidney inflammation. The potentially conflicting role of cytokines in the inductive and pathogenic phases of diseased complicates the design of therapeutic strategies. Because TLR signaling and consequent production of IFNα has been implicated in murine and human lupus, NZB/W mice lacking the IFNα receptor have been generated; these mice lack a disease phenotype; conversely, administration of IFNα to NZB/W mice markedly accelerates disease (169,170).

The NZB/W strain has been of substantial utility in preclinical studies of lupus therapeutics. Early studies demonstrated the efficacy of either continuous or intermittent cyclophosphamide in NZB/W lupus; cyclophosphamide remains a major agent in the therapeutic armamentarium in SLE. Anti-CD3 and anti-CD4 therapy was also shown to be effective therapy in this model, leading to a therapeutic focus on the T cell. Anti-CD40 ligand antibody diminishes autoantibody production in NZB/W mice and leads to improved renal function. T cells from the NZB/W mouse have been shown to respond to an immunoglobulin heavy-chain variable-region peptide. A tolerogenic exposure to this peptide leads to a markedly less severe disease. Because T cells of lupus patients also recognize this peptide, a protocol to induce tolerance with peptide is currently in early trials in patients.

CTLA-4Ig was also tested as a therapeutic agent in this strain and demonstrated good efficacy. When CTLA-4Ig is used together with even a single dose of cyclophosphamide, there is not only a cessation of progression of renal disease, but also a reversal of ongoing renal disease. This has led to speculation that some critical effects of CTLA-4Ig are on effector mechanisms of renal injury, both

extravasation of inflammatory cells into renal tissue and recruitment of resident renal cells to the inflammatory cascade (113). BAFF blockade also diminishes renal disease. Only a modest decrease in IgG autoantibodies is observed following either BAFF-R-Ig or TACl-Ig; their mechanism of action may be a reduction in B-cell number with a consequent decrease in T-cell activation (171). Agonistic antibody to CD137 (4-1BB), a T-cell costimulatory molecule belonging to the TNFR family, leads to near-normal life span in NZB/W mice, and a short treatment given after disease onset reduces ongoing disease severity (112). The mechanisms for this effect have not fully been elucidated, but current hypotheses include induction of anergy, deletion of autoreactive CD4 T cells, generation of regulatory T cells, or IFNγ-dependent regulation of T-cell function. This treatment is interesting because it shows that long-lasting restoration of tolerance can be achieved in mice with spontaneous SLE in which B and T cells are continuously being activated. This approach has not yet been applied to human disease.

NZM Mice

The NZM mouse strains are closely related to the NZB/W mice; they derive from extensive intercrossing of NZB/W mice. The NZM 2410 strain, in particular, has been studied in detail. Three large regions (SLE 1, 2, and 3) on chromosomes 1, 4, and 7 have been identified as susceptibility loci. The chromosome 1 locus includes the region identified as a susceptibility locus in NZB/W mice, and it contributes to ANA reactivity. The chromosome 4 locus also contributes to ANA reactivity, but also to T-cell activation. The chromosome 9 locus contributes both a dendritic cell activation phenotype and renal vulnerability. Together these susceptibility loci, derived from both parental strains, are sufficient to confer full lupus susceptibility on nonautoimmune C57Bl/6 mice. Extensive subsequent analyses have demonstrated that multiple susceptibility genes are present within each locus. Within the chromosome 1 locus are genes encoding Fc receptors, complement receptors, and Ly108. The Ly108 allele present in the NZM2410 mouse has been demonstrated to attenuate BCR signaling, leading to diminished negative selection in the naïve B-cell repertoire. Thus, despite the hyperreactivity of mature B cells in this strain, there may be hyporesponsiveness of immature B cells. This model is consistent with some new data discussed earlier from human patients demonstrating a persistent lack of stringency in central B-cell tolerance that could be attributable to decreased BCR signaling (reviewed in 64).

The renal pathology in the NZM2410 strain is characterized by more glomerulosclerosis and less proliferative disease than the renal disease in the NZB/W mice. Studies in the NZM strains have linked glomerular disease to stat 6 activation, as stat 6–deficient mice have high titers of

autoantibodies but little renal disease. Surprisingly, stat 4–deficient NZM mice fail to develop strong T_H1 responses and fail to produce high titers of IgG2b and IgG2a anti-DNA antibodies, yet they develop accelerated renal disease. These studies support the model that the genetic basis for induction of autoreactivity differs from the genetic basis for target-organ damage (172).

SNF1 Mouse

The F1 progeny of SWR × NZB (SNF1) also develop a lupuslike disease. T-cell reactivity to histone peptides was first identified in this strain and, subsequently, in other lupus-prone strains and in humans with SLE. In particular, a conserved peptide in H4 is recognized in the context of multiple mouse and human class II molecules, and administration of soluble peptide has been demonstrated in mice to prevent disease when presented in the appropriate fashion; trials are planned in lupus patients (173).

MRL/lpr Mouse

The MRL/lpr mouse has also been a subject of intense investigation. This mouse has a defect in Fas expression. On other genetic backgrounds, the Fas mutation can lead to no phenotype or to lymphoproliferation without autoantibody production. On the MRL background, the fas mutation leads to lymphoproliferation, autoantibody production and inflammation in the kidney and salivary glands. The most obvious phenotypic abnormality is an expansion of B220$^+$, CD4$^-$, CD8$^-$ T cells, which contribute to autoantibody production. Anti-DNA antibodies are a dominant specificity, but anti-Sm antibodies, RF, and anti-Ro and La antibodies are also present (174). MRL/lpr mice, like NZB/W mice, display low-level expression of FcRIIB on B cells. Increased FcRIIB expression leads to a marked attenuation of autoantibody production, even though the expansion of abnormal T cells persists (164).

Not all aspects of disease pathogenesis are similar between MRL/lpr and NZB/W mice. Paradoxically, TLR9 deficiency in the MRL/lpr background leads to enhanced disease, whereas TLR7 deficiency leads to attenuated disease (175). Furthermore, MRL/lpr mice deficient in Fc receptor γ-chain expression still develop renal disease (176). Finally, type I IFN attenuates disease in this strain (151). The reasons for the differences between the strains are not understood, but they raise the specter that similar heterogeneity in etiopathogenesis and response to therapy will exist in the human population and complicate the design of clinical trials.

Motheaten Mouse

The motheaten mouse (me/me) has a defective SHP-1 gene. It also develops anti-DNA antibodies and glomerulonephritis (177). Although the anti-DNA antibodies in

NZB/W, NZM, and MRL/lpr mice display extensive somatic mutation, the anti-DNA antibodies in motheaten mice appear to derive from B1 cells. B cells in this strain display marked hyperreactivity. Because SHP-1 is the phosphatase that is activated by engagement of CD22, it is not surprising that the same phenotype is observed as in CD22-deficient mice. Whether B1 cells in humans can produce pathogenic anti-DNA antibodies is not known.

BXSB Mouse

The BXSB mouse is unique in that male mice are preferentially affected. They possess a chromosomal translocation of a region of the X chromosome inserted into the Y chromosome. Because the X chromosome region includes the gene encoding TLR7, there is increased TLR7 expression in these mice, perhaps leading to increased dendritic cell and B-cell activation in the presence of RNA-containing immune complexes (178).

Other Lupus-prone Strains

The past decades have seen an enormous proliferation of genetically altered mice that develop a lupuslike serology. One feature of these models is that the disease phenotype is only apparent on particular genetic backgrounds. Appearance of clinical disease is determined by the presence of cooperating susceptibility loci, whereas absence of clinical disease in a particular strain may reflect a lack of cooperating susceptibility loci or the presence of suppressor loci that interfere with disease expression. Similar to studies of lupus genetics in the human population, susceptibility genes include those that govern antigen exposure, lymphocyte survival, activation pathways, antigen-receptor signaling, and target-organ vulnerability (reviewed in 64). Several gene deletions that affect the removal of apoptotic cells and apoptotic debris result in a lupuslike syndrome. For example, deletion of DNase 1, C1q, or SAP leads to the production of anti-DNA antibodies. Similarly, deletion of c mer, a membrane tyrosine kinase critical to the process of phagocytosis by macrophages, also leads to autoantibody production and glomerulonephritis. Overexpression of genes that prevent B-cell apoptosis, such as Bcl-2 and BAFF, are also associated with a lupuslike syndrome. A third category of genes implicated in lupus pathogenesis is those encoding inflammatory cytokines or costimulatory molecules. Deletions or overexpression of genes regulating the TCR or BCR signaling pathway may also lead to a lupuslike syndrome. The genetic manipulations that increase the strength of BCR signaling appear to lead to anti-DNA antibody production by marginal-zone or B1 cells. Recently, a few models of lupus have been developed in which the critical defect in B-cell selection appears to be within the germinal center or in the differentiation to a plasma cell. Deletion of the roquin gene leads to increased

expression of ICOS on follicular T-helper cells, enlarged germinal centers, anti-DNA production, and nephritis (70). Mice with a deletion of IBP (IRF4-binding protein) also display enlarged germinal centers and anti-DNA–antibody production (179). Although the enlarged germinal centers in this model suggest that they are the site of dysregulation of B-cell selection, this has not yet been proven. The FcRIIB deletion appears to interfere with a tolerance checkpoint before plasma cell differentiation in both T-independent and T-dependent responses (180). These genetically engineered mice very clearly demonstrate that a multiplicity of pathways of immune selection and activation and a multiplicity of tolerance checkpoints can be implicated in lupus; which of these are most frequently involved in the human disease has not yet been established.

One feature of many mouse models is activation of dendritic cells, sometimes a primary feature of disease and sometimes secondary to ingestion of nucleic acid–containing immune complexes. The proinflammatory milieu created by the presence of stimulatory immune complexes is thought to lead to a continuing expansion in the number of targeted autoantigens. Consistent with this pathophysiology, most murine models display elevated expression of BAFF, probably secondary to TLR signaling in dendritic cells, and BAFF blockade is therapeutic in some murine models of disease (181). Despite this general feature of murine models of lupus, there is as yet no predictable response to deletion of TLRs or to type I IFN blockade, as some models are exacerbated by deletion of a TLR or improved by administration of IFN (182).

Induced Models of Lupus

There are also several induced models of lupus. One model that has been studied extensively is graft-versus-host disease. Injection of some strains with immunocompetent cells of another strain leads to the production of anti-DNA antibodies by host B cells activated by donor T cells. These anti-DNA antibodies cause glomerulonephritis (183). More recently, there has been much interest in pristane-induced lupus. In this model, there appears to be activation of the innate immune response, leading to anti-DNA antibody production (184). There are also antigen-induced models. BALB/c mice immunized with a peptide mimetope of DNA develop antipeptide, anti-DNA cross-reactive antibodies. This response is T-cell–dependent, with antigen-specific T cells displaying a T_H1 pattern of cytokine production (185). Immunization with DNA-binding proteins can also induce anti-DNA antibodies, presumably because a DNA–protein complex forms in vivo and functions in a hapten-carrier fashion (186).

Finally, estradiol and prolactin have been shown to induce autoantibody production in a nonautoimmune BALB/c mouse transgenic for the heavy chain of an anti-DNA antibody. Estradiol alters B-cell selection, permitting

high-affinity DNA-reactive B cells that normally undergo deletion to mature to immunocompetence. The altered selection reflects an estrogen-induced decrease in BCR signaling. Prolactin, likewise, leads to the survival of high-affinity DNA-reactive B cells that are normally subject to negative selection, but the effects of prolactin are T-cell–dependent and appear to reflect a prolactin-induced rescue of autoreactive B cells through simultaneous upregulation of CD40 on B cells and CD40L on T cells (52).

Drug-induced lupus in humans can be caused by exposure to a number of drugs, including, most notably, hydralazine and procainamide. One important consequence of hydralazine exposure in mice is decreased DNA methylation, thereby increasing transcription of multiple genes, some of which contribute to B-cell activation. In particular, increased transcription of LFA-1 augments T-cell help to autoreactive B cells; nonautoreactive T cells that overexpress LFA-1 can induce autoantibody production in nonspontaneously autoimmune mice (187).

INFLAMMATORY ARTHRITIS

The inflammatory arthritides share a strong association with MHC haplotype and are manifested clinically by differing patterns of joint involvement and constitutional symptoms that are modulated by age, gender, and ethnicity.

RHEUMATOID ARTHRITIS

RA is a chronic inflammatory disease that targets synovial joints and can be accompanied by significant systemic symptoms and extra-articular manifestations. Disease severity, ranging from mild, nondeforming arthritis to extremely aggressive, destructive, and crippling arthritis, is influenced by an array of genetic, hormonal, and environmental factors. RA has an overall prevalence of 1% in most populations. Several epidemiologic studies using the revised American College of Rheumatology (ACR) criteria for diagnosis have concluded that the most significant risk factors include increasing age, female gender, family history, and smoking. The reported female-to-male ratio in RA ranges from 2:1 to 3:1, with the gender discrepancy being most marked in premenopausal women. Whether this female preponderance is the result of hormonal differences or other sex-associated genetic determinants is not clear; however, in contrast to systemic lupus, use of exogenous estrogen has been reported to decrease the risk of developing RA.

Clinical Manifestations

The diagnosis of RA remains a clinical determination based on the presence of symmetric polyarticular inflammatory arthritis involving the small joints of the hands and feet (excluding the distal interphalangeal joints), continuing over a minimum period of 6 weeks. The presence of morning stiffness lasting for 30 minutes or more associated with the arthritis is quite specific for RA. Joint erosions on plain radiographs are the most specific radiographic feature of RA, heralding an aggressive disease course; however, the sensitivity of radiographs for detecting articular erosions within the first 2 years of disease activity is low. Magnetic resonance imaging (MRI) and joint ultrasound are more sensitive for detecting erosive disease. The most frequent radiographic findings in early disease are soft-tissue swelling and periarticular osteopenia. Joint damage is directly attributable to the presence of destructive proteases and osteoclast-activating cytokines within the synovial tissue. Upregulation of transcription of synovial tissue proteases has been demonstrated within 2 weeks of clinical symptoms. Similarly, MRI studies demonstrate that joint erosions may be present within weeks of the onset of symptoms (188). These observations are consistent with the finding that autoantibodies and elevation of acute-phase reactants can precede onset of symptoms by years, and confirm the presence of checkpoints between autoreactivity and tissue destruction.

Many patients have constitutional complaints of fatigue, myalgias, and occasionally weight loss and fever, consistent with the elevated serum levels of IL-1, IL-6, and TNFα. Extra-articular manifestations such as rheumatoid nodules, interstitial lung disease, and leukocytoclastic vasculitis are associated almost exclusively with the presence of high titers of IgG RF and tend to occur late in the disease.

Patients with RA have increased mortality rates, with life expectancies 10 to 15 years shorter than predicted. This has been attributed to increased susceptibility to infection secondary to the disease itself and to immunosuppressive therapy, gastrointestinal bleeding secondary to therapy, accelerated atherosclerotic heart disease secondary to chronic inflammation, and lymphoproliferative disorders secondary to both the disease itself and to immunosuppressive therapy. Factors that have been associated with poor outcome include the presence of an HLA allele with the shared epitope (HLA-DRB1 haplotype), rheumatoid factor, and rheumatoid nodules (189). Both lupus and RA are associated with an increased incidence of Sjogren syndrome, which, in turn, is associated with an increased incidence of lymphoid malignancy.

Pathogenesis and Genetic Susceptibility

HLA-DRB1 alleles encoding a common amino acid sequence (the shared epitope) in the third variable region of the DRB1 molecule have been identified as the strongest genetic risk factor for RA in patients of Caucasian descent. Apart from this strong association of the MHC-encoded shared epitope with disease susceptibility, several other

disease-associated loci have been confirmed using the large North American Rheumatoid Arthritis Cohort (NARAC) (190). These include the PTPN22 polymorphism also found in SLE, the CTLA4 CT60 allele also found in type 1 diabetes, and peptidylarginine deiminase 4 (see below). CTLA-4 is upregulated on the surface of CD4$^+$ T cells following T-cell activation and outcompetes CD28 for B7 binding. CTLA4 engagement on T cells leads to inhibition of effector function. The CT60 CTLA-4 autoimmune disease–associated polymorphism has been reported to result in decreased production of soluble CTLA-4, which may act as an endogenous inhibitor of T-cell activation (3).

Synovial Architecture

Pathogenesis involves the activation of resident cells within the joint in addition to the influx of inflammatory cells in response to chemoattractants. The normal synovial membrane consists of a continuous surface of connective tissue. The intimal or lining layer is populated by two cell types; a bone marrow–derived synoviocyte with macrophagelike properties (type A) and a mesenchymal fibroblastlike synoviocyte (type B). The subintimal layer is composed of numerous blood vessels and connective tissue fibroblasts. Synovial tissue extracellular matrix is composed of a loose structure of large amounts of hyaluronan along with collagen (types III, IV, V, VI), laminin, fibronectin, and proteoglycan.

The hallmarks of synovial abnormalities in RA include microvasculature damage, synovial-lining hyperplasia, neoangiogenesis, and an inflammatory cell infiltrate of lymphocytes, macrophages, and neutrophils (191). Although the relative importance of each of these cell types is controversial, it is likely that all contribute to the synovial lesion in RA. Three patterns of lymphoid organization in rheumatoid synovial tissue have been described: (a) ectopic germinal-center arrangement with T and B cells surrounding a network of dendritic cells; (b) aggregates of T and B cells without dendritic cells and without germinal centers; and (c) T and B cells diffusely infiltrating the stroma. A very few patients will have a form of granulomatous synovitis that histologically resembles rheumatoid nodules. The organization of synovial tissue into ectopic lymphoid structures may provide advantageous conditions for antigen presentation and subsequent cellular activation.

Synovial tissues containing germinal centers produce the highest amount of IgG (192). Lymphotoxin β (LT-β) and CXCL13 (BLC) production also correlates with germinal-center structures. Interestingly, the mantle zones of these germinal centers also contain IFNγ-producing CD8$^+$ T cells, and depletion of these cells causes disintegration of the germinal centers, decreased production of lymphotoxin β, and cessation of immunoglobulin secretion. SCID mice engrafted with germinal center–containing synovial tissue and exposed to BAFF and APRIL blockade me-

diated by TACI-Ig showed a marked decrease in T-cell and dendritic cell activation and IgG production, supporting the hypothesis that B cells also sustain the activation of T cells and dendritic cells. Conversely, BAFF and APRIL blockade in SCID mice engrafted with the aggregate and diffuse forms of synovitis result in enhanced IFNγ production and T-cell activation. These data suggest the potential influence of synovial architecture in response to immunobiologic therapies.

Fibroblastlike synoviocyte proliferation occurs early in the disease process (193). Proliferation and activation of synoviocytes are early features of the rheumatoid synovial membrane, known as pannus, that extends to the cartilage and erodes periarticular bone at the margin between synovium and bone. Upregulation of the adhesion molecules VCAM-1 and integrin $\alpha(v)\beta(3)$ on activated fibroblastlike synoviocytes allows these cells to adhere to the extracellular matrix of articular cartilage and triggers intracellular signaling cascades that lead to proliferation and escape from contact inhibition. Activation of synoviocytes leads to increased production of matrix metalloproteinases (MMPS), whose potent catalytic activity is normally kept under control by endogenous inhibitors of MMPs (TIMPS). TNFα and IL-1 induce MMPs, but TNFα-independent pathways of synoviocyte activation also exist, perhaps providing an explanation for the 30% to 40% of RA patients who fail to respond to TNF blockade. Other destructive enzymes released by activated fibroblastlike synoviocytes include cathepsins B, L, and K.

Synovial fibroblasts stimulated with IL-1 and TLR-2 ligand demonstrate increased production of IL-5, MMPs, and chemokines, and several studies have now documented increased expression of TLR-2, -3, -4, and -7 and their ligands in fibroblasts and macrophages in the synovial lining of rheumatoid joints (194). Stimulation of rheumatoid dendritic cells with HSPB8, a heat-shock protein that is an endogenous ligand for TLR4, results in activation and secretion of IL-6, TNFα, and several chemokines (194). The recent finding that a functional polymorphism of TLR 2 significantly associates with susceptibility to RA in a Korean population adds to the growing appreciation of the importance of TLR signaling in this disease (195).

Autoantibodies

Although immunization with type II collagen, the cartilage protein gp39, and proteoglycans induce arthritis in animal models, and patients with RA may have antibodies that are reactive with these proteins, evidence that these molecules are inciting antigens in human disease is not strong. Several groups have demonstrated oligoclonal B-cell populations in the rheumatoid synovium with a more restricted B-cell repertoire in the synovium than in the blood (196). The identification of persistent B-cell clones in synovial fluid from patients obtained at different times is also consistent

with the theory of clonal B-cell expansion. However, most autoantibodies commonly seen in RA, in particular RF and antibodies to citrullinated proteins, are directed against ubiquitous antigens and are not joint-specific.

RF, an antibody directed against the Fc portion of IgG, remains the major laboratory finding in RA and is present in approximately 70% of patients (197). RFs are polyclonal antibodies of predominantly IgM isotype; IgG and IgA RF correlate more with aggressive disease. The "natural" low-affinity RF produced by $CD5^+$ B cells found in healthy individuals and a variety of chronic infections, inflammatory conditions, malignancies, organ transplants, and pregnancy are germline-encoded polyreactive IgM antibodies (198). In RA, the RF is high-affinity, monoreactive, and somatically mutated, and may be produced by B cells within the synovium. Furthermore, RF displays higher-affinity binding to agalactosyl IgG, which is enhanced in active disease. Deposition of immune complexes containing RF in cartilage and vasculitic lesions appears to contribute to local inflammatory changes through activation of the complement cascade and NK-cell activation. RF-positive patients have a worse prognosis, but joint histology in patients lacking RF is not obviously different than in patients who have RF.

Antibodies directed against cyclic citrullinated proteins (anti-CCP) display equal sensitivity and higher specificity for RA. Citrullinated peptides are have been identified in synovium from patients with RA, osteoarthritis, and psoriatic arthritis, but the presence of anti-CCP antibodies either in the serum or synovial fluid appears to be restricted to RA. Citrullination of proteins including fibrin, vimentin, and histones is mediated by peptidylarginine deaminases. PAD14, a peptidylarginine deiminase, has been identified as an RA-susceptibility gene (190), and citrullinated peptides have been shown to bind with high affinity to the HLA-DRB1 0401 shared epitope allele that is associated with disease (199). It has recently been demonstrated in an animal model of collagen-induced arthritis that anti-CCP antibodies bind to inflamed synovial tissue, thereby enhancing joint inflammation and damage (200). Furthermore, citrullination of proteins is enhanced in inflamed joints and is a hallmark of stressed and proapoptotic cells; therefore, both RF and anti-CCP autoantibodies appear to contribute to the synovial lesions in RA, and both are predictive of aggressive disease. Interestingly, smoking, a risk factor for disease, increases the density of citrullinated proteins in lung epithelial cells.

Both RF and anti-CCP antibodies have been shown to appear in the serum years before onset of clinical disease. Patients show significantly higher percentages of autoreactive B cells in both the new emigrant and mature naïve B-cell compartments compared to healthy controls, and 10% to 20% of these express RF or anti-CCP antibodies (198).

An excess of VkJk1 light-chain rearrangements in new emigrant B cells in some patients suggests premature termination of secondary recombination and impaired receptor editing, whereas other new emigrant B cells show evidence of a failure to downregulate recombination events. Patients who do not show evidence of defective secondary recombination may display unusually long k chains containing 11 or more amino acids in CDR3, suggesting aberrant regulation of deoxynucleotidyl transferase (TdT) (198).

Because of the therapeutic focus on macrophage activation and secretion of TNF and IL-1β and the absence of identified autoantibodies in approximately 30% of patients, B cells were considered for a long time to be peripheral players in pathogenesis. However, recent studies have highlighted a potential role of B cells in rheumatoid synovium other than autoantibody production (192). One of the most clinically compelling arguments for B-cell involvement in RA is the surprising efficacy of rituximab, an anti-CD20 chimeric B-cell–depleting antibody (201). Interestingly, rituximab often displays clinical efficacy before altering serum titers of RF, implying a potential role for B cells in antigen presentation and cytokine production.

T Cells

The strong association between specific HLA haplotypes and disease susceptibility has led to a T-cell–centric model of disease. However, numerous studies attempting to define the antigenic specificity of infiltrating oligoclonal T cells in rheumatoid synovium failed to demonstrate consistent results. Despite the failure to isolate oligoclonal T-cell populations in joints, the HLA-DRB1 shared epitope association remains a powerful susceptibility determinant.

The T cell has recently become the focus of studies linking RA to premature immune senescence (102). Aging T cells lose surface expression of CD28 and are no longer able to upregulate CD40L on their surface; without the obligate costimulatory molecules, they function poorly in MHC class II–restricted interactions. With age, T cells also acquire surface expression of the stimulatory killer immunoglobulinlike receptors (KIRs) and NKG2D that normally regulate activation of NK cells. The finding that RA patients have increased numbers of circulating $CD4^+CD28^-$ T cells with shortened telomeres suggests a senescent $CD4^+CD28^-$ profile. T cells expressing KIR receptors have also been identified in rheumatoid synovium, and an allele of KIR2DS2, one of the stimulatory KIR receptors on $CD28^-$ T cells, has been identified as a risk factor for disease (202). Furthermore, the number of $CD4^+CD28^-$ cells in patients correlates with the presence of extra-articular manifestations, erosive disease, and the risk of atherosclerotic complications of disease (102), and reversal of the T-cell phenotype has been observed in individuals treated with TNFα blockade. Synoviocytes express fractaline, which binds to CX3CR1 present on senescent T cells. Engagement of CX3CR1 by fractalkine results

in IFNγ and TNFα secretion, thereby promoting ongoing T-cell activation and inflammation. Thus, it is possible that senescent T cells are particularly responsive to stimuli from the synovium, although they are less responsive to antigen-specific stimuli.

Antigen Exposure

The role of HLA class II molecules has been intensively studied in RA because of the compelling data showing that the shared epitope constitutes a major risk factor for disease susceptibility (203). Interestingly, homozygosity for the shared epitope confers greater risk than heterozygosity, arguing against the hypothesis that disease-related class II molecules are critical in presenting certain self-peptides to CD4+ T cells. Rather, it has been speculated that the shared epitope itself may be immunogenic and homologous sequences have been identified in both bacterial and viral proteins. The exact role of the predisposing class II molecules remains unclear, because no dominant self peptides have been recovered from class II molecules in rheumatoid synovial tissue and no search for virus or bacteria has demonstrated an infectious etiology.

Cytokines

TNFα and IL-1 are potent proinflammatory cytokines secreted by macrophages, and both stimulate fibroblastlike synoviocytes to proliferate and secrete IL-6, IL-8, GM-CSF, FGF, and MMPs (204). They also act to induce adhesion molecules such as VCAM-1 and E-selection on endothelial cells, thereby contributing to endothelial-cell activation and diapedesis of additional leukocytes to sites of inflammation. TNFα, IL-8, and VEGF also promote angiogenesis, a feature of rheumatoid synovium.

Osteoclast differentiation and activation result from the binding of RANK (receptor activator of nuclear-receptor factor NFκB) to its ligand, RANKL. The relative expressions of RANK, RANKL, and osteoprotegerin (OPG), a molecule that competitively binds RANKL and thus prevents osteoclast activation, determines the amount of bone resorption at a given site. Rheumatoid joint tissue has been shown to contain increased amounts of RANKL and decreased amounts of OPG. TNFα, IL-1, and M-CSF are capable of acting directly on osteoclast precursors to promote osteoclast differentiation or indirectly by modulating RANKL and OPG expression (205).

New Therapeutic Approaches

Better understanding of the cytokines and effector molecules in rheumatoid synovium has led to the development of a number of biologic agents that selectively target pathways of disease. Clinical responses to these therapies continue to inform us about the complex interactions

in the immune system. Early biologic therapies targeting CD4 cells depleted CD4 cells in the peripheral blood but had less effect on activated and synovial T-cell populations and disappointingly little effect on disease course. In contrast, the revolutionary success of TNFα blockade for RA, and more recently, blockade of IL-6, is testimony to the fact that control of inflammatory mediators, regardless of the inciting triggers in disease pathogenesis, can provide effective treatment for this disease. Recently, the role of the adaptive immune system has been re-established with the demonstrated efficacy of CTLA-4Ig and B-cell depletion (rituximab) as treatment modalities, and additional B-cell–targeted therapies are under investigation. Blockade of RANK and RANKL has been shown to prevent bone loss in inflammatory arthritis in rodents but has not yet been used in rheumatoid arthritis.

Mouse Models of RA

Although multiple strains of mice display the spontaneous production of anti-DNA antibodies and a lupuslike disease, there are fewer spontaneous rodent models of RA (206). The MRL/lpr mouse strain, which spontaneously develops lupus, also develops an inflammatory arthritis with pannus formation and synovial proliferation. This strain may develop serologic features of RA, with both IgM and IgG RF and antibody to citrullinated peptides; it also displays an increase in a galactosyl IgG that appears to be independent of the development of arthritis (184). This coexistence of both diseases in a genetically susceptible host is of interest because lupus patients may also develop an erosive arthritis with the antibody specificities and histologic features that are present in classical RA, and some genes predisposing to RA also predispose to lupus.

More recently, inbred recombinant strains derived from C57Bl/6 and DBA/2 mice have been demonstrated to develop a rheumatoidlike arthritis. The genetic basis for this susceptibility is currently under investigation. Interestingly, female mice are predominantly affected, consistent with the 2:1 female:male incidence observed in the human disease.

In addition, genetically manipulated mice develop a rheumatoidlike disease. Mice deficient in the inhibitory receptor for IL-1, IL1Ra, will spontaneously develop inflammatory arthritis, demonstrating the critical role of IL-1 in disease pathogenesis and providing a rational for the therapeutic targeting of IL-1. As is the case in essentially all autoimmune diseases, this genetic manipulation leads to disease only in certain strains.

Similarly, mice that overexpress TNFα will develop an inflammatory arthritis with bone erosions, reinforcing the importance of TNFα in joint destruction in RA. Mice that are deficient in Zap 70 also spontaneously develop an inflammatory arthritis. The pathogenesis in this model appears to reflect a failure in thymic tolerance mechanisms

and the maturation to immunocompetence of autoreactive T cells (207).

Susceptible strains of both rat and mouse will develop an inflammatory arthritis after systemic administration of pristane or incomplete Freund adjuvant (206). This observation raises the possibility that activation of the innate immune system can lead to a non–antigen-specific inflammation localized to joints, and suggests that inhibition of TLR signaling may be of clinical benefit. In fact, hydroxychloroquine, which impedes signaling by intracellular TLRs, is an effective treatment modality. Furthermore, speculation continues regarding a relationship between RA and microbial exposure. An inciting role for microbial exposure in RA is exemplified by the streptococcal cell-wall model of disease. The bacterial peptidoglycan activates the innate immune system, triggering an inflammatory cascade that subsequently requires T-cell activation for transformation from a self-limited arthritis into a chronic inflammatory disease (208).

Injection of mycobacterium into skin or footpads causes arthritis in rats. The rat model of adjuvant-induced arthritis has been exploited extensively in studies of effector mechanisms in joint destruction, and the model has been critical in suggesting a role for heat-shock proteins (HSP) in RA pathogenesis. T cells reactive with a heat-shock protein, HSP65, can transfer disease to a syngeneic host, and prior immunization with HSP65 will prevent development of arthritis, apparently through the activation of regulatory T cells (209). Despite this, neonatal thymectomy does not offer disease protection, although it abrogates T-cell responses to protein antigens

Certain strains of rat and mouse immunized with type II collagen also develop an inflammatory joint disease (210). This model is dependent on both T- and B-cell activation and has excited significant interest because of the presence of collagen-reactive T and B cells in some patients with RA. In this model, T_H1 cells producing IFNγ are not critical to disease; rather, T_H17 cells are central to joint destruction (211). Moreover, a deficiency of IFNγ leads to enhanced disease in this model, perhaps reflecting the IFNγ-mediated inhibition of T_H17 cells. The role of the DR4 shared epitope has also been addressed in the collagen-induced model of disease. Mice transgenic for either a DR4 or DQ8 susceptibility allele develop accelerated and aggressive disease in response to collagen immunization (212); yet, as discussed previously, the role of collagen as an inciting antigen in human disease remains unproven.

Interestingly, immunization with a joint-specific antigen is not always necessary for the induction of inflammatory arthritis. Mouse strains that develop an inflammatory arthritis after immunization with type II collagen develop a similar histopathology after immunization with ovalbumin or bovine serum albumin. In mice expressing human DR-susceptibility alleles, antibody to the inciting antigen is critical for the development of arthritis.

The role of antibody in disease initiation has been elegantly studied in the KRN model of RA. Mice with a transgene-encoded T-cell receptor specific for glucose 6-phosphate isomerase (GPl) develop a RA-like disease (213). Passive transfer of anti-GPI antibody leads to joint edema and inflammation. The antibody, directed to a ubiquitous antigen, forms immune complexes that lead to mast-cell and neutrophil degranulation, and vascular permeability within the joint. The immune complexes initiate an inflammatory response through activation of the alternate pathway of complement and engagement of activating Fc receptors. It has been speculated that the inflammatory process occurs unabated in the joint because of the absence of inhibitors of the complement cascade on the surface of cartilage. Progression to chronic inflammation requires T-cell activation, but an acute inflammatory response occurs with immune complexes alone. Indeed, it appears that a similar mechanism of acute joint inflammation is responsible for the arthritis that can accompany many infectious processes and serum sickness.

Once an inflammatory reaction is initiated in the joint, there is increased citrullination of proteins locally, providing the host with a novel antigen presented in a proinflammatory milieu and providing a substrate for binding of anti-CCP antibody and the initiation or persistence of an inflammatory response (200). The contribution of T cells to histopathology is, in part, a result of their production of RANKL, which is critical in the conversion of blood-borne monocytes to bone-resorbing osteoclasts. Furthermore, all these models identify a critical role for TNFα in activating the RANK/RANKL pathway (214). These observations suggest that a rheumatoidlike histopathology in the joint may be a common final pathway that can be initiated by both antigen-specific and antigen-nonspecific exposures. These models also suggest an important role for antibody in the inductive phase of joint inflammation, consistent with the known existence of anti-CCP antibodies and RF before disease onset and a requirement for T-cell activation for progression to chronic inflammation. The actual diversity of triggers for RA in the human population is not known. So far, effective immunomodulatory therapies in RA have focused on the innate immune system and effector mechanisms, although the success of both B-cell depletion (anti-CD20) and T-cell blockade (CTLA-4Ig) suggests that blockade of the adaptive immune system will also provide benefit.

REACTIVE ARTHRITIS

The seronegative inflammatory spondyloarthropathies include reactive arthritis, ankylosing spondylitis, psoriatic arthritis, and arthritis associated with inflammatory bowel disease. All of these arthropathies are characterized clinically by spinal and peripheral joint oligoarthritis,

enthesitis (inflammation of the attachment of tendons to bone), and occasional involvement of ocular, mucocutaneous, and cardiac tissues. Reactive arthritis (ReA), also referred to as Reiter syndrome, has been selected for review in this chapter as an inflammatory arthritis with a clear genetic association and known bacterial triggers.

Clinical Manifestations

ReA was originally described as a sterile arthritis and enthesitis initiated by an infection distant from the involved joints. However, subsequent findings of viable persistent organisms and bacterial fragments in synovial tissue many years after the clinical initial infection have made this definition obsolete. The term ReA is currently used for a spectrum of clinical manifestations (arthritis, urethritis, conjunctivitis) following an infectious episode. In developed countries, ReA most frequently follows urogenital infections with *Chlamydia trachomatis;* in underdeveloped countries, ReA follows intestinal infections. *Salmonella (typhimurium* and *enteritidis)*, *Shigella*, *Campylobacter jejuni,* and *Yersinia enterocolitica* are the most common triggers for postdysenteric ReA. All of these pathogenic strains are obligate intracellular organisms, and all contain LPS in their outer membrane. The prevalence of ReA is modulated by frequency of the HLA-B27 haplotype in a given population as well as by bacterial exposure. Overall prevalence is reported as 1/1,000. A distinct male predilection with a male-to-female ratio of 9:1 in ReA following genitourinary infection may be represent an ascertainment bias, as there is no gender difference in prevalence of ReA secondary to enteric infections.

Clinical manifestations usually begin 2 to 4 weeks after the triggering infection. Classic musculoskeletal symptoms are an acute, asymmetric oligoarthritis with a predilection for the sacroiliac joints, knees, ankles, and feet. Joint fluid findings are consistent with an inflammatory process, and bacterial organisms cannot be grown using routine cultures. Constitutional signs and symptoms are not common features of this disease, and extra-articular manifestations are rare. Although most patients with ReA recover completely within 6 to 12 months, some (15%) will have a relapsing, progressive course. The majority of patients who develop a chronic course and have extra-articular manifestations are HLA-B27–positive, highlighting the importance of this genotype for disease severity as well as susceptibility.

Pathogenesis and Genetic Susceptibility

Initial hypotheses regarding pathogenesis focused on the role of HLA-B27 as an antigen-presenting molecule and molecular mimicry between bacterial and self-peptides. The finding of HLA-B27–restricted T-cell responses to bacterial antigens from *Chlamydia* and *Klebsiella* and B27-restricted epitopes derived from human aggrecanase support this theory (215). A recent comparative analysis of T-cell receptor (TCR) CDR3 sequences from synovial fluid CD8[+] T cells found a conserved motif in 12 patients infected with four types of enteric bacteria, suggesting the presence of a ubiquitous immunodominant antigen (216). However, the lack of CD8[+] T-cell involvement in rodent models transgenic for B27 does not support this model.

An alternative theory that has recently been proposed suggests that the unusually slow folding rate of the B27 polypeptide promotes the generation of misfolded molecules that accumulate in the endoplasmic reticulum leading to a proinflammatory "unfolded protein response" (217). Another consequence of the unique structure of B27 may be the formation of surface homodimers leading to increased immunogenicity. A recent study found significantly higher levels of homodimer expression in ReA patients compared to HLA-B27–positive controls and increased expression of homodimers on cells of B27–positive patients following LPS stimulation (218).

It is important to note that HLA-B27 constitutes only part of overall risk for development of ReA. Less than 5% of HLA-B27–positive individuals develop one of the B27-associated diseases. Functional polymorphisms in genes for IL-10 and TNFα have been linked to susceptibility for ReA in some populations, and longitudinal analysis of ReA patients has shown that low secretion of TNFα by circulating T lymphocytes at onset of arthritis is predictive of a chronic course. Furthermore, IL-10 is upregulated in synovial tissue from patients with chronic ReA, whereas levels of TNFα and IFNγ mRNA are decreased (219). Two pilot studies of TNFα inhibition with in ReA failed to show benefit, consistent with these data.

Role of Infection

Intact antigens from *Chlamydia*, *Yersinia*, and *Salmonella* have been demonstrated in synovial tissue and fluid years after initial infection in patients with ReA. Furthermore, detection of bacterial RNA by polymerase chain-reaction assays have established the presence of viable, albeit noncultivable, *Chlamydia* organisms in synovial tissue in several studies (220). These findings, together with T-cell proliferation in response to the infectious agents, suggest that there is impaired ability to eliminate triggering bacteria in patients with ReA. In vitro studies indicate that HLA-B27–expressing monocytes have an impaired ability to control intracellular replication of *Salmonella*. Interestingly, intracellular, viable, nonreplicating *Chlamydia* within monocytes isolated from synovial fluid and tissue of ReA patients show an aberrant phenotype characterized by downregulation of outer membrane protein (omp-1) genes and upregulation of HSP 60 genes, which encode a highly immunogenic protein that may account for the inflammatory response to persistent *Chlamydia* (221).

Mouse Models of Spondylarthritis and ReA

Because of the salience of B27 as a susceptibility factor for spondylarthritis and ReA, rodents transgenic for B27 and human β2 microglobulin have been generated (222). Rats expressing these transgenes develop arthritis, spondylitis, skin lesions, and colitis. Unfortunately, the model has not resolved whether the disease is characterized by an unfolded protein response or by an antigen-specific response. On the one hand, microarray data demonstrate an unfolded protein signature in lesional tissue (223); on the other hand, disease can be transferred by T cells (224). One hypothesis that allows for the coexistence of both pathogenetic mechanisms involves the presentation of enterobacteria-derived peptides by B27 molecules to T cells that cross-react with a peptide from a joint-specific protein. This model is consistent with the attenuated disease that occurs when B27 transgenic animals are bred in germ-free conditions.

VASCULITIS

The primary systemic vasculitides are a heterogenous group of frequently devastating diseases, renowned for their diversity of clinical manifestations that make classification schemes based on clinical and histologic data extremely difficult. Other than the well-known association between some of the medium- to small-vessel vasculitides and antineutrophilic cytoplasmic autoantibodies (ANCA), there are no known specific serologic markers for these diseases. The currently accepted classification scheme is based on vessel size.

Large-vessel Vasculitis

The large-vessel vasculitides include giant-cell arteritis (GCA) (also known as temporal arteritis) and Takayasu Arteritis (TA).

Clinical Manifestations

GCA is a disease of the elderly with few, if any, well-documented cases in individuals under the age of 50 years. The incidence of GCA is reported as 7 to 33/100,000, with highest rates seen in Northern Europe; the disease is rare in black and Hispanic populations. GCA is frequently dominated by constitutional symptoms such as malaise, fever, weight loss, stiffness of the shoulder and pelvic girdle muscles, and depression. Laboratory testing generally reveals a normochromic, normocytic anemia and markedly elevated levels of acute-phase reactants including CRP and IL-6. Localized symptoms suggestive of tissue ischemia include loss of vision, jaw claudication, and temporal artery tenderness.

GCA targets certain vascular beds while sparing others with remarkable regularity. The most likely sites of vascular involvement are the second to fifth branches of the aorta and the thoracic aorta. Diagnosis is made on the basis of a temporal artery biopsy that reveals panarteritis with mononuclear cells arranged in granulomatous infiltrates throughout the vessel wall.

In contrast, TA is a disease of young women, with a female-to-male ratio of 8 to 9:1 and an estimated incidence of 2.6 per million. The disease appears to be more common in Asian women. The vascular lesions in TA target the subclavian and carotid arteries most commonly, although there is some evidence that vascular distribution is modulated by ethnicity (225).

Pathogenesis

GCA and TA may be histologically indistinguishable. Importantly, both diseases involve only large elastic arteries that have well-developed layers, including the intima, internal elastic lamina, tunica media, external elastic lamina, and adventitia. Arterial damage occurs in response to granulomatous inflammation and takes the form of neointimal proliferation and vessel occlusion rather that arterial wall destruction, aneurism formation, and hemorrhage. Mechanistic studies of large-vessel vasculitis have focused on GCA because temporal artery biopsies are easily obtainable.

The role of adaptive immune response in GCA is supported by its association with HLA-DR4 and the presence of CD4$^+$ T cells in the inflammatory infiltrates (226). Clonally expanded, activated CD4$^+$ T cells are centered in the adventitial layer and produce abundant amounts of IFNγ. Removal of T cells from temporal artery biopsies engrafted into SCID mice results in resolution of the vasculitic lesions, and adoptive transfer of tissue-derived T cells accelerates the inflammatory response (227).

The finding of large numbers of activated dendritic cells (DCs) in the media and adventitia in temporal artery biopsies from GCA patients has led to the speculation that these DCs are responsible for T-cell recruitment and initiation of the granulomatous inflammatory response. Phenotypically, these are myeloid dendritic cells; their depletion abrogates arteritis in SCID mice transplanted with GCA arteries (228). Activated macrophages reside mostly in the tunica media of the GCA lesion, where they form granulomatous infiltrates along the media–intima border, releasing matrix metalloproteinases (MMPs) and reactive oxygen intermediates that promote tissue destruction and disruption of the elastic lamina.

Medium- and Small-sized-vessel Vasculitis

Unlike the chronic granulomatous infiltrates seen in large-vessel vasculitis, the small- and medium-sized-vessel vasculitides are characterized by a necrotizing infiltrate

in the vessel wall. In contrast to the model proposed for the large-vessel vasculitides, in which the immunologic injury is thought to occur in the adventitia, the inflammatory process is initiated on the luminal side of the vessel. This chapter will focus on ANCA-associated vasculitis.

ANCA-Associated Vasculitis

Three forms of ANCA-associated vasculitis have been identified: Wegeners granulomatosis (WG), Churg-Strauss syndrome (CSS), and microscopic polyangiitis (MPA). These are rare entities; a population-based study in England reported incidences of 8.5, 3.6, and 2.4 per million for WG, MPA, and CSS, respectively (229). Disease onset typically occurs in the fifth decade and there is a slight gender difference, with a male-to-female ratio of 2:1. Clinical features overlap substantially. Classically, WG patients demonstrate involvement of the upper airway and ears, lungs, and kidneys. MPA classically presents as a pulmonary-renal syndrome with pulmonary capillaritis and glomerulonephritis. Of the three, CSS is perhaps the easiest to distinguish because of the characteristic eosinophilia and obligatory history of allergic rhinitis and progressive asthma. Coronary arteritis and myocarditis secondary to eosinophilic infiltrates are a leading cause of morbidity and mortality in CSS, but are rarely seen in WG or MPA.

Role of ANCA in Disease Pathogenesis

The major antigenic specificities for ANCA are proteinase 3 (PR3), also known as cANCA because of the diffuse cytoplasmic staining pattern on immunofluorescence studies, and myeloperoxidase (MPO), also known as pANCA because of its perinuclear immunofluorescence pattern (230). PR3 is a serine proteinase located in azurophilic granules of neutrophils and lysosomes of monocytes, but also found on the surface of resting neutrophils. The amount of surface PR3 appears to be genetically determined, and increased expression is associated with an increased risk of disease. MPO localizes to the same intracellular compartments as PR3 but does not appear to be displayed on the surface of resting neutrophils (231). Generally, anti-PR3 antibodies associate with WG, and anti-MPO antibodies associate with MPA and CSS.

Currently, clinical, in vitro, in vivo, and animal model data support, but do not prove, a pathogenic role for ANCA (230). Multiple studies demonstrate that both PR3 and MPO ANCA are capable of activating neutrophils primed with TNFα, GM-CSF, or microbial products in vitro to degranulate, release IL-1β, IL-8, and reactive-oxygen free radicals. ANCA IgG has also been shown to stabilize adhesion of neutrophils to cultured endothelial cells, by inducing a conformational change in β2 integrins on the neutrophil surface.

Passive transfer of anti-MPO IgG derived from MPO knockout mice immunized with mouse MPO to both immune-competent and Rag2$^{-/-}$ mice results in glomerulonephritis and small-vessel vasculitis that is histologically similar to human ANCA-mediated disease, indicating that antigen-specific T cells are not required to induce the acute injury (232). However, neutrophil depletion in recipient mice completely abrogated the induction of vasculitis and glomerulonephritis (233). Although these data support a pathogenic, contributory role for ANCA, there is still no explanation for the development of ANCA. In addition, the clinical utility of ANCA titers in predicting disease flares is limited.

Treatment

Corticosteroids and cytotoxic agents constitute the current treatment strategies for the systemic vasculitides. Antibiotic therapy helps maintain remission in WG, probably through anti-inflammatory rather than microbial effects. TNF blockade has failed to show benefit in WG and in fact resulted in an increased risk of solid-tumor development (234).

SCLERODERMA

Scleroderma (systemic sclerosis; SSc) is an autoimmune disease characterized by microvascular injury, autoantibody production, and excessive collagen deposition leading to progressive cutaneous and visceral fibrosis.

Clinical Manifestations

Reports on the incidence and prevalence of SSc vary widely and appear to be heavily influenced by ethnicity and geography. The highest overall prevalence rates of 276 cases per million adults are reported in the United States, with African-Americans affected more commonly and more severely than Caucasians. An apparent increase in prevalence since 1950 may reflect a true increase, ascertainment differences, or improved survival and earlier diagnosis. Women are at higher risk of developing disease than men, with reported femal-to-male ratios of 3 to 8:1. The mean age at diagnosis tends to be in the fourth to fifth decade for Caucasian women and in the third or fourth decade for African-American women.

The two major disease subsets, diffuse cutaneous SSc (dcSSc) and limited cutaneous SSc (lcSSC), are distinguished by the extent of skin involvement. dcSSc is defined by the presence of skin thickening proximal to the elbows and knees and/or involving the torso, whereas lc SSc is characterized by skin thickening distal to the elbows and knees. Facial involvement does not distinguish between the two major disease subtypes. Defining and assigning

▌**TABLE 41.5 Scleroderma-Specific Autoantibodies**

Disease Subset	Autoantibody	HLA Association	Frequency (%)
dcSSc	Antitopoisomerase 1 (Scl-70)	DRB1*1101, *1104 DPB1*1301	10–20
	Anti-RNA-polymerase I, III		20
dcSSc and lcSSc	Anti-U-3 RNP (antifibrillarin)		5–20
	Anti-PM/Scl		3
lcSSc	Anticentromere	DRB1*01, *04 DQB1*05	20–30
	Anti-Th/To	DRB1*11	2–5
	Anti-U-1 RNP		

dcSSc, diffuse cutaneous scleroderma; lcSSc, limited cutaneous scleroderma.

individual patients to disease subsets is clinically extremely useful; dcSSC is more aggressive and is commonly associated with internal-organ involvement, whereas limited disease is more indolent but more often associated with pulmonary hypertension.

Pathogenesis and Genetic Susceptibility

Strong evidence for a genetic basis for susceptibility comes from the increased familial clustering of disease. As seen in SLE, while several studies have yielded only a very modest disease association with HLA haplotypes, the associations are much more pronounced and significant between HLA subsets and autoantibodies (Table 41.5) (235). Similarly, although the concordance for the clinical phenotype between monozygotic and dizygotic twins is the same (approximately 5%), the concordance rate for antinuclear antibodies is much higher in monozygotic (95%) compared to dizygotic twins (60%) (236). It is generally felt that SSc is triggered by an environmental insult to the susceptible host, and many infectious and chemical agents have been implicated in disease development. Geographic clusters of SSc provide strong evidence for environmental triggers (237).

Autoantibodies and Immune Dysregulation

ANA are found in more than 95% of SSc patients, and a number of scleroderma-specific autoantibodies that associate strongly with disease subsets have been identified (238). Although these autoantibodies are highly specific for SSc, biopsies of involved tissue are remarkable for the paucity of antibody or immune-complex deposition, and there is currently little data to support a causal role of these autoantibodies in disease pathogenesis.

The activated CD4+ T cells in SSc skin are skewed toward a Th2 phenotype with increased production of profibrotic cytokines, IL-4, -5, -6, -8, -10, and -13 (239). Although the cutaneous CD4+ T-cell infiltrate has been shown to be

oligoclonal, suggestive of an antigen-driven response, no inciting antigen has been elucidated.

Collagen Synthesis

SSc fibroblasts explanted from involved tissue demonstrate unique abilities to continue producing extracellular matrix components after serial passages in vitro. TGFβ, one of the most potent inducers of collagen and proteoglycan production, appears to be essential to the sclerosing process in SSc for the following reasons: (a) SSc fibroblasts have an increased expression of TGFβ receptors and therefore may be more sensitive to stimulatory effects of TGFβ; (b) there are increased plasma levels of TGFβ; and (c) TGFβ is present in early skin lesions, before collagen deposition (240,241).

Recent evidence suggests an antibody-mediated mechanism for fibroblast proliferation and collagen gene expression. Serum from SSc patients contains antibodies directed against the platelet-derived growth receptor (PDGFR) (242). Ligation of PDGFRs trigger an intracellular signaling pathway that leads to increased collagen gene expression. These studies are the first to directly imply a causal role of autoantibodies in tissue fibrosis in SSc.

New Therapeutic Approaches

The treatment of scleroderma remains difficult, and there are few effective options for the skin disease or the inflammatory lung disease. A recent blinded study of cyclophosphamide for the treatment of alveolitis yielded marginal results, consistent with previous data suggesting that anti-inflammatory and immunosuppressive agents are of limited use in SSc, perhaps reflecting the fibrotic rather than inflammatory pathology. Disappointingly, a recent Phase II clinical trial of an anti-TGFβ reagent in early scleroderma showed no efficacy and more adverse events in the treatment group (243), indicating that TGFβ blockade alone is

insufficient to halt the fibrotic process. Recently, imatinib mesylate, an inhibitor of PDGF, has been shown to reverse pulmonary hypertension in animal models (244), and a few case reports have suggested efficacy in humans.

Mouse Models of Scleroderma

There are several interesting rodent models of scleroderma, all of which suggest the centrality of TGFβ in this disease. The tight skin mouse (tsk) displays intradermal collagen deposition, autoimmunity, and vascular abnormalities. The genetic defect is a duplication of the fibrillin gene (245). Homozygosity of this duplication is an embryonic lethal mutation. Although the tsk mouse makes several of the autoantibodies that are present in patients with scleroderma, these antibodies are not crucial to disease pathogenesis. B cells, however, are critical, as CD19-deficient tsk mice display a marked attenuation of collagen deposition (246). Further genetic analyses of this strain have shown that tsk mice deficient in one or both copies of the IL-4 gene also have a markedly reduced disease phenotype, reflecting the impact of IL-4 on TGFβ transcription (247).

The bleomycin-induced model of scleroderma displays primarily an interstitial lung disease when bleomycin is administered by an intratracheal route and dermal fibrosis when bleomycin is administered subcutaneously. The disease phenotype is exaggerated in TNF-receptor–deficient mice, presumably because a TNFα-mediated pathway is responsible for collagen degradation and restoration of more normal extracellular matrix composition following the initial inflammatory response (248,249).

The skin changes of scleroderma are similar to those seen in graft-versus-host disease; not surprisingly, therefore, transfer of spleen cells to irradiated or RAG-deficient hosts has also been exploited as a model of scleroderma. The transfer of B10D2 splenocytes to RAG-deficient mice results not only in dermal and visceral fibrosis but also in the production of antibodies to Scl-70 (250).

MYOSITIS

Inflammatory myositis is a rare condition that may occur alone or in association with other autoimmune diseases such as SLE or scleroderma. Although the major clinical feature of both inflammatory myopathies, dermatomyositis (DM) and polymyositis (PM), is symmetric proximal muscle weakness, the two diseases are quite different in terms of their epidemiology, associated clinical manifestations, pathologic findings, and suspected immunopathogenesis. Both are considered autoimmune diseases on the basis of autoantibody associations, the presence of T-cell infiltrates in affected tissue, and response to immunosuppressive medications.

Clinical Manifestations

Both PM and DM are characterized by the insidious onset of symmetric proximal muscle weakness involving the neck extensor muscles, shoulder girdle, and hip girdle, with sparing of the facial and extraocular muscles. DM has additional dermatologic findings and is often associated with malignancy (251). An accurate assessment of disease prevalence is very difficult becaue of discrepancies in classification criteria; however, estimates of incidence range from 0.5 to 8.4 cases per million. DM has a bimodal age distribution, with peak incidences in the teenage years and between the fifth and sixth decades, whereas PM is extremely unusual in children and even in adults is the less common of the two. The female-to-male ratio is approximately 3:1. There is evidence that ethnicity plays a role in disease susceptibility; African-Americans are three to four times more likely to develop disease than Caucasians (252).

Biopsy is the gold standard for diagnosis of myositis (253). Histologic findings in DM characteristically include an inflammatory infiltrate invading the perivascular space and the interfascicular septae. The intramuscular vessels reveal endothelial hyperplasia with fibrin thrombi, and complement membrane attack complex (C5b-9) deposition in vessel walls. A similar type of perivascular infiltrate with CD4[+] cells is seen on skin biopsy in DM.

The findings in PM are strikingly different, with infiltrating CD8[+] T cells in an endomysial pattern. Together with activated macrophages, they flank healthy-appearing muscle fibers expressing class I MHC antigens. When class 1 antigens are seen in DM biopsies, they are expressed by damaged muscle fibers only. The diagnosis of PM relies on the finding of MHC-I/CD8[+] complexes in healthy muscle fibers.

Pathogenesis

Current understanding of the immunopathogenesis of the inflammatory myopathies proposes quite distinct entities; DM is traditionally regarded as a humorally mediated microangiopathy, whereas PM is felt to be an HLA-restricted, T-cell–mediated myotoxic immune response (251). Despite these differences, some inflammatory responses are common to both disease subsets.

The increased expression of CXCR3 and its IFNγ-inducible ligand CXCL10 in infiltrating inflammatory cells in both PM and DM, together with increased expression of MCP-1, suggests a Th1 skewing of the immune response in these diseases (254). These data are further substantiated by increased serum levels of IL-18 that parallel equally elevated levels of IFNγ in both PM and DM (255). The recent finding of large numbers of perivascular and perimysial plasmacytoid dendritic cells associated with upregulation of IFNα-inducible genes strongly suggests a role for the

innate immune system in pathogenesis of DM (256). In contrast, myeloid dendritic cells are present in PM lesions. The presence of dendritic cells in PM muscle suggests that phaocytosis and antigen presentation followed by T-cell recruitment are occurring at the involved sites or in local lymph nodes.

CD8$^+$ T cells obtained from PM biopsies are cytotoxic to autologous myotubes in vitro. Several studies have demonstrated clonally expanded circulating and invasive CD8$^+$ T cells. These data suggest an antigen-driven response; however, the nature of the antigenic target on myocytes remains unknown.

A role for MHC class I in muscle fiber damage unrelated to antigen presentation and lymphocyte response is suggested by the observations that class I expression precedes the inflammatory infiltrate in PM and persists in the absence of infiltrating cells. Similarly, class I transgenic mice develop weakness before an inflammatory infiltrate appears, and gene transfer of class I plasmids in vitro and in vivo diminishes muscle regeneration and differentiation (257). Inappropriate overexpression of class I may lead to a stress response in the endoplasmic reticulum, as has been proposed for B27-related disease. The inciting triggers for upregulation of class I, however, remain speculative and include viral infections, trauma, or denervation and hypoxia.

Autoantibodies

Autoantibodies are found in 50% of patients with inflammatory myositis; some are specific for inflammatory myositis (MSAs) and some are associated with other connective tissue diseases as well (MAAs) (Table 41.6). The antigenic targets of most MSAs are cytoplasmic proteins or ribonucleoprotein complexes involved in protein synthesis and translocation. Of the six reported antibodies to aminoacyl-transfer RNA synthetases (anti-tRNA synthetases), the most common is the anti-Jo-1 antibody to histidyl-tRNA synthetase. Apoptotic muscle cells release the NH$_2$-terminal fragment of Jo-1 that acts as a chemoattractant for activated lymphocytes to the damaged tissue. Other MSAs are directed against nuclear helicase (anti–Mi-2) and signal-recognition particle (anti-SRP) (258).

Seasonal patterns of disease onset—increased incidence of Jo-1–associated disease in the spring and increased incidence of SRP-associated disease in the winter and spring months—suggest an infectious trigger for myositis, but none has been successfully identified (251).

It has recently been reported that regenerating myositis muscle provides a rich source of autoantigen (Mi-2, Jo-1, U-1 RNP, and DNA PKS). These data implicate regenerating muscle cells as a source of ongoing antigen drive, accounting for the observed self-sustaining nature of the disease (91). This paradigm does not address the nature of the initial inciting event leading to immune activation in myositis, but it is theorized that muscle damage leading to regeneration may initiate disease in a predisposed patient.

Treatment

The treatment of inflammatory muscle disease is generally confined to the use of corticosteroids or immunosuppressive agents. Dermatomyositis associated with malignancy is most responsive to reduction in tumor mass. As therapies become more focused, it is likely that each disease will respond to different agents, as polymyositis is characterized by the activation of cytotoxic CD8$^+$ cells and dermatomyositis by antibody production and activation of CD4$^+$ cells.

▌ **TABLE 41.6 Autoantibodies in Inflammatory Myositis**

Autoantibody	Antigenic Target	Frequency
Myositis-specific antibodies		
Anti-tRNA-synthetases	Aminoacyl-tRNA-synthetase	
Anti-Jo-1	Histidyl-tRNA-sythetase	20% PM/DM
Anti-PL-7	Threonyl-tRNA-synthetase	<5% PM/DM
Anti-PL-12	Alanyl-tRNA-synthetase	<5% PM/DM
Anti-EJ	Glycyl-tRNA-synthetase	<5% PM/DM
Anti-OJ	Isoleucyl-tRNA-synthetase	<5% PM/DM
Anti-KS	Asparaginyl-tRNA-synthetase	<5% PM/DM
Anti-SRP (signal-recognition particle)	325-kDa ribonucleoprotein translocation regulation factor	<5% PM
Anti-Mi-2	Nuclear helicase	5–10% DM
Myositis-associated antibodies		
Anti-PM-ScL	Nucleolar exosome	5–25% DM/SSc
Anti-Ro, La		3–27%
Anti-U1 snRNP	Ribonuclearprotein	5–60%

Mouse Models of Myositis

Models of myositis support the hypothesis that muscle damage followed by muscle regeneration may trigger inflammation and autoreactivity. Synaptotagmin VII is a lysosomal protein involved in lysosomal exocytosis, a process that contributes to the repair of wounds in the plasma membrane. Mice deficient in this protein develop inflammation in muscle, muscle weakness, and antinuclear antibodies, suggesting that the failure to repair damaged cells can potentially trigger an autoimmune attack on muscle (259). Similarly, ectopic expression of MHC class I molecules in skeletal muscle leads to autoantibody production and muscle inflammation. Once enhanced class I expression is present on muscle, an inflammatory response develops that may reflect the antigen-presenting capacity of myocytes but more likely represents a misfolded protein response (260).

The peptide-binding motif of H-2 K^d is similar to that of HLA A2402, an MHC allele associated with polymyositis. Because polymyositis is characterized by an infiltration of $CD8^+$ cells, peptides associating with $H-2K^d$ and A2404 were sought. Pyruvate kinase M1/M2 is abundantly expressed in skeletal muscle and contains a peptide that can be anchored in the H-2 K^d abd A2404 peptide-binding grooves. Administration of dendritic cells pulsed with this peptide to BALB/c ($H-2^d$) mice leads to muscle inflammation with infiltration of predominantly $CD8^+$ T cells (261).

CONCLUSION

The systemic autoimmune diseases have in common the targeting of the musculoskeletal system, although other organ systems can also be affected. A major shared feature is the presence of ANA. Reactivity to nuclear antigens may be more than a fortuitous communality and may signal a shared abnormality in B-cell development and tolerance. Alternatively, nuclear antigens may contribute little to either the elicitation or the pathogenicity of ANA; as new cross-reactivities continue to be identified, they may provide greater insight into pathogenic processes.

SLE and RA clearly share some susceptibility genes with each other and with organ-specific autoimmune diseases; however, there is as yet no evidence for a shared genetic predisposition between these diseases and vasculitides, scleroderma, or inflammatory myopathies. Indeed, pathogenetic mechanisms appear to differ among these diseases, with different effector T-cell subsets.

Nonpathogenic autoreactivity, in particular the presence of the autoantibodies of systemic autoimmune diseases, is far more widespread than pathogenic autoreactivity. Major, and poorly understood, checkpoints exist between normal serology and ANA and then between enhanced autoreactivity and tissue damage. Finally, in persistent disease, an additional progression from cellular infiltration and inflammation to fibrosis occurs; the molecular switch for this change in tissue response is not well characterized. Nevertheless, this complicates the treatment of these diseases, as stage of disease may be a determinant in response to therapy.

The major advances in our understanding of these diseases in the past decade have been a function of the improved methodologies for the study of human cells and tissue. Although animal models continue to be critical to our understanding, it is now possible and necessary to test the validity of animal models against the human disease and to choose those models most similar to patient subsets for the design of therapeutic interventions.

Organ-Specific Autoimmunity

Matthias G. von Herrath and Dirk Homann

Misdirection and improper control of immune responses can lead to organ-specific destruction, which is classified as autoimmunity, if cells reactive to self-antigens can be identified. Although a certain genetic predisposition is associated with most organ-specific autoimmune disorders, other contributing etiologic factors remain to be identified. It is not clear whether some of the diseases that selectively affect one or few organs are due to a yet-unidentified viral infection and autoimmune responses arise secondary to such a primary attack. Once a destructive process has taken root, the outcome depends on a multitude of internal and external factors and can be influenced therapeutically. For example, alteration of the systemic or local, organ-specific cytokine milieu has proven to be of benefit. In addition to the immunopathology and etiology, novel treatments that are based on redirecting the immune system into a state of benign autoreactivity are discussed in this chapter.

GENERAL CONCEPTS IN ORGAN-SPECIFIC AUTOIMMUNITY

Immunity and Autoimmunity

Autoimmunity is the "Other" (1) of immunity, and in true dialectical fashion, immunity's inception as a scientific discipline encapsulated the conceptual problem that was to shape the immunologic debates in the first 15 and last 50 years of the 20th century. As much as the prefix *auto* assigns a specific place apart from immunity proper, the idea of immunity is not conceivable (for better or worse), without the notion of the self (2). Immunity's distinct association with the individual self stretches from its etymologic roots in the Roman legal concept of an *individual's* exemption from duty, service, or tax to its official induction into the canon of medical terminology [defined as "*idio*syncratic condition" in the 1878 edition of Littré's *Dictionnaire de Médecine* (3)] and beyond. However, with the dawn of the 20th century, in the wake of the seminal discoveries of immune protection by active immunization with attenuated pathogens (4) or passive transfer of convalescent serum (5) and the seemingly unstoppable success of the "New Immunology," the notion of the immunologic self underwent a dramatic reconfiguration. The price for immunity, it appeared, was autoimmunity, a concept so problematic that its existence had to be relegated to the realm of the almost unspeakable (that is, the Greco-Latin neologism of a "horror autotoxicus") (6). Paradoxically, the very time that saw the concept of "horror autotoxicus" acquire a quasi-dogmatic status as the "law of immunity research" (7) was also the time that A. Silverstein termed the "classical period" of autoimmunity research (8). Although declared anathema, autoimmune phenomena were reported in a quick succession of widely publicized observations. In 1902, Portier and Richet

reported the phenomenon of anaphylaxis (as opposed to *pro*phylaxis) (9); Maurice Arthus characterized the local inflammatory response that was to bear his name in 1903 (10); Donath and Landsteiner described the first human autoimmune disease (paroxysmal cold hemoglobinuria) in 1904 (11); and the term allergy ("altered reactivity") was coined by von Pirquet and Schick in their analysis of serum sickness in 1905 (12). The idea that tissue destruction may lead to expanded immunopathology (nowadays referred to as determinant spreading) was proposed by Weil and Braun in 1909: In the course of an infectious disease, "tissue alterations lead to the generation of complement-binding factors that, . . . based on their affinity to bodily cells, themselves attack and damage the cells of the organism" (13). Even the concepts of organ specificity (14), immunoprivilege, and the breakdown of regulatory mechanisms as a cause for autoimmunity (7) were developed in the early days of autoimmunity research.

This period of extraordinary productivity was followed by an almost 40-year hiatus (the "dark ages of autoimmunity research") (8). The reasons for a generalized disinterest in autoimmune phenomena are manifold and included political reconfigurations after World War I, the death of both Ehrlich (1915) and Metchnikoff (1916), a misconception of "horror autotoxicus" as the immune system's *inability* to generate responses against self, and a paradigm shift in the field of immunology in favor of immunochemical approaches (8). The renaissance of autoimmunity research had to await observations about immunologic tolerance of mice congenitally infected with lymphocytic choriomeningitis virus (LCMV) (15), description of tolerance in chimeric cattle twins (16), and Peter Medawar's work on skin transplant rejection (17–20), as well as the integration of these findings into a conceptual framework of self and non-self as determinants for immunologic reactivity (21). Burnet subsequently developed and extended these ideas into the "clonal selection theory of antibody formation" (22) thereby establishing the conceptual centrality of self, non-self, and immunologic tolerance. Although the dogmatic reading of "horror autotoxicus" was still prevalent [Ernest Witebsky delayed his publication about thyroid antibodies (23) for several years, assuming an experimental error (8)], Ehrlich's original conception as "regulatory contrivances" that prevent autoimmunity was now validated within the context of the clonal selection theory.

Again, however, the usefulness of self and non-self as distinguishing parameters was challenged at the very time they began their rise to prominence. Ludwik Fleck, in his *Genesis and Development of a Scientific Fact*, questioned the capacity of an immune system that only interacts with structures that are strictly non-self: "it is very doubtful whether an invasion in the old sense is possible, involving as it does an inference by completely foreign organisms in natural conditions. A completely foreign organism could find no receptors capable of reaction and thus could not generate a biological process" (24). This view was echoed and elaborated on in the work of Jerne (25) and Coutinho (26), and even the possibility of a beneficial role for autoimmune processes was postulated by concepts such as "physiologic autoimmunity" (27), "positive autoimmunity" (28), and "protective autoimmunity" (29). The importance of autoreactivity as an integral aspect of immunity is furthermore demonstrated by the processes of "positive selection," T cell development in the thymus, and the T cell–mediated destruction of transformed or infected tissues, which are based on the recognition of foreign (e.g., viral peptides, or even self, as in the case of some tumor-derived antigens) in the context of "self" (major histocompatibility complexes). In fact, events associated with danger or the preservation of tissue integrity rather than the discrimination between self/non-self have been postulated as a primary driving force that engages the immune system (30,31). More recently, the notion that immune reactivity is generated by the introduction of strong antigenic discontinuities ("criterion of continuity") has been proposed and may offer an elegant solution to some of the conceptual problems outlined earlier (32,33). Still, the idea of recognition (2,34,35) remains a central element common to all of these models because the immune system's principal task is cast as a differentiation between organismal states (self vs. non-self, safety vs. danger, integrity vs. damage, continuity vs. discontinuity, etc.). Such operational distinctions are indeed powerful tools for conceptualizing the functions of the immune system—with impressive success, as well as some obvious shortcomings. Yet they may also insinuate a proximity of logical and functional categories that can culminate in the postulate of a principal objective, a veritable *raison d'être* for the immune system. However, rather than rejecting the need for a comprehensive conceptual framework in favor of pure experimental work (36), we endorse continuing efforts to develop a theoretical basis for the phenomenon of "auto/immunity" and favor an evolutionary perspective that conceives of the immune system, devoid of a particular purpose (37), as "the cause of its own necessity" (38).

The notion of autoimmunity as an aberrant phenomenon has informed much of our current understanding about the immune system and its functions, and there appears to be a growing awareness that immunity and autoimmunity are both historically and conceptually intertwined. An emerging consensus indicates that the anthropomorphisms of self and non-self should be overcome [e.g., as suggested in the respective forewords to two major autoimmunity textbooks (39,40)] and that autoimmunity is likely a universal phenomenon in the evolution of the vertebrate immune system. As part of the evolving organism, the immune system processes antigen stimuli in a deterministic fashion restricted by genetics, previous antigenic experience of the host, nature of the antigen, and

the conditions of its presentation (39). However, any effort to imbue the immune system's function with an overriding purpose, no matter how important for our conceptualization and experimentation, has to recognize that evolution is ignorant of teleology. In this respect, the remark by the Darwinist Paul Ehrlich that production of autoantibodies is "dysteleological in the extreme" (6) may be extended to the functionality of the immune system as a whole; there is no teleology in autoimmunity or immunity, just the workings of a complex system under evolutionary constraints. The rules that inform immunity are the same ones that govern autoimmunity.

The Burden of Autoimmune Diseases

The existence of autoimmune diseases in humans has been known for 100 years. By now, autoimmune pathogenesis has been attributed to more than 40 human diseases (41), yet it is still far from clear which features can conclusively be proven to have an underlying autoimmune pathogenesis. It has been suggested, somewhat provocatively, that with knowledge about an infectious origin, diseases are called immunopathologically mediated, whereas lack of such knowledge results in reference to such diseases as autoimmune (42). Although this argument is akin to the medical taxonomy in which diseases of unknown origin are assigned to the domain of the "endogenous," "idiotypic," "essential," or "primary," a "positive" definition for autoimmune disease is very much needed to provide a specific diagnostic framework that allows for unequivocal identification of distinct autoimmune disorders yet remains flexible enough to accommodate new insights in etiologic and symptomatologic processes. A first attempt to provide such a basis for the establishment of the autoimmune origin of human diseases was formulated by Witebsky et al., who modeled their postulates on those of Koch: "recognition of an autoimmune response; autoantibody or cell-mediated, identification of a corresponding autoantigen, as well as induction of an analogous autoimmune response and disease in experimental animals" (43). A timely update for these criteria was proposed by Rose and Bona, who suggested a combination of direct evidence (transfer of pathogenic antibodies or T cells), indirect evidence (reproduction of disease in experimental animals), and circumstantial evidence (clinical clues) to determine an underlying autoimmune etiology for human diseases (41). However, it is important to note that any specific guidelines have to be tailored to individual autoimmune disorders. For instance, an exemplary catalogue of diagnostic criteria has been developed by the International Autoimmune Hepatitis Group to facilitate and improve the diagnosis of autoimmune hepatitis (44). This report also illustrates the importance of distinguishing between an autoimmune and infectious origin for hepatitis (44): Immunosuppressive therapy has a beneficial effect on the course of autoimmune hepatitis

(AIH), and although responsiveness to such therapy is one of the diagnostic criteria for AIH, this therapy may be detrimental when used for treatment of virus-induced hepatitis.

As a first of its kind, a metastudy published in 1997 provided a comprehensive evaluation of prevalence and incidence studies conducted for 24 autoimmune diseases since 1965 (45). Overall, 1 in 31 Americans, or approximately 8.5 million people, were estimated to be afflicted by an autoimmune disease. The most prevalent disorders, divided into organ-specific and systemic conditions (and ranked in order of prevalence), are listed in Table 42.1. The study by Jacobson and colleagues also documents some striking, if not entirely unexpected, findings. Many autoimmune conditions are clearly understudied, and some of the most frequently studied diseases exhibit comparatively low prevalence rates. The cause for this imbalance between the public health burden posed by some autoimmune disorders and their attraction as objects for scientific study remains to be elucidated but will likely include the presence or absence of effective therapy. Pernicious anemia, the sixth-most-common autoimmune disease in the United States, can be effectively managed and therefore elicits only limited epidemiologic interest. In contrast, some rare conditions may pose a pronounced burden to afflicted individuals and thus warrant continued efforts to develop more effective prophylactic and therapeutic interventions. Furthermore, the availability of certain models for autoimmune diseases (again not necessarily a reflection of the epidemiologic importance of the corresponding human autoimmune disease) has an impact on choices made by researchers charting their field of study. Finally, as in other areas of research or clinical medicine, the funds and resources available are the result of multiple factors that may or may not include the public health burden exerted by a particular autoimmune disease. Balancing these aspects appropriately to appreciate and address the burden of autoimmune diseases based on both the afflicted individual and society at large is a challenge that will require continued efforts to identify, investigate, inform, and, it is hoped, improve the therapies for many autoimmune diseases.

Differentiating Organ-specific and Systemic Autoimmune Diseases

A perennial approach in the quest to make sense of complex phenomena is the establishment of dichotomies, however fraught with shortcomings, inconsistencies, and exceptions to the rule. Steeped in clinical traditions and immediately intelligible, the distinction between systemic and organ-specific autoimmune diseases is as useful as it is inadequate. Given that the evolving understanding of autoimmune diseases requires a constant reevaluation of concepts pertaining to etiopathogenesis and effective

▎ **TABLE 42.1 Prevalence of Autoimmune Diseases**

Autoimmune Disease	Organ	Weighted Mean Prevalence Rate/100,000	Weighted Mean Incidence Rate/100,000
Thyroiditis/hypothyroidism	**Thyroid**	**1,323.8**	**21.8**
Grave's disease/hyperthyroidism	**Thyroid**	**1,151.5**	**13.9**
Rheumatoid arthritis	Joints, lung, heart, other	860.0	23.7
Vitiligo	**Skin**	**400.2**	
Type 1 diabetes	**Pancreatic β cells**	**192.0**	**12.2**
Pernicious anemia	**Stomach**	**150.9**	[a]
Multiple sclerosis	**Brain/spinal cord**	**58.3**	**3.2**
Glomerulonephritis (primary)	**Kidney**	**40.0**	**3.6**
Systemic lupus erythematosus	Skin, joints, kidney, brain, lung, heart, other	23.8	7.3
Glomerulonephritis (IgA)	**Kidney**	**23.2**	**2.4**
Sjögren's syndrome	—	14.4	[a]
Addison's disease	**Adrenal**	**5.0**	[a]
Myasthenia gravis	**Muscle**	**5.1**	**0.4**
Polymyositis/dermatomyositis	Muscle, lung, heart, joints, other	5.1	1.8
Scleroderma	Skin	4.4	0.8
Primary billiary cirrhosis	**Liver bile ducts**	**3.5**	**0.9**
Uveitis	**Eye**	**1.7**	**18.9**
Chronic active hepatitis	**Liver**	**0.4**	**0.7**

Data taken from Jacobson et al. (45), which should be consulted for details.
Organ-specific autoimmune diseases in bold, systemic autoimmune diseases in regular type face.
The prevalence/incidence rate from each study within a disease category contributed proportionately based on the
   population size of that study. The proportion or weight was calculated by dividing the study population denominator by
   the total of all the study population denominators for each disease.
[a] No studies on disease incidence are available.

treatment modalities, it would be premature to abandon such a simple and still useful classification. Instead, that porous juncture between systemic and organ-specific disorders may reveal hitherto unappreciated aspects of pathogenesis. On the surface, the patterns of pathology result from the distribution of anatomic niches that provide a suitable environment to interface antigens and immune effectors. Leaving aside the difficulties pertaining to the identification of initiating autoantigens in many human autoimmune diseases (and the challenging task of correlating markers of immunologic activity, such as autoantibodies, with cause or consequence of tissue destruction), a particularly puzzling phenomenon is the apparent organ specificity of some disorders in the face of autoimmune responses that target ubiquitous antigens. For instance, the ribonucleoprotein antigens implicated in Sjögren's syndrome or the transfer RNA synthetases targeted in polymyositis are widely expressed intracellular antigens, yet the pathology of these diseases is relatively circumscribed. Another intriguing example is the K/BxN arthritis model in which pathogenic antibodies recognize the ubiquitous cytoplasmic enzyme glucose-6-phosphate isomerase (GPI). Here, the preferential involvement of the joints apparently results from unique properties of the regional vasculature that allow for an antibody-mediated increase of vasopermeability and amplification of pathology by extracellular GPI deposition in the articular cavi-

ties (46,47). The observation that autoimmune damage is critically dependent on aspects of the local microanatomy emphasizes the importance of considering autoimmune processes in the larger context of interdependent organ systems.

Finally, an examination of some animal models used for the study of particular organ-specific autoimmune disorders further challenges the simple notion of restricted pathology and may provide clues about etiologic commonalities of ostensibly disparate clinical autoimmune syndromes. The nonobese diabetic (NOD) mouse is the most widely used animal model for the study of type 1 diabetes (T1D), a severe condition caused by autoimmune destruction of the insulin-producing β cells in the pancreas (48,49). However, NOD mice also exhibit aspects of type 2 diabetes (T2D) (50) and are prone to autoimmune sialitis, thyroiditis, peripheral neuropathy, and prostatitis (a lupus erythematosus–like syndrome that develops after exposure to killed mycobacteria), as well as, under certain circumstances, exocrine pancreatitis (49). Similar to the etiology of T1D, specific T cells are involved in the pathogenesis of all of these disorders, although antigenic targets and requirements for costimulatory interactions are distinct. Thus, as in human T1D, the NOD mouse combines a generalized genetic susceptibility to multiorgan autoimmunity that is focused on pancreatic β cells but not limited to endocrine organs.

Central and Peripheral Tolerance: Implementing an Operational Concept

A detailed historical discussion of the concept of tolerance is beyond the scope of this chapter, but some aspects of the use of the term tolerance require clarification at the outset. Tolerance in adaptive immunity, *strictu sensu*, is the absence of specific lymphocyte activity, the consequence of physical deletion or functional silencing of specific T and B cells. Some researchers refer to these tolerance mechanisms as "passive" or "recessive" tolerance to distinguish them explicitly from "active" or "dominant" tolerance. Although the latter constitutes bona fide immune responses (and therefore other researchers do not categorize them as a mode of tolerance), their particular nature results in a phenotype that is comparable to that achieved by means of passive/recessive tolerance. Distinct effector mechanisms (e.g., immunosuppressive cytokines) and possibly dedicated classes of immune cells (e.g., T regulatory cells [Tregs]) ensure that local or systemic autoimmunity is avoided. The concept of T cell suppressors, first proposed in the early 1970s by Gershon (51), has recently been resurrected in the form of professional $CD25^+FoxP3^+CD4^+$ and adaptive Tregs and has attracted considerable attention. However, although there is indeed a population of $CD25^+$ T cells committed to regulatory activity in naive, nonimmunized mice, we underscore that regulatory functions, including those that limit autoimmunity, are a feature of the immune system as a whole and can be exercised by other classes of immune cells as well (e.g., $CD8^+$ T cells, $\gamma\delta$T cell receptor [TcR], T cells, NKT cells). Thus, although $CD25^+CD4^+$ regulatory T cells occupy a distinct and important niche in the complex dynamic network of immune functions, not all Tregs are $CD25^+CD4^+$, nor do all $CD25^+CD4^+$ T cells function as suppressors. Indeed, novel markers might characterize regulatory function better; among these is the expression of the forkhead/winged helix transcription "FoxP3" (52–58) and secretion of cytokines with regulatory function such as interleukin (IL)-10 (59,60) or transforming growth factor-β (TGFβ) (61). The many efforts to understand the nature of $CD25^+CD4^+$ Tregs have been expertly reviewed elsewhere (62,63).

T Cell Tolerance

Autoreactivity, by definition, designates a specific immune response to self-antigens. Antigen-nonspecific responses such as inflammation and innate immune processes should not be considered autoimmune in the strict sense, although they may accompany, enhance, or even trigger adaptive autoimmune responses. Thus, antigen-specific T or B cell immunity would have to underlie a genuine autoimmune disorder. Furthermore, for organ-specific autoimmune diseases, antigen specificity of primary effector lymphocytes must be largely restricted to autoantigens derived from defined organs or tissues. Once initiated, organ-specific responses that precipitate or drive the localized autoimmune reaction may diversify to comprise additional specificities (determinant spreading) and pathogenic mechanisms.

How does the adaptive immune system restrict generation and activation of autoreactive lymphocytes? The central process by which the generation of T cell receptor diversity is limited is called thymic selection. Thymic selection is a developmental process that selects T cells with a biased repertoire for export into the periphery (64–68). T cells that interact at least weakly with self-peptides presented in the context of major histocompatibility class (MHC) molecules are chosen in the course of positive selection (69,70), whereas those that do not effectively interact with MHC:peptide complexes die by neglect. However, interactions above a certain avidity threshold result in elimination by negative selection and constitutes the basis for central tolerance (64,68). Thus, central tolerance prevents widespread autoimmunity as a function of lymphocyte/antigen-complex avidity and preferentially selects T cells with specificities for antigens not expressed in thymic epithelium for export into the periphery. However, central tolerance is not a complete mechanism, and a sizeable pool of T cells with intermediate avidity can escape negative selection and is exported to the periphery. The presence of these autoreactive T cells can be considered physiologic and they are not noxious for two reasons: Either they are usually not activated and exhibit a naive phenotype, or they exhibit regulatory effector functions and act as adaptive Tregs following activation. Thus, not all self-reactive lymphocytes necessarily need to exhibit an aggressive phenotype. Depending on their specific effector function, autoreactive T cells could exhibit regulatory functions and critically modulate or even abort local autoimmune processes. Such autoreactive regulators might occur physiologically and constitute the majority of autoimmune responses present in healthy individuals. Only an encounter under appropriate stimulatory conditions (i.e., presentation of autoantigen-derived peptides presented in the context of MHC class I or II molecules accompanied by antigen-nonspecific costimulatory interactions and strong inflammatory signals) can lead to their full activation and detrimental effector functions in the periphery. As "armed effectors," autoreactive T cells are potentially very dangerous and may initiate organ-specific autoimmunity if they recognize the autoantigens or closely related proteins in a defined tissue. It is thought that a few autoaggressive "driver clones" with highly detrimental effector function can sustain a localized autoimmune process.

The presence of autoreactive T cells in the periphery might suggest that detrimental autoimmunity should occur quite frequently if organ-specific autoantigens are

not expressed in the thymus. Alternatively, such physiologically occurring autoimmunity is not of a regulatory nature. Yet there are several additional mechanisms that maintain tolerance in the periphery. "Peripheral tolerance" involves a set of mechanisms that ensures that autoreactive T lymphocytes are not activated in the periphery. These mechanisms pertain to both autoreactive and heteroreactive T cells and involve the following pathways. First, it has been observed that naive T cells triggered by a strong signal through the TcR alone may lose the ability to proliferate, and some but not all effector functions become anergic (74–76). Presence of certain cytokines or costimulatory interactions can avoid the induction of anergy or may reverse an anergic state. Second, highly activated T cells will eventually undergo activation-induced cell death (AICD) (77). AICD is thought to be essential for the downmodulation of immune responses and the reestablishment of immune homeostasis. Impairment of AICD may lead to continued immune activation and generalized autoreactivity. For CD4 lymphocytes, AICD is FAS/FAS-L dependent (78,79); it is not clear which interactions precisely control AICD in CD8 cells. Third, molecules that can deliver specific negative signals, such as the B7-binding CTLA-4, are involved in "turning off" the antigen-specific T cells (80,81). Finally, other factors such as regulatory lymphocytes and regulatory antigen-presenting cells (APCs) might play important roles in maintaining peripheral tolerance (51,62,82).

B Cell Tolerance

Although they are not selected in the thymus, developing B cells are subject to similar selection processes that comprise central and peripheral tolerance mechanisms. After B cells mature in the bone marrow, clonal selection occurs after recognizing antigens in the periphery, is avidity dependent, and allows the B cells to undergo further receptor editing. Because T helper (TH) lymphocytes are needed to optimize B cell responses to most protein antigens, the T cell–dependent antibody production is referred to as "thymus dependent." TH cell–independent B cell responses occur mostly to bacterial and lipid antigens, for example, to lipopolysaccharide (LPS), and are therefore rarely autoaggressive. Thus, T cell tolerance controls directly B cell reactivity to autoantigens. In general, systemic autoimmune disorders such as systemic lupus erythematosus (SLE) are B cell dependent, and organ-specific diseases such as multiple sclerosis (MS) and T1D are less dependent on autoantibodies, although B cells could play important roles because APCs and antibodies could enhance disease pathogenesis. In both T1D and MS, autoantibodies correlate with disease progression. In thyroiditis, autoantibodies are instrumental in causing disease, and in autoim-

mune hepatitis their role is thought to be crucial (see later organ-specific sections).

In conclusion, central and peripheral tolerance mechanisms effectively control the vast majority of autoreactive lymphocytes, which ensures that autoaggressive immune responses are relatively rare (less than 5% overall population). Some of the considerations described in this subsection are illustrated in Figure 42.1.

Organ-specific Tuning: Regulatory and Destructive Autoimmunity

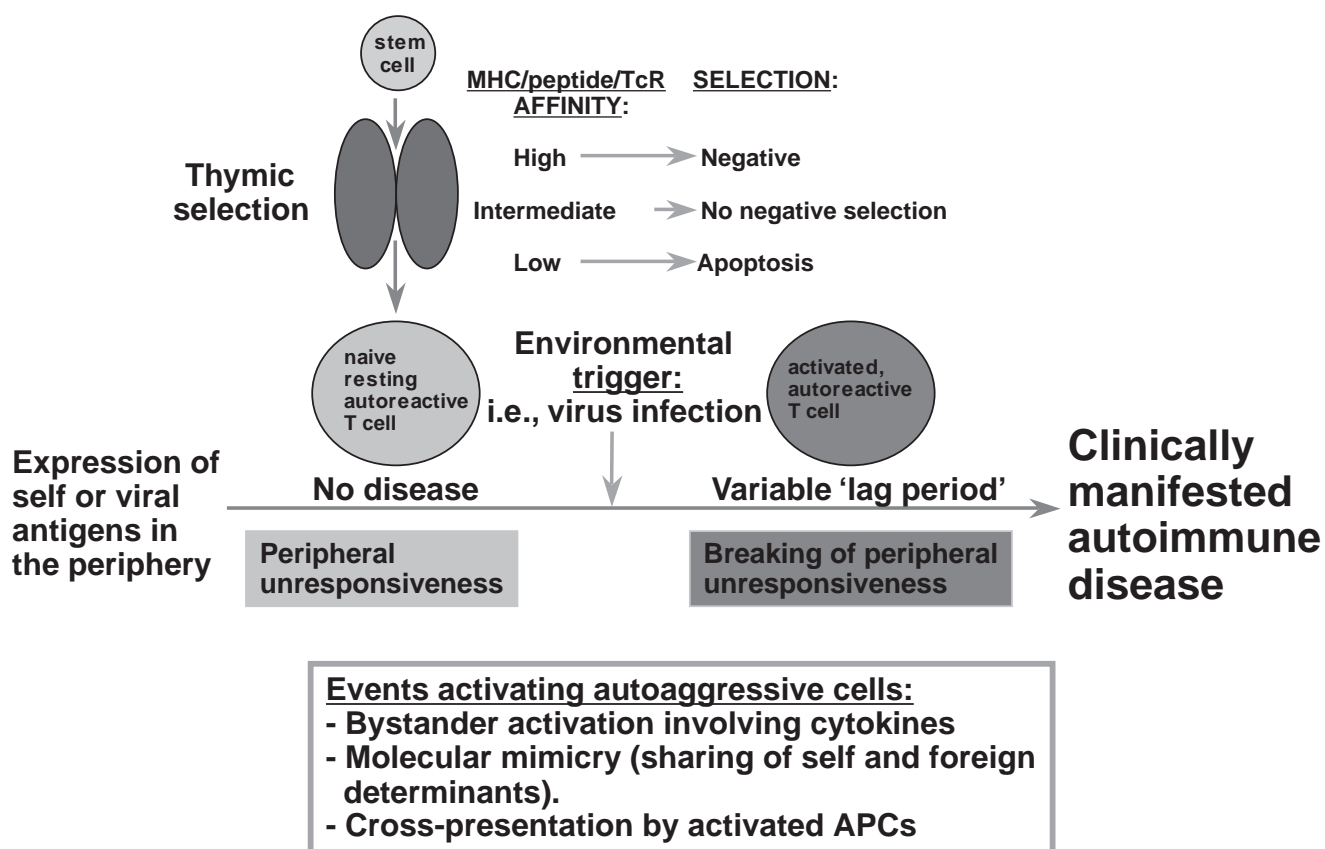
As indicated in the section The Burden of Autoimmune Diseases, although autoimmune disorders must conform to a set of general criteria, organ-specific autoimmunity must be considered in addition to the specific context of the target organ affected. Certain effector functions exerted by autoreactive lymphocytes will be detrimental only to particular cells or tissues. For example, the pancreatic β cells are more sensitive to the damaging effect of inflammatory cytokines than neighboring β cells (both cell types are part of the islets of Langerhans) and other cells in their vicinity (e.g., fibroblasts or acinar tissue of the pancreas) (83). On the other hand, some organs provide a microenvironment that suppresses inflammatory responses. For example, both the gut and the central nervous system contain relatively large amounts of TGFβ, which can have direct antiinflammatory effector functions on T cells and APCs and activate Tregs, unless IL-6 is present (61,84–87). In addition, certain large organs such as the liver may better tolerize lymphocyte responses directed toward them because they contain a high number of cells that are incapable of costimulation (e.g., hepatocytes) and consequently would shut down naive autoreactive lymphocytes that recognize them (30). Finally, the precise activation state, phenotype, and effector function of an autoreactive cell are critical in determining their impact on tissues expressing their cognate antigen. Some molecules will exert beneficial functions, for example, IL-4 and probably IL-10 and TGFβ in T1D (88–90). Antigen-specific adaptive and professional regulatory cells are likely participants of every local autoimmune process and could be essential in delaying or preventing clinical disease altogether. Although their induction is a clear therapeutic goal, phenotype and mechanistic aspects essential for regulatory function are not understood in detail. One hypothesis is that professional and adaptive Tregs exert their function by targeting and altering APC function. They may act as true bystander processors if their suppressive action via APC modulation is extended to aggressive immune responses regardless of specificity located in the microenvironment of the affected organ (Figure 42.2). Indeed, such cells have been identified in several animal models (89,91–93), but their existence and function in humans are not well defined. Alternatively, regulatory lymphocytes


FIGURE 42.1 Events important for the pathogenesis of autoimmunity. Autoreactive lymphocytes can escape thymic negative selection if they are of lower avidity. Such initially naive cells can become activated to turn into autoreactive aggressive as well as regulatory (Treg) cells. Mechanisms that play a role in addition to the genetic predisposition are probably viral infections, other inflammatory processes, and release of cytokines and chemokines. It is noteworthy that not all inflammatory processes need to foster autoimmunity because it is known that many viral infections can protect from the development of autoimmune disease. APCs, antigen-presenting cells; MHC, major histocompatibility complex.

may directly affect activated or naive aggressive lymphocytes and induce anergy or apoptosis. Furthermore, by changing the overall cytokine milieu of a given inflammatory process, the number and function of aggressive cells and cytokines/chemokines may be dampened in a localized area (94). Probably the best-understood balancing circuits used by autoreactive adaptive Tregs are the TH1/TH2 paradigm (95–97) and signaling by IL-10 (60) and/or TGFβ (61). In light of these observations, autoreactivity is not necessarily detrimental or even essential as regards Tregs.

Finally, it might be difficult or even impossible to define a general phenotype of autoaggressive lymphocytes that will cause damage at any site or organ. Instead, autoaggression has to be defined in relation to the target organ or cell that is under attack. Lymphocytes detrimental in one organ/disease might not necessarily be detrimental to other organs, with ubiquitous autoimmunity rarely occurring.

Initiating Autoimmunity: Antigens, Genes, and Environment

Antigens

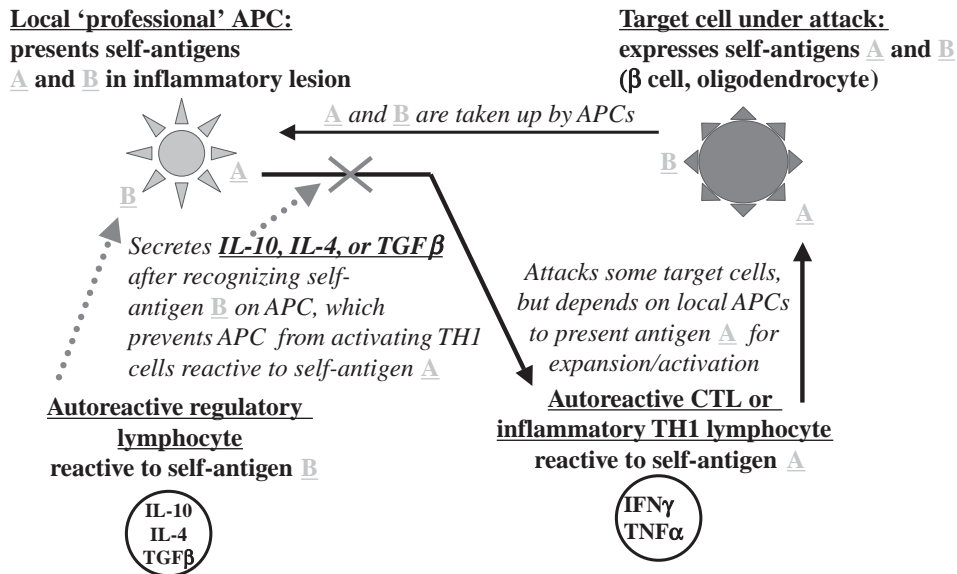
A central challenge in most human autoimmune disorders is the identification of an initiating autoantigen or autoantigens. For example, several candidate autoantigens have been identified in T1D; however, it is unclear and controversial whether any are actually involved in initiation of the disease. A similar situation exists for MS and rheumatoid arthritis (RA). Because it is unclear which antigens initiate destructive autoimmunity in the majority of human autoimmune diseases, it is important to better define the requisite properties of such antigens. A more detailed understanding of the earliest events during the development of autoimmune pathogenesis should be of direct benefit to the development of therapeutic interventions that forestall development of clinical disease.


FIGURE 42.2 The concepts of bystander suppression and infectious tolerance. Organ (cell)-specific autoantigens are taken up and presented by professional antigen-presenting cells (APCs) locally in the organ or draining lymph node. Such autoantigens can then activate autoreactive lymphocytes with diverse effector functions (aggressive vs. Treg). As a consequence, aggressive T cells directed toward antigen A could be regulated by Tregs specific for a different autoantigen B, a process termed bystander suppression by Howard Weiner. In theory, one Treg could suppress aggressive cells with multiple specificities and also foster induction of more heterologous Tregs to the same or other antigens by conditioning APCs, a process termed infectious tolerance by Hermann Waldman. Regulatory cytokines that can dampen or modulate APCs are interleukin (IL)-10, IL-4, and transforming growth factor-β (TGFβ). CTL, cytotoxic T lymphocyte; IFNγ, interferon-γ; TFNα, tissue necrosis factor-α.

The concept of processing antigens to determine self was introduced by Sercarz (98,99). Autoantigens that are not expressed in the thymus or are of cryptic nature (98,100,101) may encounter a more extensive T cell repertoire of higher avidity. Such antigens appear to be better targets. Low levels of thymic antigen expression or limited numbers of thymic medullary cells may lead to partial tolerance (102,103). In addition, the precise timing of antigen expression during embryonic development may play a major role in the establishment of tolerance. Antigens that are cryptic or not expressed during early embryonic development might become better targets later because more autoreactive T cells will be present in the periphery. It should be considered that certain embryonic antigens are involved in initiating autoimmune diseases (104).

Other parameters of importance are the constraints with which particular antigens can be presented to the immune system in a given target organ. Exogenous uptake of soluble antigens usually results in processing via the MHC class II presentation pathway. Such antigens may also be processed through the MHC class I pathway by dendritic cells (DCs), a mechanism termed cross-presentation. Cross-presentation appears to be less efficient than direct endogenous presentation of antigens through the MHC class I pathway. At this point it is not

clear which properties will make an antigen a more efficient candidate for cross-presentation. The class I pathway may be very important in the effector phase for many autoimmune disorders because cytotoxic CD8$^+$ T lymphocytes (CTLs) can be induced in this fashion and CTLs have profound detrimental effector functions (interferon-γ [IFNγ] and tumor necrosis factor-α [TNFα] secretion and lysis of target cells) (107). Clearly, recent observations have shown that cross-presentation can lead to immunity, as well as tolerance, and in this way propagate or, alternatively, halt autoimmune disease (105,108). It is less likely that autoantigens that are not presented by professional APCs or within lymphoid organs after their release from target cells/organs can initiate autoimmunity. Only under special circumstances (i.e., extremely high-density presentation of an antigen on a target cell or highly inflammatory conditions including chemotaxis) would this appear to be possible. This could possibly occur during localized or systemic viral infections and could also be an important event in lymphocyte entry into target organs, especially if chemotaxis is involved and endothelial cells present autoantigens (109). In addition, experienced or primed autoaggressive lymphocytes would be capable of becoming activated after seeing antigen in the absence of costimulation, and thus accumulating a memory pool of

autoaggressive T cells might be inherently dangerous to an organism.

Thus, the type of autoantigen will define its own potential "candidacy" in an autoimmune process. Autoantigens that are not expressed during development or were cryptic for an extended period of time, as well as antigens secreted and cross-presented in lymphoid organs by APCs, appear to be better suited for assuming the role as primary culprits.

Genes

An abundance of empirical evidence indicates the association of many organ-specific autoimmune diseases with certain human leukocyte antigen (HLA) haplotypes, as well as other susceptibility or protective genes. The principal specific genetic linkages will be discussed later separately for each condition. In general, MHC I (such as HLA-B27) (110,111) or class II (such as DR4) genes might predispose to a certain disease by enhanced presentation of pathogenic peptides in the periphery or inefficacious presentation of autoantigen-derived peptides in the thymus. For example, the human HLA-DQ8 molecule has a striking structural similarity to the mouse I-A^{g7} class II that predisposes NOD mice to spontaneous autoimmune diabetes (112,113). However, the link to disease appears not to be as simple as reasoned earlier in the chapter, and more complex mechanisms might be in place. Presentation of the pathogenic peptide in gluten-induced celiac disease involves acidic modification of the protein to generate the peptide ultimately presented by MHC class II (114), and other chemical modifications can be expected to alter peptide binding to MHC and the resulting conformation.

Other genes that encode immunoregulatory or inflammatory proteins may be involved in the disease process. Genes that support tissue or wound repair (e.g., islet cell regeneration in T1D) may be of help in preventing disease development (115). For most organ-specific autoimmune disorders the genetic links are complex and not absolute. Many susceptibility and resistance genes act in concert to modulate the clinical phenotype. Noteworthy newly emerging themes in the genetics of autoimmunity are the fact that small nucleotide polymorphisms might result in alternate forms of the same gene and the fact that the overall MHC region genes are becoming unraveled (116). A striking example for the former is the existence of an alternate splice form of the inhibitor of cellular function (CTLA-4). Vijayakrishnan et al. discovered that the presence of a secondary splice variant of the CTLA-4 gene lacking the B7.1/B7.2 binding motif could be instrumental in defining the genetic penetration of diabetes pathogenesis (117). An important area that is still largely unexplored relates to genes responsible for transcriptional control of other proteins. Experimental models indicate that transcription factors can have profound effects on the

development of autoimmune disease, and variations in expression and activity levels may be observed between susceptible and protected individuals. In summary, a complex interplay of many genes will predispose for a certain autoimmune disease, but the concordance of clinical manifestation is frequently not higher than 30% to 40% in monozygotic twins (118–124). For this reason, other factors are to be considered in studying the triggering or propagation of the organ-specific disease process.

Environment

Viral Infections

For many years viral infections have been discussed as potential candidates for triggering autoimmunity in susceptible individuals because of their capacity directly to infect target tissues and induce strong inflammatory responses. Although the association between viral infections and organ-specific autoimmune disorders is a very intriguing possibility, it has been exceedingly difficult to demonstrate a causative role for specific viruses in human autoimmune diseases. In addition to the many obstacles are the possibilities that (a) all individuals undergo a multitude of viral infections during their lifetime, (b) one has to assume that viruses are frequently cleared at the time of diagnosis, and viral footprints can be difficult to find in individuals affected by an autoimmune disease (hit and run event), (c) the precise viral strain, infection kinetics, number of T cells, and type of effector functions induced may play an instrumental role in determining its effect in an individual genetically at risk, necessitating a very detailed immunologic profiling (125), (d) due to MHC polymorphism, there is a significant variation in specificity of the antiviral response, (e) viral infections might not trigger autoimmunity per se but affect an ongoing autoimmune process in a detrimental way, and (f) there is increasing evidence that viral and other (126) infections rather prevent than enhance ongoing autoimmune responses, either by apoptosing aggressive T cells or by augmenting the Treg pool (127) (C. F. Filippi and M. G. von Herrath, unpublished). Thus, a successful approach should first explore the underlying mechanisms in virally induced autoimmunity and then apply the precise insight and paradigms developed specifically to the human situation.

The most important mechanisms to be considered are summarized in Figure 42.3:

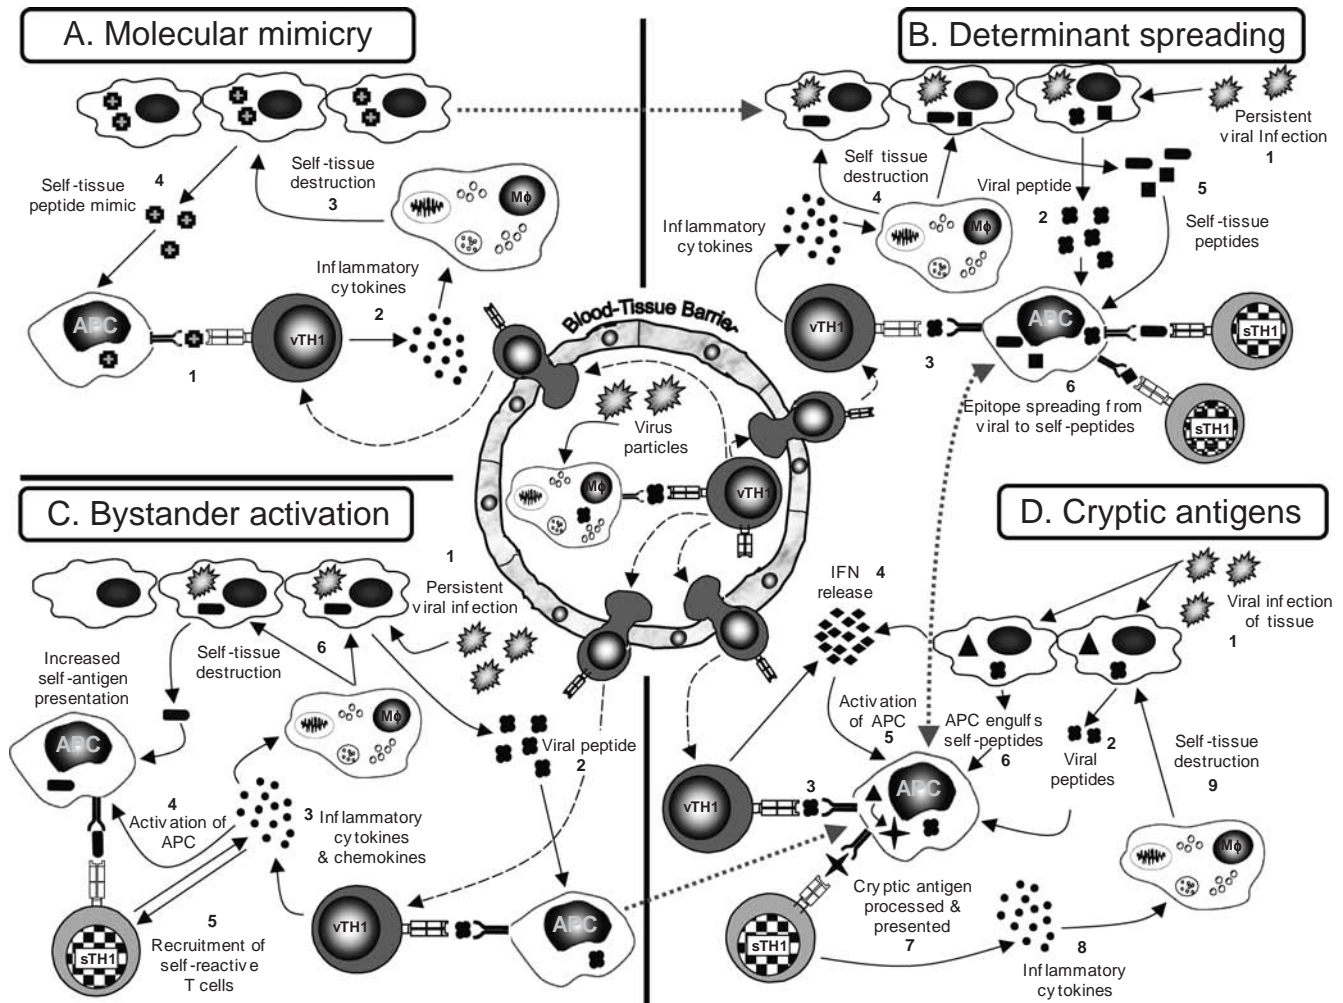
1. Molecular mimicry implies that the cross-reactivity between viral and self determinants is a principle cause or mechanism of enhancing autoimmunity (128,129).
2. Bystander activation postulates that APCs and autoreactive lymphocytes will become activated indirectly as a consequence of the cytokine/chemokine by virus infection of a particular organ (130).


FIGURE 42.3 Potential mechanisms of autoimmune disease induction. After a viral infection, activated virus-specific T helper cells (vTH1) and CD8 cytotoxic T lymphocytes (CTLs) will migrate more readily through blood–tissue barriers to infected and noninfected organs. **(A)** Molecular mimicry describes the activation of cross-reactive lymphocytes that recognize the original viral epitope and a self-epitope (1), which leads to the release of cytokines and chemokines (2), which enhance local inflammation, activate antigen-presenting cells (APCs), and indirectly or directly cause tissue destruction (3) and spreading of the autoimmune process (4). **(B)** In the epitope spread model, persistent viral infections (1) could result in the activation of virus-specific T cells (2, 3), which cause tissue damage by killing virally infected cells (4), leading to the release (5) and (cross-) presentation of more autoantigens (6). **(C)** The bystander activation model describes the non–antigen-specific activation of autoreactive T cells. Infiltration by virus-specific T cells (1, 2) leads to inflammation and upregulation of immunity throughout the tissue (3, 4), involving the activation of APCs, which now differentially process autoantigens (also *de novo* or previously cryptic antigens). This can lead to activation of lymphocytes by TcR-specific or TcR-independent mechanisms (5), which can then cause tissue damage (6). **(D)** The cryptic antigen model describes the initiation of autoimmunity by differential processing of self-antigen/peptides, which can occur under inflammatory conditions. After viral infections, interferons (IFN) (1) are secreted by antiviral T cells and infected cells (2–4). APCs are activated in this way (5), which enables them to engulf self-peptides (6, *triangle*), or to differentially process endogenous autoantigens. Cytokines can activate proteases more strongly, which might result in the presentation and processing of previously cryptic autoantigens (7–9). The displayed pathways are not mutually exclusive and are probably operational at different levels in many autoimmune responses. Currently of high interest is the presentation of neoantigens and strategies to define them. Mϕ, macrophage. (Courtesy of Steve Miller and Ludovich Croxford, Northwestern University, Chicago, Illinois.)

3. Virally induced determinant spreading involves the presentation of autoantigens (possibly previously cryptic) by virus-activated APCs (131–133).

The experimental evidence for all of these three scenarios obtained in different mouse models *in vivo* is well documented. However, none of these has been proven for any human autoimmune disorder due to the large size of human trials and the invasive nature of *in vivo* diagnostics required at the present stage. Thus, in the near future we will continue to depend on animal models until noninvasive human *in vivo* diagnostic strategies have advanced to allow for imaging of trafficking of antigen-specific lymphocytes. In addition, the prospect of directly visualizing immune processes in target organs of afflicted patients may offer improved diagnostics as well as custom-tailored therapeutic interventions. A final remark pertains to the negative association between viral infections and autoimmune disease that has been observed in several experimental models (134). These observations support the so-called "hygiene hypothesis," that is, the epidemiologic finding that the incidence of many autoimmune disorders is decreased in equatorial countries that exhibit a higher prevalence of various infectious diseases. However, no firm associations have been established.

Other Environmental Causes

Similar to viral infections, other inflammatory stimuli may trigger or enhance autoimmunity. The gut deserves particular attention in this respect. At this site each individual harbors thousands of different bacterial strains, and viral infections are common. Furthermore, the mucosal lining is permeable for nutrients and constitutes a very large interactive surface with the environment. Again, the complete absence of all bacteria results in severe immune dysfunction and possibly autoimmunity. However, it would be incorrect to conclude that infections are therefore always protective. Indeed, the commensal flora appears to be crucial in maintaining proper immune activation and function, with certain pathogens definitely eliciting strong gut immune responses that could lead to autoimmune disease (135,136).

Regulatory Circuits in Autoimmune Processes

Cytokines

Cytokines and chemokines are essential regulators of cellular and humoral immune responses and lymphocyte trafficking (137–139). They play a central role in orchestrating immune processes and constitute a multitude of positive, as well as negative, feedback loops (140). Certain cytokines can negatively or positively influence the production of other cytokines [e.g., the TH1/TH2 paradigm and the recently discovered TGFβ-mediated differentia-

tion of IL-17–producing T cells in the presence of IL-6–secreting cells or Tregs in the absence of IL-6 (84,95)] and therefore determine the balance between pro- and antiinflammatory factors in the local environment. Furthermore, autocrine production feedback can augment or shut down production of a given cytokine by one cell. Cytokine networks operate with a fair amount of redundancy, and cytokines and chemokines share common receptors. They are the most likely mediators of "bystander activation" and "suppression" processes and also offer an effective and versatile therapeutic target via the temporarily restricted use of cytokine- or chemokine-blocking antibodies. Their precise function can vary quite dramatically with respect to the autoimmune disease under investigation and will be discussed in the various disease-oriented sections. Furthermore, their level and timing of expression during an ongoing disease process will determine whether they have a positive or negative effect (or any at all; see later discussion).

Apoptosis

It appears to be a general paradigm of great functional consequence that activation of the immune system is followed by a process that reverses the activation and reestablishes homeostatic baseline levels of immunity (77,79). In the absence of such regulatory mechanisms, immune responses will overshoot their goals and excessive immunopathology will occur. Thus, activation-induced cell death is believed to play an important role in regulating autoimmunity. Apoptotic lymphocytes, for example, are easily detected in islet infiltrates in T1D (141), and targeted induction of limited apoptosis may even prevent onset of autoimmune disease (142). Although increased apoptosis of aggressive lymphocytes that exceeds the supply of newly activated cells may directly limit an ongoing autoimmune process, limited apoptosis of target tissues may indirectly facilitate induction of protective regulatory responses. On the other hand, whereas apoptosis of target cells should be limited, decreased apoptosis of autoreactive aggressive lymphocytes will propagate autoimmunity. It is important to consider precisely which cells undergo apoptosis to predict the possible outcome.

- If too many target cells die by apoptosis, organ destruction occurs more rapidly; however, at the same time, antigens released from apoptotic cells appear to propagate tolerance rather than immunity (142,143).
- If Tregs die by apoptosis, autoimmunity will be enhanced (144).
- If aggressive lymphocytes die by apoptosis, this should in general ameliorate disease. However, because they have to first be activated, they might induce organ damage during their activation phase.

Progression to disease (time)

FIGURE 42.4 Kinetic issues in autoimmune diseases. Clinical manifestation of autoimmunity is the consequence of a disequilibrium between protective (regulatory) and aggressive (effector) responses **(A).** An important consideration is that the destruction of the target cell or organ will usually lag somewhat behind the peak of the aggressive responses because organ regeneration is common. **(B)** Inflammatory stimuli will augment the effector arm of the autoreactive response, resulting in more rapid disease development. In contrast, induction of Tregs and increased regulation can delay or dampen organ destruction **(C).**

Thus, an ongoing autoimmune process can be viewed as a rather fine-tuned and fragile equilibrium of aggressive and regulatory components, and the precise activation kinetics and survival times of all lymphocyte types implicated in the process will determine the outcome. We are unable to delineate the precise *in vivo* cellular kinetics, and a more thorough understanding will require improved noninvasive diagnostic techniques.

Kinetic

One of the most important emerging areas for an improved understanding of the pathogenesis of autoimmunity is concerned with the kinetics of immune responses. The pathophysiologic or therapeutic effect of a given lymphocyte population depends not only on specificity, activation state, and effector functions, but also on the timing of each phase of the disease. Indeed, inflammatory cytokines such as IFNγ or TNFα exhibit opposing effects in T1D, depending on the precise time point of generation (145). Early expression enhances islet destruction and disease development, whereas late expression ameliorates disease by inducing apoptosis of autoaggressive cells. These kinetic issues constitute a major obstacle for successful immune intervention because they preclude the use

of specific blocking agents or administration of cytokines without precise knowledge of their kinetically differential role in the disease process. Figure 42.4 illustrates these kinetic considerations in relation to target cell destruction. A better understanding of the underlying "autoimmune kinetics" is essential, and treatments will likely have to be individualized, in particular, for antigen-specific immune-based therapies.

Therapeutic Considerations

Efficacy, Specificity, and Undesired Effects

Treatment of autoimmune disorders is not that different conceptually from cancer therapy. A fine balance must be found between efficacy of the intervention and acceptable undesired effects. The main goal of autoimmune disorder therapy is suppression of the pathologic autoimmune response. Therapeutic options range in principle from continuous immunosuppression of the entire immune system to specific, targeted, temporarily limited and local immunosuppression. Systemic immune modulation or antiinflammatory therapy will affect the entire immune system and may compromise the immune status of the individual. One of the more recent examples for effective

systemic treatment is the blockade of TNFα to ameliorate RA (146,147). Although undesired effects are relatively low, SLE-like symptoms have been observed in a few patients, as has the enhanced susceptibility to tuberculosis. This is especially encouraging because blockade of TNFα affects inflammatory pathways distinct from the targets of conventional antiinflammatory therapy with corticosteroids or nonsteroidal antiinflammatory drugs.

Autoantigen-specific immune interventions, in contrast, bear the promise of lower systemic side effects because they can be targeted to antigens that are exclusively expressed in the diseased organ (148,149). However, the efficacy might be lower, and suitable target antigens have to be chosen carefully because enhancement of autoimmunity is an important concern. The goal is either deletion of aggressive autoreactive T cells or induction of regulatory cells (150). To achieve the latter, response modifiers are probably required at the time of immunization to skew the resulting immune response to exert regulatory effector functions. Deletion of autoaggressive lymphocytes or anergy induction is even more risky because only suboptimal immunization (i.e., in the absence of costimulators) will result in this outcome. To control this *in vivo* is rather difficult. Ultimately, antigen-specific therapy will likely have to be individualized due to MHC polymorphism and distinct T cell repertoires among individual patients and should be combined with other systemically acting agents, for example, antibodies against CD3 or CD4 or costimulation blockade. Indeed, there is intriguing recent evidence along these lines in animal models; combination of a non–Fc-binding anti-CD3 antibody with mucosal immunization of insulin or insulin-derived peptides exhibited clear synergy and enhanced efficacy in reversing recent-onset diabetes in the NOD mouse (151). In this case, induction of insulin-specific adaptive Tregs and their effector function were enhanced, and protection by these Tregs was transferable and highly effective in that it prevented recent-onset T1D.

Promising Targets

For antiinflammatory interventions, the factor to be targeted should be as disease specific as possible. Therefore, blockade of TNF works well for RA but not for T1D or MS (152). Experimental evidence supports this observation because TNFα is a crucial mediator discovered to be elevated in affected joints (147) but has clearly positive, as well as negative, effector function in murine models for MS and T1D (153,154). Targeting ubiquitously present chemokines or cytokines will likely not bear much success because of the resulting generalized immune modulation or suppression.

For antigen-specific interventions, antigens that are already targeted by regulatory autoreactivity are likely to constitute good targets to augment such a preexisting response (155). These antigens should not be selected to

delete autoreactive cells, which may precipitate a loss of regulation. Instead, the induction of apoptosis or anergy should be reserved for specific lymphocytes involved in destructive autoimmune responses. However, the fact that autoimmune responses demonstrate changes in preferentially targeted antigens over time ("determinant spreading") makes such interventions difficult to design, and individualization would be necessary.

Reestablishment of Tissue-specific Immune Regulation

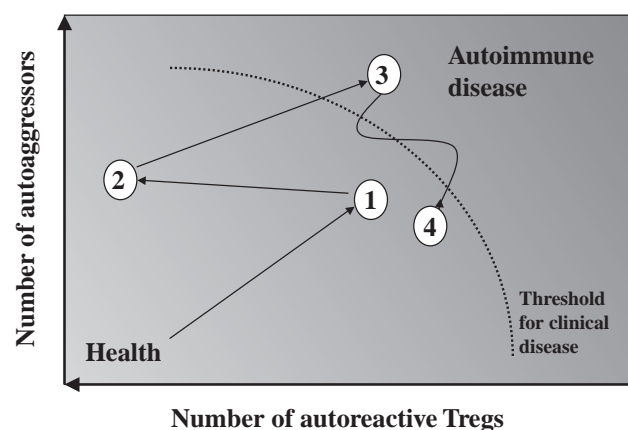
One of the factors that pose a challenge to understanding the pathogenesis of distinct autoimmune diseases may also hold a clue to developing effective and specific treatment strategies. Each target cell, tissue, or organ exhibits specific features that distinguish it from other sites in the body. These site-specific features of autoimmunity will likely offer unique target sites for interventions and lower systemic side effects. However, one concern is that reestablishing proper immune homeostasis and regulation in one organ may still affect homeostasis systemically or at another site. Therefore, thorough preclinical evaluation and careful monitoring of undesired effects is urgently needed. Ideally, treatments have to be administered before complete organ destruction has occurred in patients identified by genetic screening to be at risk of developing full-blown clinical disease. During the preclinical state, frequently regulatory autoreactive responses are still strong, and their augmentation can result in protection (Figure 42.5). During advanced stages of autoimmunity, Treg


FIGURE 42.5 Development of autoimmune disease as a function of aggression versus regulation. After induction of disease (1), distinct numbers of autoaggressive and autoreactive Tregs will be generated and activated. Oscillations between protective states and diseases states follow (2, 3), that is, the so-called "honeymoon phase" in type 1 diabetes, which can eventually lead to an irreversible state of clinical manifestation of disease (4). An additional important factor the ability of the target organ to regenerate.

function or susceptibility of effector T cells to regulation might decrease (156). The goal to reestablish homeostasis and proper regulation after initial organ-specific inflammation appears to be a natural countermeasure to which a specific immune response could be harnessed. An intriguing example is the recently emerging concept of organ repair, which could potentially be enhanced by drug therapy. In T1D, regeneration and replication of β cells could occur after giving exenatide, a glucagon-like peptide-1 agonist. This is an established intervention in T2D and in T1D is under investigation in combination with other drugs, for example, anti-CD3.

ORGAN-SPECIFIC AUTOIMMUNE DISORDERS

A comprehensive and balanced discussion of organ-specific autoimmune diseases at large is well beyond the scope of this chapter. Our choice of individual diseases for this part of the chapter was guided by their relevance to human health, that is, disease prevalence and severity, as well as recent insights into pathogenetic mechanisms that may contribute to the development of novel treatment modalities. Given these limitations, we extend our apologies to all those scientists and clinicians whose work on organ-specific autoimmune disease is not mentioned in this discussion.

Endocrine Autoimmune Diseases

Thyroid: Grave's Disease and Hashimototo's Thyroiditis

Introduction and Disease Description

The year 1956 was seminal for the field of human autoimmunity, given the discoveries of Hashimoto's thyroiditis as an autoimmune disease and of Grave's disease as caused by an autoantibody. These discoveries prompted some straightforward and relatively uncomplicated treatments *(157,158)*. In Grave's disease, autoantibodies directed against the thyroid-stimulating hormone (TSH) receptor on thyroid cells stimulate excessive production of thyroid hormone, which is normally controlled by feedback regulation. In contrast, in Hashimoto's thyroiditis, autoantibodies to thyroid peroxidase and thyroglobulin are present over years and are able to fix sublytic doses of complement to cells of the thyroid. The result is an inflammatory reaction, which is also associated with T cell–mediated cytotoxicity. Thyroid damage due to painful Hashimoto's thyroiditis may be associated with the development of Grave's disease, indicating that there is a tendency for spreading of the autoimmune reaction in humans. Treatment of thyroiditis is relatively straightforward with antithyroid drugs (methimazole) and radioactive iodine.

Autoimmune Features

Autoantigens targeted in thyroiditis are thyroid peroxidase, a cell surface protein (Hashimoto's thyroiditis), and the TSH receptor (Grave's disease). Autoimmune responses to thyroglobulin are also seen in animal models. The B cell epitopes to these autoantigens have been mapped relatively well; however, as in the case of other human autoimmune disorders, T cell responses, their tracking and specificity, and their eliciting antigens in humans have remained largely elusive *(157)*. Aberrant T cell immunity has been linked to the CTLA-4 locus, which is supported by studies of thyroiditis in NOD mice. The usual suspects, that is, APC dysfunction, autoaggressive lymphocytes, and links to viral infections, have been examined, but no conclusive etiologic or mechanistic evidence has been obtained. It is noteworthy that a role for Tregs has been established in Mason's animal model for thyroiditis *(159)*.

Genetic Features and Environmental Factors

Of interest, numerous viruses have been implicated in the pathogenesis of different thyroid diseases, but firm evidence for a direct involvement of viruses or virus-induced immune responses leading to clinically manifest disease is scarce. Subacute thyroiditis is a clinical and pathologic form of thyroid involvement that appears after infection with viruses such as measles, influenza, adenovirus, Epstein-Barr virus, and coxsackie virus *(160)*. Again, however, a causative role *in vivo* has not been shown for any single infectious agent *(161)*. Presence of viral material in the thyroid and elevated virus-specific antibody titers were found to correlate with subacute thyroiditis. In other instances direct virally induced thyroiditis has been documented epidemiologically with thyroid or parathyroid disease.

Retroviruses, in particular human immunodeficiency virus (HIV) infections, have generated much interest. Although HIV infection and acquired immunodeficiency syndrome (AIDS) may affect multiple endocrine organ systems *(162–165)*, thyroid dysfunction usually reflects weight loss, anorexia, and cachexia of advanced HIV disease rather than a direct viral effect on the thyroid *(166,167)*. Thus, direct involvement of the thyroid by HIV or by opportunistic infections is uncommon and may include subclinical hypothyroidism and "euthyroid sick syndrome." The clinical relevance is probably limited because overt hyper- or hypothyroidism does not occur with greater frequency in HIV-infected and AIDS patients as compared to patients with other nonthyroidal illnesses [HIV and the thyroid gland are reviewed elsewhere *(166)*]. Involvement of the parathyroid in patients with AIDS could be shown by reduced basal and maximal parathyroid hormone levels, but the mechanisms underlying these findings have not been elucidated *(168)*. To account for a possible role of HIV in thyroid autoimmunity, a 66% homology between the HIV-1 Nef protein and the human TSH receptor has

been noted. However, reactivity of sera from Grave's patients against a Nef peptide showed no significant difference as compared to normal controls *(169)*. This does not rule out the presence of conformationally shared T or B cell epitopes with HIV proteins. In analyzing mechanisms of molecular mimicry, studies of potential antigenic surfaces have emerged as an important supplement to analysis of sequence similarity *(170)*.

In addition, antibodies from a Grave's patient showed reactivity to the Gag proteins of another retrovirus, human foamy virus (HFV) *(170)*. The association of HFV with Grave's disease or subacute thyroiditis is controversial. Whereas one study demonstrated HFV-related sequences in the DNA of peripheral blood in two thirds of the Grave's patients but none in normal controls *(171)*, another study could not confirm these findings *(172)*.

In other studies, an association between human T cell leukemia lymphoma virus (HTLV) I and II and the occurrence of autoimmune thyroiditis or Grave's disease was reported *(172–175)*. Furthermore, as in the case of HIV, hepatitis C virus was shown to lead to a wide variety of autoimmune disorders including involvement of the thyroid gland *(176–180)*. Moreover, treatment of chronic hepatitis B and C with IFNα leads to induction or enhancement of autoimmune disease *(181–183)*. For congenital rubella infection, which has been associated with T1D, Addison's disease, growth hormone deficiencies, and thyroid disorders *(184)*, it is not clear whether thyroid involvement is the result of a direct viral effect or a more generalized dysfunction of the immune system *(161)*.

Animal Models

Animal models in mice and chicken have been used to study virus-induced thyroiditis [reviewed elsewhere *(161)*]. Mice persistently infected with LCMV showed reductions of thyroglobulin mRNA and circulating thyroid hormones in the absence of thyroid cell destruction *(185)*. Thyroiditis characterized by focal destruction of the follicular structures, inflammatory infiltration, and generation of antibodies against thyroglobulin and thyroid peroxidase was observed in a reovirus type 1 mouse model of thyroiditis *(186)*. The reovirus gene responsible for autoantibody induction was identified, and the encoded polypeptide as shown to bind to tissue-specific surface receptors *(187)*. Spontaneous lymphocytic infiltration of the thyroid is observed in the obese strain of chickens. Such chickens express an endogenous retrovirus, avian leukosis virus (ev22), not detected in healthy normal inbred strains *(188)*. Although ev22 appears to be a genetic marker rather than a cause for thyroiditis, infection of normal chicken embryos with avian leukosis virus can cause hypothyroidism *(189)*. Moreover, aberrant MHC class II expression is demonstrated in obese strain chickens, and elevated levels of 2.5-oligoadenylate synthetase and 2,5-oligoadenylate polymer levels in the cytosol of thyroid epithelial cells occur,

suggesting viral involvement *(190)*. Again, not all cross-reactivities with self ligands need to increase autoimmunity *(191)*, and regulatory cells also play a major role in modulating autoimmune thyroiditis *(159)*.

Endocrine Pancreas: T1D

Introduction and Disease Description

Although the distinct symptoms of diabetes mellitus have been known since antiquity, the underlying pathophysiologic processes were only identified in the late 19th and early 20th centuries. The proof of the involvement of the pancreas in diabetes etiology was conducted by von Mering and Minkowski, who demonstrated in 1890 that extirpation of the canine pancreas resulted in the classic symptomatology of hyperglycemia, abnormal hunger, increased thirst, polyuria, and glycosuria *(192)*. Subsequently, inflammatory changes in the endocrine pancreas, that is, the islets of Langerhans, were correlated with diabetes by Schmidt in 1902 *(193)*, and two decades later, Banting and Best identified insulin as a pancreatic hormone *(194)*. This provided the basis for insulin substitution therapy, which remains the cornerstone for T1D management. In a classic 1965 paper, Gepts noted the histopathologic similarity between thyroiditis and insulitis and suggested an immune basis for the disease *(195)*. By 1974, the concept of T1D as an autoimmune syndrome was firmly established by the discovery of islet cell antibodies and an association between T1D and certain HLA genes *(196–198)*.

Autoimmune Features

More than three decades later, the possible autoimmune origin of T1D is understood in much greater detail. However, the lymphocytic infiltration of the islets of Langerhans (Figure 42.6) and the presence of antibodies specific for β cell antigens associated with the progressive destruction of insulin-producing β cells *(199,200)* still constitute the cardinal evidence for an autoimmune etiology. Although there is a reasonably strong genetic linkage to certain HLA molecules, the disease has to be considered polygenic in nature (118), and a significant discordance of disease among monozygotic twins suggests that environmental factors contribute to trigger and/or exacerbate the disease. Furthermore, it is unclear which islet antigens are the primary targets. The earliest islet cell–specific antibodies in human individuals at risk are directed to insulin *(201,202)*, and evidence from relevant animal models and recent human studies points toward insulin as a primary antigenic target *(203)*, IGRP (islet-specific glucose-6-phosphatase catalytic subunit–related protein) *(204,205)*, and possibly glutamic acid decarboxylase (GAD) *(206)*, but definitive proof for a pathogenic role has only be ascertained in the NOD mouse model and not yet in humans *(207)*. The cellular infiltrates found in the islets contain

(See Color insert.)

both CD4⁺ and CD8⁺ T lymphocytes, and their irreducible role in β cell destruction has been documented in several animal models *(208–210)*. CD8⁺ T cells can exert direct cytotoxic effects toward MHC class I–expressing β cells, whereas CD4⁺ T cells secrete inflammatory cytokines and can provide help to CD8⁺ T cells as well as B cells. Ultimately, it is important to consider that β cells constitute about 60% of the islets, which in turn contribute only approximately 2% to the pancreas mass and demonstrate, unlike many other tissues targeted in autoimmune disorders, an exquisite sensitivity to cytokines such as IL-1, TNF, and IFNs that will result in their apoptotic cell death after prolonged exposure (83).

The detection of islet-antigen specific antibodies remains an essential tool in identifying prediabetic subjects and monitoring the progression of subclinical and clinical disease. Procedures for autoantibody determination have been substantially refined and standardized worldwide. Emerging data from clinical studies support the notion that with progression of the prediabetic phase, generation of islet antibodies also is increased *(211–213)*. Usually, antibodies to insulin become discernible first, then GAD, and then insulinoma antigen 2 (IA-2). Individuals with islet antibodies to three or more distinct antigens have a greater than 90% risk of developing T1D (124). Thus, islet antibodies are an excellent marker for disease risk. However, they appear not to play a role pathogenetically, because transfer of antibodies from mothers to children does not increase the risk for T1D, and B cells are not needed for human diabetes *(214–216)*. In this crucial respect the NOD mouse appears to provide a paradigm that might not be applicable to human diabetes because maternal antibodies are an essential factor for diabetes development in offspring of NOD mice *(217)*.

Human T cell responses to islet antigens are not yet standardized and can vary considerably among different laboratories. One reason for this may be the source of T cells that are generally subjected to specificity analysis: Blood-borne CD4⁺ or CD8⁺ T cells may not reflect the specificity distribution and frequencies of islet-specific T cells observed in the target organ, that is, pancreas and its draining lymph nodes. Even the study of spleen-derived islet-specific T cells readily obtained from NOD mice and analyzed in standardized proliferation assays has shown variations among different NOD mouse colonies *(218)*. Therefore, measurement of multiple effector functions (i.e., cytokine production) in highly standardized assays are likely required to assess T cell autoreactivity on a routine basis *(219)*. Even under those circumstances, T cell responses are expected to vary among individuals and depend on the HLA haplotype and individual trigger(s) that precipitate T1D. A recent remarkable paper *(220)* showed that tracking of immune responses to naturally processed peptide epitopes (NPPEs) can discern differences between healthy individuals and those afflicted with T1D; whereas the number of overall T cells reacting with the NPPEs was similar, individuals with T1D produced more IFNγ relative to IL-10, and the ratio was the opposite in healthy individuals.

Genetic Features and Environmental Factors

Because the discordance of T1D is significant in monozygotic twins (concordance rate approximately 35%), environmental factors have to act in concert with diabetes-susceptibility genes to orchestrate the autoimmune destruction of β cells. The initial hope that only a few genes would contribute to disease pathogenesis and that genetic links would help to directly understand the

mechanistic aspects of T1D pathogenesis has been progressively eroded. Instead, a complex network of susceptibility and resistance genes in both humans and animals (e.g., the NOD mouse) has slowly taken shape. Human T1D-associated loci "insulin-dependent type I diabetes" (IDDM1-15) comprise MHC class II genes (IDDM1), insulin (IDDM2), insulin-like growth factor 1 (IDDM3), immune-related proteins (IDDM4, intercellular adhesion molecule [ICAM]; CD3, IDDM7; HOXD8 (homeo box D8); and IDDM12, CTLA-4), as well as other candidate genes that do not have an apparent link to immune functions and/or β cells. In addition, certain maintenance, developmental, or growth factors may be involved (120). Many of these genes exhibit direct parallels to NOD mouse diabetes-susceptibility genes *(221)*.

The association between particular HLA/MHC class II haplotypes and the occurrence of human diabetes has been of particular interest. DRB1/04-DQA1/0301/B1 and DRB1/03-DQA1/0501/0201 strongly predispose to T1D, and more than 80% of patients carry either one or both alleles *(222)*. In contrast, other MHC class II haplotypes can protect from disease, as evidenced by the sixfold-reduced risk to T1D in DRB1/15-DQA1/B1/0602–expressing individuals. Recent evidence indicates that other genes in the MHC region would likely contribute significantly to T1D risk (116).

An intriguing mechanistic hypothesis was put forth in relation to McDevitt's observation that predisposing HLA class II alleles appear to express small neutral amino acids at position 57 of the DQ allele of white populations, whereas an aspartic acid is located in resistant alleles at the same position. Because position 57 is part of the peptide-anchoring pocket, amino acid substitutions in this area would affect peptide binding. Indeed, the susceptibility alleles prefer different peptides, but the contribution to T1D development is not yet clear, and a mechanistic link has to be established. Both central and peripheral tolerance mechanisms have been implicated, but no direct proof has been obtained. It is important to realize that the human susceptibility MHC class II alleles share amino acids at position 57 with the I-A^{g7} alleles expressed in the NOD mouse and are required for NOD T1D predisposition. However, as previously mentioned, polymorphisms in the MHC class II coding region alone cannot explain diabetes pathogenesis. The amount of complexity involved in the immunogenetics of T1D has been well described by Serreze and Leiter *(223,224)*:

> Many genes contributing to T1D may contribute to dysregulate different biochemical steps in a common developmental or metabolic pathway. For example, sequential expression of hundreds, if not thousands of genes would be expected in the developmental and functional maturation of a macrophage or dendritic cell from stem cell precursors. This process does not occur in a vacuum, but is contingent upon cues provided by the phys-

ical environment. In the case for APC development, the microfloral and dietary environments are crucial.

Thus, diabetes susceptibility and resistance genes contribute to disease in a polygenetic/multifactorial fashion that appears to gain in complexity as it is being unraveled. The link to environmental factors will be defined to shape gene expression and disease development. Major contributors in this respect appear to be associated with gut and viral infections.

With more than 400 m^2 of mucosal epithelium, the gut constitutes the largest interactive surface area of the human body connecting us with the environment and its pathogens (135). Therefore, exposure to antigens or pathogens through the gut, mediated by the largest outpost of the immune system, the gut-associated lymphoid tissue (GALT), will strongly affect specific and general immune functions. It is intriguing that immune tolerance to the numerous foreign protein antigens found in food, as well as bacterial antigens derived from the commensal flora, is generally well maintained *(225)*. This may be attributable to the high levels of immunoglobulin A (IgA) and TGFβ in the gut and to the phenomenon of "oral tolerance" (OT) *(226)*. OT has been observed in animal models and humans and is defined as tolerance induction to protein antigens present in the gut. It occurs via two principal mechanisms: Low amounts of antigen will induce a nonaggressive immune-regulatory response, whereas high amounts of antigen can lead to lymphocyte anergy or deletion *(227–229)*. This is likely achieved via APC modulation. In addition, the profound immune dysregulation found in the absence of a bacterial flora in both animals and humans points to an important physiologic role that foreign antigens play in immune homeostasis in the gut *(230)*. Furthermore, NOD mice only exhibit high levels of autoimmunity when kept in a clean, specific pathogen-free environment and do not develop T1D when housed under "dirty" conditions *(200)*. It is unclear whether a baseline level of immune stimulation is needed for proper development and tuning of the immune system, and which types and quantities of gut-derived or gut-induced regulatory cells are involved in the maintenance of immune tolerance. Nevertheless, CD4$^+$ TH2–like regulators, as well as $\gamma\delta$ intraepithelial lymphocytes (30% in mice, 15% in humans) *(231)*, have been associated through various lines of evidence with active mucosal tolerance. Thus, changes in mucosal functions and infections of the gut or certain dietary components may play a role in T1D pathogenesis.

Several reports and studies have attempted to establish a link between the introduction of cow's milk and development of T1D in young infants. This link was not observed in the German, Australian, and American infant diabetes studies, but it was described in a Finnish epidemiologic study *(232,233)*. The Finnish study differed from most of the others by an extended observation time

involving infant as well as childhood consumption of cow's milk. Therefore, a dietary link between milk feeding and T1D can be considered unlikely but not excluded after long-term exposure to cow albumin or other milk proteins. Similarly, wheat-derived gluten and milk-derived insulin have been implicated as a cause for childhood diabetes. The evidence, however, is not convincing at this point, and no firm links have been established. Some intriguing observations were published more recently supporting the concept of a viral etiology for T1D. The mechanistic links between viral infections and autoimmunity can be manifold and have been discussed in detail in the introductory section of this chapter. A significant association between rotavirus infection in young infants and the first occurrence of islet autoantibodies was established by Harrison's group in Australia *(234)* but not in Finnish populations *(235)*. Rotavirus is a double-stranded RNA virus, infects the intestinal mucosa, and is a common cause of seasonal childhood diarrhea. It can polyclonally activate T and B lymphocytes and might possibly harbor antigens that could immunologically mimic islet cell-derived self proteins. However, it is not clear whether it infects the pancreas or islets directly. Another case can be made for enteroviruses. Coxsackie (Cox) B4 virus has been isolated from islets of a child with acute-onset T1D *(236–238)*, and CoxB3 and 4 strains commonly infect the gut, pancreas, and heart *(239)*. They lead to profound pancreatitis if they replicate at high enough titers and might harbor a mimicry antigen (P2C protein) *(200)* cross-reactive on the T cell level with a human GAD epitope. However, this evidence could not be replicated by other laboratories and is controversial. Recently, it has become apparent, however, that CoxB3 viral strains can effectively prevent T1D in the NOD mouse *(240)*, which might be a more common scenario than enhancement of T1D. Overall, findings such as this might support the "hygiene hypothesis," which implies that infections protect from rather than enhance autoimmunity.

Similar to coxsackie, other enteroviruses such as polio or echoviruses have been detected in the pancreas and might therefore at least have enhancing effects on ongoing islet destruction in prediabetic individuals at risk *(236)*. The establishment of a firm association between viral infections and T1D is difficult because the underlying mechanistic links established in several animal models allow for the virus to be cleared before autoimmunity develops (e.g., in the rat insulin promoter, RIP-LCMV); viruses need not necessarily directly induce islet reactive T cell responses but can act as bystander activators, and, in many cases, viral infections have been found capable of preventing autoimmunity.

Animal Models

Because the pancreas and its draining lymphoid organs are notoriously difficult to access, many important insights about diabetes immunology have been gained from suitable animal models that continue to refine our understanding of the pathogenesis and the development of potential prophylactic and therapeutic strategies. There is a multiplicity of animal models for T1D. The most commonly used models take advantage of natural mutations that give rise to spontaneous diabetes onset or antigen-specific induction of disease using transgenic technology. Other models use β cell damage initiated by treatment with specific chemicals (e.g., streptozodozin) or virus infection. Encephalomyocarditis virus is diabetogeneic in mice, and the incidence of disease depends on both virus and mouse strains used (129,*237,238,241–246*). Similarly, coxsackie virus, associated with diabetes development in humans, causes extensive pancreatic tissue damage and release of sequestered autoantigens that lead to rapid diabetes development in some mouse strains *(247)*.

Models of Spontaneous Diabetes Onset. There are several animal models of spontaneous T1D *(248)*. The two most extensively used are the Bio Breeding (BB) rat, introduced in 1974 at the Bio Breeding Laboratories in Canada, and the NOD mouse strain established in 1974 in Osaka, Japan *(248)*. Because the BB rat is associated with leukopenia and other abnormalities *(248)*, the NOD mouse has been the model of choice due to its genetic linkages, which are reminiscent of human T1D *(248)*. In both models, adoptive transfer of T cells can induce disease *(249)*. Of interest, administration of viral infections, first shown with LCMV, can prevent IDDM in both BB rats and NOD mice *(250,251)*. This occurs in the absence of a general immune suppression. Although the mechanism involved is unclear, the generation of suppresser T cells has been suggested *(251,252)*.

Models of Antigen-Specific Diabetes Induction. Expression of influenza virus hemagglutinin (HA) under the control of the RIP resulted in a low incidence (10% to 20%) of spontaneous T1D, with no significant enhancement of disease occurring after infection of such RIP-HA mice with influenza virus. However, in RIP-HA mice expressing a transgenic TcR specific for a determinant of the influenza virus HA, the incidence of spontaneous T1D increased to 100% *(253)*. These studies clearly demonstrate the importance of autoreactive T cells present at sufficient numbers for induction of autoimmune disease. Thus, the inability of influenza strain PR8 to cause T1D in RIP-HA mice likely reflects the low precursor frequency of self-reactive CD8[+] T cells. Of interest, recent studies from the Sherman laboratory have demonstrated that spontaneous disease in this model is associated with cross-presentation of HA. It has been postulated that cross-presentation constitutes an important mechanism for unmasking of islet-specific antigens to autoaggressive CD8[+] T cells. When the model antigen ovalbumin (OVA) was expressed as a self-antigen in β cells using the RIP, similar observations were made,

underscoring the likely importance of cross-presentation in autoimmune diabetes. These studies also demonstrated that the clinical outcome correlated with the number of autoreactive CD4[+] and CD8[+] cells generated and determined a cutoff level below which the autoimmune reaction would not take hold in the pancreas *(254–256)*.

Similar to RIP-HA and RIP-OVA mice, the RIP was also used to express the nucleoprotein (NP) or glycoprotein (GP) of LCMV in the insulin-producing β cells *(208,257,258)*. Diabetes develops 2 to 4 weeks after infection with LCMV due to a strong CD8[+] or combined CD8[+]/CD4[+] T cell response directed to the viral/self GP or NP in the β cells. Insulitis is initiated only when the systemic antiviral response reaches its peak and continues well after the LCMV infection has been eliminated (118,259). Therefore, the localized, islet-specific autoimmune process, although initiated by a response to the viral/self transgene, can be regarded as an autoimmune process that follows kinetics distinctly, in contrast to from systemic antiviral immunity. Indeed, antigenic spreading to insulin and GAD is observed during the prediabetic phase *(211)*. Destruction of β cells requires activation of APCs *(260)* in the islets and is mediated by both perforin and inflammatory cytokines, predominantly IFNγ *(261)*. Thus, the RIP-LCMV model reproduces many features found in human diabetes as well as other mouse models. A distinct advantage of RIP-LCMV mice is that the time point for induction of the autoaggressive, LCMV-NP specific response can be chosen experimentally and that virus-specific, destructive CD4[+] and CD8[+] T cells can be enumerated, functionally evaluated, and localized using limiting dilution analysis, MHC tetramers, or intracellular cytokine stains *(262,263)*. These aspects constituted an advantage in a recently published study, in which we could demonstrate that feeding of insulin during the prediabetic period induces insulin β chain–specific CD4[+] regulatory lymphocytes that act as bystander suppressors and can locally downregulate the autoaggressive diabetogenic response in the pancreatic draining lymph node and the islets *(263)*. Other studies in the RIP-LCMV model have underlined the role of thymic selection in allowing sufficient numbers of low-avidity autoaggressive T cells to emerge in the periphery *(264)*, the role of non-MHC–linked genes in influencing the kinetics and severity of T1D even in the presence of high numbers of autoaggressive T cells *(263)*, and the importance of APCs in breaking tolerance and sustaining autoaggressive T cell responses *(265–267)*.

Under some conditions, CD4[+] or CD8[+] T cells can induce T1D by adoptive immunization *(249,268)*. In general, T1D develops more slowly or not at all in the absence of CD8[+] CTL, MHC I, or perforin (83,269). Similar considerations are true for MHC class II and costimulatory molecules, unless their elimination affects the generation of regulatory lymphocytes *(270,271)*. Cytokines, however, frequently play dual roles in T1D pathogenesis in animal models. IFNγ, in general known as a proinflammatory mediator that upregulates MHC molecules, can "unmask" β cells for immune recognition by induction of MHC class I expression, but also can exert direct antiviral effects and might be beneficial by increasing apoptosis of aggressive T lymphocytes later in the disease (83). A similar dual role is true for TNFα, which appears to enhance early disease (possibly by directly causing β cell death in conjunction with other cytokines) but ameliorates advanced autoimmunity just prior to onset of clinical disease (145,272). For these reasons, blockade of such inflammatory mediators might be problematic in T1D. Dual roles were also described for IFNα *(273–275)*, IL-2 *(276)*, and IL-10 *(277,278)*. In some of these studies the level of the cytokine might play as important a role as the precise timing of expression. The only cytokine with largely beneficial effects has been IL-4, which ameliorates the disease and therefore might be a good candidate for treating or preventing T1D *(279)*. In general, those chemokines that attract lymphocytes to the islets and activate macrophages worsen the course of autoimmune diabetes. Figure 42.7 illustrates the pathogenetic hypotheses generated through research in multiple animal models.

Treatment and Prevention

Despite intensive research, no effective prophylaxis, therapy, or cure of T1D is available. However, even under optimal disease management with insulin substitution therapy, T1D significantly shortens life expectancy due to eventual vascular complications in multiple organs. All of the strategies that look promising have either been evaluated in animal models or are in early clinical trials in humans (see next paragraphs). Part of the problem in devising such prophylactic or interventive immune-based approaches is that the only endpoints in human trials are disease prevention and insulin requirements, as well as remaining insulin production (C-peptide levels). No precise interim staging is yet possible, which makes efficient clinical evaluation very difficult compared to MS or RA, in which access to the target organ either visually by magnetic resonance imaging (MRI) or directly by sampling fluids is much easier to achieve. Animal models have provided interesting ideas and evidence for a variety of antigen-specific and systemic interventions that bear promise for human diabetes.

Antigen-specific Immunoregulation. Immunization with DNA plasmids that express islet self-antigens, with or without cytokines, that act as response modifiers can induce autoreactive regulatory CD4[+] T cells. These cells are able to suppress autoaggressive CD4 and CD8 cells locally in the pancreatic draining lymph node, where they act as bystander suppressors. Phenotypically they behave very similar to the TH2-like regulators (155,*280–283*) induced after oral antigen administration. In treated mice (using
FIGURE 42.7 Immunopathogenesis of type 1 diabetes. Viral infections and other inflammatory stimuli (1) can activate antigen-presenting cells (APCs) (2), which secrete chemotactic mediators that entice lymphocytes in blood vessels to "roll" and enter into the pancreatic islet tissue (3). Entering lymphocytes might directly destroy β cells (4) or activate APCs locally (5) and also propagate inflammation by secreting proinflammatory cytokines (6). It is unknown how long effector cells remain in a given islet and how many β cells they can eliminate in a given time frame. IFNγ, interferon-γ; IL-1β interferon-1β; TFNα, tissue necrosis factor-α. (Courtesy of Urs Christen, University of Frankfurt, Frankfurt, Germany.)

several distinct diabetes models), insulitis is permanently reduced, and progression to clinical diabetes can be prevented in 50% to 80% of the animals (149,155,*280,281*). To bring this approach to the clinic as a preventive therapy, a suitable marker would be needed that can predict early outcome, for example, levels and isotypes of autoantibodies. Like other antigen-specific interventions, this strategy will not likely be effective in late stages of the prediabetic phase and should therefore be thought of and tested as an early preventive therapy. The important advantage of this and other antigen-specific approaches is that the risk for systemic side effects is low because the effector cells will act antigen specifically only in the area, where autoimmune destruction is ongoing and their cognate antigen

(e.g., GAD, insulin, or heat shock protein) is presented. Cytokine response modifiers will be needed to avoid deleterious augmentation of aggressive responses.

Altered Peptide Ligands. Modified insulin peptides that favor a TH2-like deviation of responder cells have been developed by Neurocrine (San Diego, CA) and showed great promise in the NOD mouse model. These are being tested in preclinical safety studies, and clinical trials have not yet shown efficacy *(284–286)*.

Anergy-inducing Compounds. This strategy is based on the observation that immunization with antigen in the absence of (professional) costimulation by B7 molecules

will lead to incomplete T cell activation and may result in anergy. *In vitro* and animal studies show much promise, in that antigen-specific cells can be selectively deleted.

Modulatory DCs. A few recent studies have shown that DCs can be modulated in such a way that they can induce tolerance in an antigen-specific fashion. This is an emerging area, and it is unclear how these modulations occur and what the precise *in vivo* effector mechanisms are (59).

Combination Therapies. Safe induction of autoantigen-specific long-term tolerance is the Holy Grail for the treatment of autoimmune diseases. In animal models of T1D, oral or intranasal immunization with islet antigens induces Tregs that are capable of bystander suppression; however, such interventions are only effective early in the prediabetic phase. We demonstrated that a novel combination treatment with anti–CD3ϵ-specific antibody and intranasal proinsulin peptide can reverse recent-onset diabetes in two murine diabetes models with much higher efficacy than monotherapy with anti-CD3 or antigen alone. *In vivo*, expansion of CD25$^+$FoxP3$^+$ and insulin-specific Tregs producing IL-10, TGFβ, and IL-4 was strongly enhanced. These cells could transfer dominant tolerance to immune-competent, recent-onset diabetic recipients and suppressed heterologous autoaggressive CD8 responses. Thus, combining a systemic immune modulator with antigen-specific Treg induction is more efficacious in reverting diabetes. Because Tregs act site specifically, this strategy should also be expected to reduce the potential for systemic side effects (151).

Therapeutic Concepts Under Clinical Evaluation. These include the following:

1. Anti-CD3 treatment. One of the more recent promising ongoing trials evaluates systemic administration of non–complement binding anti-CD3/Fab$_2'$ *(287)* in human diabetes and recipients of transplants. The effector mechanism is systemic and likely relies on the induction of antigen-nonspecific regulators *(270)* that are CD62L^{high} and CD25^{high}, as well as anergy or deletion of activated aggressive lymphocytes. From data in animal models and initial data in humans, systemic immune suppression is not too profound, indicating good feasibility for this strategy. The recent completion of a randomized, controlled trial confirms the effectiveness of this approach for treatment of individuals recently diagnosed with T1D *(288)*.

2. Oral tolerance. As for MS and RA, oral antigen trials have failed so far for T1D, except in a distinct subgroup of patients *(289)*, necessitating repeat investigations. The reasons for these failures after initially very promising animal data have become increasingly clear from follow-up animal experimentation. It is likely that the dose of antigen was significantly too low (presumably by a factor of 10 to 100). This problem may be overcome by coupling the orally administered proteins to gut response modifiers such as the cholera toxin B subunit. Second, the choice of antigen is very important, and even minor amino acid changes can modify the dose–response curves. Without a reliable preclinical marker it will be very difficult to tune this treatment to the human situation *(230)*.

3. Heat shock proteins. The first very promising diabetes prevention trial has recently been published and indicates a very good reduction of insulin requirements in patients treated with a heat shock protein peptide derived from an islet heat shock protein putative autoantigen. The precise mechanism needs to be evaluated, and long-term beneficial effects are uncertain *(290)*.

4. Immunization with insulin B peptides and incomplete Freund's adjuvant. This intervention, again evaluated and developed in the NOD mouse, is in clinical phase 1 trial. The mechanism might involve immune deviation or deletion of insulin-specific effector cells; the use of incomplete Freund's adjuvant has been proven to be uncomplicated in this trial so far.

5. Islet transplants. A promising therapeutic advance was made by developing a specific protocol for gentle isolation and purification of human islets (Edmonton protocol) that appear to be less prone to rejection after intraportal implantation into diabetic subjects *(291)*. However, continued immune suppressive treatment is still necessary in recipients of such transplants to prevent renewed autoimmune destruction of islet transplants, emphasizing the need for effective immune-based strategies of T1D prevention.

Perspective and Conclusions

No single animal model accurately reflects all aspects of human T1D. Consequently, translating the successful T1D prevention and reversion strategies developed in a variety of animal models into clinical applications faces significant obstacles, as is evident from failures in recent clinical trials. For example, more than 140 therapeutic options have been developed to prevent T1D in the NOD mouse *(199)*, but not a single one is as effective in humans. To improve this situation there is a dire need for preclinical markers that accurately predict the potential success of an intervention being evaluated by a clinical trial. Better tracking reagents for blood autoreactive T cells such as tetramers, noninvasive, high-resolution *in vivo* imaging systems, and perhaps isotype profiles of islet antigen autoantibodies and their change after a given preclinical intervention are good candidates *(292)*. Similar considerations apply to the maintenance of long-term tolerance after islet transplantation, where prolonged systemic immunosuppression might not be feasible *(293–296)*. Lastly, treatment modalities will likely have to be tailored to the specific needs of individual patients.

Central Nervous System and Ocular Autoimmune Diseases

Multiple Sclerosis

Introduction and Disease Description

MS is the most predominant human demyelinating disease of the central nervous system (CNS). An autoimmune etiology is suggested by elevated frequencies of myelin basic protein (MBP)–specific T cells documented in several independent studies of individuals diagnosed with MS *(297–300)*. Furthermore, demonstrations that adoptive transfer of T cells specific for myelin or other CNS antigens can cause a CNS autoimmune syndrome in experimental animals resembling human MS support the concept of a direct T cell–mediated pathogenesis. In addition, myelin-specific and lipid-specific antibodies have been found in MS cerebrospinal fluid *(301)*. These antibodies are able to fix complement and induce antibody-dependent cellular cytotoxicity (ADCC) and may be involved in the demyelinating process. In spite of these clues, the etiology of MS is unclear, and a complex interplay of genetic and environmental factors (similar to T1D etiology) has to be postulated.

MS is a rather heterogeneous disease. However, we are only beginning to understand how clinical and pathologic differences may point toward distinct etiologies and, potentially, treatment strategies of differential applicability and efficacy. Different subtypes of MS are somewhat better histologically defined (e.g., the distinction between T cell–rich and macrophage-rich lesions, as well as the balance between demyelination and remyelination, which can vary dramatically) than those of T1D because many tissues from patients with clinically active disease are available post mortem, whereas pancreatic islets are mostly destroyed in T1D and no immunologic correlates can be established at the end stage *(302,303)*. MS predominantly affects younger women, and its frequency, dependent on geographic location, may approach up to 3 in 1,000 *(304)*. Clinically, the disease can take a mild or very debilitating course, and, intriguingly, neuritis of the optical nerve is frequently the first sign of MS. Diagnosis is usually obtained by electroencephalography and direct imaging that allows for identification of individual lesions, their development over time, and the success of therapeutic interventions. Immune-based approaches such as the use of IFNβ or Copaxone combined with systemic immune-modulatory agents has brought some limited success for certain forms of MS. Thus, a cure for MS appears possibly a little closer than for T1D.

Autoimmune Features

Although MBP- and proteolipoprotein (PLP)-specific T cells have been documented in patients with MS, some follow-up studies have reported similar frequencies in normal individuals *(305)*. More recent studies have documented increased numbers of MBP-specific T cells in MS patients reactive to six different MBP epitopes, supporting the concept of determinant spreading as a potential pathogenetic factor. Furthermore, their activation appears to be increased selectively in MS patients, and they are less dependent on costimulation *(306)*. Thus, it appears plausible that resting T cells specific for CNS antigens are present in both healthy and affected individuals, but their activation is selectively increased under conditions of disease and their epitope/antigen recognition repertoire has expanded. In addition to cellular infiltrations, MS is usually marked by edema and inflammatory signs such as MHC upregulation, cytokine, and chemokine induction. A breakdown of the blood–brain barrier facilitates antibody access to the CNS. Antibodies specific for myelin structures and lipid components *(307)* are commonly found in MS patients, and some studies indicate fluctuations, similar to T cell responses of antibody titers in parallel to exacerbations and remissions of disease. These findings await confirmation in larger patient cohorts. It is important to note that such antibodies can be directed to MBP, myelin oligodendrocyte associated protein (MOG), and other myelin constituents *(308)*. The fact that they can fix complement and enhance complement-mediated cytotoxicity implicates them as possible agents of demyelination.

Genetic Features and Environmental Factors

There is a definite genetic link between both progressive (HLA-DR3) and remitting relapsing MS (DR2) and human MHC class II alleles. However, similar to T1D, there is a significant discordance among monozygotic twins (greater than 55%). A pronounced geographic gradient (higher incidence in northern as compared to southern regions) argues for additional environmental triggers or modulators *(304)*. Many viruses have been implicated in the pathogenesis of MS, but a causal link has not been established. For example, human herpes virus 6 was discovered around MS lesions, but follow-up studies did not discover any differences comparing healthy, Alzheimer's, or Parkinson's tissues with MS lesions *(309)*. Furthermore, antibodies to corona virus have been detected in serum of MS patients, which indicates that demyelination might occur similar to the mouse hepatitis virus model. Mechanistically, the same paradigms as for diabetes might apply (described in the introductory section), but a persistent viral infection might more likely be the culprit, based on similar observations in some mouse models (e.g., the Theiler murine encephalitis virus [TMEV] model). The difficulty in establishing conclusive proof is the multiplicity of infections during the course of a lifetime and the manifold viral traces that can usually be detected in both healthy and diseased individuals. Even if the same levels of viral antigen, RNA, or DNA are observed when comparing healthy patients with MS patients, this still does not rule out the possibility that a certain virus will only induce CNS disease in conjunction with a distinct MHC haplotype. Indeed, animal models indicate that this is in fact the case. With the introduction

of improved vaccination and antiviral treatment protocols for multiple infectious agents we may be able to infer a causal relationship if the incidence of MS should recede after introduction of such an intervention.

Animal Models

Experimental allergic encephalitis (EAE) is one of the oldest and most widely studied animal models for a human autoimmune disease (99,*310,311*). EAE, a primarily CD4$^+$ T cell–mediated disease, can be induced in susceptible mouse strains (SJL, PL/J) by immunization with MBP, PLP, MOG proteins, or their respective MHC class II–restricted epitopes together with complete Freund's adjuvant and pertussis toxin. More recently, a role for CD8$^+$ T cells has also been documented. The clinical picture resembles that of a relapsing remitting disease with profound neurologic symptoms. CNS histologic findings include T cell infiltration (mainly CD4$^+$ T cell lymphocytes; Figure 42.8), APC and microglia activation, and disruption of the blood–brain barrier. Some demyelination occurs, and histologic changes can undergo periods of remission that are accompanied by remyelination. The predominant cytokine profile is TH1-like, and TH2 cytokines have protective function *(312)*. Epitope spreading occurs, and activated APCs take a central role as "drivers" of the autoimmune process (133). A shortcoming of this model is the major extent of external manipulation required to break tolerance (adjuvant, pertussis). These might be necessary to affect the blood–brain barrier, skew the systemic cytokine profile to TH1 phenotype, and support prolonged inflammation.

A lesser degree of additional nonspecific inflammatory condition is required for some virus-induced animal models for MS. Infection with TMEV, which replicates predominantly in neurons (particularly motor neurons during initial stages of infection), results in a poliomyelitis-like syndrome, including flaccid paralysis. Certain strains of mice that survive the primary infection become persistently infected and develop a chronic progressive inflammatory demyelinating disease (133). Demyelination is the consequence of the CD4$^+$ T cell response to persisting TMEV and involves determinant spreading as a consequence of infection and local inflammation (133). Studies from S. Miller's laboratory have recently shown that APCs in the CNS are crucial for diversification/epitope-spreading of the initiating anti-TMEV response to other brain self-antigens such as MBP and PLP. Furthermore, when recombinant TMEV expressing PLP epitopes or modified mimic epitopes were employed, infection resulted in enhanced disease. These experiments provided *in vivo* evidence for a possible role of molecular mimicry in CNS autoimmune disease *(313)*.

Somewhat similar to TMEV, infection with neurotropic strains of mouse hepatitis virus (MHV) induces neurologic disease accompanied by demyelination *(314)*. An interesting difference is that MHV will not persist and therefore allows for easier differentiation between the antiviral and the autoimmune responses. CD4$^+$ and CD8$^+$ lymphocytes accompanied by inflammatory cytokines are needed for destruction. These virus-induced models of demyelination suggest that a transient or persisting presence of virus in the CNS may be needed in conjunction with a nontolerized antiviral response for disease induction and/or propagation *(314)*. Indeed, another animal model of virally induced CNS disease, the transgenic MBP-LCMV model developed in analogy to the RIP-LCMV model for T1D, only exhibits mild motor dysfunction, despite good lymphocytic infiltration *(315)*. It is possible that activation of APCs is insufficient in this model to locally propagate systemically induced autoaggressive lymphocytes once they have entered the parenchyma of the CNS. These considerations are depicted in Figure 42.9.

Treatment and Prevention

Similar to observations in the diabetes models *(282)*, DNA vaccines that aim to skew the autoreactive response to MBP or PLP from a TH1 to a TH2 phenotype have shown some success in the EAE model. However, it

CD4 infiltrate, hippocampus

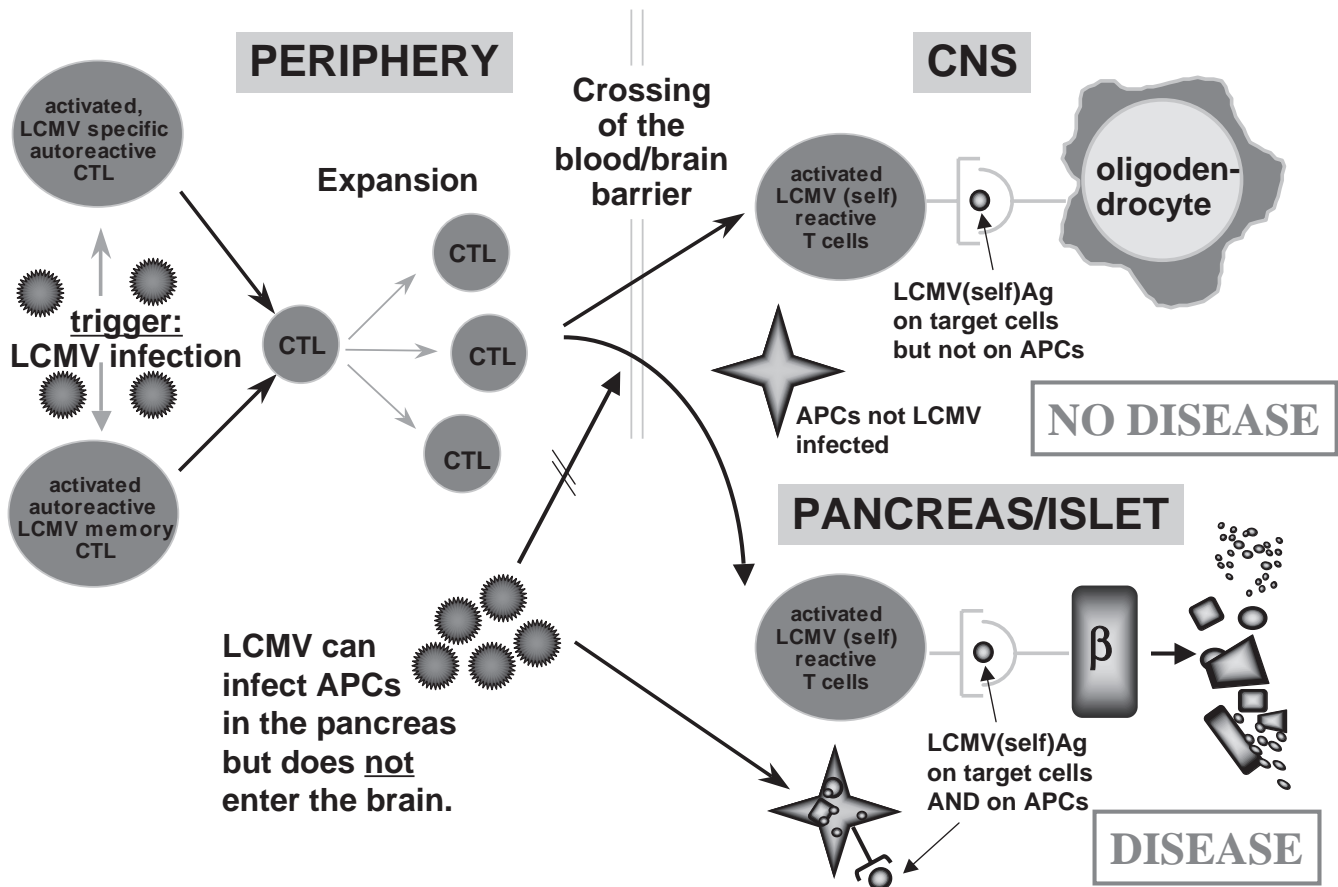
CD4 infiltrate, brain stem


FIGURE 42.9 Induction of profound autoimmune disease of the islets but only mild autoimmune infiltration in the central nervous system (CNS) in rat insulin promoter– versus myelin basic protein–lymphocytic choriomeningitis virus (LCMV) transgenic mice. Activated antigen-presenting cells (APCs) might be a crucial local driver once an autoimmune process has been initiated. This issue is illustrated well when one compares the LCMV transgenic brain and self (transgene)-directed organ-specific autoimmunity; LCMV only infects the pancreas but not the brain. Of interest, clinical disease only evolves in islets (type 1 diabetes), whereas infiltration of the brain tissue is transient, causing little damage. Ag, antigen; CTL, cytotoxic T lymphocyte.

remains to be seen whether these findings can be directly translated to humans, and clinical phase 1-2 trials are being conducted by BayHill Therapeutics (Palo Alto, CA). At least for MS there are preclinical markers that can noninvasively and continuously track the size and appearance of current lesions and in this way indicate success or failure of a given therapy in a more immediate way as compared to T1D *(316,317)*. Oral tolerance induction had shown much promise in EAE models but recently failed in a human trial *(318)*. Strong placebo effects were observed after feeding irrelevant protein versus MBP, and the outcome was therefore not conclusive, leaving a smaller read-out window. Blockade of TNFα has shown promise in animal models but not in humans (152). The antidepressive agent Rolipram is under clinical evaluation after it exhibited anti-TNF effects in animal models for MS.

From the immunologic point of view, treatment of MS is further advanced than treatment of T1D. It should be noted that life expectancy in MS is more reduced because no therapy comparable to insulin substitution is possible. Of the current regimens, IFNβ has shown very promising results in phase 3 clinical trials *(319)*. Of interest, IFNγ, in contrast, has aggravated MS *(320)*. Furthermore, Copaxone might act as a mixture of altered peptide ligands (as a polymer MBP analog), and in this way it may skew the immune responses systemically to a less aggressive phenotype and has shown promise for certain forms of early MS *(321)*. In addition, phosphodiesterase inhibitors might induce TH2 skewing, as recently demonstrated in a small-scale trial *(322)*. Finally, generalized immunosuppressive therapy with corticosteroids that are given in conjunction with relapses and thereafter slowly phased out remains an important backbone for MS treatment. Azathioprine,

cyclophosphamide, and plasmapheresis are not effective. Cyclosporin A is helpful but has profound side effects. Altered peptide ligands (APLs) to human MBP epitopes have shown strong allergic side effects and have worsened disease in one study indicating that APLs might activate both *in vivo* aggressive and regulatory lymphocytes *(323,324)*. It appears that the success of APLs can therefore vary from individual to individual. Some setbacks have been encountered with monoclonal antibodies. It is noteworthy that anti-CD40L exhibited some efficacy but led to coagulation disturbances in humans *(325)* and is on hold. In addition, integrin blockers have shown promise and have returned to clinical trials after they were on hold because combination with IFNβ had lead to reemergence of CNS viral infection in three patients.

Perspective and Conclusions

Therapeutic interventions in MS are becoming more effective but will likely have to be individualized and fine tuned with respect to the subtype of MS in a given patient. Antigen-specific therapy is in development, but better understanding of the role of T cells in MS will be needed to translate experimental findings into clinical applications. Combination of systemically acting antibodies shows good promise and will have to be further developed.

Ocular Autoimmune Diseases

Various inflammatory diseases of the eye accompany other systemic or organ-specific autoimmune disorders and are shown in Figure 42.12. Some of these diseases will be discussed very briefly because they are described in a separate chapter in this book.

Bechterew's Disease/Spondylarthoropathies

Iridocyclitis is frequently associated with Bechterew's disease (ankylosing spondylitis), which is characterized by a chronic spondylarthrosis of the ileosacral joints resulting in profound kyphosis and is associated in 30% to 50% of cases with the HLA-B27 allele *(326–328)*. Of interest, mucosal inflammation, ulcers, and vasculitis are frequently associated with this disease group. The immunologic pathogenesis is not clearly defined, but cross-reactive antibodies to bacterial proteins are frequently observed in the sera of patients with spondarthopathies such as Bechterew's disease, Reiter's syndrome, psoriasis, Crohn's disease, or ulcerative colitis. Therefore, molecular mimicry has been hypothesized as a cause for these disorders, but proof has been difficult to obtain. Several animal models have been developed, the most intriguing of which is probably a HLA-B27 transgenic rat that develops joint diseases, genital ulceration, and eye disease. Systemic immunosuppressive interventions are not effective, and the treatment of choice is nonsteroidal antiinflammatory drugs. Local steroids are frequently administered for symptoms affecting the eye.

Rheumatoid Arthritis

RA is an autoimmune joint disease (see later discussion) that is frequently associated with scleritis and episcleritis. Inflammatory infiltrates are found in the peripheral cornea leading to ulcerations. Local treatments are usually without effect, and symptoms are ameliorated in conjunction with systemic immunosuppressive therapy. In contrast, juvenile arthritis is accompanied in about 20% of patients with cataracts and iridocyclitis, and ocular symptoms are often sensitive to local and systemic immunosuppression.

Sarcoidosis

Sarcoidosis is a chronic, systemic granulomatous inflammatory disease that involves the eye (uveitis in 20% of cases) and constitutes the cause for uveitis in about 10% of patients. Multiple organs are affected, in particular the lungs. The etiology is unclear, and an autoimmune pathogenesis is suspected, with multiple inflammatory changes occurring in the eye (see Figure 42.10). Local therapy with steroids is usually helpful, and systemic immunosuppression could be considered.

Idiopathic Uveitis

About half of the cases of uveitis are not associated with a known primary syndrome, and in young adults the association (50%) with HLA-B27 is striking. Only a few of these patients will ultimately develop Bechterew's disease. Again, the etiology is quite unclear, but some evidence suggests that molecular mimicry between ocular and viral antigens, for example, herpes virus, could play a role. Peptide therapy is being evaluated; otherwise steroids are the only effective choice.

Figure 42.10 gives a summary of the eye structures and some of the systemic diseases that are associated with possible autoimmune disorders of the eye.

Animal Models

Small rodent models for autoimmune uveitis and herpes virus keratitis have been very useful for understanding the underlying immunopathology of inflammatory eye disorders.

Experimental Autoimmune Uveoretinitis (EAU). EAU is induced, similar to EAE, by immunizing susceptible rodent strains with retinal proteins such as the receptor retinoid binding protein (IRBP) *(329)*. Extensive studies by R. Caspi and colleagues have revealed that EAU follows very similar autoimmune paradigms as other experimental autoimmune diseases, including EAE and induced forms of diabetes. For example, a TH1-like response drives the aggressive EAU process *(330)*, whereas IL-10 in synergy with IL-4 has a pronounced protective function *(331,332)*.
FIGURE 42.10 Overview of the structure of the eye and some of its inflammatory diseases and their association with other systemic disorders. MS, multiple sclerosis.

Similarly, disease-resistant mice exhibit a predominantly TH2-like response to IRBP. Experimental evidence indicates that sequestration and local immune privilege of IRBP and possibly other retinal antigens leads to a lack of systemic tolerance to these proteins, and, consequently, destructive autoimmune responses can be readily induced. Conversely, tolerance can be reestablished by therapeutic application of tolerizing retinal-Ag/Ig fusion proteins, an approach that is supported by experimental induction of peripheral tolerance using transgenic antigen expression under an MHC class II promoter. Of interest, peptide therapy using an HLA-B27–restricted peptide appears to be effective in humans. The immunopathology of this EAU model in comparison to human uveitis, as found in sarcoidosis, is displayed in Figure 42.11.

Herpes Virus-induced Keratitis. Herpes virus–induced keratitis has been explored in several animal models. The most intriguing studies have come from the laboratory of H. Cantor. Inoculation of a genetically susceptible mouse strain with herpes simplex virus (HSV)-1 results in a viral infection of the eye and cornea that is accompanied by an immune response to HSV-1 (128). Of interest, damage to the eye is only initiated by the virus and strongly depends on CD4+ T cells that can cross-react with a self-protein. This animal model is one of the few that strongly indicate a direct immunopathologic role for molecular mimicry in an *in vivo* model for autoimmune disease. Studies by Rouse and colleagues have focused on the role of inflammatory bystander effects in the HSV-keratitis model *(333,334)*. In these studies, inflammatory cytokines were shown to play a major role in mediating local damage, and administration of DNA vaccine constructs expressing certain beneficial cytokines such as IL-10 ameliorated disease *(335)*.

It is important to point out that these studies were performed using a different HSV strain, and that the precise immunopathogenic process (mimicry vs. bystander effects) indeed depends on the strain of HSV used *(336)*. Additional observations have underscored the importance of regulatory cells in downmodulating a virally induced autoimmune disease. It is worthwhile mentioning that Streilein and colleagues previously demonstrated regulatory cells in ocular autoimmune disease and discovered an important role for tolerizing antigen-presenting cells *(337,338)*.

Treatment and Prevention

Due to the associated side effects, it is desirable to avoid systemic immunosuppressive interventions, as well as the local application of corticosteroids. Recently, a Munich group identified a HLA-B27–derived peptide that could function as a mimic to the retinal S antigen and induce EAU in Lewis rats *(339)*. This mimic peptide was used as an orally administered antigen and produced very promising results in two human pilot trials in Germany. Thus, antigen-specific immune modulation using retinal self-antigens or their peptide mimics may be developed as an effective therapeutic choice. It remains to be seen whether combination of such a treatment with cytokine-DNA vaccines, as demonstrated by Rouse's group for HSV keratitis or by Caspi's group for EAU, both in mouse models, might enhance efficacy. In addition, systemic immune modulation bears promise. Recently, a trial using anti-CD25 monoclonal antibody (dacluzimab) was conducted at the National Institutes for Health with promising results. It is noteworthy that in this case the dampening of effector cells rather than any effects on CD25+ Tregs appears to explain the efficacy.

Gastrointestinal Autoimmune Diseases

The gut constitutes a unique immunologic environment, given its large interactive mucosal surface area and the need to maintain tolerance toward food antigens and bacteria normally present within the gut flora. The gut-associated immune system has an important regulatory and barrier function. Immune responses are usually initiated within the Peyer's patches, which obtain a significant amount of antigen via the M cells located within the mucosa and specialized in antigen uptake and transport (136,340,341). Lymphocytes will circulate through the Peyer's patches, where B or T cell responses can be initiated. Of interest, the B cell responses are characteristically IgA high. After antigen encounter, these cells will circulate to the mesenteric lymph nodes and enter the systemic circulation. Specifically for the gut there are other extralymphoid locations where immune cells are located and where immune responses (aggressive or regulatory) can be initiated. One is the intestinal lamina propria, where MHC class II is expressed and bacterial products can be presented. Predominantly CD4 T and B cells may assume regulatory functions, and IgA is secreted with the mucus into the gut lumen. The second are intraepithelial lympho-

cytes (IELs). A significant proportion of IELs expresses the ©™ T cell receptor and have cytotoxic as well as immune-regulatory functions *(342,343)*. Certain studies after oral or intranasal feeding of autoantigens have attributed regulatory function to $\gamma\delta$ lymphocytes. Overall, the hypothesis that the gut environment is ideally suited to induce a tolerizing or regulatory immune response to antigens present in the gut lumen is of high interest and well supported by evidence from animal models (e.g., "oral tolerance") *(344)*. The rationale is that the immune system must have evolved unique mechanisms to deal with the multitude of foreign antigens present in the gut and needed as nutrients and for digestive purposes. Indeed, mice housed within a sterile environment have a shorter life span and multiple immune defects, indicating that the gut's immune system is vital for regular immune development and functions.

Pernicious Anemia and Autoimmune Gastritis

Pernicious anemia is the end stage of autoimmune gastritis observed in about 10% to 20% of patients *(345)* and represents the most common cause of vitamin B_{12} deficiency *(346)*. Autoimmune gastritis is associated with autoantibody production to parietal cells and to its secreted

product, intrinsic factor. In addition, a role for CD8 and CD4$^+$ T cells has been demonstrated *(347)*. Animal models have been developed *(348)*. Standard therapy is paternal B$_{12}$ administration. Of interest, this disease also develops in mice after thymectomy and is characterized by a relative lack of CD25$^+$ regulatory CD4$^+$ T cells (150,*349,350*).

Ulcerative Colitis

Ulcerative colitis is a chronic inflammatory disease of the gut that affects men somewhat more frequently than women. It usually begins in the distal colon and rectum and spreads proximally, resulting in severe cases of pancolitis. The hallmark is bloody mucoid diarrhea. The etiology is unclear; evidence points toward a certain genetic predisposition that has to meet triggering environmental factors. Unlike Crohn's disease, the inflammatory foci are not granulomatous and not discontinuous. Overall, inflammatory mediators are increased, but systemic symptoms are rare. Treatment is usually achieved by corticosteroids. In severe cases ulcerative colitis may require removal of the colon.

Crohn's Disease

As opposed to ulcerative colitis, Crohn's disease begins as a discontinuous, granulomatous inflammation of the proximal ileum. Ulcerations are frequent, and the disease is more severe than ulcerative colitis. The permeability of the mucosal epithelium is enhanced, which leads to a local breakdown of barrier functions and upregulation of TNF, IL-1, IL-6, and other cytokines. The immune reaction involves the whole mucosa and regional lymph nodes. In addition to standard immunosuppressive treatments, blockade of TNF appears to be promising in recent clinical trials, similar to the situation in RA *(351)*.

Hepatic Autoimmune Diseases

As an anatomic site for the induction and perpetuation of immune responses, the liver exhibits distinctive immunologic features that appear to favor an overall "tolerogenic" microenvironment. This perspective is supported by the apparent absence of liver pathology in spite of the continuous exposure to nutritional antigens and components of commensal gut flora *(352)*, the ability of viral (hepatitis B and C) and parasitic (malaria falciparum) pathogens to establish persistence, and chronic hepatitis *(353,354)*, as well as the ready acceptance of liver allografts without immunosuppression in experimental models *(355)*. Moreover, successful liver transplants in humans require comparatively less immunosuppressive therapy *(356)*, and in some cases, complete weaning of immunosuppressive drugs has been achieved without compromising the functionality of the transplant *(357)*. The prevailing notion that the liver preferentially promotes abortive immune re-

sponses and tolerance was recently challenged in a meticulous study by Klein and Crispe. Having optimized the considerable surgical feat of orthotopic liver transplants in mice, the authors conclusively demonstrated that the liver effectively initiates the bona fide activation and differentiation of specific T cell responses *(358)*. Thus, the mechanisms operative in "liver tolerance" are not the consequence of altered antigen presentation, maturation failure, or premature T cell death but instead appear to rely on the activation of poorly defined regulatory circuits by persisting antigens.

Conversely, a breakdown of such tolerance mechanisms, presciently postulated almost 100 years ago as a cause for autoimmune diseases at large (7), may contribute to pathogenesis of hepatic autoimmune disorders. Here, we discuss the three major autoimmune diseases of the liver: autoimmune hepatitis (AIH) *(359–361)*, which primarily targets hepatocytes; primary biliary cirrhosis (PBC) *(362–364)*, in which small bile ducts are destroyed; and primary sclerosing cholangitis (PSC) *(365,366)*, in which the damage is mainly focused on medium to large bile ducts. In addition, we include "halothane hepatitis" as a paradigm for an immune-mediated adverse drug reaction *(367)*.

Autoimmune Hepatitis

Introduction and Disease Description

Autoimmunity was invoked as a cause for hepatitis in the early 1950s *(368–370)*, and based on the association of AIH and antinuclear antibodies (ANAs) the term lupoid hepatitis was proposed *(371)*. AIH preferentially affects women but is observed worldwide in children and adults of both sexes in diverse ethnic groups; it represents an estimated 10% to 20% of all cases of chronic hepatitis (which for the most part is due to infections with hepatitis viruses B, C, and D) *(359,360)*. Clinical symptoms range from inapparent to fulminant disease courses, and differential diagnosis is guided by an exemplary scoring system developed by the International Autoimmune Hepatitis Group (44,*372*). The presence of autoantibodies targeting different subcellular components is commonly used to differentiate two types of AIH. The etiology of AIH is undefined, but a contribution of environmental/microbial factors and genetic predisposition, as in so many other autoimmune diseases, is invoked as a trigger for T cell–mediated, destructive autoimmunity. Finally, it is also possible that as-yet-unidentified hepatitis viruses or other chronic viral infections contribute to some AIH cases *(180,373)*.

Autoimmune Features

The presence of specific autoantibodies in AIH is a key feature in the diagnostic scoring system and the foundation for the clinical distinction of type 1 and type 2 AIH (see Table 42.2). Type 1 AIH is characterized by ANAs, a class of antibodies also observed in PBC, PSC, and other

forms of chronic hepatitis. Although smooth muscle and antiactin antibodies, atypical perinuclear antineutrophilic antibodies, and antibodies directed against soluble liver antigen and liver-pancreas antigen are specific for type 1 AIH, their combined measurements allow for a reasonable distinction from type 2 AIH and, to a certain extent, other chronic liver diseases. Ant–liver-kidney microsomal (LKM) antibodies are a serologic marker for type 2 AIH, with the majority binding the LKM1 antigen identified as cytochrome monooxygenase P450 IID6 (CYP2D6). In addition, less than 20% of type 2 AIH patients also carry autoantibodies specific for uridine diphosphate glucoronosyltransferase, designated LKM3, and 30% to 50% of patients generate antibody responses against formiminotransferase cyclodeaminase (FTCD). Of all of these targets in AIH, only one, the hepatocyte-specific asialoglycoprotein receptor (ASGPR), is cell surface expressed and may thus function as a direct immunogen for antibody-mediated hepatocyte damage. ASGPR-reactive antibodies, also not disease specific, are observed in 50% to 75% of AIH patients *(359,360,374)*. Because the generation of these autoantibodies is T helper cell dependent, it is not surprising that loss of tolerance also occurs on the T cell level, and lymphocytes isolated from the livers of patients with AIH type 2 can react *in vitro* and expand after exposure to P4502D6 antigen. This finding supports the concept of a lymphocyte-driven autoaggression and might underlie pathogenesis. Furthermore, mononuclear infiltration of the periportal areas and liver parenchyma is usually present when the disease progresses and causes the AIH-typical "piecemeal" appearance of the liver. Although evidence from animal models and human studies gives some indication that cytotoxic killing of hepatocytes could play a role, further analysis is hampered by the fact that intrahepatic lymphocytes are difficult to access in humans. The notion that defective suppressor T cell activity contributes to AIH pathogenesis, proposed more than two decades ago, was supported by recent work documenting reduced frequencies of peripheral $CD4^+CD25^+$ Treg in AIH patients as compared to healthy controls *(375)*. Cytokines also appear to play an important role in human AIH. Administration of type 1 IFN led to strong exacerbation of AIH, showing that it may play a central role in liver destruction *(376)*. IFNs upregulate MHC I and II molecules, enhance inflammation, and have strong antiviral effects. The outcome of these studies therefore argues against a role for an ongoing chronic (or acute) viral infection in patients with AIH who test negative for hepatitis virus antigen or antibodies. A negative regulatory role could possibly be attributed to IL-6 and TNFα. These two cytokines are reduced in the livers of AIH patients and have a negative effect on cytochrome P450 regulation *(377)*. As a consequence, the lower levels of IL-6 and TNF might enhance CYP2D6 expression and in this way support autoimmunity directed against CYP2D6

in patients with type 2 AIH. Finally, AIH pathogenesis is not necessarily controlled by the TH1/TH2 paradigm: $CD4^+$ T cells expressing TH1 cytokines are elevated in type 1 AIH, whereas TH2 cytokines are augmented in type 2 AIH in agreement with the high levels of CYP2D6-specific antibodies present in these patients.

Is production of autoantibodies important for AIH pathogenesis, or is it just an epiphenomenon signifying the breaking of tolerance to self-antigens? Evidence suggests that autoantibodies in AIH play a role that can be situated somewhere between T1D, in which autoantibodies and B lymphocytes likely play no pathogenetically important role in humans, and SLE, in which autoantibodies are complement fixing and enhance organ destruction. LKM antibodies found in AIH, for example, can inhibit cytochrome P450 function *in vitro* but not *in vivo* and may participate in hepatocyte dysfunction or destruction. Epitope mapping of the CYP2D6 antigen in type 2 AIH revealed two immunodominant regions spanning amino acids 256 to 269 and 181 to 245 that are recognized by most of the AIH type 2 patients' sera. Because there is a significant genetic polymorphism in humans for the CYP2D6 antigen, it is possible that patients with AIH target CYP2D6 protein selectively (LKM-1 antibodies), whereas cytochrome P4502D9 (LKM-2) is targeted in patients with drug-induced hepatitis, disulfide isomerase in halothane-induced hepatitis, or UDP-glycosyltransferases in hepatitis D virus–associated autoimmunity. As so often, identification of the major target antigens, clearly a decisive step toward a better understanding of the underlying disease process, has not yielded compelling hypotheses as to the precise pathogenetic mechanisms.

Genetic Features and Environmental Factors

No single genetic locus capable of explaining AIH etiology has been identified. HLA-DR3 and HLA-DR4 are associated with type 1 AIH, and the HLA-A1-B8-DR3 haplotype exhibits a particularly strong association with early disease onset, relapse, and the eventual necessity for liver transplantation. In contrast, type 2 AIH is associated with carriage of HLA-DR7. Genes outside the HLA loci potentially conferring disease susceptibility include complement component C4, CTLA-4, vitamin D receptor, Fas receptor, and others *(359,360,374)*.

The association with hepatitis C, D, and E virus–induced hepatitis and autoimmunity is very intriguing. However, at this point, the prevalence of hepatitis C virus (HCV) for example, exhibits drastic variations among studies performed in different countries, and autoantibody titers appear much higher in patients with HCV-negative AIH. In a more recent study it was observed that sera of 38% of chronic hepatitis C patients reacted specifically with CYP2D6, whereas none of the sera obtained from patients with chronic hepatitis B showed CYP2D6 reactivity *(376)*. Furthermore, it was discovered that HCV has

the potential to induce autoreactive $CD8^+$ T cells that cross-reactively recognize the cytochrome P450 isoforms 2A6 and 2A7, which contain sequence homology to HCV amino acids 178 to 187. In this context it may be important to emphasize that molecular mimicry also seems to be an important factor in other immune-mediated diseases of the liver. Hence, trifluoroacetyl (TFA)–protein adducts, as generated during the metabolism of halothane by CYP2E1, confer molecular mimicry to the lipoic acid prosthetic group of the pyruvate dehydrogenase complex (PDC) and other members of the 2-oxoacid dehydrogenase family (71,*208,258,378*), which in turn are major autoantigens in PBC (103). Consequently, halothane hepatitis and PBC may be linked on the level of cross-reactive autoantibodies that recognize similar target antigens. It remains to be seen whether novel subtypes of hepatitis viruses can be observed in AIH patients and whether further studies will corroborate such an association. It is likely, however, that viruses play a multifactorial role in AIH pathogenesis (similar to T1D) and that no single virus will be identified as a specific cause for liver autoimmunity.

Animal Models

Over the last 30 years, many attempts have been made to develop animal models for AIH; however, no reliable model is available that reproduces the spontaneous relapsing chronic disease course of type 1 AIH *(379,380)*.

1. In the hepatitis B virus surface antigen (HbsAg) transgenic mouse, the HBsAg is expressed in hepatocytes under control of the mouse albumin promoter. Induction of transient hepatitis is possible after adoptive transfer of activated T cells from HBsAg-primed donor mice *(381,382)*. Although not designed to reproduce features of AIH, this model has been extraordinarily helpful in understanding the role of IFNs in inducing liver damage, as well as clearing hepatitis B virus (HBV) from the liver. Results have shown that IFNs, in the absence of cytotoxicity, can purge virus from infected hepatocytes. Furthermore, induction of HBV-specific $CD4^+$ and $CD8^+$ T cell responses can be evaluated in this model. The transgenic mice exhibited profound liver damage and infiltration after transfer of HBV-specific T lymphocytes.

2. In another model system, the MHC class I molecule H-2K^b is transgenically expressed in the liver of mice that also carry transgenic T cells specific for H-2K^b. Hepatitis induction was only successful when such mice were infected with a liver-specific pathogen, indicating that bystander activation within the liver microenvironment can be very potent in causing autoimmune damage *(383)*. A similar approach was chosen in yet another model that combines liver-specific expression of a transgene [here, the immunodominant LCMV glycoprotein epitope (GP_{33})] and transgenic T cells specific for the transgene *(384)*. These mice remain tolerant to the transgene even in the presence of transferred GP_{33}-specific T cells. However, under conditions of LCMV infection and TcR-transgenic T cell transfer, these mice develop a transient form of hepatitis as indicated by elevated alanine amino transferase (ALT) levels *(384)*. Together, the foregoing findings emphasize the importance of both autoreactive T cells and generalized inflammatory alterations in the wake of microbial infection.

3. The potential pathogenic contribution of autoantibodies was recently demonstrated in a new mouse model. Injection of a monoclonal antibody derived from a patient with type 1 AIH and specific for an undefined 190-kDa cell surface protein promoted predominantly perivenular hepatocellular necrosis in mice *(385)*. However, the validity of this model remains to be critically evaluated because the pathology does not appear to closely resemble that of type 1 AIH.

4. Arguably, more compelling models have been developed for the study of type 2 AIH. DNA immunization of mice with human CYPD6 and FTCD antigens leads to the generation of LMK1 and anti-liver–cytosol type 1 autoantibodies (targeting CYPD6 and FTCD, respectively) and specific CTLs, pronounced lymphocytic infiltration of the liver, and an elevation of ALT levels indicative of liver damage *(386)*. Of interest, recent work with this model has reproduced some aspects of the genetic predisposition exerted on disease development because C57BL/6 mice demonstrated more pronounced disease than 129/Sv mice and no inflammation was observed in Balb/c mice *(387)*. Lastly, infection with a recombinant adenovirus expressing the 2D6 antigen (U. Christen and M. von Herrath, unpublished) can lead to focal and confluent liver necrosis in mice resembling that of autoimmune hepatitis (Figure 42.12). In summary, the success of most mouse models has only been partial because hepatitis was transient and induction of chronic disease appeared to be difficult to achieve. Figure 42.13 illustrates the possible pathogenetic mechanisms implicated in autoimmune hepatitis.

Treatment and Prevention

Immunosuppression is the therapy of choice for AIH. Since their introduction in 1968 *(388)*, prednisolone and azathioprine have become standard treatment regimens *(360,389)*. To a certain extent, the impressive success rate of this therapeutic approach (greater than 85% of AIH patients) may have removed the urgency to pursue basic AIH research *(380)*. Immunosuppressive therapy also improves survival of patients with severe AIH *(390)*, but no guidelines are available for individuals with minimal symptoms. End-stage AIH is an important indication for liver transplantation *(391)*. Recurrence of AIH has been reported after liver transplantation *(392)*, but was not as frequent as observed for islet transplants in T1D patients. Therapeutic

use of IFNs, effective for treatment of viral hepatitis, can worsen autoimmune liver disease *(376)* and challenges the assumption that unknown chronic viral infections of the liver, although possible initiators, maintain the active disease process.

Primary Biliary Cirrhosis

Introduction and Disease Description

PBC is a slowly progressive hepatic autoimmune disorder that primarily affects women. The disease is typically associated with high titers of antimitochondrial autoantibodies (AMAs) that presage onset of clinical disease by 5 to 10 years. Histopathologic changes include portal inflammation and destruction of intrahepatic bile ducts, which occur at various rates and degrees in different patients. The resulting decrease of bile secretion and reten-

tion of toxic substances within the liver leads to further hepatic damage, fibrosis, cirrhosis, and eventual liver failure *(362–364)*.

Autoimmune Features

Although speculation about the autoimmune pathogenesis of PBC centers around the usual suspects of genetic and environmental/microbial factors, PBC may serve as an example of how advanced knowledge about the targeted autoantigens can give rise to novel and intriguing hypotheses. The presence of AMAs in PBC were first described in the 1950s, the autoantigens cloned in the 1980s and 1990s, and B cell, CD4$^+$, and CD8$^+$ T cell epitopes of the major autoantigen PDC-E2 mapped in the 1990s and 2000s. More than 90% of PBC patients have high titers of autoantibodies directed against the 2-oxo-acid dehydrogenase complex (2-OADC) E2 subunit, in particular the

FIGURE 42.13 Pathogenesis of liver autoimmunity after viral infection in the 2D6 animal model. Viral infection leads to expression of high cytokine levels in the liver **(A).** The infection will probably also activate resident macrophages (Kupffer cells) **(B).** Antiviral T cells react against virally infected cells and destroy them. This leads to release of autoantigens from hepatocytes, which can be (cross-) presented, leading to pathogenic responses against autoantigens such as cytochrome P450 2D6. Chemokine and cytokine release **(C)** leads to enhanced inflammation and antigen presentation **(D).**

E2 component of the pyruvate dehydrogenase complex (PDC-E2) (Table 42.2). Mapping studies have identified determinants within the PDC-E2 lipoyl domains as primary targets for antibody and T cell reactivity, motifs that are also located in the E2 subunit of other 2-OADC members (OGDC-E2, BCKD-E2; the same motif is also found in E3-BP) *(363)*. Antibody reactivity to nuclear envelope proteins gp210 and p62 was observed in 10% to 30% of patients and is apparently associated with more active disease. The obvious question emerging from the identification of these autoantigens pertains to the fact that they are (a) found in every cell type and (b) located on the inner surface of the inner mitochondrial membrane, and are thus separated from immune effectors by three membranes. In addition, the existence of a clinical entity known as AMA-negative PBC, a disease very similar to PBC but without detectable AMA, appears to further argue against a pathogenic role for these autoantibodies *(364)*. Yet, certain particularities of bile duct epithelial cells may predispose them to be targets for humoral immune responses. These cells, just like salivary epithelial cells, express receptors involved in the transcytosis of IgA, and high titers of PDC-E2–specific IgA are observed in bile, saliva, and urine of PBC patients. AMA IgA was recently shown to induce apoptosis, which in turn may lead to PDC accumulation in the cytoplasm and cell surface and amplification of the immune response. Further speculation has focused on the possibility that failure of PDC glutathionylation specifically in epithelial cells may promote accumulation of immunogenic forms of PDC, a process that may be initiated by xenobiotic-modified PDC and molecular mimicry *(363)*. In the "determinant density model" *(393)*, potentially PDC-reactive T cells survive negative thymic selection due to low TcR avidity and remain "dormant" in spite of sporadic exposure to PDC-derived epitopes. However, strong inflammatory stimuli that allow for improved antigen presentation and activation of Toll-like receptors (TLRs; monocytes from PBC patients exhibit enhanced sensitivity to TLR signals), for example, through microbial molecular mimicry, may induce the breakdown of tolerance that precipitates the disease. It should be noted that the general validity of this hypothesis, including a key role for low-avidity T cells and TLRs, is fully supported by elegant studies in models for induction of autoimmune diabetes (102,394). Finally, a model has been proposed in which a primary dysfunction of endothelial cells results in overproduction of endothelins, inflammatory alterations, and ischemic damage due to vasoconstriction and the generation of PDC-specific humoral and cellular responses as a secondary event *(364)*. These hypotheses are not mutually exclusive and may be critically evaluated in two recently introduced animal models.

Genetic Features and Environmental Factors

Familial clustering of PBC and a high concordance rate in monozygotic twins (63%) indicate a genetic component to PBC pathogenesis. However, no consistent associations have been found between PBC susceptibility and carriage of particular HLA genes. Polymorphisms in vitamin D receptor and CTLA-4 genes have been suggested to be conducive to PBC development, and X chromosome monosomy in peripheral white blood cells may explain female preponderance of the disease *(363,374)*.

Animal Models

The absence of a suitable animal model has long been a serious obstacle to PBC research. However, two recent publications document important progress on this front by describing the spontaneous onset of a PBC-like disease in two mouse strains. NOD.c3c4 mice congenically derived from the NOD strain generate PDC-E2–specific autoantibodies and exhibit biliary pathology characterized by destructive cholangitis, granuloma formation, and

eosinophilic infiltration. It is significant that T cells were observed in affected areas of the biliary epithelium and that transfer of splenocytes or CD4$^+$ T cells induces disease in NOD.c3c4-SCID recipients, suggesting a central role for T cells in pathogenesis *(395)*. In the second model, abolition of TGFβ signaling in T cells (achieved by T cell–specific expression of a dominant-negative TGFβRII) resulted in the production of AMAs directed against PDC-E2, BCOADC-E2, and OGDC-E2, as well as lymphocytic liver infiltration with periportal inflammation analogous to the histologic profile in human PBC. These observations implicated the TGFβ pathway in PBC pathogenesis and suggested that the activation of intrinsically self-reactive T cells was a consequence of impaired regulatory T cell function rather than molecular mimicry *(396)*.

Treatment and Prevention

It is noteworthy that despite its presumed autoimmune etiology, PBC is not ameliorated by immunosuppressive therapy. In the absence of optimized therapeutic protocols, treatment is tailored according to individual responsiveness of PBC patients and includes management of disease symptoms (pruritus, osteoporosis, hyperlipidemia, and portal hypertension) and therapy of the underlying disease by stepwise addition of ursodeoxycholic acid (UDCA), colchicin, and methotrexate. Nevertheless, the use of colchicin and low-dose methotrexate, presumably acting as an immunomodulatory rather than antimetabolic agent, is controversial. In cases of liver failure, orthotopic liver transplantation is the only effective treatment *(362)*.

Primary Sclerosing Cholangitis

Introduction and Disease Description

PSC is a chronic cholestatic liver disease (cholestasis: suppression of biliary flow) frequently associated with inflammatory bowel disease (greater than 75% of PSC patients). It is characterized by fibrotic inflammation and destruction of the large intra- and extrahepatic bile ducts and may lead to the development of cholangiocarcinoma (in 10% to 30% of PSC patients) and ultimately death by liver failure.

Autoimmune Features

Although the etiology of PSC is undefined, a complex multistep process has been delineated and involves cholangiocyte activation through bacterial pathogen-associated molecular patterns (PAMP), production of proinflammatory cytokines in conjunction with aberrant chemokine expression and endothelial cell adhesion molecules, and the recruitment of T cells presumably specific for enterocyte antigens and primed in GALT *(366)*. The generation of autoantibodies is a common feature (Table 42.2), but most

antibodies are not specific for PSC and their contribution to disease pathogenesis is unclear *(374)*.

Genetic Features and Environmental Factors

As in AIH, susceptibility to PSC is conferred by HLA-B8 and DR3. Whether a CTLA-4 polymorphism is associated with disease susceptibility is controversial *(366)*. The relative risk of PSC among first-degree relatives of PSC patients is almost 100-fold increased compared to the general population *(365)*.

Animal Models

None of the animal models developed reproduce all pertinent aspects of human PSC *(397)*. Rat models of small bowel bacterial overgrowth and administration of bacterial cell wall components have provided some support for an ethiopathogenetic role of PAMPs. Other models include injury of biliary epithelial or vascular endothelial cells (rodents, dog, monkey) and toxic, infectious, or intraluminal biliary injury (rodents) permitting the study of cytokines, chemokines, and inflammation in the development of diffuse bile duct sclerosis *(397)*.

Treatment and Prevention

There is no effective medical therapy for PSC *(398)*. Treatment with the hydrophilic bile acid UDCA improves liver enzymes, but its effect on liver histology and prognosis is inconclusive. Orthotopic liver transplant constitutes the only established long-term treatment for PSC, with cumulative 5-year survival in approximately 70% of patients.

Halothane Hepatitis

Halothane hepatitis is a severe, life-threatening form of hepatic damage that affects a small subset of individuals exposed to the anesthetic agent halothane *(399)*; it is believed to have an immunologic basis. Sera of afflicted individuals contain autoantibodies directed against the native and the TFA form of hepatic proteins. TFA proteins are generated during the oxidative metabolism of halothane (2-bromo-2-chloro-1,1,1-trifluoroethane) and include cytochrome P450, protein disulfide isomerase, microsomal carboxlesterase, calreticulin, Erp72, GRP78 (BiP), and GRP94. Evidence suggests that such TFA proteins arise in all individuals exposed to halothane. However, the vast majority of individuals appear to tolerate this covalent protein modification. The lack of immunologic responsiveness was suggested to occur due to tolerance induced through the presence of structures in the repertoire of self-determinants, which immunochemically and structurally mimic TFA proteins very closely. In fact, lipoic acid, the prosthetic group of the constitutively expressed E2 subunits of members of the 2-oxoacid dehydrogenase complex family, was demonstrated by immunochemical and molecular modeling analysis to perfectly mimic

N^6-trifluoroacteyl-L-lysine, the major haptenic group of TFA proteins. Of interest, a fraction of patients with halothane hepatitis exhibited irregularities in the hepatic expression levels of these cross-reactive proteins. Thus, molecular mimicry of TFA-lysine by lipoic acid or the impairment thereof could be considered a susceptibility factor for individuals developing halothane hepatitis *(400)*. A small-animal model for chemically induced liver diseases has been described *(401)*.

Perspective and Conclusions

The presence of autoantibodies in AIH, PBC, and PSC is indicative of autoimmune processes, but none of the antibodies described is liver specific, and their contribution to pathogenesis is unclear. Although the complex role of T cells is subject to investigations, the same caveats regarding specificity and pathogenicity discussed earlier apply for autoimmune liver diseases *(402)*. Although the success of immunosuppressive therapy—in fact a criterion for the diagnostic scoring system for AIH *(44,372)*—further supports autoimmune etiology for AIH, it is conceivable that a viral infection might initiate disease as a "hit-and-run" event. Following elimination of viral antigens, disease may be perpetuated by immune-mediated processes and preclude the identification of a particular virus as a causative agent at the time of liver disease diagnosis. Again, the role of "foreign" and "self"-antigens becomes blurred, and their interactions with the immune system in terms of immunity or autoimmunity are conceptually problematic. Future investigations should seek to improve animal models and focus on human autoantigens and the application of contemporary tools for identification and isolation of specific lymphocytes. On the basis of such developments, future *in vivo* tracking of autoaggressive lymphocytes with noninvasive methods should substantially improve our insight into disease pathogenesis.

Renal Autoimmune Diseases

Glomerolunephritis (GN) is the major cause of chronic renal disease and kidney failure and exhibits a wide spectrum of histopathologic alterations, disease severity, and clinical outcomes. In most cases, evidence for an immune-mediated pathogenesis, including humoral and cellular responses, has been obtained *(403–406)*. The precise incidence of defined renal autoimmune disease is difficult to establish because definite diagnosis requires histologic evaluation of the kidneys. In this respect, the Italian registry of renal biopsies provides a unique repository, and information about selected glomerular disease obtained from this resource is displayed in Table 42.3 *(407,408)*. The identity of nephritogenic antigens targeted in most renal autoimmune diseases is poorly defined, with the no-

table exception of Goodpasture's syndrome, a form of anti–glomerular basement membrane (GBM) disease in which autoantibodies bind to $\alpha 3$(IV) collagen in the GBM and are associated with rapidly progressive GN and pulmonary hemorrhage. Conformational epitopes have been mapped to two regions within the noncollagenous (NC1) domain of the $\alpha 3$(IV) chain *(409)*. A role for T cells, both in providing help for autoantibody production and exerting direct effector functions, has also emerged in recent years. Cast within the reigning concept of balanced TH1 and TH2 immunity, it appears that TH1 responses are associated with proliferative and crescentic forms of GN that cause severe injury, whereas TH2 responses are associated with membranous patterns of injury *(403)*. These distinctions have also given rise to speculations that have harnessed the "hygiene hypothesis" as a potential explanation for the observation that proliferative GNs have a relatively high incidence in developing countries, whereas minimal-change disease and IgA nephropathy predominate in developed countries. Therapeutically, immunosuppression with corticosteroids, in combination with cyclophosphamide and plasma exchange (to remove damaging antibodies), is employed to manage diseases. Based on the TH1/TH2 paradigm and its role in developing therapies for other autoimmune diseases that aim to target the TH1-TH2 balance, therapeutic approaches such as oral tolerance, cytokine-based immune modulation (anti-TNFα and IL-12p40 antibodies, recombinant IL-10), antiadhesion molecules, and chemokine receptor blockade are being evaluated for use in the treatment of autoimmune renal diseases *(403)*.

Cutaneous Autoimmune Diseases

Cutaneous autoimmune disorders are commonly divided into non–organ-specific and organ-specific diseases. The former group contains skin manifestations of systemic autoimmune disorders such as SLE, Crohn's disease, and ulcerative colitis, and this group is detailed in Chapter 41. The organ-specific autoimmune skin disorders discussed

▶ **TABLE 42.4 Autoimmune Bullous Dermatoses**

Disorder	Acantholysis	Autoantigen	Autoantibody Class	T Cell Subset
Pemphigus vulgaris (PV)	Suprabasilar	Desmoglein-3 > desmoglein-1	IgG4, IgG1, IgA (occasionally)	TH1, TH2, Tr1, CD8+ CD28− Treg
Pemphigus folicaeus (PF)	Subcorneal	Desmoglein-1	IgG4, IgG1	TH1, TH2
Bullous pemphigoid (BP)	Subepidermal	BP180, BP230	IgG1, IgG4, IgA (occasionally)	TH1, TH2
Cicatricial pemphigoid (CP)	Subepidermal	BP180 > BP230, laminin 5	IgG1, IgG4, IgA (occasionally)	TH1
Pemphigus gestationis (PG)	Subepidermal	BP180, BP230	IgG1, IgG3	TH1, TH2
Dermatitis herpetiformis (DH) (associated with gluten-sensitive enteropathy)	Subepidermal	Epidermal transglutaminase	IgA	TH2
Linear IgA disease	Subepidermal	BP180, BP230	IgA	TH1, TH2
Epidermolysis bullosa acquisita (EBA)	Subepidermal	Collagen VII	IgG, IgA, IgM (occasionally)	TH1, TH2, no Treg contribution

Ig, immunoglobulin.

here include several autoimmune bullous dermatoses, as well as pigmentation disorder vitiligo. Despite a relative paucity of animal models for human autoimmune skin disorders, the skin is one of the few organs that offer direct access to target antigens and effector cells; consequently, advanced insights into mechanisms of disease induction and perpetuation have been obtained in recent years.

Autoimmune Bullous Dermatoses

Autoimmune bullous dermatoses comprise a group of severe, possibly fatal skin disorders characterized by erosions and blisters of skin and/or mucous membranes (Table 42.4, Figure 42.14). The term "pemphigus" (from the Greek and Latin for "pustule") that is featured in the name of several of these diseases dates to "pemphigoid fever" described by Hippocrates nearly 2,400 years ago and has been used to describe chronic blistering skin conditions since

the mid-18th century. All forms of pemphigus have distinctive characteristics, but they exhibit the common feature of epidermal cell-to-cell detachment known as acantholysis. On occasion, pemphigus syndromes are associated with other autoimmune diseases such as SLE, RA, myasthenia gravis, pernicious anemia, and Hashimoto's thyroiditis.

Pemphigus Vulgaris

Pemphigus vulgaris (PV) is the most common and severe form of pemphigus in the United States, constituting more than 80% of reported cases *(410,411)*. With a worldwide incidence of 1 to 5 cases per million per year in the general population, PV remains a rare disease and preferentially affects individuals in the fourth to sixth decade of life. Clinical features include flaccid, fragile, and noninflammatory bullae (from the Latin for "bubble") that arise on normal-appearing skin. These lesions tend to coalesce and rupture, leaving larger areas of denuded skin
FIGURE 42.14 Different layers of the skin and their involvement in autoimmune skin syndromes. IgA, immunoglobulin A.

that often heal poorly *(410–412)*. About half of the patients initially present with lesions confined to the oral mucosa, although any surface with squamous epithelial tissue may be affected. Blister formation begins with edema of epidermal intracellular spaces and progresses to complete loss of cohesion between epidermal cells. In PV, blisters occur in the suprabasilar region of the epidermis while leaving attachment of basal cells to the dermis largely intact *(410–414)*.

Autoimmune Features. The hallmark of PV is the presence of autoantibodies generated against the desmosomal glycoprotein desmoglein-3 (Dsg3) (Table 42.4). In fact, the unequivocal identification of this antigen makes PV one of a few human autoimmune diseases for which the relevant autoantigen has been defined. Although the pathogenic contribution of Dsg3 antibodies has been demonstrated in passive transfer experiments, recent work has emphasized the importance of specific T cells *(415)*. Peripheral CD4$^+$ and occasional CD8$^+$ T cell responses targeting Dsg3 with varying functional profiles (TH1 and TH2) have been described. These autoreactive CD4$^+$ T cells may be involved in the coordination of specific B cell responses as evidenced by TH1-regulated IgG1 and TH2-regulated Dsg3 antibodies in patient sera. Of interest, IL-10–producing, Dsg3-reactive T cells have also been identified in the majority of healthy individuals carrying PV-associated HLA alleles (see later discussion) but were described in less than 20% of PV patients *(416)*. Given these functional attributes reminiscent of the Tr1 regulatory T cell subset as well as the documentation of CD8$^+$CD28$^-$ T cells with potential regulatory function in remittent PV patients (cited in ref. *415*), it has been proposed that clinical disease may emerge as a consequence of an imbalance between autoreactive pathogenic and Tregs *(415)*.

Genetic Features and Environmental Factors. Although PV can affect anyone, an enhanced prevalence is observed in people of Mediterranean or Jewish ancestry. Associations with certain HLA alleles (HLA-26, HLA-B38, SC21, HLA-DR4) in Ashkenazi Jews and non-Ashkenazi Jews (HLA-Drw6) have been detected in PV patients, and it has been suggested that the third hypervariable region of the β1 chain of the DRB1 allele may constitute a susceptibility locus *(410–412)*. Although PV may be associated with other autoimmune diseases *(414)*, its occurrence with certain malignant diseases has been defined as a separate entity *(417)*.

Animal Models. The pathogenic role of autoantibodies has been demonstrated by passive transfer of PV patient sera into neonatal mice *(418)*. More recent studies using Dsg3-deficient mice have established that loss of tolerance and induction of autoimmunity required the presence of both autoreactive B and T cells *(419–421)*. Finally, CD4$^+$ T cells from Dsg3-immunized, HLA transgenic mice target

Dsg3 epitopes identical to those identified in humans and thus constitute a promising model with which to further analyze the regulation of Dsg3-specific T cells and autoantibody production *in vivo (415)*.

Treatment and Prevention. Corticosteroids are the treatment of choice, and supplementary immunosuppressive agents (cyclophosphamide, azathioprine, and methotrexate) are commonly used to reduce the side effects of steroids. In severe cases, plasmapheresis may be of short-term benefit.

Other Autoimmune Bullous Disorders

These include pemphigus foliaceus (PF), bullous pemphigoid (BP), cicatricial (scarring) pemphigoid, epidermolysis bullosa acquisita, dermatitis herpitiformis, and linear immunoglobulin A disease (Table 42.4). Two forms of PF are recognized, one affecting individuals irrespective of ethnic background or geography and the other, PF fogo selvagem (Portuguese for "savage fire"), endemic to certain regions of Brazil. Antibodies found in the circulation of PF patients preferentially target desmoglein-1, are of the IgG4 subclass, and, similar to PV, can induce aspects of the disease in a neonatal mouse transfer model *(410)*; TH1 and TH2 T cells specific for the same antigen have also been described *(415)*. Information about genetic association is incomplete due to the rarity of PF. However, PF fogo selvagem demonstrates associations with HLA-DR1 and HLA-DR4. Prior to the introduction of corticosteroids, fewer than 10% of patients underwent spontaneous remission, and fatalities reached up to 40% within the first 2 years of disease. Compared to PV, PF patients respond more rapidly and to smaller doses of corticosteroids *(410)*.

Together with PV, BP belongs to the best-characterized bullous disorders with regard to pathogenesis. In BP, IgG autoantibodies are directed against components of the dermoepidermal basement membrane such as BP antigens BP180 and BP230. Again, these antigens are also recognized by CD4$^+$ T cells and comprise both TH1- and TH2-type subsets *(415)*. Systemic corticosteroids with facultative addition of other immunosuppressive agents are used as treatment. The principal autoimmune targets and basic pathologic features of the remaining bullous dermatoses are listed in Table 42.4.

Perspective and Conclusions

The identification of relevant autoantigens, a task that is far from complete in the majority of human autoimmune diseases, is usually considered to be a critical step in understanding pathogenetic mechanisms and an important step toward the development of targeting immunomodulatory therapies. However, the case of PV and BP is a telling reminder that even with established knowledge about such primary autoantigens, the development of specific immunotherapies faces continuing challenges.

Vitiligo

Introduction and Disease Description

Vitiligo is an acquired, noncontagious disorder of pigmentation resulting from melanocyte loss *(422,423)*. The disease is characterized by defined areas of depigmentation that range from limited numbers of macules (focal vitiligo) to bilateral, symmetric distribution of the lesions (generalized vitiligo, the most common type) to involvement of the complete body surface area (universal vitiligo). Vitiligo is arguably the most common pigmentary disorder, affecting 0.5% to 2% of the population worldwide, and it demonstrates no predilection for gender or ethnicity. Although commonly regarded as a pathophysiologic entity with distinct clinical manifestations, recent work suggests the existence of a spectrum of vitiligo disorders with different etiologies. The potential autoimmune etiology of vitiligo has been discussed for some time and has gained traction through recent studies on genetic epidemiology. A combination of environmental, genetic, and immunologic factors is thought to contribute to autoimmune melanocyte destruction. This hypothesis is further strengthened by the reported association of vitiligo with other autoimmune diseases such as autoimmune thyroid disease, SLE, Addison's disease, and pernicious anemia *(424)*. Nevertheless, the specific causes of vitiligo are obscure, and progress is limited due to a lack of a clear definition of the disorder as well as a dearth of experimental animal models *(423)*.

Autoimmune Features

T cell infiltrates were reported in generalized vitiligo and exhibited molecular signatures indicative of CTL and TH1 responses (TNFα and IFNγ) *(425)*. CD8$^+$ T cells tend to predominate in vitiligo lesions, and high frequencies of MelanA-specific CD8$^+$ T cell subsets apparently correlate with disease severity *(426,427)*. Additional infiltrating cells include macrophages, monocytes, and DCs that produce proinflammatory cytokines. The role of DCs in local immune responses is unclear, but the DC-mediated killing of melanocytes has been suggested as a mechanism for depigmentation *(428)*. Finally, circulating autoantibodies, including those specific for the melanocyte antigen tyrosinase-related protein-1 (TRP1), have been identified in the sera of vitiligo patients, and TRP1-specific antibodies can induce melanocyte loss in mice *(429)*. Nevertheless, there appears to be an emerging consensus that alterations of humoral immunity are secondary to T cell–mediated autoimmune destruction.

Genetic Features and Environmental Factors

Evidence for genetic factors contributing to onset of generalized vitiligo has been obtained in studies of vitiligo patients' close relatives *(424,430)*. The largest vitiligo twin study demonstrated concordance for generalized vitiligo in monozygotic twins of 23%, far greater than the risk for nonidentical siblings (6.3%) and the general population risk *(424)*. At the same time, these data highlight the critical importance of environmental factors. Genetic association and linkage studies have revealed an association between vitiligo and HLA-DRB1, DLRB4, and DQB1 alleles as well as other genes, many of which await confirmation *(422,423)*. It is worth noting that the first vitiligo linkage data excluded a single candidate gene, the microophthalmia-associated transcription factor (MITF). MITF appeared to be a relevant candidate due to numerous mutations at the mouse microphthalmia (*mi*) locus associated with reduced or absent pigmentation and with the *mivit/vit* mutation presenting postnatal depigmentation that resembles human vitiligo *(431)*.

Animal Models

The lack of a tractable experimental animal model has clearly hampered progress in vitiligo research. Nevertheless, the mutant Smyth line of chickens exhibited several relevant clinical features, including melanocyte loss as a consequence of T cell infiltration *(432)*. Furthermore, the potential contribution of herpes virus infection to vitiligo induction in Smyth-line chickens *(433)* emphasizes the role of environmental factors and warrants further investigation into this model.

Treatment and Prevention

Routine nonsurgical repigmentation strategies include phototherapy, topical steroids, and inhibitors of the calcineurin pathway. These treatment modalities, although interfering with a multitude of complex pathophysiologic pathways, modulate in particular the activity of local T cell responses.

Perspective and Conclusions

In addition to genes involved in aberrant immune regulation, more than 120 genes are known to participate in the coordination of mammalian pigmentation. However, the recent identification of several candidate genes and genetic linkages associated with vitiligo will facilitate the elucidation of biological pathways involved in vitiligo pathogenesis and allow for a better differentiation of the spectrum of vitiligo disorders. As a result, novel therapeutic and prophylactic approaches will likely be developed in the near future.

Cardiac Autoimmune Diseases

The etiology for primary myocarditis is unclear, and an autoimmune cause has to be taken into account. The heart muscle is infiltrated mainly by CD4$^+$ T cells and macrophages, and the infiltrates are usually diffuse and nonfocal. The infiltrating cells produce considerable amounts of IFNγ and TNFα. As a consequence of the

inflammation, heart muscle cells can swell, the heart can dilate, and severe disturbances of the electrical conduction can occur. It is noteworthy that myocarditis can also occur in conjunction with certain systemic autoimmune diseases such as SLE, scleroderma, RA, polymyositis, and polyarteritis nodosa. Two specific scenarios are noteworthy.

The first is myocarditis occurring after Chagas' disease. In this case, cross-reactivity between antigens presented by the parasite causing Chagas' disease (*Trypanosoma cruzi*), and cardiac myosin has been observed in patients with myocarditis *(434)*. The scarcity of parasites in the chronic phase of the disease contrasts with the severe cardiac pathology observed in approximately 30% of persistently infected patients and suggests a role for autoimmunity as the origin of the pathology. In these cases, various *T. cruzi* antigens, such as B13, cruzipain, and Cha, cross-react with host antigens at the B or T cell level, and their role in pathogenesis has been widely studied. Immunization with those antigens and/or passive transfer of autoreactive T lymphocytes in mice leads to clinical disturbances similar to those observed in Chagas' disease patients. On the other hand, the parasite is becoming increasingly detected in chronically infected hosts and may also be the cause of pathology either directly or through parasite-specific mediated inflammatory responses. Thus, the issue of autoimmunity versus parasite persistence as the cause of Chagas' disease pathology is being hotly debated.

The second scenario is coxsackie B virus–associated myocarditis. Also in this situation, immunopathology outlasts the direct presence of the virus in heart muscle. This disease has been extensively studied in experimental models by Rose and colleagues *(435)*. They developed two murine models of myocarditis—one elicited by cardiotropic CoxB3 virus infection and the other by cardiac myosin immunization—to better analyze the pathogenetic mechanisms responsible for immune-mediated heart muscle disease. Both virus infection and myosin immunization produce myocardial inflammation and elicit heart-reactive antibodies that bind to the myocardium *in vivo* and recognize the cardiac myosin heavy chain. Each model offers unique advantages. The virus-induced disease more closely resembles human myocarditis; myosin immunization isolates the autoimmune components of the disease because no virus infection is involved. They also distinguished strains of mice resistant to autoimmune myocarditis (such as B10.A) from those susceptible to the autoimmune phase of disease (such as A.CA and A/J). Mice from a resistant strain to virus- or myosin-induced autoimmune heart disease develop myocardial inflammation and myosin antibodies if cotreated with TNFα or IL-1 when infected or immunized. Thus, cytokines can modulate the outcome of cardiotropic virus infection and enhance its autoimmune sequela. They also found that blocking IL-1 receptor inhibits autoimmune myocarditis in genetically susceptible

mice. Of interest, there is no regulatory function of TH2 cytokines such as IL-4, illustrating that immune regulation is an organ-specific concept rather than a global paradigm applicable to all autoimmune disease equally.

Rheumatoid Arthritis

Although RA is commonly classified as a systemic autoimmune disease, we believe that it can offer insights and paradigms that are important for understanding organ-specific diseases such as T1D and MS. A particularly interesting aspect is that diagnostic or therapeutic access to the target organ is comparatively easy achieved, and this has facilitated the development of rational and highly effective immunotherapies. In this case high levels of TNFα were detected in affected joints, and TNF blockade has proven to be a highly effective intervention in RA (see more detailed description later).

Introduction and Disease Description

RA is a severe debilitating disease with unknown etiology. Epidemiologically, the prevalence is about 1% in the overall population; women are affected three times more frequently than men, and the peak of incidence is within the fourth to sixth decades of life (147,*436*). Diagnostic criteria include typical morning stiffness, joint swelling with fluid accumulation, defined radiologic changes, subcutaneous rheumatic nodes, and positive rheumatoid factor (autoantibodies). The prognosis is worse in HLA-DR4–positive patients, and, similar to diabetes and MS, there is genetic linkage with certain MHC haplotypes (Figure 42.15). Without systemic immunosuppressive or antiinflammatory therapy, the disease eventually
Typical ulnar deviation and swan's neck deformation of the hands in rheumatoid arthritis

FIGURE 42.15 Rheumatoid arthritis.

results in destruction of many major joints and immobilizes the patient. The major cause of death is infections that easily take a more severe course in immobile individuals (147).

The etiology of RA is ill defined. Because there is a possible overlap with infection-associated arthropathies (e.g., Reiter's syndrome), bacteria have always been good candidates as a cause for arthritis, and molecular mimicry has been implicated because cross-reactivity of autoantibodies between self and bacterial proteins have been detected (111). However, although it is quite possible to demonstrate cross-reactive antibodies and T cells in human blood, proof of their pathogenetic involvement is exceedingly difficult to obtain. The immune system is likely to have developed to tolerate a low-level cross-reactivity, which might even be necessary for its proper function, and it is very difficult to prove a mechanistic link between autoreactive cells and pathologic autoimmunity in humans.

Autoimmune Features

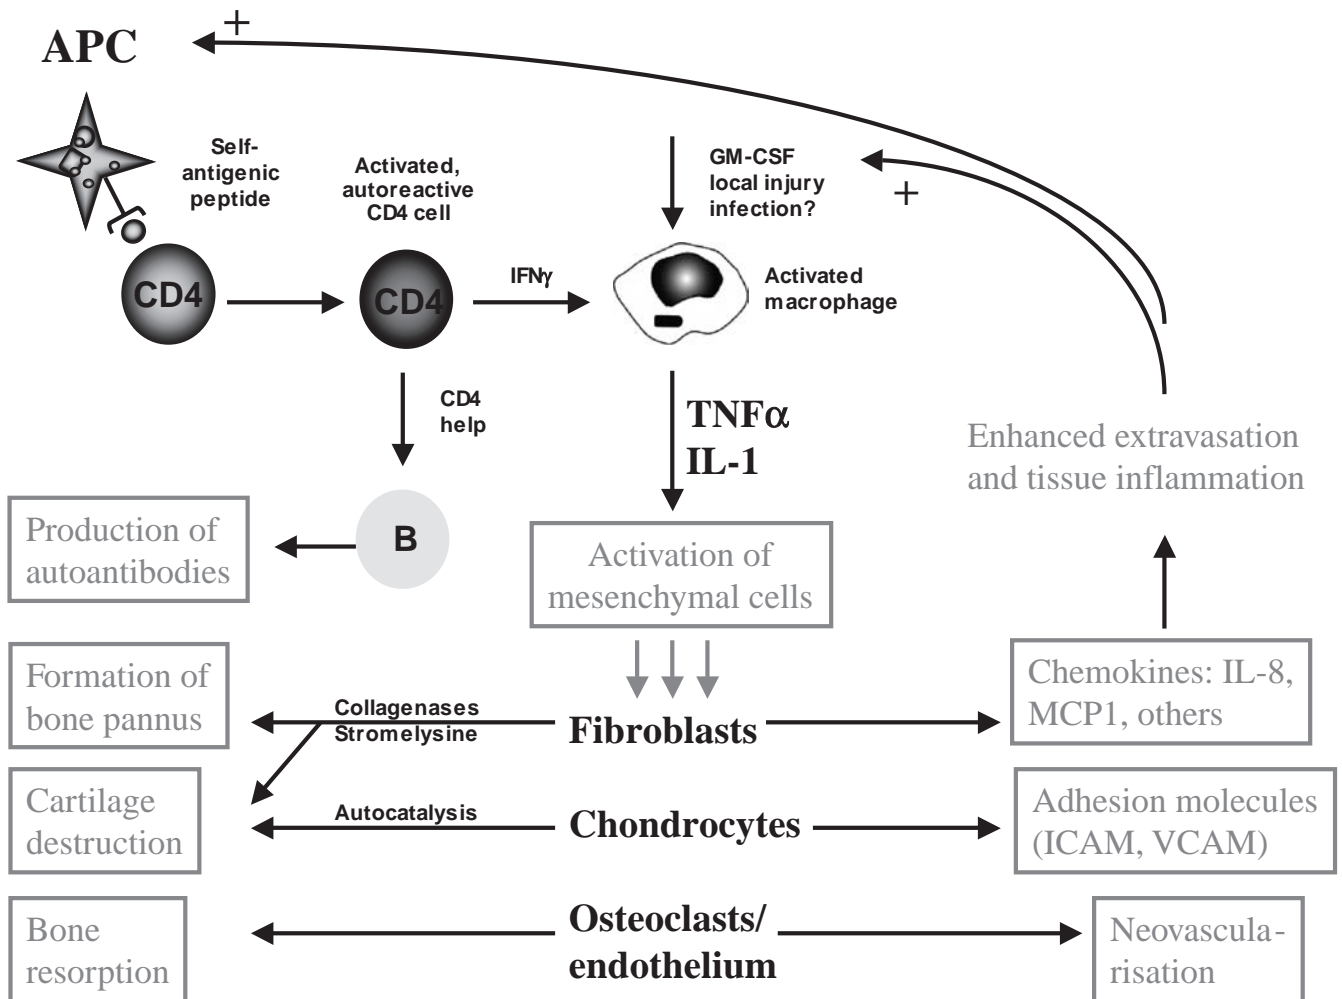
The evidence that RA is an autoimmune disease stems, as in the case of MS and T1D, from the observation that T lymphocytes in a patient's blood can react with joint-derived autoantigens, and IgM autoantibodies, as well as ANAs, are readily found in humans *(437)*. Inflammatory signs in the serum include complement activation and increased erythrocyte sedimentation rate, which indicates that the antibodies could possibly play a role in the disease process. Similarly, immunization with collagen can induce arthritis in susceptible mouse strains. Figure 42.16 summarizes the major pathogenetic pathways leading to progressive joint destruction. As in many other autoimmune disease animal


FIGURE 42.16 Pathogenic pathways leading to joint destruction in rheumatoid arthritis (RA). Note the central role of tissue necrosis factor-α (TNFα), which is strongly supported by the fact that TNF blockade ameliorates RA in humans. APC, antigen-presenting cell; GM-CSF, granulocyte-monocyte colony-stimulating factor; ICAM, intercellular adhesion molecule; IFNγ, interferon-γ; IL, interleukin; MCP1, monocyte chemotactic protein-1; VCAM, vascular cell adhesion molecule.

models, collagen-induced arthritis models require strong immunization with autoantigens and adjuvant, supporting the concept that breaking of self-tolerance, even on a genetically susceptible background, requires a rather pronounced inflammatory stimulus. In contrast, how disease is initiated in humans is unclear.

Treatment and Prevention

Treatment of RA is a difficult task because the medications that adequately suppress joint inflammation also have strong systemic side effects. Therefore, a delicate balance between different therapeutic approaches that target different stages of the inflammatory process needs to be established. Corticosteroids and nonsteroidal antiinflammatory drugs can provide some baseline relief but are not able to halt progressive joint destruction. Gold compounds, methotrexate, and cyclophosphamide are more effective but also have profound systemic side effects. For this reason, progress with novel immunomodulatory interventions is of important benefit for RA patients.

Application of cyclosporin A was shown to be effective by suppressing proliferation and activation of T lymphocytes. More recently, a more selective intervention has been established based on research by M. Feldman's group (146). TNFα was found to play a key role in an *in vitro* model of synovial destruction using human cells, and TNFα-blocking agents to be applied *in vivo* were subsequently developed. After promising preclinical results in animal models, this intervention was tested in clinical trials and is now licensed for treatment of RA. Although side effects do occur, as expected, they appear tolerable, and clinical improvement of disease is pronounced. In some patients, SLE-like symptoms were observed, indicating that blocking a cytokine beneficial for one autoimmune disorder might be detrimental for another. Indeed, TNF blockade is not helpful in MS and T1D because this cytokine exhibits complex dual functions, depending on the disease stage. Based on encouraging results with TNF blockade in RA, it may be possible to find similar key cytokines for T1D or MS treatment. It should be stressed that the successful intervention was developed based on human cell cultures and not animal models, underlining the need for direct research on human materials, if and when possible.

CONCLUSION

A common trait among diverse animal models for autoimmune diseases and the human conditions they aim to model appears to be the difficulty with which experimental autoimmunity is achieved. Breaking of tolerance to self-antigens requires in most cases strong inflammatory (e.g., pertussis toxin and adjuvant in EAE or collagen-induced arthritis) or infectious (e.g., RIP-LCMV model for T1D, and TMEV/MHV models for MS) stimuli. In addition, many animal models require a genetically susceptible background or have to rely on artificial autoantigen expression by means of transgenic technology. In contrast to the relatively easy detection of autoreactive lymphocytes in antigen-induced animal models, it has been a daunting endeavor in humans (as well as spontaneous disease models such as the NOD mouse), and data obtained often vary considerably among different patients as well as laboratories. What are the implications for our understanding of autoimmune diseases in humans, given these challenges? First, it is unlikely that strong inflammatory stimuli could be provided under natural conditions in the absence of infectious disease. Thus, viral and bacterial infections remain prime candidates for causing secondary autoimmunity (see Miller's TMEV model of APC-mediated determinant spreading to autoantigens). Infectious pathogens could provide the "danger signals" (P. Matzinger) needed for propagation of extended inflammation leading to clinical disease. Nevertheless, proof of a causal relationship is exquisitely difficult (if not impossible) because traces of pathogens detected may have no relation to the underlying disease process or may be cleared from the system by the time of secondary clinical disease. In addition, disease is likely to depend on individual pathogen strains, making a very detailed immunologic profiling in prospective clinical trials necessary. It is possible that the introduction of new antiviral treatments might unmask such an association in the future. Second, a genetically susceptible background could be required to provide a fertile field for initiating a chronic inflammation involving autoantigens. This probably occurs via a multifaceted network of multiple susceptibility and protective genes, and it will be impossible to treat a respective disease just by analyzing the background genes involved. Lastly, autoreactive lymphocytes might predominantly be present in the affected organ or site and not in the peripheral blood, which makes their identification and characterization in humans rather difficult.

A note of caution should be devoted to our interpretation of specific findings obtained in individual animal models. Animal models should serve to teach us paradigms of how a disease could develop kinetically *in vivo*. The precise parameters, targeted antigens, susceptibility genes, and effector molecules may be considerably different in humans. Thus, for example, if there is an indication that insulin is a primary antigen in the NOD mouse, this may or may not have direct relevance to the human disease. Recent evidence leads us to believe that insulin, indeed, may also be a primary antigen in human autoimmune diabetes, but other antigens such as GAD might also play a role. The opportunities as well as limits of each animal model have to be delineated. Again, the NOD mouse appears to be prone to multiorgan autoimmunity [induction of EAE *(438)*, neuritis *(439)*, arthritis, and hepatitis have all been observed in NOD or NOD-congenic mouse

strains] and exhibits, in addition to diabetes, thyroiditis, sialitis, and orchitis. Thus, diabetes in the NOD mouse is clearly different from typical human T1D. Therefore, treatments capable of correcting the systemic immune dysregulation that predominates in the NOD model may not directly apply to human T1D, where no such pronounced systemic dysregulation is present. Based on these considerations, it is not surprising that of the more than 140 therapeutic strategies that prevent diabetes in the NOD mouse, only a handful have made it to phase 1 human trials. Experiments with human cells or materials should be undertaken to solidify the choice of molecules or target antigens. The successful story with respect to blockade of TNFα to treat RA underlines the importance of this step. Employment of a multiplicity of models thus becomes imperative to evaluate potential candidate interventions, as does a careful proceeding, objective evaluation, and avoidance of premature conclusions. In addition to the researchers and clinicians, publishers as well as news media will have to share this responsibility. Continued research will undoubtedly provide us eventually with sufficient insight into the complexities of organ-specific autoimmunity, but patience and perseverance coupled with experimental objectivity will be required.

Recent therapeutic progress has been very good using monoclonal antibodies to dampen autoimmune processes in humans. One example is a non–Fc-binding anti-CD3 antibody, which has now delayed β cell destruction in two independent trials in recent-onset T1D *(288,440)*. Combination of this antibody with antigen-specific induction of regulatory cells might be a future important strategy based on its initial success in various mouse models (151). Other antibody-based therapies have been effective in psoriasis, Crohn's disease, RA, MS, and uveitis. Thus, the road map to ultimate therapeutic success might lie in a well-tuned combination of such therapeutics, likely in conjunction with autoantigen-specific approaches that involve the transfer or induction of regulatory cells (Tregs). Augmentation of adaptive as well as intrinsic Tregs might be, in the end, the key for achieving site-specific tolerance (involving bystander suppression of effector responses and "infectious" induction of more Tregs) and is being explored with much success in many preclinical models.

Immunological Mechanisms of Allergic Disease

Marsha Wills-Karp

INTRODUCTION

This chapter will provide an overview of our current understanding of diseases gathered under the rubric of "allergy." These diverse diseases (anaphylaxis, asthma, allergic rhinitis, atopic dermatitis, food allergy) are united at least superficially by the facts that: (a) these conditions all result from the expression of harmful immune responses; (b) the implicated immune responses are all associated with the generation of immunoglobin E (IgE) (whether

or not IgE is integral to pathogenesis); and (c) the antigens that driveg such immune responses are not derived from infectious pathogens. The basic cellular and molecular mechanisms that underlie the pathogenesis of allergic disorders, as well as the environmental and genetic substrates for their generation, will be closely considered. Although the study of allergic diseases has focused on the adaptive immune response in the last decade, in the period since the last edition of this book, the focus has shifted to dissecting the role of innate immune mechanisms in regulating susceptibility to the development of aberrant immune responses in allergic diseases. Thus this edition will reflect this change in perspective when possible. Although much of our current understanding of mechanism in allergic disease has derived from the study of animal models, mechanistic data on human disease will be discussed wherever possible. The chapter finishes with a brief survey of the clinical and therapeutic characteristics of the major human allergic disorders. Readers are referred to clinically oriented texts for a fuller discussion of such issues.

Historical Perspective

The term *allergy* was coined in 1906 by the astute pediatrician Clemens von Pirquet, who argued that antigenic stimuli led to two distinct categories or patterns of response: immunity and allergy *(1)*. The former, an old concept, referred to those responses that lead to protection from infectious challenge. The latter, a novel theoretical construct, referred to "altered reactivity" that itself led to host damage. This idea of allergy, that is, the notion that the immune response can itself be a cause of disease, was a powerful conceptual advance that led to novel insights into the pathogenesis of a variety of diseases. Quite naturally, this concept of allergy initially included autoimmune

diseases in addition to those conditions that are classified as allergic diseases today. As has been noted, current usage largely restricts allergy to diseases caused by the subset of harmful immune responses (to pathogen-unrelated antigens) that is associated with the generation of IgE. There is some artificiality to this. Very similar patterns of immune response can drive pathology in response to infectious pathogens such as tissue helminths. Further, IgE may be more a marker of an underlying pattern of immune response than a mechanistic participant in the immunopathogenesis of at least some subtypes of allergic disease. As long as these caveats are kept in mind, however, this concept of allergic disease, long enshrined by clinical subspecialists, has considerable theoretical and practical utility.

The trail leading to the specific identification of IgE began with demonstration by Prausnitz and Kuster in 1921 that hypersensitivity to an antigen could be passively transferred in serum from one individual to another *(2)*. The instigating antigens (allergens, in contemporary parlance) were known as atopens, and the mysterious plasma factor that conferred sensitivity was called atopic reagin. It was not until 1966 that Teruko and Kimishige Ishizaka demonstrated that reaginic activity was carried by a novel class of immunglobulin, IgE (*3,4,5*). The word *atopy* has since come to denote the propensity for developing allergic reactions to common environmental antigens (allergens), a propensity defined operationally by elevations in serum levels of IgE reactive with, or by skin test reactivity to, such antigens. Definitions of other key terms are given in Table 43.1.

Before proceeding to a direct focus on allergic diseases, it is useful to consider the classification scheme for harmful immune responses, or hypersensitivity reactions, initially outlined by Coombs and Gell *(6)*. This widely used formulation, modified by Janeway and Travers *(7)*

▎**TABLE 43.1 Definitions of Key Terms**

Allergen	An environmental antigen that typically elicits allergic responses in susceptible individuals. These antigens ordinarily have little or no intrinsic toxicity.
Allergy	Clinically adverse reactions to environmental antigens reflecting acquired immune responses that are marked phenotypically by the presence of allergen-specific IgE, along with mast-cell and eosinophil recruitment and/or activation. CD4+ T cells that produce a Th2 profile of cytokines (IL-4, IL-5, and IL-13) are thought to be central to the development of allergic responses.
Atopy	The propensity for developing immediate hypersensitivity reactions to common environmental allergens, defined operationally by elevations in serum levels of IgE reactive with allergens or by skin-test reactivity to allergens.
Allergic diseases	The group of clinical disorders (such as allergic asthma, allergic rhinitis [hay fever], and atopic dermatitis) in which IgE-associated immune responses, typically directed against otherwise innocuous environmental allergens, are thought to have a pathogenic role.

and Kay *(8)*, systematizes the major mechanisms initiating injurious processes that are mediated by the adaptive (as opposed to the innate) immune system (Table 43.2). The scheme delineates four classes of hypersensitivity: (a) type I, or immediate hypersensitivity, in which allergens interact with specific IgE (and/or IgG1 in the mouse) on the surface of mast cells or basophils, leading to the release of a variety of pharmacoactive inflammatory mediators; (b) type II hypersensitivity, or cytotoxic reactions, in which antibodies react with cell surface–associated antigens or receptors, leading to tissue injury and/or altered receptor function; (c) type III hypersensitivity, or immune complex reactions, in which damage is mediated by immune complexes generated by antibody in the presence of antigen excess; and (d) type IV, or delayed-type hypersensitivity, in which harmful T-cell–driven inflammatory processes proceed without any necessary role for antibodies.

In light of this classification scheme, beloved of generations of immunologists and medical students alike, allergic reactions seem to fall squarely into the category of type I hypersensitivity responses. Enhanced mechanistic understanding of allergic processes has inevitably complicated matters, however. Most allergic responses are multiphasic, combining elements of diverse hypersensitivity types into one "allergic cascade." For example, the initial phase of the clinical asthmatic response to an aeroallergen is often due to immediate (type I) hypersensitivity. However, this is frequently followed by late-phase responses that are more characteristic of delayed-type (type IV) hypersensitivity reactions.

General Features of Atopic Disorders

Allergic disorders are categorized by the anatomic site where disease is manifested: atopic dermatitis (skin), atopic rhinitis (nasal passages), atopic asthma (lung), food allergy (gut), and anaphylaxis (systemic) (Table 43.3). These clinical entities all involve a similar allergic effector cascade, at least superficially, with differences in presentation likely reflecting variation in the physiochemical characteristics of the allergen, the site of initial sensitization to the allergen, the route and dose of allergen exposure, and the programmed response of resident cells (e.g., epithelial cells), to injury and inflammation. Anaphylaxis aside, there is often a stereotypical sequence in the development of allergic manifestations of disease in patients with atopy, with early expression of food sensitivities or atopic dermatitis and the subsequent development of either atopic rhinitis or asthma. Many individuals will have all three of the latter clinical entities, which form the "atopic triad."

Atopic disorders represent a major health problem worldwide, affecting 5% to 30% of the population. The in-

cidence of atopic diseases, including asthma, atopic rhinitis, and atopic dermatitis, has increased dramatically in recent years in Westernized countries *(9–11)*. In such countries, 30% of the population manifests some form of atopic disease at some time in their lives. Interestingly, the low baseline level of atopic diseases in developing countries has not changed over the same time period, suggesting that factors associated with the Westernized lifestyle predispose to atopic disease. The widespread prevalence and morbidity of atopic diseases imposes a heavy burden on society.

The defining feature of atopy is the production of IgE in response to exposure (via muocosa or the skin) to a variety of ubiquitous, and otherwise innocuous, antigens. Such IgE production is a tightly regulated process, part of a complex network of cellular and molecular events necessary for the development of the allergic response. Initiation of this response appears to occur when allergen is taken up in the mucosae by antigen presenting cells which then traffick to the draining lymph nodes where they present allergens to CD4$^+$ T cells (a process referred to as sensitization). In atopic individuals, responding allergen-specific T cells polarize to a Th2 pattern of production, with the elaboration of cytokines such as IL-4, IL-13, IL-5, and IL-9 (vide infra). Although T cells from nonatopic individuals clearly recognize these same environmental antigens, the expansion and differentiation of such T cells does not involve Th2 deviation. Instead, it is thought that nonatopic individuals develop "tolerance" to these innocuous environmental antigens. The mechanisms controlling allergen-associated Th2 polarization in atopic individuals or tolerance in nonaffected individuals are not completely understood. It appears likely that genetic and environmental factors affecting the antigen-presenting process play a key role.

The elaboration of Th2 cytokines sets into motion a complex series of events leading to IgE production; the development, recruitment, and activation of effector cells such as mast cells, basophils, eosinophils, and effector T cells; and a variety of downstream effector cascades. Once an atopic individual is sensitized, the manifestations of allergy are readily induced upon re-exposure to the allergen (the elicitation phase). Although the effector phases of IgE-associated atopic disorders generally appear as a continuum, it is useful to define three temporal patterns: (a) acute reactions (developing within seconds to minutes of allergen exposure); (b) delayed or late reactions (developing hours after allergen exposure); and (c) chronic reactions (developing over days to years). Acute reactions result from crosslinking of high-affinity FcεR (FcεRI) on the surface of mast cells/basophils, induced by the interaction of allergen with cell-bound IgE. Such crosslinking results in the release of vasoactive mediators, chemotactic factors, and cytokines that initiate the so-called allergic cascade. This early reaction may resolve within minutes,

TABLE 43.2 Modified Coombs/Gell Classification of the Four Major Types of Initiating Mechanisms of Immunologically-Mediated Adverse (i.e., "Hypersensitivity") Reactions

Immunologic Specificity	Type 1: IgE Antibody (+ IgG₁ in Mouse)	Type II: IgG Antibody		Type III: IgG Antibody	Type IV: T Cells		
		a	*b*		*a1* Th1 Cell	*a2* Th2 Cell	B Cytolytic T Cells
Antigen	Soluble antigen "allergen"	Cell- or matrix-associated antigen	Cell surface receptors	Soluble antigen	Soluble antigen	Soluble antigen	Cell-associated antigen
Effector mechanism	FcεRI or FcγRIII-dependent mast cell/basophil activation, with release of mediators/cytokines	Complement, FcγR⁺ professional phagocytes, NK cells	Antibody alters signaling	FcγR⁺ cells, complement	Th1-associated effectors (e.g., macrophages)	Th2-associated effectors (e.g., eosinophils, basophils)	Direct cytotoxicity
Initial consequences	Rapidly developing (seconds to minutes) effects of mediators on target cells (usually not involving direct cytotoxicity)	Cell death and/or tissue injury	Pathology due to increased or diminished receptor-dependent cell function	Inflammation associated with recruitment and activation of neutrophils and other leukocytes	Chronic inflammation. Reactions develop slowly (hours to days) and can persist for long periods	Chronic inflammation	Death of target cells
Examples and notes	IgE- (or, in mouse, IgG₁-) dependent anaphylaxis (potentially fatal systemic reaction) or passive cutaneous anaphylaxis (a local reaction)	Certain drug reactions and reactions to incompatible blood transfusions	Graves disease (thyroid-stimulating agonist antibody); myasthenia gravis (antagonist antibody to acetylcholine receptor)	(Including mast cells in the mouse); Arthus reaction and other "immune complex-" mediated reactions	Contact dermatitis, tuberculin reaction	Chronic allergic inflammation (type I reactions may also contribute to chronic allergic inflammation)	Reactions to certain viral infected cells, certain forms of graft rejection

▶ **TABLE 43.3 Major Features of Allergic Immune Responses**

1. Responses are elicited by certain groups of environmental allergens such as foods, drugs, and proteins derived from pollens, insects (house dust mite), and animal dander.
2. In susceptible individuals, allergens are presented to naïve T cells by dendritic cells residing in the mucosa of the skin, gastrointestinal tract, or respiratory tract. For reasons that are not well understood, T cells of atopic individuals undergo differentiation to a Th2 cytokine-producing pattern.
3. Elaboration of Th2 cytokines (IL-4, IL-5, IL-3, IL-9) initiates the allergic cascade via their combined ability to regulate IgE production, FcεRI expression, mast-cell phenotype, and development, recruitment, and activation of eosinophils.
4. Under the control of Th2 cell–derived signals (IL-4, IL-13, and CD40L), B cells undergo class switching to production of the IgE subclass.
5. Upon re-exposure to the offending allergen, acute responses occurring within minutes of allergen exposure, resulting from release of preformed mediators (histamine, tryptase) from FcεRI-bearing cells via the crosslinking of allergen and IgE on their surface. Cells activated during the acute phase also release cytokines and mediators that perpetuate the Th2-driven response.
6. Late-phase responses are due to the combined effects of inflammatory cells (eosinophils and T cells) recruited to the tissues within 6 to 24 hours after the initial allergen exposure
7. Repeated allergen exposures in the context of an already-inflamed tissue results in structural changes (remodeling) such as smooth muscle thickening, tissue fibrosis, and mucus cell hyperplasia.

but it is often followed by late-phase responses that begin 3 to 6 hours after antigen challenge and may persist for days in the absence of therapy. The pathophysiologic consequences of chronic reactions are associated with the migration of eosinophils and lymphocytes from the blood into affected tissues.

ALLERGENS

Definition and General Characteristics of Allergens

Allergens are, by definition, antigens that can elicit specific IgE responses in genetically susceptible individuals. The list of structures that have been identified as allergens represents a tiny subset of the antigenic universe to which humans are routinely exposed to. Allergens are generally subdivided by route of exposure and source. Such allergens include aeroallergens (pollens, mold spores, animal dander, fecal material excreted by mites and cockroaches), food allergens, stinging insects, pharmaceuticals, and latex.

Allergen Classification

Purified allergens are named in accordance with guidelines published in 1994 by the World Health Organization International Union of Immunologic Societies Allergen Nomenclature Sub-Committee, based on their source and the order in which they were discovered *(12)*. The names incorporate the first three letters of the genus and the first letter of the species from which the allergen is derived, plus an Arabic numeral that is used to denote structurally homologous allergens from the same species. For example, the two major species of dust mite (*Dermatophagoides pteronyssinus* and *Dermatophagoides farinae*) are designated as *Der p* (*Der p 1, Der p 2*), and *Der f* (*Der f 1, Der f 2*). Other major allergens include *Fel d 1* from the cat, *Bet v 1* from birch pollen, *Amb a 1* from ragweed pollen, *Phl p 1* from the pollen of timothy grass, and *Bla g 2* from cockroach.

Biologic Properties of Allergens

The major allergens are a diverse group of proteins in which no one biologic property appears to be dominant. However, recent studies suggest that allergens may be proteins that activate the innate immune response, either through their intrinsic enzymatic activity or through activation of pattern-recognition receptors (PRRs) on mucosal epithelial cells or antigen-presenting cells (APCs) directly. Allergens from diverse sources have enzymatic activity that may bias the immune response toward a Th2 phenotype. For example, the cysteine protease of dust mite, *Der p 1*, the aspartic protease of cockroach, *Bla g 2*, the serine protease of *Aspergillus fumigatus,* and the bacterial subtilisins are all major allergenic molecules associated with the development of atopy and asthma. It is thought that these proteases induce Th2-driven inflammatory responses in the airways by disrupting the epithelial cell junctions so that these, and other molecules, gain access to, and alter the function of, underlying cells of the innate immune system (dendritic cells, mast cells, basophils, and macrophages) and B and T cells. In support of this hypothesis, *Der p 1* has been shown to activate the innate immune response via cleavage of complement components into their active components at the mucosal surface *(13)*. Moreover, through its ability to disrupt epithelial architecture, *Der p 1* may also facilitate its own passage across the (mucosal surface) epithelium, thus enhancing its own access to immune cells. Yet another potential mechanism by which proteolytic allergens such as *Der p 1* may alter the immune response is by cleaving CD25, the 55-kDa α subunit of IL-2R *(14,15)*. As a result of cleavage of CD25, peripheral blood T cells show markedly diminished proliferation and IFN-γ secretion in response to potent stimulation by anti-CD3 mAb. These findings suggest that *Der p 1* decreases the growth and expansion of antigen-specific Th1 cells, augmenting expansion of the antigen-specific Th2 cells that favor a proallergic response. *Der p 1* may also contribute to

the allergic phenotype by cleaving CD23 on murine B cells that would normally serve to inhibit IgE synthesis, thereby disrupting an important negative regulator of IgE production *(16)*. Along these lines, a recent comparison of various allergenic astigmatid mite extracts showed that all mites contain some type of enzymatic activity (phosphatase, esterase, aminopeptidase, glycosidase activity) (17). Cockroach allergens have been shown to contain serine proteases that lead to metalloproteinase (MMP) induction and proinflammatory cytokine production in the airway epithelium (18). Moreover, the potent peanut allergen *Ara h 2* is homologous to and functions as a trypsin inhibitor *(19)*. Other allergens, such as ragweed pollen, have been shown to contain intrinsic NADPH oxidases. Recently, birch pollen has been shown to contain phytoprostanes that are similar in structure to PGE_2 (20). Pollen-derived NADPH oxidases have been shown to rapidly increase the levels of reactive oxygen species (ROS) in lung epithelium as well as the amount of oxidized glutathione (GSSG) and 4-hydroxynonenal (4-HNE) in airway-lining fluid. These oxidases, as well as products of oxidative stress (such as GSSG and 4-HNE) generated by these enzymes, are thought to play a pivotal role in the development of lung inflammation (21).

Alternatively, it has recently been recognized, with the discovery of PRRs, that allergens and their soluble components may contain pathogen-associated molecular patterns (PAMPs) that actively interact with innate recognition systems present in the mucosal layer of various tissues. Specifically, it has long been appreciated that allergens contain substances such as endotoxin, chitin, or β-glycans, which are recognized by pattern-recognition receptors (TLR4, TLR2, dectin-1, mannose receptor) on cells lining mucosal surfaces such as the epithelium or on underlying dendritic cells. Activation of these PRRs both directly and indirectly provides signals required for productive interactions between dendritic cells (DCs) and T cells at mucosal surfaces. The ability to provide these danger signals to DCs likely underlies the unique ability of allergens to initiate allergic responses. Nonetheless, although many of these allergens can potentially create a microenvironment conducive to Th2 cell differentiation and expansion, normal individuals do not mount Th2 responses when exposed to these allergens, which suggests that despite the nature of these antigens, other factors are necessary for the development of allergic outcomes in susceptible individuals.

Specific Allergens

Aeroallergens

Aeroallergens are airborne proteins or glycoproteins derived from a variety of different sources, including pollinating trees and grasses, mold spores, animal dander (cat, dog, and rodent), and particulates secreted by dust mites and cockroaches. Factors that affect the growth or accumulation of these latter organisms (high humidity, well-insulated homes, fitted carpets) increase the levels of these allergens in the indoor environment. Exposure to such indoor allergens is also dependent on a variety of geographic, climatic, and socioeconomic factors. Interestingly, whereas indoor allergens are more closely associated with development of asthma, outdoor allergens (e.g., ragweed pollen) appear to be more important to the development of allergic rhinitis. The mechanisms underlying such associations remain obscure. Speculation has focused on the physiochemical nature (size, chemical structure) and pattern of exposure (acute versus chronic).

Food Allergens

Although hundreds of different foods are ingested, only a small number account for the vast majority of food allergy. The most common foods responsible for childhood food allergy are milk, egg, peanut, soy, and wheat. Responses to food allergens are relatively common in children <2 years old, but usually disappear as the child matures. In contrast, in adult food allergy, the most common offending foods are peanuts, tree nuts, fish, and shellfish. Most food allergens have been found to be water-soluble glycoproteins ranging in size from 10 to 40 kDa that are heat- and acid-stable and and resistant to proteolytic degradation. Exceptions to this are fruit and vegetable allergens. Reactions to food allergens can be fatal, with one of the most severe food reactions occurring in response to peanut allergens.

Latex Allergens

A new class of antigens associated with immediate hypersensitivity reactions to latex rubber has been identified in the last few years. Latex allergy is frequently seen in health care workers, rubber industry workers, and subjects undergoing multiple surgical procedures in early infancy *(22,23)*. Symptoms manifest as contact urticaria, rhinoconjunctivitis, asthma, and mucosal swelling. However, severe reactions and death have occurred upon exposure of patients to latex balloons on the rectal mucosa, especially in children with spina bifida. Multiple individual latex allergens have been identified, eight of which have received an international nomenclature designation. These include *Hev b 1*, rubber elongation factor; *Hev b 2*, B-1,3-glucanase; *Hev b 3*, homologous to *Hev b 1*; *Hev b 4*, a microhelix component; *Hev b 6*, prohevein/hevein; and *Hev b 7*, a patatinlike protein *(24)*. It has recently been appreciated that individuals with allergies to certain fruits such as banana, avocado, kiwi, and chestnut develop clinical symptoms upon initial contact with latex *(25)*. This phenomenon has been coined "the latex–fruit syndrome." It is thought to occur as a result of the presence of IgE

reactive to enzymes such as β-glucanase and chitinases that are present in both fruits and rubber. Interestingly, mammalian chitinases have been identified as being inducible by Th2 cytokines such as IL-13.

Pharmaceuticals

Adverse drug reactions are relatively common clinical problems. Most conventional pharmaceutical agents are relatively low-molecular-weight compounds that become allergens only after their haptenization to endogenous proteins. The penicillins are classic instigators of allergic reactions. Penicillin is associated with a relatively high incidence of allergic reactions because of the chemical reactivity of penicillin and its metabolites. Although penicillin itself is the major allergen, its metabolic products, penicilloate and penilloate, are minor allergens but are responsible for a disproportionate share of severe, life-threatening reactions. Moreover, the drug is often administered parenterally, which greatly increases the probability that an adverse IgE-associated response will be fatal. Cephalosporin drugs are structurally similar to penicillin, and penicillin-allergic individuals may have IgE antibodies that cross-react with cephalosporin. Other agents, such as quaternary ammonium compounds (neuromuscular blocking agents) and sulfonamides (antibiotics) are relatively common stimuli of allergic reactions.

Insect Venom Allergens

Stinging-insect hypersensitivity develops in both nonatopic and atopic individuals. Individuals are sensitized when relatively high levels of proteins (approximately 50 μg) in venom are injected subcutaneously during a sting. The venom-associated allergens of several vespids (yellow jacket, wasp, fire ants, and white-faced hornet) are cross-reactive and include antigen 5, phospholipase, and hyaluronidase. The honeybee venom contains distinct allergens, including two major ones, phospholipase A_2 and hyaluronidase, and a less important one, melittin. Many of these allergens have proteolytic activity.

CD4$^+$ TH2 POLARIZED IMMUNE RESPONSES IN ATOPY

As the primary orchestrators of specific immune responses to foreign antigens, the T lymphocyte has been implicated in the pathogenesis of allergic diseases. Several lines of evidence support a causal role for T lymphocytes in allergic disorders. Increased numbers of T lymphocytes are found in the bronchial mucosa, nasal mucosa, and skin of patients with allergic asthma, rhinitis, and dermatitis, respectively, when compared with nonatopic controls (26–28). In asthma and allergic rhinitis, CD4$^+$ T cells

predominate. In atopic dermatitis, however, excess CD4$^+$ and CD8$^+$ T populations are both present in skin lesions (18). Further, there is a generalized increase in T-cell activation in allergic individuals, both at the site of disease and systemically. Increased cell surface expression of T-cell activation markers such as the interleukin-2 receptor (IL-2R), class II histocompatibility antigens (HLA-DR), and very-late-activation antigen-1 (VLA-1) have been observed in all disorders in the atopic triad (27,28).

As has been covered in detail in other chapters, functional subsets of CD4$^+$ T cells have been distinguished at both clonal and population levels by the unique profiles of cytokines that they produce (29,30). The differential presence of these cytokine phenotypes in a variety of allergic and infectious diseases both in mice and in humans has provided descriptive power and theoretical insight into disease pathogenesis (30,31,*32*). Th1 cells producing TNF-β, and interferon-gamma (IFN-γ), are critical in the development of cell-mediated immunity, macrophage activation, and the production of complement-fixing antibody isotypes (29,30). Th2 cells producing IL-4, IL-13, IL-5, IL-9, and IL-6 are important in the stimulation of IgE production, mucosal mastocytosis, eosinophilia, and macrophage deactivation (29,30). Another subpopulation of T cells, referred to as regulatory T cells (Treg), have immunosuppressive functions and cytokine profiles distinct from either Th1 or Th2 cells. These cells are thought to play an important role in limiting immune responses to self- or exogenous antigens by preventing the activation and function of nonregulatory effector T cells through through cell-to-cell interactions or through elaboration of IL-10 and/or TGF-β.

Until recently, the development of allergies had been thought to be due solely to an imbalance between allergen-specific Th1 and Th2 cells, with a skew toward Th2 immune responses. However, several lines of evidence suggest that allergic diseases may arise as a result of an imbalance between allergen-specific Treg and Th2 cells resulting in a loss of tolerance mediated via Treg cells. Whether this imbalance occurs due to overzealous Th2 immune responses, to impaired Treg responses, or a combination of both, is an open question. Evidence for each will be discussed below.

Th2 Polarized Immune Responses in Atopy Disorders

Several lines of evidence support the involvement of Th2 cytokines in the pathogenesis of allergic disorders. First, T cells at the site of disease (bronchoalveolar lavage, bronchial biopsies, nasal biopsies) in allergic individuals (allergic asthma, atopic rhinitis) express elevated levels of mRNA for IL-4, IL-13, GM-CSF, and IL-5 (28–31). In atopic dermatitis patients, elevated Th2 cytokines (IL-4, IL-13, IL-5) and their receptors (IL-4R, IL-5R) are found in skin lesions in acute disease *(33)*, whereas cytokine patterns in

chronic lesions are mixed, with both Th2 cytokines (IL-5 and IL-13) and Th1 cytokines (IFN-γ) being expressed (*34*,*35*). Second, it has been shown that successful therapeutic treatment of these disorders is associated with a reduction in the Th2 cytokine pattern. For example, both steroid treatment and immunotherapeutic regimes result in reductions in Th2 cytokine levels in the nasal mucosa (36) and allergen-stimulated PBMCs (37) of patients with allergic rhinitis and in bronchoalveolar lavage (BAL) of asthmatic patients (35).

Although considerable descriptive evidence suggests that CD4$^+$ T lymphocytes and Th2 cytokines are important in the pathogenesis of atopic disorders in humans, definitive proof is of course difficult to obtain. As a result, experimental animal models have been extremely useful in mechanistic delineation of the role of CD4$^+$ T cells and T-cell–derived cytokines in the pathogenesis of allergic disorders. Murine models of antigen-driven asthma have consistently revealed a causal role for CD4$^+$ T cells in the development of the signs of allergic airway disease (38,39). In these models, sensitization with various allergens (ovalbumin, house dust mite, ragweed, aspergillius) by either intraperitoneal injections or airway challenge, followed by direct airway challenge, induces a phenotype closely resembling that observed in human asthmatics (38,39). Specifically, allergen sensitization and challenge results in airway hyperresponsiveness, eosinophilic inflammation, elevations in allergen-specific IgE levels, and mucus hypersecretion. Regardless of mouse strains or exposure protocols, an absolute requirement for CD4$^+$ T cells for the development of allergic responses is clear in such models (38). A lack of CD4$^+$ T cells, achieved either by antibody depletion (38) or gene targeting (40), is associated with prevention of the development of allergen-induced airway responses. Conversely, depletion of CD8$^+$ T cells does not affect airway responses to allergen challenge in mice (41). Furthermore, adoptive transfer of Th2 clones into the mouse lung is sufficient for the development of allergic airway symptoms (48). On the other hand, transfer of Th1 clones *(42)*, or administration of agents such as IL-12 and IFN-γ that inhibit Th2 cytokine production and stimulate Th1 pathways, prevent the development of allergen-induced airway hyperresponsiveness and eosinophilic inflammation in murine models (43,44,*45*). Conversely, mice that are deficient in T-bet, a transcription factor important in IFN-γ secretion, spontaneously develop Th2-mediated allergic airway responses *(46)*. Several studies have shown evidence of association between polymorphisms in the T-bet gene and asthma phenotypes in humans *(47)*.

The involvement of each of the specific Th2 cytokines in atopic airway responses has been demonstrated in studies in which IL-4, IL-5, IL-13, and IL-9 have been manipulated through either antibody blockade (48,49), or gene targeting (50,51,*52*,53). Similar roles for CD4$^+$ T cells and Th2 cytokines have been demonstrated in experimental mouse models of each of the atopic disorders, including atopic rhinitis *(54,55)*, food allergy *(56)*, and atopic dermatitis (53). Collectively, the Th2 cytokines orchestrate the elicitation of the allergic response via their ability to regulate IgE production and recruitment and activation of various effector cells (e.g., mast cells, eosinophils). In particular, IL-4, through its critical role in Th2 differentiation, has been shown to be essential in the initiation of allergic airway responses (57,58). IL-5 clearly plays a role in eosinophil development, recruitment, and activation at the site of Th2-inflammatory responses (59), whereas IL-9 appears to be an important regulator of mast-cell activation *(60)*. IL-13 has been shown to have a singular role in the effector phase of the allergic response (39,61). Specifically, it is sufficient to induce many of the manifestations of allergic disease, including airway inflammation, airway hyperresponsiveness, and mucus cell hypersecretion in allergic airway diseases (39,61). Recently, another Th2-specific cytokine, IL-21, which is a member of the common γ-chain family of cytokines, has been shown to be important in the development of Th2 immune responses (62) IL-21R–deficient mice have impaired development of airway hyperresponsiveness (AHR), and eosoinophilic inflammation concomitant with a reduction in IL-13 levels in BAL fluids. Although the mechanisms by which IL-21 regulates allergic inflammation are unknown, IL-21 is not thought to be required for Th2 differentiation, but may be important for migration and/or survival of Th2 cells.

Role of NK T Cells in Allergic Disease

Although allergic diseases have clearly been associated with polarized Th2 cytokine production in tissues, the source of these Th2 cytokines has been recently debated. Specifically, recent studies have implicated invariant TCR$^+$ CD1d-restricted CD4$^+$ natural killer T cells (NKT cells) as one of the major sources of Th2 cytokines (63–65). Akbari et al. demonstrated that NKT-deficient mice do not develop airway hyperresponsiveness in response to systemtic ovalbumin priming in the presence of adjuvants and subsequent allergen aerosol challenge. The resistance of these mice to the development of allergen-specific airway hyperrepsonsiveness can be overcome by adoptive transfer of tetramer-purified NKT cells producing IL-4 and IL-13 or by rIL-13 treatment. In support of a role for NKT cells, Morishima et al. have shown that priming of mice with ovalbumin plus the NKT cell ligand, α-GalCer, overcomes the tolerance that is normally seen with airway exposure to OVA alone *(66)*. In this model, the development of Th2-mediated AHR is CD1d$^+$-dependent; however, it does not occur in mice that are deficient in MHC class II, suggesting that NKT cells are necessary but not sufficient to induce Th2-mediated responses. Interestingly, a single administration of α-GalCer to the mouse airway induces AHR, suggesting that NKT cells may serve as effector cells in the

absence of conventional Th2 responses through their ability to produce Th2 cytokines such as IL-13. The effect of NKT cell activation appears to depend on the timing and context of activation, as other studies have shown that activation of NKT cells with α-GalCer + OVA in OVA-primed mice actually inhibits AHR, and Th2 cytokine production, in a NKT cell– and IFN-γ–dependent manner *(66,67)*. In support of a role for NKT cells in human asthma, Akbari et al. demonstrated that a large fraction of CD4$^+$CD3$^+$ cells in the lungs of allergic asthmatic individuals are not MHC class II–restricted, but rather natural killer T cells (68). Similarly, Sen et al. (69) found that Vα24$^+$-invariant natural killer T cells (iNKT cells) in the blood of patients with asthma selectively expressed CCR9, and that large numbers of CCR9$^+$ and Vα24$^+$ cells were present in bronchial biopsy samples from patients with asthma, but not from control subjects. They also showed that conventional CD3$^+$ α/β T cells could be polarized to a Th2 phenotype by cell-to-cell contact with Vα24$^+$-invariant natural killer T cells, with enhanced expression of CCR9, from patients with asthma. The induction of Th2 cytokine production requires CCL25 and CCR9 to activate adjacent membrane signaling by CD226, a leukocyte-adhesion molecule, that is expressed on monocytes. CD226 appears to be critical for activating Vα24$^+$-invariant natural killer T cells for the induction of a Th2 bias in conventional T cells. Dendritic cells and epithelial cells are major sources of CCL25. They also showed that the numbers of CCR9$^+$ Vα24$^+$ NKT cells in the peripheral blood of symptomatic patients with asthma decreased after steroid treatment and when asthma was clinically silent. Interestingly, iNKT cells do not appear to be required for the development of another allergic disorder, namely, atopic dermatitis (70). Taken together, these studies suggest that NKT cells play a prominent role in the development of some Th2 immune allergic responses; however, the exact nature of their role depends on both the timing and dose of the activating ligand. Thus, NKT cells can function as an adjuvant when iNKT cells are activated during adminstration of a protein antigen, can direct induction of AHR when they are activated in the absence of other signals, or can function to prevent the development of AHR when they are activated by strong NKT cell–activating agents once inflammation is established. The most likely scenario is one in which NKT cells and conventional CD4$^+$ T cells responding to their respective glycolipid and peptide antigens work in concert to mediate the development of allergic responses. Although the exact mechanisms by which NKT cells are activated during Th2 immune responses are currently unknown, there are several possibilities: (a) allergens such as pollens may contain glycolipids that are recognized by the invariant TCR of NKT cells (71,72); (b) self-glycolipid antigens may be released and/or recognized during the course of inflammatory responses; or (c) conventional T cells may augment the numbers of NKT cells at mucosal surfaces

through cytokine production, costimulatory molecules, or through other mechanisms in the absence of NKT cell ligands. Further studies will be required to determine the extent of the contribution of NKT cells in various allergic disorders and to determine the specific endogenous or exogenous glycoplipid antigens that are activating NKT cells in allergic patients.

Impaired Treg Cell Function in Atopic Individuals

It has recently been hypothesized that under noninflammatory conditions the outcome of immune responses to innocuous environmental allergens is the development of immunologic tolerance. Moreover, it is thought that a loss of tolerance results in Th2-biased immune responses at mucosal surfaces. Although the specific immunologic events that mediate tolerance in this setting are not well understood, recent studies have suggested that regulatory T cells protect against the development of allergic disease and that their function is impaired in genetically susceptible individuals. As is described in depth in other chapters, T-regulatory cells (Treg) are cells that inhibit the development and function of other nonregulatory T cells. To date, two major categories of Treg cells have been described. The first is the naturally occurring, thymically derived CD4$^+$CD25$^+$ Treg cells that express high levels of the transcription factor Foxp3, which is essential for their development and function. The other major category is the antigen-specific Treg, which can be induced in vitro and in vivo under particular conditions of antigen stimulation. These antigen-specific Treg secrete anti-inflammatory cytokines such as IL-10 and TGF-β, and regulate immune responses and inflammatory pathologies. Antigen-induced Treg that secrete IL-10 are oftern referred to as IL-10 Treg cells, or Tr1 cells, whereas those that secrete TGF-β have been referred to as Th3 cells.

Several lines of evidence from both human and animal studies have suggested that alterations in Treg populations and function may contribute to susceptibility to allergic disease. In animal models, several studies show that adoptive transfer of CD4$^+$CD25$^+$ Treg can reverse established airway inflammation through an IL-10–dependent process. Conversely, reduced expression of membrane-bound TGF-β exacerbates airway pathology in an asthma model (73). Furthermore, environmental exposures to agents that induce Treg cell expansion have been shown to ameliorate the development of asthma. In particular, exposure of mice early in life to lipopolysaccharide (LPS) resulted in the expansion of T cells expressing CD25 and IL-10 concomitant with reduced allergic manifestations upon sensitization and challenge compared to those mice without exposure to LPS *(74)*. Treatment of mice with mycobacterium-induced allergen-specific Treg cells producing IL-10 and TGF-β protected against airway inflammation (75). Similarly,

heat-killed *Listeria monocytogenes* treatment induced allergen-specific Treg producing IFN-γ and IL-10, which protected against food allergy in dogs *(76)*.

Although fewer conclusive studies have been conducted in humans, several studies support the hypothesis that impaired Treg function may contribute to development of Th2-dependent pathologies in humans. For example, the frequency of allergen-specific IL-10–secreting cells was significantly decreased in allergic patients compared to nonatopic individuals (77). Whether the IL-10 is derived from Treg or activated effector T cells is unknown. In addition to a relative lack of Treg in atopic individuals, Ling et al. (78) have shown that CD4$^+$CD25$^+$ cells from atopic individuals have impaired ability to suppress effector T-cell cytokine production. Another interesting observation regarding the role of Treg in susceptibility to atopy is the finding that children who outgrew milk allergy had higher numbers of CD4$^+$CD25$^+$ cells in their blood (79). Furthermore, therapies shown to be beneficial in the treatment of allergy and asthma, such as allergen immunotherapy or glucocorticoid therapy, have been shown to increase the induction of allergen-specific IL-10–secreting Treg cells, concomitant with a reduction in allergen-specific Th2 responses (80).

Although the mechanisms by which Treg regulate the development of allergic inflammation are not completely understood, they are thought to prevent allergic symptoms by suppression of Th2-cell effector function through the elaboration of the suppressive cytokines, IL-10 and TGF-β. However, recent studies now support the concept that Treg may alter sensitization and ongoing Th2 immune responses by regulating airway DC function. Mice lacking the transcription factor RunX3, which is involved in downstream TGF-β signaling, spontaneously develop symptoms of asthma concomitant with increased numbers of lung DCs, displaying a mature phenotype with increased expression of MHC II, OX40 ligand, and CCR7 (81). Moreover, dendritic cells from RunX3-deficient mice induce inflammatory responses to otherwise harmless inhaled antigens, possibly through their lack of responsiveness to locally secreted TGF-β. In further support of a role for T regulation of DCs, it has been shown that in mice (C3H/HeJ) that are resistant to HDM-induced asthma and airway hyperresponsiveness, Treg depletion with the CD25-depleting antibody similarly led to increased numbers of pulmonary myeloid DCs with increased expression of MHC II, CD80, and CD86 and an increased capacity to stimulate T-cell proliferation and Th2 cytokine production (82). In contrast, Treg from normally susceptible A/J mice do not suppress inflammation and AHR. These data suggest that resistance to allergen-driven AHR is mediated in part by CD4$^+$CD25$^+$ Treg suppression of DC activation and that the absence of this regulatory pathway contributes to susceptibility.

The lack of allergen-specific tolerance in allergic individuals has been hypothesized to be related to improved hygiene in industrialized countries, possibly due to reduced infections, alterations in commensal microflora in the intestinal tract, and/or reduced Toll-like receptor (TLR) signaling. This will be discussed in more detail in the following sections. Taken together, these studies suggest that Treg may induce tolerance to or provide protection from inhaled allergens in healthy individuals and that an imbalance between allergen-specific Treg and Th2 cytokine–producing cells may underlie susceptibility to the development of atopic diseases.

Determinants of Susceptibility to Th2 Immune Responses in Atopic Individuals

Overview

Very little is known conclusively about the underlying causes of the aberrant expansion of Th2 cytokine-producing cells in atopic humans. However, the skewed Th2 immune responses in atopic disorders may be due to either overzealous Th2 immune responses, impaired ability to generate either Th1 or T regulatory responses, a lack of exposure to Th1- and Treg-promoting agents, or a combination of these. This balance is influenced by a number of genetic and environmental factors that control both the innate and adapative immune responses to allergens at mucosal surfaces. There is supportive data for each of these determinants in atopic diseases (Figure 43.1).

Genetic Influences on Allergen Sensitization

There is substantial evidence suggesting that the development of atopic diseases is genetically controlled (*83,84*). Familial aggregation and twins studies have confirmed a fundamental contribution of genetic factors to the development of atopy and specific clinical atopic phenotypes (85). Specifically, individuals with a first-degree relative with atopic phenotypes are at a significantly greater risk of developing atopy. Moreover, individuals with two "atopic" parents are at a greater risk of developing an allergic disease than those with only one atopic parent. However, inheritance of atopic disorders appears to be preferentially associated with the atopic status of the mother *(86)*. Further support for a genetic basis of asthma is the fact that there is a greater concordance for atopic disease between monozygotic twins compared to dizygotic twins (*87,88,*89). The concordance is not 100%, suggesting that asthma is a polygenic disorder with strong environmental influences. Despite the complex genetic nature of atopic disorders, multiple studies have reported evidence of linkage of atopic-related traits with six primary chromosomal regions, including (a) the Th2 cytokine gene cluster on 5q31-q33, including the IL-4, IL-13, CD14, SPINK5, LTC4S, and CYFIP2 genes; (b) the HLA region on 6p21, including both classical (HLA-DRB1, HLA-DQB1, HLA-G)

FIGURE 43.1 Allergic diseases are associated with aberrant adaptive immune responses to innocuous environmental antigens. The development of allergic responses to harmless antigens is influenced both by environmental factors and by the genetic background of the individual. Under conditions in which microbial exposure is minimal, such as in Westernized countries, T cells differentiate along a Th2 pattern with elaboration of IL-4, IL-13, IL-5, IL-9, and IL-21. In contrast, microbial exposure in early life protects against the development of harmful Th2 immune responses via the induction of regulatory T cells.
and nonclassical HLA genes (TNF, LTA); (c) the region that contains the high-affinity IgE receptor gene (FcεRIb) on 11q13; (d) a large region on chromosome 12q14 that spans several candidate genes (Stat6, interferon-γ, stem cell factor, nitric oxide synthase 1); (e) a region of 16q containing the IL4RA; and (f) a region of 20p containing the first positionally cloned asthma gene, ADAM33. In addition, >100 genes have been associated with atopic disorders through candidate gene and positional cloning efforts (see reviews in 90,91) (Table 43.4). The involvement of specific candidate genes in atopic disease pathogenesis will be addressed in relevant sections throughout the text.

Environmental Influences on Development of Atopic Disease

Despite the clear heritable component of asthma, the incomplete concordance of disease in twins studies and the rapid shift in the rate at which the incidence of atopic disorders is rising suggest a recent change in environmental influences on this process. Changes in exposures to allergens, infectious agents or their by-products, and/or pollutants have all been suspected. It is likely that multiple environmental factors influence the development of allergic diseases, and that there may be complex interactions between these individual factors.

Timing and Dose of Allergen Exposure

The spectrum of antigens an asthmatic individual is sensitized to is dependent on their environment in early life. This tenet is based on the positive correlations observed

between allergen exposures present during the month of birth and the development of sensitization to the same allergens later in childhood (e.g., birch, grass, and dust mite allergens) *(92,93)*. For example, Scandinavian babies born in late winter or early spring are more likely to develop IgE antibody to birch pollen, which is prevalent during the spring, than those born at other times of the year *(92)*. In addition, avoidance or withholding certain allergenic foods during the first few months of life tends to prevent sensitization and subsequent allergic responses to these particular foods.

Numerous studies have demonstrated the relationship between sensitization risk and the level of allergen exposure *(94,95)*. This has been best studied in relationship to dust mite and cat antigens in early life. When both parents are atopic, dust mite sensitization occurred with <1% prevalence when infants were exposed to <0.1 μg of house dust mite allergen per gram of dust, but this value increased to 6% with allergen levels >10 μg per gram of dust *(94)*. Although antigen dose is positively correlated with sensitization, recent studies suggest that the relationship may be more complex. Specifically, high exposure to animal dander early in life has been shown to be protective against manifestations of asthma *(96)*. Whether this represents immune tolerance as a result of high antigen dose or concomitant exposure to other factors such as endotoxin as a result of living in close proximity to a pet is unknown.

More important than the actual dose of allergen is the age at which exposure occurs. It has recently been hypothesized that exposure to environmental antigens occurs both prenatally and postnatally. In this regard, several independent studies have provided support for the postulate that prenatal events may influence susceptibility to allergic diseases (84,97). For example, it has been shown that cord-blood mononuclear cells respond to inhalant and food allergens, suggesting that initial priming of allergen-specific T-cell responses may occur before birth (84,97). It has been demonstrated that the responding cord-blood T cells were indeed of fetal origin, as they did not respond to common vaccine antigens such as tetanus toxoid, against which the majority of adults in the study population expressed active immunity (84). These findings suggest that transfer of substances from mother to child (e.g., allergens, antibodies, toxins, hormones, or other immune mediators via the placenta) may occur during gestation, which might prime or sensitize the developing infant to environmental antigens. In addition, factors present in the *in utero* environment may serve to influence the nature of the immune response of the fetus to allergens that cross the placenta. Indeed, mediators such as PGE2 and high levels of progesterone, which has been shown to alter the Th1/Th2 balance by either suppressing Th1 cytokine production or inducing a Th2 pattern, are present during pregnancy. Th2 skewing is thought to take place to suppress IFN-γ production, which is toxic to the fetus. Accordingly, exogenous antigens

that leak across the placenta are likely to be presented to the fetal immune system within a milieu conducive to selection for Th2 immunity. This contention is supported by studies showing that cord-blood cells from both allergic and nonallergic infants both produce high levels of Th2 cytokines and low IFN-γ levels *(98)*. Although these studies clearly demonstrate that initial allergen priming may occur *in utero*, they also suggest that the Th2 cell phenotype is determined to a substantial degree after birth, as only a minority of the infants who exhibit allergen-specific Th2 responses at birth go on to develop disease.

Although immune responses in neonates are skewed toward a Th2 phenotype, studies of human infants indicate that this Th2 skew gradually diminishes during the first 2 years of life in nonallergic individuals (84,99). In allergic infants, the reverse occurs, with the strength of neonatal Th2 responses increasing over a similar period (84,99). The persistence of this neonatal bias and the failure to produce Th1 or T-regulatory type responses may be an important feature of the atopic disease state *(100)*.

The redirection of Th2 responses is thought to occur simultaneously with childhood bacterial or viral infections in early life. This relationship has been capsulated in the "hygiene hypothesis," which argues that early childhood infections inhibit the tendency to develop allergic disease (101). Several epidemiologic studies have provided support for this hypothesis. For example, Von Mutius (102) compared allergic sensitization and atopy in children from West Germany and East Germany. She noted that the frequency of atopy was considerably higher in West German children (36.7%) than in their peers in East Germany (18.2%). The authors attributed the increase in allergy to the "Western lifestyle," with decreased family size, improved housing, and prevention of infectious diseases in early childhood. Further epidemiologic support for this hypothesis comes from studies demonstrating an inverse relationship between farm living, pet ownership, daycare attendance in early life, and atopy. Although the general implication of these studies is that protection from allergy seems to be associated with an increase in microbial exposure, the link has remained fairly indirect. One study that has addressed the relationship between asthma and a specific pathogen is a cross-sectional study of Italian military recruits (103). The authors found a significant inverse association between the presence of antibodies to hepatitis A and various measures of atopy. In all likelihood, such evidence of previous infection with hepatitis A merely provides evidence of a risk of exposure to fecal–oral pathogens. However, recent studies suggested that perhaps exposure to hepatitis A is protective against the development of atopy, as polymorphisms in the receptor for hepatitis A, TIM-1 (T-cell immunoglobulin– and mucin domain–containing molecule-1), are associated with protection from atopy (104). Interestingly, the association of TIM-1 mutations with protection is only observed in

patients who show serologic evidence of HepA infection. At a population level, Shirakawa et al. *(105)* found that among Japanese schoolchildren there was a strong inverse association between delayed-type hypersensitivity (Th1-mediated immune response) to Bacillus Calmette-Guerin (BCG) and atopy. Positive tuberculin responses predicted a lower incidence of asthma, lower serum IgE levels, and cytokine profile biases toward a type 1 profile. These results suggest that exposure and response to bacteria may, by modification of immune cytokines profiles, inhibit atopic disorders. In a study of defined infectious exposures, Aaby et al. documented that vaccination with *Mycobacterium bovis* BCG was associated with a reduction in the prevalence of allergy in Guinea-Bissau *(106)*. However, such protection was not observed in a similar retrospective study of BCG vaccination in Swedish children with a family history of allergy.

The complex interface with the microbial world provided by the gastrointestinal tract might well be important to the interrelationship between infection and allergy. The endogenous flora of the gut provide a wealth of stimuli for the developing immune system at birth. There seem to be both quantitative and qualitative differences in early-childhood patterns of bacterial colonization between the developed and developing world. For example, a study of Swedish and Pakistani infants indicates that intestinal colonization with aerobic gram-negative bacteria tends to occur later in Westernized than in developing countries (107). Once they are colonized, infants in developed countries tend to carry the same enterobacterial strains, whereas infants in developing countries are often colonized serially with different strains. Differences in intestinal flora have also been found between allergic and nonallergic children in Europe *(108,109)*. Allergic children seem to be colonized less often with lactobacilli in Sweden and Estonia than nonallergic controls (110). This idea is consistent with the observation that oral tolerance cannot be induced in germ-free mice *(111)*. Furthermore, elimination of commensal intestinal microflora and toll like receptor (TLR) signaling with broad-spectrum antibiotics also prevented oral tolerance from developing, enhanced allergic sensitization, and resulted in susceptibility to intestinal inflammation. These observations suggest that TLR signaling by commensal bacteria under normal steady-state conditions is required for maintenance of intestinal epithelial homeostatsis, and possibly for the induction of some forms of Treg. The intestine has been shown to affect immune response at other mucosal surfaces, including the respiratory tract, lacrimal, salivary and mammary glands, through secretory IgA antibodies *(112,113)*.

Further support for this hypothesis is the striking association between polymorphisms in genes in the Toll pathways and atopic phenotypes. Specifically, an association has been consistently reported between a polymorphism in the CD14 gene, increased levels of sCD14, and decreased levels of IgE, reflecting the importance of bacterial LPS in downregulating Th2 responses (114). Moreover, a polymorphism in the coding region of the TLR4 gene (A/G 896) resulting in reduced cell surface expression of TLR4 and subsequent disruption of LPS-mediated signaling has been associated with atopy in children (115). However, the data in asthma are conflicting, with some studies showing an association between asthma and TLR4 polymorphisms (115), whereas others do not (116). Interestingly, inheritance of both the TLR4 SNP (A/G+896) and the IL-4 SNP (−590) confers greater risk of asthma pathogenesis in females *(117)*. Clearly, these innate immune pathways play a critical role in determining the inflammatory reactions of the airways and the outcome of T-cell respones to inhaled allergens.

Although the hygiene hypothesis is likely oversimplified, it is theoretically possible that DCs at mucosal surfaces in atopic individuals receive less innate immune stimulation in the form of microbial stimuli (LPS, peptidoglycans, mycobacterial antigens) and therefore fail to redirect weak Th2 responses into protective Th1 responses or T-regulatory responses. This hypothesis may provide a plausible explanation for the rising prevalence of these disorders in Westernized countries.

Exposure to other environmental agents such as diesel particles, ozone, second-hand tobacco smoke, and viruses (respiratory synctial virus (RSV), rhinoviruses) can also enhance sensitization to allergens in young children (110). Numerous epidemiologic studies illustrate clear associations between exposure to these agents and enhanced antigenic sensitization and worsening of disease. Nasal challenge with diesel particles alone increased IgE production in both atopic and nonatopic individuals, suggesting that diesel particles indeed may be a sensitizer *(118)*. When evaluated together with allergen, diesel exposure of ragweed-sensitive subjects resulted in a significant increase in allergen-specific IgE, with an increase in Th2 cytokine production. Ozone can alter both immediate and late-phase responses of asthmatics and allergic rhinitics to inhaled allergen *(119)*. Epidemiologic studies have shown that exposure to environmental tobacco smoke (ETS) in childhood is associated with increased skin-test reactivity, serum IgE, and prevalence of eosinophilia *(120–122)*. Recently, it has been shown that controlled chamber exposures of ragweed-sensitive subjects to ETS resulted in enhanced production of allergen-specific IgE, Th2 cytokines, and decreased IFN-γ levels in nasal lavage fluids (123). Although there is controversy regarding whether RSV is an inducer of allergic asthma or rather a predictor of aberrant immune responses, severe RSV infections are strongly associated with asthma *(124)*. Similarly, rhinoviral infections are strongly associated with exacerbations in atopic airway disease *(125)*. In summary, the complex interplay between genetic and environmental factors likely governs susceptibility to the development of atopic disorders.

FACTORS REGULATING TH2 IMMUNE RESPONSES IN ALLERGIC INDIVIDUALS

Antigen Presentation in Atopic Individuals

The nature of the T-cell response to antigens encountered at the mucosal surface depends on three signals provided by professional APCs (Figure 43.2). Although a number of professional APCs, such as dendritic cells, Langerhans cells (LCs), B cells, and macrophages, are present at mucosal surfaces and have the cellular specialization to capture and process antigen for presentation to T cells, it has become increasingly clear over the last decade that DCs and Langerhan cells are the most important professional APCs at mucosal surfaces. DCs migrate as precursor cells to sites of the body where antigen entry
FIGURE 43.2 Postulated factors regulating dendritic cell instruction of T-cell differentiation in atopic disorders. Dendritic cell recruitment, activation, and maturation are controlled both by direct stimulation by PAMPs contained in allergens themselves and through indirect signals derived from surrounding resident cells such as epithelial cells. Immature DCs are recruited to mucosal surfaces following the release of chemokines (i.e., CCL20) and inflammatory mediators (IL-8, IL-6) by epithelial cells in response to inflammatory stimuli such as allergens, pollutants, irritants, and/or viral infections. Although the mechanisms by which these stimuli elicit chemokine release are unknown, certain allergens contain protease activity that has been shown to activate epithelial cells via stimulation of PAR-2 receptors on the epithelium. In addition to activating epithelial cells to release chemokines and cytokines, allergen-derived proteases can also cause disruption of epithelial tight junctions and allow antigens to gain access to DCs located beneath their surface. Allergens are taken up, processed, and presented to T cells in the context of MHC class II molecules. DCs mature and express costimulatory molecules (i.e., CD86, OX40) under the influence of cytokines (GM-CSF, IL-6) and mediators (TSLP, PGE2) derived from surrounding tissues or through direct stimulation of PRRs (likely TLR4, 2) expressed on their surface. In atopic individuals, it has been postulated that myeloid DCs appear to be the predominant population of DCs taking up antigen and driving the differentiation of naïve T cells toward a Th2 profile. In contrast, in nonatopics, allergen is taken up in the context of microbial signals, which preferentially stimulate plasmacytoid DCs through TLR9 expression. Activation of pDCs results in the stimulation of naïve T cells to differentiate into T-regulatory cells expressing an array of inhibitory molecules such as CTLA4, PD-1, IL-10R, and TGF-βRI and II. Activation of the production of IL-10 and TGF-β as well as 2,3-IDO results in the inhibition of Th2 effector cell function as well as inhibition of myeloid DC activation, leading to the development of immunological tolerance to environmental antigen exposure.

occurs (i.e., lung, skin, GI tract). At these sites they form an extensive network of cells, extending cell projections in between resident cell types that ensure accessibility to allergens. DCs that reside in the periphery have an immature phenotype, specialized for uptake and recognition of antigens, but are not yet capable of stimulating naïve T cells, because they lack costimulatory molecules on their surface (CD80, CD86). Normally, DCs present antigens quite inefficiently; however, when antigen is encountered in an inflammatory context (e.g., in the presence of antigen-derived danger signals) or through indirect sensing of "danger" from surrounding cells via the release of inflammatory cytokines (IL-1β, TNF-α, IL-6, PGE$_2$, GM-CSF), DCs undergo a developmental program referred to as maturation. During maturation, they lose their ability to take up antigen and acquire a phenotype of professional APCs expressing all the costimulatory molecules and chemokines required to attract and stimulate naïve T cells. Once DCs have acquired antigens at the mucosal surface, they migrate to T-cell areas of draining lymph nodes and present their antigen cargo to naïve T cells. During this interaction with naïve T cells in the lymph nodes, DCs have an opportunity to influence T-cell differentiation along a Th1, Th2, or regulatory T-cell pattern, by secretion of a specific cytokine pattern, depending on their lineage, their maturation status, and the consequent costimulatory molecule pattern. Thus, alterations in the signals provided by DCs to T cells may underlie the development of polarized Th2-cell responses in the context of allergic disease. Considerable evidence is accumulating to support this tenet.

Indeed, several lines of evidence in murine models of allergic disease as well as in atopic humans support a pivotal role for DCs in the development of allergic responses. For example, Lambrecht et al. (126) have demonstrated that infusion of antigen-pulsed bone marrow–derived DCs into the respiratory tract of mice primed them for development of Th2-mediated immune responses upon subsequent antigen challenge. Conversely, using a suicide-gene approach to specifically deplete DCs, it was demonstrated that antigen exposure did not induce allergic responses in the absence of DCs (126). In humans, a critical role for DC in generation of allergic responses is the demonstration that regular use of budesonide and fluticasone, which is associated with improvement in lung function, is associated with a reduction in the number of CD1a$^+$ HLA-DR$^+$ DCs in the airways of asthmatic patients (127).

Altered DC Phenotype and Function in Allergic Diseases

DCs play a major role in the surveillance of peripheral tissue sites for incoming antigens, a function that is dependent on their capacity for tightly controlled migration between different compartments. Under steady-state conditions, there is a continuous turnover of DC at mucosal surfaces, with the recruitment of immature DC from circulating precursors balanced by the exit of mature, antigen-loaded cells to regional lymph nodes. In both humans and mice, DCs are not constitutively present in the tracheal-bronchial mucosa in the first year of life; their occurrence appears to be dependent on exposure to inflammatory stimuli from the local environment (128,129). Indeed, the numbers of HLA-DR expressing dendritic cell numbers are increased in the mucosal tissues of asthmatic, allergic rhinitic, and atopic dermatitis patients when compared to the low level of DCs found in specimens from normal controls (127,*130–133*). Although the exact signals that regulate the rapid recruitment of immature DCs from the blood into the mucosal tissues are not fully understood, exposure to a number of environmental triggers (allergens, particulate matter, smoke, RSV, ozone) have been shown to dramatically increase the recruitment of DCs in both animal models of atopic disease and atopic humans (134–136). These triggers likely attract DCs to mucosal surfaces through their ability to induce a set of chemokines that bind to receptors expressed exclusively on immature DCs. Indeed, it has been shown that epithelial cells synthesize and secrete the CCR6 ligand, MIP-3α/CCL20, in response to allergens and particulate matter (137,*138*). Interestingly, though *Der p 1* stimulation of bronchial epithelial cells from patients with asthma results in CCL20 production and migration of LC precursors, this effect is not observed in cells from healthy individuals (139). The ability of these triggers to induce DC chemokines may explain the adjuvant effect of each of these irritants in induction of allergic responses. Taken together, these studies suggest that responsiveness of mucosal epithelial cells to certain pathogens and/or environmental stimuli early in childhood may enhance or inhibit sensitization to allergens by affecting DC recruitment.

The maturational state of DCs is thought to be an important determinant of the development of tolerance or immunity. It has been suggested that DC immaturity may contribute to the development of tolerance *(140)*. Indeed, studies from both animal models and atopic humans suggest that the magnitude and pattern of costimulatory molecule expression on DCs is strongly associated with susceptibility to atopic disease. In this regard, DCs influence the nature of the immune response to antigen stimulation through the balance of positive signals provided by CD28 engagement of B7–1, B7–2, B7-H3, and B7-H4 on resting T cells and negative signals provided through ligation of CTLA4 and PD-1 on resting T cells. Indeed, differences in the relative expression of these positive and negative signals have been shown to be important in various murine models of allergic disease. Specifically, it has been reported in numerous studies that Th2-mediated immune responses are predominantly dependent on DC expression of CD86, not CD80 *(141)*. In contrast, stimulation of CTLA4,

TIM-3, and BTLA have all been shown to decrease allergic responses *(142)*. CTLA4 in particular is predominantly expressed on Treg and is thought to mediate its inhibitory effects through Treg suppressive functions. More recently, it has been shown that the PD-1 ligand B7-H1 may also be an important regulator of tolerance through its ability to induce Treg (143). Several studies have shown that B7RP–ICOS interactions mediate tolerance through the induction of IL-10–secreting Tr1 cells (144,*145*), but other studies report that ICOS positively regulates allergic responses (146).

Several studies have suggested that DCs from atopic individuals have a different phenotype from those of nonatopic individuals (147,148,*149*). First, the functional capacity of DCs from atopic individuals has been elegantly studied in a humanized severe combined immune deficiency mouse model (150). In this model, it has been demonstrated that adoptive transfer of DC from atopic individuals reconstitutes Th2 polarized immunity associated with allergic inflammation in the lungs of mice. In contrast, transfer of DC from nonatopics resulted in combined Th1/Th2 responses. In another study, it has shown that *Der p 1* stimulation of monocyte-derived DC from *Der p 1*–sensitive patients resulted in preferential upregulation of CD86 expression and proinflammatory cytokine production (IL-1β, TNF-α, IL-6) when compared to cells from nonallergic patients or pollen-sensitive subjects (148). Purified T cells from house dust mite (HDM)-sensitive patients stimulated by autologous *Der p 1*–pulsed DC preferentially produced IL-4. Interestingly, DCs from nonatopic individuals stimulated with *Der p 1* expressed CD80, produced IL-12, and stimulated IFN-γ production in T cells. Another intriguing finding of this study was that the effects of *Der p 1* on costimulatory molecule expression in DC from allergic patients was dependent on the enzymatic activity of *Der p 1*, as a cysteine protease inhibitor prevented these effects. It has also been shown that differences in inhibitory molecule expression may play a role in susceptibility to allergic disease. Specifically, Akdis et al. showed that allergen-specific (*Der p 1*) T cells from nonatopics produced high levels of IL-10 that were associated with elevated T-cell surface expression of IL-10R, CTLA4, TGF-βR1 and II, CD25, and PD-1 compared to those of atopic individuals. Neutralization of these suppressor pathways led to increased production of Th2 cytokines, suggesting that ligation of these inhibitory receptors on T cells by their DC ligands is critical in maintaining the balance between Th2 and tolerogenic T-cell responses (151). Taken together, these studies suggest that DCs from atopic individuals display altered costimulatory molecule patterns compared to normal individuals in response to direct stimulation with allergens and the PAMPs they may contain. Although the pattern and level of expression of costimulatory molecules on DCs and their ligands on T cells may be controlled by exogenous signals, polymorphisms in several costim-

ulatory molecules have been shown to be associated with increased risk of development of Th2-mediated immune responses and atopic diseases such as asthma and atopic dermatitis. Specifically, polymorphisms in ICOS (1413G/A) are associated with allergic sensitization and Th2 cytokine production (152), and polymorphisms in the CTLA4 gene are associated with early-onset infant atopic dermatitis (153) and asthma (154).

Innate Immune Responses to Environmental Antigens

Allergens interact with innate recognition systems present in the mucosal layer and with various receptors present on a diversity of cells at the mucosal surface of the respiratory tract, skin, and GI tract, including epithelial cells, and phagocytic cells (dendritic cells, macrophages). As the primary interface with the environment, the epithelial cell layer represents the front-line defense against injury by pathogens or environmental irritants. Emerging evidence suggests that epithelial cells play a critical role in both antigen recognition and danger recognition. Although it is not entirely clear whether they present antigens, they actively interact with environmental antigens/allergens, both in healthy individuals and patients with allergic diseases. Allergenic particles and their associated soluble components interact directly with epithelial cells through a variety of diverse mechanisms, including (a) binding of pattern-recognition receptors, including various members of the Toll-like receptor family; and (b) activation of protease receptors (PARs). Activation of epithelial cells through these diverse pathways can induce the release of cytokines, chemokines, and growth factors that both facilitate entry of antigens into mucosa and interation with APCs, providing instructive signals to dendritic cells in the mucosa. There is mounting evidence that alterations in innate immune responses occurring at the epithelial–environmental interface may be important determinants of susceptibility or resistance to the development of allergic diseases.

Although allergens are not infectious in nature, they contain bio-organic substances (pollens, excreta of insects and mites, degraded plant products) that are actively recognized by PRRs such as TLRs. Indeed, epithelial cells cultured with various triggers of asthma have been shown to produce a number of inflammatory chemokines and cytokines in a TLR-dependent manner (155). Whether this is due to recognition of PAMPs within the allergens themselves or to endotoxin contamination is currently unknown. However, there is emerging evidence that allergens do indeed contain PAMPs that interact with various PRRs, including TLR4, TLR2, and TLR9. A requirement for PAMP recognition to induce sensitization to inhaled antigens has been shown for LPS in a murine model of OVA-induced asthma. In this model, wild-type mice were sensitized to inhaled OVA, whereas TLR4-deficient mice were not (151).

However, the relationship is complex, depending on the timing and dose of LPS exposure. LPS exposure during sensitization inhibits Th2-driven immune responses and drives a tolerogenic response *(156)*. In contrast, delivery of LPS to sensitized mice exacerbates Th2 responses (157). Moreover, the dose of LPS has been shown to be critical, as high dose exposure induces Th1 responses, whereas low-dose LPS drives Th2 immune responses (158). The exact explanation for this complexity is unknown, but it may reflect differences in the types of cells activated at different times during an immune response or to the differential expression of TLRs on different populations of DCs, as will be discussed later. The role of TLR2 in Th2-mediated immune responses is complex as well. For example, delivery of the TLR2 agonist Pam3Cys along with allergen at the time of sensitization enhanced the prominent Th2-biased immune response and the symptoms of asthma in mice (159). Activation of APCs by Pam3Cys resulted in the induction of Th2-associated effector molecules such as IL-13, IL-1β, and GM-CSF and upregulation of B7RP-1 expression. In contrast, if TLR2 agonists are administered to mice previously sensitized and challenged with OVA, they markedly reduced Th2 cytokine production, airway inflammation, and IgE production *(160)*. Although Pam3CSK4 (a synthetic bacterial lipopeptide) therapy increased IFN-γ, IL-12, and IL-10 production, the anti-inflammatory effect of Pam3CSK4 was independent of IL-10 or TGF-β, but was critically dependent on IL-12. In contrast, stimulation of TLR9 by allergens as well as bacterial antigens has been shown to provide protection from the development of allergic responses (161). Despite our rudimentary understanding of the role of PAMPs in allergic responses, one may speculate that either differences in exposures to microbial products or polymorphisms in genes of the TLR pathway may both be important determinants of the risk of developing allergic disease through altering the phenotype and function of DCs. Along these lines, genetic studies show that polymorphisms of different components of innate recognition pathways may partly explain susceptibility to atopy. For instance, polymorphisms in CD14 have been shown to be associated with sCD14 levels, total IgE levels, and positive skin tests (162,163). Similarly, a polymorphism in the TLR2 gene (TLR2–16934) was shown to be a major susceptibility gene for children living on farms (164). Polymorphisms of the intracellular NOD1 protein, which binds cell wall peptidoglycans of gram-negative bacteria, were shown to be especially associated with atopic eczema and asthma (165).

Several of the common allergens (*Der p 3*, *Der p 9*, cockroach extracts, pollens) have been shown to have protease activity. Allergens containing protease activity, such as *Der p 1*, a cysteine protease, have been demonstrated to produce functional changes in the barrier function of the epithelium, probably by disrupting the epithelial tight junctions by degrading the tight junction proteins ZO-1

and desmoplakin (166). Disruption of the tight junctions may facilitate access of allergens to the underlying cells including DCs but may also directly initiate inflammatory cascades (modulate the function or immune and structural cells) in DCs and/or airway epithelium. Although the cellular mechanisms by which protease activity induces cytokine release remain unclear, members of a recently identified G-protein–coupled family of cell surface receptors, designated protease-activated receptors (PARs), have been implicated. Indeed, allergens such as the house dust mite serine proteases, *Der p 3*, *Der p 9*, cockroach extracts, and pollens activate PARs. Asokananthan et al. (167) showed that endogenous peptidases caused the release of cytokines through the activation of PAR receptors on the respiratory epithelium, and that all four members of the PAR family were expressed on respiratory epithelial cells. PAR-2 receptor activation leads to two main functional responses: production of prostaglandin E2 and production of proinflammatory cytokines (IL-8, MCP-1, IL-6). In vivo experiments in experimental allergen models support the contention that activation of PAR receptor pathways is associated with enhanced allergic responses. Specifically, PAR-2 overexpression enhanced ovalbumin-induced eosinophilia and bronchial hyperresponsiveness, whereas PAR-2 deficiency was associated with reduced allergen-driven eosinophilia and IgE production (168). As alluded to earlier, differences in DC responsiveness to allergen-derived proteases may be an important determinant of DC activation and atopic sensitization. Indeed, there is evidence that alterations in the expression of the protease receptor PAR-2 on epithelial cells may lead to greater *Der p 1* induction of DC chemokines and mediators from these cells obtained from asthmatics compared to nonatopic individuals. Taken together, these studies suggest that altered recognition and/or responsiveness to activators of the innate immune response at the epithelial–DC interface may contribute to sensitization to environmental antigens.

Altered DC Subset Distribution and Activation in Atopic Disorders

Recent evidence suggests that the development of tolerance may also be a function of specialized DC subsets (169,*170,171*). Although classification of DC subsets is an evolving field, in humans and in mice, multiple DC subsets have been identified based on their origin, phenotype, and function (169,*170–172*,173). Briefly, in humans, two major DC subsets have been identified that include CD11c^{high} myeloid cells (mDC) and CD11c^{low} plasmacytoid cells (pDC). mDCs are monocyte-derived cells and were originally referred to as DC1, as they were thought to produce predominantly IL-12 and drive Th1 immune responses. Plasmacytoid DCs were originally referred to as DC2, as they could promote Th2 immune responses. However, they also have the unique potential of

promoting Th1 responses by releasing large amounts of type 1 IFN in the presence of viruses (174) and dampening immune responses by inducing IL-10–producing CD4$^+$ regulatory T cells *(175)*. Recent studies suggest that the function of these two subsets is variable, depending on their location and the inflammatory context. Interestingly, these two subsets have unique expression profiles of immune molecules such as TLRs and chemokine receptors, suggesting distinctive compartmentalization and specific functions of these DC subsets (176). mDCs express TLR2, TLR4, TLR5, and/or TLR3, whereas pDCs express a more restricted profile of TLRs, including TLR9 and TLR7. Thus differences in recruitment, antigen uptake, or activation of DC subsets may play a role in altered immune responses in atopic individuals.

Several lines of evidence suggest that alterations in the relative proportion of specific DC subsets taking up antigen at mucosal surfaces may play an important role in the development of immunity or tolerance. For example, adoptive transfer of myeloid DCs to the murine airway prior to antigen exposure has been shown to induce Th2-mediated immune responses to a tolerogenic antigen (177). On the other hand, Lambrecht and colleagues (178) have shown that depletion of pDCs in mice during inhalation of the normally inert antigen OVA via the airways without systemic priming led to a Th2 response and all the features of asthma, whereas adoptive transfer of pDCs before sensitization prevented disease. These results strongly suggested that pDCs may provide intrinsic protection against inflammatory responses to harmless antigens. Although the precise mechanisms by which pDCs promote tolerance are unknown, several possibilities exist. First, pDCs may deliver a negative signal to T cells or mDCs directly, through their high-level of expression of programmed death ligand 1 (179). Additionally, pDCs can produce the tryptophan-metabolizing enzyme indoleamine 2,3-dioxygenase, which has a strong inhibitory activity on T-cell proliferation (180). Another explanation for the tolerogenic properties of pDCs is related to their immature phenotype, because it has been demonstrated that immature DCs can induce Treg ex vivo (181). Moreover, human pDCs activated by CpG oligonucleotides induce the generation of Treg (175). In contrast, it is speculated that mDCs may drive the development of Th2 responses by producing IL-6, which counteracts the suppression by naturally occurring CD4$^+$CD25$^+$ Treg. Further support for the importance of DC subsets to Th2 immune responses was provided by Lewkowich et al. (82), who reported that differential susceptibility of certain murine strains to allergen-induced asthma is associated with differences in the ratio of pDCs to mDCs recruited to the lung following allergen exposure. Although the exact factors regulating the recruitment and/or activation of different DC subsets is unknown, Kohl et al. (182) have shown that complement activation at the airway surface is an important regulator of DC subset recruitment and

activation. Specifically, they demonstrate that C5a preferentially results in the recrutment of pDCs to the lung, which is associated with protection against the development of Th2-mediated allergic airway responses. Taken together, these studies suggest that the balance between mDCs and pDCs may play a pivotal role in T-cell responses to antigen encounter at mucosal surfaces, with myeloid cells driving immunity while pDCs mediate tolerance to mucosal antigens. Dysregulation of the balance of mDCs and pDCs present in tissues in early life might predispose to atopic sensitization.

Because of the difficulty in sampling DC populations in tissues from atopic individuals, the role of mDC and pDCs in atopic individuals remains controversial. For example, Hagendorens et al. *(183)* compared DC populations in cord blood from children at low versus high risk of atopy and did not detect any differences. In contrast, a moderate reduction in pDC numbers in the blood was reported in atopic asthmatic children compared with healthy controls, which the authors suggested might be due to increased migration of pDCs to the target organ. In contrast, Matsuda et al. *(184)* showed that adult patients with asthma have increased numbers of pDCs in the blood compared to healthy controls. However, Upham showed that mDC numbers were reduced in the blood of patients after allergen challenge, suggesting that circulating mDCs are being recruited to the airway mucosa (136). In atopic dermatitis patients, Hashizume et al. reported an overall increase in the numbers of DCs in the blood, with a relative increase in pDCs over mDCs *(185)*. However, when DCs were evaluated in the nasal epithelium of atopic rhinitis patients, the number of pDCs was reduced. Although there is controversy as to the relative proportion of individual DC subsets present in the blood and tissues of atopic individuals, there is evidence that DC subsets may be functionally different between atopic and healthy individuals. Specifically, *Der p 1*–pulsed mDCs from healthy donors produced IL-10, whereas mDCs from allergic patients did not *(186)*. Although the study of DC subsets in human disease is in its infancy, taken together, these studies suggest that differences in the balance of DC subsets and their activation state may play an important role in determining the development of tolerance or immunity to environmental antigens. However, additional studies of DC subsets in relevant tissues are needed.

DC Cytokine Regulation of Th2 Differentiation in Allergic Disease

One of the most important variables in instruction of T-cell differentiation comes from the local cytokine milieu at the time of antigen presentation. Although much is still to be learned about these factors, well-documented examples are Th1 cell polarizing factors such as IL-12, and IL-27. Th2 cell polarizing factors include IL-6, TSLP,
FIGURE 43.3 Cytokines and downstream transcription factors are important in instructing T-cell differentiation to Th1-cells (IL-12, IL-27), Th2-cells (IL-6, TSLP, GM-CSF, PGE$_2$, IL-4), or T-regulatory cells (IL-10, TGF-β).

GM-CSF, PGE$_2$, and IL-4. Treg cell polarizing factors include IL-10 and TGF-β (Figure 43.3). Alterations in either the production of, or responsiveness to, these signals could lead to the development of aberrant Th2 immune responses in atopic individuals. Indeed, there is evidence to support each of these possibilities.

Potential Dysregulation of Th2 Differentiation Factors in Atopy

The exact mechanisms regulating differentiation of uncommitted T-cell responses into Th2 cells remain obscure. However, factors released by DC themselves (IL-6) or factors produced by the surrounding tissues (TSLP, PGE$_2$, GM-CSF) may play an important role in regulating DC cytokine production and subsequent T-cell responses. In addition, T cells in atopic individuals may respond more strongly to Th2-differentiating stimuli as a result of primary alterations in transcription factors regulating Th2 differentiation.

IL-6 has been shown to be an important determinant of Th2 cell differentiation, as it is secreted by cells of the innate immune system and induces the expansion of Th2 effector cells *(187)*. The mechanism by which IL-6 drives Th2 differentiation is controversial, as some studies suggest that IL-6 is able to polarize naïve CD4$^+$ T cells to effector Th2 cells by inducing the initial production of IL-4 in CD4$^+$ T cells (188), whereas other studies suggest that IL-6 produced by mucosal DCs impedes Th1 immune responses via suppression of DC IL-12 rather than through induction of IL-4 *(189)*. Additionally, IL-6 released by DCs has been shown to inhibit the suppressive function of CD4$^+$CD25$^+$

Treg cells, thus inhibiting the development of tolerance (190). More recent studies suggest that IL-6 plays a complex role in Th2 differentiation through distinct actions mediated via its binding of the membrane and soluble forms of its receptor *(191)*. Specifically, IL-6 can bind to the soluble IL-6R, and through a mechanism called trans-signaling, induces proliferation of cells expressing the cognate receptor gp130. This mechanism appears to be used for proliferation by developed Th2 cells in the airways, as blockade of the soluble IL-6R with the fusion protein gp130Fc reduces Th2 cells in the lung. In contrast, through the membrane-bound IL-6R, IL-6 controls CD4$^+$CD25$^+$ survival, as well as the initial stages of Th2 cell development in the lung. In support of a role for IL-6 in allergic disorders, serum levels of sIL-6R are increased in patients with asthma and are further increased during a spontaneous attack or following experimental allergen challenge (192). Although the mechanisms of altered IL-6 production are unknown, several triggers of allergic asthma (i.e., allergens, pollutants, ozone) induce IL-6 production in the epithelial cells lining mucosal tissues. Furthermore, variants in the IL-6 gene have been associated with hayfever and atopy *(193)*. Through the ability of IL-6 both to suppress Treg function and to inhibit Th1 differentiation, IL-6 signaling may drive Th2 cell differentiation in atopic disorders.

Epithelial cells lining mucosal tissues release a number of mediators in response to triggers of allergic disease such as allergens (i.e., *Der p 1, Pench 13* [aspergillus], cockroach antigens (194), viral infections (RSV), and pollutants (cigarette smoke, ozone, particulate matter) that may contribute to the instruction of T cells by DCs to polarize to a

Th2 cytokine–producing phenotype. These include thymic stromal lymphopoietin (TSLP), GM-CSF, and the arachidonic acid product, prostaglandin E2 (PGE2) *(195,196)*.

TSLP has been shown to activate DCs such that they acquire the ability to prime naïve T cells for the production of pr-inflammatory cytokines while downregulating IFN-γ and IL-10. In support of a role for TSLP in Th2 responses, TSLP levels have been shown to be elevated in both animal models of atopic disease as well as in the airways of asthmatic individuals *(197)*. Overexpression of TSLP in the lungs of mice has been shown to lead to the development of Th2 immune responses (198). In contrast, TSLPR-knockout mice develop strong Th1 responses to allergen and are protected against the development of allergen-driven asthmatic responses (199). Although the underlying mechanism of TSLP's ability to prime DCs is not known, TSLP-stimulated dendritic cells have been shown to prime human CD4$^+$ T cells into Th2 cytokine–producing cells in the absence of exogenous IL-4 and APCs. Interestingly, IL-4 blockade inhibited TSLP-mediated Th2 differentiation, demonstrating that IL-4 is involved in this process. Further analysis has shown that TSLP-induced Th2 differentiation is dependent on Stat6 and independent of IL-2. Moreover TSLP treatment leads to immediate, direct IL-4 gene transcription *(200)*. Although the mechanisms by which TSLP induces Th2 cytokine production are unknown, one mechanism that has been postulated is that TSLP induces DCs to express OX40 ligand (OX40L) but not IL-12. In support of this contention, TSLP-induced OX40L on DCs was required for triggering naïve CD4$^+$ T cells to produce IL-4, -5, and -13 (201). Taken together, these studies suggest that TSLP production at the mucosal surface may be an important determinant of polarized Th2 immune responses to environmental stimuli. The mechanisms regulating TSLP production remain to be elucidated.

GM-CSF is produced by airway epithelial cells in response to several triggers of allergic disease. It is thought to contribute to the recruitment, priming, and survival of DCs in the airways. Interestingly, overexpression of GM-CSF in the murine lung has been shown to be sufficient to prime Th2-mediated immune responses (202). Indeed, GM-CSF–dependent priming of Th2 responses occurred following challenge with ragweed *(203)*, but not when the innocuous antigen ovalbumin was delivered to the airways in the absence of added adjuvants. Although the mechanism(s) by which it preferentially leads to Th2 responses are unknown, it has been shown to be a preferential growth factor for myloid DCs.

The arachidonic acid product prostaglandin E2 (PGE2) has been shown to influence the local polarization of T cells by impairing the ability of maturing DCs to produce bioactive IL-12 p70. It has also been shown to cause early development of immature DC1 into Th2-promoting cells. In support of a role for PGE2 in Th2 immune responses,

PGE2 levels are consistently elevated in patients with allergic diseases (204,*205*). As described earlier, birch pollen may preferentially induce Th2 immune responses by virtue of its phytoprostanecontent, which is a plant homolog of PGE2.

Clearly, the presence of IL-4 at the site of antigen presentation is a dominant factor in determining the likelihood for Th2 polarization of the naïve Th cell in both mice and humans. It has been noted that intranodal Th2 cells deviate bystander Th1 responses within the same lymph node toward the Th2 phenotype via secretion of IL-4, thus providing a potential mechanism for progressive spreading of sensitization to encompass additional allergen specificities in chronic atopic asthma. In support of a central role for IL-4 in Th2 polarization in atopic disorders, the results of several studies suggest that genes regulating IL-4 production may be altered in atopic diseases and in particular in asthma. First, a specific polymorphism in the IL-4 gene itself has been shown to correlate with high serum IgE levels and enhanced IL-4 gene expression *(206)*. A similar association has been reported between the T allele of the −590C/T polymorphism of the IL-4 gene promoter region and atopic dermatitis *(207)*. Moreover, several groups have shown that expression of a mutant form of the IL-4 receptor α chain in allergic patients is associated with increased IL-4 signaling (110). Furthermore support for the role of IL-4 signaling in Th2 polarization in atopic disorders is the demonstration of the importance of the signal transducer and activator of transcription protein 6 (STAT6) in development of Th2 differentiation and development of allergic responses in mice *(208)*. Indeed, elevations in STAT6 expression in asthmatic tissues have been reported *(209)*. Moreover, a GT repeat polymorphism in the first exon of the STAT6 gene has recently been associated with increased prevalence of several atopic disorders (bronchial asthma, atopic dermatitis, food allergies) *(210)*.

Another factor expressed in Th2 cells that appears to function as a potent coactivator of IL-4 gene transcription is NFAT (nuclear factor of activated T cells). Several studies in mice have shown that alterations in a number of the family members of the NFAT protein family may result in altered IL-4 gene expression and polarization of T-cell responses toward the type 2 pattern. NFAT proteins are expressed on T cells, B cells, and mast cells, and control the transcription of a number of genes relevant to allergic disorders, including IL-4. Several studies have now shown that loss of NFATC1 activity results in impaired T-lymphocyte activity and secretion of IL-4 in mice (211,212). These experiments suggest that deficiencies in this transcription factor may lead to the development of the allergic phenotype.

A transcription factor that may be more widely involved in the induction and maintenance of the Th2 pattern of cytokine secretion is GATA-3. GATA-3 belongs to a subfamily of zinc-finger transcription factors that interact with

specific DNA-binding sequences in the regulatory regions of genes encoding T-helper 2–like cytokines. GATA-3, has been shown to be differentially expressed in Th2 and Th1 cells, and expression of this gene is sufficient to drive Th2 differentiation *(213)*. Altered regulation of GATA-3 expression may be important in atopy, as GATA-3 expression has been shown to be elevated in bronchoalveolar lavage fluids and bronchial biopsies of asthmatics when compared to normals *(209,214)*. Furthermore, blockade of this gene with a dominant negative mutant of GATA-3 inhibits allergic inflammation in mice (215). Recent evidence suggests that STAT5A can induce IL-4 production in naïve T cells by rendering the IL-4 gene accessible (216). However, overexpression of both STAT5A and GATA-3 provides maximal IL-4 production. Interestingly, a role for the transcriptional repressor gene growth factor independent 1 (Gfi1) in Th2 expansion has also been recently shown *(217)*.

Several other genes or chromosomal regions have been shown to be important in susceptibility to mounting Th2-driven immune responses in murine models; these include CNS-1 and TIM (T-cell immunoglobulin– and mucin domain–containing molecule). It has been shown that deletion of a noncoding segment, CNS-1 on murine chromosome 11 (human 5q), which is in the intergenic region between the IL-4 and IL-13 genes, results in the diminution of Th2 cytokine production in T cells (218). Similarly, a member of the TIM family of genes, also located on murine chromosome 11, has been shown to confer susceptibility to asthma in mice. Recent studies confirm an association of variants in TIM-1 and susceptibility to asthma (219). Although it is not currently known whether inheritance of a single gene variant or a combination of genetic variants is required to drive Th2 cell commitment in atopic individuals, considerable evidence is mounting to suggest that genetic differences in factors important in Th2 cell commitment may underlie susceptibility to development of atopic disorders.

Altered Th1-Promoting Cytokines in Atopic Disorders

Although Th2 cell polarization in atopic disorders can clearly arise as a result of aberrant expression of the genes important in Th2 differentiation, alterations in factors controlling expansion of the opposing Th1 pathways may also play an important role. In this regard, IL-12, a product of monocytes and DCs, is a primary determinant of T-cell differentiation to a Th1 pattern (220). Impaired IL-12 production has been reported in each of the atopic disorders *(221,222)*. Furthermore, successful steroid treatment was characterized by a significant increase in the numbers of cells expressing IL-12 mRNA, whereas steroid therapy in steroid-resistant patients did not result in an increase in IL-12–expressing cells. Further support for the importance of IL-12 in prevention of antigen-induced allergic airway responses has been provided by the observation that blockade of endogenous production of IL-12 in naturally resistant murine strains (C3H/HeJ) renders them susceptible to the development of allergen-induced AHR and eosinophilic inflammation *(223)*. Taken together, these studies suggest that dysregulation of endogenous IL-12 levels may be an important mechanism governing the pathogenesis of allergic disorders.

The mechanisms that give rise to alterations in IL-12 production are unclear at the present time; however, several possibilities exist, such as altered expression of the genes encoding either one or both of the individual subunits of the functional cytokine, or alternations in pathways regulating IL-12 production in DCs. To date, several studies have shown an association between IL-12B (IL-12p40) promoter polymorphisms and allergic phenotypes *(224,225)*, whereas others do not *(226)*. Alternatively, the deficient production of IL-12 in atopic disorders may occur as a result of altered regulation of DC IL-12 production by mediators and cytokines, which either positively (IFN-γ, C5a), or negatively (IL-4, PGE$_2$, IL-10, C3a), regulate its production. Recent studies suggest that perhaps complement components produced by cells in the mucosa, such as epithelial cells, may regulate IL-12 production *(227)*. It is postulated that C5a and C3a play a reciprocal role in regulating IL-12 production, with C5a inducing IL-12 and C3a inhibiting its production *(227)*. Interestingly, allergens such as house dust mite contain proteases that cleave both C5 and C3 into their active fragments, suggesting that allergens may directly activate complement and thereby regulate the type of immune response elicited at the mucosal surface *(13)*. Consistent with a potential role for complement, several studies have now demonstrated that animals deficient in either C3 or C3a do not develop allergic airway responses and have reduced Th2 cytokine production compared to wild-type mice (228,229). Conversely, lack of a functional C5 gene renders mice susceptible to development of allergen-driven Th2 immune responses (230). Support for a role for complement in human atopic diseases is provided by recent studies demonstrating enhanced expression of complement components in airway tissues from asthmatics (228) and the association of polymorphisms in complement genes, C5 *(140,141)*, and C3 *(231,232)*, with asthma phenotypes.

Another member of the IL-12 family, IL-27, has been shown to play an important role in the initiation of Th1 differentiation. In addition, IL-27 has been shown to regulate the Th2 differentiation factor, GATA-3. IL-27 consists of two subunits, the Epstein–Barr virus–induced gene 3 (EBI3) and p28. The actions of IL-27 are mediated by the WSX-1 receptor chain, which is highly expressed on CD4$^+$ T lymphocytes and NK cells. IL-27/WSX-1 signaling has been shown to inhibit allergen-driven airway hyperreactivity and lung inflammation in mice (233). Moreover, a recent study suggests that a polymorphism in the IL-27p28

gene (G964A) is associated with susceptibility to asthma *(234)*. Taken together, these studies support the possibility that alterations in Th1-promoting pathways may contribute to the aberrant Th2 polarization observed in atopic disorders.

Altered Treg Cell–Promoting Cytokines in Atopic Disorders

Several lines of evidence suggest that the production of cytokines by DCs leading to Treg generation is altered in atopic individuals. The DC cytokines that are known to regulate Treg differentiation are IL-10 and TGF-β. Although altered levels of IL-10 have been observed in atopic disorders, the relationship is not straightforward. For example, there are conflicting reports about the levels of IL-10 in atopic patients, with some studies demonstrating elevations in IL-10 levels in bronchial biopsies *(235)*, PBMCs *(236)*, bronchoalveolar lavage fluids *(237)*, and in the gut mucosa of asthmatic patients *(238)*, while others report diminished IL-10 production in sputum from asthmatic patients *(239)* and isolated T cells from children with asthma or atopic dermatitis *(240)*. Results from animal studies show similar disparities. IL-10–knockout mice have been shown to have both reduced allergic responses *(241)* as well as enhanced responses to allergen challenge (242). Investigators have suggested that the discrepancies in the results of studies with IL-10–deficient mice may be dependent on the genetic background of the strain (242). In contrast, studies in which animals have been treated with recombinant IL-10 *(243)* or overexpress the IL-10 gene (244) uniformly demonstrate that IL-10 suppresses inflammation and decreases development of Th2-mediated immune responses. Moreover, adoptive transfer of IL-10–expressing DC cells induced tolerance to allergen exposure (245). The variability in the results may reflect the pleiotrophic actions of IL-10 during the course of allergic reactions. IL-10 can clearly influence T-cell differentiation through its inhibitory actions on IL-12 as well as its ability to reduce antigen presentation to T cells by limiting class II, CD80 and CD86 expression on APCs. IL-10 not only generates tolerance in T cells, it is a potent anti-inflammatory cytokine, which can serve to dampen inflammation once initiated *(246)*. In this regard, it has been shown to reduce total and specific IgE production while increasing protective IgG4 levels *(247)*. The fact that steroids *(248)*, lactobacillus *(249)*, and standard immunotherapy regimes *(250)*, all of which successfully resolve symptoms in atopic diseases, induce IL-10 production suggests that perhaps IL-10 is protective and that IL-10 production may be impaired in atopic individuals. Diminished IL-10 production may lead both to loss of tolerance to environmental antigens as well as an inability to control inflammation once initiated. The elevations in IL-10 tissue levels observed during challenge with allergens may reflect compensatory

mechanisms designed to suppress harmful inflammatory responses. In this regard, genetic polymorphisms in the promoter of the IL-10 gene (C to A change at position 571) have been associated with asthma and elevated serum IgE levels (251).

Another DC-derived factor that regulates Treg differentiation is TGF-β. Although TGF-β is a pleiotrophic cytokine, it has been shown to play an important role in Treg differentiation and function. Specifically, it plays a role in the conversion of naïve CD4 T cells into the regulatory phenotype and has been reported to mediate the cell contact–dependent suppressive activity of Treg (252). Elemental to this conversion process is induction of expression of the forkhead transcription factor, Foxp3, in $CD4^+CD25^-$ T cells by TGF-β. Importantly, in a murine asthma model, administration of these TGF-β–induced suppressor T cells prevented house dust mite–induced allergic responses *(253)*. More recent studies show that the induction of Treg suppressor function and FoxP3 expression by TGF-β is dependent on TGF-β's ability to enhance CD80:CTLA-4 interactions on T cells. Consistent with an important role for TGF-β in regulation of T-cell differentiation, several studies (253), but not all *(254)*, suggest that SNPs in the TGF-β1 gene may be associated with atopic and asthma phenotypes *(255)*.

Several other mediators commonly present in inflamed tissues regulate Treg function as well. These include the arachidonic acid product prostaglandin D2 (PGD2) and heme-oxygenase (HO-1). The mast-cell mediator, PGD2, through stimulation of the DP1 receptor, has been shown to enhance Treg function through inhibiting DC IL-12p70 and p40 expression (256,257) and increasing $Foxp3^+$ $CD4^+$ regulatory T cells that suppress inflammation in an IL-10–dependent pathway (258). HO-1 enhances the secretion of IL-10 and increases the percentage of Treg *(259)*. Collectively, these studies suggest that dysregulation of factors controlling Treg cell differentiation and/or function may predispose to the development of deleterious Th2-mediated allergic responses to environmental antigens.

Role of DCs in Secondary Immune Responses

In addition to their contribution to the primary immune response leading to sensitization, DCs are likely to contribute to secondary immune responses in atopic individuals. Several lines of evidence support the absolute requirement of these cells in the secondary response, despite the previously held view that memory/effector T cells are less dependent on costimulation and, in theory, respond to any APC such as B cells, macrophages, and even eosinophils. First, during secondary immune responses, both human and rodent DC are rapidly recruited to mucosal surfaces (134). Second, depletion of DC in allergen-primed mice completely prevented the development of Th2-mediated

allergic inflammation *(260)*. Lastly, Hammad et al. (148) showed that adoptive transfer of myeloid DCs into PBMC-reconstituted hu-SCID mice boosted the production of house dust mite–specific IgE, illustrating that DCs stimulate memory Th2 cells to enhance secondary immune responses. These results provide strong evidence that DCs play a pivotal role in the primary as well as secondary response to allergens, although the mechanisms remain obscure.

Dendritic cells may play a role in secondary immune responses via their surface expression of the high-affinity IgE receptor. Indeed, CD1a$^+$ airway DCs express the α chain of the high-affinity IgE receptor. When allergen is recognized via the FcεRI on DCs, it is very efficiently targeted to the MHC class II–rich endocytic compartment, the site of peptide loading onto MHC class II. It has been suggested that the presence of IgE on DCs lowers the threshold for allergen recognition, boosting the secondary immune response by efficiently stimulating memory T cells. In support of this concept, Coyle et al. (261) showed that when allergen-specific IgE was captured by a nonanaphylactogenic anti-IgE antibody in sensitized mice, the mice failed to produce Th2 cytokines upon re-exposure to the sensitizing allergen. This perpetuation of the allergic response may indeed occur in atopic patients, in that the proportion of DCs expressing the α subunit of the high-affinity IgE receptor is significantly increased in asthmatic and atopic dermatitis patients compared to nonatopic controls *(262)*. This increase in FcεRI on DCs may also be the result of higher endogenous levels of IL-4, a known modulator of immunoglobulin Fc receptors.

Collectively, these studies suggest that altered DC function may underlie the propensity of atopic individuals to mount Th2-biased immune responses to environmental allergens. More detailed information regarding the exact mechanisms awaits further study of DC biology.

TH2 CYTOKINE REGULATION OF ALLERGIC INFLAMMATION

The dependence of the immunopathogenic consequences of allergic immune responses on Th2 cells likely stems from their pivotal role in regulating the primary effectors of both the acute and late-phase reactions, namely, IgE and eosinophils. In addition, as will be discussed in a later section, Th2 cell-derived cytokines, themselves, also serve as effector cells of the allergic response.

One of the major roles of IL-4 in allergic inflammation is as the primary inducer of immunoglobulin-class switching in B cells that leads to the synthesis and secretion of IgE (263). The importance of IL-4 to IgE synthesis has been demonstrated by the fact that neither IL-4– nor STAT6–deficient mice produce IgE *(208)*. The exact mechanisms by which IL-4 regulates IgE class switching will be dis-

cussed later. IL-13 is also able to regulate IgE synthesis in humans, but its role in IgE synthesis in mice is controversial. The combination of IL-4's effects on IgE synthesis and mast-cell growth suggests a primary role for IL-4 in the development of the early-phase response. As will be discussed in greater detail in a later section, IgE activation of mast cells leads to the synthesis and release of a number of inflammatory mediators that may contribute to the vascular, smooth muscle, and mucus changes observed in the early-phase response to allergen challenge.

Through their unique and overlapping actions IL-4, IL-13, and IL-5 coordinately regulate the development, recruitment, and activation of eosinophils. IL-4 and IL-13 have both been shown to contribute to the recruitment of eosinophils into sites of inflammation, as evidenced by the fact that inhibition of either IL-4 or IL-13 by antibody blockade, or gene deletion eliminates allergen-driven increases in tissue eosinophils (58,61). Conversely, overexpression of these cytokine genes in mice results in tissue eosinophilia (51,264). Because IL-5 has been shown to be the primary determinant of eosinophil differentiation, activation, and survival, it plays a critical role in eosinophil regulation in allergic responses. The importance of IL-5 in antigen-induced eosinophilia has been examined in numerous animal studies *(265)*. For example, blockade of endogenous IL-5 levels in antigen-sensitized guinea pigs *(265)* and in mice (49) has resulted in significant suppression of both BAL and tissue eosinophilia. More definitively, mice in which the IL-5 gene has been disrupted do not develop eosinophilic inflammation (50). Reconstitution of these mice with IL-5 completely restored aeroallergen-induced eosinophilia. Thus, through the coordinate regulation of IgE and eosinophilia, Th2 cytokines orchestrate the elicitation phase of allergic immune responses. In the next section we will discuss in more detail the steps involved in IgE regulation.

REGULATION OF IGE SYNTHESIS

Ishizaka and colleagues purified immunoglobulin E in 1966 (4,266). IgE has the shortest half-life (2.5 days) of all classes of immunoglobulins. In addition, it is present in serum at levels considerably lower than those of other immunoglobulin classes such as IgG. There is considerable heterogeneity in the levels of IgE among individuals. For example, levels of <100 ng/mL are observed in most normals, whereas IgE levels can reach as high as 1,000 ng/mL in parasitized or atopic individuals. The high variability in serum levels contrasts strikingly to other immunoglobulin isotypes and suggests that tight control of IgE may therefore be important to prevent the potentially lethal consequences of IgE-mediated inflammation. Indeed, synthesis of IgE and its receptor expression appear to be regulated by a series of steps involving both

cell–cell contact with CD4$^+$ Th2 cells and activation by cytokines secreted by these cells. In this section we will discuss our current knowledge of the complex steps involved in regulation of IgE synthesis, and expression of its receptors.

Isotype Class Switching to IgE Production

The production of IgE antibodies by B cells is triggered by a complex series of secreted signals and cell surface interactions, followed by molecular genetic rearrangements at the immunoglobulin heavy-chain locus, IgH (Figure 43.4). The first step in IgE production is the binding of allergen to allergen-specific B cells via their membrane-bound immunoglobulin receptor (BCR). The B cells then internalize and process the allergen, and present the processed allergen to T cells as peptide fragments in association with MHC class II molecules. The peptide–MHC II complex is then recognized by the TCR on Th2 cells. Initially, all

B cells produce IgM antibodies. At this point, a $V_H(D)J_H$ cassette of sequences encoding the variable domain is immediately adjacent to the $C\mu$ exons, which encode the IgM-constant regions at the 5′ end of the IgH locus. Farther downstream in IgH are several widely spaced clusters of exons. C regions encode the constant-region domains of the IgG, IgE, and IgA heavy-chain isotypes. Upon stimulation by cytokines, along with critical cell–cell interactions with CD4$^+$ T-cell surface accessory molecules, B cells can change the isotype of the antibodies (or effector functions) they produce while retaining their original antigenic specificity. This process requires that genomic DNA be spliced and rejoined to move the VDJ elements from their location proximal to $C\mu$ to a position many kilobases downstream, next to the C-region exons encoding the heavy chains of other isotypes. A large amount of intervening DNA is excised and discarded in this irreversible process, and therefore the mechanism is referred to as deletional switch recombination.
FIGURE 43.4 The regulation of IgE synthesis involves many sequential steps: *(1)* recognition of antigen/MHC class II by the T-cell receptor; *(2)* TCR activation leads to the induction of CD40 ligand on the T cell, which is then recognized by CD40 on the B cell; *(3)* CD40/CD40L cognate interaction leads to induction of CD80/CD86 on the B cell, which can then interact with CD28; *(4)* the Th2 cell secretes IL-4 and IL-13; *(5)* IL-4 and IL-13 bind their cognate receptors on B cells and result in activation of Stat6; *(6)* IL-4 and IL-13 signaling events result in initiation of transcription at the Iε promotor and the production of immature germline ε transcripts; *(7)* the CD40/CD40L interaction provides the necessary second signal required for recombination of the germline locus; *(8)* transcription of mature ε transcripts from the rearranged locus followed by translation and secretion of IgE.

Isotype switching to IgE production requires two signals (267). The first signal is provided by the Th2 cytokines IL-4 and IL-13 and is IgE isotype–specific. IL-4 and IL-13 stimulate transcription at the Cε gene locus, which contains the exons encoding the constant-region domains of the IgE ε heavy chain. This transcription is initiated at a site upstream the ε switch region designated Iε. The second signal is a B-cell–activating signal provided through CD40/CD40L interactions. Together these interactions result in induction of the necessary deletional switch recombination that brings into proximity all of the elements of a functional ε heavy chain.

The first signal for IgE class switching is provided by the T-cell–derived cytokines IL-4/IL-13. IL-4 induces RNA transcription at the Cε locus via stimulation of STAT6 through binding the type I IL-4 receptor composed of the IL-4Rα chain and the γ c chain. IL-13 has also been shown to regulate IgE class switching in humans through binding the type II IL-4 receptor composed of the IL-4Rα and IL-13Rα1 chains. However, there is considerable controversy about the role of IL-13 in IgE class switching in mice. Following either IL-4 or IL-13 binding to its respective receptor complex, JAK kinases phosphorylate tyrosine residues in the intracellular domains of the receptor chains, providing docking sites for STAT6. These STAT6 molecules become phosphorylated and then form homodimers that translocate to the nucleus. In the nucleus they bind to specific sequences (TTCN(N)GAA) in the promoter of IL-4/IL-13–responsive genes, including Iε. The importance of STAT6 in IL-4–induced isotype switching is supported by the fact that germline transcription and IgE class switching are markedly impaired in STAT6-deficient mice (268). Other transcription factors are also important in induction of germline transcription of the Cε locus. The importance of NF-κB for the induction of germline transcripts has been recently confirmed by the finding that expression of germline transcripts for Cε are severely diminished in NF-κB p50 knockout mice *(269)*.

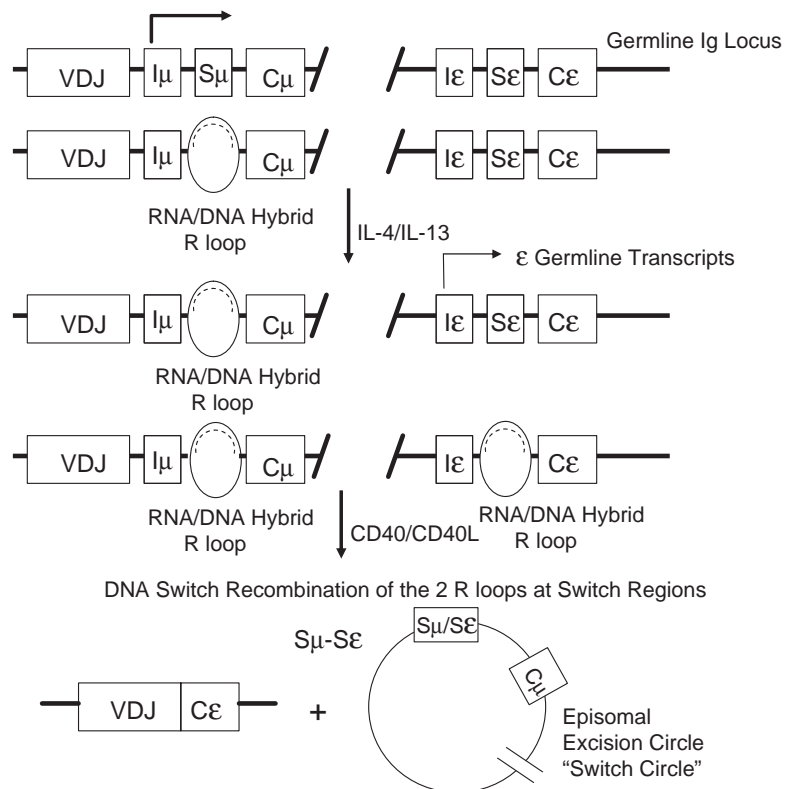
IL-4– and/or IL-13–induced transcription factor binding to the Cε locus results in germline transcription of the Cε locus (Figure 43.5). Germline transcripts originate from a 5$'$ promoter of the Iε exon, which is located just upstream of the 4 Cε exons. IL-4 induces the appearance of 1.7- to 1.9-kb germline Cε transcripts that contain an Iε exon, located 2 kb upstream of Sε, spliced to the Cε1 to Cε4 exons. After processing, the mature germline mRNA's include the 140-bp Iε exon and exons Cε1 to Cε4. These transcripts have been referred to as sterile, because of the presence of stop codons in each of the three reading frames of Iε . However, it is the process of transcription itself that appears to facilitate the deletional switch recombination event. For example, Harriman et al. (270) analyzed IgA switching using mice retaining a normal Iα promoter in which the Iα exon was replaced by an HPRT minigene, and found that switching can occur to the locus despite the absence of complete Iα-containing transcripts. This has been


FIGURE 43.5 Schematic representation of the molecular steps involved in IgE class switching. In naïve resting B cells, the VDJ sequences encoding the variable region are located at the 5$'$ end of the Ig locus. After stimulation by IL-4 or IL-13, transcription is initiated at the Iε promotor to produce ε germline transcripts. Sε RNA remains hybridized to the Sε DNA, forming an RNA–DNA hybrid structure, called an R loop. The R loop serves as a substrate for nucleases that result in double-stranded DNA breaks. Switch recombination and joining is dependent on a second signal provided by the CD40/CD40L interaction. This process results in the formation of an episomal excision circle that is eventually lost during cell division.

demonstrated at the Cε locus in that switch recombination occurred at the Cε locus when the Iε exon and promoter were intact but Cε exons were absent (271).

The second signal for IgE class switching is dependent on cell-to-cell contact between T and B cells. Specifically, the interaction between CD40 on the surface of B cells with CD40L on the T-cell surface is critical to drive the IgE switch to completion and lead to IgE production. CD40 is a 50-kDa surface glycoprotein that is constitutively expressed on all human B lymphocytes. CD40L is transiently induced on T cells after stimulation of the T-cell receptor by antigen/MHC complexes. Binding of newly expressed CD40L with CD40 on B cells provides the second signal for induction of deletional switch recombination to IgE.

Several lines of evidence support a critical role for CD40/CD40L interactions in isotype switching. First, it had been shown by numerous groups that isotype switching requires the presence of and contact with T cells. After an extensive search for the T-cell contact signal, it was discovered that CD40/CD40L interactions were responsible for the T-cell dependency of this process. Proof of this was provided by the observation that activation of CD40L could completely substitute for T-cell help (272). Furthermore, a soluble form of CD40 inhibits its interactions with CD40L, blocking IL-4–driven IgE synthesis in human B cells (273). Lastly, genetic deficiencies in CD40L or CD40 in humans and mice, respectively, disrupt IgE synthesis. In humans, CD40L is encoded on the X chromosome, and individuals with the X-linked hyper-IgM syndrome are deficient in CD40L. Their B cells are unable to produce IgG, IgA, or IgE *(274)*. Similarly, mice that are deficient in either the CD40L or CD40 genes have the same defect in antibody production (275,276).

CD40/CD40L interactions are thought to provide a second signal via stimulation of a number of signaling pathways that likely synergize with those initiated by IL-4 and IL-13 to achieve e-germline transcription. Specifically, after interaction with CD40L on the B-cell surface, CD40 aggregation triggers signal tranduction through four intracellular proteins, which belong to the family of TNF receptor–associated factors (TRAFs). TRAFs 2, 5, 6 are known to associate with the intracytoplasmic domain of CD40 after its multimerization by interaction with CD40L. TRAF-2, TRAF-5, and TRAF-6 promote the dissociation of NF-κB from its inhibitor, IκB. In turn, NF-κB can synergize with STAT6 induced by IL-4/IL-13 signaling to activate the Iε promoter, as described previously. In addition to triggering TRAF associations, engagement of CD40 activates protein tyrosine kinases (PTKs), such as JAK kinases.

Another mechanism by which cytokine and CD40L activation may induce class switching is via induction of expression of proteins required in deletional recombination. Specifically, both cytokine and CD40L induction of class switching have been shown to require the synthesis of new proteins. One of these proteins has been recently identi-

fied as activation-induced cytidine deaminase (AID) *(277)*. AID is expressed in activated B cells and in germinal centers of lymph nodes. Mice that are deficient in AID have a dramatic impairment in isotype switching, with elevated IgM levels and low or absent IgE, IgG, and IgA isotypes (278). Interestingly, a rare autosomal form of hyper-IgM syndrome has now been attributed to mutations in this gene *(279)*. Although these studies suggest that this protein is critical to isotype switching, the mechanisms by which it participates in switch recombination remain obscure at present. AID has homology to the RNA editing enzyme APOBEC, which modifies specific sites in ApoB precursor RNA to give rise to a transcript encoding the functional apoB48 protein. AID might execute a similar RNA-editing function in B cells, processing pre-RNA–encoding proteins involved in the mechanisms of switch recombination and hypermutation. Alternatively, AID might mediate the construction of ribozymes, complex RNA structures with nuclease activity, or it could act directly on DNA substrates in the heavy-chain locus. Currently, the weight of evidence favors the action of AID as a DNA-editing enzyme.

Deletional Switch Recombination

Following the delivery of both IL-4 and CD40/CD40L signals, deletional switch recombination occurs through a series of molecular events that are not yet fully understood (271,280). However, the current data are consistent with a model in which IL-4/IL-13–driven transcription originating at the Iε promoter alters the ε heavy-chain locus in a way that permits isotype switch recombination. However, because the ε-germline transcripts do not encode a functional protein, their precise role in isotype switching has long eluded investigators. Recently a number of reports have begun to shed light on this subject. It appears that germline transcripts participate in the assembly of complex DNA–RNA hybrid structures, which then target nucleases to the ε locus for the initial DNA cleavage in the cut-and-paste reaction of deletional switch recombination. In deletional switch recombination at the ε locus, DNA cleavage and ligation are carried out within the switch (Sε) cassette, which contains repeats of GAGCT and GGGGT and is located between the Iε and Cε exons. ε-Germline transcripts, originating at the Iε promoter, pass through the Sε region and then on into the Cε exons. Transcription experiments have shown that the S region–encoding RNA does not separate from its genomic template but rather remains associated to form a DNA–RNA hybrid. Another group has shown that these hybrids create R loops, in which the S transcript hybridizes to the template DNA, leaving the opposite strand as single-stranded DNA. Two endogenous excision-repair nucleases, XPF-ERCC1 and XPG, previously known to target duplex single-strand junctions, have been shown to be capable of cleaving these R loops. These new observations have given rise to a model

in which R loops formed by the association of Sε RNA with its Sε genomic template serve as substrates for nucleases that generate double-strand DNA breaks in the first step of deletional switching. In later steps, these breaks can be annealed by DNA end joining to analogous breaks in Sμ, located between V$_H$(D)J$_H$ and the Cμ exons. This rearrangement brings the V$_H$(D)J$_H$ segments encoding the antigen-binding site into the immediate proximity of the Cε exons encoding the constant domains. The product of this recombination is the de novo generation of a complete multiexon gene that can be transcribed as a single message encoding the full ε heavy chain. Although these new reports establish the existence of R loops and demonstrate that these two nucleases can cleave these structures, it has not been definitively shown that these enzymes are the nucleases relevant to the deletional isotype switch mechanism. The specific nucleases used by B cells still need to be identified. These proteins may be constitutively expressed in B cells, but, as discussed previously, proteins such as AID may be induced as a result of either IL-4/IL-13 or CD40/CD40L interactions.

Negative Regulation of IgE Synthesis

Several cytokines, including TGF-β, IFN-α, and IFN-γ, can inhibit IL-4-dependent IgE synthesis in both mice *(281)* and humans *(282)*. IFN-γ suppresses the expression of ε-germline transcripts in murine B cells stimulated with IL-4 and LPS. IFN-γ may affect recombination events without affecting the expression of ε-germline transcripts. Other agents, including IL-12 *(283)* and IL-10 (247), have been reported to inhibit IgE while enhancing IgG4 *(283)*. Interestingly, the Th2 cytokine IL-21 has recently been shown to inhibit IgE isotype class switching and IgE$^+$ cell clonal expansion (284). Although the exact mechanism by which IL-21 regulates IgE production is not entirely understood, it is thought that IL-21 directly antagonizes IL-4 and LPS-induced Iε switch recombination (285). Because IL-21 does not alter proliferation or STAT6 phosphorylation of murine B cells in response to IL-4, the mechanism is unknown. Another mechanism of regulation of IgE is through the competition with IL-4–driven IgG4-blocking antibodies. IgE-mediated hypersensitivity reactions are rare in patients with chronic helminth infections, even though FcεRI-bearing cells are sensitized with antiparasite IgE. The inhibition of allergic reactivity is due mainly to IgG4-blocking antibodies, as evidenced by the fact that the depletion of IgG4 specifically removes the blocking activity from the sera of microfilaremic patients. IgG4-blocking activity has also been detected in patients receiving immunotherapy for insect venom *(286)* and house dust mite hypersensitivity *(287)*. Blocking IgG4 competes with cell-bound IgE for allergen binding. Because the IgG4 molecule is functionally monovalent, does not fix complement, and binds weakly to Fcγ receptors, antigen binding to IgG4 has

no harmful consequences. However, competition between IgG4 and IgE can occur only if the two antibody isotypes have at least in part the same antigen specificity. A molecular mechanism for this overlap in specificity was provided by the demonstration that isotype switching can occur sequentially from IgM to IgE through IgG4. This has been formally demonstrated, in that IgG antibody in mice can completely suppress IgE-mediated anaphylaxis (288).

IgE Receptors

The two major Fc receptors for IgE are called FcεRI and FcεRII (CD23) *(289)*. They are distinguished by their structure and their relative affinities for IgE. The high-affinity IgE receptor FcεRI binds monomeric IgE with an affinity constant of 1010 M^{-1}, whereas CD23 binds with a much lower affinity (10^8 M^{-1}). The high-affinity receptors are constitutively expressed at high levels on mast cells and basophils. They are also found, albeit at lower levels, on peripheral blood dendritic cells, monocytes, and human Langerhans cells. The low-affinity receptor is also expressed on a wide variety of cells, including B cells, T cells, Langerhans cells, monocytes, macrophages, platelets, and eosinophils.

FcεRI-Mediated Signal Transduction

The FcεRI is a member of the multisubunit immune response receptor (MIRR) family of cell surface receptors that lack intrinsic enzymatic activity but transduce intracellular signals through association with cytoplasmic tyrosine kinases *(289)*. In rodents, FcεRI is expressed on mast cells and basophils as a heterotetramer consisting of a single IgE-binding α subunit, a β subunit, and two disulfide-linked γ subunits. The α chain consists of two extracellular Ig-like loops, a single transmembrane region containing an aspartic acid residue, and a short cytoplasmic domain that lacks signal transduction motifs. The charged amino acid within the transmembrane domain mediates the association of the α subunit with the signaling component of the γ subunit. The β subunit consists of four membrane-spanning domains and a cytoplasmic tail capable of transducing intracellular signals that amplify γ-mediated signaling events. In rodents, all three subunits are required for the cell surface expression of FcεRI *(289,290)*. In contrast, in humans the receptor can be expressed as two different isoforms, a tetramer ($\alpha,\beta,\gamma 2$) or a trimer ($\alpha\gamma 2$). The tetrameric complex ($\alpha\beta\gamma 2$) is expressed on mast cells and basophils, whereas the trimer is expressed on Langerhans cells, dendritic cells, monocytes and macrophages, and eosinophils.

FcεRI signaling occurs upon IgE binding to the receptor. This requires two sequential events: (a) binding of IgE antibody to the FcεRI and (b) crosslinking of IgE antibody by bivalent or multivalent antigen. Crosslinking of the

receptor initiates a coordinated sequence of biochemical and morphologic events that result in: (a) exocytosis of secretory granules containing histamine and other performed mediators; (b) synthesis and secretion of newly formed lipid mediators, such as prostaglandins and leukotrienes; and (c) synthesis and secretion of cytokines. Although the exact signaling pathways governing each of these functions are not known, the following model has been proposed. The β and γ subunits each contain a conserved immunoreceptor tyrosine-based activation motif (ITAM) within their cytoplasmic tails that is rapidly phosphorylated on tyrosine after FcεRI aggregation (*290*,291). Tyrosine phosphorylation of the β and γ ITAMs is mediated by Lyn, which is constitutively associated with the β subunit and activated after antigen-mediated FcεRI aggregation. FcεRI crosslinking leads to recruitment and activation of the tyrosine kinase Syk, which binds to the tyrosine-phosphorylated γ ITAMS through its tandem SH2 domains *(289)*. Recruitment of Syk occurs upstream of several signal transduction pathways. The importance of Syk is demonstrated by using Syk-deficient mast cells, which fail to degranulate, synthesize leukotrienes, and secrete cytokines after FcεRI stimulation *(292)*. Ultimately, this pathway leads to the activation of MAP kinases, and activation of PKC pathways. PKC pathways are thought to be important in exocytosis and granule-content release and gene expression. Activation of MAP kinases also regulates the enzymatic activity of PLA$_2$, leading to generation of a variety of lipid mediators (PAF, PGD$_2$, and LTC$_4$). Antigen-mediated aggregation of FcεRI also stimulates the recruitment and activation of p21ras, which has been implicated in FcεRI-induced cytokine transcription and secretion *(289)*.

Regulation of FcεRI Surface Expression

Although the expression of FcεRI on the surface of mast cells appears to occur early in their differentiation and/or maturation in vivo, the levels are known to be regulated by several factors postmaturation. Studies in both mice and humans have revealed that the levels of FcεRI on mast cells can be regulated by IgE itself as well as by Th2 cytokines. Indeed, atopic individuals with high serum IgE levels show markedly upregulated mast cell and basophil FcεRI levels (293,*294*). Moreover, anti-IgE treatment of atopic individuals results in downregulation of FcεRI expression on human basophils *(295)*. Further evidence is provided by murine studies in which IgE-deficient mice exhibit dramatically reduced levels of receptors on mast cells and basophils. Because IgE-deficient mice still express receptors, albeit at lower levels, other mechanisms of regulation are thought to exist. In fact, cytokines such as IL-4 and IL-13 have been shown to upregulate FcεRIα expression on mast cells, basophils, and monocytes. Glucocorticoids have been shown to inhibit IL-4– and

IL-13–induced upregulation of the FcεRIα chain on monocytes *(296)*. Together these results suggest that, through a multistep positive feedback process, Th2 cytokines enhance both the production of IgE and the expression of its receptor, which lead to further mast-cell activation and release of Th2 cytokines in the local microenvironment, serving to perpetuate the allergic response.

Mast-cell activation is subject to negative regulation by a growing family of structurally and functionally related inhibitory receptors. These include FcγRIIB, CTLA4, killer cell inhibitory receptors (KIRs), and gp^{49b1} on mast cells. Indeed, gp^{45b1}-deficient mice exhibit more severe anaphylactic reactions than their normal counterparts (297). Each of these receptors possesses an immunoreceptor tyrosine-based inhibitory motif (ITIM). Coaggregation of FcεRI and these inhibitory receptors on the surface of mast cells results in inhibition of FcεRI-induced mast-cell activation *(298,299)*. In general, inhibitory receptors are thought to inhibit the actions of activation receptors containing ITAM motifs by recruiting phosphatases through an immunoreceptor tyrosine-based inhibition motif (ITIM) (300).

FcεRII (CD23)

In humans, CD23 (FcεRII, B-cell differentiation antigen) is a Ca^{2+}-dependent C-type lectin of 45 kDa. It has wide distribution among hematopoietic and structural cells and exists in two forms, CD23a, and CD23b, resulting from alternative splicing at the N terminus and differing by five amino acids in the cytoplasmic domain. The isoforms of CD23 are found on B cells; one is constitutively expressed (CD23a), whereas the other form, CD23b, is induced by factors such as IL-4 (301) and CD40L in conjunction with IL-4. CD23b is also found on non-B cells such as T cells, Langerhans cells, monocytes, macrophages, platelets, and eosinophils *(302,303)* and mediates different biologic functions. The b form has been shown to be associated with phagocytosis of soluble IgE complexes, while the a form is associated with endocytosis of IgE-coated particles *(304)*.

Structurally, CD23 presents a single membrane-spanning domain followed by an extracellular domain that consists of three regions: the α-helical coiled-coil stalk region, which mediates the formation of trimers, followed by the lectin head, which binds IgE, and at the C terminus a short tail containing an inverse RGD sequence, a common recognition site of integrins *(305,306)*. CD23 is cleaved at the membrane to yield a series of soluble fragments. sCD23s of varying molecular weights arise by an autocatalytic process involving matrix metalloproteinase cleavage of membrane-bound CD23. The endogenous proteases that participate in CD23 shedding have not been identified. However, interestingly, *Der p 1*, the major house dust mite antigen, has been shown to selectively cleave CD23 and to promote IgE synthesis (16). CD23 expression

is upregulated by several factors, including by its ligand, IgE *(307)*, and by IL-4 (301). On the other hand, IFN-γ counteracts the inducing effect of IL-4 on CD23 expression.

CD23 is thought to mediate a number of effects, including regulation of IgE synthesis, antigen presentation, proliferation and differentiation of B cells, and activation of monocytes, effects that can be ascribed to the membrane and soluble forms of CD23 *(306,308)*. Binding of IgE to the membrane-bound form of the receptor transduces an inhibitory signal that prevents further IgE synthesis *(309)*. In contrast, the soluble forms described previously upregulate IgE production, and their release has been found to be inhibited by IgE binding *(310)*. Soluble CD23 also ligates CD11b/CD11c to promote release of proinflammatory mediators such as IL-1β, IL-6, and TNF-α (311).

CD23 expression on B cells and monocytes and sCD23 production is markedly increased in allergic disorders *(33,312,313)*. Moreover, reduction of allergen-induced CD23 expression on B cells has been observed after successful desensitization therapy *(314)*. Dysregulation of the CD23 pathway in atopic patients might be part of their propensity to develop IgE antibodies and of an enhancement of the inflammatory reaction, through the action of sCD23 as well as through IgE-dependent triggering of CD23 on non–B cells.

EFFECTOR CELLS OF THE ALLERGIC RESPONSE

Overview

Once a genetically susceptible individual is sensitized to a given allergen and IgE antibody has been formed, subsequent exposure to allergens readily induces the manifestations of atopic disease. Although these responses are generally a continium, they have been categorized into three types based on their temporal sequence: (a) acute or immediate responses, (b) late-phase reactions, and (c) chronic allergic inflammation.

Exposure of a sensitized individual to allergens results in immediate reactions, the characteristics of which depend on the site of entry of the allergen. In the nasal mucosa, allergen provocation of sensitized individuals results in sneezing, itching, and nasal discharge. Acute allergic reactions, elicited in the skin at the sites of allergen injection, are characterized by intense itching, redness, and edema. In asthmatic patients subjected to allergen inhalation, these mediators rapidly elicit bronchial mucosa edema, mucus production, and smooth muscle constriction. Acute or immediate responses are thought to be due to the release of preformed mediators released by antigen interaction with Fc receptors and IgE on IgE-bearing cells (mast cells and basophils). The release of mast-cell prod-

ucts produces multiple local effects, including enhanced local vascular permeability (leading to leakage of plasma proteins, including fibrogen, resulting in local deposition of cross-linked fibrin and tissue swelling), increased cutaneous blood flow, with intravascular fluid from postcapillary venules, producing erythema), and other effects, such as itching, due to the stimulation of cutaneous sensory nerves by histamine. Typically, these reactions are detectable within a few minutes of allergen challenge, reach a maximum in 30 to 60 minutes, then rapidly wane.

In many individuals the acute phase is followed by what has been termed a late-phase reaction (LPR) that occurs within 6 to 48 hours after allergen exposure and can persist for several days in the absence of therapy. The characteristic signs and symptoms of late-phase reactions are reddening and swelling of the skin, sneezing and nasal discharge, and wheezing and cough upon lower-airway challenge. Late-phase reactions are thought to occur as a result of recruitment of circulating leukocytes to the site of allergen exposure following antigen presentation to T cells. Both eosinophils and T cells are assumed to mediate the late-phase response. However, mast cells may also contribute to the late-phase response. The importance of leukocyte recruitment is supported by the fact that a variety of treatments, which are associated with a reduction in leukocyte recruitment that is elicited at sites of LPRs, can also reduce the signs and symptoms of these responses.

In naturally occurring allergic diseases, patients typically experience repeated exposure to the offending allergens over a period of weeks to years. Although the specific features of pathology of each of these diseases vary according to the anatomic site affected, it has been generally recognized that the structural changes that occur in each tissue are due to the persistence of inflammation. These tissue changes range from thickened skin and fibrotic papules to extensive remodeling of the airway wall with smooth muscle hypertrophy, subepithelial fibrosis, and mucus cell hypertrophy. In each case, these structural changes are associated with significant alterations in their function.

Development of Mast Cells and Basophils

History and Overview

Mast cells and basophils were discovered by Paul Ehrlich in the late 1800s, based on staining of their cytoplasmic granules with aniline and basophilic dyes, respectively *(315)*. It was once thought that basophils might be circulating precursors of mast cells or that mast cells were "tissue basophils," but current evidence suggest that they are indeed distinct cell types. Although these cell types have unique functions and release a unique profile of mediators, they also produce an overlapping array of mediators that are known to contribute to the allergic diathesis. It is hypothesized that IgE produced by allergen-reactive

B cells binds to FcεR receptors present on the surface of mast cells and basophils, and that when challenged with allergen, these cells release vasoactive mediators as well as chemotactic factors and cytokines that promote leukocyte infiltration and exacerbate the inflammatory response. Through the production and release of these proinflammatory molecules, mast cells and basophils set into motion a series of events that result in immediate responses to allergens in the skin, lungs, and nose of atopic individuals and may also contribute to the late-phase response.

Basophils

Basophils are a small population of peripheral blood leukocytes containing cytoplasmic granules that stain with basophilic dyes. They typically exhibit a segmented nucleus with marked condensation of nuclear chromatin and contain round or oval cytoplasmic granules. Basophils are thought to arise from pluripotent CD34$^+$ progenitors found in cord blood, peripheral blood, and bone marrow. They have been suggested to evolve from CD34$^+$/IL-3Rα^+/IL-5$^+$ eosinophil/basophil progenitors, as supported by the occurrence of granulocytes with a hybrid eosinophil/basophil phenotype in patients with chronic or acute myelogenous leukemia or in cell culture *(316–318)*. Unlike mast cells, basophils differentiate and mature in the bone marrow and then circulate in the blood, where they constitute <1% of circulating leukocytes. IL-3 appears to be an important developmental factor for basophils *(319)*, although many other growth factors, such as IL-5, GM-CSF, TGF-α, and nerve growth factor, likely influence their development *(320–322)*. Like mast cells, basophils possess high-affinity IgE receptors (FcεR1) that are cross-linked upon engagement of receptor-bound IgE with corresponding antigens, resulting in release of a number of mediators that are in part common for both cell types.

The study of basophil biology has been severely hampered by the lack of specific markers for detection of basophils in tissues and the inability to isolate significant numbers of these cells from peripheral blood. Participation of basophils in allergic reactions has traditionally been documented by indirect means, such as by determining the pattern of mast-cell– or basophil–specific mediators such as histamine (derived from both), PGD$_2$ (mast cells only), and LTC$_4$ (primarily from basophils). Despite the difficulties in studying basophils, recent studies suggest that they rapidly produce large amounts of the immunoregulatory cytokines IL-4 and IL-13 and constitutively express CD40L and CCR3 on their surface. These findings, taken together with the demonstration that they are rapidly recruited to the skin (323), lung *(324)*, and nose *(325)* after allergen challenge, suggests that these cells likely play an important role in allergic diseases. However, because much more is known about the role of mast cells in the immune response,

we will confine our discussion to mast cells except where specific information about basophils is available.

Mast Cells

Mast cells typically appear as round or elongated cells with a nonsegmented or occasionally bi- or multinucleated nucleus. Their intracellular granules stain purple when stained with aniline blue dyes. This change in color represents the interaction of the dyes with the highly acidic heparin contained in the mast-cell granules. Mast cells, like other granulocytes, are derived from CD34$^+$ hematopoietic progenitor cells; however, they are distinct from other granulocytes in that they mature in the periphery. Several lines of evidence suggest that interactions between the tyrosine kinase receptor c-kit, which is expressed on the surface of mast cells, and the c-kit ligand, stem cell factor (SCF), are essential for normal mast-cell development and survival. For example, mice with mutations that result in either markedly impaired c-kit function or a reduction in c-kit virtually lack mast cells. Reconstitution with rSCF can induce mast-cell hyperplasia in vivo in mice, rats, primates, and humans *(326)*.

Mast cells are distributed throughout normal connective tissues, where they often lie adjacent to blood and lymphatic vessels, near or within nerves, beneath epithelial surfaces that are exposed to the external environment, such as those of the respiratory tract, GI tract, and skin (Figure 43.6). At these locations they are ideally situated to encounter foreign antigens and to release their products in close proximity to their respective target cells (i.e., epithelial cells, vascular endothelium, smooth muscle, and fibroblasts). In humans and mice, the number of mast cells in a tissue varies markedly, depending on the anatomic site and the immunologic status of the host.

The mast-cell population is composed of a heterogeneous group of cells with respect to their structure and function *(327)*. On the basis of their content of neutral serine proteases, they had previously been divided into two phenotypes. One subset, designated MC$_{TC}$, contains tryptase, chymase, cathespsin G, and carboxypeptidase, whereas the other phenotype, designated MC$_T$, contains only tryptase. MC$_{TC}$ is found predominantly in skin and at subepithelial locations in the bronchial, nasal, and GI mucosa, whereas the MC$_T$ is located predominantly in alveolar walls, intestinal epithelium, and in airway epithelium in patients with allergic disease. However, more recent studies in both humans and animal models suggest that mast cells in different anatomic sites and even within a single site can vary in several aspects of their phenotype, including morphology, responsiveness to various stimuli, and activation and mediator content.

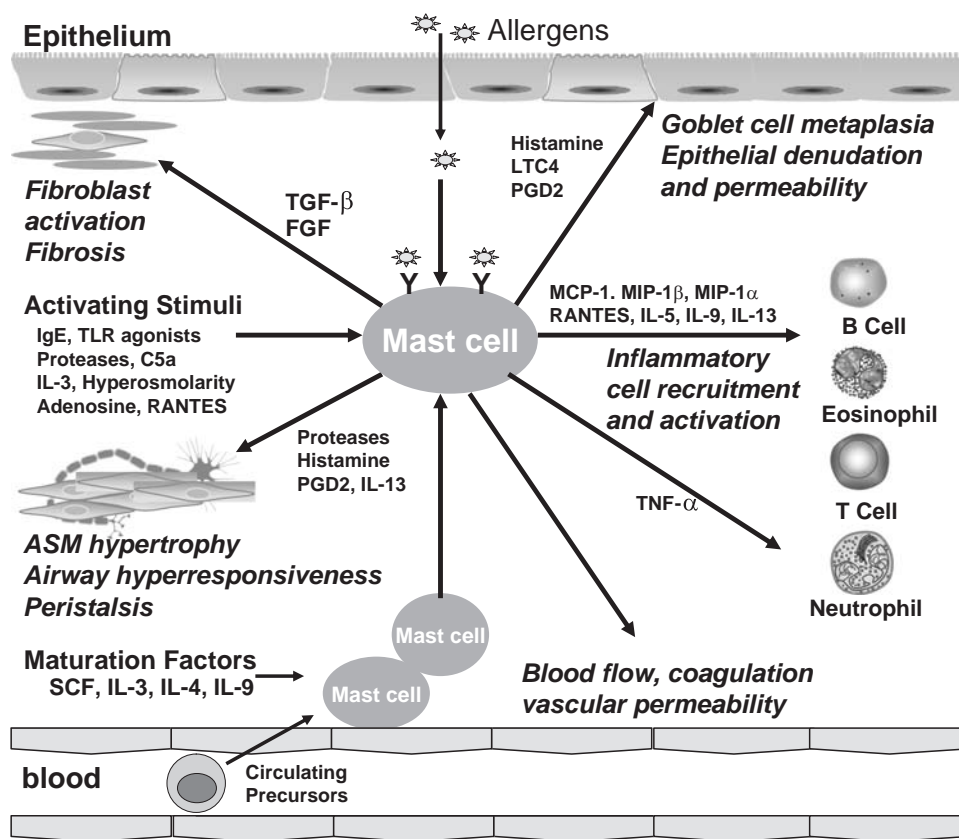
The tissue levels of mast cells and their specific phenotypes are likely controlled by a complex interplay between SCF, other growth factors, and cytokines. SCF is


FIGURE 43.6 Mast cells are produced in the bone marrow and released into the circulation as immature precursors. They mature in tissues under the influence of stem cell factor, SCF, IL-3, IL-4, and IL-9. Once activated by either antigen crosslinking of surface IgE or via a variety of other factors (TLR ligands, proteases, C5a, IL-3, hyperosmolarity, adenosine, RANTES), mast cells degranulate and release a variety of mediators, including vasoactive and bronchoactive mediators (histamine, LTC4, PGD$_2$, proteases), chemokines (MCP-1, MIP-1α, MIP-1β, RANTES), cytokines (IL-9, IL-13, IL-5, TNF-α), and growth factors (TGF-β and FGF). Through the release of this vast array of mediators, mast cells induce many features of the early-phase allergic response, including enhanced vascular and epithelial permeability, mucus secretion, and airway hyperresponsiveness. They also contribute to the late-phase allergic response via the recruitment and activation of a number of inflammatory cells, including neutrophils, eosinophils, T cells, and B cells. Through the activation of inflammatory cells as well as direct effects on mucosal cells, mast cells also contribute to the remodeling (goblet cell metaplasia, tissue fibrosis, and smooth muscle hypertrophy) of mucosal tissues observed in chronic statges of the allergic response.

necessary to elicit the c-kit–mediated signaling that ensures the expansion of cells of the mast-cell lineage, whereas the development of different phenotypes appears to be determined by their responsiveness to signals from T cells. Specifically MC$_T$-cell expansion appears to be T-cell–dependent, whereas expansion of the MC$_{TC}$ population is T-cell–independent. This contention is supported by the fact that humans with T-cell deficiencies have a lack of intraepithelial intestinal mast cells, while maintaining submucosal mast-cell populations *(328)*. Similarly, athymic mice lack intraepithelial cells and are unable to expand this population in the GI tract in response to helminthic infections (329). IL-3, IL-4, and IL-9, in particular, are among the T-cell–derived cytokines known to influence mast-cell

development and phenotypic characteristics. A role for IL-3 in mast-cell hyperplasia has been demonstrated in intestinal helminthic infections in which IL-3 depletion inhibits the intraepithelial mast cell hyperplasia normally observed in the jejunum of infected mice (330). A similar case can be made for IL-9, because IL-9 transgenic mice spontaneously develop intraepithelial mast-cell hyperplasia in the jejunum *(331)*. The action of IL-9 can be blocked by depletion of SCF. Moreover, IL-9 and IL-10 reversibly induce MMCP-1 and MMCP-2 expression in mast cells through transcript stabilization, suggesting that T-cell–derived cytokines can influence the spectrum of mediators produced by a given mast cell. Taken together, these studies suggest that the regulation of mast-cell

phenotype in the microenvironment is dynamic and that T-cell–derived cytokines are major determinants of the numbers, distribution, and phenotype of mast cells in tissues.

Mast-Cell–Derived Mediators

Mast cells and basophils release a wide array of potent biologically active mediators that have both unique and overlapping activities on various target cells (Table 43.5). Some of these products are stored preformed in the cytoplasmic granules, whereas others are synthesized upon activation of the cell by IgE-dependent processes or non–IgE-dependent stimuli. These mediators can be categorized into three main groups: (a) preformed secretory granule–associated mediators, (b) lipid-derived mediators, and (c) cytokines.

Preformed Mediators

The secretory granules of human mast cells contain a crystalline complex of preformed inflammatory mediators bound ionically to a matrix of proteoglycan. When mast-cell activation occurs, the granules swell and lose their crystalline nature and the individual mediators are released by exocytosis. The mediators stored in mast cells include histamine, proteoglycans, serine proteases, carboxypeptidase A, and small amounts of sulphatases. In mouse and rat mast cells, the granules also contain serotonin (332–334).

The mediator most associated with the mast cell is histamine. Histamine is a biogenic amine formed in mast cells and basophils by the decarboxylation of histidine. It is present in the granules at approximately 100 mmol/L or 1 pg/cell. Histamine has many potent activities which are pertinent to the early phase of the allergic response, including vasodilatation, increased vasopermeability, smooth muscle contraction, and increased mucus production. Histamine exerts its biologic and pathologic effects via specific receptors on various cells such as smooth muscle, endothelial cells, and nerves. At least three types of histamine receptors have been identified: H1, H2, and H3. Histamine is very rapidly metabolized, with a half-life of about 1 minute, by histamine N-methyltransferase and histaminase. Increased levels of histamine have been found in BAL fluids of asthmatic, atopic dermatitis, and allergic rhinitis patients (335). Interestingly, although antihistamines inhibit the immediate allergic responses, they do not seem to inhibit late-phase responses.

Heparin is the predominant proteoglycan in human mast cells. It constitutes about 75% of the total. The remainder is comprised of chondroitin sulfhates. The proteoglycan is the storage matrix inside the granule, and the acid sulfate groups of the glycosaminoglycans provide binding sites for the other preformed mediators. Proteoglycans also have anticoagulant, anticomplement, and

▌ TABLE 43.5 Products of Mast Cells and Basophils

Mediators	*Actions*
Preformed mediators	
Histamine	Increase vascular permeability, smooth muscle contraction
Neutral proteases	
Tryptase, chymase	Physiologic function uncertain (different mast-cell populations express diffrent combinations of proteases)
Cathepsin G	
Carboxypeptidase	
Lipid mediators	
PGD_2	Smooth muscle contraction
LTC_4	Increase vascular Permeability, smooth muscle constration, increase mucus production
LTB_4	Neutrophil chemotaxis
TXA_2	Vasoconstrictor, platelet aggregation, smooth muscle constration
PAF	Vasoconstrictor, platelet aggregation, smooth muscle constration, chemotactic for neutrophils and eosinophils
Cytokines	
TNF-α,IL-6,IL-8,IL-1α	Numerous proinflammatory action
IL-4,IL-13	Switch factor for Ige, VCAM-1 expression
IL-5	Regulation of eosinophils
Chemokines	
MIP-1α,MCP-1,	Chemotactic for monocyte/macrophages
MIP-1B, RANTES	
Growth factors	
FGP, VEGF	Include growth of fibroblasts and endothelial cells, respectively

PGD2, prostaglandin D2; LTC4, leukotrene C4; PAF, plalelet-activating factor; FGP, fibroblast growth factor;
   VEGF, vascular endothelial growth factor.

antikallikrein effects. In addition to regulating the kinetics of release of mediators from the granule matrices, proteoglycans can also regulate the activity of some of the associated mediators.

The major mast-cell protease, which is present in all types of mast cells, is tryptase. Tryptase is a serine protease, and it is stored fully active in the granule. There are two distinct forms of tryptase with 90% amino acid sequence homology: α-tryptase and β-tryptase *(336,337)*. The β-tryptase form is a useful clinical biomarker for anaphylaxis. Tryptase levels measured within 4 hours of a presumed anaphylactic reaction are more sensitive than serum or urine histamine in implicating mast-cell activation and degranulation *(338,339,340)*. By weight, tryptase is the major enzyme stored in the cytoplasmic granules of human mast cells, and it occurs in all human mast-cell populations. It has many activities, including cleavage of peptides such as vasoactive intestinal peptide, bronchodilator peptides, and calcitonin gene-related peptide, but not substance P; sensitization of smooth muscle; cleavage of type IV collagen, fibronectin, and type VI collagen; upregulation of ICAM-1 on epithelial cells; and mitogenic activity for fibroblasts and epithelial cells *(334)*. Some of these activities have led to speculation that mast cells may be involved in chronic inflammation and tissue remodeling *(341)*.

The other major neutral protease in mast cells is chymase. It is also a serine protease that is stored in the active form in the granules of some human mast cells. Unlike tryptase, chymase is only present in a subset of mast cells. Chymase can cleave angiotensin I and neurotensin, but it has no activities on VIP or substance P. Importantly, it can degrade IL-4. Some subsets of mast cells also contain other proteinases, such as carboxypeptidase and cathepsin G.

Newly Synthesized Mediators

Lipid Mediators

Activation of mast cells not only results in release of preformed granule-associated mediators, it can also initiate the de novo synthesis of certain lipid-derived substances. Of particular importance are the cyclooxygenase and lipoxygenase metabolites of arachidonic acid, because these products possess potent inflammatory activity. Lipoxygenases generate leukotrienes (LTs), hydroperoxyeicosatetraenoic acids (HPETEs), and the reduced products of HPETES, hydroxyeicosatetrenoic acids (HETEs), whereas cyclooxygenase products include prostaglandins and thromboxanes.

Leukotrienes are produced by the activity of 5-lipoxygenase on arachidonic acid (AA). Arachidonic acid is converted to 5-HPETE, which can then be converted to LTB_4 through the action of the LTA_4 hydrolase or to LTC_4 via LTC_4 synthase. LTC_4 can then be converted to LTD_4 and

LTE_4. Human mast cells generally produce more LTC_4 than LTB_4. The leukotrienes were originally discovered in 1938 and referred to as the slow-reacting substance of anaphylaxis until their structural elucidation in 1979 *(342,343)*. In 1983, Samuelson identified the slow-reacting substance of anaphylaxis (SRS-A) as the cysteinyl leukotrienes, LTC_4, D_4, and E_4.

Leukotrienes induce a prolonged cutaneous wheal-and-flare response, stimulate prolonged bronchoconstriction (10 to 1,000 times more potently than histamine), enhance vascular permeability, promote bronchial mucus secretion *(344)*, and induce constriction of arterial and intestinal smooth muscle (345,*346–348*). Cysteinyl leukotrienes have been detected in the BAL fluid of asthmatic patients and in the urine of patients following inhaled allergen challenge or aspirin challenge in sensitive individuals. Cysteinyl leukotriene receptor antagonists and leukotriene synthesis blockers have been introduced into clinical practice as novel therapies for asthma. In asthmatic patients, clinical trials have demonstrated that approximately 80% of the early bronchoconstrictor response can be eliminated with cysteinyl leukotriene antagonists *(349–351)*. These blockers also block 50% of the late-phase response to inhaled allergen, supporting the importance of cysteinyl leukotrienes in the late phase of the allergic response *(349–351)*. However, the fact that PGD_2 and tryptase are not found in BAL fluid during the late-phase reaction suggests that the cysteinyl leukotrienes noted in the late phase are the product of basophils or eosinophils and not mast cells.

In contrast to the cysteinyl leukotrienes, mast cells produce very little LTB_4. LTB_4 is a potent chemotactic factor for neutrophils and to a lesser extent for eosinophils *(352)*. Certain mast-cell types, including bone-marrow–derived murine mast cells and human lung mast cells, may also secrete platelet-activating factor (PAF) *(353,354)*. PAF has several actions that suggest that it is an important mediator of anaphylaxis, including (a) its ability to induce aggregation and degranulation of platelets; (b) its induction of wheal-and-flare reactions in human skin, (c) its ability to increase lung resistance, and (d) induction of systemic hypotension.

The major cyclo-oxygenase–derived product in mast cells is PGD_2, which is a potent bronchoconstrictor. PGD_2 is rapidly degraded to $9\alpha,11\beta$-PGF_2, producing another potent bronchoconstrictor. Maximal activation of mast cells yields 50 to 100 ng PGD_2 per 10^6 mast cells *(355)*. Although PGD_2 is 100-fold less potent than cysteinyl leukotrienes, it is released in larger molar amounts and thus is important in the early bronchoconstrictor response to airway allergen challenge (356). PGD_2 exerts its effects by interacting with the thromboxane receptor on airway smooth muscle *(357)*. PGD_2 is also chemotactic for neutrophils and is an inhibitor of platelet aggregation. There is considerable evidence that prostanoids are generated

during allergic reactions in vivo. PGD_2 is elevated in the BAL of asthmatic subjects following inhaled allergen challenge *(358)*. Furthermore, the metabolite of PGD_2, $9\alpha,11\beta$-PGF_2, increases markedly in the urine after allergen or aspirin challenge of sensitive asthmatics *(359)*. Significantly raised PGF2α and PGE_2 levels are reported in the serum of asthmatics *(360,361)*. These findings are confused by the fact that there is no therapeutic benefit from cyclo-oxygenase (COX) inhibitors and, in fact, COX inhibitors often exacerbate underlying asthma *(362,363)*.

Mast-Cell–Derived Cytokines

Mast cells may be important initiators of both the early- and late-phase allergic reaction by their ability to synthesize and secrete cytokines. Mast cells express message for a number of cytokines, including proinflammatory cytokines, immunoregulatory cytokines, and chemokines.

Mast cells contain preformed stores of several proinflammatory cytokines, including TNF-α, IL-8, IL-6, and IL-1α. Release of these cytokines early in the immune response likely contributes to the recruitment of leukocytes during the late-phase response via their ability to increase expression of adhesion molecules such as P- and E-selectin, vascular cell adhesion molecule (VCAM-1),and intercellular adhesion molecule-1 (ICAM-1) on vascular endothelial cells. Mast cells appear to be an important initial source of TNF-α during allergic responses. Mast cells produce a number of immunoregulatory cytokines, such as IL-3, IL-4, IL-5, GM-CSF, IL-13, and IL-16. In the human bronchial mucosa, IL-4 immunoreactivity is seen in approximately 80% of mast cells (364,*365*). Indeed, it has been suggested that mast cells are the primary source of IL-4 protein in inflamed airways. Although cytokine production by basophils has not been as extensively studied as that in mast cells, they have been shown to produce large quantities of IL-4 and IL-13. The rapid and perhaps sustained production of cytokines by these cells at sites of allergic inflammation may intensify or perpetuate IgE production and Th2 cell differentiation. Mast cells have also been shown to produce a number of chemokines such as MCP-1, MIP-1β, MIP-1α, and RANTES. Elaboration of these chemokines may contribute to the cellular component of the late-phase response.

Mast-Cell Activation

Mast-cell activation may be initiated upon interaction of a multivalent antigen with its specific IgE antibody attached to the cell membrane via its high-affinity receptor, FcεR1. Cross-linking of IgE by the interaction of allergen with specific determinants on the Fab portion of the molecule brings the receptors into juxtaposition and initiates mast-cell activation and mediator generation and release. Mast

cells may also be activated by non-IgE–mediated stimuli such as neuropeptides, complement components, and drugs such as opiates. In addition to IgE-dependent stimuli, several non–IgE-dependent stimuli activate mast cells and basophils. C5a, IL-3, fMLP, and certain chemokines (RANTES) are known to induce histamine and mediator release in mast cells and basophils. Hyperosmolarity itself also stimulates mediator secretion from these cells. Degranulation produced by both IgE-dependent and non–IgE dependent stimuli appear similar. However, the biochemical processes that lead to mediator release may differ.

Role of Mast Cells in Acute-Phase Responses

Several lines of evidence suggest that mast cells and basophils play a pivotal role in the generation of acute-phase responses. First, allergen provocation of atopic individuals is associated with extensive activation of mast cells, as judged by the detection of the release of mast-cell–associated mediators (histamine, tryptase) at the site of allergen challenge. Second, therapeutics that inhibit the release of these mediators (mast-cell stabilizers) or their actions (antihistamines) effectively attenuate acute allergic responses. Despite this evidence in humans, the data in animal models is conflicting. The preponderance of studies in mice suggests that acute responses are mast-cell– and IgE–dependent, but others suggest that these responses are IgE–independent. For example, it has been shown that responses induced in mice by passive transfer of allergen-specific IgE antibodies and subsequent intravenous allergen challenge are inhibited in genetically mast-cell–deficient Kit^w/Kit^{W-v} mice. When these mice were reconstituted with mast cells by adoptive transfer, their acute-phase responses were restored *(366)*. In contrast, some investigators have reported that anaphylactic responses develop normally in IgE-deficient mice (367). Although these conflicting results may reflect inherent differences in mast-cell biology between humans and mice, they imply that both mast-cell– and IgE–dependent and –independent processes are likely involved in the expression of the physiologic features of the acute-phase reaction.

Role of Mast Cells in Late-Phase Responses

Although it has long been thought that mast cells contribute only to the early acute response, recent evidence demonstrates their potential contribution to the late-phase response. First, through the elaboration of proinflammatory cytokines, chemokines, and immunoregulatory cytokines as discussed previously, mast cells may contribute to the cellular component of the late-phase response as well as favor the acquisition of the Th2 phenotype by providing

a continuously high concentration of IL-4. Second, mast-cell–derived mediators may also contribute to the chronic remodeling of mucosal tissues, because many of the mediators they release influence turnover of connective tissue. Specifically, histamine and tryptase have been shown to stimulate fibroblast growth and collagen synthesis in vitro and in vivo. Lastly, studies in humans have shown that stabilization of mast cells with sodium nedocromil effectively inhibits both the early- and late-phase responses to allergen exposure *(368)*. Furthermore, recent clinical trials utilizing a monoclonal antibody against IgE resulted in reductions in symptoms and improvement in lung function in asthmatics (369). Although together these reports support a role for mast cells in the late-phase response, studies of animal models of atopic dermatitis and asthma suggest that late-phase reactions are similar in wild-type and IgE-deficient mice (53,*370*) suggesting that although mast cells are capable of inducing late-phase responses, additional mast-cell–independent processes also contribute to the development of late-phase responses.

EOSINOPHIL BIOLOGY

Eosinophil blood and tissue levels are generally quite low in the absence of parasitic infection or atopy. One of the hallmarks of allergic disorders is heightened production of eosinophils in the bone marrow and the accumulation of eosinophils in tissues and blood. Eosinophil differentiation, recruitment, and activation are under the regulation of a series of molecular events orchestrated by Th2 cytokines. Although the exact role of eosinophils in the pathology of allergic responses is not known, eosinophils are known to release a myriad of mediators and cytokines that have the potential to induce the symptoms of allergy as well as amplify the allergic response through the release of immunoregulatory and proinflammatory cytokines.

Eosinophils are bone marrow–derived granulocytes that are characterized by their bilobed nuclei and their distinctive cytoplasmic granules (Figure 43.7) (371,372). They contain three distinct types of cytoplasmic granules: (a) eosinophil-specific granules, which contain electron-dense crystalloid cores; (b) primary granules, which lack a crystalloid core and develop early in eosinophil maturation; and (c) smaller granules, which contain arylsulfatase and other enzymes. Eosinophils also contain varying numbers of lipid bodies. Lipid bodies are non–membrane-bound, lipid-rich inclusions that are also found in macrophages and mast cells, and are thought to contribute to the formation of eicosanoid mediators. Eosinophils are generally identified in blood and tissues by the affinity of their cytoplasmic granules for acid aniline dyes such as eosin and in tissues by immunostaining for eosinophil-specific proteins (in particular, major basic protein [MBP]).

Eosinophil-Derived Mediators

Eosinophil-Specific Cationic Proteins

Eosinophils store four highly basic, low-molecular-weight proteins in their cytoplasmic granules: MBP, eosinophil-derived neurotoxin (EDN), eosinophil peroxidase (EPO), and eosinophil cationic protein (ECP). MBP, EPO, and ECP are potent toxins for helminths and bacteria, and they are strongly implicated as mediators of allergic diseases such as asthma, atopic dermatitis, and allergic rhinitis (Figure 43.7). MBP is potently toxic for mammalian cells in vitro, and high levels of MBP are found in the body fluids of patients with asthma and other allergic disorders (373). Both MBP and ECP exert their toxicity by damaging target-cell membranes through charge-mediated interactions. In addition to its toxic properties, MBP activates platelets, mast cells, and basophils, which in turn release histamine. Furthermore, MBP administration to primates induces airway hyperresponsiveness. MBP may induce AHR through its demonstrated ability to competitively inhibit binding to cholinergic muscarinic M2 receptors on parasympathetic nerves *(374)*. These receptors normally function as autoreceptors that inhibit the release of acetylcholine from the nerve ending. Thus, inhibition of these receptors by MBP would enhance the release of acetylcholine in the airway wall, resulting in heightened contractile responses. Both ECP and EDN have partial sequence identity with pancreatic ribonucleases; however, EDN is more potent as a ribonuclease than is ECP.

Eosinophil peroxidase (EPO), which is distinct from the myeloperoxidase of neutrophils and monocytes, consists of two polypeptides of about 15 and 55 kDa. It catalyzes the formation of hypobromous acid from hydrogen peroxidase and halide ions (preferentially bromide). HOBr reacts with primary amines to form bromamines, and it converts tyrosine to 3-bromotyrosine. Increases in the levels of 3-bromotyrosine in BAL proteins have been observed in asthmatics following allergen provocation (375). Thus, the oxidative pathways induced in activated eosinophils may damage biomolecules in vivo (375).

Another prominent component of eosinophil primary granules is Charcot Leyden crystals (CLC). This protein comprises up to 10% of the total cellular protein in human eosinophils. Although the CLC protein possesses lysophospholipase activity, structural analysis suggest that the CLC protein is similar to that of galectins 1 and 2, members of the "S-type" lectin superfamily *(376)*. Recent studies in the mouse lung suggest that CLC may contain a protein called YM-1 (T-lymphocyte–derived eosinophil chemotactic factor), which has sequence homology to chitinase *(377)*. Chitinase activity of these proteins may explain the strong association between eosinophilia and parasite infestations. These crystals are often found in sputum, feces, and tissues in patients with allergic asthma and

FIGURE 43.7 Schematic representation of eosinophil: **(A)** maturation, **(B)** migration, **(C)** activation, and (D) pleiotrophic actions during allergic immune responses. Eosinophils develop in the bone marrow, where they differentiate from hematopoietic progenitor cells into mature eosinophils under the control of several transcription factors, including GATA-1, PU.1, and c/EBP. Th2 cytokines coordinately regulate eosinophil recruitment, activation, and accumulation at the site of antigen exposure. Following allergen-specific induction of Th2 cytokine production (IL-5, IL-4, IL-13, IL-3, GM-CSF), IL-5 rapidly induces differentiation of eosinophils from myeloid precursors in the bone marrow to stimulate their release into the bloodstream. IL-4 and/or IL-13 promote eosinophil egress from the vascular compartment by upregulating VCAM-1 expression on vascular endothelial cells. Subsequently, IL-4 and IL-13 guide eosinophils to the site of allergen exposure by regulating the production of various chemokines (e.g., RANTES, eotaxin) by local cells such as macrophages and epithelial cells. Once these cells accumulate in tissues, locally produced IL-5, along with other cytokines, such as GM-CSF, and IL-3 promote their actions by prolonging their survival in tissues. Eosinophils store and release a number of proteins in their specific granules. Specifically, MBP is stored in the core of the granule, whereas ECP, EDN, EPO are found in the matrix of the granules. Eosinophils also contain lipid bodies in which products of lipoxygenase and cycloxygenase are formed. Eosinophils also release a number of cytokines, chemokines, and neuropeptides that are important in the allergic diathesis.

other eosinophil-related diseases characterized by significant eosinophilia.

Lipid Mediators

Upon stimulation, eosinophils elaborate several bioactive lipids, including products of the 5- and 15-lipooxygenase pathway; products of the cyclooxygenase pathway, and platelet-activating factor (PAF). Lipid bodies, or intracellular lipid-rich domains, are induced to develop in many activated eosinophils in vivo and are sites for enhanced synthesis of both lipoxygenase- and cyclo-oxygenase–derived eicosanoids. The activities of eosinophil-derived lipids, which are generally proinflammatory, are multiple and include potent smooth muscle contraction, vasoactivity, and mucus secretion activities.

Cytokines

In recent years it has been recognized that eosinophils are a major source of cytokines and appear to store some if not all of these cytokines in cytoplasmic specific granules. Triggering of eosinophils by engagement of receptors for cytokines Ig and C3 can lead to secretion of an array of proinflammatory and immunoregulatory cytokines, chemokines, and growth factors, including IL-2, IL-3, IL-4, IL-5, IL-6, IL-8, IL-10, IL-12, IFN-γ, TNF-α, GM-CSF, TGF-β, TGF-α, RANTES, MIP-1α, eotaxin, VEGF, PDGF-β, and heparin-binding epidermal growth factor (see 59). Through the quick release of this diverse array of cytokines at the inflammatory loci, the eosinophil is poised to perpetuate and/or intensify the eosinophil-mediated inflammatory response, both by enhancing its own activation and through the release of Th2 cytokines.

Recruitment of Eosinophils to Sites of Inflammation

Preferential accumulation of eosinophils at sites of allergic inflammation involves multiple molecular events that are integrated and controlled by Th2 cytokines *(378)*. These include (a) differentiation and release of mature eosinophils from the bone marrow into the bloodstream; (b) upregulation of specific adhesion molecules on eosinophils and endothelium; (c) stimulation of C-C chemokine production and egress of eosinophils from the blood into the tissues; and (d) production of eosinophil-active cytokines that increase eosinophil survival in tissues.

Eosinophils are terminally differentiated granulocytes that develop from CD34$^+$ hematopoietic progenitor cells in the bone marrow. Under the influence of GM-CSF, IL-3, and IL-5, they differentiate into mature eosinophils. These cytokines likely promote eosinophilopoiesis via induction of GATA-1, PU.1, or C/EPS through their shared common β-chain (379,380). Of these, IL-5 has the most specific effects on eosinophil differentiation and production. In addition to its effects on eosinophil differentiation, IL-5 can rapidly induce the release of developed eosinophils from the bone marrow into the peripheral circulation. The importance of IL-5 to blood and tissue eosinophilia has been repeatedly shown in in vitro and in vivo studies of gene-targeted and overexpressing mouse lines (50,381).

Circulating eosinophils are recruited to sites of inflammation by the combined actions of inflammatory mediators, adhesion molecules, and chemoattractants (Figure 43.7). Several cell adhesion molecules have been implicated in eosinophil adherence to cytokine-stimulated vascular endothelium, including ICAM-1, E-selectin, L-selectin, and the very late antigen-4/VCAM-1. The importance of VCAM-1 to eosinophil recruitment has been shown in primate and mouse studies in which blockade of VCAM-1/VLA-4 interactions inhibits eosinophil infiltration of tissues *(382)*. IL-4 and IL-13 induce VCAM-1 expression on the surface of vascular endothelial cells, leading to preferential recruitment of eosinophils into sites of allergic inflammation.

Eosinophil migration to the sites of inflammatory loci is mediated by a number of chemoattractants. Until the last decade, mediators such as PAF, C5a, and LTB$_4$ were considered to be the most important eosinophil chemoattractants. Although they are potent chemoattractants, they do not show any specificity for eosinophils. However, there are a number of C-C chemokines that are eosinophil chemoattractants (RANTES [regulation on activated, normal T-cell expression and secretion, CCL5], eotaxin [CCL11], monocyte chemoattractant proteins MCP-4 [CCL13], MCP-3 [CCL7], and MIP-α [CCL3]). The levels of most of these chemokines have been shown to be upregulated in the mucosal tissues of asthmatics, atopic rhinitics, and atopic dermatitis patients. Although each of these chemokines is implicated in eosinophil chemotaxis, it was originally hypothesized that eotaxin would play a pivotal role in eosinophilic inflammation in that it binds specifically to the chemokine receptor 3 (CCR3), whereas the other C-C chemokines bind multiple receptors. The fact that CCR3 is highly expressed on eosinophils, basophils, and Th2 cells, but not on neutrophils, suggested that it plays an important role in Th2-mediated inflammatory responses (383,384). Surprisingly, though, eotaxin-deficient mice have shown only minor defects in eosinophil accumulation (385,*386*), indicating that eotaxin is not uniquely required for eosinophil accumulation. Along these lines, complete abrogation of eosinophil migration has not been observed by inhibition of any one chemokine (41,385,387,388,*389*), suggesting that multiple chemokines working in concert are required to direct leukocytes to specific sites of inflammation. Thus it has been postulated that a panopy of chemokines may be required to establish the multiple chemical gradients required for eosinophils to migrate through several local compartments from the vascular spaces to the mucosal surfaces in the nose, airway, and skin.

Lastly, eosinophils rapidly undergo apoptosis unless provided with signals from eosinophil growth factors such as IL-5, GM-CSF, and IL-3. Prolonged survival of eosinophils under the influence of locally generated growth factors is thought to be an important mechanism for selective eosinophil accumulation in atopic diseases. Direct evidence for prolonged survival of eosinophils in atopic disease comes from the fact that glucocorticoid treatment of atopic individuals results in a rapid loss of tissue eosinophils.

Based on the independent and overlapping roles of IL-4, IL-13, and IL-5, discussed previously, we can envision the following paradigm for regulation of allergen-induced tissues eosinophilia. Following allergen-specific induction of Th2 cytokine production, IL-5 would rapidly induce

differentiation of eosinophils from myeloid precursors in the bone marrow and stimulate their release into the bloodstream. IL-4 and/or IL-13 would promote eosinophil egress from the vascular compartment by upregulating VCAM-1 expression on vascular endothelial cells. Once the cells accumulate in tissues, locally produced IL-5 along with other mediators such as eotaxin would promote their actions by prolonging their survival in tissues. Within this paradigm, allergen-driven eosinophil recruitment into tissues is coordinately regulated by the Th2 cytokines, IL-4, IL-13, and IL-5.

Mechanisms of Eosinophil Activation

The effector functions of eosinophils are mediated by stimuli that induce degranulation. Eosinophil degranulation can be regulated by multiple components, including those that primarily stimulate the cells (e.g., immunoglobulins and lipid mediators), priming agents (e.g., cytokines), and chemokines. However, the precise mechanisms by which eosinophil degranulation occurs in vivo are still poorly understood.

Eosinophils express receptors for several immunoglobulins, including IgG, IgA, and IgE. Surfaces coated with IgG, IgA, and secretory IgA stimulate eosinophil degranulation in vitro. Of these immunoglobulins, sIgA is best for inducing eosinophil degranulation and does not stimulate neutrophil degranulation. Because IgA is the most abundant immunoglobulin isotype in mucosal secretions of the respiratory and gastrointestinal tracts, it may be an important regulator of eosinophil activation at these sites. IgE may also be important for eosinophil activation, because eosinophils can bind IgE via three distinct structures: the S-type lectin galectin-3, FcεRII/CD23, and FcεRI. It was initially shown that eosinophils, isolated from patients with parasite-induced eosinophilia, degranulate in response to IgE antibody or IgE-coated parasites (390,391). Subsequent studies showed that local allergen provocation induces expression of FcεRI by eosinophils infiltrating into the airways *(392)* and skin of patients with allergic diseases *(393,394)*. In studies using sera from ragweed-allergic patients with hay fever, ragweed-specific IgG, but not IgE, induced allergen-dependent eosinophil degranulation in vitro *(395,396)*. Thus it remains to be determined whether IgE is an important regulator of eosinophil degranulation in atopy.

Eosinophil degranulation may also be induced by soluble stimuli alone. Cytokines, especially those with eosinophilopoietic activity, such as GM-CSF and IL-5, are potent inducers of eosinophil granule protein release. Interestingly, eosinophil granule proteins themselves, including MBP and EPO, stimulate eosinophils and cause degranulation, suggesting an autocrine mechanism of eosinophil degranulation *(397)*. Other physiologic stimuli for eosinophil degranulation include PAF, the complement

fragments C5a and C3a, and the neuropeptide, substance P *(398)*. As discussed briefly previously, chemokines may also activate eosinophils by binding CCR3. In this regard, eotaxin induces eosinophil degranulation and leukotriene C$_4$ (LTC$_4$) release.

Eosinophils as Effector Cells in Allergic Responses

Eosinophils, through the elaboration of a plethora of preformed mediators and lipid mediators described previously, are postulated to play a role in several aspects of the allergic response, including antigen presentation, T-cell proliferation and differentiation, as well as mast-cell activation and airway remodeling. Although it remains controversial, it has recently been shown that eosinophils may function in antigen presentation *(399)*. Specifically, eosinophils have been shown to effectively present soluble parasitic antigens to CD4$^+$ T cells, thereby promoting T-cell proliferation and polarization. They may also regulate T-cell proliferation, activation, and polarization via the array of cytokines they produce, as well as through their ability to synthesize indoleamine 2,3-dioxygenase (IDO) *(400)*.

Circumstantial evidence for a causative role of eosinophils in allergic inflammation as well as the clinical symptoms of atopic disorders comes from a variety of studies (401). First, elevated levels of activated eosinophils and their protein products (MBP, ECP, EPO, EDN) have been consistently demonstrated in BAL fluids and airway biopsy tissues from patients with asthma (401), in nasal biopsy specimens from allergic rhinitic patients (nasal fluids and nasal biopsies) (402), and in skin lesions from patients with atopic dermatitis (403). Second, in each of these diseases, increased levels of eosinophils and their proteins correlate with disease severity. Lastly, successful steroid treatment is associated with a marked reduction in both blood and tissue eosinophil levels in asthma and atopic rhinitis *(404–406)*.

Despite the substantial body of circumstantial evidence that supports a causative role for eosinophils in the pathophysiology of atopic disorders, the results of studies designed to define a pathogenic role for eosinophils in atopic disorders are conflicting. Studies in IL-5 gene knockout (50) and transgenic mice (381) show that both eosinophilia and AHR are IL-5–dependent. In addition, anti-IL-5 treatment of cynomolgus monkeys inhibits allergen-induced airway reactivity and BAL eosinophilia *(407)*. In contrast, other investigators have demonstrated that blockade of eosinophils by IL-5 ablation did not affect AHR (50,408). This dissociation between eosinophils and the late-phase response has recently been confirmed in a multiple-center study in human asthmatics that demonstrated that whereas anti-IL-5 treatment suppressed pulmonary eosinophils, it did not inhibit either early or late

responses to inhaled allergens or improve lung function (409). There may be multiple explanations for a lack of effect in this study, including the small study size, dosing schedule, and/or acute nature of treatment, but these studies suggest that blockade of eosinophils and IL-5 alone are not sufficient to inhibit clinical symptoms of atopic disease. Arguably, the study was underpowered and the dosing regime did not result in complete ablation of eosinophils in lung tissues, leaving the question open as to whether complete ablation is necessary to achieve therapeutic benefit. In a follow-up study using a multiple dosing regime, it was shown that anti-IL-5 attenuated several indices of airway remodeling, including enhanced matrix protein deposition (procollagen, tenascin, laminin), profibrotic molecule expression (TGF–β), and airway smooth muscle hypertrophy, without effects on airway physiology. The failure of anti–IL-5 treatment to ameliorate allergic symptoms in humans has brought into question the importance of eosinophils in human asthma. However, as long as existing therapies do not completely eliminate tissue eosinophils, the issue will not be resolved.

In order to address this issue, several groups have undertaken the task of developing eosinophil-deficient mice (410,*411*). One group generated an eosinophil-deficient mouse via insertion of a cytocidal protein (diphtheria toxin A) in the promoter of the eosinophil peroxidase (EPO) gene. These mice were reported to be completely devoid of eosinophils in all tissues (410). Moreover, all features of the allergic phenotype were absent (AHR, mucus, eosinophilia, Th2 cytokine production) in these mice following allergen challenge. The other eosinophil-deficient mouse line harbors a deletion of a high-affinity GATA-binding site in the GATA-1 promoter, leading to the specific ablation of the eosinophil lineage *(411)*. In this line, eosinophil depletion had no effect on AHR, mucus production, or Th2 cytokine production, but did reduce airway remodeling assessed by collagen deposition. Interestingly, the results of this study mirror that observed in the human anti–IL-5 trials. However, the exact reasons for the discrepancies in the mouse models are unknown. However, they may be due to the presence of residual eosinophils in the dbl-GATA mice or to unappreciated hematologic abnormalities, or toxic effects of diptheria toxin on noneosinophils in the EPO-diphtheria toxin A mice.

Th2 Cells as Effector Cells

Our recent understanding of the role of Th2 cells in the allergic diathesis suggest that they are important effector cells in the allergic response in addition to their well-accepted role as orchestrators of the inflammatory process. Specifically, the Th2 cytokine IL-13 has been implicated as an effector molecule in allergic disease. Evidence for this contention comes from studies in which blockade of

endogenous levels of IL-13 in antigen-sensitized mice by administration of a soluble form of the IL-13RA2 chain, which binds only IL-13, completely reversed AHR and pulmonary mucus cell hyperplasia (39,61). Furthermore, it was shown that recombinant IL-13 was able to re-create the symptoms of asthma (airway hyperresponsiveness, mucus hypersecretion, eosinophilia) in the absence of functional T cells or B cells (39). These effects were shown to be independent of eosinophils as well *(412)*. These results suggested that IL-13's effects were not due to its known role in regulating IgE or eosinophil recruitment. Interestingly, despite the similarities in function between IL-13 and IL-4, IL-4 blockade at the time of antigen challenge does not ablate airway hyperresponsiveness *(413)*. This was further supported by the finding that transfer of Th2 cells derived from IL-4–deficient mice was still able to confer airway hyperresponsiveness *(42)*. Moreover chronic expression of IL-13 in the mouse lung results in development of these features, as well as subepithelial fibrosis and the formation of Charcot-Leyden crystals (264). In contrast, overexpression of the IL-4 gene in the murine lung does not result in AHR or subepithelial fibrosis *(414)*. Taken together, these studies suggest that IL-4 is essential for the initiation of Th2 polarized immune responses to allergenic peptides, whereas IL-13 alone may mediate the main physiologic consequences of allergic airway disease, namely, airway hyperresponsiveness, mucus hypersecretion, and subepithelial fibrosis.

As IL-4 and IL-13 share a functional receptor, one of the questions puzzling immunologists is how IL-13 may play a preferential role in the effector arm of the allergic response. Several explanations have been postulated, including the possibility that IL-4 production at the site of inflammation is short-lived and that IL-13 may persist, giving the allusion that IL-13 is the more important mediator of the effector phase of the response. This hypothesis is not without merit, as IL-4 is difficult to measure at the site of inflammation and kinetic studies have shown sustained IL-13 production in the lungs of asthmatic patients *(415)*. However, several in vitro studies have also claimed to observe unique functions of these cytokines in systems in which the level of cytokines is controlled. It can always be debated that any differences observed in these systems may be due to differences in degradation of these two proteins in culture or that the recombinant forms of these proteins do not have equivalent potency. Another potential hypothesis is that IL-13 may act through an as-yet-unidentified receptor complex. In support of this hypothesis, a recent study demonstrated that although AHR and eosinophilia induced by adoptive transfer of IL-13–sufficient T cells are STAT6-dependent, these effects appear to occur independently of the IL-4Rα chain *(416)*. These studies suggest that an as–yet-unidentified IL-13–binding chain may exist or that different configurations of the existing chains may mediate distinct effects of

IL-13 stimulation. As will be discussed later, the IL-13Rα2 chain may play a role in mediating processes unique to IL-13 under some circumstances. Alternatively, it has recently been shown that IL-4 may induce inhibitory pathways through the type I receptor that limit its proallergic effects mediated through the type II receptor *(417)*. On the other hand, it has been shown that IL-13 induces a small set of epithelial-specific genes that are not upregulated by IL-4 in vivo but are, however, STAT6-dependent. This apparent IL-13 selectivity occurs either via IL-13 stimulation of a unique receptor complex or as a result of IL-4 inhibition of these putative pathways. Although the mystery underlying the unique functions of IL-4 and IL-13 is far from solved, multiple explanations for their apparently unique functions are emerging.

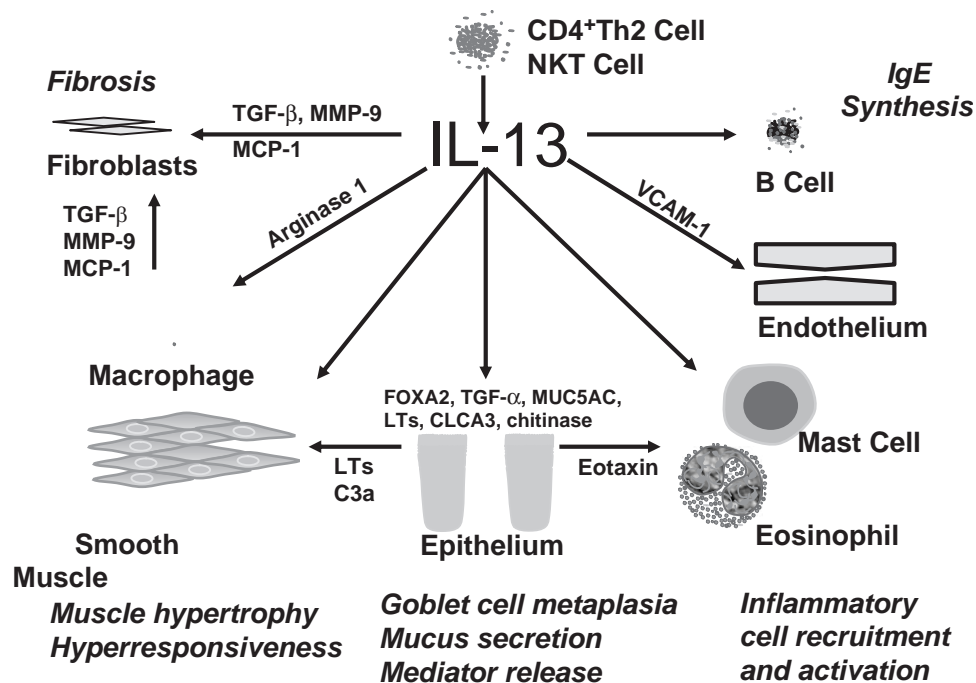
IL-13 has several actions that implicate it as an effector in the allergic diathesis, such as its role in mucus production, fibrotic processes, and perhaps bronchoconstriction (Figure 43.8). First, it has been shown to play an important role in mucus hypersecretion. Mucus hypersecretion is a consistent feature of the allergic phenotype in both the upper and lower respiratory tracts. In fact, extensive plugging of the airway lumen has been associated with fatal episodes of asthma. This response is a Th2 cell-dependent process, as adoptive transfer of Th2 cells into the murine lung reconstitutes the effect of antigen challenge *(42)*. Several lines of evidence suggest that mucus cell metaplasia is an IL-13–, not IL-4–, dependent process. For example, transfer of Th2 cells devoid of IL-4 or IL-5 genes still induce extensive goblet cell metaplasia in the murine lung. However, blockade of the IL-4Rα chain or deficiency in STAT6 prevents the development of mucus cell metaplasia following allergen challenge, suggesting that IL-13 may be the ligand for the IL-4/STAT6 pathway in mucus cell changes *(208)*. Indeed, administration of soluble IL-13RA2 reversed the metaplastic response of goblet cells induced by allergen sensitization and challenge. Administration of rIL-13 in vivo or overexpression of the IL-13 gene


FIGURE 43.8 Schematic representation of the role of interleukin-13 (IL-13) in the effector phase of the allergic response. IL-13 is produced in the airway by a variety of cells, including T cells (CD4[+], NK T cells), eosinophils, and mast cells. IL-13 binds its receptor on multiple cell types and induces the expression of a variety of genes in target cells. The consequencecs of IL-13 receptor activation include IgE synthesis, adhesion molecule expression on endothelial cells (VCAM-1) and egress of inflammatory cells into mucosal tissues, inflammatory cell activation (eosinophils and mast cells), epithelial cell activation leading to mucus hypersecretion (FOXA2, CLCA1/3, TGF-α, MUC5AC) and mediator release (LTs, C3, eotaxin), smooth muscle activation and hypertrophy, airway hyperresponsiveness, activation of macrophages and fibroblasts leading to the production of various enzymes involved in collagen synthesis (arginase I, MMP-9, TGF-β, PDGF-AA), and deposition leading to tissue fibrosis. C3a, complement factor 3; VCAM-1, vascular cell adhesion molecule 1; CLCA1/2, Ca^{2+}, activating chloride channel gene 1/3; MMP9, metalloproteinase 9; TGF-α, transforming growth factor-α; FOXA2, forkhead box a2 transcription factor; MUC5AC, mucin gene 5AC.

recapitulates antigen effects on mucus production. Conversely, allergen-induced goblet cell metaplasia is significantly reduced in IL-13–deficient mice *(418)*. This was not further reduced when IL-4 was blocked with neutralizing antibodies, suggesting that indeed IL-13 is the primary regulator in vivo of mucus cell hyperplasia. The mechanisms by which IL-13 regulates mucus production are not entirely clear, but it has been shown to coordinately regulate a number of processes in the airway epithelium, which may contribute to mucus hypersecretion such as the induction of mucin gene expression, and ion-channel gene expression and activity *(419)*.

Another feature of the chronic inflammatory response in both the skin and the airways is the presence of a fibrotic process. Recent data suggest that IL-13 is an important regulator of fibrotic processes. For example, overexpression of IL-13 in the murine lung induces a dramatic fibrotic response in the airway wall (264). Furthermore, IL-13 transgenic mice express matrix proteases such as MMP and cathepsins that are thought to be important in the fibrotic response (420). A clear demarcation of function for IL-4 and IL-13 in fibrosis has been demonstrated in Th2-mediated pathology of *Schistosome mansoni* infection in mice. Schistosome-induced collagen deposition is reduced in the lungs of STAT-6–deficient animals, but not in IL-4–deficient mice (421). Furthermore, sIL-13RA2-Ig delivery completely prevented the fibrotic response in parasite-infected mice. Thus in several models of Th2-mediated fibrosis, blockade of IL-13 selectively inhibited fibrotic remodeling processes, suggesting that this cytokine may be an important mediator of inflammation-induced tissue fibrosis.

Although the mechanisms by which IL-13 induces tissue fibrosis are far from understood, several recent studies have begun to shed light on the sequence of events leading to IL-13–induced fibrosis. IL-13 likely regulates tissue fibrosis through a series of coordinated actions on a number of cells types within the lung. First, IL-13 has been shown by several investigators to upregulate the synthesis of arginase I (422,423). Arginase I is an enzyme that hydrolyzes L-arginine to urea and L-ornithine, which is a necessary metabolite for the production of polyamines and prolines required for collagen synthesis by fibroblasts. Evidence of an in vivo role for this pathway in tissues fibrosis was provided by Hesse et al. (422). Specifically, they showed that blockade of ornithine-aminodecarboxylase, which ultimately results in the generation of proline, markedly enhanced parasite-driven tissue fibrosis. Consistent with a role for arginase I in asthma, Rothenberg et al. (423) demonstrated that the enzyme is upregulated in an ovalbumin model of asthma and in animals exposed to recombinant IL-13 as well as in lung tissues of asthmatics, compared to normal individuals.

Second, IL-13–dependent lung fibrosis is mediated via its ability to induce and activate the profibrotic mediator

TGF-β *(424)*. In this regard, IL-13 induces the production of TGF-β both directly in epithelial cells *(425)*, and indirectly in monocytes/macrophages via its ability to recruit and activate these cells *(424)*. This is thought to occur via the interaction of MCP-1 with its receptor CCR2 on monocyte/macrophages, as both lung fibrosis and TGF-β production in IL-13 transgenic mice are diminished in mice devoid of CCR2 *(426)*. Further support for this argument is the fact that MCP-1 has been shown to stimulate TGF-β1 production in lung fibroblasts *(427)*. In addition to stimulation of TGF-β synthesis, IL-13 also activates latent TGF-β through the induction of MPP9 *(424)*.

Lastly, IL-13 may also have a direct effect on fibrotic processes by stimulating the proliferation of myofibroblasts via a STAT6-dependent process involving platelet-derived growth factor AA (PDGF-AA) *(428)*. Lung fibrosis may also arise as a result of IL-13's ability to stimulate the accumulation of the nucleoside, adenosine (429). Specifically, it has been shown that IL-13–overexpressing mice have increased adenosine levels and reduced adenosine deaminase (ADA) gene expression and enzyme activity, while exhibiting marked increases in lung collagen. Furthermore, blockade of adenosine levels in the lung by ADA enzyme therapy diminished IL-13–induced fibrosis concomitant with a reduction in elaboration of a selective set of chemokines (MCP-1, -2, -3, -5 and eotaxin). Collectively these studies suggest that a number of IL-13–driven processes culminate in the generation of fibrogenic processes in the lung.

Airway hyperresponsiveness (AHR) or an exaggerated response to specific and nonspecific stimuli is a hallmark of asthma. The exact mechanisms by which IL-13 induces airway hyperresponsiveness are currently unknown. Several lines of evidence suggest that IL-13 can induce airway hyperresponsiveness in the absence of inflammatory cells. The initial IL-13Rα2Ig studies showed that IL-13 blockade inhibited AHR without affecting inflammatory cell recruitment or IgE synthesis (61). Moreover, Grunig et al. (39) demonstrated that T and B cells were not essential for IL-13's effects on AHR. Support for this contention is provided by Vargaftig et al. (430), who demonstrated that pretreatment of mice with vinblastine, a granulocyte inhibitor, failed to inhibit IL-13–induced AHR. In support of this theory, IL-13 has been shown to induce hyperresponsiveness as early as 6 hours after administration, long before significant inflammation has occurred *(431)*. In addition, Kibe et al. *(432)* reported that glucocorticoid treatment that inhibits lung eosinophilia did not attenuate AHR induced by IL-13. More definitely, studies in mast-cell–deficient *(433)* and eotaxin/IL-5 double-knockout mice *(412)* confirm the contention that the traditional effector cells, B cells, mast cells, and eosinophils, are not required for IL-13 to induce AHR. Collectively, these results suggest that although IL-13 is able to direct the recruitment of inflammatory cells into the airways, they are likely not necessary for induction of

AHR. Alternatively, IL-13 may induce AHR via direct effects on resident airway cells.

Whether airway hyperresponsiveness is mediated by direct effects on airway smooth muscle (ASM) or indirectly via effects on resident airway cells such as the epithelium is currently a matter of debate. IL-13 could potentially induce direct effects on ASM, as these cells do indeed express the IL-13 receptor chains including the IL-4Rα, the IL-13Rα1, and the IL-13Rα2 chain, but not the common γ chain. In this regard, several investigators have shown in both murine *(434)* and rabbit tracheal strips *(435)* that IL-13 treatment enhanced maximal carbachol- and KCL-induced force generation, while IL-4 had no effect. One group has provided strong evidence that this effect is likely mediated via resident airway cells, as IL-13 overexpression in mice with STAT6 expressed only in the airway epithelium are hyperresponsive (208). Nonetheless, IL-13 has been shown to enhance bradykinin-, histamine-, and acetylcholine-induced intracellular calcium fluxes in isolated smooth muscle cells *(436)*. Consistent with these findings, Shore et al. have shown that IL-13 increases LTD4-stimulated changes in isolated smooth muscle cell stiffness—a surrogate of contraction. It is speculated that these changes may be mediated via the ability of IL-13 to increase cysteinyl leukotriene receptor (CysLT1) expression on smooth muscle cells *(437)*. This is particularly interesting, as IL-4 does not upregulate CysLT1 expression. However, this would likely not explain the effects of IL-13 on responses to other contractile agonists. A more general mechanism by which IL-13 may alter contractile function of ASM has been recently been postulated by Panettieri et al. (438). Specifically, they showed that IL-13 induces calcium fluxes in ASM via increasing CD38 expression and cADP-ribosyl cyclase (cADPR) activity, as evidenced by the ability of an cADPR inhibitor to block these responses. Taken together, these results suggest that although no one to date has shown direct contraction of ASM in response to IL-13, it is likely that through its ability to induce calcium activation pathways and/or LTD4-receptor expression, it enhances responses to other endogenous contractile agonists. Alternatively, IL-13 may also affect contractile properties of smooth muscle by altering the ability of smooth muscle to relax once contracted. For example, several groups have reported that IL-13 significantly reduces B-adrenoceptor–induced relaxation of airway smooth muscle *(435,439)*. The effects of IL-13 on smooth muscle function may also be a result of significant increases in the area of airway smooth muscle in the airway wall. Although IL-13 likely does not directly mediate smooth muscle proliferation, it may influence muscle proliferation indirectly via stimulation of CysLTs *(437)*. Specifically, although IL-13 treatment of ASM cells in culture alone did not induce smooth muscle proliferation, pretreatment of cells with IL-13 enhanced proliferation induced by LTD4. Similar effects were also observed with TGF-β treatment of cells. The enhanced proliferation was prevented by pretreatment of the cytokine-primed cells with a selective Cys-LT receptor antagonist. The authors speculate that muscle thickening may be due to positive feedback interactions between leukotrienes, IL-13 and TGF-β. Alternatively, IL-13 may induce smooth muscle proliferation through its ability to increase vascular endothelial growth factor (VEGF) from human airway smooth muscle that in turn induces fibronectin expression in these cells *(440)*. Fibronectin also promotes ASM mitogenesis in vitro *(441)*. Although the exact mechanism(s) through which IL-13 regulates smooth muscle function are only beginning to be understood, the collective data support the ability of IL-13 to alter airway smooth muscle function both indirectly and perhaps directly via binding its receptors on smooth muscle.

Another potential mechanism by which IL-13 may regulate airway tone is via the induction of the AMCase chitinase gene (442). In an elegant paper, Zhu et al. have recently shown that IL-13 induces the expression of an acidic mammalian chitinase (AMCase) in airway epithelium and macrophages and that either inhibition of chitinase enzyme activity or treatment of mice with antiserum directed against the chitinase abolished IL-13–induced AHR. Although the exact mechanisms by which IL-13 induction of chitinase results in the development of airway hyperresponsiveness are currently unknown, expression of the chitinase gene in mouse airway epithelial cells resulted in elaboration of several chemokines, namely, eotaxin and MCP-1. As discussed previously, both of these chemokines have been shown to be important in allergic inflammation and airway reactivity.

Chitin is a common carbohydrate polymer found in nematodes, insects, and fungi. In this regard, it is also found in organisms that provide a rich source of allergens, such as house dust mite and cockroaches. As such, it is interesting to speculate that these chitins may serve as environmental triggers for Th2 immune responses in general. Thus, one may envision a scenario in which the Th2 immune response likely arose as a defense against chitin-containing parasitic organisms, but for some unknown reason, in susceptible individuals, this response has been co-opted to defend against chitin-containing organisms (HDM, cockroaches) that are neither infectious nor inherently harmful. Clearly, defining the role of chitinases in allergic asthma and more broadly in Th2-mediated immune responses is an area ripe for study.

Whether IL-13 mediates AHR via sequential activation of the above-mentioned pathways, through a combination of these pathways, or by yet-unidentified pathways, the stimulation of IL-13 receptors on the epithelium clearly plays an important role in IL-13–mediated airway hyperresponsiveness. Nonetheless, as the studies referenced previously suggest that IL-13 also has direct effects on airway

smooth muscle, airway hyperresponsiveness likely arises via the combined actions of IL-13 on the epithelium and airway smooth muscle.

Although IL-13 does not appear to have direct effects on T-cell differentiation, several lines of evidence suggest that it may affect or perpetuate the Th2 response via several pathways. First, it induces the expression of several chemokines that are thought to selectively recruit Th2 cells, namely, TARC and MDC (443). Second, it can recruit additional dendritic cells to the site of allergen exposure via the induction of MMP9 and TARC *(444)*. Further, it appears to promote its own production via regulation of the production of several mediators such as adenosine and histamine, which, in turn, stimulate cells such as eosinophils, mast cells, basophils, and smooth muscle cells to produce more IL-13. Through stimulation of these pathways, IL-13 may be an important contributor to the chronicity of allergic disease. Thus, blockade of IL-13 may have the added benefit of breaking this vicious Th2-promoting positive feedback loop.

The importance of IL-13 in allergic disorders in humans is supported by numerous reports of exaggerated IL-13 production in asthma, atopic rhinitis, and allergic dermatitis (445). In asthma in particular, both message and protein levels of IL-13 are elevated in bronchial biopsy specimens and BAL cells from allergic individuals when compared with those of control subjects *(222)*. Conversely, IL-13 levels are reduced in asthmatic and rhinitis patients undergoing allergen desensitization treatment regimes or steroid treatment *(222)*. Moreover, a recent cohort study of neonates demonstrates that high IL-13 productive capacity of cord-blood CD4$^+$ T cells is a significant predictor of risk for subsequent development of atopic diseases *(446)*. In support of the notion that IL-13 is a central effector of allergic immune responses, several groups have reported strong associations of polymorphisms in the IL-13 promoter and coding region with various features of the asthmatic phenotype (447,448). Of particular interest is the Arg130/Gln substitution in the coding region of IL-13 noted by multiple groups and detected across multiple ethnic groups. Moreover, Arima et al. have recently provided evidence that the Arg110Gln may be a functional variant *(449)*. Utilizing a mutant recombinant IL-13, they show that recombinant IL-13 containing the Gln110 variant bound the IL-13 receptor α2 chain with lower affinity than the wild-type IL-13, resulting in a lower clearance rate of the cytokine. Interestingly, they demonstrated that although the IL-13 variant did not alter any biologic properties of IL-13, asthmatic patients homozygous for the Gln110 variant have higher serum levels of IL-13 than those without the variant. They postulated that impaired binding of IL-13 by the soluble IL-13Rα2 chain leads to higher serum levels and prolonged activity of IL-13 in vivo. Vercelli et al. (450) have also shown that the -1112T variant of the IL-13 promoter is functional, as expression of it

in human and murine CD4$^+$ Th2 lymphocytes enhanced IL13 promoter activity. Interestingly, increased expression of IL13-1112T in Th2 cells was associated with the creation of a Yin-Yang 1 binding site that overlapped a STAT motif involved in negative regulation of IL-13 expression and attenuated STAT6-mediated transcriptional repression. The enhanced IL-13 secretion in IL13-1112TT homozygotes suggests that expression of this allele may underlie its association with susceptibility to allergic inflammation.

Unifying Hypothesis

The elicitation of allergic airway responses in a sensitized individual upon re-exposure to offending allergens is likely the culmination of a complex network of cellular and molecular events (Figure 43.). Following antigen challenge, cross-linking of antigen and IgE on IgE-bearing cells leads to the immediate release of substances such as histamine, leukotrienes, PGD$_2$, and tryptase. The actions of these mediators account for the immediate symptoms, such as smooth muscle constriction, vasodilation, and increased vascular permeability. It is possible that the release of IL-13 by either mast cells or basophils can also induce many of these same symptoms. Secretion of chemokines (eotaxin) and cytokines (IL-4, IL-5) by basophils and mast cells also serve to attract more T cells, antigen-presenting cells, and effector cells such as eosinophils to the site of insult. Simultaneously, dendritic cells within the mucosa are presenting allergen to T cells and, within 6 to 48 hours, additional T cells are recruited to the area. The expression of FcεRI on the surface of dendritic cells greatly facilitates their uptake, processing, and presentation of allergens to T cells during the elicitation phase of the response. Furthermore, the cytokine milieu created as a result of mast-cell and basophil activation, namely, a Th2 cytokine environment, most likely drives a polarized Th2 response. Further production of Th2 cytokines at the local site augments the recruitment and activation of additional eosinophils and T cells. During the late phase, release of mediators from mast cells, basophils, eosinophils, and T cells act in concert to induce the vascular changes, bronchoconstrictor, and mucus changes observed during the late-phase response. Many repetitions of this sequence lead to persistent inflammation, resulting in alterations in the structure and function of resident mucosal cells such as smooth muscle, fibroblasts, and epithelial cells. As many of the actions of these effector cells are redundant, it is not surprising that neither depletion of mast cells nor depletion of eosinophils has been sufficient to significantly ablate the physiologic consequences of allergen exposure. One point of convergence is the production of IL-13 by all of the likely suspects (e.g., basophils, mast cells, eosinophils, and T cells). Given its ability to induce effector functions, elevations in IL-13 levels may not only provide a unifying explanation for the
FIGURE 43.9 Overview of the acute, late, and chronic phases of the allergic response. Crosslinking of surface IgE on sensitized mast cells by antigen results in mast-cell degranulation and release of numerous mediators, including histamine, tryptase, PDG_2, and cytokines. These mediators are largely responsible for the early phase of the allergic response. Antigen presentation by dendritic cells to Th2 cells results in activation and clonal expansion of antigen-specific T cells and the subsequent release of Th2 cytokines, IL-4, IL-5, and IL-13. These cytokines result in recruitment of eosinophils, chemokine expression, smooth muscle hypertrophy, and mucus hypersecretion. Ultimately, long-term exposure to IL-13 and eosinophilic effector molecules leads to the structural changes observed in tissues of individuals with chronic disease.

importance of multiple effector cells in allergic responses, it may also provide an ideal target for therapy.

CHARACTERISTICS OF SPECIFIC ATOPIC DISORDERS

In this section, we will briefly discuss the clinical manifestations, pathogenesis, and therapeutic strategies for the treatment of the classical atopic syndromes, including anaphylaxis, allergic rhinitis, atopic dermatitis, and asthma. Readers should consult clinical allergy textbooks for further details on these disorders.

Anaphylaxis

Anaphylaxis refers to a systemic, immediate hypersensitivity reaction that results from IgE-mediated release of vasoactive and inflammatory mediators from mast cells and basophils. Death from anaphylaxis is most often due to respiratory obstruction and/or cardiovascular collapse. The initial experimental description of the phenomenon dates to a paper published in 1902, in which Portier and Richet *(451)* described the sensitization of dogs to sea anemone venom, a process with fatal sequelae upon subsequent exposure to nonlethal doses of the venom. In opposition to prophylaxis, this was termed *anaphylaxis,* meaning against or without protection. Common causes of anaphylaxis in humans include exposure to antibiotics and other drugs, radiocontrast media, latex, venom, and foods. The cause of anaphylaxis remains unidentified in up to two thirds of patients. Whereas anaphylactic reactions involve IgE-mediated mast cell and basophil degranulation by definition, anaphylactoid reactions result from mast-cell and basophil degranulation by IgE-independent means. Underlying etiologies, where known, include drugs, biologic agents, and physical factors (e.g.,

pressure, cold, sunlight); a substantial proportion of cases are idiopathic.

Allergic Rhinitis

In 1819, John Bostock first described catarrus aestivus or hay fever *(452)*. In 1873, Charles Blackley recognized that pollen grains were the causative agents of hay fever. In the 1800s, hay fever was considererd a rare disorder, restricted to the privileged class. This is certainly no longer the case. According to recent estimates, up to 40% of children in the United States are affected by allergic rhinitis *(453)*, making it the most common atopic disorder in the industrial North. Allergic rhinitis is an IgE-mediated disease characterized by sneezing, rhinorrhea, nasal congestion, and nasal pruritis *(454,455)*. The seasonal form is caused by allergens released during tree, grass, or weed pollination; the perennial form is associated with allergies to animal dander, dust mites, and/or mold spores. Skin testing—the experimental interrogation of the ability of a panel of antigen extracts to induce cutaneous immediate-type hypersensitivity responses—is often employed for diagnostic confirmation of atopy, and to determine the allergens to which an individual is sensitized.

Treatment strategies include allergen avoidance, antihistamines, α-adrenergic agonists, intranasal steroids, topical ipratropium bromide, and immunotherapy regimes. Immunotherapy, introduced by Noon and Freeman in 1911 as a method for protecting patients against the effects of "pollen toxin" *(456)*, has been used since as a treatment for patients with allergic rhinitis and allergic asthma. Conventional allergen immunotherapy involves the subcutaneous injection of graded quantities of allergen. Although such immunotherapy has been associated with therapeutic benefit, the relevant immunologic mechanisms remain obscure. In patients with venom anaphylaxis, allergen immunotherapy is the prophylactic treatment of choice.

Food Allergy

Food allergy needs careful distinction from the more common adverse reactions to ingested substances (e.g., food intolerance, dose-related toxic reactions) that are not immune-mediated. True food allergy afflicts approximately 8% of children under the age of 3 years, and 2% of the adult population. Such food hypersensitivity comprises several disorders that vary in time of onset, severity, and persistence. The most common type of food allergy is immediate gastrointestinal hypersensitivity. Symptoms, consisting of nausea, abdominal pain, colic, vomiting, and/or diarrhea, develop within minutes to 2 hours of antigen exposure. Infants with this syndrome may present with intermittent vomiting and poor weight gain. The predominant response to orally ingested antigens is the induction of tolerance. Food allergy represents an aberration

of this process. Only a small number of foodstuffs account for the vast majority of offending allergens. In childhood, the most common allergens derive from milk, egg, peanut, soy, and wheat. In adults, the most common foods implicated are peanuts, tree nuts, fish, and shellfish. Most food allergens are relatively small, water-soluble, heat- and acid-stable glycoproteins that are resistant to proteolytic degradation. The higher incidence of disease in childhood is presumably related to factors regulating the ontogeny of the gut and immune system development *(457,458)*. Therapy revolves around avoidance of the offending allergen. Interestingly, patients with atopic dermatitis commonly have subclinical food hypersensitivity, with ingestion of the relevant allergen leading to worsening of their dermatitis.

Oral allergy syndrome represents a second type of food hypersensitivity. This is an immediate-type contact allergy that leads to pruritus, tingling, and swelling of the lips, palate, and throat following ingestion of the offending allergen, usually in fruits or vegetables. Oral allergy syndrome affects up to 40% of adults with defined pollen allergy, due to cross-reacting allergens. Therapy involves allergen avoidance.

The eosinophilic gastroenteritides (eosinophilic esophagitis, gastritis, gastroenteritis), though not thought in general to be due to food allergy, deserve brief mention here. These syndromes are characterized pathologically by eosinophil infiltration, and clinically by a variety of nonspecific symptoms, including abdominal pain, nausea, vomiting, and diarrhea, although the etiology and pathogenesis remain unclear in most cases. Some cases are due to hypersensitivity reactions to antigens derived from *Anycylostoma caninum,* a common dog hookworm that is poorly adapted to, and causes nonpatent infection of, humans *(459)*. Some cases may indeed be due to food allergy.

Atopic Dermatitis

Atopic dermatitis is a common, chronic, relapsing, inflammatory skin disease characterized by dry skin, severe pruritis, secondary excoriation which can lead to lichenification, and a heightened susceptibility to cutaneous infections. Atopic dermatitis can lead to significant suffering, both physical and psychologic. The prevalence of atopic dermatitis has increased in the last few decades; currently, 10% are affected at some point during childhood in the United States. Both environmental and genetic factors seem to play a role in susceptibility. Given the fact that the heritability of atopy appears to be largely disease type–independent, it is notable that parental atopic dermatitis confers a higher risk for the development of atopic dermatitis than for either allergic asthma or allergic rhinitis in offspring, suggesting the likelihood of atopic dermatitis–specific genes *(460)*. Disease generally presents early in childhood and is associated with sensitivity to food and/or inhalant allergens. In adults, disease is primarily

associated with sensitivity to inhalant allergens. Apart from exposure to specific food and inhalant allergens, environmental triggers such as irritating substances, emotional stress, climactic factors, hormones, and local infections are all known to be important in the expression of atopic dermatitis. Skin lesions generally display evidence of mast-cell, eosinophil, and T-cell infiltration and activation. In contrast to other atopic disorders, a biphasic pattern of T-cell polarization or reactivity is present in atopic dermatitis: Th2 cytokines predominate in acute lesions, whereas chronic lesions express a mix of Th1 and Th2 cytokines.

Current treatment of atopic dermatitis is directed at symptomatic relief, skin hydration, the reduction of cutaneous inflammation, and avoidance of inciting antigens. Therapies include antihistamines, topical immunosuppressive agents (glucocorticoids, FK506), moisturizers, environmental control measures for inhalant allergens, and food-elimination diets for food allergens. Recent Phase I and II studies have supported the efficacy of short-term IFN-γ therapy in the treatment of severe atopic dermatitis *(461)*, although the mechanism of action remains unclear.

Asthma

The term *asthma* was coined by Hippocrates to refer to attacks of breathlessness and wheezing. Asthma is a complex inflammatory disease of the lung in which the prevalence, morbidity, and mortality have been increasing markedly over the last few decades. Asthma is a heterogeneous disorder with variations in the age of onset, severity of disease, and underlying pathogenesis. Although asthma is multifactorial in origin, with both environmental and genetic influences, atopy is the strongest identifiable predisposing factor for the development of asthma. Most childhood asthma is allergic in nature and is referred to as extrinsic or atopic asthma; however, asthma that develops in adulthood and some forms of childhood asthma are not associated with elevated IgE, and this form is referred to as intrinsic or nonatopic asthma. In the most common form of the disease, extrinsic asthma, the inflammatory process is thought to arise as a result of inappropriate immune responses to commonly inhaled antigens. The inflammatory response in the asthmatic lung is characterized by infiltration of the airway wall with lymphocytes, predominantly CD4$^+$ T cells, eosinophils, and degranulated mast cells. Structurally, the airways of asthmatics are characterized by mucus cell hyperplasia, subepithelial membrane thickening, and loss of epithelial cell integrity. These cellular findings have consistently been associated with the main physiologic abnormalities of the disease, including variable airflow obstruction and airway hyperresponsiveness. As discussed extensively in this chapter, the pathologic consequences of this disease are thought to arise as a result of skewed T-cell responses to inhaled antigens, which in turn lead to activation and recruitment of the primary effector cells, mast cells, eosinophils, and T cells. Activation of these cells results in the release of a plethora of mediators that individually or in concert induce changes in airway geometry and produce the symptoms of the disease.

Current guidelines for asthma management emphasize environmental control measures, objective monitoring, and pharmacotherapy for comprehensive asthma management. The exact combination of pharmacotherapy is dependent on the severity of disease, with short-acting bronchodilators (β-adrenergic agonists) being recommended for mild intermittent asthma, with the addition of anti-inflammatory medication including inhaled or oral corticosteroids, cromolyn or nedocromil, or a leukotriene antagonists being indicated for more severe disease. Several new therapies have been introduced over the last few years, including the anti-IgE monoclonal antibody omalizumab (Xolair), which is a recombinant humanized monoclonal anti-IgE antibody that has demonstrated efficacy in allergic asthma and other IgE-related allergic illnesses (seasonal and perennial allergic rhinitis). In three pivotal, placebo-controlled trials in patients with moderate-to-severe allergic asthma, omalizumab provided effective disease control, significantly reducing exacerbations and the need for unscheduled outpatient visits, emergency room visits, and hospitalizations (see review, 462). Trials in humans have shown that Amb a 1, a ragweed-pollen antigen, conjugated to a phosphorothioate oligodeoxyribonucleotide immunostimulatory sequence of DNA, greatly reduced allergenicity, and may offer long-term clinical efficacy in the treatment of allergic rhinitis (463). Clinical trials aimed at blocking IL-13 and/or IL-4 pathways are underway, and early reports suggest that this approach may be promising: however, as clinical testing of these new therapies is in early stages, determination of their efficacy in asthma therapy awaits further study.

Transplantation Immunology

Megan Sykes, Kathryn Wood, and David H. Sachs

The transplantation of organs and cells between individuals saves or prolongs thousands of lives each year. The growing list of organs transplanted includes corneas, kidneys, livers, hearts, lungs, small intestines, pancreata, and even hands and faces. Currently, clinical cellular transplantation includes islets of Langerhans and hematopoietic cells, but the list is likely to expand in the future to include other cell types, such as hepatocytes and myoblasts, which are currently under investigation in experimental models. Success of all types of transplants depends on the ability to avoid rejection due to a host-versus-graft immune re-

sponse. Hematopoietic cell transplantation is, in addition, associated with some special considerations because the administration of a donor graft that contains mature T cells to a conditioned, and consequently immunoincompetent, recipient is associated with the risk of rejection in the graft-versus-host direction, that is, graft-versus-host disease (GVHD). Because all of these transplants are performed between different humans, that is, members of the same species, they are referred to as *allotransplants*. However, improvements in immunosuppressive therapies have increased the success of allotransplantation to the

point that a new limitation has been encountered, namely, the insufficient supply of human organs.

Although this insufficiency can be partly overcome by the increasing use of living donors as sources of kidneys, liver, and lungs, such procedures are associated with significant risks to the donor, and some organs (e.g., the heart) can obviously be obtained only from cadaveric donors. This organ shortage has led to considerable interest in alternatives, such as artificial organs, tissue grafts engineered *in vitro* from stem cells, and organs from other species. Transplants from other species, referred to as *xenografts*, are a promising solution to the organ shortage, but present even greater immunologic challenges than allografts, as well as potentially novel infectious risks, and these problems must be addressed before xenotransplantation can be effectively used in the clinic. This chapter presents an overview of the immunology of organ and cellular allotransplantation, as well as xenotransplantation. Allogeneic and xenogeneic responses differ from other immunologic responses in at least two fundamental ways. First, they exhibit extraordinary strength and, probably for that reason, include unusual types of responses that cannot be detected in other areas of immunology. Second, they can be stimulated by two different sets of antigen-presenting cells, those of the donor and those of the recipient. In this chapter, we will emphasize these differences from classical immunology as we describe our current understanding of the immune responses that cause graft rejection.

ORIGINS OF TRANSPLANTATION IMMUNOLOGY

Early History

Although there were sporadic reports of tissue transplants in ancient times *(1)*, skin grafting did not become an accepted practice until the late 1800s. However, even then many workers did not distinguish between autografts (donor and recipient the same individual) and allografts (donor and recipient of the same species) or even, sometimes, xenografts (donor and recipient of different species). The last of these formed the basis for an extensive practice known as zoografting in which patients were subjected to grafts from animals ranging from pigs to frogs *(2)*. Billingham *(3)* points out that no one apparently cared whether the grafted skin "took" or merely promoted healing of the wound. The results of these efforts led to a period of confusion in transplantation. Without any clear understanding of the processes involved, surgeons embarked on all sorts of transplants, and a series of operations were reported that we know, from our present understanding of the laws of transplantation, could not possibly have been successful. The transplantation of internal organs awaited

the development of techniques for vascular anastomosis. In. 1908, Carrel *(4)*, one of the pioneers of vascular surgery, reported the results of *en bloc* allotransplantation of both kidneys in a series of nine cats. He was able to obtain up to 25 days of urine output in some cats, but ultimately all of them died. Although other investigators repeated and modified Carrel's experiments, no major advances in prolonging the function of allografts or in understanding the cause for their failure were made for the following 3 decades.

During this same period, the closely related field of tumor transplantation gained momentum *(3)*. Although many of the experiments with tumor transplants provided information essential to an understanding of transplantation immunology, this was not clear at the time. Many workers were committed to the idea that they were studying an effect peculiar to tumor tissues. In his Harvey Lecture, Medawar summed up the confusion neatly by the statement, "Nearly everyone who supposed that he was using transplantation to study tumors was in fact using tumors to study transplantation" (5).

In. 1936, Voronoy, a Russian surgeon, reported the first clinical renal allograft *(1)*. There was apparently a mismatch of blood types and the patient died having demonstrated only minimal renal function. The early postwar years saw reports of attempts at clinical renal homotransplantation from various locales around the world. In. 1952, the first successful renal transplant was performed in Boston using the kidney of an identical twin (6).

One of the important contributions to the understanding of transplantation in this era was the work of Medawar. In. 1943, Gibson and Medawar reported their experience with autologous and allogeneic skin grafts on a woman who had suffered extensive third-degree burns. The allografts in this case were taken from the patient's sibling, and for clinical reasons were transplanted in two different stages separated by about a week. The authors observed accelerated rejection of the second grafts. Appreciating the possible significance of these observations, Medawar *(5)* followed them with a series of grafting experiments in rabbits and mice. By. 1945, he was able to conclude that "resistance to homologous grafted skin therefore belongs to the general category of actively acquired immune reactions" *(5)*, thereby establishing the relationship of clinical transplantation to the field of immunology.

History, Principles, and Discoveries of Immunogenetics

Inbred Strains

Rodents have provided an invaluable model for the study of the genetic basis for graft rejection. One of the main features that has made them so valuable is the availability

of a large number of inbred strains. Such strains consist of animals that have been produced by sequential pedigreed brother-sister matings for at least 20 generations and which are, therefore, essentially genetically identical. With the exception of the sex chromosomes, chromosomes in such strains are homozygous and therefore produce identical homozygous progeny.

The reason that sequential inbreeding leads to homozygosity is illustrated in Figure 44.1. For the sake of simplicity, the first generation illustrated in this figure is indicated as a brother-sister mating in which, for any given autosomal locus, the alleles being bred will be of the form AB × AB. The more general case of AB × CD can also be analyzed statistically by a similar, although slightly more complicated, mathematical treatment. The ratio of genotypes of the offspring from this breeding is given by the binomial formula (AA:AB:BB = 1:2:1). Thus, as illustrated at the second generation, when a single brother-sister pair is chosen, the chance that both animals will have the genotype AA at the locus in question is 1/16. Similarly, the probability that the second-generation mating will take the form BB × BB is also 1/16. In either of these eventualities, all future generations will be fixed as homozygotes (either AA or BB)

and therefore we speak of the locus as being fixed. Thus, the probability of fixation of a given autosomal locus at this generation is 1/8.

For segregation of a large number of independent loci, it is mathematically equivalent to state that the probability of fixing a given locus is 1/8, or that on the average 1/8 of the segregating loci will be fixed. If the locus in question is not fixed during this random breeding, then the chances that it will be fixed at the next breeding are still approximately 1/8 (actually a little higher). In other words, 1/8 of the loci would be expected to fix at the second inbreeding generation, 1/8 of the remaining unfixed loci would be expected to fix at the next generation, and so on. As indicated in Figure 44.1, the probability of fixation (Pfix) is given by the formula:

$$P_{\text{fix}} = 1 - \left(\frac{7}{8}\right)^{n-1}$$

This equation describes a curve that rises asymptotically toward a probability of 100% fixation (Figure 44.2). Because genes travel at meiosis in groups rather than individually, there is a finite number of units of genetic

Mating	Generation	Probability of Fixation
♂AB × ♀AB → ♂AA ♂AB ♂AB ♂BB	1	0
(Grid AA AB AB BB / AA AB AB BB) = AA or BB at 12.5% of Loci	2	$1 - 7/8$
AA or BB at 23.4% of Loci	3	$1 - (7/8)^2$
AA or BB at 33.0% of Loci	4	$1 - (7/8)^3$
AA or BB at all loci	n	$1 - (7/8)^{n-1}$
FIGURE 44.1 Breeding scheme for inbred strains.
FIGURE 44.2 Probablity of fixation curve.

information that segregate. Therefore, for practical purposes, one can consider a strain inbred after 20 such brother-sister matings because at this point there is a very small chance that any locus will not have reached homozygosity. All loci will be of the genotype either AA or BB, and there will no longer be any loci of the heterozygous form AB. The strain so derived is defined as an inbred strain. Hundreds of such well-characterized inbred strains are now available.

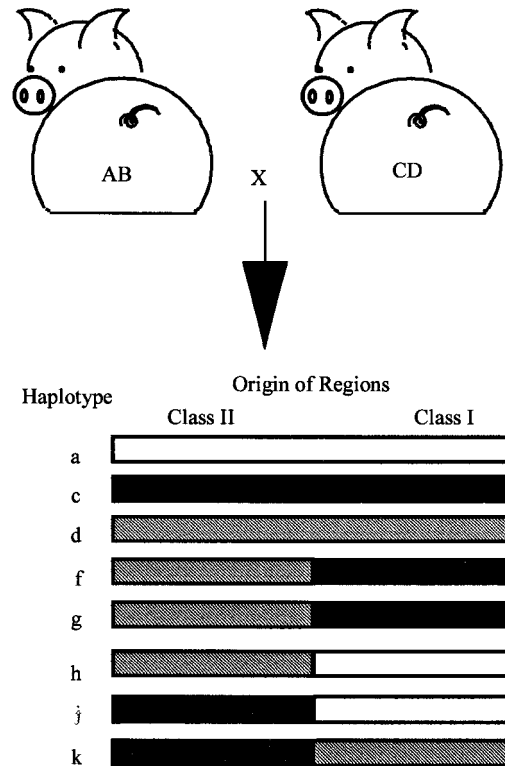
Inbred strains have also been produced in several other species including rats, guinea pigs, and rabbits. However, both space requirements and other genetic features, such as gestation times, age of sexual maturity, and litter size, make production of inbred strains in larger species much more difficult. Indeed, until recently, there were no inbred large-animal species available. However, during the past 35 years, studies in one of our laboratories (D. H. Sachs, Boston, MA, USA) have produced highly inbred miniature swine (7,8). Swine were chosen for this purpose because they represent one of the few large-animal species in which breeding characteristics make genetic experiments possible. Swine have a relatively large litter size (three to ten offspring) and a short gestation time (3 months). They reach sexual maturity at approximately 6 months of age, and sows have an estrous cycle every 3 weeks. These breeding characteristics made it possible to develop major histocompatibility complex (MHC) homozygous lines of miniature swine in a relatively short time *(7)*, to isolate new MHC recombinants and breed them to homozygosity, and to carry out short-term backcross experiments in order to identify and study the segregation of genetic characteristics. These miniature swine now represent the only large-animal model in which MHC genetics can be reproducibly controlled. As such, these animals have been particularly useful in assessing the effects of MHC matching on rejection and/or tolerance induction *(9)*.


FIGURE 44.3 Origin of miniature swine haplotypes.

At present, swine of three homozygous SLA haplotypes, SLA^a, SLA^c, SLA^d, and five lines bearing intra-SLA recombinant haplotypes are maintained, as illustrated in Figure 44.3. All of these lines differ by minor histocompatibility loci, thus providing a model in which most of the transplantation combinations relevant to human transplantation can be mimicked. Thus, for example, transplants within an MHC homozygous herd simulate transplants between HLA identical siblings, while transplants between herds resemble cadaveric or nonmatched sibling transplants. Likewise, transplants between pairs of heterozygotes can be chosen to resemble parent into offspring or one-haplotype mismatched sibling transplants. In addition, one subline of SLA^{dd} animals was selected for further inbreeding in order to produce a fully inbred line of miniature swine. This subline has now reached a coefficient of inbreeding of more than 94%, and is now sufficiently inbred for histocompatibility, that is, reciprocal skin grafts among the offspring have not been rejected (8). These animals should be particularly useful in permitting adoptive transfer studies for the first time in a large-animal model.

One problem in maintaining true homozygosity of inbred strains is that of mutation. The average mutation frequency for mammalian genes has been estimated to be approximately 10^{-6} per base pair per meiosis. Because there

are more than 10^6 genetic loci in mammalian organisms, one would expect at least one mutation to occur somewhere in the genome at every generation. This source of reintroduction of heterozygosity cannot be avoided, but one can ensure that such heterozygosity, once introduced, will not remain for long by maintaining a strict brother-sister pedigreed mating scheme for the reference line of any inbred strain. As indicated in Figure 44.1, such a scheme will ensure that any mutation that occurs will either be lost or be fixed as a homozygous allele by this procedure. However, when the same strain is maintained in two different colonies, the pedigreed reference lines will of course accumulate different mutations, leading to the phenomenon of "drift," with each line remaining truly inbred, but differing for an increasing number of fixed mutations. Such separated lines are called *sublines* and are designated by a series of letters following the strain designation that indicate the origin and location of the pedigreed reference line. Thus, for example, the C3H/HeJ and C3H/HeN lines are two different sublines of the C3H strain. Both were originally maintained by Heston (He), one subline then being maintained at Jackson Laboratory (C3H/HeJ) and the other at the National Institutes of Health (C3H/HeN). Although these strains are still quite similar for many properties, there are already several known differences between them, such as the responsiveness of their lymphocytes to lipopolysaccharide. Often differences between sublines are first detected when results from one laboratory are found difficult to reproduce in another.

Genetic Principles Governing Tissue Transplantation: The "Laws of Transplantation"

In the early 1900s it was noted by tumor biologists that tumors arising in inbred animals could frequently be transplanted successfully to other animals of the same line, while this was usually impossible in outbred animals. Little *(10)* then studied this phenomenon systematically, and in the process produced and characterized a large number of inbred strains of mice. In summarizing the results of these studies of tumor grafting in mice, Little described what have since been called the "five laws of transplantation" (Table 44.1). Little's remarkable insight was to reconcile these observations with the classical Mendelian principles by proposing that recipients would reject grafts if the donor expressed a product of any histocompatibility (tissue compatibility) locus that was not expressed by the recipient. His explanation for the unusual inheritance pattern in Table 44.1 was to suggest, first, that there must be codominant expression of the histocompatibility genes, and second, that there must be a relatively large number of histocompatibility loci. Under these conditions, members of the F1 generation would express both parental alleles at all histocompatibility loci (and thus would fail to reject

▶ TABLE 44.1 The Laws of Transplantation

1. Transplants within inbred strains will succeed.
2. Transplants between inbred strains will fail.
3. Transplants from a member of an inbred parental strain to an F_1 offspring will succeed but those in the reverse direction will fail.
4. Transplants from F_2 and all subsequent generations to F_1 animals will succeed.
5. Transplants from inbred parental strains to the F_2 generation will usually, but not always, fail.

grafts from parental, F2, or subsequent generations) and members of the F2 generation would be unlikely to express all of the products of histocompatibility genes that are expressed by either parental generation (and thus would usually reject parental allografts).

Estimating the Number of Histocompatibility Genes

One can experimentally determine the number of histocompatibility loci by which any two inbred strains differ by breeding a large F2 population between these strains and then transplanting tissues from one of the parental strains to all of the F2 offspring, measuring the fraction of grafts that survive. As illustrated in Figure 44.4, if the two strains were to differ at only one histocompatibility locus, one would predict that 3/4 of the grafts would survive. If, however, if the two strains differed by two independently segregating histocompatibility loci, then one would predict that $(3/4)^2$ or 9/16 of the grafts would survive. Similarly, if there were n loci by which these two strains differed, one would expect $(3/4)^n$ to be the fraction of surviving grafts. When this equation has been solved for "n" experimentally, using skin grafts as the challenging transplant, numbers as high

as 30 to 50 have been reported (11). Because there are only 20 chromosome pairs in the mouse genome, these larger numbers imply that many chromosomes carry more than one histocompatibility locus.

Producing Congenic Strains: Identifying the Major Histocompatibility Complex

A process to generate strains differing from one another genetically at only a single one of these numerous histocompatibility loci was pursued by Snell *(12)* at Jackson Laboratory, and involved the production of congenic strains (inbred strains that differ from one another at only one independently segregating genetic locus) using the rejection of parental skin grafts as the trait used to select successive matings. It became apparent during this process that one histocompatibility locus could be distinguished from all the others by the speed with which it caused skin graft rejection. This is now called the *major histocompatibility complex* (MHC). All of the other 30 to 50 histocompatibility loci have since been called minor histocompatibility loci. There are now a very large number of H-2 congenic strains of mice available (Table 44.2), as well as some that isolate minor histocompatibility loci and some rat congenic strains.

MHC, major histocompatibility complex.

One of the most useful breeding schemes to produce CR lines is illustrated in Figure 44.5. Starting with two inbred strains, labeled for simplicity strain A and strain B, the objective is to obtain a strain that will share its entire genome with strain A except for the major histocompatibility locus H-2, which will be derived from strain B. The end product will be designated strain A.B. Using the cross-intercross scheme illustrated in Figure 44.4, a skin graft or tumor graft from strain A is placed onto all F2 offspring. Animals that reject the graft must be of genotype bb in at least one histocompatibility locus. Obviously, because there are many histocompatibility loci, most animals at this generation will reject the graft. However, if only animals rejecting vigorously are chosen, and if numerous such animals are selected, then one can be reasonably certain to have selected bb homozygotes at the H-2 locus by this procedure. The process is then repeated sequentially, mating rejectors back to strain A animals at each F2 generation. At each sequential F2 generation, the fraction of animals rejecting grafts vigorously will be smaller than it was at the previous generation. By selecting only vigorous rejectors one will ensure the selection of the bb homozygote at the H-2 locus. By the time nine cycles have been completed, one would expect only one histocompatibility locus to be segregating, so that only 25% of the intercross offspring should be capable of rejecting the graft. Assuming that vigorous rejection has been demanded throughout, one can be relatively certain that the selected locus will be H-2. In addition, the chances that any other nonselected locus will still be heterozygous rather than having reverted to the homozygous aa genotype will have fallen to less than 0.2%. Stated another way, more than 99.8% of nonselected loci will be expected to be identical to their counterparts in strain A. A male and a female homozygote from the final intercross are selected and used to establish a pedigreed inbred congenic line A.B.

Because mammalian genes are transferred as linked units in chromosomes, this process will always lead to the retention of a variable amount of bb genetic information at genes closely linked to the locus being selected. However, as described later, the occurrence of recombination during intercrossing generations leads also to fixation of the aa genotype at loci on the same chromosome as the MHC (chromosome 17 in mice) but at a variable distance from H-2. For practical purposes, animals that have been through at least nine cycles of such selected breeding are considered to be congenic.

As indicated in Table 44.2, there are now a large number of H-2 congenic mouse strains available on a variety of backgrounds. In general, the names of each of these strains follow the rule A.B, with strain A being the background strain used in the production of the congenic, and strain B being the other parental strain from which the alternate allele at H-2 was selected. All of the early inbred mouse strains were assigned a small-letter designation to
FIGURE 44.5 Schematic representation for production of a congenic line.

represent the particular constellation of alleles that they possessed at genes in the MHC. This small-letter designation is often called the *haplotype designation*, as indicated in Table 44.2. Thus, for example, strain C57BL/10 (or B10) is assigned the haplotype designation H-2b, and strain DBA/2 the haplotype designation H-2d. Thus, the congenic strain B10.D2 represents a line in which the background is derived from the C57BL/10 and the MHC from the DBA/2. It thus resembles in almost every way the C57BL/10 congenic partner, except that it differs from this partner for all properties controlled by MHC-linked genes.

Intra-MHC Recombinant Strains: Class I and II Antigens

As can be seen in Figure 44.5, every alternate generation in this mating scheme involves the crossing of animals heterozygous at H-2. Whenever heterozygotes are bred, there is always a possibility of recombination between autosomal chromosomes at meiosis. During the production of congenic lines, such recombination will tend to decrease the amount of linked genetic information carried into the congenic from the H-2 source. Therefore, the more backcrosses a particular congenic line has been subjected to, the closer will be the boundaries on either side of H-2 at

which the chromosome reverts to the background strain. Because it soon became apparent that the MHC was in fact made up of multiple loci, there was also the possibility for recombination within H-2 to occur during such crosses. Fortunately, mouse geneticists were aware of this possibility and saved numerous recombinants during the production of H-2 congenic lines. Indeed, it was through the detection and characterization of such recombinants that the linkage map of H-2 was constructed. Thus, for example, there are now a series of recombinants between strain C57BL/10(H-2b) and A/WySn(H-2a) that were isolated by Stimpfling during production of the B10.A CR line and which have provided a great deal of information on the genetic fine structure of the H-2 complex. Strains B10.A(2R) and B10.A(4R), for example, have been used to map a variety of immune response genes within the MHC. Table 44.3 presents a listing of many of the most useful congenic recombinant strains now available and their known or presumed points of recombination. Among the most important contributions that came from the study of intra-MHC recombinant strains was the progressive understanding that the loci within the MHC encoded two general types of MHC antigens, now referred to as class I and class II MHC antigens.

DONOR ANTIGENS RESPONSIBLE FOR GRAFT REJECTION

Major Histocompatibility Antigens

MHC antigens are called *histocompatibility* antigens because of their powerful role in causing graft rejection; yet they did not evolve in nature to prevent tissue grafting. Although the name serves to emphasize the historical importance of transplantation in the discovery of the MHC, the essential role of MHC antigens is now understood to involve the presentation of peptides of foreign antigens to responding T cells (see Chapter 19). Table 44.4 summarizes important aspects of the MHC antigens that are worth emphasizing in this chapter on transplantation, while a much more detailed description of their structure and function can be found in Chapter 19.

Basic Features of MHC Antigens

Class I and Class II Antigens

Different loci within the complex encode two general types of MHC antigens, termed *class I and class II antigens*. Originally, the class I antigens were identified most easily by serologic techniques, while class II antigens were defined by their ability to induce proliferative responses

▶ **TABLE 44.4** Summary of Features of MHC

Class I antigens	Single polymorphic chain
	Three domains: alpha 1, 2, and 3
	MW: 45,000
	Associated with beta 2 microglobulin
	A, B, and C loci in humans
	Expressed on all tissues and cells
Class II antigens	Two polymorphic chains: alpha and beta
	Each with two domains: alpha 1 and 2, beta 1 and 2
	MW: 33,000 and 28,000
	DP, DQ, and DR loci in humans
	Expressed on macrophages, dendritic cells and B cells; vascular endothelium; activated human T cells

MHC, major histocompatibility complex.

of allogeneic lymphocytes *(13)*. Class I and class II MHC antigens evoke allogeneic responses that differ in magnitude, as will be discussed later.

Polymorphism

The MHC antigens exhibit extraordinary polymorphism. This polymorphism presumably provides an advantage to members of the species by ensuring a broad capacity to present the peptides of, and thus respond to, a large number of foreign antigens. In the human HLA complex, for example, there are currently at least 300 known alleles at each of the HLA-B (class I) and DRB1 (class II) loci (14). The high degree of polymorphism has important consequences for transplantation. Given that there are three class I loci (A, B, and C) and three to four class II loci (DQ, DP, DRB1, $\pm$ an expressed DRB 3,4 or 5 locus present in some haplotypes) on each haplotype, the likelihood of achieving identity for MHC antigens in two unrelated humans is extremely small.

Tissue Distribution

The tissue distribution of the two types of MHC antigens differs. Class I antigens are present on all nucleated cells of the body, but may be sparsely represented on some types of cells *(15)*. Class II MHC antigens are more selective in their distribution *(16)*. They are especially frequent on macrophages, dendritic cells (DCs), and B lymphocytes. They are present on other lymphoid cells under some circumstances, and on vascular endothelium. Their expression on some tissues of the body is regulated according to various stimuli *(17)* and differs between species. One of the important distinctions between rodents and many larger species is the lack of constitutive expression of class II antigens on the vascular endothelium and other cell populations in rodents. In contrast, pigs, monkeys and humans express class II antigens on these tissues *(18)*.

The Importance of MHC Antigens in Alloreactivity. Alloreactivity is the immune response to foreign antigens of other members of the same species. MHC antigens are exceptionally important in stimulating alloresponses, both *in vivo* and *in vitro*.

VIGOROUS GRAFT REJECTION. Early experiments showed that mouse skin grafts differing only in their MHC antigens were typically rejected in 8 to 10 days, whereas grafts differing by only a few minor histocompatibility antigens were typically rejected in 3 or more weeks. Subsequent experiments have confirmed the importance of MHC antigens for other types of grafts. In pigs, primarily-vascularized organs, such as the kidney, may survive indefinitely in some cases, even without immunosuppression, if all of their MHC antigens are matched, whereas MHC-mismatched kidneys are always rejected within 2 weeks *(18)*. However, the importance of MHC antigen matching becomes

harder to detect, especially for highly immunogenic skin graft survival, when comparing MHC-mismatched grafts with grafts differing for multiple minor histocompatibility antigens.

STRONG in vitro ALLORESPONSES. Allogeneic MHC antigens also stimulate an extraordinarily strong T-cell response *in vitro*. This strength is manifested partly by the ability to readily achieve primary *in vitro* cell-mediated responses to allogeneic MHC antigens, whereas *in vitro* responses to non-MHC antigens generally require *in vivo* priming. The standard *in vitro* assay of helper function in cellular immunity is the mixed lymphocyte response. This assay uses uptake of radiolabeled thymidine or loss of a fluorescent intracellular dye on successive cell divisions *(19)* to measure proliferation of T cells after allogeneic stimulation. Such analyses have led to frequency estimates of approximately 1% to 7% of T cells proliferating in a particular alloresponse *(19–22)*, while naïve T cells reactive with an exogenous peptide generally represent only approximately one in tens to hundreds of thousands of the same T-cell pool *(23,24,25)*. Much higher precursor frequencies of alloreactive T cells compared with those for a particular peptide presented by a self-MHC molecule are measurable in limiting dilution assays. The helper response can also be quantified and characterized by measuring the production of particular cytokines such as interleukin 2 (IL-2) using biologic assays, enzyme-linked immunosorbent assay (ELISA), and enzyme-linked immunosorbent spot (ELISPOT) assay *(26,27)*, intracellular cytokine staining with flow cytometry *(28)*, and polymerase chain reaction (PCR).

Likewise, strong primary direct alloresponses of CD8[+] T cells can be measured *in vitro*, either in standard cell-mediated lympholysis (CML) assays, in limiting dilution assays measuring cytotoxic T lymphocyte (CTL) precursor frequencies or in cytokine production assays similar to those previously described for CD4 cells. The CML assay measures T-cell–mediated cytotoxicity against allogeneic targets. Alloreactive CTLs can easily be generated from naïve T cells after about 5 to 7 days of *in vitro* stimulation with MHC-disparate cells. Generation of CTLs to peptides of minor antigens presented by self MHC molecules, however, requires that the T cells first be primed *in vivo*. The amount of cytotoxicity measured *in vitro* is a function of both the helper activation and the number of precursor CTLs available at the start of the *in vitro* culture. Therefore, to focus on just the cytotoxic effector function the assay is often performed with the addition of exogenous helper factors, such as IL-2, in order to provide an excess of help.

The presence of T cells that can kill donor targets without a period of *in vitro* sensitization (direct cytolytic activity) *(29)*, an increased precursor frequency of alloreactive T cells, and development of CTL under modified conditions *(30)* has been used to demonstrate *in vivo* activation

▶ **TABLE 44.5** *In vitro* **Pathways of Alloreactivity**

	Helper Pathways				Cytotoxic Pathways	
	Direct		Indirect			
	I	II	I	II	I	II
CD4+	−	+ + ++	−	+ + +	−	++
CD8+	++	−	+/−	−	+ + ++	++

by alloantigens. More recently developed techniques, including ELISPOT and intracellular cytokine staining, have enhanced the ability to detect nonproliferating or noncytolytic CD8 T cells that have been sensitized *in vivo (28)*.

In general, the rule that CD4 cells recognize class II antigens and CD8 cells recognize class I antigens has been borne up by extensive investigation of the pathways of alloreactivity. However, this strong bias for recognition of each class of MHC antigen is more stringent for CD4 cells than for CD8 cells. The summary shown in Table 44.5 indicates the relative magnitude of the response for each T-cell subpopulation in response to each type of antigenic challenge. It should be noted that in some cases where the response is shown in Table 44.5 to be absent (based on bulk culture experiments), there have been T-cell clones derived (presumably exceptional cases) that demonstrate this specificity.

Direct Recognition of Allogeneic MHC Antigens. As indicated in Table 44.5, the extraordinary strength of alloreactivity largely reflects the ability of T cells to recognize allogeneic MHC antigens presented on donor APC, which is referred to as "direct" allorecognition. "Indirect" allorecognition, on the other hand, denotes presentation of donor-derived peptides on MHC antigens of recipient APC. Although these responses are much weaker than direct alloresponses, they are nevertheless important (see later discussion). Three different, but not mutually exclusive, hypotheses have been proposed to

explain the high frequency of directly alloreactive T cells: (i) a genetic bias favoring T-cell receptor genes that bind to MHC antigens, (ii) a high density of individual allogeneic MHC determinants on the surface of allogeneic APCs, and (iii) a large number of different allogeneic MHC/peptide determinants expressed on the donor APCs.

GENETIC BIAS. Because the thymus only positively selects T cells with some degree of MHC reactivity, a T-cell receptor (TCR) gene pool that encodes a broad range of specificities (as is the case for B cells) would produce many useless precursors. A narrower pool of T-cell receptor genes, however, would allow for more efficient thymic selection. Considerable evidence supports the hypothesis that TCRs have intrinsic affinity for MHC molecules before positive and negative selection (*31–37,38,39*). Although thymocytes must survive positive selection in order to mature and enter the peripheral T-cell pool, the TCR affinity for self-MHC/peptide complexes required for positive selection is much lower than that involved in negative selection (38). Positive selection results in enrichment for TCRs capable of seeing modified self-MHC antigens. Those receptors with strong affinity for the same MHC antigens plus self-peptides are deleted through negative selection. Because TCRs are not normally negatively selected in the presence of allogeneic MHC molecules, intrinsic allogeneic MHC reactivity persists within a T-cell repertoire that has been negatively selected only by "self" MHC-peptide complexes. Alloreactivity can occur despite the influence of positive selection because negative selection never occurs for the vast majority of T cells recognizing allogeneic MHC antigens.

THE "DETERMINANT DENSITY" HYPOTHESIS. As illustrated in Figure 44.6A, the density of a given specific peptide determinant expressed by a self-APC would be quite low (as most MHC antigens present other peptides), whereas the density of a peptide-independent allogeneic MHC determinant on allogeneic APCs would be very high (as every MHC antigen would include the foreign determinant). According to this hypothesis, a high frequency

Donor APC with donor MHC antigens (O), all of which are foreign.

Self APC with self MHC molecules (□). The rare self MHC molecule presents a peptide (X) of an environmental pathogen.

A

Donor MHC antigens (O). Each presents different "self peptides," generating different foreign determinants.

Self MHC molecules (□) also present self peptides (Y$_{1...N}$), but these are all self determinants.

B

FIGURE 44.6 **A:** Determinant density hypothesis. **B:** Determinant frequency hypothesis. APC, antigen-pressenting cell; MHC, major histocompatibility complex.

of alloreactive T cells might be apparent because abundant allogeneic MHC determinants would activate many cross-reactive T cells with relatively low affinities. This hypothesis implies that allogeneic MHC molecules can be recognized at least partly independently of the peptides they present, and T-cell clones recognizing MHC antigens in a completely or partially peptide-independent manner have indeed been demonstrated in the alloreactive TCR repertoire (40,*41–46*).

THE "DETERMINANT FREQUENCY" HYPOTHESIS. T cells specific for allogeneic MHC antigens are influenced by the peptides presented by these MHC molecules *(47)*. Whereas MHC molecules on self-APCs present peptides of self proteins (say $X_{1,2,...n}$), allogeneic MHC antigens may present peptides of polymorphic allogeneic "self" proteins (e.g., "Allo + X_1, Allo + X_2, ... Allo + X_n") (Fig. 44.6B). Alternatively, the self-peptides presented by self or allogeneic MHC molecules might be identical, but these complexes would stimulate different TCRs because crystal structure data indicate that both peptide and MHC alpha helix residues contribute to the surface that is recognized by a TCR *(48–51)*. In both cases, the set of determinants represented by "Self + $X_{1...n}$" would differ from that represented by "Allo + $X_{1...n}$". T cells responsive to self-peptides on self-APCs (Self + X_1, Self + $X_{2,...}$ etc.) are eliminated by the induction of self-tolerance, leaving only self-MHC molecules presenting peptides of foreign antigens to stimulate an immune response. On the other hand, self-tolerance would not affect the response to the many self-peptides on allogeneic APCs (Allo + X_1, Allo + $X_{2,...}$ etc.). Thus, alloreactive T cells are more frequent because each allogeneic MHC antigen generates a large number of different foreign determinants. Consistent with this hypothesis, many alloreactive T cells have been shown to be peptide-specific or at least partially peptide-selective *(41,42,52–59)*. Cardiac allografting studies using $DM^{-/-}$ mice, which lack the capacity to replace invariant chain-derived CLIP peptide with a more diverse array of peptides, provide strong *in vivo* evidence for the importance of peptides in direct allorecognition (60).

Clearly, both peptide-dependent and -independent alloreactive TCRs exist, and both types are likely to contribute to the high frequency of alloreactive TCRs. Overall, the available information supports the inherent MHC binding capacity of TCRs, as well as the determinant frequency and the determinant density hypothesis, as explanations for the high frequency of T cells recognizing alloantigens through the direct pathway.

Minor Histocompatibility Antigens

Although initially defined by their ability to cause rapid graft rejection, major histocompatibility antigens are currently defined in part by the location of the genes encoding them and in part by the well-characterized structure of both class I and class II antigens (see Chapter 19). For example, Qa and Tla antigens are generally considered class I-like products because of their structure and location in the genome, even though they are weak transplantation antigens in terms of rejection. Minor histocompatibility antigens, on the other hand, are those capable of eliciting a T-cell immune response, but which lack the structural characteristics of MHC products *(61)*. Rather than being allelic cell surface proteins, minor histocompatibility antigens, like other antigens recognized by T cells, are peptides of donor proteins that are presented by MHC molecules *(62–66,67,68,69)*. In mice, antigens derived from enzymes encoded by mitochondrial DNA are presented by nonclassical class I molecules and may function as maternally inherited minor histocompatibility antigens (70). Because individuals are tolerant to the peptides derived from their own proteins, they only respond to the peptides of another individual's proteins that have allelic variation, that is, polymorphism. Antigens that can cause rejection through B-cell responses without a T-cell response are not considered to be minor histocompatibility antigens.

It has been estimated that there may be as many as 720 minor histocompatibility loci in mice (71), and at least 50 have been mapped to autosomes in the murine genome. Minor histocompatibility antigens can be expressed ubiquitously or in a tissue-selective or tissue-specific manner *(72)*. Some of the peptides representing minor histocompatibility antigens have been isolated in mice and humans, and the proteins from which they are derived have been identified *(67,68,69,71,73,74,75,76,77,78,79–83,84)*. These proteins are often intracellular proteins such as nuclear transcription factors and myosin. However, CD31 is a polymorphic cell-surface glycoprotein that functions as a minor histocompatibility antigen with controversial significance for GVHD risk in bone marrow transplant (BMT) recipients *(85,86)*. Presumably any cellular protein with allelic variation could function as a minor histocompatibility antigen as long as a peptide expressing that allelic variation can be processed and presented by an MHC antigen.

Some minor antigens are diallelic peptides, both of which can be represented by a particular MHC molecule (73,75), resulting in bidirectional recognition (e.g., the murine *H13* locus [75]). Alternatively, allelic variation in the capacity of a peptide to bind to an MHC molecule can result in one allele being presented and the other not (e.g., the human HA-1 minor antigen, in which only one of two allelic peptides binds effectively to HLA-A2 [73]). Minor antigenic determinants can also result from the failure of one allele to be processed to a peptide, as has been observed for the HLA-A2–restricted minor determinant HA-8. Although both alleles, when provided as peptides, can be recognized by HA-8–specific CTL, only one allele is naturally produced, apparently because the other is

transported poorly by the TAP (transporter associated with antigen presentation) complex (76).

It is very difficult to detect humoral responses to minor antigens, presumably because individual peptide/MHC complexes are too low in abundance on the cell surface to either stimulate an antibody response or be detected on the cell surface with antibodies. An exception is the recent discovery of antibodies against H-Y (Y chromosome-encoded) antigens in association with chronic GVHD *(87)*. Additionally, antibody responses to tumor-associated antigens, which, similar to minor antigens, are presented as peptides in the context of MHC molecules, have been detected in humans with various malignancies *(88)*.

When multiple minor antigenic disparities exist, the immune response to one of these antigens often predominates in a phenomenon known as *immunodominance (89–94)*. Removal of the immunodominant recognition sometimes produces strong responses to antigens that previously evoked weak or no responses. This phenomenon may be due to competition between peptides of different minor antigens for presentation by MHC molecules (71). The duration of antigen presentation and TCR avidities may also determine immunodominance *(95)*. An exceptionally immunodominant peptide, H60, which is derived from an NKG2D-binding protein, produces responses that are comparable in potency to those elicited by MHC alloantigens, apparently because of the existence of a very high frequency of TCR in the naïve repertoire with specificity for this peptide (96). However, immunodominance of CTL responses measured *in vitro* does not necessarily reflect the immunodominance of the same antigens *in vivo*, as has been revealed by studies of GVHD in mice (71,97). This discrepancy may reflect the importance of tissue distribution of minor antigen expression or of helper T-cell responses to minor antigens in inducing GVHD *(80)*.

The H-Y antigens are encoded by several genes on the Y chromosome, and are therefore expressed only by males of a given species (71,78,*98–101*). Some mouse strains are capable of rejecting H-Y-disparate (otherwise histocompatible) grafts while others are not. Such rejection requires that the antigen generate both helper determinants, recognized by CD4$^+$ cells in association with class II MHC antigens, and cytotoxic determinants, recognized by CD8$^+$ cells in association with class I antigens, suggesting that to be identifiable as minor histocompatibility antigen, proteins must generate at least two different peptide fragments with allelic variation (102). Exceptions are observed in TCR transgenic mice with an unphysiologically high frequency of a single clone recognizing an H-Y peptide *(103)*.

Because of the relative ease with which CTL assays can be used to measure peptide-specific responses, minor histocompatibility antigens have been identified as determinants recognized by CTL. In humans, these have been identified mainly in the setting of HLA-identical sibling donor bone marrow transplantation, in association with GVHD

and marrow graft rejection (74,76,*80,81,104,105*). Immunodominance of CTL responses to particular H-Y and HA determinants as well as expansion of minor antigen-specific CTL detected with tetrameric complexes of HLA molecules and minor antigenic peptides (*81,105*,106) have been associated with GVHD and marrow graft rejection (107), and certain incompatibilities (e.g., HA-1) may predispose to GVHD *(74,108)*. The use of DCs as APC has permitted the recent molecular identification of minor antigenic peptide epitopes recognized by CD4$^+$ Th *(109)*.

Other Antigens of Potential Importance in Transplantation

Superantigens

Like MHC antigens, superantigens can stimulate primary *in vitro* T-cell proliferative responses and activate a high proportion of the T-cell repertoire. However, these antigens are not presented as peptides in the binding groove of MHC molecules, but instead bind to distinct regions of class II MHC molecules, and engage nonvariable portions of Vβ components of the TCR, rather than the hypervariable regions that recognize peptides. Endogenous superantigens are not classical transplantation antigens, perhaps because of their restricted tissue expression patterns *(110–114)*. However, they may contribute to GVHD in mice (115).

Tissue-Specific Antigens

Some peptides presented by MHC molecules may be derived from proteins with limited tissue distribution *(116–119)*. Responses to such peptides will not be detected by *in vitro* assays to measure T-cell responsiveness to donor antigens when lymphohematopoietic cells are used as the stimulating cell population. The existence of tissue-specific antigens suggests that transplantation tolerance induced by one set of donor cells might not always induce complete tolerance to donor cells of a different sort. For example, the existence of skin-specific antigens may result in skin graft rejection despite the presence of stable hematopoietic chimerism induced by hematopoietic cell transplantation (HCT) (120). Tissue-specific proteins do not necessarily need to show allelic variation to be regarded as alloantigens in bone marrow chimeras as the determinant formed by a given peptide with an allogeneic MHC molecule would be different from that formed by the same peptide with a recipient MHC molecule.

Several human minor histocompatibility antigens may be expressed only on hematopoietic cells (72,121). GVH-alloreactive donor T cells that recognize such antigens could potentially achieve graft-versus-leukemia (GVL) effects without GVHD. However, disparities for some of these minor antigens (e.g., HA-1) have in fact been associated with an increased incidence of GVHD *(74,108)*. It is

of interest that effector and regulatory CD8 T cells recognizing the donor HA-1 peptide have been detected, in association with microchimerism, in HLA-identical kidney graft recipients (122).

Endothelial Glycoproteins

Blood Group Antigens

Blood group antigens are important in relation to blood transfusion but also in the context of transplantation. The blood group antigens do not evoke cell-mediated immune responses and hence are not classified as minor histocompatibility antigens. They are expressed on erythrocytes and other cells and, importantly, on vascular endothelium, where they may serve as the targets for antibody-mediated attack on blood vessels of organ grafts. Blood group antigens are the products of glycosylation enzymes that are not the same in all individuals. Blood group A and B individuals each express their respective antigen but O individuals have neither. The natural antibodies against blood group antigens an individual lacks probably arise because of cross-reactions with common carbohydrate determinants of environmental microorganisms. Thus, type O individuals have antibodies to the antigens of A and B donors, while A and B individuals only have antibodies reactive with antigens from each other, and AB individuals have antibodies to neither. Therefore, O recipients can only receive transfusions from O donors; A and B recipients can receive transfusions from O donors or from individuals sharing their blood type; and AB recipients can receive blood from donors of any blood type. The same rules apply to the transplantation of most primarily vascularized organs in man *(123)*. Recently, advances have been made in the ability to successfully transplant kidneys across ABO barriers by adsorbing antibody from the plasma and depleting B cells (124). Blood group antigens are of lesser importance, but nevertheless significant, in hematopoietic cell transplantation. ABO incompatibility in the host-versus-graft direction can lead to prolonged red cell aplasia following HCT; incompatibility in the GVH direction can result in initial hemolytic anemia, but this complication can be avoided by washing the donor HCT preparation to rid it of plasma *(125)*. In addition to the ABO locus, there are other loci determining blood group antigens on erythrocytes, but these are irrelevant to organ transplantation because they are not expressed on vascular endothelium.

Other Allogeneic Endothelial Glycoproteins

Other glycoproteins expressed on the vascular endothelium may serve as targets for humoral responses. Very rarely, preformed antibodies to these antigens may give rise to hyperacute rejection of primarily-vascularized organs *(126)*. Although antibody responses to non-HLA, non-ABO endothelial antigens have been associated with chronic rejection *(127–129)*, the specificity and pathogenic role of these antibodies is unknown.

Species-specific Carbohydrate Determinants

Closely analogous to the blood group antigens are the carbohydrate determinants expressed on vascular endothelium that show species specificity. For example, pigs, which are of interest as a potential xenograft source animal (see later discussion), as well as most other species, express an α-1,3-galactosyltransferase (αGal transferase) enzyme that is not expressed by humans. This enzyme glycosylates β-galactosyl N-acetyl glucosamine to form a Galα1-3Galβ1-4GlcNAc (αGal) determinant. During evolution, at the level of Old World primates, the gene for this transferase lost its function because of mutation. Because the Gal antigen is found on bacteria and other environmental antigens, humans and Old World primates make a large amount of antibody against Gal. Thus, "natural" antibodies are present in human serum, which reacts to the non–self-pig determinant αGal (130,*131*), and these can cause hyperacute rejection of primarily vascularized xenogeneic transplants. αGal may also be recognized by other components of the innate immune system, such as macrophages (132).

"Missing Self" and Natural Killer Cell Recognition

In apparent violation of the laws of transplantation previously described, (AxB) F1 mice are capable of rejecting bone marrow from parental donors, a phenomenon termed *hybrid resistance*. This phenomenon, as well as rapid rejection of fully allogeneic marrow, is mediated by natural killer (NK) cells *(133)*. NK cells are large granular lymphocytes that lack TCRs, and that have the ability to mediate cytolysis against certain tumor targets and hematopoietic cells. NK cells also produce a number of proinflammatory, hematopoietic, and even anti-inflammatory cytokines, and may be divided into subsets on the basis of their cytokine production pattern *(134)*.

The originally puzzling specificity of NK cell-mediated marrow rejection is due to the expression by NK cells of inhibitory receptors that recognize specific groups of class I MHC alleles on target cells and prevent cytolysis by the NK cell. These class I receptors are type II C lectins (Ly49 family) or dimers of CD94 with NKG2 lectins in the mouse, and are either immunoglobulin family members (KIR) or CD94/NKG2 in humans. Recognition by an inhibitory receptor of a class I ligand results in intracellular transmission of an inhibitory signal via an immune receptor tyrosine-based inhibitory motif that interacts with a tyrosine phosphatase and counteracts activating signals transmitted from other cell-surface molecules. Recognition of "self" class I inhibitory ligands is believed to be important in preventing the NK cell from killing normal autologous cells *(135,136)*. Additional inhibitory NK cell receptors recognize ligands other than class I MHC (137). Molecules of the KIR, Ly-49, and NKG2 families lacking an intracellular immune receptor tyrosine-based inhibitory motif are

capable of associating with molecules that contain tyrosine-based activating motifs (DAP-10 and DAP-12) *(138–140)* that activate cytolytic activity by NK cells (see Chapter 16). There are several other types of NK cell-activating receptors as well, including Fc receptors and natural cytotoxicity receptors (141). The effects of at least some activating receptors can be overridden by inhibitory signals *(142)*. Thus, the ability of an NK cell to kill an allogeneic target will depend on the interplay of inhibitory and activating receptors on the NK cell and the respective ligands expressed by the potential target cells.

Inhibitory receptors are clonally distributed on NK cells, each of which may express one or more different inhibitory receptor. For NK cells to be functional yet tolerant of "self" they must express at least one inhibitory receptor for a self-class I MHC molecule (*143*,144). Thus, as is illustrated in Figure 44.7, an AxB F1 recipient will have subsets of NK cells with inhibitory receptors that recognize MHC of either the A parent, the B parent, or both. The absence of "B" class I molecules on, for example, AA parental hematopoietic cells, permits subsets of (AxB)F1 NK cells

that have inhibitory receptors only for class I molecules from the B parent, to destroy AA cells. Thus, hybrid resistance and NK cell-mediated resistance to fully allogeneic marrow grafts can be explained on the basis of "missing self" *(136)*. The possible role of NK cells in mediating graft rejection is discussed in a later section.

MECHANISMS OF GRAFT REJECTION

At least four distinct mechanisms that can cause graft rejection have been defined according to the time frame in which they tend to occur in clinical practice. Although their names (hyperacute rejection, accelerated rejection, acute rejection, and chronic rejection) have a clear temporal distinction, it is increasingly possible to characterize these mechanisms according to the cell types and processes involved and, in some cases, they may occur at uncharacteristic times.

Rejection Caused by Preformed Antibodies (Hyperacute Rejection)

Hyperacute rejection occurs within minutes to hours after blood flow is established to a transplanted vascularized organ (145,*146,147*). The phenomenon is visible and dramatic: the organ turns blue and its function ceases. Microscopically, there is extensive evidence of vascular thrombosis and hemorrhage.

There are several important components involved in the mechanism of hyperacute rejection. First, there are donor endothelial MHC antigens or carbohydrate determinants (see previous discussion). Second, there are preformed antibodies that can bind these antigens. Third, the complement and coagulation cascades are activated by the binding of preformed antibodies to the donor antigens on the vascular endothelium. The interaction of these components leading to hyperacute rejection is diagrammed in Figure 44.8.

Endothelium

Complement Activation

Endothelial Activation Type 1

Complement Regulatory Proteins

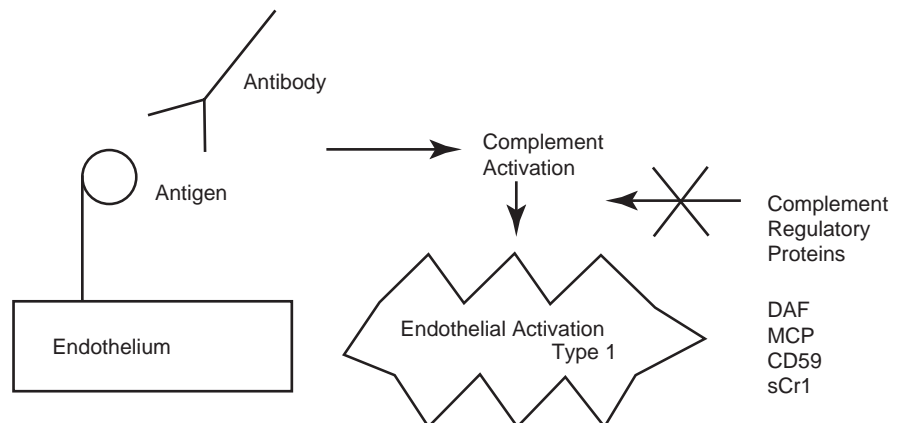
DAF
MCP
CD59
sCr1


FIGURE 44.8 Schematic representation of hyperacute rejection.

The role of complement in hyperacute rejection is inferred both from the accumulation of various complement components in the grafts and from the fact that complement depletion leads to prolonged survival of xenografts *(148)*. Complement activation leads to production of active protein fragments and complexes of complement components, which cause tissue injury either directly or by recruiting effector cells that mediate destruction of the graft. In allogeneic combinations, this is initiated by antibody-mediated activation of complement through the classical pathway, while in xenogeneic combinations, the alternative pathway may also be involved (149). In both cases the membrane attack complex, produced by the ordered interaction of several complement components, initiates the destructive pathway.

Complement activation is controlled by several regulatory molecules, including complement receptor 1, decay accelerating factor (DAF, CD55), membrane cofactor protein (MCP, CD46), and CD59, which act at different stages along the cascade (see Chapter 33). Many of these molecules are produced by the vascular endothelial cells. Because these regulatory proteins prevent unwanted complement activation in the face of low levels of perturbation to the system, the titer and avidity of the preformed antibodies must be high enough to activate despite these down-regulating molecules. Thus, preformed antibodies directed at MHC antigens almost always accomplish this activation, whereas the lower-affinity blood group antibodies lead to hyperacute rejection in only about 25% of kidneys. One of the reasons that hyperacute rejection is such an important feature in xenogeneic transplantation is that the complement regulatory proteins produced by the donor vascular endothelium of one species do not always function effectively with complement molecules derived from a different species. Because of this homologous restriction, lower levels of an initial triggering signal lead to explosive complement activation.

Although the membrane attack complex is often thought of as a lytic molecule, its effect on the donor vascular endothelium, even before cell lysis, is to cause endothelial activation. This occurs rapidly, before there is time for new gene transcription or protein synthesis, and has been referred to as *type I endothelial activation*. The two principal manifestations of this activation are cell retraction, leading to gaps between endothelial cells, and initiation of coagulation pathways due to the loss of antithrombotic molecules from the endothelium *(150)*. Thus, type I endothelial activation is responsible for the two principal pathologic findings in hyperacute rejection: extravascular hemorrhage and edema, and intravascular thrombosis.

There are no known treatments that can stop the process of hyperacute rejection once it has started and, thus, it is essential to avoid the circumstances that initiate it. Experimentally, this can be accomplished for relatively short periods of time by administration of com-plement inhibitors, such as cobra venom factor, which depletes complement. In clinical practice, this is accomplished by avoiding transplantation in the face of preformed antibodies, both by avoiding blood group antigen disparities and by testing recipients before transplantation to determine whether they have preformed antidonor antibodies.

Not all organs and tissues are equally susceptible to hyperacute rejection. Most primarily vascularized organs, such as kidneys and hearts, are very susceptible, but the liver can often survive without hyperacute rejection despite pre-existing antidonor antibodies *(151)*. However, resistance of the liver to hyperacute rejection is not absolute. The other types of transplants that are resistant to hyperacute rejection are those that do not immediately expose donor vascular endothelium to the recipient's circulation, such as skin grafts, whose blood vessels are not in communication with those of the recipient until about a week after transplantation. After this, large doses of exogenously administered antidonor antibodies can destroy skin grafts through a complement-dependent mechanism *(152)*. Free cellular transplants, such as bone marrow cells or hepatocytes, as well as islet grafts *(153)* are not fed by their own blood vessels and thus are not susceptible to the mechanisms of hyperacute rejection. However, in many cases these cell transplants do express some of the antigens recognized by preformed antibodies, and antibodies can impair engraftment *(154)*. In the case of HCT, this resistance can be overcome by transplanting larger numbers of cells *(154–156)*. Additionally, antibody-independent complement activation has been shown to be a significant factor diminishing the engraftment of xenogeneic bone marrow (157).

Acute Humoral Rejection (Accelerated Rejection)

A second mechanism of rejection, also caused by antibodies, occurs as a result of antibodies that are induced very rapidly after a transplant is performed. This type of rejection has been called *acute humoral* or *accelerated* rejection because it typically occurs within the first 5 days posttransplant. The process is characterized by fibrinoid necrosis of donor arterioles with intravascular thrombosis (158).

Accelerated rejection is rare in allogeneic combinations because it requires that an antibody response occur before the T-cell response that is typically responsible for acute rejection episodes (see later discussion). Indeed, it is very difficult experimentally to induce an allogeneic B-cell response in the absence of T-cell immunity. The best examples of accelerated rejection are observed in vascularized organ transplants between closely related concordant xenogeneic species and between discordant species following adsorption of anti-Gal antibodies. In these cases, the levels of preformed antibodies are not sufficient

to cause hyperacute rejection, but antidonor antibodies appear rapidly (within 3 to 4 days), causing rejection. The pathology of acute humoral rejection reveals a paucity of lymphocytes infiltrating the donor graft, antibody binding to donor vascular endothelium, and fibrinoid necrosis of the donor vessels. Vigorous anti–T-cell immunosuppression has little effect on acute humoral rejection, whereas immunosuppression with reagents that affect B-cell responses, such as cyclophosphamide, delays its onset until more typical T-cell–mediated rejection occurs *(159)*.

Like hyperacute rejection, acute humoral rejection is usually initiated by antibody binding to antigens on the donor vascular endothelium. In this case, however, the subsequent endothelial changes occur more slowly, allowing time for gene transcription and new protein synthesis. This later form of activation has been called *type II endothelial activation* (149,160). Many of its features appear to be mediated by the transcription factor NFκB, which generates many of the responses associated with inflammation, including the secretion of inflammatory cytokines such as IL-1 and IL-8 and the expression of adhesion molecules such as E-selectin and intercellular adhesion molecule (ICAM)-1 *(161)*. In addition, type II endothelial activation causes the loss of thrombomodulin and other prothrombotic changes *(162)*. Thus, the events following type II endothelial activation are associated with the pathologic changes that occur with "accelerated" rejection, including the tendency toward intravascular thrombosis and the inflammatory destruction of donor vessels that occurs in the absence of infiltrating lymphocytes.

Just as there are regulatory processes for complement activation, there are regulatory molecules that counter the tendency toward intravascular coagulation and the process of type II endothelial activation, for example, tissue factor protein inhibitor (expressed by vascular endothelium, which inhibits factor Xa of the clotting cascade) and a number of other protective molecules, including Bcl-x_L, Bcl-2, and A20 (149,163). Although these are often thought of as antiapoptotic molecules, they also tend to inhibit activation mediated by NFκB. Like the regulatory molecules of complement, some of these regulators may not function across species differences, leading to disordered regulation of the coagulation system *(164)*.

Although vigorous early antibody responses generate type II endothelial activation and accelerated rejection, later antibody responses usually fail to do so. The process that enables transplanted organs to survive in the face of circulating antibodies that can bind endothelial antigens has been called *accommodation* (149,165). In xenogeneic combinations, and some allogeneic combinations with preformed blood group antibodies, accommodation has been achieved by the removal of preformed antibodies for a period of 1 to 2 weeks and the allowance of their slow return after this time. Similarly, resistance to type II endothelial activation has been achieved *in vitro* by pretreatment with low levels of antiendothelial antibodies that are insufficient to trigger activation *(166)*. The achievement of accommodation is associated with increased expression of the antiapoptotic genes previously described and with changes in the isotype of the recipient's antibody responses (160,*167*). However, accommodation has not yet been convincingly demonstrated in a pig-to-primate xenograft model.

An important difference between hyperacute and acute humoral rejection is that there is no known therapy to stop graft destruction by hyperacute rejection, whereas acute humoral rejection can sometimes be reversed by plasmapheresis to remove antidonor antibodies and treatment with anti–B-cell reagents *(159,168)*.

Acute Cellular Rejection and Acute Graft-versus-Host Disease

"Acute cellular rejection," which is characterized by a mononuclear cell infiltrate in the graft, is the most common type of organ allograft rejection treated by clinicians. Acute rejection occurs with decreasing frequency after the first 3 months, but rejection by apparently similar mechanisms may occur much later, especially if immunosuppressive medication is withdrawn. Acute rejection is T-cell–dependent, as demonstrated in humans by the efficacy of reagents that specifically block T-cell responses in preventing and treating rejection. Treatment of acute rejection usually includes increased doses of standard immunosuppressive drugs or antilymphocyte antibodies. These strategies are so likely to be successful that the diagnosis of acute rejection is doubtful if they are not.

Whereas 30 years ago the majority of transplant recipients suffered one or more rejection episode, and only about half of the recipients were able to keep their transplanted organ for a full year, the use of newer immunosuppressive drugs and anti–T-cell antibodies has changed these numbers considerably. Currently, as many as 80% of kidney transplant recipients never experience an episode of acute rejection *(169)*, and it is now quite rare to lose a transplanted organ to cell-mediated rejection during the first year after transplantation. However, the use of these highly effective immunosuppressive treatments is associated with significant morbidity.

The study of cell-mediated rejection *in vivo* has used four types of experiments. First, there have been the studies of clinical transplants, which are obviously highly relevant, but which are always performed in the presence of immunosuppression and without the capacity to control and manipulate important variables. Second, there have been studies of skin grafts, heart graft fragments, artificial "sponge" allografts or islet transplants in rodents, which provide large amounts of controlled data on highly immunogenic grafts, but which may not accurately reflect

the processes of rejection for primarily vascularized organs. Third, there have been studies of heart and other types of primarily vascularized organ transplants in rodents, but these types of transplants are more tolerogenic and hence more easily accepted than similar transplants in large animals and humans. Finally, there have been studies of primarily vascularized organ transplants in large animals, such as monkeys or pigs, which have obvious clinical relevance. Unfortunately, these studies are expensive, difficult to perform in large numbers, and are limited by the lack of monitoring and support at the same level that is possible in humans. The conclusions suggested by these different approaches have not always been the same, and thus, the description of the general mechanisms of T-cell–mediated rejection is complicated by the need to identify exceptions and features that occur only in special cases.

Acute GVHD is the counterpart of cellular rejection that involves graft-versus-host alloreactivity in the context of HCT and certain organ transplants in which significant amounts of donor lymphoid tissue are implanted (e.g., liver and small bowel transplantation). Like acute rejection, acute GVHD is T-cell–dependent, as illustrated by its effective prevention by T-cell–depletion of the graft, and by the ability of T-cell–suppressive or depleting agents to prevent and treat acute GVHD. T-cell depletion of the donor graft prevents GVHD, but it is associated with increased rates of graft rejection and relapse of malignant diseases.

Extensive study has suggested a major role for interactions between alloreactive CD4 helper cells producing cytokines of the "Th1" type and alloreactive cytotoxic CD8$^+$ effector cells in mediating rejection (reviewed in ref. *170*) and GVHD. Nevertheless, a number of additional pathways contribute to acute rejection and GVHD, involving both the innate and the adaptive immune systems (reviewed in

ref. 171). There is extraordinary redundancy in the many different pathways that can cause rejection and GVHD, making it impossible to suppress rejection without strong immunosuppression or tolerance induction.

The concepts of "direct" and "indirect" allorecognition previously introduced must be considered at both the sensitization and effector phases of an immune response. As shown in Figure 44.9, there are three major T-cell pathways to consider in relation to graft rejection. These include: (i) direct recognition of donor alloantigens by CD4$^+$ T cells, which generate effector CD4 cells and provide help for the generation of effector CD8 cells; (ii) direct activation of CD8 T cells by donor APC; and (iii) CD4$^+$ T-cell activation by recipient APCs presenting reprocessed donor antigens (the indirect pathway of sensitization). This pathway is important in providing help for immunoglobulin (Ig) production by B cells. *Cross-priming* is a term specifically denoting sensitization of CD8 T cells through the indirect pathway. A role in rejection for cross-primed CD8$^+$ T cells is not included in Figure 44.9 because this pathway has not been shown to play a role in solid organ allograft rejection. However, such a pathway may play a role under certain circumstances, as described later. The multiplicity of T-cell sensitization and effector pathways involved in graft rejection and GVHD is demonstrated by the frequent failure of elimination of either CD4$^+$ or CD8$^+$ T cells from the recipient to prevent graft rejection or GVHD *(172–174)*. As a result of the high precursor frequency of T cells that respond to allogeneic MHC antigens directly, populations of T cells that ordinarily have minimal significance become functionally important.

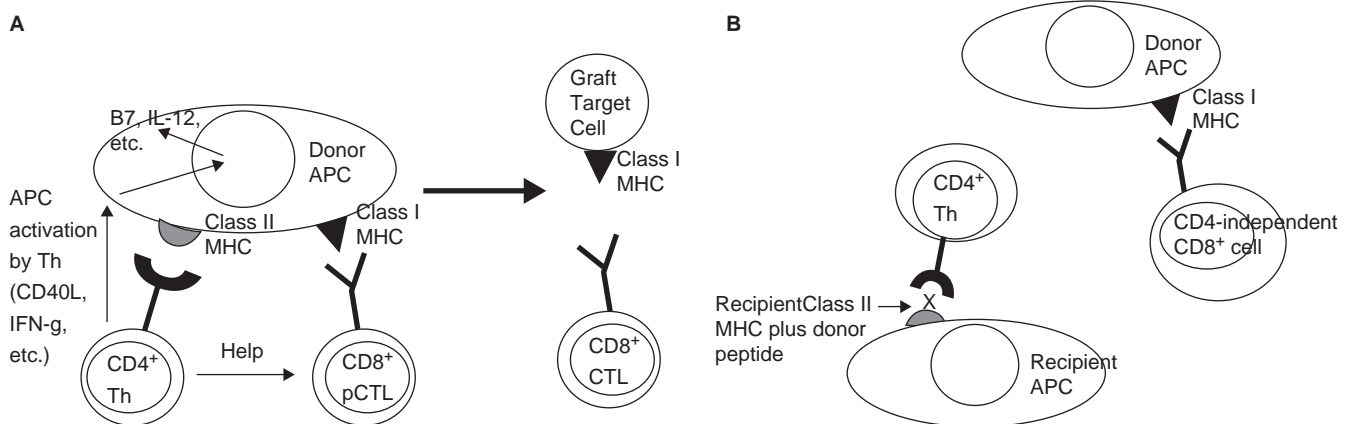
Table 44.5 summarizes the pathways and specificities that have been identified *in vitro* for recognition by helper and cytotoxic CD4 and CD8 T cells. These *in vitro* studies provide a framework from which to understand the role of the various cell populations in allograft rejection.


FIGURE 44.9 Model of T-cell–mediated rejection. **A:** Interactions between CD4$^+$ Th, donor antigen-presenting complex (APC), and CD8$^+$ cytotoxic T lymphocyte (CTL). **B:** Additional pathways of T-cell sensitization that can lead to rejection. MHC, major histocompatibility complex.

Sensitization and Cell Trafficking During Rejection and GVHD

Transplanted tissue contains passenger leukocytes of donor origin that have the characteristics of immature DCs *(175)*. In response to the inflammatory signals that are triggered by retrieval and transplantation, both within the tissue itself as well as in the recipient, the donor-derived passenger leukocytes rapidly leave the graft and migrate to the secondary lymphoid tissues of the recipient (176). Secondary lymphoid tissues comprise the spleen, lymph nodes, and gut or mucosal-associated lymphoid tissue and depending on the location of the graft, the passenger leukocytes will migrate to the tissue that drains the graft site where they encounter naïve T cells. After transplantation, *in situ* within the tissue and during migration, the passenger leukocytes acquire the phenotypic and functional characteristics of mature DCs, expressing high levels of MHC class I and II molecules as well as other cell-surface costimulatory molecules necessary to fully activate naïve CD4[+] and CD8[+] T cells *(177)*. Once in the secondary lymphoid tissues they act as professional APCs, presenting antigens expressed in the transplanted tissue to recipient T cells via the direct pathway of allorecognition.

Naïve T cells recirculate around the body and are constantly moving through the secondary lymphoid tissues sampling the APC, both host- and (after transplantation) donor-derived, for antigen (178). If a naïve T cell with a TCR that can recognize a donor MHC molecule encounters the donor-derived passenger leukocyte in the draining lymphoid tissue as it recirculates, it will stop, interact, and differentiate into an antigen-experienced, effector T cell. In support of the secondary lymphoid tissue being the primary site for sensitization of naïve T cells and initiation of rejection after solid organ transplantation, Lakkis and colleagues (179) showed that cardiac allografts were not rejected in splenectomized aly/aly mice that lack secondary lymphoid tissue as a result of a recessive mutation in the gene encoding Nf-kb–inducing kinase *(180)*, and suggested that in this situation permanent graft acceptance was not due to tolerance but rather immunologic ignorance. Other studies indicating that secondary lymphoid tissues draining the graft are the key site for initiation of the immune response have followed the fate of T cells of a known specificity for donor antigen as they respond *(181)*. It should be noted after transplantation of a primarily vascularized graft, it takes time for the lymphatic drainage to be reestablished; thus in the early posttransplant period, the spleen and the graft itself may be important (176). Similarly, after bone marrow transplantation, the initiation of GVHD takes place in the secondary lymphoid tissue, with evidence for the initial proliferation of donor CD4[+] T cells followed by CD8[+] T cells in secondary lymphoid organs with subsequent homing to the intestines, liver, and skin *(182,*183). Another study had suggested that Peyer's

patches played a critical role in the initiation of GVHD (184). Visualizing the T cells as they respond during the initiation of GVHD showed that while Peyer's patches are involved, they are not the only secondary lymphoid tissue to contribute to the activation of T cells that can home to the gut; mesenteric lymph nodes and spleen are also sites where gut homing T cells were activated (183).

However, in solid-organ transplantation, exclusive initiation of rejection in the secondary lymphoid tissues conflicts with the earlier hypothesis that rejection was initiated within the graft itself by donor endothelial cells lining the vessels of vascularized organ and tissue grafts that could activate T cells directly as they passed through the graft *(185,*186). Since publication of these early articles, there have been a number of studies that support this hypothesis. For example, human endothelial cells have been shown to activate naïve T cells *in vitro (187)* and in the mouse, APCs that are not of hematopoietic origin have been shown to activate CD8[+] T cells *in vitro* and *in vivo (188)*, thus supporting the concept that T cells may be activated in the graft rather than in the secondary lymphoid tissue. Moreover, splenectomized lymphotoxin α and lymphotoxin β knockout mice that also lack secondary lymphoid tissues were found to reject cardiac allografts, albeit at a slower tempo (189). Each of these models is subtly different immunologically, and therefore different components of the immune response to an allograft may be differentially affected by the presence or absence of secondary lymphoid tissue. Clearly in the absence of secondary lymphoid tissue, the initiation of the rejection response by naïve T cells is less aggressive.

Although antigen presentation via the direct pathway plays a dominant role in initiating the response to a transplant, there are a finite number of donor-derived passenger leukocytes transferred within a transplanted organ. Thus, the role of the direct pathway in allograft rejection diminishes with time as eventually only "nonprofessional" APCs such as endothelial cells remain to stimulate direct pathway T cells. Endothelial cells within the graft may assume a greater significance with time after transplantation both for the initiation and as a target for direct pathway effector cells. Activation of naïve T cells may occur predominantly in the secondary lymphoid tissue after transplantation, activation of memory T cells in presensitized recipients is quite different. Unlike naïve T cells, memory T cells can migrate to nonlymphoid tissues in the periphery *(190)* and can trigger rejection through pathways that are independent of secondary lymphoid tissues (191). Thus, in humans where there are likely to be both naïve and memory T cells that can recognize or cross-react with donor MHC molecules, rejection may be initiated both within the secondary lymphoid tissue and within the allograft by naïve and memory T cells, respectively.

At the same time that donor-derived passenger leukocytes are leaving the graft, recipient leukocytes, including

APCs, are attracted to the graft by the inflammatory mediators and chemokines released in the vicinity of the transplanted tissue. As these cells traffic through the graft they phagocytose debris arising from tissue damage at the time of transplantation before migrating to the draining lymphoid tissue. The ingested antigens are processed and presented on recipient MHC molecules to T cells in the recipient lymphoid tissue *(192)*. In addition, soluble antigens released from the graft will also be transported in the blood to the draining lymphoid tissue, where they will be taken up and presented by resident APCs. Common antigenic peptides presented by the indirect pathway are the hypervariable peptide binding regions of MHC molecules (193). Indirect pathway responses undoubtedly contribute to acute rejection, although the tempo of rejection may be slower because of the lower frequency of T cells that can respond. However, unlike direct pathway allorecognition, the indirect pathway is available for antigen presentation for as long as the graft remains *in situ*, and therefore becomes the dominant mode of allorecognition long term.

Traffic of naïve lymphocytes is usually restricted to recirculation between the blood and lymphatic systems. However, once they have been primed in the secondary lymphoid tissues, activated lymphocytes as well as other activated leukocytes must be able to migrate into the graft in order to destroy the transplanted tissue, a process known as *leukocyte recruitment*.

The inflammatory processes at the site of transplantation generate chemotactic cytokines called chemokines, and up-regulation of chemokine receptor expression by activated leukocytes enables them to migrate along the chemoattractant gradient to reach the graft *(194)*.

Inflammatory signals also affect blood vessels in the vicinity of the transplant, causing vasodilation and endothelial activation. Activated endothelial cells rapidly externalize preformed granules called Weibel-Palade bodies that contain the adhesion molecule P-selectin *(195)* and rapidly up-regulate expression of VCAM and CD62E (E-selectin). At the same time, chemokines released from the graft become tethered to the endothelium, and these alterations in endothelial surface markers advertise to passing leukocytes that an inflammatory process is occurring in the neighboring tissue.

Leukocytes are usually conveyed within the fast laminar flow at the center of blood vessels, but once activated leukocytes reach postcapillary venules in proximity to the graft, they are able to leave this rapid flow and move toward the edge of the vessel. This occurs in response to the local chemokine gradient and is assisted by the slower blood flow in the vasodilated blood vessels near the graft. Leukocyte extravasation is a multistep process (see Chapters 13,26). Initially, low affinity interactions develop between endothelial P-selectin and sialyl-Lewis^X moieties that are present on the surface of activated leukocytes. These interactions continually form and break down and the leuko-

cyte "rolls" along the endothelial surface. If chemokines are present on the endothelial surface, conformational changes in leukocyte integrin molecules occur that allow them to bind other endothelial adhesion molecules such as ICAM-1. These higher-affinity interactions cause arrest of the leukocyte on the endothelial surface, allowing it to commence extravasation. Having entered the tissues, the activated leukocytes continue to migrate along chemokine gradients in order to invade the graft.

Antigen Recognition and T-Cell Help in Graft Rejection and GVHD

Role of Direct CD4 Allorecognition

Figure 44.9A depicts a model whereby direct CD4 T-cell sensitization by donor class II MHC antigens may both generate CD4$^+$ effector cells and provide help for the activation, differentiation, and proliferation of cytotoxic CD8$^+$ cells. These recipient CD8$^+$ cells directly recognize donor class I MHC antigens. In the classical Th1 CD4/CD8 pathway of rejection, CD4 cells provide help for the differentiation of cytotoxic CD8 effector cells that destroy the graft. Priming of naïve, directly alloreactive T cells requires professional APC that leave the graft and enter the recipient's lymphoid tissues. The CD4 help for CD8 cells consists of both cytokine (e.g., IL-2) production and "conditioning" of the APC, for example, by production of interferon (IFN)-γ and by interactions of CD40 on the APC with CD40L on the activated CD4 cell. These interactions induce APC expression of CD80, CD86, and other costimulatory molecules, cytokines such as IL-12, and MHC, making it more effective at activating both CD4 and CD8 cells. Virus-specific CD8 cells primed to antigen in the absence of CD4 help are defective in the ability to clear viral infections and lack full effector function *(196)*, and "helpless" CD8 cells seem to die via a TRAIL-mediated pathway on secondary antigen encounter *(197)*. IL-2 during the priming phase can be critical for the ability of CD8 memory cells to expand on later encounter with the antigen *(198)*. A third pathway of CD4 help may involve direct interactions with CD40 induced on the surface of activated CD8 cells *(199)*.

Studies involving very limited (not clinically relevant) antigenic disparities between donors and recipients suggested that a "three-cell cluster" model involving interactions between helper T cells, effector T cells, and APCs was essential for rejection (200,*201–203*). For example, tail skin grafts from class I mutant mice (bm7) placed on B6 recipients are not rejected, apparently because of a lack of helper stimulation. On the other hand, grafts from (bm12 × bm7)F1 mice, which express an additional class II antigen disparity, are rejected. A bm12 graft on one side of a B6 mouse, although itself rejected, does not induce the rejection of a bm7 graft on the other side of the same animal, whereas a (bm12 × bm7)F1 graft on one side of a recipient does induce rejection of a bm7 graft on the other

side. These results suggest that the CD4 help elicited during rejection of a bm12 graft cannot function elsewhere in the body to assist potential effector cells specific for the bm7 graft. On the other hand, when both the bm12 and bm7 antigens are expressed on the same graft, and therefore on the same APCs, effector cells are generated that can function elsewhere in the body. However, these observations may not be applicable to more clinically relevant histoincompatibilities, and other experimental evidence *(204,205)* suggests that CD4 helper cells sensitized by antigen presented on recipient APCs can provide help for CD8$^+$ effector cells recognizing antigen presented by donor APCs. One possible explanation for such results is that a three-cell cluster is still essential for CD4 cells to provide help to CD8 cells mediating rejection, and that, for example, donor class I MHC/peptide complexes might be transferred and picked up by recipient MHC so recipient directly alloreactive CD8 T cells encounter their ligands on the same recipient APC that an indirectly alloreactive CD4 cell recognizes. Transfer of class I/peptide antigens from dead cells, leading to such "cross-dressing" of APC, has recently been described (206).

Depletion of donor APCs can markedly prolong graft survival *(207–211)*, illustrating the importance of direct allorecognition in inducing rejection. Direct allorecognition by recipient CD4 T cells is necessary to induce cardiac allograft rejection in mice (212).

CD4$^+$ T cells alone can cause rejection of many types of grafts in the absence of CD8 cells, indicating that CD4 T cells can mediate effector functions in addition to functioning as helper cells. Directly alloreactive CD4 cells alone can reject grafts with full MHC disparities (212,*213*), class II antigen disparities alone, and multiple minor antigen disparities alone (*173,*214,*215*). In BMT recipients, they can induce GVHD in the absence of CD8 cells in the setting of class II, full MHC, or multiple minor histoincompatibilities (*216,217,*218,*219*). CD4$^+$ cells have been shown to reject class II and minor antigen-mismatched bone marrow grafts (220,*221*).

Role of Indirect CD4 Cell-Mediated Allorecognition

There is considerable evidence for a role for the indirect pathway of CD4 cell-mediated allorecognition in skin and solid-organ graft rejection (*222–226,*227,*228–229*). One major role of the indirect pathway is to induce class-switched alloantibody responses *(230)* through cognate interactions between recipient class II-restricted indirectly alloreactive CD4 cells and host B cells that recognize donor MHC molecules through their Ig receptors, process them, and present donor MHC peptides with their class II molecules. CD4 cells contribute to rejection of bone marrow grafts differing only at class I MHC loci, suggesting a role for indirect allorecognition (220,*221*).

Rejection by CD4 cells of skin grafts lacking class II antigen expression shows that the indirect pathway of rejection can be powerful *(204,222)*. Rejection of islet xenografts from highly disparate species in mice is very dependent on CD4$^+$ T cells, even though CD4$^+$ direct activation measured *in vitro* is very weak *(231)*, suggesting a dominant role for the indirect pathway in this setting. Clinically, sensitization of indirect CD4 responses to donor MHC-derived peptides has been demonstrated in patients undergoing graft rejection, and some studies have suggested that an increase in the precursor frequency of T cells responding through the indirect pathway provides the best correlation with clinical events *(232–239)*. A major role for indirect allorecognition has been suggested in the setting of chronic rejection (193,240,*241*), in part because this pathway is critical for the induction of antibody responses, which have been implicated in the pathogenesis of chronic rejection (*242,243,*244,245,*246–248*). Moreover, the eventual replacement of donor APC by recipient APC suggests that the latter may be responsible for fueling the immune response on a long-term basis. Experimental *(210,249)* and clinical *(238,246)* evidence has supported this hypothesis. Indeed, direct alloresponses tend to subside over time in patients with heart or kidney allografts (250,*251,252*).

In view of the apparent importance of the indirect pathway of allorecognition in graft rejection, it is not obvious why donor APC depletion or the lack of donor class II MHC expression should be effective in preventing rejection in some situations (*207–211,*212). An essential role for indirect allorecognition has been difficult to demonstrate in acute rejection, and this pathway alone may simply be too weak to induce it. CD4$^+$ cells alone are incapable of rejecting some skin grafts with minimal class I or minor histoincompatibilities (200,*253,254*) or of inducing GVHD when class I and minor histocompatibility barriers alone are present *(216,217)*. In the case of renal and cardiac allografts, donor APC depletion may allow the inherent tolerogenicity of the parenchymal tissue to prevail and spread to the indirect pathway. Initial sensitization through the direct pathway may be essential in producing the inflammatory conditions necessary to promote indirect pathway sensitization, so that the latter does not occur or is tolerogenic in the absence of the former. An alternative explanation might be that donor APCs are essential for the sensitization of the effector cells responsible for graft rejection, while indirect presentation is important for the sensitization of helper cells. In the absence of donor APCs, potential effector cells might become anergic as a result of encountering donor antigens directly only on parenchymal cells of a graft.

Role of Helper-Independent CD8$^+$ T Cells

CD8 T cells can readily reject allografts in the absence of CD4 cells, suggesting that CD4 help is not critical in the presence of the high frequency of alloreactive CD8 cells existing in the naïve repertoire. Indeed, CD8$^+$ T cells alone can reject skin and bone marrow grafts with isolated MHC

class I antigen disparity (*172*,200,220,*221*,*255*,*256*) and alloreactive CD8 T-cell memory can be generated and maintained in the absence of CD4 cells *(181)*.

CD8 cells can induce GVHD without CD4 T cells in the setting of full MHC, class I only, and minor antigen histoincompatibility *(257,258)*. Direct recognition of recipient minor histocompatibility antigens on recipient APCs has shown to be essential for the induction of CD8-dependent, CD4-independent GVHD in an MHC-identical, lethally irradiated mouse model *(259)*, but indirect CD8 recognition of recipient antigens presented by donor APC amplifies the process *(260)*.

Grafts expressing only class I antigen disparities are usually rejected more slowly than class II disparate grafts, and responses dependent on CD8[+] helper responses are more easily suppressed by cyclosporine *(261–263)*. Many primarily vascularized grafts that express only a class I antigen disparity still require CD4[+] cells to initiate rejection, probably because of the defects in function, survival, and secondary expansion described previously for "helpless" CD8 cells. Probably as a result of these limitations, CD4-independent rejection by CD8[+] cells is influenced by several factors that do not seem to be as important for CD4[+] T cells. First, CD8[+] direct activation is very dependent on the number of donor APCs in a graft *(172,222)*. Second, CD8[+] direct activation fails to initiate rejection of grafts with only a small number of minor antigen disparities and provides only a weak helper response even when there are a large number of foreign minor antigens. CD8[+] helper cells also differ from CD4[+] helper cells in being unable to provide help for other cell populations (264). Apparently the IL-2 produced by these cells is used by the cells themselves as they develop effector function. CD8[+] helper cells cannot provide help for CD8[+] cells with a different specificity and cannot provide help for B-cell antibody responses.

Although Table 44.5 includes CD8[+] CTL with specificity for class II antigens because these have been detected *in vitro*, CD8[+] cells alone cannot reject skin grafts with only limited class II antigen disparities (200,218,*253*,*265*).

Cross-Primed CD8 Cells

Peptides of exogenous antigens were originally thought to be presented by MHC class II antigens while those of endogenous antigens are presented by MHC class I molecules (*266,267*). However, it has more recently become clear that class I presentation of exogenous peptides is essential for many immune responses *(169,268–270)*, and several pathways have now been delineated for the processing and presentation of exogenous antigens by class I molecules (271). The phenomenon, termed *cross-priming*, was originally demonstrated in a transplantation model by Bevan *(66)*, who showed that when minor antigen-disparate grafts with MHC antigens of type A were placed on MHC (AxB) F1 recipients, the CD8[+] cells of these recip-

ients became sensitized to the minor antigens presented by both A and B types of class I MHC molecules. Activation of cross-primed CD8 cells has been shown to be strongly dependent on CD4 help and IL-2 *(272)*. Cross-primed CD8 cells seem most likely to play a significant role in rejection because of donor minor histocompatibility antigens and MHC-derived peptides when there is sharing of class I alleles between the donor and recipient. In the absence of class I MHC sharing between donor and recipient (273), the self-class I/allogeneic peptide epitope cannot be presented by the parenchymal or endothelial cells of the graft. However, even without class I sharing, indirect CD8[+] cell sensitization can lead to the rejection of skin allografts, perhaps because of recognition of donor peptides presented by recipient endothelial cells on host-derived vessels that revascularize the graft (274,275). Cross-primed CD8 cells might also contribute to graft rejection via indirect effector mechanisms on antigen recognition on host APC in the graft or by producing cytokines that contribute to the overall regulation of the immune response *(275,276)*. Thus, the question of how CD8[+] indirect sensitization might affect graft rejection remains one of the open issues in transplantation immunology.

Effector Mechanisms of Acute Rejection and GVHD

Although CD4[+] and CD8[+] cytotoxic T cells are important effectors of graft rejection and GVHD and can account for the precise selectivity of graft destruction that is sometimes observed, the role of additional tissue-destructive mechanisms, and particularly of "indirect" effector mechanisms initiated by T cells specific for modified self-MHC antigens, is being increasingly appreciated. Some of these mechanisms involve effector cells of the innate immune system and cytokines as final mediators of tissue destruction. The net result of this multiplicity of pathways is that there is considerable redundancy between the mechanisms of graft rejection. A brief review of the available data on these issues ensues.

Cytotoxic Mechanisms of Acute Cellular Graft Rejection and GVHD

Solid-organ graft rejection can be correlated with the presence in the graft of proteins and mRNA encoding perforin, granzymes, and proteases associated with cell-mediated cytotoxicity *(277–284)*. The presence in urine of cell-derived RNA encoding perforin and granzyme B has been associated with renal allograft rejection in humans (285). A functional analysis of the role of various cytotoxic pathways in graft rejection and GVHD has been facilitated by the use of mice deficient in one or more effector proteins involved in CTL activity, particularly perforin, granzyme, and Fas/Fas ligand *(286,287)*. Although the perforin/granzyme pathway is the major cytolytic pathway for CD8 T cells and CD4 cells tend to use the Fas/FasL

pathway (288), both subsets are capable of both types of cytolytic activity (*289*,290), and the perforin pathway is available to both T-cell subsets mediating GVHD *(286)*. All of these cytotoxic proteins play contributory roles and no single protein has been found to be critical for the induction of solid-organ graft rejection *(287,291–293)*, GVHD *(294–297)*, or bone marrow graft rejection *(298)* in the presence of clinically relevant mismatches. Critical cytotoxic interactions have been identified in a few special situations. For example, GVHD directed at isolated class II MHC disparities is markedly reduced in the absence of Fas/FasL interactions *(297)*, and the survival of K^b mutant class I-only mismatched heart allografts is markedly prolonged in perforin-deficient recipients *(287)*. Fas ligand may be critical role for induction of lymphoid hypoplasia (299) and skin and liver GVHD (299). Although the perforin-granzyme pathway contributes to GVHD (*297*,299), the Fas-mediated cytotoxic pathway appears to be of greater overall importance in causing GVHD. In contrast, the perforin/granzyme pathway and TRAIL pathways may play a predominant role in antileukemic effects, especially of CD8 cells, and selective blockade of the Fas/FasL pathway may ameliorate CD8-mediated GVHD without eliminating GVL effects *(296,300–303)*.

Evidence for a Role for Non-CTL Mechanisms in Graft Rejection and GVHD

Strong evidence supports the ability of T cells to effect rejection of grafts whose parenchymal cells do not express the ligand of the TCR, that is, the existence of indirect effector mechanisms. When syngeneic skin from bone marrow chimeras in which the APCs of the skin had been replaced by cells derived from an allogeneic donor bone marrow was transplanted, the entire graft was rejected (304). Thus, entire skin grafts can be rejected when only the APCs are foreign, indicating that nonselective destruction of grafted tissue can occur, especially if the inflammatory response is sufficiently vigorous. Several studies have clearly shown a role for indirect CD4 cell-mediated rejection of skin *(305,306)* and cardiac (307) allografts lacking the determinant recognized by the CD4 T-cell population. In the case of cardiac allografts, replacement of graft endothelium by the host was shown to be a key element in the induction of acute and chronic rejection through this indirect effector mechanism (307). Moreover, GVHD, mediated in part by cytokines but associated with significant liver and intestinal injury, can be induced by donor T cells in MHC-deficient hosts receiving wild type host DCs, suggesting that indirect effector mechanisms may mediate GVHD *(308,309)*. However, the capacity of CD4 T cells to mediate GVHD across minor histocompatibility barriers is markedly attenuated when the target antigens are expressed only on hematopoietic cells (310). Together, these results suggest that indirect effector mechanisms can destroy transplanted tissue (or recipient tissue, in the case of

HCT) under some circumstances, but less efficiently than direct mechanisms.

The lack of correlation between rejection and the ability to detect CTL *in vitro* in some situations also suggests the existence of noncytotoxic rejection mechanisms. CD4 effector cells can reject class I-only disparate grafts in recipients depleted of CD8 T cells (200,218,*253,265, 311,312*,313), even though *in vitro* assays have generally failed to reveal cytotoxic CD4 cells specific for class I alloantigens. Some studies suggest that mice depleted of CD8 T cells by antibody treatment still have a population of cytotoxic precursors (apparently of the CD8 lineage despite the absence of the CD8 antigen) *(314,315)*, and others suggest that there is an effector mechanism mediated by CD4 cells specific for class I peptides presented by class II molecules *(316)*. These results do not distinguish a direct from an indirect effector mechanism because the donor and recipient class II molecules were identical in these experiments, but they do suggest that noncytotoxic cells may be effectors of rejection, as $CD4^+$ cytotoxic T cells were not detectable.

Because CTL activity to minor histocompatibility antigens can only be measured *in vitro* after *in vivo* priming, minor disparate graft rejection provides an opportunity to test whether every case of rejection is associated with the development of CTL activity. Skin grafts that differ by only the H-Y antigens are rejected by some, but not other strains of mice, and rejection does not correlate with the generation of *in vitro* cytotoxicity. In some cases, CTLs are detectable *in vitro* despite the absence of graft rejection, and vice versa *(317–319)*, again suggesting the existence of noncytotoxic mechanisms.

Graft-Infiltrating Cells

Many types of cells infiltrate rejecting grafts, including CD4 and CD8 T cells, NK cells, and macrophages (313,*320,321,322,323.324–327*). There are, however, relatively few B cells *(328)*. Repertoire analysis of allotransplantation revealed marked polyclonality (*21*,329), and propagation of graft-infiltrating cells reveals polyclonal cytotoxic and IL-2–producing lymphocytes of both CD4 and CD8 lineages *(330,331)*. Many T cells seem to be recruited nonspecifically into rejecting grafts, as only a fraction of them recognize donor antigens, but only the donor-reactive CTL show evidence of having been activated *in vivo*, as indicated by their ability to respond to donor antigens without further antigen-specific stimulation *(332)*. Early reports suggesting that an oligoclonal T-cell response occurs during allograft rejection *(333)* might have been subject to *in vitro* culturing artefacts and sampling error *(328)*. A polyclonal TCR repertoire was detected in rejecting rodent heart allografts, whereas evidence of oligoclonal dominance was detected in heart grafts of animals that were rendered tolerant to their grafts *(334)*. However, graft-infiltrating

T cells of long-term rejected human kidneys *(335)* and of acutely rejecting rat heart allografts *(336)* have been reported to show skewed CDR3 length distributions within some Vβ families, suggesting some degree of oligoclonal dominance. T cells infiltrating xenografts did not show such skewing, suggesting an even broader use of the TCR repertoire in xenograft rejection *(336–338)*. Analyses of T cells mediating GVHD in the setting of multiple minor histoincompatibilities have revealed a markedly skewed repertoire, but still with the involvement of several different Vβ families, each exhibiting an oligoclonal response *(339,340)*. Clinical studies suggest that the antiminor histocompatibility antigen TCR repertoire is most often polyclonal (341).

The number of invading T cells in a graft is not necessarily correlated with the speed of rejection. Whole MHC and class II disparate grafts generally elicit dense cellular infiltrates, while class I-disparate grafts are generally sparsely infiltrated, and only to a similar extent as syngeneic grafts *(328)*. The number of cells within minor antigen disparate grafts is generally far greater than the number invading grafts with class I-only differences, even when the rejection of the class I grafts is faster *(328)*.This finding has suggested that certain critical elements of the graft, such as its blood vessels, are the actual site of graft destruction and, indeed, endothelialitis is an important hallmark of clinically significant rejection activity (342).

Role of Natural Killer Cells

Although the role of NK cells in mediating hybrid resistance and allogeneic marrow rejection is well established in mice, the amount of resistance mediated by NK cells to allogeneic pluripotent hematopoietic stem cells (PHSC) is limited, and can be readily overcome by increasing the dose of donor stem cells administered *(343,344)*. Furthermore, a role for NK cells in resisting human allogeneic marrow engraftment has not been clearly demonstrated. However, their role may become more significant if mismatched transplants are attempted with less toxic, nonmyeloablative regimens instead of more traditional myeloablative conditioning. Consistent with this possibility, patients with severe combined (T and B cell) immunodeficiency (SCID) who have functional NK cells require cytotoxic conditioning to permit engraftment of haploidentical marrow. In contrast, those lacking NK cells have a low incidence of rejection in the absence of any such treatment *(345)*.

A strategy for exploiting the ability of NK cells to be triggered by "missing self" has recently been reported in patients receiving HLA-mismatched related donor HCT and in mice (346). Donor-derived NK cells with graft-versus-host reactivity due to the lack of donor class I MHC inhibitory ligands in the recipient can apparently kill residual host leukemia cells and alloreactive cells that resist the marrow graft without causing GVHD. The alloreactive donor NK cells may actually reduce susceptibility to GVHD by killing recipient APCs needed to activate donor T cells (346). Although striking antileukemia effects of such killer cell immunoglobulin-like receptor (KIR) mismatching were detected in heavily conditioned patients receiving high doses of haploidentical CD34 stem cells (346), the effect of KIR incompatibility has been more variable in other clinical studies *(347–349)*.

The possible role of NK cells in rejecting solid-organ grafts is somewhat controversial. NK cells are prominent among cells infiltrating rejecting organ allografts, and may be the earliest producers of inflammatory cytokines and chemokines and inducers of DC maturation *(350,351,352,353)*. If NK cells make an important contribution to solid-organ allograft rejection under normal circumstances they must be dependent on T cells, as mice lacking T cells are unable to reject nonhematopoietic allografts. Furthermore, whereas bone marrow allografts from class I-deficient donors (β2m$^{-/-}$) are subject to potent NK-mediated rejection (because these cells cannot trigger inhibitory receptors on host NK cells *[354]*), β2m$^{-/-}$ skin grafts are not rejected by β2m$^+$ recipients *(355)*. However, NK cells have recently been reported to play a critical role in cardiac allograft rejection in CD28 knockout mice *(356,357)*. Interactions between NK cells and T cells have also been implicated in chronic allograft vasculopathy in a murine cardiac allograft model (352).

Inhibitory receptors on NK cells are quite broad in their class I specificity (358), and recognition of even fully allogeneic class I molecules can confer some protection from NK-mediated marrow destruction compared with that observed for cells deficient in class I expression *(354–357,358,359)*. Because of the increased disparity of xenogeneic compared with allogeneic MHC molecules, NK cells may receive fewer inhibitory signals from xenogeneic than allogeneic cells. Indeed, transduction of human HLA molecules into porcine endothelial cells has proven to be an effective means of reducing NK cell-mediated xenogeneic cell adhesion and cytotoxicity *(360,361,362)*. However, some inhibitory receptors, such as killer cell lectin-like receptor G1 (KLRG1), do recognize xenogeneic ligands such as E-cadherin *(363)*. In addition to failing to receive inhibitory signals from xenogeneic MHC molecules, NK cells may also be activated by interactions of activating receptors with ligands on xenogeneic cells *(364–366)*. Examples include the effective activation achieved by interactions of human NKG2D and NKp44 with their ligands on porcine endothelial cells *(366)*. There is some evidence that activating human NK cell receptors may bind to carbohydrate epitopes expressed by pigs and not humans *(367)*.

On balance, many xenogeneic NK cell-target interactions appear to show a predominance of functional activating interactions over inhibitory ones, resulting in high levels of reactivity. Indeed, NK cells resist xenogeneic marrow engraftment to a greater extent than allogeneic marrow *(343,368,369,370)*. NK cells have also been implicated

in the acute vascular rejection (371) that can destroy solid-organ xenografts that have escaped hyperacute rejection (see later discussion) and in xenogeneic skin graft rejection (372). Because one mechanism by which NK cells mediate cytolysis is antibody-dependent cell-mediated cytotoxicity, it is possible that IgG natural antibodies play a significant role in initiating NK cell-mediated rejection. NK cells also release cytokines, such as IFN-γ and tumor necrosis factor-α (TNF-α), which activate macrophages and endothelial cells and induce inflammation (371).

Role of NKT Cells

A subset of murine and human T cells expresses NK cell-associated phenotypic surface markers. Many of these recognize glycolipid antigens presented by CD-1 nonclassical class I molecules, and major subsets express an "invariant" TCR α chain and restricted β chains *(373)*. They produce a variety of cytokines, the most prominent of which are IFN-γ and IL-4 *(374)*, have cytolytic activity, and may provide an important link between innate and adaptive immunity *(375,376)*. Most NKT cells are either CD4$^+$CD8$^-$ or CD4$^-$CD8$^-$. Although these cells have apparent inhibitory effects on graft rejection (377,*378–380*), GVHD (381,*382*), and other immune responses, NKT cells also promote antimicrobial and antitumor immunity and have been reported to participate in islet allograft *(383)* and isograft (384) rejection in mice.

Role of Monocytes/Macrophages and Eosinophils as Effectors of Rejection

Classical delayed-type hypersensitivity responses are thought to depend on the activation of macrophages by helper T cells through production of IFN-γ. It is likely that proinflammatory cytokines and chemokines produced by activated monocytes and macrophages play a role in endothelial cell activation and lymphocyte recruitment. Additionally, activated macrophages may damage tissue through the production of toxic molecules such as nitric oxide (385).

Macrophages play an especially important role in the rejection of cellular xenografts such as islets *(386,387)*, whose rejection they can effect after activation in the presence of T cells *(388)*. Macrophages cause almost immediate rejection of xenogeneic bone marrow, even in the absence of adaptive immunity *(389–391)*. Human macrophages can phagocytose porcine cells in an antibody- and complement-independent manner (392). Additional studies have implicated macrophages in solid-organ and skin xenograft rejection *(393–398)*. These powerful effects of xenogeneic macrophages may be accounted for by the combined ability of certain xenogeneic receptors to activate macrophages *(399)* while important inhibitory interactions, such as that between CD47 and its macrophage ligand SIRPα, are not effective (400).

Eosinophils recruited to allografts by Th2 T-cell responses have been reported to be effectors of graft rejection in some experimental models, and eosinophils are often found clinically in rejecting allografts (reviewed in ref. 171). Th2-derived IL-4 and IL-5 recruit and activate eosinophils, which release highly cytotoxic substances from granules into the tissue. Th2-mediated rejection is apparently down-modulated by alloreactive CD8 CTL, which kill donor DCs in the T-cell areas of lymph nodes, thereby limiting direct alloantigen presentation to CD4 cells *(401)*. These results emphasize the fact that Th2 responses are not necessarily benign and conducive to graft acceptance.

Cytokines as Mediators of Graft Rejection and GVHD

Cytokines have complex roles as both regulators and effectors of immune reactivity, and studies of their role in transplantation have consequently yielded many paradoxical findings. Many studies have correlated the onset of graft rejection with the presence of cytokines or mRNA encoding them in the graft and, with renal transplantation, in the urine (285). Although the "classical" rejection pathway involves the Th1 cytokines IFN-γ and IL-2 and cytotoxic T cells, a great redundancy of rejection pathways is suggested by studies detecting both Th1 (IL-2, IFN-γ) and Th2 (IL-4, IL-5, IL-10) cytokines in rejecting allografts *(283,402–409)*. Although the concept that Th2 cytokines are anti-inflammatory and may suppress rejection and GVHD has attracted considerable interest (*410–413*,414–417,*418*), Th2 responses have been clearly shown to contribute to both graft rejection *(410,419–421)* and GVHD *(422–425)*. With a few special exceptions *(426–428)*, studies using various cytokine knockout mice as recipients have failed to reveal any single molecule that is essential for rejection (*429–434*,435) or GVHD (*422*,436,437). In a model involving adoptive transfer of T cells to immunodeficient mice, allogeneic heart allografts required IFN-γ receptor expression in order to be rejected by CD4$^+$ cells, and additional data suggested that IFN-γ may itself be a critical effector molecule of graft destruction in this system (438).

In GVHD, cytokines such as TNF-α and IFN-γ play a role in the inflammatory cascade involving macrophage activation by lipopolysaccharide from the damaged gut epithelium and by IFN-γ to release TNF-α, nitric oxide, and other mediators of tissue injury (385,*439–442*). In certain models, TNF-α had been shown to play a critical role in wasting disease and intestinal GVHD *(443,444)*. Although the relative contribution of cytokine-dependent mechanisms versus direct cell-mediated cytotoxicity to GVHD is still a matter of debate, the capacity to induce GVHD with T cells lacking both the perforin-mediated and the Fas-mediated pathways of cytotoxicity, even in mice also lacking TNF receptor1 (TNFR1)-mediated signaling pathways *(297,445,446)*, demonstrates the redundancy of GVHD effector mechanisms.

The generation of a newly discovered class of cytokine-producing CD4 T cell, the "Th-17" cell, is antagonized by Th-1 cells and promoted by IL-23, transforming growth factor (TGF)-β, and IL-6. Th-17 cells produce IL-17, a proinflammatory cytokine that has been implicated in various models of immune injury, including allergic, autoimmune, and infectious diseases (447). A role for Th-17 has been suggested in animal models of heart and aortic allograft rejection and in clinical lung transplantation (447). A more complete understanding of the role of Th-17 in transplantation is likely to emerge in the near future.

Chronic Rejection and Chronic GVHD

Most experimental studies of rejection are performed without immunosuppression and, therefore, graft destruction usually occurs within the first several days or weeks by one of the mechanisms previously described. In clinical practice, however, the use of immunosuppression usually allows graft survival for much longer periods of time. Nonetheless, clinical survival statistics reveal that even when 1-year graft survival has been achieved, the loss of transplanted organs continues to occur at a rate of about 3% to 5% per year and a significant proportion of this delayed or late graft failure appears to be due to immunologic mechanisms.

The term *chronic rejection* has been used to describe this later process of delayed graft destruction. As immunosuppressive reagents have become more effective at controlling acute rejection, chronic rejection has emerged as one of the most important problems in clinical practice. There has been ongoing improvement during the past 30 years in the 1-year graft survival rates for kidney transplants, but the half-life for organs that have survived for 1 year has not changed significantly during that entire period of time and, as a result of this ongoing loss, only about 50% of transplants are still functioning 10 years later.

Although almost every type of organ transplant suffers from chronic rejection, the pathologic manifestations are different in each case. Kidney biopsies tend to show interstitial fibrosis along with arterial narrowing from hyalinization of the vessels. In the heart, the process is manifested principally as a diffuse myointimal hyperplasia proceeding to fibrosis of the coronary arteries that has often been referred to as *accelerated atherosclerosis* or *transplant arteriosclerosis*. Chronic rejection in lung transplants primarily affects the bronchioles with progressive narrowing of these structures, and is referred to as *bronchiolitis obliterans*. The liver may be the one type of organ transplant that is relatively resistant to chronic rejection, but the progressive destruction of bile ducts referred to as the *vanishing bile duct syndrome* may be another manifestation of this process.

Some of the causes of chronic graft destruction may not be immunologic in origin *(448,449)*. Analysis of sequen-

tial kidney transplant biopsies suggests that chronic rejection represents cumulative and incremental damage to the graft from time-dependent nonimmunologic and immunologic causes (450). Potential nonimmunologic factors that have been considered to contribute to the development of chronic rejection include the initial ischemic insult, the reduced mass of transplanted tissue (especially in the case of kidney transplants leading to hyperfiltration injury), the denervation of the transplanted organ, the hyperlipidemia and hypertension associated with immunosuppressive drugs, the immunosuppressive drugs themselves, and chronic viral injury, among others. Nonetheless, although these factors undoubtedly contribute to the process, there is a marked difference in survival between syngeneic and allogeneic transplants in experimental models. Thus, there is almost certainly an important immunologic component in most cases of chronic rejection.

Several important observations regarding the pathogenesis of chronic rejection have emerged from clinical practice, particularly the analysis of biopsy samples. In kidney transplants, two distinctive phases of injury as chronic allograft nephropathy evolved have been described (450). Previous studies have suggested that there is a high correlation between the onset of chronic rejection and a history of early acute and subclinical rejection episodes *(451,452)*. Analysis of protocol biopsies has revealed that the onset of mild chronic rejection by 1 year after kidney transplantation is associated with an initial phase of early tubulointerstitial damage from ischemic injury that occurs before severe rejection is detected. Beyond 1 year, a later phase of chronic allograft nephropathy was characterized by microvascular and glomerular injury (450). Importantly for long-term outcomes, the clinical data show that the process of chronic rejection is usually refractory to increases in immunosuppressive therapy, in contrast to acute rejection episodes that almost always respond to treatment. The development of chronic rejection has also frequently been associated with the presence of antidonor antibodies *(453,454)* and the deposition of complement component C4d in the allograft.

Taken together, these clinical observations have suggested to some that chronic rejection is the result of chronic B-cell alloantibody production, while others believe that chronic rejection requires the early sensitization of the immune system to donor antigens. Moreover, there are also now data emerging to suggest that components of the innate immune system such as NK cells can also contribute *(455)*. Alloantibody production might equally well be a marker for other rejection mechanisms as opposed to a cause of chronic rejection. Moreover, the presence of alloantibody and C4d may be transient and there are clear examples of chronic changes in the graft in their absence *(456)*. In addition, early rejection episodes probably reflect primarily the degree of antidonor immunoreactivity, and may not be required for chronic rejection

themselves. Therefore, even if sufficient immunosuppression were given to prevent acute rejection, chronic rejection might still occur when the suppression was reduced to levels tolerable to the recipient over the long term, even if acute rejection had never occurred. Finally, experimental studies have suggested that the mechanisms of chronic rejection are not absolutely dependent on either antibody formation or on the occurrence of acute rejection episodes.

The uncertainties that arise from the interpretation of the clinical data make it important to develop experimental models for studying the mechanisms of chronic rejection. It is difficult in the laboratory, however, to mimic a process that may take 5 or 10 years to develop in patients treated with immunosuppressive drugs. Thus, the effort to study chronic rejection experimentally has depended on surrogate short-term pathologic markers that are thought to predict the long-term changes of chronic rejection. In particular, these studies have concentrated on the development of the myointimal proliferation that is thought to be the precursor of the chronic vascular changes typically observed in patients. In rodents, pigs, and primates this has often been done with grafts after an initial period of immunosuppression that prevents acute rejection *(457–459)*. All of these experimental studies are subject to the caveat that the surrogate pathologic lesion occurs much earlier than the typical changes of chronic rejection in patients. Thus, the process being studied experimentally may not be the same as the clinical process.

Pathologic Manifestations of Experimental Chronic Rejection

The typical pathologic features of the experimental lesion associated with chronic rejection are shown in Figure 44.10 *(460)*. The marked narrowing of the vascular
FIGURE 44.10 Histology of chronic rejection.

lumen is caused by the substantial proliferation of endothelial and then smooth muscle cells that can be host-derived *(461)*. Associated with this proliferation is progressive destruction of the media. In time, the cellular proliferation becomes less pronounced and is replaced by concentric fibrosis that narrows the vascular lumen. Immunohistologic staining indicates that there is increased expression of several adhesion molecules *(460)*, intracellular proteins such as vimentin *(462,463)*, and easily detectable levels of several molecules, including nitric oxide synthase *(464)*, acidic fibroblast growth factor, insulinlike growth factor, IFN-γ *(465)*, and endothelin, each *(466)* of which may play a role. Ultimately, the ischemia resulting from vascular occlusion results in fibrosis in the parenchyma of the organ, and consequent organ dysfunction (467). In the case of the lung or the liver, chronic injury may cause changes most prominently in the bronchioles or the bile ducts, but this is also associated with arterial lumen loss, which may be the primary lesion causing bronchiolitis obliterans or bile duct fibrosis, respectively (467).

Immunologic Mechanisms of Chronic Rejection

Rejection requires a dialogue between the innate and adaptive immune system. Innate immunity is most likely involved at the outset of the process that leads to the development of chronic rejection and there is evidence to suggest that NK cells *(455,468)* and complement activation can be involved (469). At the level of the adaptive response, because it is assumed that stimulation of direct pathway T cells is likely to diminish over time as donor APCs are replaced by recipient APC (see previous discussion), it is commonly assumed that the predominant immune response that causes chronic rejection occurs through the indirect pathway.

Studies in pigs have suggested that the vascular changes of chronic rejection are more apt to develop when there are class I antigenic disparities than when there are only class II disparities and have suggested that the development of the lesion depend especially on CD8 T cells. In mouse models, in contrast, there is evidence that either CD4 or CD8 T cells can produce the lesion and that either class I or class II antigenic disparities are sufficient to stimulate chronic rejection *(470)*. The finding that class II antigenic disparities are themselves sufficient to induce this pathology is consistent with the observation of class II MHC expression on the vascular endothelium and medial smooth muscle cells of mouse cardiac allografts with these vascular lesions *(471)*. Because class II MHC is not constitutively expressed by mouse vascular endothelial cells, indirect recognition of donor class II transferred from passenger leukocytes may be responsible for inducing an inflammatory response that leads to subsequent up-regulation of class II on the donor vascular endothelium. In keeping with the prediction

of many clinical studies, adoptive transfer experiments into SCID mice have shown that alloantibodies in the absence of T cells can induce the typical pathologic vascular changes, and lesions can develop in T-cell–deficient mice (245). However, T cells without B cells have also been shown to cause the lesion, although there may be somewhat less tendency to progress to end-stage fibrosis (244).

Several studies have indicated that the induction of donor-specific tolerance can prevent the development of the vascular changes of chronic rejection, although not all of the short-term manipulations that have been effective in preventing acute rejection have necessarily prevented the later onset of chronic rejection. Remarkably, mice rendered tolerant by neonatal injection of donor splenocytes, or by the induction of high levels of lasting, multilineage mixed chimerism with demonstrated central deletion of donor-reactive T cells and permanent acceptance of donor-specific skin grafts, demonstrate graft vasculopathy in donor cardiac allografts (468). Thus, in the complete absence of antidonor T-cell reactivity, other cell types such as NK cells may induce these types of lesions in cardiac allografts. In addition, T-cell recognition of cardiac-specific antigens presented by donor MHC and not shared by donor hematopoietic cells could play a possible role in the development of these lesions in immunocompetent, tolerant mice (455).

From these data, it seems likely that multiple immunologic mechanisms may be capable of creating the graft arteriosclerotic lesions that are characteristic of chronic rejection, and that T-cell alloreactivity is not essential for their induction. Whether there is a critical final common mediator involved in all of these pathways is not currently known. However, IFN-γ has been shown to play an important role in the development of lesions in several models (465,472), and STAT4-deficient mice, which do not respond to IL-12 and therefore cannot generate Th1 responses, show markedly reduced severity of graft vasculopathy compared with wild type mice (473). TGF-β has been shown to attenuate the lesions, but has also been detected within the lesions and implicated in the development of fibrosis (474).

Chronic Graft-versus-Host Disease

Chronic graft-versus-host disease (cGVHD) is the most common and severe complication among patients surviving for more than 100 days after allogeneic bone marrow transplantation. Clinically, acute and cGVHD can be distinguished on the basis of the time of onset, clinical manifestations, and distinct pathobiologic mechanisms. Acute GVHD usually occurs within 2 to 6 weeks following allogeneic BMT and primarily affects the skin, liver, and the gastrointestinal tract with T-cell infiltration of the epithelia of the skin, mucous membranes, bile ducts, and gut. However, acute GVHD has been noted to occur later in recent protocols involving nonmyeloablative conditioning for HCT. In contrast, cGVHD involves a wider range of organs and clinical manifestations include scleroderma, liver failure, immune complex disease, glomerulonephritis, and autoantibody formation.

The pathogenesis of cGVHD, like chronic rejection, is poorly understood. The disease involves T-cell responses to alloantigens or autoantigens. Because most BMT is performed between HLA-identical or closely HLA-matched pairs, alloreactivity may be directed against minor histocompatibility antigens (miHA) presented by shared MHC molecules, or against MHC alloantigens when present. T cells developing *de novo* in a recipient thymus that is damaged by GVHD may result in the emergence of autoreactive T cells into the peripheral repertoire (475). The injury to target organs is poorly understood, but may involve TGF-β, which promotes fibrosis and other cytokines, as well as B-cell activation and production of autoantibodies.

The main risk factors for the onset of cGVHD are donor and patient age and sex, source of progenitor cells, graft composition, and previous acute GVHD. cGVHD can be treated, but infections resulting from immunosuppression due to the disease itself and its treatment are a major source of morbidity. Extensive skin involvement, thrombocytopenia, and progression are poor prognostic factors.

PHYSIOLOGIC INTERACTIONS THAT MODULATE GRAFT REJECTION AND GVHD

All immune responses are modulated by down-regulatory components that help to limit or terminate the response. Although graft rejection and GVHD often involve exceptionally strong immune responses, these responses are still accompanied by down-regulatory components that can be manipulated to promote graft survival. Many of these manipulations are described in the section on tolerance, but some of the regulatory components of the rejection response are briefly described here.

Down-modulating Signals Following T-Cell Activation

Interactions between Fas and Fas Ligand (FasL), which is up-regulated during rejection responses, may help to mitigate GVHD and graft rejection by mediating destruction of activated T cells and APCs (293). Consistent with this concept, FasL-deficient recipients are more susceptible than normal mice to the development of GVHD (476) and high levels of FasL in the microenvironment may help to explain the resistance to rejection of tissues transplanted to some "privileged sites," such as the testis or the anterior chamber of the eye (477). Although investigators have attempted to exploit this pathway to achieve graft

survival, the overexpression of FasL causes a nonspecific inflammatory syndrome associated with prominent neutrophil infiltration *(478)*, and overexpression of Fas ligand in pancreatic islets has made them more susceptible to destruction (479). Forced FasL overexpression on donor DCs also induces this neutrophil response, which augments graft rejection *(480)*.

CTLA4 is clearly important in the maintenance of self-tolerance, as evidenced by the T-cell lymphoproliferative autoimmune syndrome that develops in CTLA4 knockout mice *(481,482)*. Blockade of CTLA4 accelerates cardiac allograft rejection *(483)* and increases GVHD *(484)*, and CTLA4 has been shown to play a role in T-cell tolerance in many systems (435,485,*486–497*). CD28 knockout mice can reject allografts, despite unopposed signaling through CTLA-4 *(498)*, but their capacity to induce GVHD is diminished *(484)*. PD1, an additional down-regulatory molecule expressed by activated T cells that recognizes the B7 family members PDL-1 and PDL-2, also mitigates graft rejection (499) and GVHD *(500)*. Studies of cardiac allograft rejection suggest that PD1 plays an important modulatory role in the presence of extensive antigenic disparities between the donor and recipient, but that the BTLA-HVEM inhibitory pathway plays a predominant role in the presence of more restricted antigenic disparities *(501)*.

Regulatory Cytokines

The inflammatory condition that develops in IL-2 knockout mice is clear evidence of the important immunomodulatory role of this cytokine, and studies in several graft rejection *(502)* and GVHD *(503)* models have confirmed such a role in transplantation. Much of this effect is the result of the important role of IL-2 in activating and expanding regulatory cells (504,*505*), as is discussed elsewhere in this chapter, and IL-2 can also promote activation-induced cell death of alloreactive CD8 cells (504,*506*). Although IFN-γ can also promote graft rejection, rejection occurs rapidly in IFN-γ knockout mice *(434,507)* and is even accelerated in certain models *(508)*. Moreover, IFN-γ has been shown to play a down-regulatory role in GVHD (*422*,436) and solid-organ graft survival *(509,510)*. Although the mechanism by which IFN-γ inhibits graft rejection is not fully understood, this cytokine has antiproliferative effects on CD4 and CD8 cells *(437,512)*, increases T-cell apoptosis via the Fas/FasL pathway *(511,512)*, up-regulates the production of nitric oxide *(513–516)*, which has immunomodulatory properties (385), and promotes regulatory T-cell function (517). IFN-γ inhibits both CD4- and CD8-mediated GVHD, and mitigates the expansion of both T-cell subsets (436,*518*). Moreover, the major cytokines that induce IFN-γ, IL-12, and IL-18, can down-modulate graft rejection (*433,435,519*) and GVHD (436,*520,521*). This down-modulatory role of IL-12 and IL-18 is dependent on IFN-γ and the Fas-FasL pathway (436,*521,522*).

Despite interest in the concept that Th2 cytokines are anti-inflammatory and may suppress rejection and GVHD (*410–413*,414,415,*416*,417,*418*), IL-4 deficiency does not accelerate graft rejection *(508,523)* and can actually down-modulate GVHD (422). However, there clearly are situations in which the balance of cytokines allows an immunomodulatory effect to be achieved by Th2 cytokines. For example, the use of total lymphoid irradiation can alter the balance between NKT cells and conventional T cells in BMT recipients, and IL-4 production by enriched recipient NKT cells down-modulates GVHD *(524)*. This approach has recently been extended to a clinical trial of HLA-identical HCT, and impressively low rates of acute GVHD were reported (525).

Anti-inflammatory cytokines such as IL-10 or TGF-β, given either exogenously or via gene transfer, may down-modulate the process of graft destruction *(526–529)*. Cardiac allograft rejection was accelerated in transiently immunosuppressed IL-10–deficient mice *(508)* and GVHD was accelerated when donors were IL-10–deficient *(423)*, suggesting a physiologically relevant role for this cytokine in modulating these responses *in vivo*. The important role of these cells in regulatory T-cell function is discussed elsewhere in this chapter. On the other hand, IL-10 can enhance cytolytic mechanisms of islet graft rejection *(530)* and high doses can accelerate GVHD *(423)*.

The Presence of the Transplanted Organ

Although early rejection episodes occur with most types of organ transplants, there are some exceptions to this rule. Kidney and liver transplants in mice can survive for long periods without immunosuppression, even with MHC disparities (*531,532*,533), and there have been cases of prolonged liver transplant survival in pigs without immunosuppression *(534)*. In addition, many types of rodent transplants, such as heart grafts, require only a short course of immunosuppression to achieve prolonged survival *(535,536)*. In these experimental systems, the long survival of these transplanted organs often diminishes, or even prevents, the subsequent rejection of antigenically identical donor skin grafts *(531,537)*. In the porcine model, the presence of a tolerogenic class I-mismatched renal allograft can promote the survival of a donor-matched cardiac allograft with a short course of immunosuppression *(538)*. Even in clinical transplantation, it appears that the long survival of a transplanted organ may diminish the rejection response because much less immunosuppression is required late after transplantation than in the early period. Thus, the mere survival of a transplanted organ can markedly down-modulate the specific antidonor immune response. Extensive data implicate regulatory cells induced by tolerogenic organs as a major mechanism of this type of immune modulation (see later discussion).

There are two important features to emphasize regarding the capacity of transplanted organs to regulate their own survival. First, their capacity to do so often confuses the results of experimental studies designed to test tolerance-inducing strategies. For example, it is frequently reported that a particular form of immunosuppression induces tolerance when provided at the time of murine cardiac transplantation. However, the conclusion that the form of immunosuppression employed leads to tolerance is not justified. The heart, which is initially protected from rejection by the immunosuppression, may be largely responsible for the tolerant condition. Second, the processes that down-regulate graft rejection may be inhibited by the standard forms of immunosuppression that are used clinically to achieve excellent graft survival *(539)* because these drugs inhibit T-cell signaling and therefore may inhibit active processes of tolerance induction.

Role of Graft and Tissue Injury

Graft injury, such as that associated with ischemia-reperfusion, and host tissue injury induced by conditioning therapy in the case of HCT, play an important role in promoting graft rejection and GVHD, respectively, probably because of the effects of tissue injury on both T-cell activation and recruitment. As discussed in the section "Sensitization and Cell Trafficking during Rejection and GVHD," APC migration from tissues to lymph nodes, where T-cell priming occurs, is promoted by inflammatory signals in the tissues. For example, the inflammatory cytokines TNF-α and IL-1α promote migration of Langerhans cells from the skin to the lymphoid tissues *(540–544)*.

The impact of tissue inflammation on trafficking of activated T cells to tissues is illustrated dramatically in murine allogeneic HCT models. Administration of large numbers of nontolerant donor lymphocytes to established mixed bone marrow chimeras (i.e., animals not recently treated with conditioning therapy) leads to a GVH response that attacks only lymphohematopoietic tissues and does not cause GVHD, a disease of epithelial tissues such as skin, intestines, and liver *(545,546)*. In contrast, similar numbers of T cells cause rapidly lethal, severe GVHD in freshly irradiated hosts *(545,547)*. Both ablative and nonmyeloablative conditioning with syngeneic hematopoietic reconstitution *(548)* are associated with very early production of chemokines in the GVHD target tissues. The conditioning-induced chemokine up-regulation is followed by immigration of T cells that then elicit a further cascade of chemokines that amplifies the response *(548)*. A similar scenario likely applies to adhesion molecules that promote leukocyte infiltration through the microvasculature of these tissues. Lethal TBI and cyclophosphamide, for example, up-regulate the proinflammatory cytokines IL-1, IL-6 and TNF-α *(549–551)*, which can up- regulate endothelial cell E-selectin, P-selectin, ICAM-1, and VCAM-1 *(552,553)*. In the absence of such host target tissue inflam-

mation, mature, activated GVH-reactive effector T cells are unable to traffic into skin and induce injury *(547)*. Provision of a local toll-like receptor (TLR) stimulus promotes the entry of such cells into the skin and induces localized GVHD *(547)*, indicating that tissue inflammation provides a critical checkpoint for T-cell recruitment to GVHD target tissues. Nevertheless, GVHD can occur when very large numbers of nontolerant parental T cells are administered to genetically tolerant F1 hosts *(554)*, indicating that, in the presence of sufficiently powerful GVH responses, the need for tissue inflammation to induce GVHD can be bypassed.

All forms of organ and tissue transplantation involve ischemic and traumatic injury to the donor tissue, which may be one of the reasons that rejection episodes occur most frequently early after transplantation. The surgical trauma associated with even a syngeneic skin or heart graft *(350,555)* is associated with very early production of chemokines in the graft. Allogeneic but not syngeneic skin grafts are then infiltrated by NK cells that induce further chemokine production (350). Chemokines produced in response to ischemia-reperfusion injury promote the early infiltration of neutrophils *(556)*, which in turn perpetuate inflammation that promotes subsequent T-cell infiltration *(557)*. These observations collectively support the concept that a "danger" signal helps regulate graft rejection (558). These danger signals likely include products of cell death such as nucleic acids that function as endogenous ligands for TLRs (see later discussion) and other receptors for products of stressed cells. In addition, later inflammation may trigger late rejection episodes. Nevertheless, skin and cardiac allografts that are allowed to heal in before being exposed to alloreactive T cells developing *de novo* posttransplant or following adoptive transfer, are rapidly rejected if there is sufficient antigenic disparity between donor and host (559,560). Skin grafts bearing only minimal antigenic disparities from the host may have a more absolute requirement for innate immune stimuli or other sources of inflammation to induce rejection *(561)*. Similarly, even achieving organ transplant survival for many years in clinical practice is rarely sufficient to allow the cessation of immunosuppression without rejection. Therefore, nonspecific danger signals are not a critical requirement for graft rejection and it is better to picture the antigenic disparity and the recipient's immune responsiveness as the dominant features controlling graft rejection, while danger signals may influence the timing, intensity, or character of the rejection response.

Role of the Innate Immune System

The innate immune system comprises a group of cells and molecules that provide a first line of defence against pathogens, and which also play an important role in allograft rejection. Primary adaptive immune system responses that rely on the activation and expansion of antigen-specific T and B cells take several days to reach

maturity. In contrast, the innate immune system can be considered as a "preformed" defense mechanism that is immediately available to defend the host until either the dangerous stimulus is cleared or the adaptive immune system is able to mount an antigen-specific response *(562)*. Clearly, this is a somewhat simplistic view; while many components of the innate immune system can be recruited very quickly after transplantation, their activity can be amplified after activation.

As previously discussed, the physical process of graft retrieval and implantation generates signals within the graft and the recipient that trigger rejection *(562)*. Pattern recognition receptors exist to detect the unwanted presence of bacterial or viral pathogen-associated molecular patterns, but after transplantation the TLRs that form part of the pattern recognition receptor family can also be used to detect the molecules produced as a result of implantation of the graft. These signals include heat shock proteins, reactive oxygen species, nucleic acids, complement breakdown products, and molecules associated with tissue fibrosis that activate cells of the innate immune system via TLR ligation (see Chapter 14).

Dying cells are an inevitable consequence of the ischemia and reperfusion injury that is caused by organ and tissue retrieval. Macrophages and other phagocytic cells ingest necrotic tissue and, when activated, release cytokines such as TNF-α, IL-1, and IL-6 that all contribute to the local inflammatory environment. IFN-γ, whose early production may require CD8 T-cell activation, also activates macrophages to become effective APCs and release chemokines *(563–565)*. The early infiltration of macrophages into a graft at the onset of rejection has been suggested to be a poor prognostic sign for transplant survival. Macrophage colony-stimulating factor (M-CSF) produced by tubular and mesangial cells promotes macrophage infiltration and proliferation and may play a pathogenic role in acute rejection.

Damaged tissue can also trigger complement activation in the absence as well as the presence of antibody, and complement has been demonstrated to contribute to ischemia reperfusion injury (566). Activated complement components constitute a proteolytic cascade that generates a range of effector molecules. The anaphylatoxins C5a and C3a are chemoattractant molecules that assist leukocytes to home to the graft while other soluble mediators are able to opsonize cells, targeting them for destruction by phagocytes. Recognition of C3b, C4b, or their fragments covalently bound to target cells by complement receptors on the surface of leucocytes facilitates antigen presentation and T- and B-cell activation *(567,568)*. Generation of the terminal components of the complement cascade (C5b-9) results in formation of the membrane attack complex within the target cell membrane and initiation of target cell lysis. This has been demonstrated to play an important role in ischemia-reperfusion injury (566). In addition to the potential of the damaged tissue itself to acti-

vate complement, there is also evidence that natural IgM antibody can trigger the complement activation via both the classical and mannose binding lectin pathway *(569)*. Studies in muscle reperfusion models initially identified natural IgM as a major initiator of pathology through the activation of the complement system and recruitment of inflammatory cells. When the repertoire of natural IgM antibodies was altered, significant protection of the myocardial tissue was observed with only limited apoptosis of cardiomyocytes and decreased neutrophil infiltration compared with when natural antibody was present (570). As previously mentioned, there is also increasing evidence that complement can influence graft outcomes, contributing to the development of acute and/or chronic rejection, either directly or through antibody-dependent mechanisms *(469,571)*.

The potential role of NK cells in graft rejection has been discussed earlier. Polymorphism of NK cell-receptor targets should theoretically generate alloreactive NK cells that could contribute to tissue damage following transplantation. However, to date there has been no direct demonstration that they play an essential role in acute allograft rejection *(572)*, although as previously mentioned, there is evidence that they may contribute to the development to chronic rejection *(455)*. Interestingly, NK cells have recently been shown to promote tolerance induction (see later discussion) by killing donor APCs *(573)*.

Increasing evidence demonstrates the important role that components of the innate immune system play in activating the adaptive immune system. In particular, ligation of TLRs on DCs induces maturation, as defined by up-regulation of costimulatory molecules and MHC class II, enhancing their ability to act as a bridge between the innate and adaptive immune system *(574)*. TLRs are critical sentinels of the innate immune system and contribute to the early response after transplantation. Using HY grafts, Goldstein and colleagues *(575)* showed that rejection was not triggered in the absence of MyD88 TLR signaling pathway because of the migration of a reduced number of mature DCs to the draining lymph nodes that resulted in the impaired generation of antigraft-reactive T cells and Th1 immunity. Further studies using fully allogeneic grafts have shown that multiple TLR signaling pathways contribute to the initiation of rejection (575,576,577). As well as stimulating rejection, TLR signaling and activation of the innate immune system may also prevent or increase the difficulty of inducing tolerance to alloantigens *(578)* (see later discussion).

MANIPULATIONS TO PREVENT GRAFT REJECTION

The importance of transplantation immunology lies ultimately in the application of its principles to clinical transplantation. Thus, the critical issue is to determine how the

components and regulatory interactions involved in graft rejection might be manipulated to allow graft acceptance. One level of immunosuppression involves nonspecific approaches, reducing the overall immunocompetence of the recipient to all foreign antigens, and the second level seeks to prevent responses only to the antigens of a particular donor. Ultimately, the goal is to achieve tolerance, which is lasting donor-specific nonresponsiveness.

Nonspecific Techniques

Standard Drugs

Reviewing the pharmacology of the nonspecific immunosuppressive drugs commonly used in clinical transplantation is beyond the scope of this chapter. It is important to note, however, that most of the major advances in clinical transplantation that have occurred over the past 4 decades have been made possible largely because of these agents. Most recipients of allogeneic organs today receive exogenous immunosuppression in the form of combination therapy with several drugs (Table 44.6), including steroids, a calcineurin inhibitor (cyclosporine or tacrolimus), and an antimetabolite (e.g., azathioprine or mycophenolate mofetil). Newer drugs, including sirolimus and several other agents, are tested as substitutes for the calcineurin inhibitors in some regimens, and both steroid-free and single-drug regimens are being tested *(579–582)*, as are strategies incorporating immunosuppressive antibodies (583). In general terms, both standard and experimental immunosuppressive drugs suppress immune responses either by depleting immune cells, by blocking costimulation, or by inhibiting lymphocyte gene transcription (e.g., cyclosporine, tacrolimus), cytokine signal transduction (e.g., rapamycin), or nucleotide synthesis (e.g., azathioprine, mycophenolate mofetil).

Experimental Drugs

The list of standard drugs will almost certainly be modified in the near future by the addition of drugs that are now considered experimental (Table 44.6). 15-Deoxyspergualin is a distinctly different agent that has no effect on IL-2 production or utilization. It appears to prevent activated T and B cells from differentiating into mature effector cells. It is currently under clinical evaluation for rejection crises and for prophylaxis in highly sensitized patients. Leflunomide is an orally bioavailable prodrug that is converted to the active metabolite A77 1726, which has shown promise in treating acute and chronic rejection in animal models. It prevents lymphocyte proliferation both by inhibiting *de novo* pyrimidine synthesis and by inhibiting the activity of tyrosine kinases associated with cytokine receptors. Leflunomide can also prevent smooth muscle proliferation, and hence may be beneficial in preventing graft vasculopathy. Leflunomide has not only prolonged allo- and xenograft survival, but has also prevented the production of antidonor antibodies in animal models. Clinical trials are also in progress using a new immunosuppressive agent called FTY720. This drug has the unusual effect of altering T-cell trafficking, apparently in ways that prevent entry of the cells into donor grafts *(584)*.

Anti–T-Cell Antibodies

Another form of nonspecific immunosuppressive therapy used both clinically and experimentally is that achieved with antibodies specific for T cells of the recipient. Originally, anti–T-cell antibodies were obtained from heterologous antisera prepared against lymphocytes (ALG) or thymocytes (ATG) of the recipient species. These powerful immunosuppressants are still used in some induction regimens and for the treatment of rejection episodes. Their

> **TABLE 44.6 Immunosuppressive Medications**

Type of Drug	Examples	Mode of Action
Antirejection medication		
1st Generation	Prednisone	Anti-inflammatory; inhibition of cytokines
	Azathioprine	Anti-metabolite (purine analog)
2nd Generation	Cyclosporin	Calcineurin inhibition (down-regulates IL-2)
	FK-506	Calcineurin inhibition (down-regulates IL-2)
	MMF	Inhibitor of nucleotide synthesis
	Rapamycin	Inhibitor of signal transduction
Polyclonal Abs	ATG	T-cell depletion
	Thymoglobulin	T-cell depletion
Monoclonal Abs	Anti-CD3	T-cell sequestration
	Anti-CD25	Activated T cells
	Anti-CD2	T-cell depletion and costimulation blockade
	Anti-CD154	Costimulation blockade
	CTLA4-Ig	Costimulation blockade
	Anti-CD40	Costimulation blockade

IL, interleukin.

major side effects include serum sickness and infectious complications. A variety of monoclonal antibodies (mAb) are also being used actively in clinical transplantation or are being tested in clinical trials (Table 44.6). These include OKT3, the first mouse anti-CD3 mAb to be used in this way, Campath-1, an anti-CD52 mAb that depletes T and B cells, and numerous other, newer mAbs. In general, these antibodies are now either "humanized" from the mouse versions by genetic engineering or prepared in mice carrying human immunoglobulin genes *(585)* to avoid immunization of the recipients.

Monoclonal antibodies to the α chain of the IL-2 receptor (CD25) have been used in an effort to achieve greater antigen specificity with anti–T-cell antibodies, based on the hypothesis that these mAbs might selectively eliminate only those T cells activated by the transplant. Clinical results using humanized anti-CD25 mAbs have so far demonstrated immunosuppression, but not tolerance induction *(586)* perhaps because CD25$^+$ regulatory T cells are also depleted. Some mAbs have also been used in attempts to block the effector mechanism of graft rejection, including anti-ICAM antibodies and anti-TNF antibodies. Costimulatory blockers have shown promise, and will be discussed later.

Donor-specific Tolerance Induction

The Need for Tolerance-inducing Regimens

Immune tolerance denotes a state in which donor-specific nonresponsiveness is maintained without immunosuppressive agents. This definition might include allograft acceptance without immunosuppression, regardless of whether or not the immune system will accept other organs and tissues from the same donor (i.e., whether or not tolerance is "systemic" throughout the immune system); others define tolerance as a systemic state of immune nonresponsiveness to the donor. In both definitions, the recipient can reject organs from a third-party donor. For the purpose of this discussion, we will define tolerance as specific acceptance of a donor organ, and will qualify the term as "systemic" when it applies to the entire immune system. Systemic tolerance seems less likely to be perturbed and permit graft rejection when environmental conditions change in the recipient; for example, when a viral infection involves the donor organ.

Transplantation tolerance is a desirable goal for three major reasons. First, although improvements in immunosuppressive therapy have dramatically increased the success of clinical organ transplantation, these drugs are associated with life−long increased risks of infection and malignancy. Second, despite improved immunosuppression, chronic rejection still contributes to constantly downsloping long-term survival curves for organ allografts. Chronic rejection is less likely to occur in tolerant recipients. Third, a critical shortage of allogeneic organs

has increased interest in the use of other species as organ and tissue sources. However, immune barriers to xenografts are greater than those to allografts, and the induction of both B-cell and T-cell tolerance may be essential to the ultimate success of xenotransplantation.

Central and Peripheral Tolerance

Other chapters in this book describe the mechanisms by which tolerance to self-antigens is achieved (see Chapter 29). For most developing T cells, these processes take place in the thymus, which is the central organ for T-cell development. Induction of deletional tolerance or anergy among developing thymocytes is referred to as *central*, as distinguished from the *peripheral* tolerance that may develop among already-mature T cells when they encounter antigen in the peripheral tissues. Peripheral tolerance may result from the action of regulatory T cells or other cell types, or by deletion or anergy. Peripheral tolerance mechanisms play an important role in tolerizing T cells that recognize tissue-specific self-antigens that may not be encountered in the thymus during T-cell development. However, a remarkable number of antigens previously thought to be "tissue-specific" and present only on peripheral tissues have recently been found to be expressed in the thymus and to induce central tolerance *(587,588)*. Expression of many of these genes in the thymus is controlled by the *AIRE* transcription factor, and humans and mice with a defect in *AIRE* develop multiorgan autoimmune syndromes *(589,590)*. B cells are also susceptible to tolerance induction by several mechanisms during development in the marrow or on encounter with antigens in the periphery, as is discussed later.

Mechanisms of Transplantation Tolerance

The known mechanisms for inducing T- and B-cell tolerance can be grouped into the categories deletion, anergy, and suppression. In addition, a graft may simply be ignored by recipient lymphocytes but in most transplant settings this is unlikely to be a reliable mechanism for sustaining tolerance. Each of these mechanisms will be described briefly, and our current understanding of the role of each mechanism is then discussed in relation to particular strategies to induce transplantation tolerance.

Clonal Deletion

B cells: Studies using Ig receptor transgenic mice suggest that B cells are susceptible to deletion at particular stages of development on recognition of membrane-bound antigen *(591)*. Antigen expression on either radioresistant host cells or on a small population of hematopoietic cells appears to be sufficient to delete immature B cells specific for that antigen *(592)*. When a developing B cell with

autoreactivity encounters self-antigen, it undergoes developmental arrest. *RAG* gene-dependent light chain receptor editing then takes place; if this results in the formation of a nonautoreactive Ig receptor, the B cell survives; if not, the B cell undergoes apoptosis. The mechanisms of these processes have recently been reviewed (593). Cells of the B-1 subset, which produce natural antibodies responsible for xenograft hyperacute rejection *(594)*, can be deleted by an apoptotic process in mice when their surface Ig is cross-linked by cell-bound antigen *(595)*. Deletion and/or receptor editing is responsible for the long-term tolerance of natural antibody-producing B-1 cells in mice rendered mixed chimeric with bone marrow expressing an antigen for which natural antibody-producing cells pre-exist in the recipient *(156,596,597)*.

T cells: Most central T-cell tolerance occurs via a deletional mechanism due to recognition of self-antigens presented by hematopoietic cells and thymic epithelial cells (reviewed in refs. *598* and *599*). In addition, T cells recognizing self-antigens presented only by nonhematopoietic thymic stromal cells may be rendered anergic to such antigens *(600)*. Antigens presented by thymic epithelium may also lead to the development of regulatory cells that recognize them and tolerize other T cells in the periphery *(601–603)*. Deletion of self-reactive T cells is believed to occur when the avidity of an interaction between an immature thymocyte and an APC in the thymus is sufficiently high to induce apoptotic cell death *(604,605)*. This high avidity includes a relatively high-affinity interaction between a rearranged TCR and a self-peptide/MHC complex presented in the thymus. TCR with lower affinity for such complexes are more likely to survive this process, and other mechanisms are required to prevent their activation in the periphery under conditions of, for example, inflammation and antigen up-regulation on normal tissues. Several hematopoietic cell types, including DCs *(606)*, B cells *(607)*, and thymocytes *(608,609)*, as well as nonhematopoietic cells of the thymic stroma *(610,611)* (reviewed in refs. 558 and *612*), have the capacity to induce intrathymic tolerance by deletional and nondeletional mechanisms. Transplantation tolerance induced by intrathymic deletion should be very reliable, as the absence of lymphocytes with reactivity to the donor would ensure that a specific response to donor antigens could not be induced under any circumstances.

Peripheral deletion has also been described for mature T cells on exposure to antigen *in vivo (613–615)*. Deletion seems to be the natural consequence, under noninflammatory conditions, of cross-presentation by lymph node DCs of self-antigen expressed in parenchymal tissues to CD8 CTL *(616–618)*. Peripheral CD8 cells may undergo clonal deletion in a process termed *exhaustion* in the presence of a large antigen load that persists *(619,620)*. A possibly related phenomenon has been observed for host-reactive CTL in the context of GVHD *(621,622)*. Peripheral deletion

of donor-reactive T cells has been demonstrated in several transplantation tolerance models involving costimulatory blockade with donor lymphocyte or bone marrow infusion (485,623,624) and was suggested in recipients of allografts with anti-CD154 and rapamycin (625). In addition, veto cells (see later discussion) can delete alloreactive CTL precursors. Recently, a non-veto mechanism mediated by $CD4^-CD8^-$ cytotoxic regulatory cells has been reported to lead to the deletion of alloreactive CD8 T cells with the same specificity as the regulatory cells *(626)*.

Anergy

Anergy is a state that may result when T cells recognize peptide/MHC complexes, but without receiving adequate accessory or costimulatory signals *(600,627,628,629)*. A lymphocyte is considered to be "anergic" if it cannot proliferate in response to the antigen for which it is specific. T-cell anergy has been associated with altered signaling and tyrosine phosphorylation patterns *(630–633)* and with a lack of IL-2 production. T-cell anergy can often *(634)*, but not always *(635)*, be overcome by providing exogenous IL-2. In some cases anergy has been associated with TCR down-modulation *(615,636–638)*.

T cells may become anergic if they encounter antigen without costimulation (639), or if they encounter peptide ligands for which they have low affinity *(604,605)*. In addition to mature peripheral T cells, thymocytes are also susceptible to anergy induction by antigens presented on hematopoietic *(607)* or nonhematopoietic stromal *(640–642)* cells. Anergy is generally reversible *in vivo* and can be overcome by infection *(643)* or by removal of antigen *(644–647)*, and therefore may not be as robust a form of tolerance as deletion. Although deletion has been reported to follow the induction of anergy of T cells in the continued presence of antigen *(648,649)*, this is not a universal outcome, and anergic T cells may persist for long periods of time *(650,651)*. In a transplantation model involving BMT under cover of costimulatory blockade, peripheral donor-reactive CD4 T cells have been shown to be rendered anergic prior to their deletion over a period of weeks (652). Anergic T cells may also down-regulate the activity of other T cells, so that they function as "suppressor" or "regulatory" T cells *(653,654)*. This regulation may occur via conditioning of an APC by an anergic T cell so that naïve T cells recognizing the same or different antigens on the same APC are also tolerized *(655)*.

Anergy is an important tolerance mechanism for the many self-reactive B cells that escape deletion in the bone marrow *(656,657)*. Most of these B cells die within the peripheral lymphoid tissues or are anergic, particularly if they recognize abundant but low-avidity antigens (*591*, reviewed in ref. 593). Anergy requires persistent antigen and is characterized by Ig receptor down-regulation *(591)*, altered signaling patterns, and increased apoptosis on antigen encounter *(592)*. The failure of anergic B cells

to up-regulate BAFF receptors plays an important role in their inability to compete for survival in germinal centers. T-cell tolerance and the resulting absence of help is important for the maintenance of B-cell anergy, as anergic B cells can be activated in the presence of high-avidity antigen and T-cell help (593). Anergy is responsible for the early tolerance of natural antibody-producing B-1 cells in mice rendered mixed chimeric with bone marrow cells expressing an antigen recognized by natural antibody-producing cells in the recipient *(155,596,597)*.

Suppression

Regulatory T Cells. The concept of antigen-specific suppression and the existence of a specialized population of T cells, known initially as suppressor cells and more recently as regulatory T cells (Treg), that could control immune responsiveness originated in the 1970s from the studies of Gershon and Kondo *(658)* among others, who demonstrated the existence of complex regulatory networks involving several levels of T-cell–mediated suppression. In the specific setting of transplantation, a role for suppressor cells in transplantation tolerance was also identified *(659)*. However, despite the efforts of many groups through the. 1980s, the cellular and molecular characteristics of these suppressor cells were never defined with any precision, even though the phenomenon of suppression was highly reproducible *in vivo*, particularly in transplant models.

In 1990, Hall and colleagues *(660)* re-examined the function of T-cell subpopulations present in rats with long-term surviving cardiac allografts after cyclosporine treatment and, interestingly, reported that tolerance could be adoptively transferred by CD25$^+$CD4$^+$ cells. However, interest in characterizing suppressor/regulatory T cells was not fully revived until Sakaguchi and colleagues *(661)* followed up on data showing that susceptible strains of neonatally thymectomized mice developed multiorgan autoimmune disease. These workers found that neonatal thymectomy resulted in a loss of T cells with suppressor or regulatory properties that could be enriched among T cells expressing CD25, the alpha chain of the IL-2 receptor.

Naturally occurring CD25$^+$CD4$^+$ T cells with regulatory properties are generated in the thymus through interaction between the developing thymocytes with an intermediate affinity ligand, too low for negative selection, expressed on nonhematopoietic cells of the thymus for their positive selection *(662,663)*. Cortical thymic epithelium has been found to be the site of the MHC class II expression required for the development of functional Treg *(601)*. In addition to the naturally occurring populations of CD25$^+$CD4$^+$ T cells with regulatory activity, populations of T cells with regulatory properties that also express CD25 can be induced in the periphery following exposure to antigen under certain conditions (664). It is likely that following transplantation or exposure to alloantigen, Treg that can control the im-

mune response and prevent rejection will be derived from both the naturally occurring and induced populations (see later discussion). In addition to the wealth of data in mice, CD4$^+$ T cells expressing high levels of CD25 in the peripheral blood and thymus have also been shown to have suppressive activity in humans *(665–670)* and are present in transplant recipients with long-term surviving allografts *(671)*.

CD25 is by no means an exclusive marker for T cells with regulatory activity. Although the kinetics of expression are different, CD25 is also expressed by activated T cells. Indeed in transplantation, monoclonal antibodies targeting CD25 are licensed for use as antirejection therapies. Thus, there is a need to define other markers for Treg. The list of potential cell surface markers has been growing steadily, and includes CD152 (CTLA4), CD103, and glucocorticoid-induced TNFR-related protein, among many others. However, as yet, the "perfect marker" has not been identified. As well as cell surface and intracellular proteins, transcription factors can also potentially provide a tool for identifying committed cell lineages. In both humans and mice, *foxp3*, a forkhead/winged-helix transcription factor designated Scurfin in mice has been shown to be a potential master regulator for the development and function of Treg as mutations in the *Fox p3* gene lead to uncontrolled activation/expansion of CD4$^+$ T cells *(672,673)*. A direct link between *Foxp3* expression and regulatory activity came from retroviral gene transfer studies where transduction of naïve mouse T cells with *foxp3* resulted in acquisition of regulatory function *(674)*. This correlation between *Foxp3* and regulation has been strengthened by the generation of *Foxp3* transgenic mice where cells expressing *Foxp3* protein express either green *(675)* or red fluorescent protein *(676)*, allowing such cells to be identified and their function explored. Although in mice the relationship between *Foxp3* expression and regulation may be tightly linked, the situation may not be so straightforward in humans, as Foxp3 protein has also been found in activated T cells in some situations *(677)*.

Recipient-derived CD25$^+$CD4$^+$ T cells were shown to have potent regulatory properties in both the induction and maintenance phases of tolerance to alloantigens *in vivo* in mice (e.g., *678,679,680,681*). In BMT, donor CD25$^+$CD4$^+$ T cells present in the bone marrow inoculum were found to protect from GVHD *(682,683,684)*. In humans, CD25^{high}CD4$^+$ T cells have been found in the peripheral blood of immunosuppression-free allograft recipients *(671)* and their presence may contribute to long-term graft survival. As mentioned previously, Treg with capacity to control immune responses to a transplant most likely comprise naturally occurring and induced Treg populations. Naturally occurring Treg present in naïve, unmanipulated adult mice have been shown to be capable of preventing rejection of allografts mismatched for a single minor

histocompatibility antigen, for example, H-Y. However, they appear to be much less potent than Treg induced following exposure to alloantigen, as studies comparing the activity of naturally occurring and induced Treg directly suggest that 10 times fewer induced Treg are needed to prevent allograft rejection. These findings may explain why in situations where grafts are mismatched for multiple major and minor histocompatibility antigens, it has sometimes been difficult to demonstrate that naturally occurring Treg can control the rejection response.

After transplantation, the ability to generate Tregs *in vivo* may be influenced by the microenvironment. It has been shown that the balance between the presence of IL-6 and TGF-β *in vivo* can have a dramatic impact on which T-cell population develops. Importantly, Treg generation can be prevented by inflammation *(685,686)*, a situation that occurs commonly *in vivo* after cell or organ transplantation, leading instead to the generation of cells capable of mediating tissue damage, including T_H17 cells *(685–687)*.

The mechanisms of regulation effected by Treg to prevent allograft rejection involve a variety of different pathways. When Tregs are reactivated by their cognate antigen through TCR they can rapidly and transiently produce IFN-γ that is needed to mediate their regulatory activity and prevent rejection (517). Interestingly, IFN-γ has been shown previously to be an essential mediator for the induction of tolerance in mouse models in which costimulation blockade was used to prevent graft rejection *(688)*. The transient production of IFN-γ by Tregs can have multiple effects on cells with which they interact (689), including other T cells, mediated either directly or indirectly through effects on APCs *(690)*. Treg activity can result in inhibition of cytokine production and secretion, down-regulation of costimulatory and/or adhesion molecule expression, inhibition of proliferation, induction of anergy, elimination of the effector population by promoting cell death, or even conversion of naïve and/or effector T cells to a regulatory phenotype, a process known as *infectious tolerance (691–694)*. IL-2, IL-10 and TGF-β may have roles in this phenomenon *(695)*. If this process is effective, any new T cells entering the repertoire after transplantation where immunoregulation is the dominant mechanism of tolerance will be converted to Treg, thereby propagating and reinforcing the tolerant state throughout the posttransplant course.

Indoleamine 2,3 dioxygenase (IDO), an enzyme that catalyses the initial and rate limiting step of the kynurenine pathway of tryptophan catabolism, is known to be subject to transcriptional regulation by IFN-γ *(696–699)*, dependent on STAT-1 signalling *(698)*. IFN-γ released by Treg can lead to the development of IDO-competent DCs that may acquire the capacity to control T cells locally through tryptophan depletion; overexpression of IDO inhibits alloimmune responses (e.g., *[699–701]*). The molecular mechanism responsible for the conversion of DCs to become IDO competent requires further investigation, but roles for TGF-β and IL-10 have been suggested *(692,693)*.

In addition, the activity of Treg *in vivo* in transplant models has been shown to be dependent on IL-10 *(680)*, TGF-β *(702)*, and CTLA-4 (e.g., refs. *492,679,703–706)*. CTLA-4 (CD152) is constitutively expressed by Treg and engagement of CD80/86 on DC can also induce IDO (707). In addition, CTLA-4 has been found to modulate T-cell motility by activating LFA-1 clustering and adhesion *(708)*, thereby altering the threshold for T-cell activation *(709)*. Although the mechanistic links between each of these mediators still requires clarification, it is important to note that many of the same molecules have also been found to be required for Treg activity in other settings, including autoimmune diseases, suggesting that Treg capable of controlling disease states *in vivo* have many properties in common.

One property of Tregs that can potentially be exploited in the context of transplantation is their ability to mediate bystander regulation in a defined microenvironment *in vivo*. To elaborate their functional activity, Treg need to be activated through their TCR. Data obtained by Thornton and Shevach *(709) in vitro* showed that reactivation of Treg with a defined antigen specificity through their TCR-enabled the cells to suppress the response of other cells present in the same *in vitro* cultures. Karim and colleagues (710) have shown that it is possible to exploit this observation *in vivo* to enable Tregs that are generated and respond to an unrelated protein antigen, such as human gamma globulin, to control rejection when the cells are restimulated through TCR immediately before they are asked to function *in vivo*.

Despite the current interest in the role of CD25$^+$CD4 Treg, it is important to remember that regulatory activity is not exclusive to CD4 T cells, and CD8 *(711–713)*, CD8CD28$^-$ *(714)*, TCR$^+$CD4$^-$CD8$^-$ ("double negative") *(626)*, and NKT cells (377,715) have also been shown to have regulatory activities in different situations after transplantation. In fact, regulatory mechanisms in both the innate and adaptive immune systems will most likely contribute to the overall outcome after transplantation. This is highlighted by the finding that both NKT cells and CD25$^+$CD4 Treg play a role in preventing acute GVHD after allogeneic BMT *(682,683,684,715)* and a recent study showing that inhibitory NK cell receptors can play a regulatory role in T-cell homeostasis *(716)*.

It may be possible to exploit Treg to control the immune response after transplantation either by developing strategies using immunosuppressive agents that promote Treg generation and/or do not inhibit their function or by generating Treg *ex vivo* and using them as a cellular therapy at different stages in the posttransplant course to prevent rejection and re-establish control. Understanding the impact of immunosuppressive drugs on Treg generation and
FIGURE 44.11 Administration of anti-CD25 monocloncal antibodies after the induction of Treg (regulatory T cells) can prevent long-term graft survival.

function is an important part of using the potential of Treg *in vivo*. Data from mouse models suggest that the calcineurin inhibitors have the capacity to inhibit T-cell apoptosis after activation, thereby preventing a reduction in the frequency of effector T cells that would allow Tregs to assume a more dominant functional role (625,717; Bushell and Wood, personal communication). Similarly, administration of anti-CD25 monoclonal antibodies after the induction of Treg can prevent long-term graft survival (Figure 44.11). On the other hand, other classes of immunosuppressive drug, such as the mTOR inhibitors sirolimus and everolimus, may enhance the generation of Tregs. Strategies to generate and/or expand Tregs *ex vivo* for therapeutic purposes are being developed with potential application in cell and organ transplantation. A variety of different approaches have been shown to be successful for generating and/or expanding T cells with regulatory capacity in both mice and humans including exposure to TGF-β, IFN-γ, and stimulation with anti-CD3/CD28 in the presence of IL-2, to name just some (e.g., refs. *718* and *719*). The development, maintenance, and expansion of Treg is critically dependent on IL-2 *(720,721)*. In each case at the end of the culture period, T cells that emerge have been shown either *in vitro,* and in some studies *in vivo*, to have regulatory activity that can prevent allograft rejection or GVHD *(722)*.

Antibody-mediated Suppression. Idiotypes are unique antigenic determinants that characterize the binding sites of antibody or T-cell receptors. These determinants can be antigenic and induce the production of anti-idiotypic antibodies *(723)*. Antibody-mediated suppression could theoretically occur through the recognition of idiotypes of antidonor Ig receptors. Anti-idiotypic antibodies can suppress antibody reactivity by directly binding to the antigen-binding site of the antibody, and the development of such

antibodies has been suggested as one of the possible benefits of pre–kidney transplant blood transfusions. Such antibodies have also been suggested to contribute to the apparent hyporesponsiveness to noninherited maternal antigens in renal allograft recipients. In the past, it was also considered possible that anti-idiotypic antibodies might inhibit T-cell recognition of antigen, but this now seems unlikely, given that T cells recognize peptide/MHC complexes, whereas antibodies recognize epitopes of intact molecules. It continues to be an intriguing question whether normal regulatory mechanisms for B-cell responses might include anti-idiotypes, as suggested by Jerne. However, efforts to control transplantation using exogenous anti-idiotypic antibodies to either T- or B-cell receptors have been disappointing *(724)*.

Antibodies can also induce tolerance through a process known as *enhancement*. Enhancement is defined as prolongation of graft survival achieved by the presence of antigraft antibodies *(725)*. This phenomenon was first described in experiments involving allogeneic tumor growth. Subsequently, enhancing regimens using anti-MHC antibodies and/or soluble antigen were shown to produce long-term tolerance for rodent allogeneic kidney transplants *(726)*. The simple interpretation was that anti-MHC antibodies bind to the antigen and thereby block the immune response, but this explanation has not turned out to be sufficient. For example, tolerance following enhancement can be transferred by cells and not serum from enhanced recipients. Apparently, the administered antibody sets up a host reaction that leads to specific immunosuppression. An idiotype/anti-idiotype network would be an attractive explanation for this phenomenon. Unfortunately, the spectacular success obtained using enhancement for kidney graft survival in rats has not been observed for grafts in other species and this approach has largely been abandoned, at least for the present.

LYMPHOCYTES IGNORING GRAFT ANTIGENS ("IGNORANCE"). Experimental situations have been described in which antigens are ignored by T cells *(638,727,728)* or B cells *(591)* that could potentially recognize them. This may be due to the presentation of these antigens by "nonprofessional APCs," which are unable to activate T cells, or it may reflect a failure of recipient T cells to migrate to the antigen-bearing tissue, as has been described in murine solid-tumor models *(729)*. The level of peripheral antigen expression, how recently the responding T cell has emerged from the thymus *(638,730)*, and the presence of proinflammatory cytokines *(731,732)* and up-regulated costimulatory molecules within peripheral tissues *(733)* may all influence the decision of a T cell to ignore or respond to peripheral antigens. However, "ignorance" may be a precarious state that can be upset by additional immunologic stimuli provoked by inflammation that may be induced, for example, by infection *(728)* or by presentation of antigen on professional APCs, as has been described for endocrine allografts that are depleted of APCs prior to transplantation *(734)*.

Strategies for Inducing Transplantation Tolerance

Strategies to Achieve Central Tolerance

Mixed Chimerism. It has been known for 60 years that hematopoietic chimerism induced *in utero* is associated with transplantation tolerance (reviewed in ref. 735). The capacity of hematopoietic cells to induce tolerance results largely from their ability to induce intrathymic clonal deletion of thymocytes that recognize them. Thus, bone marrow engraftment can reliably induce tolerance to the most immunogenic allografts, such as fully MHC-mismatched skin and small bowel grafts *(368,736,737)*. Despite this powerful tolerance-inducing capacity, HCT has not yet been routinely applied to the induction of tolerance in man. HCT for tolerance induction in rodents originally involved recipient treatment with lethal whole-body irradiation. Removal of mature donor T cells before transplantation was shown to prevent GVHD *(738–741)*, which allowed the development of a new immune system that is tolerant to both donor and recipient antigens. For wide application for organ allograft tolerance, HCT must be successful and safe across MHC barriers. However, MHC-mismatched allogeneic HCT in larger animals, including humans, has proved to be less successful and more dangerous than in rodents because of the toxicity associated with myeloablative conditioning, and the inordinately high risks of GVHD and engraftment failure (reviewed in ref. 742). Marrow rejection is increased when donor marrow is T-cell–depleted to prevent GVHD. Therefore, it will be essential to develop more specific and effective methods of overcoming the barriers to marrow engraftment with minimal GVHD risk before this highly effective approach to tolerance induction can

be routinely used in patients to achieve organ allograft tolerance.

Achievement of a state of mixed rather than full allogeneic hematopoietic chimerism would be desirable for the purpose of allograft tolerance induction for several reasons. First, mixed chimerism can be achieved with less toxic (nonmyeloablative) conditioning regimens than those that lead to full donor chimerism. In addition to being less toxic than myeloablative conditioning, nonmyeloablative regimens allow recovery of host hematopoiesis, so that life-threatening marrow failure does not occur, even in the event that rejection of donor marrow occurs. Secondly, compared with fully allogeneic chimeras, improved immunocompetence has been observed in mixed chimeras, which contain host-type APC in the periphery, allowing optimal antigen presentation to T cells that have developed in the host thymus, and which therefore preferentially recognize peptide antigens presented by host-type MHC molecules (120,743). Although the premise that hematopoietic cells do not participate in positive selection is controversial and has recently been challenged *(744)*, studies of antiviral CTL responses in mixed chimeras showed exquisite specificity for recipient-derived MHC-restricting elements *(745)*. Third, mixed chimeras contain hematopoietic cells from both the recipient and the donor in the thymus and hence delete both host-reactive and donor-reactive T cells, resulting in a peripheral T-cell repertoire that is deleted of cells that recognize the donor or the host *(746,747)*. Although nonhematopoietic thymic stromal cells have some capacity to induce deletional tolerance, the capacity of hematopoietic cells, especially DCs, to do so, is particularly powerful. Thus, intrathymic deletion of host-reactive cells in addition to donor-reactive cells occurs in mixed chimeras to a greater extent than in full chimeras *(746,748)*. As might be expected, tolerance induced by intrathymic deletional mechanisms is systemic, as shown by both *in vivo* and *in vitro* studies (reviewed in ref. 599).

Several nonmyeloablative approaches have been recently developed to permit the use of BMT to achieve mixed chimerism and specific tolerance, bringing the approach toward clinical application. In mixed chimeras prepared with a nonmyeloablative regimen consisting of low-dose (3-Gy) TBI, T-cell depleting mAbs and thymic irradiation *(368)*, intrathymic deletion was shown to be the major mechanism maintaining donor-specific tolerance *(746)*. Although anergy may play a role in tolerizing the few peripheral T cells that escape depletion with mAbs in this model, long-term tolerance appears to be maintained purely by a deletional mechanism. Administration of donor MHC-specific antibody to eliminate donor chimerism from established mixed chimeras results in loss of tolerance, and in the *de novo* appearance in the periphery of T cells with receptors that recognize donor antigens. However, if the recipient thymus is removed prior to elimination of

chimerism with antidonor antibody, specific tolerance to the donor is preserved, and donor-reactive TCRs do not appear in the periphery (749). Thus, chimerism is needed *only* in the thymus and not in the periphery in order to ensure persistent tolerance. This is consistent with a purely central deletional mechanism, as peripheral anergy and suppression generally require the relevant antigen to maintain the tolerance. Because thymic APCs are continually turning over, this observation emphasizes the need for hematopoietic stem cell engraftment at sufficient levels in order to ensure an uninterrupted supply of donor APCs in the recipient thymus for the life of the mixed chimera. The absence of suppressive tolerance mechanisms makes these animals particularly vulnerable to breaking of tolerance when nontolerant T cells emerge from the thymus after intentional depletion of donor antigen, or after exogenous administration of nontolerant host-type T cells (652,749).

These and other studies have led to an evolving understanding of the minimal requirements for achievement of lasting chimerism. These requirements are summarized in Figure 44.12. T-cell alloreactivity in both the thymus and periphery must be overcome in order to permit allogeneic stem cell engraftment and early seeding of the thymus with allogeneic APC. Intrathymic alloreactivity can be overcome with thymic irradiation *(368)*, high doses of T-cell–depleting antibodies *(750)*, or costimulatory blockers such as anti-CD154 or CTLA4Ig (751,752). Peripheral T-cell–mediated alloreactivity can be overcome with T-cell–depleting mAbs *(368,753)*, or with costimulatory blockers (751). Low-dose TBI or busulfan is often used in nonmyeloablative regimens to achieve mixed chimerism, creating an environment that facilitates the engraftment of donor hematopoietic stem cells in the host *(750,754)*. Although such myelosuppressive treatments can be omit-

ted by administering very high marrow doses *(753)*, and all preconditioning can be eliminated by giving a high dose of fully MHC-mismatched donor marrow followed by a single injection of each of two costimulatory blockers *(755)* or repeated injections of anti-CD154 *(756)*, methods of obtaining sufficient donor stem cells to permit engraftment without some minimal host myelosuppression do not yet exist clinically. The mechanisms of peripheral tolerance achieved with the combination of costimulatory blockade and allogeneic BMT are discussed later in the section on peripheral tolerance (see "Costimulatory Blockade with Infusion of Donor Hematopoietic Cells.").

Mixed chimerism induced with costimulatory blockade or T-cell–depleting antibodies is associated with a systemic state of tolerance, as evidenced by specific unresponsiveness to the donor in mixed lymphocyte response and CML assays and the acceptance of donor skin grafted at any time post-BMT *(368,752,755,757)*. In contrast, tolerance approaches that do not lead to mixed chimerism generally do not induce systemic tolerance, suggesting that tolerance might be less robust.

Additional approaches to achieving mixed chimerism for tolerance induction include the use of total lymphoid irradiation plus BMT, which has been more successful in rodents *(758,759)* than in humans *(760,761)*. Other regimens involving various combinations of anti–T-cell antibodies, irradiation, and immunosuppressive drugs have also permitted the achievement of mixed chimerism in both large *(762,763–765)* and small *(766–769)* animals. The successful induction of tolerance in a primate model using a nonmyeloablative approach to inducing mixed chimerism (762), combined with murine studies demonstrating the utility of mixed chimerism followed by delayed donor lymphocyte infusions (DLI) as an approach to achieving
FIGURE 44.12 Requirements for induction of long-term mixed hematopoietic chimerism. GVHD, graft-versus-host disease.

1) Treatments are given to block peripheral and intrathymic rejection of donor hematopioetic cells (e.g., anti-T cell mAbs, thymic RTX). Donor stem cells cells are given intravenously.

3) New T cells mature and become "educated" in the recipient thymus in the presence of donor and recipient hematopoietic cells. Thus, thymocytes recognizing these antigens are deleted.

— Recipient
······ Donor

4) The emerging T cells that repopulate the immune system are tolerant of donor and recipient. A donor organ is accepted and there is no GVHD.

······▶ Blood cells are a mixture of donor and
— host (mixed chimera)

2) Donor stem cells go to recipient marrow. Stem cells in the marrow send progeny to the recipient thymus.

GVL effects without GVHD *(545,546)*, has been used as the basis for a clinical trial of mixed chimerism induction followed by DLI for the treatment of patients with hematologic malignancies *(770,771)*. Success with this approach led to a pilot evaluation of combined HLA-identical kidney and bone marrow transplantation with this non-myeloablative regimen in patients with renal failure due to multiple myeloma, which provided the first demonstration that transplantation tolerance could be intentionally induced in humans (772).

The ability to replace recipient T-cell depletion with costimulatory blockade in the murine models is encouraging for several reasons. First, it has been difficult to achieve T-cell depletion with antibodies in large animals and humans that is as exhaustive as that achieved in the previously mentioned rodent models, perhaps because of the use of inadequate doses or suboptimal reagents. A second concern is that, if sufficiently exhaustive T-cell depletion could be achieved in humans, T-cell recovery from the thymus might be dangerously slow, especially in older individuals (reviewed in ref. 773). The ability to replace some *(757)* or all *(751,755,756)* T-cell depleting antibodies with costimulatory blockade is therefore of considerable interest.

GVHD does not occur in the rodent models previously discussed, despite the use of unseparated donor bone marrow cells. This is most readily explained by the continued presence of the T-cell–depleting or costimulatory blocking antibodies in the serum of the hosts at the time of BMT *(774)*. These levels are sufficient to prevent alloreactivity by the relatively small number of mature T cells in the donor marrow.

An alternative to using allogeneic hematopoietic engraftment to achieve tolerance is to reconstitute recipients with autologous bone marrow cells that have been transduced with genes encoding foreign transplantation antigens *(775)*. Although this approach is limited because the full spectrum of donor antigens cannot be transduced, active regulatory mechanisms may allow the tolerance to spread from those transduced into the donor stem cells to others expressed by the graft *(776)*.

Extension of the Mixed Chimerism Approach to Xenotransplantation. Host treatment with mAbs to T cells and NK cells along with a low dose (3 Gy) of total body irradiation has also permitted rat marrow engraftment in mice, resulting in mixed xenogeneic chimerism and donor-specific tolerance *(369)*. Both $\gamma\delta$ T cells and NK cells play an important role in resisting xenogeneic marrow engraftment (370). Costimulatory blockade with anti-CD154 mAb can overcome the requirement for CD4 cell depletion to achieve engraftment of rat marrow *(777)*. Once mixed chimerism is achieved in the rat to mouse species combination, donor-specific tolerance is observed at the level of both T cells and B cells *(59,369,778–780)*. Pigs are widely believed to be the most suitable xenogeneic donor species for transplantation to humans, but transplantation from this species is impeded by the presence in human sera of "natural" antibody (Nab) that cause hyperacute rejection of porcine vascularized xenografts. The major specificity recognized by human natural antibody on porcine tissues is a ubiquitous carbohydrate epitope, Galα1–3Galβ1–4GlcNAc-R (αGal). Humans lack a functional α1–3Gal transferase (GalT) enzyme, as do GalT knockout mice, which also make anti-αGal Nab. Both pre-existing and newly developing B cells producing anti-αGal antibodies are tolerized by the induction of mixed chimerism in GalT knockout mice receiving αGal-expressing allogeneic or xenogeneic marrow *(156,596,781)*. The induction of mixed xenogeneic chimerism prevents hyperacute rejection, acute vascular rejection, and cell-mediated rejection of primarily vascularized cardiac xenografts *(779)*. Long-term mixed xenogeneic chimeras produced in GalT knockout mice lack anti-Gal surface Ig-bearing cells in the spleen, and show tolerance in ELISPOT assays *(596,779)*. The major IgM Nab-producing cell population in mice is a B-1b cell population in the spleen *(594)*, and these are tolerized rapidly by an anergy mechanism, which is followed later by clonal deletion and/or receptor editing of Gal-specific B cells *(597)*. Splenic B cells, possibly of a similar subset, are also, along with immature plasma cells, the major anti-Gal IgM-producing population in nonhuman primates and baboons *(782)*.

Studies in mixed allogeneic chimeras show that recipient NK cells are tolerized to the donor *(783)* and studies in the rat to mouse combination also indicate a state of tolerance *(784)*. Despite this T, B, and NK cell tolerance, the levels of donor chimerism decline gradually over time, the result of a competitive advantage of recipient mouse marrow over xenogeneic rat marrow as the host recovers from low-dose TBI *(785)*. Species specificity or selectivity of cytokines, adhesion molecules, and other interactions that regulate hematopoiesis *(786)* probably account for this advantage. Achievement of xenogeneic hematopoietic repopulation has proved to be an even more formidable challenge in highly disparate (discordant) species combinations. Administration of exogenous donor species-specific cytokines can partially overcome this barrier *(787,788)*, and high levels of porcine hematopoietic stem cell engraftment have been achieved in immunodeficient mice transgenically expressing the porcine hematopoietic cytokines IL-3, stem cell factor, and GM-CSF *(789)*. The use of these mice has permitted demonstration that mouse T cells *(790)* and, importantly, using a humanized mouse model, that human T cells *(791)* can be centrally tolerized to porcine xenoantigens via induction of mixed xenogeneic chimerism.

Macrophages also play a significant role in resisting engraftment of xenogeneic marrow from highly disparate species *(389,390)*. It seems likely that macrophages and other cellular components of the innate system recognize

foreign lipids and carbohydrates on highly disparate xenogeneic cells via specific activating receptors and that the failure of inhibitory interactions may increase susceptibility to destruction by such cells, as suggested by recent studies (400).

Xenogeneic Thymic Transplantation

An alternative approach to achieving xenogeneic T-cell tolerance involves replacement of the recipient thymus with a xenogeneic donor thymus after host T-cell depletion and thymectomy. Immunocompetent mice treated in this way reconstitute CD4$^+$ T cells in xenogeneic porcine thymic grafts *(792)*. These cells repopulate the periphery, are competent to resist infection *(793)*, and are tolerant of porcine donor antigens *(792,794)*. Tolerance to both donor and host develops, at least in part, by intrathymic deletional mechanisms in these animals, reflecting the presence of class IIhigh APCs from both species within the thymic graft *(794,795)*. T cells that differentiate in a xenogeneic thymus respond to peptide antigens presented by host MHC *(793)*. Studies using TCR transgenic mouse recipients showed that positive selection in such grafts is mediated only by porcine thymic MHC, with no influence of mouse MHC *(796,797)*. However, the excellent immune function achieved in these mice *(793)* and in humans receiving HLA-mismatched allogeneic thymic transplantation for the treatment of congenital thymic aplasia (DiGeorge syndrome) *(798,799)*, suggests that "restriction incompatibility" due to MHC disparity between the positive selecting cells in the thymus and the APCs in the periphery may not be a major obstacle to the achievement of adequate immune function, perhaps reflecting the fact that MHC reactivity is inherent in unselected TCR sequences (33,38). Importantly, human T cells can also be rendered specifically tolerant of the porcine donor by developing in xenogeneic porcine thymus grafts (800). This approach has been applied and has demonstrated promise in pig-to-primate xenograft models *(801,802)*.

Transplantation of allogeneic *(803)* and concordant xenogeneic *(804)* thymic epithelial tissue obtained from fetuses before seeding with hematopoietic cells can also induce tolerance. The mechanism of tolerance in such animals seems to predominantly involve generation of donor-specific regulatory cells *(805,806)*. Transplantation of xenogeneic thymic tissue into congenitally athymic recipients has frequently resulted in the development of a multiorgan autoimmune syndrome, possibly resulting from the lack of recipient-type thymic epithelium needed for the development of regulatory cells with specificity for certain recipient antigens *(601,602,807,808,809,810)*. This complication occurs much less frequently in thymectomized, T-cell–depleted mice than in congenitally athymic mice receiving porcine thymic transplants *(811)*, probably because of the persistence of regulatory cells derived from the host thymus prior to thymectomy and T-cell depletion.

Development of Chimerism Without Host Conditioning

Developmentally Immunoincompetent Recipients. One of the first demonstrations of acquired tolerance was obtained in Freemartin cattle, which are fraternal twins that share a placental circulation and develop mixed chimerism spontaneously *in utero* (812,813). Because prenatal diagnosis of a number of congenital diseases has become possible, injection of allogeneic PHSC to preimmune human fetuses has been explored and used successfully to correct immunodeficiency diseases diagnosed *in utero* (*814,815,*816). Chimerism was detected in the T-cell compartment afflicted by the congenital deficiency, and not in other hematopoietic lineages. Low levels of chimerism have also been achieved in preimmune normal mouse fetuses and sheep receiving *in utero* transplants *(817)*. In a large-animal model, successful engraftment of enriched human PHSC populations has been successfully achieved without GVHD (*818,819,*820). Although the ability of *in utero* HCT to induce transplantation tolerance has been somewhat unpredictable *(821,822)*, durable chimerism and renal allograft tolerance have recently been achieved in a porcine model involving *in utero* transplantation of T-cell–depleted adult bone marrow *(823)*.

Acquired immune tolerance was first demonstrated by Billlingham and colleagues *(824)*, who injected allogeneic cells and tissue lysates into untreated neonatal mice, which then demonstrated unresponsiveness to donor skin grafts. Lasting microchimerism and even sufficient levels of chimerism for flow cytometric detection (macrochimerism) have been observed in some neonatally tolerized mice (825,*826,827*). Both intrathymic and extrathymic deletional mechanisms of tolerance have been implicated in some strain combinations (825,*826*). The presence of microchimerism does not predict skin graft tolerance in perinatally injected mice, and nontolerant animals can maintain microchimerism following donor graft rejection *(828,829)*. Regulatory cells probably play a role in rodents in which neonatal tolerance has been induced, as tolerance cannot be easily broken by the infusion of nontolerant host−type lymphocytes (825,*830,831*). In contrast, when deletional tolerance is induced in animals in which the pre-existing peripheral T-cell response has been fully ablated (e.g., mixed chimeras prepared with the myeloablative or nonmyeloablative regimens previously described), the absence of suppressive cell populations makes it easy to abolish tolerance by the infusion of nontolerant host-type lymphocytes (749,*832*). Neonatal mice tend to produce Th2 responses, which may promote donor-specific skin graft acceptance *(413,*414). However, neonatal mice are capable of mounting CTL and Th1 responses under certain conditions *(833,834)*. The ability of allogeneic spleen cell infusions to induce tolerance may also reflect the high ratio of non-costimulatory APCs (T and B cells) in donor inocula to recipient T cells in

the neonate, rather than to any unique susceptibility to tolerance induction *(835)*.

Adult Recipients. Based on the recent observation that microchimerism can exist for many years in the tissues of human recipients of solid-organ allograft recipients who did not receive hematopoietic cell transplants *(836)*, it has been hypothesized that microchimerism, resulting from emigration of passenger leukocytes from the graft to recipient tissues, leads to donor-specific tolerance *(837)*. "Microchimerism," which requires highly sensitive techniques for its detection, should be distinguished from the mixed chimerism previously discussed, in which multilineage chimerism is readily measurable by flow cytometry. Mechanisms by which microchimerism might conceivably promote peripheral T-cell tolerance include nonprofessional APC function of donor-derived B or T cells *(838–840)* and veto activity of T cells, NK cells, and other cell types, eliminating CTL reactive against antigens expressed on the veto cells *(841)*. If low numbers of donor hematopoietic stem cells engraft, donor leukocytes migrating to recipient thymi might induce central tolerance among T cells that develop subsequently. Adult rodent liver grafts contain self-renewing hematopoietic stem cells *(842,843)*, and DC progenitors have been detected in the marrow of mice that spontaneously accept mouse liver allografts *(844)*.

However, the hypothesis that microchimerism leads to tolerance is controversial (845), and it is currently unclear whether microchimerism is even associated with tolerance. Lasting microchimerism does not appear to play a role in several animal models of tolerance in which the issue has been carefully examined *(846–848)*, and tolerance is by no means assured in the presence of microchimerism *(849)*. It is also clear in humans that microchimerism neither denotes a state of tolerance nor is required to maintain an allograft under all circumstances (845,849–851).

Recently, several groups have evaluated the ability of donor bone marrow cell infusions given without recipient myelosuppression or T-cell depletion to enhance graft survival in recipients of standard chronic immunosuppressive therapy *(852,853)*. Such transplants can be associated with significant risks from possible immunosuppressive effects of the transplant and from GVHD *(854,855)*. Although no significant impact on acute rejection episodes or immunosuppressive medication doses were observed *(854)*, the incidence of chronic renal allograft rejection was significantly reduced on longer follow-up in one of these series (856). Studies with living donor renal transplantation *(857)* or cadaveric liver transplantation (858) did not reveal significant improvements in outcomes or reductions in immunosuppression in recipients of donor bone marrow, despite the persistence of and gradual increase in low levels of chimerism *(857)*.

These studies did not include intentional peripheral T-cell depletion of the hosts. In a nonhuman primate model that includes recipient pretreatment with antilymphocyte serum for T-cell depletion, and, for optimal results, total lymphoid irradiation (TLI), veto cells in donor bone marrow that inactivate recipient CTLp may promote graft acceptance *(859)*. However, only a fraction of recipients show long-term graft acceptance, with the best results obtained when the donor and recipient share a DR class II MHC allele (860). The combination of anti-lymphocyte globulin and TLI with donor BMT has begun to be evaluated in pilot clinical studies (see "From Animal Models to Clinical Transplantation Tolerance").

In contrast to the model using anti-lymphocyte serum without irradiation, macroscopically detectable, though transient, chimerism has been observed in an otherwise similar primate model that includes a sublethal dose of host irradiation (762). The mechanism by which myelosuppressive conditioning promotes marrow engraftment may include both the creation of physical niches due to the destruction of host hematopoietic cells, and the up-regulation of cytokines that promote hematopoiesis. Recent studies have implicated up-regulation of chemokine SDF-1, which binds to stem cell CXCR4, and complement (C3) cleavage fragments in radiation-induced marrow injury and promotion of stem cell homing to that microenvironment *(861)*. In mice, myelosuppression is required to promote engraftment of syngeneic marrow cells given in numbers similar to those that could be obtained from marrow of living human allogeneic marrow donors *(750)*. However, this requirement can be overcome by the administration of very high doses of syngeneic marrow *(862,863)*. Furthermore, engraftment of high doses of allogeneic marrow can be achieved without myelosuppressive treatment in mice that receive T-cell–depleting mAbs *(753)* or costimulatory blockade *(755,756)*. This approach has been successfully extended to a full haplotype-mismatched porcine model *(764)*. These studies demonstrate that multilineage mixed chimerism and lasting, systemic deletional tolerance can be achieved without requiring recipient T-cell depletion or myelosuppression. However, practical approaches to obtaining such numbers of allogeneic PHSC in humans have not yet been developed.

Strategies to Achieve Peripheral Tolerance

Donor Specific Transfusion/Gene Therapy with Autologous Cells

In rodents, donor-specific transfusions (DSTs) have the ability to prolong allograft survival *(864)*, and in certain donor/recipient combinations have been shown to induce operational tolerance *(865)*. In most other species, DST alone has a less dramatic impact on graft outcome, but there is no doubt that it can influence graft survival in a positive manner and even in humans has been shown to be

beneficial to graft outcome *(866,867)*. However, alongside these potential positive effects, infusion of cells expressing alloantigens from the organ donor can also have negative effects, including sensitizing the recipient to donor alloantigens, thereby increasing the risk of hyperacute rejection. Moreover, with the introduction of erythropoietin into clinical practice there was no longer a medical need to use transfusions to treat dialysis patients on transplant waiting this; thus, the practice has largely stopped.

Investigations into the mechanisms by which alloantigen infusion or donor antigens released from the graft at the time of transplantation can manipulate the immune response to a subsequent transplant have provided important insights into how the adult immune system can be manipulated *in vivo*. Studies in rodents have shown that the level of unresponsiveness induced varies considerably depending on the quantity and source of alloantigen infused as well as the immune status of the recipient *(868)*. Interestingly, it was not found necessary to pretreat recipients with every donor major and minor histocompatibility antigen they would subsequently encounter on the allograft. Exposure to a single-donor alloantigen was sufficient to induce some graft prolongation as long as the allograft also expressed the same alloantigen *(869,*870). This phenomenon was demonstrated in a number of experimental systems both in models of transplantation and autoimmune disease and is referred to as *linked unresponsiveness* or *suppression* (871,*872,873)*. The mechanisms underpinning this effect have subsequently been elucidated and involve regulatory or suppressor T cells *(874)* that once activated can mediate so-called bystander suppression, a mechanism identified initially *in vitro (709)* that also operates *in vivo*, thereby influencing the functional activity of other leukocytes present in the same microenvironment *in vivo* (710).

An alternative strategy to using allogeneic cells for inducing specific unresponsiveness is to manipulate recipient cells to express defined MHC molecules that are subsequently expressed by the graft. The first proof of concept study using this approach transfected a fibroblast cell line of recipient origin with a mouse MHC class I gene, *H2K^b* (870). When the transfectants were used to pretreat recipient mice before transplantation, graft survival was prolonged. Obviously, cell lines are not applicable to the clinical situation and therefore recipient or autologous bone marrow cells and hematopoietic stem cells were investigated as alternatives. This approach, using either replication defective retroviral or adenovirus constructs, has permitted markedly prolonged survival of class I–disparate skin grafts bearing the class I gene that was introduced into the autologous marrow *(775)* and fully allogeneic heart allografts *(875)*. In some settings, tolerance to the transduced antigens can be induced either by infusing the transduced cells alone *(876)*, or by combining the transduced cells with other immune modulating agents (776,877,878).

As with other approaches to tolerance induction, the persistence of the antigen, either in the form of the transduced cells, or after transplantation, from the graft is critical to the maintenance of the unresponsive state *in vivo (879)*.

Tolerogenic APCs

DCs are central to the activation/priming of an immune response, but paradoxically they can also promote the development of tolerance (*880,*881). The key to both functions center on the state of maturation of the DC when it functions *in vivo* and/or its lineage. Initially, immature myeloid DCs that express low levels of MHC class II and costimulatory molecules at the cell surface were identified as the dominant form of DC that had the capacity to induce T-cell tolerance. In contrast, mature myeloid DCs that express much higher levels of both MHC and costimulatory molecules were required for priming T-cell responses. However, mature DCs have subsequently also been shown to have the capacity induce tolerance; therefore, the relationship between the state of maturity of a DC and its tolerogenic potential is now less clear. In addition, plasmacytoid DCs (pDCs) have also been found to have a role in tolerance induction. pDCs were originally defined by their capacity to secrete large amounts of type I interferons in response to viruses and to play an essential role in protecting individuals against inflammatory responses to harmless antigens but they have now also been shown to be able to induce human regulatory T cells *in vitro* that produce significant amounts of IL-10, low IFN-γ, and no IL-4, IL-5, or TGF-β *(712)*. pDCs, unlike myeloid DCs, can rapidly express ICOS-L (ligand of inducible costimulatory protein) on maturation, which has been found to play a key role in the generation of IL-10–producing regulatory T cells *(882)*. In mice, preplasmacytoid DCs appear to be capable of facilitating hematopoietic stem cell engraftment, thereby promoting donor-specific skin graft tolerance in allogeneic recipients *(883)*. However, the exact role and practicality of using preplasmacytoid DCs in this setting requires clarification, as T cells are more abundant and hence more powerful in promoting engraftment. Significantly, donor-derived preplasmacytoid DCs infused 7 days before transplant were found to prolong subsequent heart allograft survival (from 9 to 22 days) in the absence of immunosuppressive therapy *(884)*, but this effect was markedly enhanced by anti-CD154 mAb administration *(885)*.

Immature DCs have been shown to promote tolerance to solid-organ allografts and bone marrow grafts. For example, a single injection of immature donor-derived DCs 7 days before transplantation of an MHC-mismatched heart allograft extends *(886)* or prolongs survival indefinitely *(887)* in a donor-specific manner. The potential tolerogenic effects of immature DCs can be potentiated by the coadministration of immune modulating agents such as costimulation blockade *(888)*. Among several distinct approaches to generate stably immature DCs,

pharmacologic manipulation may offer a promising and clinically applicable option. For example, sirolimus has been found to inhibit DC maturation and effector function *(889)*. "Alternatively activated" or "regulatory" DCs, which have low costimulatory ability, were also found to protect MHC-mismatched skin grafts from rejection *(890)* and to protect mice from lethal acute GVHD when administered 7 days before transplantation *(891)*.

Reports showing that mature DCs can induce tolerance despite expressing high levels of MHC and costimulatory molecules include *in vitro* data with human cells demonstrating that maturation of human monocyte-derived DC with TNF-α and prostaglandin E2 triggered cross-priming and proliferation of CD8$^+$ T cells with tolerogenic properties *(892)* and that mature but not immature DCs can prime CD4$^+$ T cells that inhibit allogeneic mixed leukocyte reactions *(893)*. *In vivo*, bone marrow-derived DC matured with TNF-γ, but not lipopolysaccharide or antibody to CD40, protected mice from CD4$^+$ T cell-mediated experimental autoimmune encephalomyelitis, despite the expression of high levels of MHC class II and costimulatory molecules *(894)*.

Taking the data using different populations of DC together, it seems that both myeloid and pDCs can promote tolerance, and that maturation by itself is not the distinguishing feature that separates their immunogenic from their tolerogenic function. Indeed, maturation is more of a continuum than an "on-off" switch, and a "semimature" state, in which DCs are phenotypically mature but remain poor producers or proinflammatory cytokines, appears to be linked to tolerogenic function (895). The combination of DCs administered with costimulatory blockade may be the most promising approach identified thus far.

T-cell Depleting Antibodies

Many tolerance induction strategies that have been investigated in small- and large-animal studies have used depletion of leukocytes (antithymocyte globulin, anti-CD52) or T cells (anti-CD3 with or without immunotoxin, CD2, CD4, and CD8) to create an environment *in vivo* that allows "reprogramming of the immune system" (896). In small animals, the short-term depletion of T cells, in combination with an allograft, appears to be sufficient in some situations for tolerance to develop and be maintained in the long term. The success rate can be enhanced by removing the thymus before transplantation to prevent repopulation of the periphery with T cells after transplantation *(897)*. Initial data from primates using immunotoxin conjugated anti-CD3 alone before transplantation or in combination with deoxyspergualin, a drug which inhibits NF-κB and therefore monocytes and macrophages, at the time of transplantation suggested that T-cell depletion can be used to induce tolerance to donor alloantigens *(898–900)*. However, follow-up trials in humans undergoing renal transplantation and T-cell depletion with the anti-CD52 mono-

clonal antibody alemtuzumab with or without deoxyspergualin revealed that neither profound T-cell depletion alone or in combination with deoxyspergualin induced tolerance in humans *(901,902)*. However, clinical results, across organ systems, reveal that steroid-free regimens with reduced maintenance doses of immunosuppression may be used after alemtuzumab therapy (*903,904,905*).

Depletion of leukocytes at the time of transplantation creates a transient immunodeficiency in the recipient, compromising the recipient's ability to reject the transplant. The degree and duration of leukocyte depletion achieved determine how effective and for how long the graft is protected from immune attack *(906,907)*. The downstream events that occur once leukocytes begin to reappear in the recipient's circulation are not understood clearly. Studies using TCR transgenic recipients have shown that when leukocytes are depleted, the maintenance of tolerance depends on transplantation of the graft within a time window of depletion of donor-reactive cells in the thymus and periphery *(908)*. If the organ graft is transplanted at the appropriate time, donor-reactive cells fail to repopulate from the thymus in an antigen-selective manner. Although donor-reactive cells do not reappear in the periphery, cells with reactivity to other antigens repopulated the periphery of recipients with long-term surviving organ grafts. These data can be used to suggest a mechanism for the long-term survival observed in primates treated with anti-CD3 immunotoxin complex. In this case one can argue that the CD3$^+$ T cells are depleted by the immunotoxin before transplantation. A window of opportunity is created such that when a renal allograft is transplanted, no donor-reactive cells are present in the periphery. As cells repopulate the periphery with time after the transplantation, donor-reactive cells are deleted or eliminated as a result of the presence of the surviving graft.

Costimulatory Blockade and Other Biological Proteins

With Solid Organs. T-cell activation, and hence rejection, depends on multiple signals. Cell-surface costimulatory molecules provide "signal 2." which, when combined with "signal 1" through TCR, triggers the activation of naïve T cells *(909,910)*. When signal 1 is forced to act on its own, T cells have been shown to undergo anergy or apoptosis (627). The original concept of a single costimulatory pathway has long been superseded and it is now clear that there are multiple levels at which costimulation can participate both in initiating and determining the direction that an immune response takes (911). Nevertheless, targeting costimulatory pathways with either monoclonal antibodies or recombinant fusion proteins specific for the costimulatory molecule itself or the ligand with which it interacts can be very effective at suppressing immune responses and in some cases may have the capacity to induce tolerance to donor antigens *in vivo*.

Members of the immunoglobulin and TNF/TNFR superfamilies make up many of the costimulatory molecules that are integral to positive costimulation in the pathway of T-cell activation. Two pairs of ligand-receptor interactions that seem to play key roles in positive costimulation are CD40/CD40-ligand (CD154), which are members of the TNF/TNFR superfamily and CD80/CD86 and CD28, which belong to the Ig superfamily (911). Although the precise role that each of these costimulatory pathways plays during rejection and tolerance is still not completely understood, the complete abrogation or attenuation of either of these pathways can modulate the immune response to an allograft *in vivo*. Recent development of CD28 blockade by CTLA-4Ig (Abatacept) for rheumatoid arthritis and clinical trials with modified CTLA-4 Ig (Belatacept) for transplantation shows promise for the utilization of costimulation blockade in suppressing effector responses (912,913).

The B7:CD28/CTLA-4 Pathway. CD80(B7-1) and CD86(B7-2) are expressed as cell surface molecules by APCs and are responsible for delivering additional signals to T cells when they interact with CD28. CD86 and CD80 can also interact with a second molecule, CD152 (CTLA4), which is expressed by T cells later in the activation process and is expressed constitutively by regulatory T cells. CD86 and CD80 can exhibit preferential binding to CD28 and CD152, respectively *(914)*. In contrast to CD28, CTLA4 negatively regulates T-cell activation when it engages its ligand on the APC and, as described previously, is implicated in normal homeostasis in the immune system *(915)*. However, the precise role that CTLA4 plays during T-cell activation and regulation requires further clarification *(916)*. CTLA4 is pivotal in regulating the threshold of signals during T-cell activation and recent findings suggest that up-regulation of CTLA-4 expression increases T-cell motility and overrides the TCR-induced stop signal required for stable conjugate formation between T cells and APCs. This results in reduced contact periods between T cells and APCs, leading to decreased cytokine production and proliferation *(916)*.

Using the B7:CD28/CTLA-4 Pathway for Therapeutics. When CTLA4Ig, an immunoglobulin fusion protein of CTLA4, was produced, it was shown to inhibit graft rejection in xenogeneic and allogeneic systems *(917,918)*. In rodent models, CTLA4Ig therapy has been shown to have the capacity to induce tolerance to some types of grafts *(917,919)*, an effect that was enhanced when infused donor antigen was included in the treatment protocol (919,*920,921*). This effect has not been found in every experimental model examined, however. For example, the use of CTLA4Ig monotherapy in primates has not been reported to be capable of inducing long-term graft survival *(922)*.

The mechanism by which CTLA4Ig promotes graft survival has been investigated in a mouse model. Blockade of CD80 and CD86 at the time of alloantigen recognition has been suggested to trigger T-cell apoptosis in the early phase after transplantation (625); however, it should be noted that no specific markers for alloantigen-specific T cells were incorporated into this analysis and therefore more detailed studies to confirm this property would add value. When an antiapoptotic gene, *bcl-x_L*, was expressed in the responding lymphocytes, deletion did not occur, and graft prolongation was prevented. This finding suggests that CTLA4Ig facilitates the development of long-term graft function by reducing the number of donor-reactive cells that have to be controlled downstream in the posttransplant course.

Although primate models using CTLA4Ig to induce tolerance proved to be largely unsuccessful, the theoretical foundation of blocking this pathway to promote graft survival continued to intrigue researchers. Additionally, it was known that the binding properties of CTLA4 could be manipulated to optimize the ligation of both CD80 and CD86, a crucial component to experimental efforts at tolerance induction (912).

Belatacept. Experiments using CTLA4Ig laid the groundwork for further development of therapeutic agents targeting the B7:CD28/CTLA4 pathway. Belatacept, LEA29Y, was originally derived from the fusion protein CTLA4Ig, or Abatacept (913,*923*). It differs from CTLA4Ig by two amino acids, conferring an approximately twofold increased binding capacity to CD80 and CD86. This increase in avidity allows for a tenfold increase in the *in vitro* suppression of T-cell activation when compared with CTLA4Ig and in nonhuman primate studies, Belatacept was found to prolong renal allograft survival and inhibit donor-specific alloantibody production both alone and in combination with other traditionally used immunosuppressive regimens *(923)*. These and other findings allowed for the translation of LEA29Y to renal transplant patients in the clinics. To date, results of phase 2 trials comparing Belatacept with cyclosporine in partially randomized studies across 22 centers in North America and Europe of more than 200 patients suggest that Belatacept is not inferior to cyclosporine. In fact, results of this trial revealed that patients with Belatacept-based therapy had improved renal function, reduction in chronic allograft nephropathy, and decreased calcineurin-related toxicity *(924)*. Additionally, recent experiments in nonhuman primates using neonatal porcine islet grafts have revealed long-term xenograft survival under the cover of CD28-CD154 blockade with maintenance immunosuppression of sirolimus and Belatacept (925). Although promising, further trials and vigilant follow-ups are necessary to accurately assess the efficacy of these new therapeutic regimens.

CD40-CD154 Pathway. The CD40-CD154 pathway has been targeted to inhibit graft rejection using monoclonal antibody therapy either alone *(926,927,928)* or in combination with alloantigen infusion *(929)*. CD154, or CD40-ligand, is a type 2 membrane protein of the TNF family and is expressed predominantly by activated CD4+ T cells and by a small proportion of CD8+ T cells, NK cells and eosinophils *(930)*, and, significantly, on platelets as well *(931)*. Structural models predict that CD154 forms a homotrimer that binds to CD40 on the surface of APCs. CD40 is expressed by B cells, macrophages, DCs, thymic epithelium, and is inducible on the surface of endothelial cells and fibroblasts.

The CD40-CD154 pathway interaction is pivotal for the induction of humoral and cellular responses to nominal antigens as well as alloantigens. A CD40-Ig fusion protein and a blocking monoclonal antibody to CD154 were shown to inhibit B-cell cycling, proliferation, and differentiation into plasma cells in response to T-cell–dependent antigens *(932)*. *In vivo* studies using CD154 monoclonal antibody or CD40 or CD154 knockout mice *(933,934)* demonstrated a crucial role for this interaction in the generation of primary and secondary humoral responses to T-cell–dependent antigens, class switching, and development of germinal centers. The lack of a humoral response in the absence of CD40-CD40L interaction is caused not only by a lack of signalling through CD40 on the B-cell surface, but also the inhibition of priming of CD4+ T cells through CD40L *(935)*.

CD40 triggering on the APC primes the APC for stimulation. Signals through CD40 have been shown to upregulate expression of CD80 and CD86, as well as induce IL-12 *(936)*. Activation of DCs through CD40 promotes their ability to present antigen to T cells; this may explain why targeting CD154 and blocking its ability to interact with CD40 has a profound effect on T-cell–dependent immune responses *in vivo*. If modification of APC function is also a route to the development of tolerance *in vivo*, as previously outlined, blocking CD154-CD40 interactions may also influence tolerance induction by altering both the interaction and signals between APC and immunoregulatory and suppressor T cells *(937)*.

Using the CD40-CD154 Pathway for Therapeutic Intervention in Cell and Organ Transplantation. Long-term acceptance of cardiac, renal, and islet allografts in several mouse and nonhuman primate models has been achieved with CD40 blockade using anti-CD154 monoclonal antibody as monotherapy or in conjunction with CTLA4Ig *(926,929,938,939)*. With the exception of BMT, in which durable chimerism and tolerance can be achieved with anti-CD154 mAb (see later discussion), so-called tolerant states generated by anti-CD154 therapy alone have been shown to disappear when therapy is withdrawn, leading to rejection. Even with CD28 blockade, anti-CD154 therapy

must be sustained to promote permanent engraftment of cardiac or islet grafts *(938,940,941)*.

Although promising results were reported in experimental models, anti-CD154 therapy was found to have the unexpected complication of thrombogenesis. It was then that CD154 was found to play key roles in coagulation and clotting, with some reports suggesting that CD154 acts to stabilize thrombi while others implicate CD154 in platelet activation *(933)*. Whatever the role that CD154 may play in transplantation tolerance, it is clear that this molecule acts via independent pathways in a variety of cascades unrelated to tolerance induction.

Interest in this approach was also reflected in reports that a humanized monoclonal antibody specific for CD154 (hu5c8) was capable of prolonging the survival of renal and islet allografts in rhesus monkeys *(922,927,942)*. The initial data from these primate studies appeared encouraging, with rejection-free survival of the kidney grafts, provided that antibody therapy at a relatively high dose (25 mg/kg) was continued in the first 6 months posttransplant. When anti-CD154 therapy was discontinued after the first month posttransplant, rejection episodes did occur. Analysis of the status of recipients with long-term surviving grafts showed that peripheral lymphocytes from the monkeys failed to respond *in vitro* to donor antigens, but the recipients developed antidonor antibodies, and biopsy samples from some of the long-term surviving grafts revealed T-cell infiltrates. Together, these observations were sufficiently encouraging to initiate a pilot clinical study using hu5c8 in renal transplantation. In this study, hu5c8 was administered to seven patients with low-dose steroid alone and five patients experienced episodes of rejection (943).

Other variants of costimulatory blockade that target different epitopes of CD154 have been developed with hopes of improved tolerance induction and without promotion of thrombogenesis. Recent experimental results in cardiac allografts of cynomolgus monkeys treated with an inhibitor of CD154, IDEC-131, either alone or in combination with leukocyte depletion in the form of antithymocyte globulin prolonged allograft survival; however, tolerance was not induced, as alloantibody production and transplant vasculopathy, while delayed, still occurred (944). Recently, the utilization of triple therapy with an abbreviated course of mTOR inhibition (sirolimus), a donor-specific transfusion, and IDEC-131 prevented allograft rejection and induced operational tolerance in rhesus monkeys undergoing MHC-mismatched renal transplantation (945). Still other anti-CD154 antibodies, such as ABI793, have been developed, but have also been plagued with continued thromboembolic complications (946).

To understand why CD154 blockade was effective in some but not other settings, an analysis in the mouse revealed that that only when rejection depended on CD4+ T cells was CD154 blockade on its own effective at prolonging graft survival. In fact, in donor-recipient combinations in

which CD8 T cells also play a role in rejection, many studies have shown that the CD8 T cell subset is unaffected by CD154 monoclonal antibody therapy *(947,948)* such that CD8 T cells become activated, proliferate, and home to the graft in the presence of high-dose continued anti-CD154 monoclonal antibody therapy *in vivo (948)*.

Further studies have been undertaken to evaluate antibodies to CD40 in order to bypass the potential ramifications of CD154 blockade. Initial animal knockout models revealed a propensity of CD154 knockout mice to develop unstable thrombi, a phenomenon not seen in CD40 knockout mice *(949)*. Preliminary studies in the rhesus monkey renal allograft model reveal somewhat promising results with a short course of low-dose calcineurin inhibitor administered concomitantly with anti-CD40/anti-CD86 costimulation blockade (950). In this study, two of four animals developed 3-year drug-free graft survival, and none of the animals developed alloantibodies to the donor, suggestive of tolerance induction (950).

Targeting CD3 and Accessory Molecules. Initially, administration of depleting anti-CD4 and anti-CD8 monoclonal antibodies was shown to result in prolonged graft survival *(951–953)*. That this treatment strategy resulted in antigen-specific tolerance was first shown most clearly when a protein antigen was administered in conjunction with a depleting anti-CD4 monoclonal antibody *(954–956)*. Refinements of these types of protocols have resulted in the ability to achieve long-term T-cell unresponsiveness to protein and alloantigens in the absence of T-cell depletion in experimental models *(957–959)*. In fact, many other accessory molecules, other than anti-CD4 and anti-CD8, have been targeted in an attempt to induce tolerance in models of bone marrow *(960,961)*, islet *(962–964)*, renal *(965)*, and cardiac allografts *(961,966,967)*, to name a few.

OKT3, a murine antihuman CD3 monoclonal antibody, received approval for human use in 1986 in kidney transplant patients undergoing rejection and eventually for liver and cardiac transplant recipients as well (968). Although widely used, OKT3 brings with it the undesired complications of the human antimouse antibody response as well as a first-dose reaction characterized by fevers, chills, gastrointestinal, respiratory, and cardiac complications *(969,970)*. These ramifications are thought to be the result of T-cell activation and subsequent cytokine release (968). Therefore, many investigators have attempted to construct pharmacotherapeutics that mimic the efficacy of OKT3 with less immunogenicity. A few of these OKT3-derived molecules in preliminary studies such as hu12F6, hOKT3gamma1 (Ala-Ala), and ChAglyCD3 have proven to be more effective in T-cell suppression and less immunogenic when compared with OKT3 (968,*971,972*).

Along with anti-CD3, antibodies to CD11a (leukocyte function associated antigen-1, LFA-1) and its ligands, ICAM-1, -2, and -3, have been investigated and have led to prolonged graft survival in many of the aforementioned models. LFA-1 has been implicated as an essential molecule for cellular trafficking and motility as well as T-cell activation *(973,974)*. Additionally, reports also suggest that the interaction of LFA-1 and the ICAM molecules serve as a costimulatory pairing for T-cell activation *(975)*.

Operational tolerance induced by these strategies has been shown to develop over several weeks after the initial antigen encounter *(976,977)*. When a combination of donor antigen and monoclonal antibody therapy targeting accessory molecules is used, the precise mechanism of tolerance induction in part depends on the amount of antigen infused *(959)*. Deletion also may be used as one of the mechanisms of tolerance initially *(868,978)*, but in the absence of complete deletion of donor-reactive cells, immunoregulation develops. When antibodies targeting accessory molecules are used as therapeutic agents at the time of transplantation, immunoregulation is the dominant mechanism that comes into play to maintain tolerance in the longer term *(979)*.

In these systems, tolerance to donor antigens is induced and/or maintained as a result of the development of a population of regulatory and suppressor T cells that can mediate unresponsiveness to the initiating donor antigen as well as other antigens present on the graft, the phenomenon of linked unresponsiveness *(980)*. In mice and rats, this type of tolerance has been shown to be infectious *(691)*; it can be transferred from one generation of cells to another, provided there is sufficient period of contact between the two populations.

The maintenance of tolerance in these systems requires the persistent presence of antigen in the form of the organ when the thymus is still functional *(981)*. In the absence of donor antigen, tolerance is eventually lost, presumably as a result of the export of naïve cells T cells from the thymus into the periphery. Quantitatively, if these cells fail to encounter antigen, they eventually outnumber the unresponsive T cells induced by the monoclonal antibody therapy.

Costimulatory Blockade with Infusion of Donor Hematopoietic Cells

Although long-term tolerance is maintained by intrathymic deletion in mixed chimeras prepared with costimulatory blockade *(751,755,757)*, initial tolerance of peripheral T cells involves specific deletion of donor-reactive CD4 *(652,751,982,983)* and CD8 *(485)* T cells. The deletion of CD4 cells achieved following BMT with anti-CD154 is not due to binding of anti-CD154 mAb to activated T cells, and only requires failure of the CD154-CD40 interaction *(984)*. This CD4 cell deletion is Fas-independent and is not blocked by cyclosporine, arguing against a role for "activation-induced cell death" *(983)*, which, in contrast, is thought to be involved in tolerance induction with anti-CD154 mAb plus rapamycin *(717)*. Peripheral

deletion of donor-reactive CD8 cells has been observed both in mice receiving donor-specific transfusions and/or BMT with costimulatory blockade *(485,623,624)*. CD8 deletion occurs within 1 to 2 weeks and requires the presence of CD25-negative CD4 cells *(485)*. CD4 regulatory cells are not required for maintenance of tolerance after this initial 2-week period *(485)*. Deletion of donor-reactive CD4 cells occurs more slowly, over 4 to 5 weeks, and is preceded by a state of specific anergy toward the donor *(652,984)*. Regulatory cells do not appear to play a major role in maintaining the long-term tolerance induced by costimulatory blockade with BMT because tolerance and chimerism are obliterated by the infusion of relatively small numbers of nontolerant recipient-type spleen cells in this model and linked suppression is not observed *(652)*. Because hematopoietic stem cell engraftment ensures complete central deletional tolerance in these long-term chimeras *(751,755,757,982)*, and specific peripheral deletion is quite complete, there may be insufficient donor-reactive T cells present to induce the expansion and maintenance of specific regulatory cells.

Administration of DST under cover of blocking anti-CD40L mAb prevents islet allograft rejection *(938)*. Like BMT, the use of DST involves administration of hematopoietic cells, but only BMT with mixed chimerism induction leads to engraftment of hematopoietic stem cells and intrathymic deletion as the mechanism maintaining long-term tolerance *(752,755)*. In thymectomized mice, the combination of DST and anti-CD40L leads to long-term skin graft survival in fully MHC-mismatched recipients *(491)*. In euthymic mice, only a small fraction of animals achieve long-term skin graft survival with this treatment *(929)* indicating the failure to establish central tolerance without hematopoietic stem cell chimerism *(623)*. In addition, the inability to resist breaking of tolerance by new thymic emigrants in this model argues that powerful peripheral regulatory mechanisms (suppression) are not operative in these animals. However, regulatory mechanisms may play a role in the initial suppression of alloresponses, as depletion of CD4 cells abrogated skin graft acceptance *(491)*. Both CTLA4 and IFN-γ have been shown to play an important role in the induction of tolerance in this model *(491,496,985)*. CTLA4 appears to also be critical for the achievement of mixed chimerism and tolerance with BMT and anti-CD154 mAb (J. Kurtz and M. Sykes, unpublished data, 1998), but IFN-γ and IL-2 do not play a requisite role *(485)*, consistent with the lack of requirement for "natural" regulatory cells. DST in this model promotes peripheral deletion of donor-reactive CD8 T cells *(623)*, and can be replaced by CD8 depletion with mAb *(985)*. The combination of anti-CD154, BMT and DST seems to be particularly effective in achieving mixed chimerism, largely because of the capacity of DST to overcome residual CD8 T cell-mediated alloresistance *(624,986)*.

Costimulatory blockers have been explored for the induction of graft-versus-host tolerance in order to prevent GVHD in BMT recipients. GVHD has been inhibited by B7/CD28 blockade or anti-CD154 mAb *(987–989)*. Pre-BMT exposure of donor T cells to recipient alloantigens in the presence of anti-CD40L inhibits GVHD via a mechanism involving CD25$^+$ regulatory CD4 cells *(682)*. Clinically, a reduced incidence of acute GVHD has been observed in leukemic patients receiving HLA-mismatched bone marrow transplants that had been exposed to recipient alloantigens in the presence of CD28 blockade with CTLA4Ig *(990)*. Blockade of 4–1BB/4–1BBL costimulatory interaction can also suppress GVHD and GVL *(991)*.

A Large-animal Tolerance Model

MHC-defined, inbred miniature swine have provided an instructive model for delineation of the role of various histoincompatibilities in tolerance and rejection in large animals. Studies of pig renal transplantation have demonstrated that spontaneous tolerance can be induced by organ grafts when MHC antigens are matched. The ability to achieve such tolerance depends on one or possibly two non–MHC-linked genetic loci in the recipient animals. The presence of the "acceptor" phenotype also permits the spontaneous acceptance of single haplotype class I–mismatched kidney grafts *(9)*. Graft acceptance is associated with donor-specific CTL unresponsiveness, apparently because of a deficiency in help for these CTL, and not because of a deletional mechanism. Thus, in class II–matched, class I–mismatched porcine donor-recipient pairs, a 12-day course of high-dose (10 mg/kg/day) CsA permits long-term renal allograft acceptance in 100% of cases *(9)*.

The requirement that class II antigens be matched between donor and recipient in order for this tolerance to be achieved may reflect the influence of a major difference in class II antigen expression that exists between large and small animals. Unlike large animals and man, in which class II antigens are expressed constitutively on vascular endothelial cells, the corresponding endothelial cells of rodent species do not express MHC class II molecules *(992,993)*. Consistent with this interpretation, the use of a short course of CsA can facilitate the ability of renal allografts to induce tolerance in rodents across fully MHC-mismatched barriers, but tolerance induction in swine requires class II matching between donor and recipient for uniform success.

Animals accepting class II matched allografts are systemically tolerant to the donor's class I and minor antigens, as indicated by the fact that the accepted graft can be removed and replaced by a second donor-matched graft, which is accepted without immunosuppressive therapy. This ability of CsA to facilitate tolerance induction, and the ability of exogenous IL-2 to prevent the induction of

tolerance in this model *(9)*, are consistent with the interpretation that induction of tolerance of donor class I–reactive CTL is due, at least in part, to the absence of adequate T-cell "help" during the time of initial exposure to antigen. A selective decrease of expression of the Th1-associated cytokine IFN-γ relative to the Th2-associated cytokine IL-10 has been observed in these accepted grafts *(994)*. The thymus appears to play a role in the induction of tolerance among pre-existing peripheral T cells in this model, as removal of the host thymus prior to kidney allotransplantation leads to rejection *(995)*. The possible mechanisms responsible for this role of the thymus in inducing peripheral tolerance phenomena are discussed elsewhere in this chapter. The kidney allograft itself clearly plays an important role in the tolerance induced in this model. Class II–matched cardiac allografts are not accepted after a similar short course of CsA, but they are accepted if grafted to animals that are tolerized in this manner to kidney allografts bearing the same mismatched class I alleles as the donor heart *(538)*. The mechanisms of this tolerance have been demonstrated to involve regulatory T cells that can specifically suppress antidonor CTL responses *(996,997,998,999)*.

The Relationship Between Peripheral T-Cell Tolerance and Central Tolerance

In the pig model previously described, the thymus plays a role in the induction of tolerance among pre-existing peripheral T cells *(995)*. It is possible that T cells that are activated in the periphery by the organ allograft recirculate to the thymus *(1000)*, and may be tolerized there, with or without encounter with donor antigen. Alternatively, the migration of donor antigens or cells to the thymus may induce the development of regulatory T cells that specifically recognize the donor antigens and down-regulate alloreactive T cells when they enter the periphery *(1001,1002)*. The role of the thymus in the development of Treg has already been discussed previously. Finally, it is possible that recent thymic emigrants are required for the peripheral development of regulatory cells.

A second model involving the thymus in peripheral tolerance involves injection of donor antigens intrathymically. The initial idea underlying this approach was to use antibody treatment to deplete peripheral T cells and to induce central tolerance among recovering T cells by direct introduction of antigen into the thymus. However, more recent studies have shown that tolerance can be induced by intrathymic injection of soluble alloantigens without peripheral T-cell depletion *(1003)*. Because removal of the thymus before or within the first few days of allografting results in rejection of the allograft *(1004)*, the thymus must play an active role in tolerizing pre-existing peripheral T cells, possibly by one of the mechanisms proposed in the preceding paragraph. Evidence has been obtained

for recirculation of activated donor-reactive T cells to the recipient thymus in this model *(1005,1006)*, and active regulatory cell populations have been described *(1007)*. Transferable tolerance is not induced by intrathymic marrow injection alone without an organ allograft in rats *(1008)*, suggesting that the graft itself helps to tolerize the pre-existing T-cell repertoire. The intrathymic injection approach has not been successful in "high-responder" rat strain combinations *(1008,1009)*, and has not successfully allowed xenotolerance induction. Furthermore, chronic rejection of cardiac allografts was not prevented by intrathymic injection of donor spleen cells in antilymphocyte serum-treated rats *(1010)*. While one attempt to use this approach in nonhuman primates was discouraging *(1011)*, donor-specific skin graft prolongation was reported in three animals receiving allogeneic or xenogeneic (human) CD34$^+$ cells intrathymically *(1012)*.

From Animal Models to Clinical Transplantation Tolerance

Almost every transplant clinician has treated patients who have chosen to withdraw immunosuppressive therapy for a variety of reasons. The majority of such patients reject their allograft, but rare cases achieve "spontaneous" tolerance in this manner, demonstrating that tolerance can be achieved in humans. Extensive efforts are underway to identify markers that would distinguish such tolerant patients prospectively before withdrawal of immunosuppression, but so far none have been proven to be reliable. Although clinical trials have already begun in which tolerance-inducing strategies are combined with conventional pharmacologic immunosuppression, none of the strategies for achieving transplantation tolerance have been used to replace such chronic therapy in a large clinical series. In general, short-term results of most organ allograft transplants are excellent, making it essential to have extremely reliable methods of inducing tolerance in order to ethically justify their use in place of conventional chronic immunosuppressive therapies. Because the risk of rejection due to immunosuppression withdrawal is difficult to accept in patients, it is our opinion that extension of results from animal models to humans should only be attempted after: (i) rodent studies have demonstrated robust tolerance in multiple strain combinations using extensively histoincompatible, highly immunogenic grafts such as skin; (ii) efficacy has been demonstrated in large animal models; and (iii) acceptable toxicity has been demonstrated in large-animal models. When complete removal of immunosuppression can be achieved, the level of toxicity accepted in the short term may be somewhat higher than that which could be accepted on a long-term basis.

Although induction of central deletional tolerance with hematopoietic cell grafts is a reliable and durable approach to achieving permanent graft survival, earlier techniques

for achieving central tolerance have involved more vigorous ablation of the lymphohematopoietic system than can be safely achieved in larger animals. Thus, the major challenge in bringing the mixed chimerism/central tolerance approach to clinical application is to develop highly specific, nontoxic methods of conditioning the host for acceptance of a hematopoietic allograft or xenograft. The extensive animal data that have been accumulated on the ability of mixed chimerism induced with reduced intensity conditioning to achieve robust transplantation tolerance, including its demonstration in large-animal models (762,*1013*), combined with clinical data obtained in patients with a more conventional indication for HCT, have allowed clinical evaluation of this approach for tolerance induction. Mixed chimerism can be achieved with reduced toxicity using nonmyeloablative conditioning in patients with hematologic malignancies *(770)*, and lymphohematopoietic GVH reactions induced by DLI can be used to achieve graft-versus-tumor effects *(771)*. These observations provided an opportunity to evaluate the potential of this approach to induce transplantation tolerance in patients with a hematologic malignancy, multiple myeloma, and consequent renal failure. Six patients have received a simultaneous nonmyeloablative bone marrow transplant and renal allograft from HLA-identical siblings, and have accepted their kidney grafts without any immunosuppression for periods as long as 9 years, with very good tumor responses. Similar to the primate model previously described, in which BMT has been shown to be essential for tolerance induction *(1014)*, chimerism in several of these patients was only transient (772), suggesting that the kidney graft itself may participate in tolerance induction and/or maintenance after chimerism has played its initial role. Mechanistic studies performed in these patients suggest that tolerance may be specific for donor antigens expressed by the kidney, while responses to antigens expressed on hematopoietic cells but not the kidney may even be sensitized (772). Additional data suggest a possible role for regulatory cells in maintaining tolerance in such patients, but the precise nature of these cells is unclear (772). The promising results obtained in these patients have provided an important proof of principle, and another trial has now been initiated at the Massachusetts General Hospital in patients without malignancy who receive HLA-mismatched haploidentical bone marrow and kidney grafts with a regimen that leads to transient mixed chimerism without GVHD. Four of five patients receiving combined kidney and bone marrow transplantation with this protocol have achieved graft survival of immunosuppression for periods of one to >4 years. These patients show *in vitro* evidence of systemic donor-specific underesponsivness (1015). Thus, proof of principle has been obtained that organ allograft tolerance can be achieved across HLA barriers in humans using non-myeloablative bone marrow transplantation. Efforts to achieve HLA-mismatched kidney allograft tolerance with donor BMT

using the TLI/anti-thymocyte globulin conditioning regimen were unsuccessful *(761)*, but this approach did succeed in one patient receiving an HLA-identical donor transplant (1016).

Most techniques to achieve peripheral tolerance in larger animals have not been as effective as in rodent models. Furthermore, peripheral mechanisms alone have not been sufficient to reliably overcome the most stringent transplantation barrier imposed by fully MHC-mismatched primary skin allografts in rodents. The "infectious" nature of suppressive mechanisms of tolerance makes them potentially attractive as a means of inducing robust and durable tolerance. However, it will be difficult to control the development of such mechanisms until they are better understood. It seems likely that the optimal approach to achieving clinical transplantation tolerance might require combinations of both central and peripheral strategies.

TRANSPLANTATION OF SPECIFIC ORGANS AND TISSUES

Kidney Transplantation

Kidneys are the most frequently transplanted human organs, with approximately 10,000 kidney transplants being performed annually in the United States. Renal allograft survival has increased steadily since its inception, and at present there is more than 95% patient survival and more than 91% organ survival at 1 year *(1017)* However, even well-matched recipients of renal transplants must continue to take immunosuppressive medications for the rest of their lives, with complications including an increased risk of infection, cancer, hypertension, and metabolic bone disease. In addition, even when immunosuppression is well managed, there is an inexorable loss of kidneys to chronic rejection at a rate of approximately 5% to 7% per year. Both of these problems might be eliminated by the induction of tolerance. However, the success of clinical transplantation using immunosuppressive drugs has made it difficult to justify the risk of new approaches to tolerance. Only recently have clinical trials of tolerance induction for renal transplantation begun in earnest ([772,1015,1016] and see previous section).

As for other organs, a major obstacle in kidney transplantation is the shortage of organs, which has been a paradoxical consequence of the success of this field. Unlike hearts and livers, where the inadequate supply of cadaveric organs spells death for many potential recipients, candidates for renal transplants are instead faced with long periods on dialysis while they wait for a kidney. This waiting time can be 4 or more years even for unsensitized candidates, and even greater for those with high levels of sensitization. To avoid this delay, many patients are now being offered kidneys from living donors, and in many transplant centers the number of living donor renal transplants

performed per year now exceeds the number of transplants from cadaveric donors.

Sensitization of renal transplant candidates usually results from prior antigen exposure, either by blood transfusions or previous transplants. Such highly sensitized patients are said to have "high panel reactivity"; they may wait many years to obtain a kidney that is cross-match–negative, and some never receive a transplant at all. Indeed, as discussed later, these patients may be among the first to benefit if and when xenotransplantation becomes a clinical reality (1018).

Finally, as previously discussed, "chronic rejection" of kidney transplants is a continuing problem to the field and probably involves both immunologic reactivity and other factors, including the effects of the early ischemic injury and the ongoing effects of drugs and metabolic abnormalities in the recipient *(452)*. This process leads to an inexorable loss of organs at the rate of approximately 5% to 7% per year. Thus, although the 1-year survival rate for kidney transplants has improved from approximately 40% to more than 90% during the past 40 years, at 5 years there is only 71% graft survival and the half-life for kidney transplants has barely increased, remaining less than 10 years.

Liver Transplantation

Transplantation of the liver represents a major technical challenge. For this reason the organ and patient survival rates have not been as high as those for renal transplantation, but have nevertheless increased yearly, with a current 1-year organ survival rate of about 80% and patient survival rate of about 86% *(1017)*. There are currently about 6,000 liver transplants carried out in the United States per year. The severe shortage of available organs has recently led to use of living donors, although the number is still small, accounting for only about 5% of liver transplants, or about 300 cases per year in the United States. Living donation constitutes a higher proportion of liver transplants in countries such as Japan, where cadaveric donation is less widely accepted.

Immunologically, the liver is relatively resistant to early antibody-mediated rejection, allowing successful transplantation even across blood group barriers and in the face of a positive crossmatch, although a negative crossmatch is generally considered preferable *(1019–1021)*. In addition, long-term survival of liver transplants does not appear to be improved by HLA matching between donor and recipient *(1021)*. Both of these immunologic features may be responsible for the fact that the long-term results of liver transplantation are almost as good as those for kidney, with 65% graft survival and 71% patient survival at 5 years. Finally, transplantation of the liver carries with it large numbers of donor lymphoid cells, thus creating the potential for inducing GVHD *(1023)*. The symptoms can range from antibody-dependent hemolysis of recipient red blood cells across a blood group incompatibility to severe or even fatal, full-blown GVHD.

Heart and Lung Transplantation

There are approximately 2,000 heart transplants performed annually in the United States. As might be expected for this vital organ, the 1-year statistics for heart transplantation are approximately the same for patient (87%) and graft (86%) survival *(1017)*. One of the immunologic issues of particular importance in heart transplantation is the high rate of atherosclerotic disease in the coronary arteries of the donor organ, due at least partly to chronic rejection, as previously discussed. Nevertheless, patient and graft survivals are about 70% for heart transplants at 5 years.

The number of lung transplants performed annually in the United States is approximately 1,200, while only about 30 combined heart and lung transplants are performed. The statistics for lung transplant survival are about the same as for liver (82% graft survival and 83% patient survival) over the first year, but then decrease much faster, with 5-year survivals of only about 45% for grafts and 46% for patients *(1017)*. A major cause of graft loss is a process called *bronchiolitis obliterans*, thought to be the pulmonary manifestation of chronic rejection *(1024)*. However, these patients are also highly susceptible to pulmonary infections, which undoubtedly contributes to the poor long-term statistics.

Pancreas and Islet Transplantation

Transplantation of the whole pancreas was almost without success until about. 1980, largely for technical reasons. More recently, successful pancreas transplantation to treat diabetes mellitus has been achieved using new technical approaches, and with success rates of about 92% at 1 year, approaching those for kidney transplantation, as long as the two organs are transplanted together. There are approximately 850 simultaneous kidney/pancreas transplants per year in the United States. The lower survival rates (77% graft survival at 1 year) achieved when pancreas transplantation is performed alone (about 500 cases annually) probably reflect the difficulty in diagnosing rejection episodes involving this organ. By the time blood sugar levels begin to rise, destruction of the pancreas is generally so far advanced that it cannot be reversed by immunosuppressive therapy. Measurement of the serum creatinine, reflecting early dysfunction of a simultaneous kidney transplant, allows much earlier detection of rejection activity and, thus, better outcomes.

Simultaneous transplantation of both a kidney and a pancreas from a single donor has demonstrated, surprisingly, that rejection activity in one organ is not always associated with rejection activity in the other. It is not known whether this occasional dichotomy reflects tissue-specific antigens or localized inflammatory events in one, but not the other organ.

Most pancreas transplantation is carried out as a curative treatment for diabetes mellitus. For this purpose, the potential also exists of transplanting only the insulin-producing islet cells rather than the whole pancreas. In rodent models, both allogeneic and xenogeneic islet transplants have successfully achieved normoglycemia in diabetic animals *(1025,1026)*. Attempts to extend these results to patients, however, have met with limited success *(1027,1028)*, and until recently, the results of whole-organ pancreas transplantation in correcting the hyperglycemia of diabetes have been far superior to those of islet transplantation *(1029–1031)*. In 2000, the "Edmonton Protocol" (1032) showed much improved survival of islet transplants at 1 year in 4 of 12 patients, using a new combination of immunosuppressive drugs that appeared to cause less damage to transplanted islets. However, this protocol required use of two or sometimes three pancreases for a single recipient, and by 5 years, in a much larger series of patients, only 10% of patients have remained insulin-independent *(1033–1035)*. Thus, these results, while representing an improvement, remain much inferior to the results of whole-organ pancreas transplantation.

Hematopoietic Cell Transplantation

Bone marrow transplants, and more recently, transplants of hematopoietic stem cells and progenitors mobilized from the marrow into peripheral blood by treatment with G-CSF, are used most commonly for the treatment of otherwise incurable leukemias and lymphomas, aplastic anemia, and congenital immunodeficiency states. Additional applications include hemoglobinopathies and inborn errors of metabolism. Autologous HCT is used for hematologic rescue following high-dose chemotherapy/radiotherapy for the treatment of malignancies and is currently being explored as a treatment for autoimmune diseases. However, autologous HCT will not be considered further here as it does not involve the broaching of any immunologic barriers.

One fundamental difference between HCT and the transplantation of all other organs is that the recipient's treatment for his or her malignancy usually results in ablation of the immune and hematopoietic systems prior to transplantation, that is, the "conditioning" for transplantation is myeloablative. Originally, hematopoietic cell allografts were administered only as a means of replacing ablated host hematopoiesis. However, clinical experience revealed that one of the main therapeutic benefits of allogeneic HCT is due to the GVL effect of donor lymphocytes (reviewed in ref. 1036). With the recognition of this immunotherapeutic benefit of allogeneic HCT, clinicians began to evaluate less toxic, nonmyeloablative conditioning as a means of allowing allogeneic marrow to engraft so that donor lymphocytes can mediate GVL effects *(770,771,1037,1038)*. In contrast to HCT for malignancies and other indications in immunocompetent re-

cipients, transplantation for immunodeficiency states does not require myeloablation or immunoablation in order to achieve alloengraftment, which is often associated with reconstitution only of the deficient immune system and not other hematopoietic lineages.

Another major distinguishing feature of HCT is that the recovering immune system in bone marrow transplant recipients is tolerant to the donor alloantigens, so there is no requirement for immunosuppressive therapy to prevent allograft rejection once the initial immune resistance to the allograft has been overcome.

A third unique feature of HCT (as well as transplants of other organs that are rich in lymphoid tissue, such as small intestinal grafts and, to a lesser extent, liver grafts) is the ability of T cells in the allograft to mount an immunologic attack on the recipient's tissues, resulting in GVHD. GVHD rates and severity are reduced using prophylaxis with nonspecific immunosuppressive drugs, but still afflicts about 50% of recipients of HLA-matched sibling HCT. The frequency and severity of the GVHD that develops when extensive HLA barriers are traversed has essentially precluded the routine performance of such transplants, making HCT unavailable to many for whom no other curative treatment exists. The establishment of large marrow donor registries has permitted the performance of closely matched transplants from unrelated donors, but these transplants are also associated with a high incidence of severe GVHD, resulting from the existence of HLA mismatches that are undetected by conventional serologic HLA typing techniques (1039), which are now being replaced by more specific molecular typing techniques (see "HLA and Hematopoietic Cell Transplantation"). Additionally, greater minor histoincompatibilities can be expected in unrelated compared with related donor transplants.

The GVL effect of allogeneic lymphocytes, especially T cells, transferred with the donor graft, is due largely to recognition by donor T cells of host alloantigens, which are also expressed on malignant cells. Therefore, while T-cell depletion of the donor graft decreases the incidence of GVHD, this benefit is offset by increased relapse rates (1040) and increased risk of engraftment failure due to rejection *(1041)*. Graft rejection can be offset by more intensive host conditioning and high doses of donor hematopoietic stem cells, even with extensively (one haplotype) HLA-mismatched stem cell grafts *(1042)*, but at the expense of delayed immune reconstitution *(1043)*. While T-cell–mediated GVL effects due to GVH reactivity are greatly diminished with such an approach, this may be compensated for by the ability of NK cells to mediate GVL when the host lacks inhibitory MHC ligands recognized by the donor, at least for patients with acute myelogenous leukemia (346). Such alloreactive NK cells may also help to promote donor engraftment by eliminating alloresistant host T cells (346).

A major and elusive goal in the HCT field has been to separate the GVL effect of donor T cells from their

potential to cause GVHD. Recently, several new approaches for inhibiting GVHD have been attempted. The use of costimulatory blockade has already been discussed. Because these approaches might be expected to block donor-antihost responses, including those that eliminate residual leukemia in the host, it seems quite likely that they would also impair GVL responses and might have their greatest utility in the treatment of nonmalignant diseases. Alternative approaches involve immunostimulatory cytokines such as IL-2, IFN-γ, IL-12, IL-11, and IL-18, all of which, paradoxically, inhibit GVHD in mouse models *(503,520,1044,1045)*. These cytokines have been shown to preserve or enhance GVL effects while GVHD is inhibited *(518,1046–1048)*. The inhibitory effect of IL-12 on GVHD is mediated by IFN-γ, which also promotes the GVL effect of CD8 T cells (436,1050). Keratinocyte growth factor also appears to inhibit GVHD while preserving GVL and promoting alloengraftment, through mechanisms that are not fully understood (*1051*,1052). Blockade of Fas/FasL, perforin, TNF-α, and IL-1 pathways have shown some efficacy in animal models and the latter have entered clinical trials (reviewed in ref. 437). Many other strategies, such as immune deviation and the use of NKT cells have been discussed elsewhere in the chapter.

Another approach to separating GVL from the GVHD-inducing capacity of MHC-directed alloreactivity is to separate the hematopoietic cell transplant and the administration of donor T cells in time, so that the T cells are given after some host recovery from the initial conditioning regimen has occurred. Mixed chimeras are immunologically tolerant of their original marrow donor's antigens and a GVH reaction occurs after administration of nontolerant DLIs, resulting in conversion of mixed hematopoietic chimerism to full donor chimerism. Remarkably, this powerful GVH alloreaction against lymphohematopoietic cells is not associated with GVHD in mice, even though donor T cells are given in numbers that would cause rapidly lethal GVHD in freshly conditioned recipients *(545,546)*. Although antihost MHC alloreactivity mediates the most potent GVL effects (1053,*1054*) and GVH-reactive donor T cells can clearly be shown to be activated and proliferating in mixed chimeric recipients of DLI *(547, 1054)*, these cells do not migrate to epithelial GVHD target tissues in the absence of inflammatory signals in those tissues *(547)*, as is discussed in the section "Role of Graft and Tissue Injury." The observation that GVH reactions can be confined to the lymphohematopoietic system suggests an approach to separating GVHD from GVL reactions, as hematologic malignancies reside largely in the lymphohematopoietic system. Proof of principle has been obtained that similar results can be achieved in patients receiving nonmyeloablative BMT with *in vivo* T-cell depletion of the donor and recipient, followed by delayed DLI for the treatment of lymphomas (772,1055), but the desired outcome is not always achieved, and further understanding should

lead to refinements in this approach. In addition to recovery of epithelial GVHD target tissues from conditioning-induced injury, increasing resistance to GVHD with time may be conferred by recovering T-cell populations that down-regulate GVH reactions (1056,*1057*) while permitting GVL effects to be achieved (1058). Eradication of relapsed leukemia following delayed DLI is somewhat variably associated with GVHD in patients, but generally to a lesser degree than would be expected in freshly conditioned recipients of similar cell numbers (1036,*1059*).

Additional strategies for separating GVHD from allogeneic graft-versus-tumor effects include the transduction of donor T cells with suicide genes so that the alloresponse can be turned off at will, hopefully after residual tumor has been eradicated (*1060*,1061). Another approach is to avoid the GVH alloresponse, and try to target the donor immune response to tumor-specific antigens (1062). Idiotypic determinants associated with unique Ig receptors and TCRs on the surface of B- and T-cell malignancies, respectively, may trigger an immune response when presented by professional APCs such as DCs *(1063,1064)*. However, limitations to this approach include the low frequency of tumor antigen-specific T cells pre-existing in a given T-cell repertoire. These frequencies are even lower than those against minor histocompatibility antigens, and the generation of meaningful tumor-specific responses is likely to necessitate donor presensitization along with *in vitro* expansion of tumor-specific effector cells, a process that can limit the homing capacity of injected cells. Such prolonged cultures may be impractical for use in the setting of HCT, in which leukemia-reactive cells must eliminate exponentially expanding leukemic cells. Immunization of HCT donors with tumor antigens could potentially overcome these limitations. Minor histocompatibility alloantigens expressed by lymphohematopoietic cells (including leukemias and lymphomas) but not by the epithelial GVHD target tissues may also be targeted using *in vitro* expanded CTL. Such antigens have recently been identified *(72)*. Recently, it was shown that administration of primed T cells specific for a single immunodominant class I-restricted minor histocompatibility antigen could mediate GVL without GVHD. Avoidance of GVHD was dependent on the absence of GVH-reactive T cells with additional specificities in the donor inoculum *(1065)*. In theory, the less-risky strategy of generating tumor-specific responses from autologous T cells could achieve similar outcomes. However, T-cell immunity may be markedly impaired in the tumor-bearing host *(1066)*, and the use of immunologically unimpaired allogeneic donors is therefore appealing. Another approach to overcoming such immune suppression, which may be mediated in part by regulatory T cells, is to use chemotherapy to deplete regulatory cells and create space for lymphopenia-driven expansion of autologous lymphocytes, which may then mediate significant antitumor effects (1067).

Xenogeneic Transplantation

During the past decade, the increasing shortage of allogeneic donor organs has evoked a worldwide resurgence of interest in xenotransplantation, that is, the replacement of human organs or tissues with those from a donor of a different species. Routine clinical application of this therapeutic modality is still in the future. However, recent progress, which is reviewed briefly here, offers cause for optimism.

Concordant versus Discordant Xenotransplantation

Xenotransplants have been classified into two groups—"concordant" and "discordant"—on the basis of phylogenetic distance between the species combination, speed of the rejection, and levels of detectable preformed antibodies *(1068)*. Animals that are evolutionarily closely related and that have minimal or no preformed natural antibodies specific for each other are called *concordant,* while animals that belong to evolutionarily distant species and reject organs in a hyperacute manner are termed *discordant*. There are, of course, many gradations between these extremes, and there are also a variety of known exceptions to the rule, making this nomenclature less than ideal.

Choice of Donor Species for Clinical Xenotransplantation

From a phylogenetic viewpoint, nonhuman primates would undoubtedly be the most similar to allotransplants immunologically. However, because of considerations of size, availability, and likelihood of transmission of infectious disease, most investigators have decided against the use of primates as a future source of xenogeneic organs. Instead, the discordant species, swine, has been chosen by many as the most suitable xenograft donor. The pig has essentially unlimited availability, as well as favorable breeding characteristics, and many of its organ systems are similar to those of humans. Partially inbred miniature swine are a particularly attractive choice because of their size (adult weights of approximately 120 kg), their physiology (also similar to humans for many organ systems), and their breeding characteristics, which have permitted inbreeding and genetic manipulation (1069).

Mechanisms of Xenograft Rejection

Xenografts are subject to all four of the rejection mechanisms described earlier in this chapter and give rise to more powerful immune responses than allografts, probably for each type of rejection. There are two fundamental reasons for this finding. First, xenografts offer more foreign antigens as targets for an immune response. Second, there are frequently molecular incompatibilities between members of different species that prevent the nor-

mal function of receptor–ligand interactions. Because in many cases the occurrence of "homologous restriction" for receptor–ligand pairs has been found to impair the regulatory processes that normally control immune and inflammatory responses, the result is that rejection mechanisms that may be relatively weak in allogeneic combinations become explosive following xenogeneic transplantation.

The well-recognized susceptibility of xenografts to hyperacute rejection illustrates both of these fundamental problems. As is discussed in the section on transplantation antigen, (see "Species-specific Carbohydrate Determinats") primates have large amounts of anti-αGal natural antibodies that then react with pig tissues after xenotransplantation, causing vigorous rejection.

As already discussed, the hyperacute rejection that occurs with pig-to-primate transplantation is more vigorous than in the case of allogeneic blood group disparities, at least in part because the complement regulatory proteins expressed by pig endothelium are less efficient in controlling human complement activation than are the human regulatory proteins expressed by human organs. Thus, these molecular incompatibilities also contribute to the increased intensity of the hyperacute rejection mechanism.

Similarly, the factors responsible for accelerated graft rejection are more prominent in xenogeneic than in allogeneic transplantation, probably also because the process is magnified considerably by the failure of regulatory molecules to function effectively with human coagulation factors, thus increasing the tendency toward intravascular thrombosis (163). The biological reasons for the likely participation of NK cells in this form of xenograft rejection *(1070)* have been discussed previously.

The available evidence also suggests that cell-mediated immune responses to xenografts are more powerful than those directed to allografts *(1071)*. Initially, there was some uncertainty about this point because cell-mediated immune responses to xenogeneic stimulating cells were first studied using mouse T cells, for which molecular incompatibilities with human cells lead to weaker direct recognition of xenogeneic than allogeneic stimulators *in vitro*. In this case, the incompatibilities turned out to involve the accessory molecules that are required for T-cell activation rather than a lack of antigens that stimulate TCRs. Thus, it seemed that cell-mediated rejection *in vivo* might also be weak. However, cell-mediated xenograft rejection, even by mice, has consistently been found to be extremely powerful *in vivo,* apparently initiated by CD4$^+$ T cells responding to the many additional antigenic peptides through the indirect pathway.

For reasons of potential clinical applicability, greatest attention has been directed at investigation of the human-antipig cellular response. In contrast to the murine studies, direct responses by human CD4 and CD8 T cells to pig stimulators can be readily measured *in vitro (1072)*. In addition, the cell-mediated reaction *in vitro* has been found

to include a significant contribution by NK cells that can lyse pig targets. Most of the other molecular interactions involved in cellular immunity that have been examined appear to be at least partially functional in primate antipig responses. Therefore, human-antipig T-cell responses are likely to be as great as or greater than those in allogeneic combinations.

Therapeutic Strategies for Xenotransplantation

There are three main strategies that have been pursued to achieve long-term survival of xenogeneic transplants. The first has been to seek nonspecific immunosuppressive drugs that might prove especially effective for xenotransplantation. Unfortunately, none of the new drugs that have contributed to improved outcomes for allografts have proven sufficient to make xenografting possible, and considering the immunologic barriers to xenotransplantation discussed earlier, it is unlikely that any such drug exists. Furthermore, the heightened immune response to xenografts compared with allografts suggests that larger amounts of exogenous immunosuppression will be required to achieve xenograft survival comparable to that of allografts. Given the narrow therapeutic window that already exists in allogeneic transplantation, most investigators believe that more than just immunosuppressive drugs will be needed to accomplish widespread clinical application of xenogeneic transplantation. Data so far for long-term survival of functioning pig-to-primate transplants of organs (802) and of islets (925,*1073*) support this impression.

The second therapeutic approach has been to use genetic engineering of donor animals to lessen the immuno-logic barriers to xenografts. Because the two features that distinguish xenografts from allografts are the larger number of antigens and the molecular incompatibilities between species, these genetic modifications have been aimed primarily at correcting these two disadvantages of xenografts (Figure 44.13). The first transgenic pigs produced by genetic engineering for xenotransplantation attempted to make use of the species specificity of complement regulatory proteins. Transgenic pigs were produced that expressed human genes for several of these proteins. Organs from animals expressing one of these molecules (hDAF) have been studied extensively, and appear to be more resistant to hyperacute rejection than are those from wild type pigs *(1074)*, but nevertheless susceptible to acute humoral rejection *(1075)*. Numerous other transgenes (Figure 44.13) have been tested in attempts to further alter the primate host's humoral response to pig xenografts, but none to date has prolonged the survival of organ transplants beyond the survivals achieved with hDAF organs (163).

The alternative genetic engineering strategy to the addition of transgenes is the removal or inactivation of genes through knockout technology *(1076)*. In mice, the availability of embryonic stem cells has made it possible to use homologous recombination to generate numerous knockouts *(1076,1077)*, including mice that do not express the α-1,3-galactosyltransferase that is responsible for generating the Gal determinant. Until recently, this technology was not available in larger animals because embryonic stem cells have only been derived in certain strains of mice. However, the advent of cloning through nuclear transfer technology, first demonstrated in the famous sheep

"Dolly" *(1078)*, has made knockout technology possible in several large-animal species, including pigs. Because, as described earlier, the major stumbling block in pig-to-primate xenotransplantation has been the large amount of natural antibody directed toward the Gal determinant, investigators have used this technology to eliminate the Gal-producing enzyme from pigs (1079,*1080–1082)*. These new knockout pigs (called *GalT-KO*), like humans and Old World primates, do not put Gal onto the surface of their cells. As a result, xenotransplants can now be performed without the powerful rejection previously caused by natural anti-Gal antibodies. The results have been remarkable, with increased survivals of both heart and kidney transplants from pigs to baboons (802,*1083)*. Using immunosuppressive drugs, organ survivals were prolonged using these new Gal knockout (GalT-KO) pigs, but new antibodies soon appeared, causing rejection (802,*1083)*. However, using a regimen directed toward induction of tolerance (see later discussion), organ survivals were prolonged markedly, and no rejection was seen (802). There are still problems to be resolved before such transplants will be attempted in patients, but survivals are now being measured in months rather than in days, as they were only a few years ago.

The third strategy to achieve successful xenotransplantation is the induction of tolerance to donor antigens. Potential applications of this strategy have been described earlier in this chapter, with reference mainly to transplantation in rodent models (see previous discussion). There have been attempts to use either mixed chimerism or thymic transplantation to induce tolerance across xenogeneic barriers in primates. So far, long-term success by the mixed chimerism approach has been attained only for concordant cynomolgus monkey-to-baboon renal transplants *(1084)*. Both mixed chimerism and thymic transplantation approaches had been attempted for the discordant pig-to-baboon combination before the availability of GalT-KO swine, but with limited success *(1085–1087)*. However, combining the thymic transplantation approach with the use of the GalT-KO as a source of pig kidneys has extended survivals to more than 3 months (802). Thus, it seems possible that elimination of the natural antibody problem along with tolerance induction could make discordant xenotransplantation as successful as allogeneic transplantation in providing a long-term solution for patients waiting for transplants. Of course, it is possible that when these barriers are overcome, other obstacles, not yet apparent, will still limit the survival of xenogeneic transplants, and additional measures will be required to achieve success.

Nonimmunologic Barriers to Xenotransplantation

In addition to the immunologic mechanisms that prevent successful xenografting, there are two other potentially im-portant obstacles to clinical application. First, molecular incompatibilities between species may cause physiologic dysfunction of xenogeneic organs. This kind of incompatibility is least likely for the heart, for which the function, albeit vital, is relatively simple. It could certainly become an obstacle, however, for the liver, as the liver is known to produce so many different products, including serum proteins and enzymes, that it is likely that at least some of these products may not function properly in a primate host. On the other hand, if the number of incompatibilities leading to physiologic dysfunction is limited, they could be correctable through knockout and transgenic technology. Thus, the physiologic dysfunction of xenogeneic organs is unlikely to be an insurmountable barrier to xenotransplantation.

The other nonimmunologic barrier to xenotransplantation is the risk of cross-species transfer of infectious agents, potentially creating a health hazard, not only for the recipient, but also for society as a whole. This possibility has gained significant attention, both in the scientific literature and in the lay press, and the issue has become confused by enormous uncertainties about the true risks that are involved. *Zoonosis* is a term that has been used for some time to describe the general process of cross-species infection, and the term *xenozoonosis* has been developed to describe infection transmission that might occur as a result of xenotransplantation (1088). It is important to realize that from the point of view of the individual recipient, the risk of transmitting infection by xenotransplantation is likely to be less than by current clinical allotransplantation, both because of the natural resistance to cross-species transmission of infectious diseases and because it should be possible to screen for and eliminate the presence of known pathogens from the herd of donor pigs.

The major infectious concern, therefore, is that endogenous retroviral sequences from donor cells might infect the recipient's cells, giving rise to previously unrecognized pathogenic viruses *(1089)*. The concern has been raised that such new viruses might prove hazardous to other human beings in addition to the xenograft recipient *(1090)*. However, to date there is no evidence that such cross-species transfer after a pig-to-human transplant would generate a virus that would be infectious or pathogenic. Indeed, studies of humans exposed to pig tissues have not revealed any cases of detectable pig endogenous retroviruses *(1091,1092)*. Nevertheless, the concern about infections from xenotransplantation involves fear of the unknown, for which it is impossible to assign an accurate level of risk. At this time, therefore, public health agencies and members of the transplant community are attempting to design rational approaches for identifying the true risks of xenotransplantation and detecting untoward events rapidly, while at the same time allowing further progress in this potentially enormously important field of transplantation *(1093)*.

Clinical Progress in Xenotransplantation

Early clinical efforts in xenotransplantation took place in the 1960s, and involved organ transplants from non-human primates (163). One of the patients survived for 9 months with normal renal function provided by the kidney of a chimpanzee *(1094)*. Additional clinical trials thereafter, using baboon hearts and livers, were considerably less successful. More recent clinical trials have involved fetal pig cells transplanted into the brains of patients with Parkinson or Huntington diseases. Survival of pig tissue 8 months after the transplant was documented in a patient taking only moderate doses of immunosuppression *(1095)*. These studies suggest that cellular xenotransplantation may be achieved more easily, and thus may be performed sooner, than solid-organ transplants, especially because free cellular transplants lack the vascular endothelium that is the target for both hyperacute and accelerated rejection. For organ xenotransplantation, most investigators believe that further clinical trials should await a reasonable expectation of success on the basis of pig-to-nonhuman primate experimental studies, a goal that is becoming closer but has not yet been realized.

SOME IMMUNOLOGIC ISSUES IN CLINICAL TRANSPLANTATION

The Effect of Antigen Matching on Organ Graft Survival

Clinical Data

In the absence of transplantation-antigen disparities, graft rejection does not occur. However, the importance of antigen matching is one of the controversial issues in clinical transplantation. The debate is frequently confused by failure to focus on the quantitative issue of whether improved, but incomplete, antigen matching influences the outcome of organ transplantation sufficiently to warrant its logistical difficulties.

The evidence from transplantation of kidneys using living related donors provides a clinical demonstration of the importance of antigen matching in subsequent graft survival. Two siblings may share all of their HLA antigens (25% likelihood), half of their HLA antigens (50% likelihood), or none of their HLA antigens (25% likelihood). Identical twins share all of their transplantation antigens, but siblings are generally matched for only about half of the minor antigens that distinguish their parents, even if they are HLA-identical. Data from a large international database on kidney allograft survival from 1985 to 1999 showed a survival half-life of HLA-identical sibling allografts of 23.4 years, as compared with 12.8 years for haploidentical-related allografts (14). These data support

the basic concept that antigen matching matters, and for related donors, MHC antigen matching is widely agreed to be advantageous.

In the absence of a living related donor, transplantation is performed with organs from unrelated donors, usually from cadaveric sources. Because of the extensive polymorphism of MHC antigens, unrelated donors selected in a random fashion would not be expected to share many HLA antigens with the recipient. Similarly, there would only be sporadic matching of the minor histocompatibility antigens. Correspondingly, the survival of organs from cadaveric donors (half-life of 11.1 years in the large registry referred to previously [14]) has generally been shorter than that of HLA-identical or one-haplotype–mismatched-related transplants. Although longer ischemic time of cadaveric compared with living donor kidney transplants could account for some of this difference, a significant inverse correlation between graft survival and number of (serologically determined) HLA mismatches was evident among cadaveric donor recipients, and was still evident among the subgroup with short ischemic times. A similar effect could also be seen in recipients of living unrelated donor transplants with various mismatches (14). A long-term benefit for increased HLA matching could also be seen in recipients of cardiac, but not liver, allografts (14). Because all of these analyses are retrospective, an unanswered question is whether the potential added ischemic time required for nonrandom distribution of cadaveric organs to achieve a larger number of matched antigens would lead to better results.

A second question for all unrelated transplants is whether the more specific information provided by molecular typing confers a graft survival advantage over serologic typing. It appears that the typing for loci that cannot be typed serologically, such as HLA-DP, as well as DNA typing within a serotype, can benefit the survival of cadaveric transplants in heavily presensitized recipients, but probably not in unsensitized recipients (14). Thus, for the majority of recipients, it remains unclear that the distribution of organs to achieve better matching would be worth the effort, expense, and increased ischemic time, which might negatively affect outcome.

Experimental Data

As previously discussed, miniature swine provide a particularly useful large-animal model for testing experimentally the importance of antigen matching. Over the past 30 years, three herds of these animals have been developed for studies of transplantation biology, with each herd bred to homozygosity for a different allele at the MHC (termed *SLA* in swine) (Figure 44.3). Subsequent breeding was intentionally randomized within herds in order to maintain a variety of segregating minor histocompatibility loci, so that transplants among these

▌**TABLE 44.7 Graft survival and antigen matching in minipigs**

| | Mismatch | | | |
Graft	Minors only	Major and minors	Class I[a]	Class II[a]
Skin	11.8 ± 0.9	7.0 ± 0.4	10.8 ± 2.3	7.8 ± 1.0
Kidney	30.0 ± 15.0 (2/3)	12 ± 1.9	19.5 ± 6.8 (2/3)	21.8 ± 10.4
	>120 (1/3)		>120 (1/3)	

[a]Single haplotype mismatch.

animals resemble the situation within human families, that is, HLA-identical versus nonidentical siblings.

Studies of skin and renal allografts between these animals produced the results shown in Table 44.7. The difference observed for skin graft survival between SLA-matched and SLA-mismatched animals was modest, but matching had a much more profound effect on kidney graft survival. One third of the grafts between SLA-matched animals survived indefinitely without immunosuppression, despite the existence of multiple minor histoincompatibilities. The ability to reject renal allografts across minor differences was found to depend on an autosomal dominant gene, not linked to the MHC *(9)*.

Using intra-MHC recombinants between miniature swine haplotypes, the relative importance of class I versus class II matching on renal allograft survival was examined in these large animals *(9)*. The survival of renal allografts with class I–only differences and with class II–only differences is shown in Table 44.7. As in the mouse, both class I and class II differences appeared sufficient to cause prompt skin graft rejection. However, for kidney allografts, class II matching was of particular importance in determining the outcome. In fact, the results for minor plus class I differences were indistinguishable from those for minor histocompatibility antigen differences alone.

These experimental data were obtained without the exogenous immunosuppression always administered in clinical studies. They demonstrate the biological principle that antigen matching is important to graft survival and further indicate that class II antigen matching is likely to be particularly important. No experimental system is likely to settle the empirical issue in clinical medicine, however, of how much benefit will be obtained under the conditions of current practice.

HLA and Hematopoietic Cell Transplantation

In contrast to the results described previously for solid-organ transplants, the importance of HLA matching for unrelated HCT is unquestioned. Until quite recently, HCT was performed almost exclusively in HLA-identical (or single HLA-antigen mismatched) sibling pairs. Although this restriction has severely limited the use of HCT (only 25% of individuals have an HLA-identical sibling; another 5% has a single antigen-mismatched–related donor), the complications of HLA-mismatched transplantation have prohibited its widespread use. Among these complications, GVHD is the most prevalent and severe, with a severe form of the disease occurring in 75% to 80% of recipients of related donor transplants differing at one to three HLA A, B, or DR loci *(1096)*. Additionally, the incidence of marrow graft rejection increases in the presence of HLA disparity: while only 2% of HLA-identical related donor grafts are rejected, the figure increases to approximately 12% in recipients of unmodified haploidentical-related donor grafts (1039,*1097*).

Similar to solid-organ graft rejection, GVHD appears to be a particularly severe problem in the setting of class II MHC mismatching (1039,*1098*), but class I mismatching can also confer GVHD risk *(1099)* and synergizes with class II disparity (1039).

With respect to marrow graft rejection, class I (including HLA-A,B, and C) disparities have been most strongly associated with increased risk, which increases in proportion to the number of such disparities (14,1039,*1097*). Although the importance of class I mismatching, and particularly that of HLA-C, might suggest a role for NK cell-mediated rejection, antidonor NK reactivity was not demonstrable during the time of rejection in a patient receiving marrow from a donor whose HLA class I alleles would be incapable of triggering recipient KIRs recognizing recipient class I alleles *(1100)*. Thus far, a role for NK cells in mediating marrow allograft rejection has not been demonstrated in heavily conditioned hosts, but their role may become more significant if mismatched transplants are attempted with less toxic, nonmyeloablative regimens. In contrast, a role for classical CTL is well established in the rejection of even HLA-identical donor marrow following myeloablative conditioning *(1011)*. Rejection of HLA-identical HCT is rare unless the donor product is T-cell depleted *(1038,1102,1103)*, but occurs quite frequently in the setting of HLA-mismatched transplants, even without T-cell depletion *(1097)*, and increases even further with T-cell depletion *(1104,1105)*. Antidonor CTL specific for the mismatched donor class I allele have been associated with marrow rejection following unrelated donor transplantation *(1105)*. Class II disparities may also play a role in unrelated donor stem cell graft rejection (1039), and such rejection may be mediated by CD4[+] CTL *(29)*.

High resolution, PCR-based HLA typing methods have increased the capacity to avoid HLA disparities that would have previously (when only serologic HLA typing was available) gone unrecognized. However, higher-resolution HLA typing will obviously reduce the chance of finding a fully matched unrelated donor, even with the availability of large registries such as the National Marrow Donor Program in the United States, which currently contains

more than 5 million volunteer registrants. Already, many patients do not succeed in finding an unrelated donor, and thus the identification of "acceptable" mismatches in the unrelated donor setting is of the utmost importance.

Crossmatch

There are several tests designed to detect pre-existing antibodies with specificity for donor antigens in the serum of potential recipients. First, recipients and donors must be matched for ABO blood type because, with the exception of organs from donors of the A_2 blood group, transplantation across blood group barriers may cause hyperacute rejection (see previous discussion). Second, immediate pretransplant sera from prospective recipients are tested for reactivity against lymphocytes of potential donors. This "crossmatch" is generally performed by a two-step, antibody-mediated, complement-dependent cytotoxicity assay, although methods using flow cytometry are now becoming more popular in many centers.

"Sensitized" Candidate for Organ Transplantation

Because kidneys and many other vascularized organs cannot be transplanted safely into recipients with pre-existing antibodies, the clinical goal is to avoid the formation of antibodies reactive with donor antigens or to find organs that do not express the particular HLA antigens against which the recipient has been sensitized. Except for blood group antibodies, recipient sensitization to transplantation antigens generally occurs by prior exposure to allogeneic tissue. This may occur as a result of blood transfusion, as a result of previous organ transplantation, or, in women, by exposure to paternal antigens on fetal cells during parturition. The degree of sensitization of a potential kidney recipient is measured regularly by testing sera on a panel of lymphocytes selected from individuals who collectively express a broad representation of the HLA antigens, resulting in assessment of high panel reactivity, as defined earlier. Highly sensitized candidates may wait many years to receive a kidney transplant.

The level of sensitization manifested by transplantation candidates fluctuates over time. As a result, it is possible for recipients to have a negative crossmatch with a donor's cells using recently obtained serum, but a positive crossmatch using previously collected sera. Transplantation in the face of this "historical positive crossmatch" has been performed successfully. Obtaining crossmatch-negative donors by locating well-matched organs or waiting for a decline in the level of sensitization represent the primary solutions currently available for sensitized patients. Recently, however, there have been successful reports of renal transplants in the face of antidonor antibodies as a means of using otherwise available kidneys, through plasmapheresis and treatment with anti-CD20

mAb and/or IVIG, followed by immunosuppression geared toward preventing antibody responses *(1107,1108)*.

The Diagnosis of Rejection

In clinical organ transplantation, the most obvious manifestation of the rejection process is usually diminished function of the transplanted organ, but it is important to confirm the immunologic origin of the event before increasing immunosuppression. Unfortunately, no clinical sign is by itself sufficient to diagnose rejection and *in vitro* assays have been disappointing. Recent reports suggest that measurement of urinary perforin and granzyme B levels may be useful in this diagnosis (285,*1109,1110*). Nevertheless, the gold standard remains histologic examination of the biopsy of the transplanted organ itself. Pathologists have been able to identify the abnormal lymphocytic infiltrate within grafts, to grade the intensity of the infiltrate, and, for some organs, to describe histologic findings characterizing the effects of immunologic injury *(1111)*. Some pathologic changes, including a lymphocytic infiltrate of the vascular wall, seem to be well correlated with rejection activity *(1011,1012)*. In addition, pathologic changes suggesting nonimmunologic causes of renal dysfunction may be helpful in patient management. Recently, the immunohistologic finding of deposition of the complement component C4d in the peritubular capillaries has been reported to be indicative of rejection, especially in the kidney (*1113*), although controversy remains as to whether this finding can also be indicative of accommodation *(1113,1114)*, the phenomenon of organ graft prolongation in the presence of antidonor antibodies (see previous discussion).

Despite the widespread reliance on the biopsy to define episodes of rejection, however, diagnosis of rejection is often difficult even by this means because of problems differentiating this diagnosis from drug toxicity and/or viral infection. Furthermore, when routine "protocol" biopsies of transplanted organs have been performed instead of biopsies for suspected rejection, they have revealed a poor correlation between histologic findings and clinical evidence of rejection. These results are consistent with several experimental models of tolerance induction that have shown intense lymphocytic infiltrates in organs that go on to survive indefinitely and/or in recipients who develop tolerance to the donor antigens *(117,1114)*. These studies suggest that the amount of lymphocytic infiltrate detected pathologically may not be helpful in diagnosing rejection episodes and determining the need for treatment.

How Much Immunosuppression Is Enough?

Although the majority of transplant recipients respond immunologically to their new organ despite immunosuppression, some patients seem never to generate any rejection activity and maintain their transplanted organ with very

small doses of immunosuppressive drugs. Indeed, a few patients have been known to stop all of their medications but have kept their transplant for years without rejection. On the other hand, some patients seem to require and tolerate very high doses of exogenous immunosuppression, while others seem to be severely immunocompromised by low doses of these drugs. These observations make it clear that the amount of immunosuppression that is required or that is safe is not the same for every individual or for all grafts. Unfortunately there is no well-established assay to determine the amount of immunosuppression an individual requires and can safely tolerate for their particular transplant.

CONCLUSION

The great danger in any textbook chapter is that the need to summarize what we think is known will obscure the much greater amount still left to be learned. In recent years, enormous progress has been made in the study of the major histocompatibility antigens, yet we still know too little about the products of the numerous other histocompatibility loci that encode the minor histocompatibility antigens. Recently we have gained important insight into the role of antigen-presenting cells in T-cell sensitization, but we still have not explored adequately the role that indirect presentation of alloantigens plays in graft rejection. During the past 2 decades we have learned much about the generation and function of cytotoxic T lymphocytes and about their likely role in some mechanisms of graft rejection and GVHD; however, our understanding of noncytolytic mechanisms of rejection and GVHD, which clearly exist, is much more limited.

Finally, this chapter has outlined several techniques for the generation of immunologic tolerance to alloantigens in experimental systems; however, as is described earlier, the first human beings have only recently been transplanted with a tolerance-inducing regimen (nonmyeloablative allogeneic BMT with simultaneous donor kidney transplantation) that allows the early discontinuation of nonspecific immunosuppression. The encouraging initial results achieved with this approach raise hopes that routine tolerance induction may soon become a clinical reality. It is, of course, the great fascination of transplantation immunology that new insights into basic immunologic issues will likely have important consequences for clinical transplantation in the future.

Conclusion

INTRODUCTION

In recent years, the field of tumor immunology has grown
explosively, and the boundaries of the field, never particu-
larly clear, have become less distinct. If one were to con-
sider tumor immunology as comprising all of the possi-
ble interactions of immune cells with tumors, it seems
that the topic of tumor immunology is enormous and
would include components of fields as diverse as angio-
genesis and carcinogenesis. Although our focus in the
present chapter is on harnessing the immune system to
control tumor growth, it has become clear that tumor
growth can be promoted by inflammatory immune re-
sponses. Immune cells have been shown to express a vari-
ety of factors that promote angiogenesis as well as metas-
tasis (1). Anti-inflammatory medications reduce the rate
of intestinal neoplasia, and ulcerative colitis is associated
with an increase in the incidence of human colorectal can-
cers (2). Studies in murine model systems indicate that
pro-inflammatory cytokines such as tumor necrosis fac-

tor (TNF)-α play a role in enhancing cell growth and de-
velopment through activation of NF-κB, which enhances
the expression of a variety of anti-apoptotic genes *(3–5)*.
The complexity of these regulatory pathways was revealed
by a recent report demonstrating enhanced tumorogeneis
in hepatocytes that fail to up-regulate NF-kB, an effect that
results from sustained activation of c-Jun N-terminal ki-
nase in response to TNF-α treatment (6). In a recent report,
production of interleukin (IL)-23 appeared to play role
in up-regulating expression of pro-angiogenic factors in
the tumor environment *(7)*. Although transforming growth
factor (TGF)-β has been shown to suppress tumor growth,
in some circumstances it can actually promote the growth
of tumor cells that have developed resistance to the pro-
apoptotic actions of TGF-β (reviewed in [8]). In a murine
model system, catecholamines produced in response to
stress were found to promote tumor growth by stimulating
angiogenesis *(9)*. Overall, these results indicate that the im-
mune system can act through a variety of mechanisms to
promote rather than suppress tumor growth. Nevertheless,

results of a variety of animal model studies as well human clinical trials have demonstrated that cells of the immune system can be effective at controlling and eliminating even large tumor deposits, which is a primary focus of our review.

Studies first carried out in the 1940s using transplantable murine tumors indicated that T cells could recognize antigens expressed on tumor cells and that these cells were capable of mediating tumor regression. These findings lead to the identification in the 1980s of genes that encoded tumor rejection antigens expressed on murine tumors as well as the subsequent identification of antigens recognized by human tumor reactive T cells. The observation that many of the human tumor antigens represented widely expressed, nonmutated gene products lead to the expectation that effective vaccine therapies could be developed for the treatment of cancer patients. The results of vaccination therapies that boost the immune response of individuals with cancer have, however, to this point been disappointing. Vaccination with virus like particles expressing human papilloma virus (HPV) proteins appear to be successful in preventing the establishment of cervical cancer, which should lead to a significant reduction in the mortality resulting from this form of cancer. However, the HPV vaccine prevents viral infection, interfering with events that lead to cellular proliferation and transformation. Thus the HPV vaccine represents and extension of the success of vaccines against infectious disease and should not be viewed as a therapeutic cancer vaccine *per se*: In spite of the presence of highly immunogenic HPV epitopes, vaccination appears to be ineffective at treating patients with existing diseases that appear to result from infection with this virus. Therapies have been developed, however, that are capable of resulting in the regression of large established tumor metastases. In a current clinical protocol involving the adoptive transfer of melanoma reactive T cells, objective clinical responses have been observed in approximately 50% of treated patients, and in between 10% and 15% of treated, long-term tumor regression has been seen. A better understanding of the basic mechanisms that regulate immune responses will hopefully lead to the development of even more effective adoptive immunotherapies and may also lead to the development of effective cancer vaccines.

INITIAL DEMONSTRATIONS OF TUMOR RECOGNITION BY CELLS OF THE IMMUNE SYSTEM

Studies first carried out in the 1980s demonstrated that normal spleen cells cultured in IL-2, termed lymphokine activated killer cells (*LAK* cells), had the ability to lyse fresh as well as cultured tumor cells. Uncultured cells derived from normal tissues were not lysed by LAK cells. Lysis

of autologous as well as allogeneic tumor cells was observed, demonstrating that recognition of target cells was not MHC restricted.

Evidence for specific tumor recognition by cells of the immune system was obtained in experiments first conducted over 5 decades ago using murine tumors generated through the use of the mutagen methylcholanthrene (MCA). Mice that received a surgical resection of previously inoculated tumors could be protected against a subsequent tumor challenge *(10)*; however, while these mice were protected against challenge with the immunizing tumor, either no or limited protection was observed against challenge with other MCA tumors (11,*12*). Subsequent observations indicated that CD8[+] cytotoxic T cells were the cells that were primarily responsible for mediating the rejection of MCA induced tumors as well as other tumors (13,*14,15*).

The nature of antigens recognized by T cells was first revealed by studies carried out using the mouse mastocytoma P815. Variants of P815 generated by mutagenesis resulted in the generation of variants, termed *tum-*, that were rejected by syngeneic mice (16). The *in vitro* stimulation of T cells derived from the mice that had rejected the tum- cell lines resulted in the generation of several cytotoxic T lymphocyte (CTL) clones that appeared to recognize tumor antigens, some of which were also expressed on the parental P815 cell line. Tumors that arose following the injection of relatively low numbers of P815 cells would partially regress in the majority of injected mice, followed by regrowth of the tumor, leading to the eventual death of injected mice *(17)*. The recurrent tumors had lost the expression of antigens detected with P815-specific T cell clones, indicating that *in vivo* immunoselection had occurred and providing evidence that these antigens represented tumor rejection antigens.

The genes encoding tumor antigens expressed on mutagenized P815 cells that were initially cloned by screening with tumor reactive CTL clones were found to contain point mutations (18). These mutations resulted in the generation of the specific peptide epitopes that were the target of the CTL clones that appeared to be responsible for tumor rejection. Subsequent studies, however, indicated that tumor rejection antigens could be derived from normal cellular genes. The P1A antigen, which was isolated from P815, represented a nonmutated product (19). This gene product was also expressed on a mastocytoma cell line and was found to represent a differentiation antigen with a limited tissue distribution. Immunization of mice with a transfectant of L1210 leukemia cells that coexpressed P1A as well as the costimulatory molecule B7–1 resulted in the protection against lethal challenge with wild-type P815 tumor cells (20). These observations, as well as subsequent studies carried out in human clinical trials, described below, provide evidence that nonmutated self-antigens represent potent targets for tumor rejection.

Approaches to the Identification of Tumor Antigens

Three major approaches have been used to identify the molecular nature of antigens that are naturally processed and presented on tumor cells, which to date comprise more than 100 antigenic proteins and/or epitopes (Table 45.1). Most antigens have been identified using T cells with the ability to recognize intact cancer cells, as assessed by either specific cytokine release or lysis when T cells and cancer cells are co-cultured. These T cells can be derived by repeated *in vitro* sensitization with tumor cells or by the culture of tumor infiltrating lymphocytes (TIL). These anti-tumor T cells can be used to screen tumor cDNA libraries transfected into target cells containing the appropriate restriction element. Alternatively, peptides can be eluted from cancer cells and used to pulse HLA-matched target cells that are then tested for recognition by the anti-tumor T cells. To identify HLA class II–restricted tumor antigens, cellular proteins can be fractionated and fed to antigen presenting cells (APC) until a single protein species is identified.

A second approach to identify cancer antigens uses a "reverse immunology" method in which putative antigens are used to generate tumor reactive T cells by repeated *in vitro* sensitization with candidate peptides from proteins that were primarily identified through the use of previously described peptide–MHC binding motifs. For example, the HLA-binding motif for the HLA-A2 class I molecule, which is expressed by approximately 50% of Caucasians, consists of an optimal methionine, leucine, or isoleucine anchor residue at position two and a valine at the carboxy-terminal anchor residue position, generally position nine or ten (21). The peptide reactive T cells are then tested for the ability to recognize intact cancer cells to determine whether the identified peptides are naturally processed and presented on the surface of cancer cells. Alternatively, mice transgenic for human major histocompatibility complex (MHC) molecules have been immunized with candidate antigens and the murine T cells used to test for cancer cell recognition. Observations indicate that only a small percentage of the potential epitopes are naturally presented on the cell surface at sufficient levels to allow detection by T cells, which results at least in part from the fact that the majority of peptides that are presented on the cell surface in association with class I molecules appear to be processed in the proteasome, a multi-subunit catalytic complex that is responsible for generating the carboxy-terminus of processed peptides (22). Thus, although it has been surprisingly easy to use these techniques to generate T cells against individual peptides, only a limited number of these peptides are naturally presented on the surface of tumor cells.

A third approach to the identification of tumor antigens is a method that has been termed *SEREX* (serological

analysis of recombinant cDNA expression libraries) (23). This method, which utilizes antisera from cancer patients to screen cDNA libraries constructed from tumor cells, has resulted in the identification of thousands of target molecules (online list available at http://www2.licr.org/CancerImmunomeDB, registration is required). Although some of the proteins identified using this technique are expressed in a tumor-specific manner, many of the proteins identified using this technique are expressed in normal tissues but appear to be overexpressed in tumor cells. Normal proteins released from large masses of necrotic and apoptotic tumor cells may also be processed by dendritic cells (DC) and may also lead to the generation of antibodies against intracellular products that are normally sequestered from the immune system.

CATEGORIES OF TUMOR ANTIGENS CAN BE DEFINED BY EXPRESSION PATTERNS

Nonmutated Self-antigens Recognized by CD8[+] and CD4[+] T Cells

Cancer/Testis Antigens

The genes that encode a wide variety of antigens expressed in both murine and human tumors have now been identified either using T cells that have been deliberately sensitized against tumor cells or by culturing TIL cells *in vitro* with IL-2. The first antigen shown to be recognized by human tumor reactive T cells, termed *MAGE-1,* was isolated by screening a melanoma genomic DNA library derived from the MZ2-MEL cell line with a CTL clone that recognized MZ2-MEL cells (24). MAGE-1 was found to be a nonmutated gene that was a member of a large, previously unidentified gene family. The T cell epitope identified using the MAGE-1 reactive CTL clone was recognized in the context of the HLA-A1 restriction element. Several additional members of the MAGE gene family have now been shown to encode T cell epitopes recognized by tumor reactive T cells *(25,26)*. These genes are expressed exclusively either in the testes alone or in testes and placenta, but not in other normal tissues, and have been termed *cancer/testis antigens.* These tissues fail to express HLA molecules and thus are not recognized by T cells reactive with members of this gene family. Members of the MAGE gene family are expressed in a variety of tumor types, including melanoma, breast, prostate and esophageal cancer. Although variable levels of expression were observed in these tumor types, DNA methylation was found to play a predominant role in regulating expression of MAGE family genes. Cells in which the MAGE-1 gene was highly methylated failed to express this gene product, and treatment of cultured cells with the demethylating agent 5-aza-2′-deoxycytidine up-regulated gene expression in tumor cells as well as normal cultured fibroblasts (27,*28*).

The NY-ESO-1 antigen, which was initially identified using the SEREX technique (29), represents a cancer/testis antigen that is unrelated to the MAGE family of genes. The peripheral blood of a melanoma patient with a high serum titer of anti-NY-ESO-1 antibodies was found to contain HLA class I–restricted T cells directed against this antigen, and further studies resulted in the identification of the NY-ESO-1:157-165 peptide as a dominant epitope recognized by HLA-A2–restricted, NY-ESO-1–reactive T cells (30,*31*). The NY-ESO-1 molecule is expressed in approximately 30% of breast, prostate, as well as melanoma tumors. In contrast to other antigens such as tyrosinase and MAGE-1, for which infrequent antibody responses have been observed, 10 out of 12 patients with NY-ESO-1–positive tumors possessed serum antibodies directed against this antigen *(32)*. In addition, tumor burden was positively associated with the titer of anti-NY-ESO-1 antibodies *(31),* and the presence of NY-ESO-1 antibodies was associated with the presence of T cells directed against the NY-ESO-1:157-165 HLA-A2–restricted epitope (33).

The presence of relatively high-affinity anti-NY-ESO-1 IgG antibodies is indicative of the presence of cognate help resulting either from the recognition of NY-ESO-1 class II–restricted epitopes that are presented on the tumor cell surface or epitopes that are processed and presented by APC that have taken up NY-ESO-1 protein released from tumor cells. Multiple NY-ESO-1 epitopes that are recognized by CD4[+] T cells have been identified by *in vitro* stimulation with candidate epitopes (*34*,35,36). It is not clear that these epitopes are naturally processed and presented *in vivo*, however, as evidence that T cells generated *in vitro* using these peptides recognized tumor cells or APCs that have been pulsed with tumor cell lysates was not presented in many of these studies.

Melanocyte Differentiation Antigens

The gene encoding the melanoma antigen designated MART-1 (37) or Melan-A (38) was isolated following the screening of melanoma cDNA libraries with an HLA-A2–restricted tumor reactive TIL and a CTL clone derived by *in vitro* sensitization, respectively. The MART-1 gene encoded a 118 amino acid protein that is expressed in between 80% and 90% of fresh melanomas and cultured melanoma cell lines *(39)*. The majority of melanoma-reactive, HLA-A2–restricted TIL were shown to recognize MART-1, indicating that this is a highly immunodominant antigen (40,*41*).

The MART-1 antigen is representative of a set of gene products, termed *melanocyte differentiation antigens* (MDAs), that are expressed in melanoma as well as in normal melanocytes present in the skin as well as in the retina. Tumors arising from glial cells have also been shown to express MDAs, and low levels of expression of these products have been detected in normal brain tissue *(42–44)*. Expression of these genes products results from the activity of

tissue-specific promoters *(45)*, an observation that is consistent with the fact that that normal melanocytes as well as glial cells are derived from neuroectrodermal tissue.

In an attempt to identify the dominant T cell epitope recognized by MART-1–reactive, HLA-A2–restricted T cells, a set of 23 candidate peptides from MART-1 were synthesized and tested for their ability to be recognized by MART-1–reactive T cells. The peptides that were synthesized conformed to the optimal HLA-A2–binding motif, which consists of a leucine, isoleucine, or methionine at the primary anchor position 2 and a valine at the carboxy-terminal primary anchor position (21). In addition, MART-1 peptides that contained an optimal residue at one of the primary anchor positions but a conservative substitution at the second primary anchor position were synthesized. The results of peptide screening assays demonstrated that HLA-A2–restricted, MART-1–reactive T cells recognized a single nonamer peptide AAGIGILTV(MART-1:27-35) as well as two overlapping decamers EAAGIGILTV and AAGIGILTVI (40). Nine out of 10 HLA-A2–restricted TIL cultures recognized the MART-1 gene product, and each of these cultures recognized that MART-1:27-35 epitope. Subsequent studies carried out by mass spectrometric analysis of peptides eluted from HLA-A2 molecules isolated from the surface of melanoma cells indicated that the AAGIGILTV(MART-1:27-35) nonamer represented the predominant MART-1 epitope that was naturally processed and presented on the surface of melanomas, as neither of the overlapping decamer peptides were isolated using this technique *(46)*. The MART-1:27-35 peptide did not conform to the optimal HLA-A2 binding motif, as it contained an alanine residue at the second position and was found to bind HLA-A2 with a relatively low affinity (47). These results have lead to further studies to explore the factors that may be involved with the expansion of T cells reactive with this epitope, as well as attempts to sensitize T cells using peptide variants that bind HLA-A2 with a higher affinity, which are discussed later in this chapter.

Several proteins were initially shown to be involved in the synthesis of melanin but were subsequently found to represent MDAs, including the gp100, tyrosinase, tyrosine-related protein (TRP-1), and TRP-2 gene products. In one study, pools of peptides eluted from the surface of melanoma cells were separated on HPLC columns and tested for their ability to sensitize target cells for T cell recognition (48). Candidate peptides present in positive subpools were then sequenced using a triple quadrupole mass spectrometer. They were then synthesized and tested for T cell recognition, resulting in the identification of the gp100 peptide YLEPGPVTA (gp100:280-288) as an epitope that was recognized by 5 out of 5 *in vitro* cultured CTL lines. Further studies resulted in the identification of multiple immunodominant HLA-A2–restricted epitopes from the 661 amino acid gp100 glycoprotein. Following the

screening of four gp100-reactive TIL lines with 169 peptides from the gp100 protein identified as potential candidates based on the use of the HLA-A2 binding motif, three additional gp100 epitopes, ITDQVPFSA(gp100:209-217), KTWGQYWQV (gp100:154-162), and VLYRYGSFSV (gp100:476- 485) were identified (47). As noted earlier for the MART-1 epitope, the ITDQVPFSA(gp100:209-217) and KTWGQYWQV (gp100:154–162) peptides do not conform to the consensus HLA-A2 binding motif, which lead to further studies described later in this chapter examining the antigenicity and immunogenicity of variants of these epitopes that conformed to this binding motif.

Epitopes from many of the MDAs have been found to be recognized in the context of restriction elements other than HLA-A2, and in addition, epitopes on these molecules recognized by murine tumor reactive T cells have been identified. Tyrosinase *(49,50)*, TRP-1- and TRP-2-reactive T cells (*51,52*,53) have been shown to these gene products in the context of a variety of HLA class I alleles. A peptide epitope recognized by HLA-A2–restricted, TRP-2–reactive T cells, SVYDFFVWL (TRP-2:180-188), also represented a dominant epitope recognized by H-2K^b restricted T cells (54). Adoptive immunotherapy studies carried out using the B16 murine melanoma also demonstrated that this represented a tumor rejection antigen.

One of the epitopes of tyrosinase found initially to be recognized by CD8$^+$ T cells in the context of HLA-A2 was also found to be recognized by CD4$^+$ T cells (55), an observation that, while unusual, has been reported for another melanoma-reactive CD4$^+$ T cell (56). The lack of dependence on CD8 for target cell recognition indicates that these cells may express particularly high-affinity T cell receptors (TCR).

Several of the MDAs initially identified as the targets of class I–restricted T cells have also been shown to be recognized by class II–restricted CD4$^+$ T cells. Two epitopes of tyrosinase were found to be recognized in the context of HLA-DRβ1*0401 (57). Additional shared class II–restricted epitopes that have been described include an epitope that is shared between TRP-1 and TRP-2 *(58)* as well as multiples epitopes derived from the gp100 glycoprotein *(59–61)*.

Overexpressed Gene Products

Gene products that are expressed at low levels in normal tissues but that are overexpressed in a variety of tumor types have also been shown to be recognized by T cells. Screening of an autologous renal carcinoma cDNA library with a tumor reactive, HLA-A3–restricted T cell clone resulted in the isolation of FGF5 (62), a protein that was expressed only at low levels in normal tissues but upregulated in multiple renal carcinomas as well as prostate and breast carcinomas. Use of a similar approach with an HLA-A24–restricted melanoma-reactive T cell clone

resulted in the isolation of a previously undescribed gene that was termed *PRAME* (63). This gene product appeared to be expressed are relatively high levels in melanomas as well as additional tumor types, but was also detected in a variety of normal tissues that included testis, endometrium, ovary, and adrenals. The HLA-A24–restricted PRAME-reactive T cell clone, however, expressed the natural killer (NK) inhibitory receptor p58.2, and tumor cell recognition was dependent upon loss of expression of the HLA Cw-7 allele that represented the ligand for the inhibitory receptor, which may explain the lack of recognition of normal tissues that express relatively high levels of this HLA gene product. Products derived from endogenous retroviral sequences that are overexpressed specifically in tumor cells have been shown to be recognized by murine *(64)* as well as human T cells *(65)*.

Generation of T Cells Using Candidate Epitopes ("Reverse Immunology")

Candidate epitope approaches have been utilized to generate T cells reactive with peptides derived from over-expressed gene products, as well as to generate T cells reactive with additional epitopes of previously identified tumor antigens. In many cases, HLA binding motifs have been used to identify a panel of peptides that are then synthesized and tested for their ability to bind to a particular MHC allele, followed by *in vitro* sensitization or *in vivo* immunization with candidate peptides. Using this approach, immunogenic peptides have been identified in the human carcinoembryonic antigen (CEA) (66), a protein that is overexpressed in colon and breast carcinomas. Similar approaches have been used to identify epitopes in proteins that are overexpressed in prostate carcinomas such as prostate-specific antigen (PSA) *(67)* and prostate specific membrane antigen (PSMA) *(68)*.

Attempts to generate T cells reactive with Her-2/neu, a protein that is frequently overexpressed in a variety of tumor type including breast carcinomas, have primarily focused on the Her-2/neu:369-377 peptide, a peptide that binds with high affinity to HLA-A2. Initial studies indicated that T cells generated with this peptide recognized the appropriate tumor targets (69). Subsequently, immunization of patients with the same peptide in Freund's incomplete adjuvant was found to result in the generation of peptide-reactive T cells following two *in vitro* stimulations of postvaccination peripheral blood mononuclear cell (PBMC) from three out of the four patients who were tested (70). Although these T cells recognized targets cells that were pulsed with relatively low concentrations of the Her-2/neu:369-377 peptide, they failed to recognize HLA-A2[+]/Her-2/neu[+] tumor cells, and objective clinical responses were not observed in this trial.

A peptide corresponding to amino acids 540-548 of the human telomerase catalytic subunit (hTERT) was initially reported to generate tumor reactive T cells (71). The re-

sults reported by additional investigators, however, have failed to provide evidence that T cells generated using this peptide recognized tumor targets (72,73). Inefficient processing may be responsible for these findings, as the incubation of a long peptide corresponding to amino acids 534-554 of the telomerase protein with purified proteasomes resulted in the production of multiple cleavage products but did not result in the generation of peptides containing the appropriate carboxy terminus (72), in contrast to results observed with naturally processed T cell epitopes.

It is not clear why there is disagreement with regard to the ability of T cells generated using candidate antigens to recognize unmanipulated tumor cells. Factors such as patient-to-patient variation, as well as the use of different treatments, such as incubation of *in vitro* cultured cell lines with interferon (INF)-γ, may play a role in these findings. Inadequate specificity controls as well as the use of bulk, uncloned T cell lines, however, may also at least in part be responsible for these discrepancies.

Another factor that appears to contribute to the difficulty in identifying naturally processed T cell epitopes is the fact that only a small percentage of the potential epitopes that are capable of binding to a particular MHC molecule are naturally processed and presented on the cell surface at sufficient levels to activate a T cell. The carboxy-terminus of the majority of processed peptides is generated within the proteasome, a multi-subunit complex of proteolytic enzymes that possess preferential polypeptide cleavage sites. Based on these findings, additional techniques have been used to identify naturally processed peptides. In one study, 27-mer polypeptides that encompassed 19 potential HLA-A2 binding peptides from the PRAME antigen were incubated with proteasomes, followed by the analysis of the peptides that resulted from proteasomal degradation (75). Four peptides were identified as potential candidates on the basis of the production of peptides containing the correct carboxy-terminus as well as the lack of internal cleavage of the peptides following proteasomal digestion, and T cells generated using these peptides were shown to recognize endogenously processed antigen. Using a similar approach, an immunogenic epitope was identified from the widely expressed antigen SSX-2 *(76)*.

Another method that has been used to identify naturally processed epitopes is the use of mass spectrometry to sequence peptides that have been eluted from MHC molecules isolated from the surface of human tumor cells. Use of this technique, coupled with microarray gene expression profiling, resulted in the identification of peptides that were derived from proteins that were overexpressed in tumor cells (77). Peptides identified using this approach may in many cases not be immunogenic, as the expression of these proteins at some level in normal tissues may lead to self-tolerance; however, one of the peptides that was identified in this study also appeared to be recognized by human tumor reactive T cells.

Epitopes Identified through the Use of HLA Transgenic Mice

Transgenic mice that express human HLA molecules have also been immunized in an attempt to identify T cell epitopes that are naturally processed and presented on tumor cells. Mis-sense mutations have been shown to result in overexpression of p53 in a wide variety of tumor types; however, self-tolerance due to the wide expression of p53 in normal cells appears to be responsible for the difficulty in generating T cells capable of recognizing nonmutated p53 epitopes (*78,79,*80). High-affinity, p53 reactive T cells, however, were generated by immunization of HLA transgenic mice with the human p53:264-272 peptide that contained only a single substitution of asparagine for aspartic acid at the fifth position (81). Human T cells that were transduced with the murine p53 TCR were capable of recognizing a variety of human tumor cells that overexpressed p53 (82). Both CD8$^+$ and CD4$^+$ T cells that were transduced with the murine p53 TCR recognized p53 overexpressing tumors, as expected on the basis of previous observation of a high affinity.

Transgenic mice expressing human MHC molecules have also been used to identify HLA class II restricted T cell epitopes. Mice expressing the human HLA-DRβ1*0401 class II restriction element were immunized with the NY-ESO-1 protein and screened for their ability to recognize peptides derived from the native protein. One of the epitopes that was identified using this approach, NY-ESO-1:160-180, was then used to sensitize human T cells. The T cells that were generated using this approach were found to recognize an epitope of NY-ESO-1 in the context of the HLA-DPβ1*0401 and 0402 alleles, which are expressed by more than 80% of patients (35). This epitope overlapped with a previously described immunodominant HLA-A2–restricted epitope NY-EOS-1:157-165. Subsequent studies, however, have failed to confirm the association between expression of the HLA-DP4 allele and NY-ESO-1 immunity *(83)*, and peripheral CD4$^+$ T cells from 11 out of 13 melanoma patients were found to recognize additional NY-ESO-1 epitopes in the context of multiple HLA class II alleles (36). Immunization of HLA-DRβ1*0401 mice has also resulted in the identification of T cells that recognize epitopes of gp100 *(60)*.

T Cell Epitopes Identified Using Full Length Recombinant Tumor Antigens

Recombinant proteins, as well as viruses that encode full-length tumor antigens, have also been used to carry out *in vitro* sensitization of human T cells to identify T cell epitopes. Pulsing of PBMC with recombinant gp100 protein followed by *in vitro* sensitization resulted in the identification of an HLA class II–restricted epitope of gp100 (61). The use of T cell–depleted PBMC infected with recombinant adenovirus, vaccinia virus, or fowl pox virus encoding NY-ESO-1 to stimulate autologous T cells resulted in the identification of NY-ESO-1 epitopes that were recognized in a variety of MHC class II gene products (36).

Mutated Antigens

Mutated Gene Products Recognized by CD8$^+$ and CD4$^+$ T cells

A variety of mutated antigens have also been identified as targets of tumor reactive T cells. While these studies have not providing generally useful targets for therapy, they have in some cases provided insights into mechanisms involved with tumor development. The CDK4 gene product that was cloned using a CTL clone contained a point mutation that enhanced the binding to the HLA-A2 restriction element (84). This mutation, which was identified in one out of an additional 28 melanomas that were analyzed, lead to inhibition of binding to the cell cycle inhibitory protein p16^{INK4a} and may have played a role in the loss of growth control in this tumor cell. A point-mutated product of the β-catenin gene containing a substitution of phenylalanine for serine at position 37 was isolated by screening a cDNA library with an HLA-24–restricted, melanoma reactive TIL line (85). The peptide epitope corresponded to amino acids 27 to 35 of the mutated β-catenin gene product, and the phenylalanine substitution appeared to have generated an optimal peptide for binding to HLA-A24. This mutation was found to stabilize the β-catenin gene product by altering a critical serine phosphorylation site, and two out of 24 additional melanoma cell lines were found to express transcripts with identical mutations (86). Previous studies demonstrating that β-catenin functions as a transcriptional activator are consistent with the hypothesis that the mutated gene products may have played a role in the development of these tumors. A mutated caspase-8 transcript was identified using T cells reactive with head and neck cancer (87), and overlapping frame-shifted transcripts of the p14ARF and p16INK4 genes were found to encode an epitope recognized by melanoma reactive T cells (88). These observations provide support for the notion that mutated gene products that play a role in promoting tumoriogenesis may frequently serve as the targets of tumor reactive T cells, as there may have been selective pressure to maintain expression of these products (89–91).

The observations made in murine studies indicating that immunization against an individual tumor does not generally result in cross-protection against multiple tumors has lead to the suggestion that mutant T cell epitopes represent the dominant antigens responsible for tumor rejection *(92)*. The identification of mutated antigens is also more difficult due to the problems with identifying the appropriate class I or class II restriction element and may have lead to their being underrepresented in studies attempting to identify human cancer antigens. In addition,

the nature of mutated antigens may make them more potent targets, as T cells reactive with these epitopes may not have undergone the same degree of negative selection as those that are reactive with normal, nonmutated self-antigens. Nevertheless, the studies described in this chapter suggest that normal self-proteins can represent tumor rejection antigens, as the adoptive transfer of cells whose predominant reactivity is directed against MDAs such as MART-1 and gp100 can lead to the regression of even bulky tumor deposits.

Common Mutations Can Provide Candidate Epitopes for T Cell Generation

Attempts have been made to generate tumor reactive T cells using epitopes that result from mutational hot spots that are present in some oncogenes. This approach has been used to generate responses against p21ras, which is frequently mutated at position 12 and 61, as well as peptides that result from junctional sequences present in bcr-abl fusion products that are frequently expressed in cancers such as acute lymphoblastic leukemia (reviewed in [93]). While caution is needed in evaluating the reactivity of T cells generated using candidate epitope approaches, antigen presentation of class II–restricted epitopes may not result from direct recognition of tumor cells. Constitutive expression of HLA class II has been observed in some tumor types, in particular melanoma, but is not generally observed in other tumor histologies. APCs such as DCs and monocytes, however, can process and present exogenous proteins derived from tumor cells to class II–restricted T cells *(94)*. Cross-priming of HLA class I–restricted tumor reactive T cells has been observed *(94,95)*, and thus it is also theoretically possible that these epitopes could be presented by DC. These observations have been made in experimental systems and may not contribute significantly to normal *in vivo* immune responses to human tumors, however, as tumors generally appear to be capable of directly presenting HLA class I–restricted epitopes to appropriately activated T cells.

Cancers with Viral Etiologies May Provide Potent Targets for Immune Responses

Although the expression of viral oncogenes has been shown in experimental systems to lead to the development of a wide variety of cancers, viruses have not been shown to play a role in the development of the majority of human cancers. Nevertheless, it is now clear that viruses play an important role in the etiology of cancers such as genital and hepatic carcinomas. Infection with papilloma viruses, a group of double-stranded DNA viruses that infect squamous epithelium, is highly associated with the development of a variety of genital lesions that range from warts to carcinoma. Cancer of the cervix is now the second most

common cancer in women worldwide and poses a particular threat to women in third-world countries where routine pap smears are not carried out. Nearly 100 HPV genotypes have been identified, and infection with HPV 16 and 18 as well as several additional genotypes is highly associated with the development of genital cancers (reviewed in [96]). The viral proteins E6 and E7 have been shown to lead to cellular transformation *in vitro (97)* and appear to be responsible for the induction of tumorogeneis following *in vivo* infection with HPV. The role of the immune system in controlling HPV infection and development of malignancy was demonstrated by the observation that neutralizing antibodies directed against the major viral capsid protein L1 are highly protective, as demonstrated in passive transfer studies carried out in animals (98). Cell-mediated immunity may also play a protective role, however, as spontaneously regressing genital warts have been found to contain dense infiltrates of lymphocytes and macrophages *(99)*. Recombinant vaccines have been produced by the generation of virus-like particles (VLP), self-assembling particles that form following the expression of the HPV L1 protein in recombinant viral and yeast systems, were initially found to be protective in animal models (98,*100*). The results of a phase II trial in which 2,392 women between 16 and 23 years of age were immunized with HPV16 VLPs indicated that 100% of the vacinees protected against infection with HPV 16 (101). The results of another hase II trail carried out with an HPV 6,11,16,18 quadrivalent vaccine demonstrated a reduction of infection with HPV 6,11,16 and 18 by 90% compared with placebo (102). Although vaccination with VLP does not lead to the regression of established disease, a variety of therapeutic vaccination strategies are also being tested.

A role for both hepatitis B virus (HBV) and hepatitis C virus (HCV) infection in the development of cirrhosis as well as hepatocellular carcinoma has been clearly demonstrated. Hepatitis is a noncytopathic virus, and infection of normal healthy individuals generally lead to spontaneous regression as a result of immune responses directed against HBV; however, in about 3% of individuals, chronic infection leads to cirrhosis and hepatocellular carcinoma (103). Damage to the liver appears to result in the most part from immune responses directed against HBV-infected cells and nonspecific inflammatory responses (reviewed in [104]). In contrast to HPV, studies have failed to provide evidence that oncogenic proteins derived from HBV or HCV result in transformation. The increased cell turnover resulting from chronic hepatitis infection may lead to carcinoma development by increasing the number of somatic mutations generated in normal hepatocytes *(105)*. Vaccination with HBV has been found to be effective at reducing the rate of development of hepatic carcinoma; however, immunization is only partially effective in some populations, particularly children born to HBV positive women *(106)*. The challenge for the future is to develop effective

preventive vaccines for HCV as well as effective therapeutic vaccines for HBV and HCV.

Functional TCR Avidity/Affinity and Diversity

Observations made in several studies suggest that there are wide variations in functional avidity of T cells reactive with a particular peptide epitope. Vaccination with the MART-1:26-35 native peptide was reported to increase the avidity of T cells present in peripheral blood reactive with this epitope, as defined by the ability of those cells to recognize target cells pulsed with titrated doses of the cognate peptide (107). Analysis of the T cell repertoire in this study indicated that the increase in avidity resulted from an oligoclonal T cell expansion.

The identification and isolation of T cells with high affinity has also been carried out through the use of specific peptide–MHC tetramers, complexes that can be generated by incubating biotinylated MHC molecules that have been refolded in the presence of a specific MHC-binding peptide with streptavidin *(108)*. The levels of binding of HLA-A2 MART-1:27-35 tetramers was found to correlate with functional T cell avidity (109), and similar findings were reported for additional T cell epitopes *(110)*. A lack of correlation between tetramer binding and avidity, however, has been noted in some studies (111,*112*), which may reflect the fact that many variables can affect tetramer binding. These findings have lead to attempts to devise methods to more reliably evaluate TCR affinity. Measurement of the off-rate of tetramer binding has been shown to be more directly correlated with affinity than direct binding *(113)*. Tetramers prepared with mutated MHC molecules that fail to interact with CD8 have also been used to identify high-affinity TCRs. While the wild-type HLA-A2 molecule was found to bind to CD8 with an estimated affinity of 137 μM, binding of an HLA-A2 mutant containing both a substitution of aspartic acid for lysine at position 227 and of threonine for alanine at position 228, termed D227K/T228A, to CD8 was essentially undetectable ($>$10,000 μM) (114). A comparison of the levels of binding of native and A2 227/228 KA tetramers has provided the means to distinguish high affinity from low affinity TCR *(115)*. Further studies carried out using the D227K/228A mutant have demonstrated that antibodies to CD8 can enhance or inhibit T cell activation, and this activity appears to be independent of the binding of CD8 to MHC molecules *(116)*. Observations indicating that the CD8 molecule present on the cell surface plays an important role in organizing the TCR on the cell surface *(117)* and may in fact directly interact with the TCR *(118,119)* are consistent with these findings.

In a recent study, a panel of MART-1 reactive T cell clones were examined for their ability to recognize tumor and peptide pulsed target cells, as well as for their ability to bind to the wild-type or mutant D227K/T228A HLA-A2 tetramers (120). The T cell clones that produced high levels of cytokines in response to tumors as well as peptide pulsed targets bound to both the wild-type and mutant tetramers, whereas clones that produced relatively low levels of cytokines bound to the wild type-but not the mutant tetramer, results that were confirmed by studies carried out using the TCRs that were isolated from these cells.

Additional studies have provided evidence for a restriction in the repertoire of MART-1 reactive T cells. While a variety of TCR beta chain variable (TR-BV) sequences have been associated with recognition of MART-1 *(121)*, the majority of receptors directed against this epitope were found in multiple studies to express TR-AV 12 (120,122). The dominant usage of particular TCR α chains observed in responses against both tumor and viral antigens suggests that structural features of germline encoded α chain residues may play an important role in dictating TCR specificity, while α chain junctional diversity along with β chain usage may influence TCR affinity *(123)*.

Multiple Mechanisms Involved with Generating T Cell Epitopes Revealed by Tumor Antigen Studies

A variety of previously unconventional mechanisms have been shown to be involved with generating epitopes that have been identified using T cells derived either by *in vitro* or *in vivo* tumor stimulation. While introns are normally spliced from RNA transcripts prior to being exported to the cytoplasm, multiple T cell epitopes have been found to encoded by intronic sequences *(124–127)*. Although unspliced transcripts may occur at relatively low frequencies in both normal and malignant cells, a transcript containing an intronic sequence of the N-acetylglucosaminyltransferase V gene that encoded a T cell epitope recognized by tumor reactive T cells was found to be expressed in approximately 50% of melanomas (128). Normal cells did not express transcripts containing intronic sequences, indicating that splicing was altered in tumor cells. Alternative open reading frames have also been found to antigens recognized by tumor reactive T cells *(129–132)*. An influenza epitope translated from an alternative open reading frame appears to result from read-through of the normal initiation codon at a low frequency that is dependent on the context of that codon and the number of additional start codons that precede the alternative open reading frame (133), and the open reading frame encoding an antigen expressed in renal cancer cells was initiated from a non-AUG codon (134). A T cell epitope was found be encoded by frame-shifted transcripts of p16^{INK4a}, and p14^{ARF} was identified using melanoma reactive T cells (88). Alternative splicing of transcripts derived from the CDKN2A tumor suppressor gene locus gives rise to both p16^{INK4a} and p14^{ARF}, and small exonic

deletions that result in frame-shifted transcripts of this locus have been frequently observed in tumor types such as acute myeloid leukemia (AML) and melanoma *(135,136)*.

Unconventional mechanisms of protein processing are also involved with generating tumor antigen epitopes. An HLA-A2–restricted epitope from tyrosinase was found to contain an aspartic acid residue that resulted from deglycosylation of an asparagine residue that represented a glycosylation site in the native protein (137). In addition, an epitope derived from the FGF-5 molecule that was recognized by renal cancer reactive T cells was generated as a result of protein splicing (138,*139*), a mechanism of protein processing that had not previously been shown to occur in eukaryotes, having only been demonstrated in unicellular organisms (140) and plants *(141)*.

Additional results have demonstrated altered antigen processing in cells expressing the immunoproteasome, which is expressed in professional APCs as well as interferon gamma (IFN-γ)–treated cells and differs in substrate specificity from the proteasome as a result of the replacement of the $\beta1$, $\beta2$, and $\beta5$ subunits with the INF-γ inducible subunits LMP2, MECL1, and LMP7 (74). The results of *in vitro* studies suggested that the MART-1:26–35 and gp100:209-217 epitopes were inefficiently processed in melanomas that had been treated for several daya with IFN-γ to induce expression of the immunoproteasome (142). Expression of the immunoproteasome is needed, however, for the efficient processing of many additional T cell epitopes (143,*144*).

Enhanced Antigenicity and Immunogenicity of High-affinity Altered Peptide Ligands

Peptide binding studies have revealed that the native MART-1:27-35 peptide as well as the gp100:209-217 and 280-288 peptides possessed relatively low binding affinities to HLA-A2. The observation that the sequence of these peptides does not conform to the consensus HLA-A2 binding motif lead to studies aimed at generating a higher affinity peptide that is more immunogenic than the native peptide. The substitution of methionine for the threonine at position two in the native gp100:209-217 peptide lead to a peptide with a nine-fold higher affinity for HLA-A2 than the native peptide, and the substitution of an optimal valine for the alanine present at position nine in the gp100:280-288 peptide lead to a 10-fold higher affinity than the native peptide (145). Variants containing additional modifications at these positions as well as at positions one and three were generated and found in some cases to bind with higher affinity to HLA-A2 than these variants; however, gp100 reactive TIL recognized the gp100:209-217 2M and gp100:280-288 9V peptides as well as the wild-type peptides, in contrast to many of the other variants tested. Tumor reactive T cells were also more efficiently induced when the modified gp100:209-217 2M and 280-288

9V peptides were used to carry out *in vitro* sensitizations of PBMC from HLA A2$^+$ individuals.

Recent results have demonstrated that the off rate of the gp100:209-217 2M peptide for binding to HLA-A2 is enhanced by seven-fold over the native peptide, while crystallographic studies have demonstrated that the structure of the complex of HLA-A2 with both the native and modified peptides is essentially identical *(146)*. The analysis of peripheral blood samples from 95 melanoma patients also indicated that the frequencies of T cells that recognize either the native or the modified peptides were essentially identical, further supporting the use of the gp100:209-217 2M peptide in vaccination strategies.

In murine studies, immunization of mice with a vaccinia virus construct encoding the human gp100 protein resulted in the induction of T cells that cross-reacted with murine gp100 (147). A dominant T cell epitope that was recognized in the context of H-2D^b, gp100:25-33, contained three differences in the amino terminus of the peptide that were responsible for enhancing the binding of the peptide to H-2D^b by a factor of between 100 and 1,000-fold.

Modified variants of the MART-1 peptide that have enhanced binding to HLA-A2 have also been identified and utilized for *in vitro* sensitization of T cells. The peptides ALGIGILTV (MART-1:27-35[28L]) and AMGIGILTV (MART-1:27-35[28M]) that contained substitutions of optimal position-two anchor residues, leucine or methionine, for the alanine in the MART-1:27-35 nonamer AAGIGILTV, bound with high affinity to HLA-A2 (148). Multiple T cell clones that reacted with the wild-type peptide, however, failed to recognize the modified nonamers peptides containing substitutions at the second position. The peptide decamer ELAGIGILTV containing a substitution of a leucine for the alanine at position two in the MART-1:26-35 decamer (MART-1:26-35[2L]) bound to HLA-A2 with a nine-fold higher affinity than the native nonamer. The majority of T cell clones reactive with the native MART-1 peptide recognized targets pulsed with the MART-1:26-35(2L) peptide, and the five CTL clones that were tested in this study recognized targets pulsed with between 30-fold and 20,000-fold lower concentrations of the MART-1:26-35(2L) peptide than the native peptide. The MART-1:26-35(2L) peptide exhibited a significantly slower dissociation rate from HLA-A2 than the native peptide, which may be the primary factor responsible for the significant enhancement of the antigenicity of the modified peptide. In addition, *in vitro* sensitization with the MART-1:26-35(2L) peptide was more efficient at inducing peptide and tumor reactive T cells than sensitization with the native peptide. Modification of the native nonamer by substitution of a leucine for the alanine at position one, MART-1:27-35(1L), also resulted in a peptide that appeared to possess increased immunogenicity, although this did not result in enhanced binding to HLA-A2 (148). Stimulation with the

MART-1:27-35(1L) peptide was also reported to enhance the secretion of IL-2 by MART-1 reactive T cells *(149)*.

Additional studies have further extended the observation that high frequencies of T cells reactive with the MART-1:27-35 epitope are present in HLA-A2 individuals. Limiting dilution analysis demonstrated the presence of high frequencies of MART-1 reactive T cells in the peripheral blood of melanoma patients, as the frequency of MART-1 reactive T cells was found to be >1 in 2,000 peripheral blood cells in four out of nine melanoma patients who were analyzed, while in the remaining patients frequencies on the order of 1 in 40,000 cells were detected (150). Using HLA-A2 tetramers that were prepared with the MART-1:26-35(2L) peptide because of the instability of the native MART-1 peptide complexes with HLA-A2, it was demonstrated that detectable levels of MART-1 reactive T cells were found in the peripheral blood of 10 out of 13 melanoma patients and 6 out of 10 healthy HLA-A2 individuals (151). Further investigations have revealed that MART-1 reactive T cells can recognize peptides derived from self-proteins as well as foreign pathogens (152,*153*), indicating that the relatively high frequencies of T cells reactive with the MART-1 epitope in normal individuals as well as melanoma patients may at least in part result from the presence of subsets of cross-reactive T cells.

The immunogenicity of the dominant NY-ESO-1:157-165 HLA-A2 epitope was also enhanced by the substitution of an optimal valine for the carboxyl-terminal cysteine residue (154). Crystallographic data indicated that complementarity between the peptide and MHC binding groove, as well as between the TCR and the peptide–MHC complex was enhanced by the valine substitution. The immunogenicity of the native cysteine containing peptide was also enhanced by inclusion of reducing agents in *in vitro* assays to reduce cysteinylation as well as dimerization of the native peptide *(155)*.

Multiple Factors Influence *in vivo* T Cell Function

Phenotype of Tumor Reactive T Cells *in vivo*

Relatively high percentages of tumor reactive T cells have been detected in both the peripheral blood and tumor tissues of patients with growing melanomas, but far less so if at all in patients with other types of solid cancers. These observations in melanoma patients have lead to the analysis of the state of differentiation and activation of cells present in these sites. The majority of MART-1:27-35 tetramer reactive T cells in the peripheral blood of healthy donors expressed a naïve phenotype, whereas those present in the peripheral blood of melanoma patients contained a mixture of T cells with a naïve and effector phenotype (151,156,*157*).

The tumor reactive T cells present in melanoma patients were found in many reports to respond normally to *in vitro* peptide stimulation; however, peripheral T cells isolated from a melanoma patient that were reactive with the MART-1:27-35 and tyrosinase:369-377 epitopes were shown in one study to be deficient in their ability to release cytokines in response to mitogens, as well as their ability to lyse melanoma target cells (158). Peripheral T cell responses to recall antigens such as tetanus toxoid, as well as responses to polyclonal activators, have been reported to be depressed in patients with breast cancer *(159)* as well as additional tumor types *(160)*, and specific effects on the responsiveness of CD4+ T cells has been noted *(161)*. Diminished immune responses may, however, also result from chemotherapy or other treatments administered to patients, rather than reflecting systemic immune suppression resulting from tumor cell growth. Peripheral T cells isolated from the majority of cancer patients do not, however, appear to exhibit a state of either generalized immunosuppression or suppression of specific tumor antigen responses, as demonstrated by the ability of patients with progressive disease to respond to vaccination with tumor antigen peptides (162–164). In addition, many of the tumor antigen epitopes that have been studied represent self-antigens that bind MHC molecules with relatively low affinities and may not efficiently activate peripheral T cells, which are generally in a resting state.

Immunosuppression in the Tumor Micro-environment

Considerable evidence exists, however, for the functional impairment of T cells present within the tumor micro-environment. The analysis of T cells present within melanomas as well as tumor-invaded lymph nodes has provided evidence for the functional impairment of T cells present at these sites, whereas T cells present in the peripheral blood analyzed simultaneously did not show evidence for impairment (165). Myeloid cells present in the tumor micro-environment have also been shown to express arginase, resulting in down-regulation of TCR zeta chain expression and impaired T cell function in a mouse tumor model *(166)*, and have been observed in human renal cancer patients *(167)*. Expression of arginase as well as nitric oxide synthase, which also plays a role in arginine metabolism, has also been observed in human prostate carcinomas (168). Expression of the inhibitory molecule indoleamine 2,3 dioxygenase, which is involved with degradation of tryptophan, was also observed in plasmacytoid DCs within tumor-draining lymph nodes *(169)*. Mouse studies have provided evidence that a subpopulation of monocytes that express the Gr-1 molecule can down-regulate T cell responses *(170,171)*. The ability of tumors to secrete granulocyte macrophage colony stimulating factor (GM-CSF) has been associated with the accumulation of a population of CD34+ suppressor cells that may correspond in humans to a recent

described population of cells termed *myeloid suppressor cells* (172).

The identification of T regulatory (Treg) cells as potent modulators of immune responses has lead to an examination of their potential role in modulating anti-tumor responses. In a murine tumor model system, Gr-1$^+$ monocytes have been reported to induce T regulatory cells (173). Recent analyses carried out using antibodies directed against the Forkhead box P3 (FoxP3) protein indicate that relatively high numbers of regulatory T cells may be present in the tumor micro-environment (164,174,*175,176*), which may act to limit anti-cancer immune responses. The expansion of Treg cells may result from expression of TGF-β in the tumor environment *(177)*.

Additional data have suggested that the levels of T cell subsets detected within tumors can be associated with enhanced or decreased survival of patients with a variety of tumor types, including ovarian cancer *(178)*, melanoma *(179)*, and colon cancer (180). Conflicting data concerning the exact phenotypic properties associated with prognosis has led to considerable confusion in this area. These findings may reflect the presence of an ongoing anti-tumor immune response that may act to limit the growth of malignant cells. The cross-presentation of tumor antigens by DC, which can be influenced by many factors *(181)*, may also be important for priming effective immune responses. Thus, the balance between factors that act to promote effective anti-tumor immune responses and suppressive factors that act to limit those responses may thus be responsible for determining progression of tumor growth.

CANCER THERAPIES

A wide variety of therapies have been evaluated in model systems and are now being developed for treatment of patients with cancer, which include those that involve direct immunization of patients with a variety of immunogens, as well as the adoptive transfer of activated effector cells. The identification of multiple antigens recognized by T cells has provided targets that can be utilized in a variety of contexts. Vaccination has been carried out using peptides either in saline or in adjuvants such as incomplete Freund's adjuvant, DCs that have been pulsed with peptides, with naked DNA encoding T cell epitopes, preparations of heat shock proteins prepared from tumor cells, as well as whole tumor cells and tumor lysates that have been pulsed on APCs. In addition, recombinant immunogens have been incorporated into viruses such as vaccinia, bird poxviruses, and adenoviruses that have been used successfully to protect against infectious diseases (182). The use of standard oncologic criteria is, however, needed to properly evaluate and compare the results of therapy trials. One commonly used definition of clinical response developed by the World Health Organization is a decrease in the sum of the products of the perpendicular diameters of all lesions by greater than 50% with less than a 25% increase in any lesion, a criterion that has been used to evaluate all of the studies carried out in the Surgery Branch, National Cancer Institute (NCI). Another set of criteria that has recently been proposed is the Response Evaluation Criteria in Solid Tumors (RECIST), which defines a response as a 30% reduction in the sum of the maximum diameters of all lesions and no new or progressive lesions. Another important issue is the application of results obtained from animal model systems to human clinical trials. Although these have provided important clues that may lead to improved therapies, it is important to note that model systems that employ tumor protection do not appear to be relevant to the treatment of patients with bulky metastases. Short-term lung metastasis models involve the treatment of relatively small, nonvascularized tumors, and again may not be directly relevant to the majority of tumors that are the targets of current clinical trials.

Nonantigen-specific Therapies

IL-2 Therapy

The best available evidence that immunologic reactions can mediate the regression of large, vascularized metastatic cancers comes from humans who have received the administration of recombinant IL-2. Initial murine tumor treatment model studies demonstrated that the administration of high-dose IL-2 could result in substantial tumor regression (183). In subsequent clinical trials employing treatment with high-dose IL-2, objective tumor regression was observed in between 10% and 20% of treated melanoma and renal cancer patients (184). Almost half of the responses are complete, and more than 80% of these are ongoing beyond 10 years. Thus, although the frequency of response is relatively low, response durations can be substantial, and in many cases curative. These results led to the approval of IL-2 by the FDA for the treatment of patients with metastatic melanoma and renal cancer. The factors that influence clinical responses to IL-2 therapy are not clear; however, recent findings demonstrate that IL-2 administration can lead to the expansion of peripheral Treg cells (185,*186*). Many tumors have also been shown to contain relatively high frequencies of Treg cells, and thus the relative balance between Treg and effector T cells within the tumor environment may at least in part influence the degree of responsiveness to this therapy.

Anti-CTLA-4 Antibody Therapy

CTL-associated antigen 4 (CTLA-4) is an immunomodulatory molecule expressed on both CD8$^+$ and CD4$^+$ T cells that maintains peripheral tolerance by suppressing T cell activation and proliferation. Triggering through CTLA-4 results in a decrease in T cell responsiveness and raises the threshold for T cell activation (reviewed in [187]). Mice

genetically deficient in the expression of CTLA-4 develop profound autoimmunity and die of a lymphoproliferative disease at 4 weeks of age. Similarly, in humans, CTLA-4 gene polymorphisms have been linked to the development of various autoimmune diseases, including autoimmune hypothyroidism and type 1 diabetes.

Blockade of CTLA-4 function provides a compelling means of enhancing anti-tumor immunity since tumors primarily express nonmutated, self-antigens. Administration of an anti-CTLA-4 blocking antibody has been shown to result in enhanced regression in murine tumor model systems when administered in combination with an anti-CD25 antibody and tumor vaccination *(188)* or with antibodies directed against activating molecules such as 4-1BB (189). More significantly, recent translation of these findings in clinical trials demonstrated that the administration of an anti–CTLA-4 blocking antibody mediates objective responses in approximately 15% to 20% of patients with metastatic melanoma (190). Objective responses correlated with grade III/IV autoimmune manifestations, including dermatitis, enterocolitis, hepatitis, and hypophysitis. Recent evidence using a knock-in humanized CTLA-4 transgenic mouse model indicates that cancer immunity can occur also in the absence of autoimmune disease (191).

While these results clearly demonstrate the importance of signaling through CTLA-4 in regulating T cell activation, the cellular mechanisms underlying the blockade of CTLA-4 negative regulation remain poorly defined. Some groups have shown that CTLA-4 blockade directly enhances $CD8^+$ T cell activation, proliferation, and cytotoxic activity even in the absence of $CD4^+$ T cell help (192). Blockade of CTLA-4 together with GM-CSF–producing vaccines was ineffective in treating large, vascularized subcutaneous murine tumors, however, and results obtained by other investigators indicate that the lack of CTLA-4 expression on $CD8^+$ T cells alone was insufficient to break peripheral tolerance and enhance effector functions of self-/tumor reactive T cells (193). In tumor treatment as well as prevention studies carried out with pmel-1 transgenic T cells expressing a TCR directed against an unmutated murine gp100 epitope, deletion of the CTLA-4 locus through a genetic knockout failed to enhanced the efficacy of $CD8^+$ pmel-1 T cells. Unlike previous reports indicating that the absence of CTLA-4 had a greater impact on activated rather than on naïve T cells *(194)*, CTLA-4 blockade did not appear to enhance the function of activated pmel-1 T cells.

These findings do not appear to be restricted to self-antigen systems, because similar results have been observed with T cells that recognize foreign epitopes. The lack of CTLA-4 did not affect the ability of adoptively transferred $CD8^+$ transgenic T cells expressing the alloreactive 2C TCR on a Rag-2 knockout background to control B16 SIY growth (195). Moreover, in the lymphocytic choriomeningitis viral model, the absence of CTLA-4 on p33-specific transgenic TCR $CD8^+$ T cells did not affect

antiviral T cell responses (196). Removal of $CD4^+$ T cells by crossing the pmel-1 CLTA-4$^{-/-}$ mouse onto a Rag-1$^{-/-}$ background resulted in the complete abrogation of $CD8^+$ T cell activation and autoimmune manifestations; nevertheless, the effects of $CD4^+$ CLTA-4$^{-/-}$ T cells were dependent on the absence of CTLA-4 on $CD8^+$ T cells. These results indicated that dysregulation of $CD4^+$ T cell function through inactivation of CTLA-4 promoted the autoimmunity as well as tumor immunity that was mediated by $CD8^+$ CLTA-4$^{-/-}$ T cells.

Active Immunization Approaches to Cancer Therapy

Cancer vaccines aim to stimulate the adaptive arm of the immune system directly *in vivo*. Despite a wealth of knowledge relevant to basic aspects of tumor immunology, however, the clinical realization of effective therapeutic vaccines for solid tumors have not yet been convincingly achieved. There is a telling paucity of murine tumor models that suggest that active vaccine approaches can mediate the regression of established vascularized tumors, so it is not surprising that these approaches have shown little efficacy in humans. Enthusiasm about the effectiveness of cancer vaccines has often been grounded in surrogate and subjective endpoints, rather than reliable objective cancer regressions using standard oncologic criteria. In a recent review of 1,306 vaccine treatments, including those conducted in the Surgery Branch at the NCI, a 3.3% overall objective response rate was observed (197). In addition to the relatively low response rates observed in these studies, however, in many cases relatively soft criteria such as stable disease or the regression of individual metastases in the presence of progressive disease at other sites have been reported. The presence of numerous and redundant negative influences of the host immune system and tumor microenvironment also may act to limit the effectiveness of "active immunotherapy" with therapeutic vaccines. These observations underscore the need to improve current cancer vaccines and to develop alternative immunotherapeutic strategies for the treatment of metastatic cancer.

Peptide Vaccines

Multiple trials have also been carried out by administering peptides to patients either in saline or oil-in-water emulsions such as Montanide. Immunization resulted in the expansion of T cells reactive with peptides such as the dominant gp100:280–288 (198) and tyrosinase:369-377 (199) peptides; however, the levels of T cells reactive with these epitopes was generally less than 0.01% of peripheral $CD8^+$ T cells. Similar levels have been observed using recombinant viral vaccines directed against epitopes derived from carcinoembryonic antigen *(200)* and prostate-specific antigen (201). Prime-boost regimens employing immunization with recombinant viral constructs followed by boosting

with peptide immunization is a strategy that has been found to result in enhanced frequencies of T cells reactive with viral epitopes. In one study, immunization with a canarypox (Alvac) recombinant virus containing a minigene construct encoding the HLA-A1–restricted MAGE-1:161-169 and MAGE-3:168-176 epitopes followed by peptide immunization did appear to enhance the frequencies of tumor reactive T cells. In this trial, a partial response was observed in 1 out of the 40 treated patients, but again the frequency of reactive cell was less than 0.001% of peripheral blood $CD8^+$ T cells. Further studies revealed that the frequency of T cells reactive with additional antigens such as the gp100:209-217 and MAGE-C2:336-344 epitopes was increased after vaccination to approximately 0.01% of peripheral blood $CD8^+$ T cells (202). The analysis of individual T cell clonotypes that recognize these antigens that were identified on the basis of specific TCR beta chain variable region (TCR-BV) sequences revealed that the high frequencies of T cells approached 10% of the $CD8^+$ T cells in regressing cutaneous metastasis and an invaded lymph node, while prior to vaccination frequencies of less than 0.1% of $CD8^+$ T cells were observed. The expansion of cells that recognize epitopes that are not included in the vaccine may have occurred through a bystander effect; however, it is difficult to interpret observations made with a single tumor metastasis that may have regressed due to unrelated mechanisms. The results of *in vitro* sensitization with the NY-ESO-1:157-165 peptide demonstrated that peptide reactive T cells could be induced from PBMC of 2 out of 10 HLA-A2$^+$ melanoma patients who were evaluated *(31)*. In addition, a low frequency of tetramer+ T cells, corresponding to 0.04% of peripheral blood $CD8^+$ T cells, was detected in 1 out of the 10 HLA-A2$^+$ patients who were examined. In an additional trial, immunization with the modified gp100:209-217 2M peptide in combination with IL-2 appeared to result in significantly higher response rates than treatment with IL-2 alone (203); however, the majority of responses that were observed in this trial were found to be transient, and most of the responding patients succumbed to recurrent tumors.

A variety of studies have demonstrated that T cells directed against the MART-1:27-35 epitope can be more readily detected than those directed against additional tumor epitopes, which are compatible with studies suggesting that responses against this epitope are highly dominant in HLA-A2$^+$ melanoma patients. In one study, *in vitro* sensitization with the MART-1:27-35 peptide resulted in the induction of tumor reactive T cells from 13 out of 13 HLA-A2$^+$ melanoma patients, as well as 5 out of 9 HLA-A2$^+$ healthy donors (204). In addition, vaccination appeared to enhance the generation of tumor reactive T cells resulting from *in vitro* peptide sensitization *(205)*. Subsequent studies carried out with MART-1 tetramers demonstrated that significant levels of T cells reactive with the MART-1:27-35 epitope could be detected in the peripheral blood of a sig-

nificant percentage of unimmunized HLA-A2$^+$ melanoma patients as normal individuals. Significant percentages of T cells reactive with the MART-1 tetramer could be detected in the peripheral blood of 7 out of 10 HLA-A2$^+$ melanoma patients and 6 out of 10 healthy donors at levels between 0.04% and approximately 0.2% of peripheral $CD8^+$ T cells (151).

Patients have also been immunized with multiple peptides in attempts to circumvent the escape of antigen loss variants. Evidence has been presented indicating that it is possible to generate T cell responses directed against multiple melanoma antigen (206), and increases in the frequency of T cells reactive with multiple peptides used for immunization were observed in peripheral blood as well as in sentinel lymph nodes that drain the immunization site (207). In one report, however, immunization with multiple peptides mixed together in incomplete Freund's adjuvant altered peptide immunogenicity (208).

Synthetic oligodeoxynucleotides containing CpG motifs that are potent stimulators of the Toll-like receptor (TLR) TLR9 have been identified and have been used as adjuvants in peptide vaccination trials *(209)*. In a recent study, immunization with the MART-1:26-35 peptide in combination with CpG oligodeoxynucleotide Vaccimmune/CPG 7909 was found to generate an enhanced frequency of peptide reactive T cells in the blood of melanoma patients (164). Immunization was not associated with enhanced frequencies of peptide reactive tumor infiltrating T cells, however, but appeared to be associated with high frequencies of FoxP3$^+$ T regulatory cells within the tumor.

Several clinical trials have been carried out involving immunization with serologically defined antigens such as GM2 ganglioside, which represents one of the most immunogenic gangliosides expressed on melanoma cells. Early studies demonstrated that administration of GM2 with combination with *Bacillus* Calmette-Guérin (BCG) induced immunoglobulin (Ig)M anti-GM2 antibodies in the majority of immunized patients, and a correlation between antibody responses with improved recurrence free survival and overall survival in stage 3 melanoma patients was noted (210). Studies comparing different vaccine formulations resulted in selection of a commercial formulation consisting of GM2 coupled to keyhole limpet hemocyanin (GMK) in combination with the QS-21 adjuvant, which, in contrast to earlier trials, induced high titers of IgM antibodies in more than 80% of patients as well as IgG antibodies, which had not been previously observed with GM2 plus BCG. The results of a large randomized study comparing GMK to high-dose interferon alpha (IFN-α-2b), however, indicated that the GMK vaccine was inferior to IFN-α-2b (211).

Although the expansion of T cells directed against the immunizing peptide was generally observed in these trials, generally less than 5% of the treated patients demonstrated

clinical responses, and strict oncologic criteria have not always been utilized in reporting these results. One possible explanation for the lack of clinical responses is the fact that these immunizations generally have been shown to result in the stimulation of frequencies of peptide reactive T cells that are less than 0.1% of peripheral T cells. It has been estimated that frequencies on the order of 1% or more of peripheral blood T cells, however, may be required to mount an effective anti-tumor response (212,*213*), though little reliable data is available to support this statement. Additional findings demonstrate, however, that tumor progression can occur even in the presence of relatively high frequencies of tumor antigen reactive T cells. In an adjuvant trial of patients with no evidence of disease at the start of the course of vaccination, multiple course of peptide immunization carried out over a course of approximately 1 year with the modified gp100:209-217 2M peptide was shown to result in the induction of high levels of peptide and tumor reactive T cells (163). Analysis of reactivity of PBMC obtained following multiple ELISPOT assays indicated that in 44% of the immunized patients between 1% and 10% of all peripheral CD8$^+$ T cells recognized the immunogen, and in 17% of patients >10% of peripheral CD8$^+$ T cells recognized this peptide. Although immunoselection for loss of antigen or HLA-A2 expression could have been partially responsible for some of the recurrences, recurrences of tumors that clearly expressed both antigen and HLA-A2 were observed in this trial.

Whole Cell Vaccines

Clinical trials employing whole tumor cells as vaccines represents can theoretically activate cells reactive against multiple antigenic targets, and early model studies have demonstrated the ability of autologous tumor cell vaccination to protect mice from subsequent tumor inoculation (11,*12*). In a trial comparing treatment with a combination of an allogeneic melanoma vaccine with the adjuvant DETOX, there was no significant increase in relapse free survival when compared to patients randomized to observation without further therapy (214). Treatment with a combination of three irradiated allogeneic melanoma cells with BCG (Canvaxin trial) resulted in an overall survival rate of 49%, as opposed to a rate of 37% in patients who did not receive the vaccine (215). Further evaluation of this approach in phase III trials, however, showed no significant difference in survival of patients with stage III or IV melanoma receiving this treatment compared to controls receiving BCG alone (216).

Gene modified cells have been evaluated for their effectiveness in cancer therapy protocols. In a murine model system, mice that were immunized with B16 melanoma cells transduced with genes encoding 10 cytokines were examined for their resistance to a subsequent inoculation of the wild-type B16 tumor (217). The results indicated that tumors transduced with the GM-CSF gene provided significant protection against B16 tumor challenge, and a lower level of protection was observed in mice immunized with IL-4 and IL-6 transduced tumors. In a clinical trial involving immunization of patients with autologous renal carcinoma cells that had been transduced with the GM-CSF gene, immune responses against the parental renal carcinomas were observed, as measured by delayed type hypersensitivity (DTH) responses, and an objective clinical response was observed in 1 out of the 16 fully evaluable patients (218). Melanoma patients have also been immunized with allogeneic irradiated melanomas transduced with GM-CSF. Analysis of DTH responses provided evidence for priming of reactivity against autologous tumor cells in 17 out of 25 patients, and one complete and one partial response was observed (219), but again it is difficult to evaluate the effectiveness of this approach in this relatively small trial.

DC Vaccines

Other approaches have utilized immunization with professional APCs such as autologous DC. In one trial, patients were vaccinated with autologous DC that were pulsed either with peptide or melanoma lysates. Objective clinical responses were observed in 5 out of 16 treated patients (220); however, follow-up studies involving treatment of larger numbers of patients using this approach have not been reported by this group. Another approach has employed immunization of patients with DCs that have been transfected either with mRNA encoding individual tumor antigens or bulk mRNA isolated from tumor cells (221,*222*). Although expansion of tumor reactive T cells following these treatments has been reported, only sporadic cases of tumor regression were observed in these trials. In one study carried out by the Dendreon Corporation (Seattle, WA), an APC vaccine loaded with an antigen called prostatic acid phosphatase linked to GM-CSF was used to treat men with hormone-refractory prostate cancer (223), and in a retrospective subset analysis, limited clinical efficacy was claimed. Additional trials are also being carried out using DCs pulsed with either tumor lysates or using hybrids of DCs and cancer cells (224).

Recombinant Vaccines

Multiple trials have been carried out using either recombinant viral constructs or naked DNA encoding particular tumor antigens. In these trials, recombinants containing either full-length gene products or mini-genes containing individual or multiple T cell epitopes were evaluated. The failure in general to detect enhanced precursor frequencies directed against the tumor antigens may have resulted from the dominance of viral epitopes.

Attempts have also been made to enhance the potency of vaccination protocols through the provisions of costimulatory signals. In studies carried out in a mouse model system, evidence for enhanced immunity was obtained following immunization with a recombinant virus that contained the genes encoding the candidate tumor antigen CEA along with genes encoding LFA-3, ICAM-1, and B7–1, termed *TRICOM* (225). In an ongoing clinical trial, injection of a vaccinia virus TRICOM construct directly into melanoma lesion resulted in one partial response and one complete response out of the 12 treated patients (226). One objective response was also observed in 58 patients with advanced CEA-expressing cancers that were treated with TRICOM-CEA (227), but larger randomized patient studies will be needed to establish the efficacy of this approach.

Heat Shock Proteins (HSP)

The first autologous HSP vaccine introduced in clinical trials was Oncophage or, HSPPC-96 (heat shock protein-peptide complex 96; Antigenics Inc., Woburn, MA) produced from surgically resected cancer tissue and formulated for intradermal or subcutaneous injection. Numerous HSP vaccine trials have been carried out in a variety of patients including those with resected pancreatic adenocarcinoma, renal cell carcinoma, melanoma, colorectal cancer, non-Hodgkin's lymphoma, and gastric cancer. The results of these trials, however, have failed to demonstrate the effectiveness of HSP-based vaccines (reviewed in [228]).

Idiotypic Determinants as Therapeutic Targets

The presence of idiotypic determinants on the Ig molecules expressed by B cell lymphomas has presented investigators with unique targets for vaccine trials of patients with hematopoietic malignancies. Immunization with idiotypic proteins that have been coupled to carrier proteins has been shown to result in long-term tumor regression in significant numbers of treated patients (229). These responses were associated with serological anti-idiotypic responses as well as FcγRIIIa polymorphisms, suggesting that humoral immunity may play a significant role in these responses. Immunization with DCs that have been pulsed with idiotype protein was also shown to result in tumor regression in 4 out of 10 vaccinated patients (230).

In summary, although some success has been achieved in clinical vaccination studies carried out with leukemias and lymphomas, possibly as a result of the unique nature of the antigenic targets expressed on these tumors, the results of active immunization trials carried out in patients with other malignancies have been disappointing. These have included trials involving treatment of patients with melanoma, a patient population demonstrating significant response rates to cellular therapies, as described later

in this chapter. Many of the murine model systems that have been studied employed either prevention protocols in which the vaccination may have prevented implantation of the tumor or relied on the treatment of relatively small, nonvascularized tumors. Another problem encountered in these early trials is the observation that antigenically complex vaccines such as those employing recombinant viral constructs contain immunodominant determinants that overshadow responses to relatively weak tumor antigens present in these constructs.

Passive Immunological Treatments

Adoptive Cell Transfer

The transfer of in vitro cultured LAK cells to syngeneic mice along with IL-2 was found to lead to the regression of relatively small established pulmonary metastases as well as prolonged survival *(231)*. Subsequent studies in human adoptive immunotherapy trials resulted in durable complete tumor responses (232); however, there was no significant differences in long-term survival between patients treated with LAK cells plus IL-2 compared to IL-2 alone.

Further studies carried out using TILs demonstrated that cultured TIL contained potent effector cells that, in mouse models, were between 50- and 100-fold more active than LAK cells (233) and lead to TIL adoptive immunotherapy trials. The identification of CD8$^+$ T cells as potent effectors of the adaptive anti-tumor immune response has lead to the extensive use of these cells in both experimental model systems and clinical trials. Tumor-specific CD4$^+$ T cells have been also identified, but their functionality can be manifold because CD4$^+$ T cells can help or hinder anti-tumor immune responses. The target antigens recognized by tumor reactive T cells have been described earlier. A number of advances in basic immunology have made a substantial impact on therapies based on the adoptive transfer of T cells. The molecular signals that modulate T cell activation, function, and memory are being elucidated. Both positive and negative signals from costimulatory molecules have been shown to shape the anti-tumor response. Cytokines, including those with receptors that contain the common cytokine-receptor γ-chain, have been shown to alter the programming of T cells.

Adoptive cell transfer (ACT) therapies accomplish T cell stimulation *ex vivo* by activating and expanding autologous self-/tumor reactive T cells to large numbers that are then transferred back to the patient. Early attempts of ACT therapies using TILs in immuno-replete patients met with some success (234), although the lack of persistence of the transferred cells appeared to limit their clinical effectiveness. Previous preclinical studies, however, had indicated that immune ablation is an effective preconditioning regimen that can enhance T cell responses after adoptive transfer (235). The adoptive transfer of TILs after
FIGURE 45.1 Tumor destruction and autoimmunity following the adoptive cell transfer of TILs, in the setting of chemotherapy-mediated lymphoablation. **A:** Computed tomography (CT) scan of liver metastases in a melanoma patient. Metastatic lesions progressed rapidly before the treatment (from day −45 to day −25), then regressed dramatically after adoptive T cell transfer (day +34). **B:** Extensive destruction of normal melanocytes (vitiligo) in a patient who experienced a remarkable clinical response. **C:** Anterior uveitis (inflammation of the eye) in a patient who exhibited >99% tumor reduction (*320*).

nonmyeloablative but lymphodepleting systemic chemotherapy can induce objective anti-cancer responses in approximately 50% of patients with metastatic, multivisceral, bulky melanoma that is refractory to standard treatments including chemotherapy, radiation therapy, and IL-2 administration (236) (Figure 45.1).

These clinical studies that combine a lymphodepleting preparative regimen followed by the administration of activated anti-tumor T cells and IL-2 provide the clearest evidence that antigen-specific immunotherapies can result in cancer regression when appropriate treatment and host factors are combined. Studies carried out in both animal model systems as well as in patients have now provided clues as to the factors that influence tumor regression following the transfer of self-/tumor-reactive T cells into lymphopenic recipients. Further studies have begun to elucidate the phenotypic and functional characteristics of tumor-specific T cells that mediate anti-tumor responses *in vivo*. Many of these factors, which are described in the following section, provide the bases for rational design of new ACT-based immunotherapies that incorporate vaccines, increased intensity preconditioning regimens with hematopoietic stem cell (HSC) transplantation, and alternative methods for the generation and selection of T cells for transfer.

Lymphodepletion Increases the Efficacy of ACT through a Variety of Mechanisms

It has long been observed in mice that depletion of immune cells prior to ACT can dramatically improve the anti-tumor efficacy of transferred CD8[+] T cells, but the specific mechanisms that contribute to this increased immunity have only recently begun to be elucidated. Although it seems counterintuitive that the efficacy of ACT-

based tumor immunotherapy can be improved by the removal of the host immune system, several mechanisms might underlie the augmented efficacy of tumor reactive T cells in the lymphopenic environment. These factors include the elimination of immunosuppressive cells such as CD4[+]CD25[+] Treg cells, the depletion of endogenous cells that compete for activating cytokines, and the increased function and availability of APCs (Figure 45.2).

Elimination of Immunosuppressive Cells

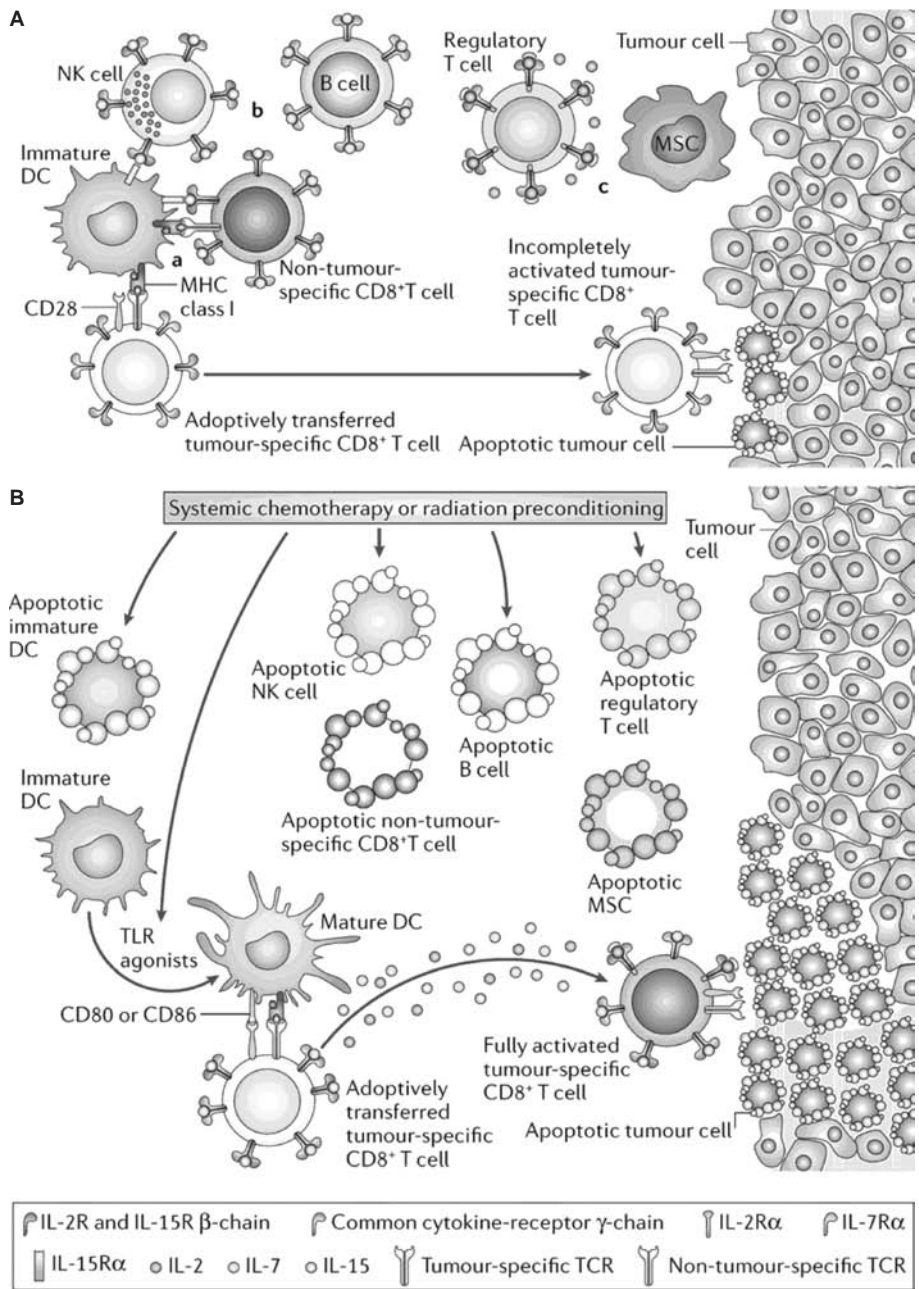
Extensive studies have now demonstrated that Treg cells are critically involved in the maintenance of peripheral self-tolerance; however, more recent studies have provided evidence that Treg cells may also down-regulate anti-tumor immune responses. These cells constitutively express high levels of the transcription factor FoxP3 as well as several cell-surface molecules associated with T cell activation. These include IL-2Rα (CD25), which together with the IL2-Rβ and γ chains forms the high-affinity IL-2 receptor, glucocorticoid-induced TNF receptor–related protein (GITR) and CTL-associated antigen-4 (CTLA4). An exclusive molecular signature for human Treg cells does not currently exist, however, because activation of CD4[+] T cells can also result in up-regulation of FoxP3 expression. Experiments using mice lacking Treg cells owing to specific gene defects, as well as the "add-back" of these cells, have convincingly shown that they are capable of suppressing the anti-tumor activities of adoptively transferred self-/tumor reactive T cells. Augmented anti-tumor responses were observed after ACT of self-/tumor reactive effector CD8[+] T cells to tumor-bearing CD4$^{-/-}$, but not CD8$^{-/-}$, mice, indicating that the immunoregulatory cells are contained in the CD4[+] T cell population. The suppressive activity was restricted to the CD25[+] T cell subset because


FIGURE 45.2 The rationale for lymphodepletion. **A:** In immunoreplete hosts, competition for homeostatic and activating cytokines such as IL-2, IL-7, and IL-15 can inhibit the functions of adoptively transferred T cells. Treg, NK cells, and other immune cell populations (e.g., macrophages) can display suppressive activity either by direct cell-to-cell contact or release of suppressive cytokines, and the tumor itself might act as a negative regulator of T cell activation. **B:** Lymphodepleting preconditioning using systemic chemotherapy or radiation can augment the functions of adoptively transferred T cells by reducing competing "cytokine sinks" and regulatory elements. In addition, the pro-inflammatory environment can activate immature DCs as well as enhancing MHC expression on tumor cells. Abbreviations: DC, dendritic cell; IL, interleukin; NK cells, natural killer cells (271).

transfer of CD4$^+$CD25$^+$ Treg cells alone, or in combination with CD4$^+$CD25$^-$ T helper (T$_H$) cells, to mice receiving CD8$^+$ anti-tumor cells inhibited effective immunotherapy in lymphopenic mice. By contrast, transfer of T$_H$ cells alone in this setting resulted in profound autoimmunity and eradication of established tumors. The maintenance and function of effector CD8$^+$ T cells required the presence of T$_H$ cells able to produce IL-2.

The immunosuppressive role of Treg cells in patients with cancer has only recently begun to be explored. Treg cells have been reported to be overrepresented in tumor lesions from patients with ovarian and lung cancer

(237). Cells that possess characteristics of Treg cells have been isolated following the *in vitro* culture of melanoma TIL (238,239), although the *in vivo* significance of these observation has not been established. Reduced survival was reportedly associated with increased tumor infiltration by Treg cells in patients with ovarian cancer (240), although these findings have been recently contradicted (241). Therefore, at present, no conclusive data link the *in vivo* function of Treg cells and the progression of cancer. Nevertheless, the suppressive effects of Treg cells might contribute to the poor clinical response rates reported in patients with cancer who receive immunotherapy in

nonlymphodepleting settings. Selective elimination of Treg cells from patient TILs might further improve the efficacy of ACT approaches in the lymphodepleting setting, because the proliferation of Treg cells can be enhanced by the lymphopenic environment and the presence of exogenous IL-2. Further, removal of Treg cells from PBMC might enrich for a T_H-cell population able to bolster the response of self-/tumor-specific CD8$^+$ T cells *in vivo*.

Other immune cells including NKT cells, NK cells, and CD11b$^+$Gr1$^+$ myeloid suppressor cells (MSCs) have been shown to dampen T cell function. Some studies have suggested that NKT cells mediate suppression through the production of cytokines such as IL-13 (242). Although the precise lineage of MSCs has not been clearly defined, these cells appear to comprise a heterogeneous population of cells that comprises myeloid cells at various stages of differentiation, including monocytes, granulocytes, and a subset of immature myelo-monocytic cells (170). Increased frequencies of MSCs are found in conditions characterized by impaired T cell function, including tumors and chronic infections (243), and MSCs may play an important role in the induction of Treg cells in the tumor environment (173). The expression of arginase and inducible nitric oxide synthase (iNOS) by MSCs leads to the release highly reactive peroxynitrates may play an important role in mediating T cell suppression (168), but MSCs may also mediate suppression through direct contact with T cells. Depletion of MSCs using a Gr1-specific antibody has also been shown to result in protection from tumor challenge (244). Therefore, removal of MSCs, and thereby their suppressive activity, might contribute to the increased anti-tumor T cell responses observed after ACT in patients who have been lymphodepleted.

Minimizing Cellular Cytokine Sinks

Transfer of small numbers of antigen-specific T cells into a lymphopenic host results in T cell clonal expansion and activation, a process known as *homeostatic proliferation*. In the lymphopenic environment, antigen-experienced T cells proliferate independently of self-peptide–MHC complexes. However, either cotransferring an "irrelevant" population of T cells or increasing the number of transferred cells can reduce the level of homeostatic proliferation in a dose-dependent manner showing that other elements exist that limit homeostatic proliferation. Although host-mediated inhibition of the proliferation of adoptively transferred T cells might involve direct cellular contact, competition might also exist between transferred and host T cells for a limited amount of the cytokines that are required to support CD8$^+$ T cell homeostasis, and such competition is known as the "cytokine sink" effect.

The importance of the availability of these cytokines has been shown in experiments in which mice deficient for IL-7 or IL-15 showed impaired homeostatic maintenance and proliferation of memory CD8$^+$ T cells (245).

Conversely, transgenic mice overexpressing IL-7 or IL-15 have increased numbers of T cells owing to the preferential expansion of the memory CD8$^+$CD44^{high} T cell population (246). In the pmel-1 mouse model of ACT therapy, lymphodepletion before cell transfer increased the persistence of self-/tumor-specific T cells, as well as their effector function and tumor regression, compared to immunoreplete hosts (247). Conversely, increased anti-tumor responses were seen when these cytokines were exogenously administered or when the endogenous competition (that is host lymphocytes) for these cytokines was removed by using mice lacking both recombination-activating gene 2 (RAG2) and γ_C (247). These findings show that a key mechanism underlying the improved efficacy of ACT therapies after lymphodepletion is the transient eradication of endogenous lymphocytes, which serve as cellular cytokine sinks. The use of cytokines such as IL-7, which is capable of supporting the survival of CD4$^+$ and CD8$^+$ T effector and memory T cells but does not promote the survival of Treg cells, might also be advantageous for adoptive cell transfer therapy. Depletion of cells expressing NK1.1 (using an NK1.1-specific antibody) improves the efficacy of ACT therapy in tumor-bearing *Rag1*$^{-/-}$ mice and implicates NK cells as key players in the cytokine sink effect, a process that might be mediated by consumption of IL-15, a critical cytokine for the survival and proliferation of both T and NK cells *in vivo*.

Another cytokine whose receptor contains the γ_C signaling chain IL-2 is a T cell growth factor commonly used to promote the expansion and function of self-/tumor-specific T cell populations *in vitro* and *in vivo*. Perhaps more importantly, however, IL-2 is essential for the maintenance of peripheral self-tolerance. Mice deficient in either IL-2 or components of the IL-2 receptor spontaneously develop lymphoproliferative and autoimmune disorders (248). These observations have been linked to impaired Treg cell homeostasis and "metabolic fitness" *in vivo*, rather than suppressive function, because Treg cells from either IL-2– or IL-2Rα (CD25)–deficient mice are competent when tested in *in vitro* assays of suppressive function. More recent findings, however, have shown that *in vivo* IL-2 signaling is important not only for maintaining Treg-cell "fitness" but also for their suppressive function. The anti-tumor activity of adoptively transferred self-/tumor-specific CD8$^+$ T cells was inhibited in wild-type but not IL-2Rα–deficient mice, despite both animals having comparable numbers of FoxP3$^+$ Treg cells (249). Further, blockade of IL-2Rα with specific antibody has been shown to induce profound autoimmunity resulting from impaired Treg cell function, rather than depletion of these cells (250). These results indicate that *in vivo* immunoregulation by Treg cells might, in part, be a product of their constitutive expression of the component of the IL-2 receptor with highest affinity for IL-2, IL-2Rα (CD25), and their increased capacity to consume IL-2. Therefore,

removal of Treg cells by lymphodepletion might result in increased anti-tumor reactivity of adoptively transferred CD8$^+$ T cells not only by the elimination of direct cellular inhibition, but also by increasing the availability of IL-2.

Improved APC Function and Availability

Systemic chemotherapy and total body irradiation have both been used before ACT to deplete the lymphoid compartment of the host and create a niche for the transferred cells. Investigators have long hypothesized that these treatments might also cause necrosis or apoptosis of tumor cells, resulting in APC uptake of tumor antigens and the subsequent cross-presentation of these antigens to the adoptively transferred self-/tumor reactive CD8$^+$ T cells. Although lymphodepletion can reduce the absolute number of APCs *in vivo,* it can also promote their transition to an activated state. In mice, the expression of the activation markers CD86 and I-A (MHC class II) has been reported to be up-regulated on the surface of splenic DCs after irradiation (251). Further, DCs isolated after irradiation released substantially more IL-12 in comparison with DCs isolated from nonirradiated mice (252). Activation of DCs after chemotherapy or irradiation might be triggered by translocation of bacterial products, such as lipopolysaccharide (LPS) and other TLR agonists, into the bloodstream following damage to the integrity of mucosal barriers. The production of pro-inflammatory cytokines such as TNF, IL-1, and IL-4 by host cells might be also involved in mediating DC maturation. In addition, the lymphopenic environment might facilitate the activation of transferred self-/tumor reactive T cells through decreased competition at the surface of antigen-bearing APCs. Although the net effect of lymphodepletion on APC function is less clear than its impact on Treg cells and cellular cytokine sinks, ablation might ultimately increase the anti-tumor reactivity of transferred T cells by increasing the activation and availability of APCs.

T Cell Differentiation State and ACT-Based Immunotherapies

Lymphodepletion can have a marked impact on ACT-based immunotherapies, but it is not the only factor that has been shown to impact clinical responses. Emerging findings from both mouse studies and clinical trials indicate that intrinsic properties related to the differentiation state of the adoptively transferred T cell populations are critical to the success of ACT-based approaches.

In both mice and humans, CD8$^+$ T cell subsets have been categorized into distinct differentiation states using a variety of phenotypic and functional attributes. A progressive pathway of CD8$^+$ T cell differentiation has gained acceptance based on the findings of *ex vivo* phenotypic analyses of virus-specific T cells, measurement of telomere length, gene-expression profiling, and *in vitro* differentiation studies. Within this paradigm, activation of naïve

CD8$^+$ T cells results in proliferation and progressive differentiation through early, intermediate, and late effector stages depending on signal strength. Memory CD8$^+$ T cells might reflect T cells arrested at intermediate stages of the differentiation pathway, but there remains some debate regarding the pathways by which effector and memory T cells develop.

The phenotypic and functional characteristics of self-/tumor-specific CD8$^+$ T cells that are associated with optimal *in vivo* tumor responses in the pmel-1 mouse model of ACT therapy have recently been elucidated. Self-/tumor-specific CD8$^+$ T cells at progressive stages of differentiation were generated using multiple *in vitro* stimulations with antigen. Surprisingly, CD8$^+$ T cells that acquired terminal effector properties and had increased anti-tumor activity *in vitro* were found to be less effective at triggering tumor regression *in vivo* (253). Terminally differentiated CD8$^+$ T cells were nearly 100-fold less effective *in vivo* on a per cell basis than T cells at an early stage of differentiation. Similar findings have been reported by other groups employing different mouse tumor and allogeneic HSC transplantation models. The *in vitro* expansion of T cells for ACT—as it is currently performed for clinical use—induces progressive CD8$^+$ T cell differentiation toward a late effector state resulting in phenotypic and functional changes that may render T cells less "fit" to mediate anti-tumor responses *in vivo* and less able to benefit from the activating cues present in the lymphopenic host (Figure 45.3). For example, less differentiated, central memory–like T cells have a high proliferative potential, are less prone to apoptosis than more differentiated cells, and have a higher ability to respond to homeostatic cytokines, because they express receptors such as IL-7Rα. Therefore, less differentiated central memory–like T cells might proliferate and become fully activated in the lymphopenic environment, which is rife with homeostatic cytokines such as IL-7.

The Importance of Trafficking to Lymph Nodes

Tumor immunologists have long sought to cause T cells to specifically traffic to their tumor targets. The loss of expression of the lymphoid homing molecule CD62L and the acquisition of CD44 expression were reported to be associated with increased anti-tumor effects of adoptively transferred T cells (254). It is now clear in both tumor and viral models, however, that T cells able to home to secondary lymph nodes, where they can be effectively stimulated by DCs, are more effective in adoptive immunotherapy (253,255). Anti-tumor responses have also been found to be abrogated in hosts devoid of peripheral lymphoid tissues and with a disrupted splenic structure (256), which is consistent with additional studies that indicate that that tumors alone are inefficient at triggering effective immune responses. Similarly, CD62L$^-$ T cells were less effective at mediating allo-responses in an allogeneic HSC

FIGURE 45.3 Inverse relationship of *in vitro* and *in vivo* antitumor functions of adoptively transferred naive and effector T cell subsets. As time and the strength of stimulation increases, naïve CD8$^+$ T cells proliferate and progressively differentiate through early, intermediate, and late effector stages. The phenotypic and functional changes that characterize this process are illustrated as no expression (–), intermediate expression (+), and high expression (hi) of the various markers. The progressive acquisition of full effector functions (dashed burgundy line) is associated with a decreased ability of T cells to cause tumor regression after adoptive transfer (black line). This may result from progressive telomere shortening, loss of proliferative potential, decreased expression by T cells of lymph-node homing and costimulatory molecules and the inability of terminally differentiated T cells to produce IL-2, as well as a reduction in the levels of receptors required to receive activating signals from homeostatic cytokines. KLRG1, killer-cell lectin-like receptor G1 (*321*).

transplantation model (257). Therefore, down-regulation of expression of lymph node homing molecules at the intermediate and late stages of effector CD8$^+$ T cell differentiation can result in impairment of their anti-tumor capacity. The principle that T cells must home to lymph nodes to be effective has not been established in humans, as CD62L$^-$ and CCR7$^-$ TILs were able to engraft, proliferate, and ultimately lead to objective responses in approximately 50% of treated patients. Nevertheless, it is possible that the expression of additional T cell homing molecules may play an important role in these therapies.

Costimulatory Molecules and T Cell Persistence

Transition from an early to an intermediate effector stage is marked by down-regulation of CD28 expression. The interaction of CD28 with CD80 or CD86 on APCs amplifies TCR-mediated T cell activation and proliferation. Enhanced IL-2 secretion, the induction of anti-apoptotic

molecules, as well as increases in cell-cycle progression have been associated with T cell expression of CD28. The role of CD28 expression in ACT-based clinical trials has been recently investigated in detail. Self-/tumor-specific TILs express low but detectable levels of CD28. After cell infusion, immediate and high expression of CD28 was detected on circulating self-/tumor reactive T cells, indicating that either rapid up-regulation of CD28 expression or early selective expansion and survival of the CD28$^+$ T cell population had occurred (258). Analysis of clonotypes derived from TIL that either did or did not persist after adoptive transfer provided some evidence for the preferential survival of clones that expressed the highest levels of CD28 (259), indicating that there may be a survival advantage for transferred T cells that possess an early effector phenotype.

Engagement of the costimulatory molecule CD27 can also augment TCR-induced T cell proliferation and

appears to play an important role in the generation and maintenance of T cell memory *in vivo* (260,261). Consistent with a late effector state, T cells lacking CD27 have been shown to exert potent cytolytic function and reduced secretion of IL-2. In the pmel-1 mouse model, self-/tumor-specific late effector cells were less effective at mediating tumor regression after adoptive transfer relative to early effector T cells that express high levels of CD27. Moreover, the administration of soluble CD27 ligand, CD70, augmented *in vivo* CD8$^+$ T cell responses to viral infection and tumor challenge by increasing the clonal expansion and maintenance of antigen-specific T cells, indicating that CD27 expression is not only a marker of less differentiated T cells but also functionally critical for optimal immune responses. In the clinical arena, expression of CD27 was found to be up-regulated to varying degrees by culturing TIL in the absence of IL-2 for 2 days, and based on this analysis, the numbers of CD27$^+$ TILs that were administered to patients who responded to therapy were significantly higher than the numbers of CD27$^+$ cells administered to nonresponders (262). In addition, after ACT, the percentage of persistent T cells in peripheral blood that expressed CD27 gradually increased and was associated with the long-term maintenance of stable tumor reactive T cells in treated patients (258,*263*). These results, taken together with results obtained in studies carried out with viral epitopes, indicate that T cells expressing CD27 may selectively persist *in vivo* and give rise to a stable memory CD8$^+$ T cell population.

Homeostatic Cytokine Signals and T Cell Persistence

Increased access to homeostatic cytokines has been shown to be critical for the increased anti-tumor responses following ACT to lymphodepleted hosts. Homeostatic signals can be regulated by both the availability of cytokines in the host and the level of expression of the cytokine receptors on the surface of transferred CD8$^+$ T cells. Expression of IL-7Rα by a subset of effector CD8$^+$ T cells might identify precursors destined to become long-lived memory cells. IL-7Rα^{low} self-/tumor-specific late effector CD8$^+$ T cells transferred to tumor-bearing mice persisted at decreased numbers and were less effective at inducing anti-tumor responses than IL-7Rα^{high} early effector CD8$^+$ T cells. In patients, IL-7Rα was expressed at low levels on all TIL populations at the time of ACT but was up-regulated immediately after infusion on the surface of robustly proliferating self-/tumor-specific T cells that persisted (258). Therefore, IL-7 signaling seems to be important for the immediate and long-term survival of self-/tumor-specific T cells after ACT. Only low levels of IL-15Rα were detected on the majority of cells present in TILs used for ACT and, unlike IL-7Rα, IL-15Rα was not up-regulated on persisting self-/tumor-specific T cells after ACT (258). Nevertheless, IL-15 signaling might play an important role in the *in vivo* persistence of adoptively transferred T cells because

transpresentation of IL-15 by APCs and stromal cells can occur.

T Cell Persistence and Anti-Tumor Responses

Because IL-2 is provided both *in vitro* during T cell clonal expansion and *in vivo* in the immediate aftermath of cell infusion, self-/tumor-reactive CD8$^+$ T cells might undergo apoptosis after IL-2 withdrawal. As early effector T cells have the capacity to release IL-2, selective survival of these cells might occur in an autocrine fashion. In addition, early effector T cells have survival advantages compared to intermediate and late effector T cells, as reflected by the expression of lower levels of the pro-apoptotic molecules, BID (B-cell lymphoma 2 [BCL-2]–homology domain 3 [BH3]–interacting-domain death agonist), BAD (BCL-2-antagonist of cell death), and CD95L (CD95 ligand; also known as FASL), and higher levels of anti-apoptotic molecules (253). The intrinsic proliferative capacity of adoptively transferred T cells might also affect their ability to engraft and persist. Greater proliferation of the early effector T cell subset has been seen *in vitro* and *in vivo* following stimulation with cognate antigen. In parallel with T cell proliferation and progressive differentiation, gradual telomere erosion occurs until a critical degree of shortening results in chromosomal abnormalities and cell death or senescence. This process might be partially compensated for by telomerase activity, and therefore telomere length and telomerase activity can critically influence T cell replicative capacity. Interestingly, recent analyses of human TILs have shown a correlation between the telomere length of transferred cells and persistence of T cells *in vivo* following ACT, indicating that in addition to self-/tumor-antigen recognition, the intrinsic proliferative capacity of adoptively transferred T cells might also be a factor affecting persistence and successful tumor treatment (259).

Optimizing Tumor-Reactive T cells for ACT

The finding that less differentiated, central memory–like T cells might be the optimal population for ACT-based immunotherapies raises a relevant clinical problem. Data from animal studies indicate a direct correlation between the number of adoptively transferred T cells and anti-tumor responses *in vivo*, fostering the notion that high numbers of self-/tumor reactive T cells must be administered to patients to obtain therapeutically effective anti-tumor responses. Therefore, in clinical trials, tumor reactive CD8$^+$ T cells are expanded to large numbers *in vitro* with CD3-specific antibody and IL-2 or specific antigen stimulation and IL-2, which drives differentiation of T cells to intermediate and late effector stages of differentiation. New findings in mice emphasize that the quantity of transferred T cells is a critical factor when T cells with the same quality and fitness are being used for ACT (253). To this end, increased anti-tumor responses were observed

in mice after adoptive transfer of lower numbers of early effector T cells compared to higher numbers of late effector T cells. Therefore, one of the greatest challenges in the field is currently the generation of large numbers of "fit" T cells for ACT.

Modifications of Current *in vitro* Expansion Protocols

Using a standard rapid expansion protocol, TILs for transfer are selected and populations are expanded for about 2 weeks with CD3-specific antibody, high doses of IL-2, and irradiated allogeneic feeder cells (Figure 45.4). This procedure results in the differentiation of self-/tumor-specific CD8$^+$ T cells to an intermediate and late effec-

tor state. Limiting the *in vitro* expansion phase to a short duration might markedly improve the "fitness" of the transferred T cells because a greater percentage of self-/tumor reactive T cells express CCR7, costimulatory molecules, and IL-7Rα and are actively dividing in the first week of growth. The question remains whether this improvement in fitness can compensate for the reduced number of cells generated soon after activation.

Cytokines, acting in concert with signals through the TCR and costimulatory molecules, can function as accelerators or brakes for T cell proliferation and differentiation. IL-2 has been shown to be an effective T cell growth factor but has undesirable effects, including
FIGURE 45.4 Three general approaches to adoptive cell transfer using a preconditioning lymphodepleting regimen consisting of chemoradiotherapy in conjunction with administration of exogenous cytokines. **A:** Autologous TILs isolated from patient tumor samples are tested, expanded, and reinfused. **B:** Allogeneic cells derived from TILs that are harvested from another patient or generated *in vitro* from peripheral blood lymphocytes of an allogeneic healthy donor are selected for their ability to recognize patient tumor cells. **C:** Effector T cells are generated by the transduction of recombinant lentiviral or retroviral vectors that encode TCRs, directed against tumor antigens. Tumor-reactive T cells generated using any of these approaches can be further manipulated cells before transfer by the transduction of genes that encode cytokines, adhesion molecules, or anti-apoptotic molecules. Abbreviations: HSC, hematopoietic stem cells; PBL, peripheral blood lymphocytes; TCR, T-cell receptor; TIL, tumor-infiltrating lymphocyte (*322*).

the ability to decrease the expression of lymphoid-organ homing molecules and promote the terminal differentiation of T cells, predisposing them to activation-induced cell death. Other cytokines with a receptor that contains γc such as IL-15 can analogously induce the *in vitro* expansion of self-/tumor reactive CD8$^+$ T cell populations for ACT. Studies carried out in a mouse model indicate that IL-15 may be superior to IL-2 in promoting the development of long-lasting viral immunity, perhaps through the generation of cells with more of a central memory than an effector memory phenotype (264). The ability of murine transgenic gp100 reactive pmel T cells stimulated *in vitro* with IL-15 to more effectively treat B16 tumors than cells generated with IL-2 is consistent with this model (256). Additional γc receptor chain cytokines, including IL-7 and IL-21, evaluated in a similar manner did not promote robust proliferation or differentiation of self-/tumor reactive CD8$^+$ T cells *in vitro,* but the resultant cells had a greater anti-tumor efficacy *in vivo* than cells expanded *in vitro* with IL-2 (N. Restifo, unpublished data). By contrast, no differences in the differentiation state of self-/tumor reactive T cells from patients who were vaccinated were detected when the cells were stimulated *ex vivo* with cognate antigen in the presence of IL-2, IL-7, or IL-15 (265). Results using human cells probably reflect the use of antigen-experienced T cells, which have already differentiated into intermediate and late effector stages, instead of the naïve populations used in mouse studies. Indeed, stimulation of naïve human self-/tumor reactive T cells in the presence of IL-21 induced the preferential expansion of a less differentiated CD28^{high}CD45RO$^+$ T cell population able to release IL-2 after stimulation with cognate antigen. Therefore, the ability to obtain naïve self-/tumor-specific CD8$^+$ T cells may provide the means to improving current ACT-based therapies.

Genetic Modification of T Cells for ACT

Naturally occurring self-/tumor-specific T cells have been described in patients with cancer, as well as in healthy individuals. The inability to appropriately trigger these endogenous cells, as evidenced by the failure of current vaccination strategies, has lead to current adoptive immunotherapy trials. Although effective tumor reactive T cells cannot be readily generated in patients with the majority of common cancers, they can be generated by the transduction of PBMC from patients bearing tumors that express widely shared antigens with TCR that recognize those epitopes. In a recent study, PBMCs that were transduced with a TCR recognizing the MART-1/HLA-A2 epitope, in addition to efficiently recognizing appropriate tumor cell targets *in vitro,* mediated tumor regression in 2 out of the 17 treated melanoma patients (266). The affinity of the TCR selected for transduction, the level of transduced TCR expressed on the cell surface, and the differentiation state of the transduced T cells used for ACT might critically contribute to the success of trials following

TCR transduction. Additional screening has identified TCR that appear to possess a higher functional avidity than the MART-1 TCR used in the initial clinical trial cited earlier (120). Natural variations between the sequences of particular peptide epitopes between species has also facilitated the generation of high-affinity TCRs, such as the murine TCR identified for a nonmutated, HLA-A2–restricted human p53 epitope (81). In addition, random mutagenesis of TCR complementary-determining regions generated in an *in vitro* phage display system resulted in the isolation of TCRs with up to a million-fold higher affinity than the nonmutated receptor with no apparent loss of binding specificity (267). Additional studies have demonstrated that T cells that were genetically engineered to express mutated TCRs with enhanced affinities displayed a higher degree of cross-reactivity with variants of the native epitope than cells expressing a wild-type TCR (268), and further, T cells expressing high-affinity variants of the murine allo-reactive 2C TCR, in contrast to cells expressing the wild-type 2C TCR, recognized endogenously processed antigens expressed on normal autologous spleen cells *(269)*.

The Future of Adoptive Immunotherapy

ACT to a lymphodepleted host has emerged as a promising advance in cancer immunotherapy. Preclinical and clinical studies have identified multiple mechanisms contributing to successful adoptive immunotherapies, including host-related factors, as well as the phenotypic and functional characteristics of the self-/tumor reactive T cells used for transfer. These findings provide the rationale for the design of the novel clinical protocols for the treatment of patients with cancer.

The improved effectiveness of immunotherapy following a nonmyeloablative lymphodepleting regimen provides the rational basis for the evaluation of more intensive conditioning regimens, such as a myeloablative treatment in conjunction with autologous HSC transplantation. In the pmel-1 mouse model of ACT, the use of a myeloablative regimen profoundly depleted host immunosuppressive cells and cellular sinks for activating cytokines, resulting in an increased ratio of effector cells to endogenous cells and increased anti-tumor responses compared to nonmyeloablative conditioning (270). The improved therapeutic effect was independent of antigen-specific vaccination but required the transfer of HSCs, which enhanced the proliferation and survival of coadministered self-/tumor reactive T cells possibly through the release of cytokines, growth factors, and anti-apoptotic factors. The finding that myeloablative conditioning with a HSC transplant obviated the need for specific vaccination has important implications for ACT-based immunotherapies in humans, which employ polyclonal TILs with often-unknown specificity for which effective vaccines are not available. The use of a myeloablative preconditioning regimen involving chemotherapy and total body irradiation together with

HSC transplantation in humans is currently under evaluation.

Increased immunity might be achieved with the use of more selective approaches to lymphodepletion to eliminate the toxicities associated with the use of nonspecific preconditioning regimens based on chemotherapy and radiation. For example, Treg cells and other immunosuppressive cells might be selectively depleted with directed immunotoxins. To overcome the sink effect of competing endogenous cells, saturating levels of activating cytokines might be provided exogenously. Alternatively, T_H cells able to produce manifold cytokines might be cotransferred with self-/tumor reactive T cells. Selective engagement of activation-associated molecules such as TLRs can also be utilized to activate APCs. Further, the use of combinatorial approaches might be of greater clinical benefit compared to single modality strategies.

Murine models have now shown that early effector T cells mediate superior *in vivo* anti-tumor responses compared to intermediate and late effector T cells on the basis of their increased proliferative and survival potential, receptiveness to homeostatic and costimulatory signals, homing to secondary lymphoid tissues, and ability to secrete IL-2 (reviewed in [271]). In humans, suggestive data supports the preclinical finding that less differentiated T cells may represent the ideal cells for ACT. These findings indicate that the measurement of IFN-γ release or cytolytic ability represents inadequate criteria for selection of T cells for ACT and suggest that additional factors such as T cell phenotype, telomere length, TCR affinity, as well as the ability of cells to secrete cytokines such as IL-2 should be considered in selecting cells for therapy. The next generation of ACT-based immunotherapies might rely upon the ability to endow "fit" cells with elevated cell-surface expression of high-affinity, self-/tumor-specific TCRs by gene transfer technology that can be used in conjunction with specific vaccines. Ultimately, the TCR gene therapy approach might hold the key to the widespread application of ACT-based therapy to the treatment of cancers of multiple histologies.

Stem Cell Transplantation and the Potential Role of NK Cells in Cancer Therapies

Several clinical trials have evaluated the use of allogeneic HSC transplantation (HCT) for the treatment of patients with leukemia, and results suggest that a subset of T cells that mediate graft versus host responses may be directed against antigens that are expressed specifically on leukemia cells, or what has been termed *graft versus leukemia* (reviewed in [272]). Minor histocompatibility antigens that are limited in their expression to hematopoietic cells and that are recognized by T cells have been identified (273). The transfer of donor lymphocytes is also associated with enhanced survival of patients who relapsed following transplantation of T cell–depleted bone marrow

(274). The significant improvement in survival noted in many of these study of donor lymphocyte infusions provides further evidence that a graft versus leukemia effect mediated by T cells that recognize target antigens on tumor cells are responsible for tumor regression. These products have also been shown to be recognized by specific T cells and may play an important role in mediating graft versus leukemia effects. Additional results, however, indicate that NK cells may play an important role in mediating the anti-tumor effects of bone marrow transplantation. The presence of killer inhibitory receptors (KIRs) that recognize HLA gene products on target cells is responsible for blunting the response of NK cells to targets that express those molecules, and in patients with leukemia who are receiving cells from HLA nonidentical donors, responses were associated with a lack of expression of the appropriate KIRs on recipient cells (275). In addition, an improved outcome was noted in patients who received transplants from HLA-identical siblings if the recipient cells lacked the presence of KIR recognized by donor NK cells (276). Although these results indicate that these approaches may provide a treatment option for patients with tumors arising from hematopoietic cells, it is not clear that these treatments will be effective for patients with solid tumors.

Antibody-based Therapies

Cell surface proteins that are overexpressed on tumors have been targeted with either unmodified antibodies or antibodies that have been linked to toxins or radionuclides. The glycoprotein CEA is overexpressed on colon and breast cancer, although significant expression of this protein is observed in normal tissues, particularly in intestinal crypts. Antibodies that bind to monocytes or DCs through Fc receptors have been shown to mediate the lysis of target cells *in vitro* through antibody dependent cellular cytotoxicity (ADCC), and the *in vitro* effectiveness of immunotoxins has been clearly demonstrated. There has, however, been a lack of success in the treatment of solid tumors with these reagents, which appears to arise from the lack of effective penetration of tumor tissues *in vivo* by these reagents.

There have been examples of successful treatments using antibody-based therapies. Substantial clinical responses have been observed in breast cancer patients who have been treated with antibodies directed against Her-2/neu (277). The Her-2/neu protein is involved with signaling through a growth factor receptor, and thus the function of the protein may play an important role in the therapy mediated by this antibody *(278)*. The antibody rituximab, which is directed against the B cell surface protein CD20, has also been shown to mediate effective anti-cancer effects against B cell leukemias (reviewed in [279]). It is not clear how the effects of the unconjugated antibody are mediated but may involve the induction of apoptosis, complement mediated

lysis of tumor cells, as well as through ADCC mechanisms. Additional trials have tested the use of rituximab that has been conjugated with radionuclides for cancer treatment *(280)*. The treatment of a blood-borne tumor by an antibody, however, may represent a special case, as antibodies administered intravenously may be particularly effective against these tumors, as they would have a direct access to tumor cells which are present in the blood.

Chimeric T Cell Receptors

Cell surface antigens that are overexpressed on tumor cells such as ERB-b2 also provide potential targets for cellular therapies, as antibodies linked to intracellular signaling domains have been shown to deliver activation signals to gene-modified T cells. In an initial demonstration of the function of these receptors, constructs generated by linking antibody heavy and light chain variable regions to TCR α and β constant regions were shown to function in a murine T cell hybridoma (281). Subsequent studies have primarily been carried out using single chain antibody constructs in which an amino terminal antibody heavy chain variable region is followed by an appropriate light chain variable region. This single chain Fv fragment has been linked through a flexible spacer to the transmembrane and cytoplasmic domains derived either from the Fc receptor γ chain (282) or the TCR ζ signaling chain (283). Additional studies have revealed that the proliferation and survival of T cells that have been engineered to express recombinant "T-bodies" appears to be enhanced by the linkage of intracellular signaling domains from costimulatory molecules such as CD28 *(284)* and OX40 *(285)*.

Initial studies carried out in model systems have provided evidence for the ability of T cells that have been redirected using T-bodies to mediate tumor regression. Intratumoral injection of human T cells transduced with a T-body directed against a protein that is overexpressed in a variety of tumors, erbB2, was found to cause regression of established prostatic adenocarcinomas in a mouse xenograft model (286). Similarly, murine T cells transduced with a chimeric construct that encoded a single chain antibody directed against prostate-specific membrane antigen eradicated human prostate tumors in a xenogeneic murine model system *(287)*. Clinical trials have now been carried out using single chain antibodies directed against the human folate binding protein, a molecule that is overexpressed on ovarian carcinomas (288), as well as carbonic anhydrase IX, an antigen that is overexpressed in renal carcinomas (289). Objective responses were not observed in either trial, and there was evidence of liver toxicity in the renal cancer trial that limited the cell doses that could be administered to patients. Nevertheless, these reagents may provide tools for the development of widely applicable cancer therapies, as the recognition of target cells is not restricted by the MHC molecules expressed on the tumor cell surface.

Single chain constructs containing a flexible linker between conventional TCR α and β chains as well as intracellular signaling domains similar to those present in T-bodies have also been found to confer on T cells the ability to recognize cognate peptide antigen–MHC complexes *(290)*. Single chain TCRs possess potential advantages over dual chain TCRs, which can interact with endogenous α and β chains, leading to a significant reduction in the number of appropriately paired receptors on the T cell surface. In one study comparing a single chain TCR with the corresponding dual chain TCR, the dual chain TCR conferred more potent effector functions on the gene modified T cells than the single chain receptor (291); however, additional modifications such as those employed in T-bodies may enhance single chain TCR signaling.

INFLUENCE OF IMMUNE SYSTEM ON TUMOR DEVELOPMENT

Immunosurveillance

Although appropriate T cell activation can lead in some cases to tumor regression, the normal role of the immune system in controlling tumor development is unclear. Burnet and Thomas theorized in the 1950s that the immune system played an important role in preventing the outgrowth of tumors, a concept that was termed *immunosurveillance* (292). Further studies demonstrated that immunodeficient mice that lacked T cells did not generally develop high rates of tumors; however, additional cells such as NK cells that were present in T cell–deficient mice may have been responsible for controlling tumor growth (293). Immunodeficient patients exhibit only a slightly higher rate of solid malignancies, with the exception of relatively rare diseases such as Kaposi's sarcoma, which develop in HIV patients. More recent studies in mice have provided some evidence that the immune system may prevent the outgrowth of tumors bearing highly immunogenic antigens, while tumors that possess mechanisms that prevent the immune system from responding appropriately can grow progressively, a mechanism that has been termed "immunoediting" (reviewed in [294]). Factors that influence tumor cell growth include the immunogenicity of antigens expressed by that cell as well as the sensitivity to host factors that regulate immune responses. Tumors isolated from immunodeficient mice in many cases are rejected following injection into normal mice *(295)*, and enhanced rates of tumor development in response to carcinogen treatment have been observed in mice that lack responsiveness to IFN-γ *(296)*. Expression of proinflammatory cytokines such as IFN-γ may be necessary to overcome the effects of soluble inhibitory factors such as TGF-β and IL-10, as well as products expressed in T cells such as CTLA-4 and PD-1 that act to limit normal anti-tumor responses *(297,298)*.

Examination of the association between lymphocyte infiltration of tumor sites and patient survival has provided some support for the role of immunosurveillance in controlling tumor growth. The presence of brisk infiltrates of TIL in a variety of tumor types has been associated with improved survival multiple studies (*178,179*,180,*299*). As the presence of a higher ratio of T regulatory cells to CD8+ T cells within tumors has been associated with poor prognosis (240,*300*), further analysis of tumor as well as other sites may be needed to evaluate this issue.

Immune Escape

One of the correlates of immunoediting models is that selective pressure exerted by the immune system can then lead to the outgrowth of tumor variants containing mutations that lead to the loss of recognition by cells of the immune system. Relatively small groups of malignant or premalignant cells that avoid detection by the immune system initially develop random mutations, and pressure exerted by immune cells can then lead to the selective outgrowth of variants that have lost expression of gene products such as HLA class I molecules. Recent studies have demonstrated a complex interplay of positive and negative factors that regulate responses to tumors, however, and thus it is difficult to evaluate the role of any individual factors in tumor progression. The laws of natural selection may also be at work when cancer cells that possess genetic and epigenetic traits that are beneficial to their survival or proliferation are conferred growth advantage over others, and the outcome of this passive process is determined by multiple factors in the tumor environment such as growth factors, nutrient supply, and immune pressure. Nevertheless, it is reasonable to assume that the immune system can play some role in sculpting the phenotypic characteristics of spontaneously arising tumors. In addition, anti-tumor immunotherapies that lead to partial tumor cell elimination represents an additional scenario where selective pressure can lead to the outgrowth of preexisting tumor escape variants.

Loss or Down-regulation of HLA Class I Antigens

Tumor antigens are processed largely by the proteasome to generate peptides, which are transported by transporter associated with antigen processing (TAP) to the endoplasmic reticulum, where they bind to HLA class I heavy chain in association with β_2-microglobulin. The HLA–peptide complexes are then transported through the Golgi to cell surface. Several mechanisms have been shown to result in the loss or down-regulation of HLA class I expression. β_2-microglobulin mutation/deletion results in HLA class I total loss. Defects in components of the antigen-processing machinery that lead to decreased HLA class I expression on the cell surface of human tumors have been described (301). Selective loss of an HLA class I haplotype, locus, or

allele has also been observed in human tumor cells *(302)*, as well as the loss of β_2-microglobulin *(303)*, although a causal relationship between these changes and tumor growth in such clinical scenarios is difficult to demonstrate unequivocally.

While partial or complete losses of HLA class I could theoretically lead to immune escape, those cells should then be more susceptibility to lysis by NK cells. Recent studies have shown, however, that NK cells express activating receptors such as NKG2D, which bind to stressed-induced ligands (MICA and MICB) that can be up-regulated in a variety of tumors (reviewed in [304]). Activation of NK cells through this signaling pathway can overcome the inhibitory effect of HLA class I binding receptors (KIRs). From these data, it is clear that HLA class I–negative tumors should be susceptible to NK killing. Loss or down-regulation of MICA/B expression by actively growing tumors has been suggested as an escape strategy, but there is no experimental evidence for this, and actively proliferating tumor cells have been found to express MICA/B independently of cellular stress.

An alternative explanation for why tumor cells that have lost HLA class I are not destroyed by NK cells may be derived from the activation-inhibition model. NK cells are rapidly activated in the presence of stimulatory factors such as IL-12, IL-2, or type 1 INFs that are released in response to inflammatory conditions associated with microbial infections. In "sterile" environments, as seen with tumors or transplantation, such stimulatory factors may not be readily available and the cross-talk between DCs and resting NK cells that normally leads to NK cell activation may not occur. In addition, the production of immunomodulatory cytokines such as TGF-β or macrophage migration inhibitory factor (MIF) by tumor cells may directly inhibit NK cell activation and function. Loss of expression of surface antigens can occur independently of the dysregulation of HLA class I expression. It is possible that increases in the potency of T cell–based tumor immunotherapy may increase the prominence of escape mechanisms such as antigen loss.

Defective Death Receptor Signaling

Defective death receptor signaling is another mechanism that may contribute to the survival and proliferation of tumor cells. Recent studies have shown the expression of the caspase-8 inhibitor cFLIP (cellular FLICE inhibitory protein) in various tumors. In these cases, cFLIP may render tumor cells resistant to death receptor–mediated apoptosis and may contribute to immunoresistance to T cells *in vivo* (305,*306*). Down-regulation or loss of Fas expression in tumors may also contribute to their resistance to apoptosis. Missense mutations and loss of the Fas gene have been identified in hematological cancers such as multiple myeloma *(307)* as well as in melanomas (308).

Lack of Costimulation

As discussed earlier, most tumors seem to grow in a non-inflammatory microenvironment that is not conducive to immune activation. Histologically, tumors generally coexist innocuously with normal tissues, apparently without giving or inducing immune activating signals, especially during the early stage of growth. Recognition of tumor antigens by DCs in this condition will not lead to DC activation and maturation. In addition, like most normal tissues, tumor cells usually do not express costimulatory molecules such as B7-1 (CD80), B7-2 (CD86), and CD40. Recognition of tumor antigens by CD4$^+$ and CD8$^+$ T lymphocytes without adequate costimulation will lead to T cell anergy. Insertion of the genes encoding B7-1, B7-2, or both into tumor in the experimental setting will generally increase the immunogencity of a tumor but does not *necessarily* lead to regression.

Immunosuppressive Cytokines

Activation or inhibition of T cells also depends on the presence or absence of cytokines in their immediate microenvironment. Tumor cells have been known to elaborate a variety of cytokines and chemokines that can negatively effect maturation and function of immune cells. Vascular endothelial growth factor (VEGF), which is a cytokine that is produced by most tumors, has been shown in several *in vitro* studies to inhibit DC differentiation and maturation through suppression of the transcription factor NF-κB in HSCs (309). In patients with lung, head and neck, and breast cancers, there was a decrease in function and number of mature DCs, which was associated with increased plasma level of VEGF (310). Elevated levels of IL-10, a molecule that has been shown to inhibit DC maturation, has also frequently been detected in serum of patients with cancer (*311*,312). Additionally, IL-10 may protect tumor cells from CTL by down-regulation of HLA class I, class II, and ICAM-1. Further, the loss of HLA class I expression may be due to IL-10–mediated down-regulation of TAP1 and TAP2 proteins in tumor cells. Prostaglandin E2 (PGE-2) represents an immunosuppressive factor that is expressed by tumors owing to enhanced expression of the enzyme cyclooxygenase 2 (COX2), which is the rate-limiting enzyme for PGE-2 synthesis. Relatively high levels of PGE-2 have been found in the serum of renal cancer patients *(313)*. Increased expression of PGE-2 in the blood of cancer patients has also been associated increased production of IL-10 from monocytes (314); however, the results of another study suggest that IL10 may inhibit PGE-2 production (315).

High levels of transforming growth factor (TGF)-β are frequently found in cancer patients and are associated with progression of disease and poor response to immunotherapy, an observation that may reflect the ability of this cytokine to inhibit the activation and proliferation of lymphocytes. Tumors may not necessarily produce these cytokines as escape mechanisms, however, as the hypothesized immunosuppressive functions may be mere side effects of the angiogenic and growth factor functions of these cytokines.

The Controversy Involving Apoptosis of Activated T Cells

One of the more controversial mechanisms of tumor escape is the expression of death receptor ligands by tumor cells. A variety of cancer cells have been reported to express functional FasL that induces apoptosis of Fas+ susceptible target cells (316). These include lung carcinoma, melanoma, colon carcinoma, and hepatocellular carcinoma. The most recent study on this controversial topic asserted that FasL was coexpressed with melanosomal and lysosomal markers in multivesicular bodies (MVB) in human melanoma cells (317). These data have been questioned, however, due to a lack of appropriate negative controls, technical concerns such as the use of nonspecific antibodies, nonintron spanning polymerase chain reaction (PCR) primers without proper controls, and in functional assays that employ the Jurkat cell line, which itself can be induced to express FasL. Additional studies have failed to provide evidence of FasL expression in melanoma either at mRNA or protein levels, however, and Fas susceptible targets were not lysed by melanoma cells in controlled functional assays (318). In fact, all well-controlled *in vivo* experiments using FasL-transfected tumor cells have shown accelerated rejection accompanied by neutrophil infiltration (319). The activity of FasL may be modulated by the presence or absence of certain cytokines within the tumor microenvironment, and TGF-β has been shown to regulate the pro-inflammatory effects of FasL. It is now apparent that upon activation by tumor antigen recognition, T cells express high levels of FasL, which induces apoptosis in themselves ("suicide") and each other ("fratricide").

Tumor Escape and Immunotherapy

Despite recent progress in tumor immunobiology and technical advances in the field of tumor immunotherapy, current antigen-specific immunotherapeutic strategies have only been successful in patients with melanoma and not other cancer types. It is not clear whether tumor escape accounts for these failures, or whether lack of observed tumor regression is due to inadequacies of the immunotherapies themselves.

The balance of immune activation and immune inhibition must be in favor of the former if tumors are to come under immune pressure. However, even in some instances where effective anti-tumor responses can be achieved with immunotherapy, tumors often recur. It seems likely that as

the tumor immunologist's armamentarium becomes more powerful and immunotherapies become more effective, the selection of tumor variants with immunoresistant phenotypes will be observed with greater frequency. Tumor escape may ultimately thwart some dramatic responses to immunotherapy. Indeed, some tumors that recur after successful immunotherapy often possess immunoresistant phenotypes.

CONCLUSION

The identification of antigens that are either specifically expressed or are overexpressed on tumor cells has provided an opportunity to explore therapies for the treatment of patients with a wide variety of tumor types. The results of an extensive series of clinical trials employing a wide variety of treatments, however, have in general failed to provide evidence that vaccination can lead to tumor regression. With the exception of trials employing treatments against tumor of hematopoietic origin such as lymphomas and leukemias, responses have generally been observed in 5% or less of treated patients, which may in some cases reflect a low background of spontaneous tumor regression. The development of preventive vaccination protocols against cancers such as HPV has demonstrated the ability of the immune system to control the development of virally induced cancers but unfortunately may not be relevant to the control of naturally arising tumors of nonviral origin. Adoptive immunotherapy approaches have demonstrated that expanded populations of tumor reactive T cells can lead to the destruction of bulky metastatic lesions; however, long-term tumor regressions are observed in only a minority of treated patients.

These clinical trial results clearly point to the need to develop a better understanding of the basic mechanisms that regulate anti-cancer immune responses. The presence of regulatory T cells, inhibitory factors expressed by tumor cells and by infiltrating monocytes or other cell types, represent some of the factors that may limit these responses. In addition, the failure to generate appropriately activated APCs within the tumor microenvironment may contribute to the lack of responses observed in patients undergoing therapy. Nevertheless, these and other studies provide opportunities to explore the role of factors such as host conditioning on response to therapy and will hopefully facilitate the development of treatments that result in long-term tumor regression in the majority of treated patients.

Primary Immunodeficiency Diseases

Rebecca H. Buckley

INTRODUCTION

Recognition of the first human primary immunodeficiency diseases more than a half century ago (1,2) set the stage for an exponential increase in information about the functions of the various components of the immune system. Since then, more than 200 human primary immunodeficiency disorders have been recognized (3,4). These discoveries, together with several naturally occurring immune defects in animal species and the ability to create "knockout mice," have seemingly opened the door to the ultimate dissection of the immune system.

Primary, or genetically determined, immunodeficiency disorders may affect one or more components of the immune system, including T, B, and NK lymphocytes, phagocytic cells, and complement proteins. This chapter focuses on the genetic bases of and/or faulty immunologic mechanisms underlying some of the most important human immunodeficiency diseases involving lymphocytes (Table 46.1).

Immunodeficiency diseases are characterized by undue susceptibility to infection. Paradoxically, many immunodeficiency syndromes are also characterized by autoimmune diseases and/or excessive production of

▶ **TABLE 46.1 Abnormal Genes Known to Cause Primary Immunodeficiency**

Chromosome	*Disease*
1q21	MCH class II antigen deficiency caused by RFX5 mutation[a]
1q22-q25	SCID due to CD3 ζ chain deficiency[a]
1q23	ALPS type 1b caused by deficiency of Fas ligand (CD178)[a]
1q25	Chronic granulomatous disease (CGD) caused by gp67[phox] deficiency[a]
1q31-q32	SCID due to CD45 deficiency[a]
1q42-q43	Chediak-Higashi syndrome[a]
2p11	Kappa-chain deficiency[a]
2p12	CD8 deficiency due to CD8 antigen α polypeptide deficiency[a]
2q12	CD8 lymphocytopenia caused by ZAP70 deficiency[a]
2q33	Autosomal recessive CVID due to ICOS deficiency[a]
2q33-q34	ALPS types IIa and IIb caused by deficiencies of caspase 10 or 8[a]
2q35	CID with microcephaly due to Cernunnos deficiency[a]
5p13	SCID or Omenn's syndrome due to IL-7 receptor α-chain deficiency[a]
5q31.1-q33.1	IL-12 p40 deficiency[a]
6p21.3	MHC class I antigen defects caused by TAP1, TAP2, or tapasin deficiency[a]
6p21.3	(?) CVID and selective IgA deficiency
6q23-q24	IFNγ receptor 1 deficiency due to α chain deficiency[a]
7q11.23	CGD caused by gp47[phox] deficiency[a]
8q21	Nijmegen breakage syndrome due to mutations in *Nibrin*[a]
9p13	Cartilage hair hypoplasia due to deficiency of RNA component of mitochondrial RNA-processing endoribonuclease[a]
10p13	SCID (Athabascan, radiation sensitive) due to mutations in the *Artemis gene*[a]
10p13	DiGeorge's syndrome/velocardiofacial syndrome
10q23.2-q23.33	Agammaglobulinemia due to BLNK deficiency[a]
10q23-q24	ALPS type 1a due to CD95 (Fas) deficiency[a]
11p13	IL-2 receptor α chain deficiency[a]
11p13	SCID or Omenn's syndrome caused by RAG-1 or RAG-2 deficiency[a]
11q14.3-q21	LAD2 due to deficiency of sialyl-Lewis[X]
11q22.3	AT, attributable to AT mutation, causing deficiency of DNA-dependent kinase[a]
11q23	SCID or non-SCID due to CD3 γ, δ, or ε chain deficiency[a]
12	Hyper IgM syndrome cause by deficiency of uracil-DNA glycosylase[a]
12p13	Hyper IgM caused by deficiency of activation-induced cytidine deaminase[a]
12q12	Interleukin-1 receptor-associated kinase-4 deficiency[a]
13q	MHC class II antigen deficiency caused by RFXAP deficiency[a]
13q33-q34	Ligase 4 deficiency
14q13.1	Purine nucleoside phosphorylase deficiency[a]
14q32.3	Immunoglobulin heavy-chain deletion[a]
15q21	Griscelli's syndrome due to myosin VA or Rab27a deficiency[a]
16p11.2	CVID due to CD19 deficiency[a]
16p13	MHC class II antigen deficiency caused by CIITA deficiency[a]
17p11.2	CVID or IgA deficiency due to TACI deficiency[a]
16q24	CGD caused by gp22[phox] deficiency[a]
17q11-q12	Human nude defect due to *FOXN1* deficiency[a]
19p12	MHC class II antigen deficiency caused by RFXANK deficiency[a]
19p13.1	IL-12R β chain deficiency[a]
19p13.1	SCID caused by Janus kinase 3 deficiency[a]
19p13.2	Agammaglobulinemia caused by mutations in *Igα* gene[a]
20q12-q13.2	Hyper IgM syndrome due to CD40 deficiency
20q13.2-q13.11	SCID caused by adenosine deaminase deficiency[a]
21q22.1-q22.2	IFNγ receptor 2 deficiency due to β chain deficiency[a]
21q22.3	APCED due to AIRE deficiency[a]
21q22.3	Leukocyte adhesion deficiency type 1, caused by CD18 deficiency[a]
22q11.2	Agammaglobulinemia caused by mutations in λ5 surrogate light chain gene[a]
22q11.2	DiGeorge's/velocardiofacial syndrome
22q13.1-q13.3	CVID due to BAFF-R deficiency
Xp21.1	CGD caused by gp91[phox] deficiency[a]

▌ **TABLE 46.1** Abnormal Genes Known to Cause Primary
Immunodeficiency (Continued)

Chromosome	Disease
Xp11.22	WAS caused by WAS protein deficiency[a]
Xp11.23	IPEX due to FOXP3 deficiency[a]
Xp11.3-p21.1	Properdin deficiency[a]
Xq13.1-q13.3	X-linked SCID caused by common γ-chain deficiency[a]
Xq22	X-linked agammaglobulinemia caused by Bruton tyrosine kinase deficiency[a]
Xq25-26	X-linked lymphoproliferative syndrome caused by mutations in the *SH2D1A* gene[a]
Xq26	Immunodeficiency with hyper IgM caused by CD154 (CD40 ligand) deficiency[a]
Xq28	Anhidrotic ectodermal dysplasia with immunodeficiency caused by mutations in the nuclear factor κB essential modulator[a]

AIRE, autoimmune regulator; ALPS, autoimmune lymphoproliferative syndrome; APECED, autoimmune polyendocrinopathy-candidiasis ectodermal dysplasia; AT, ataxia-telangiectasia; BAFF-R, B cell–activating factor of the tumor necrosis factor family receptor; BLNK, B cell linker; CGD, chronic granulomatous disease; CID, combined immunodeficiency; CIITA, MHC class II transactivator; CVID, common variable immunodeficiency; FOXP3, forkhead box P3; ICOS, inducible costimulator; IFN, interferon; Ig, immunoglobulin; IL, interleukin; IPEX, immune dysregulation, polyendocrinopathy, enteropathy, X-linked syndrome; LAD, leukocyte adhesion deficiency; MCH, major histocompatibility complex; RAG, recombination activating gene; RFXAP, RFX-associated protein; SCID, severe combined immunodeficiency; TACI, transmembrane activator, calcium-modulator and cyclophilin ligand interactor; WAS, Wiskott-Aldrich syndrome; ZAP70, ζ-chain–associated protein-70.
[a]Gene cloned and sequenced; gene product known.

immunoglobulin E (IgE) antibodies. Due to the ability of antibiotics to control many types of infections, diagnosis of these diseases is often delayed, and autoimmunity or allergy may be the presenting manifestation. Finally, there is an increased incidence of malignancy in patients with immunodeficiency diseases (5). Whether this is due to increased susceptibility to infection with agents predisposing to malignancy or to defective tumor immunosurveillance is unknown.

With the exception of selective IgA deficiency, genetically determined immunodeficiency is considered to be rare (3). However, the true incidence and prevalence of these diseases are unknown because there is no screening for any of these disorders at birth or during infancy, childhood, or adulthood anywhere in the world. B cell defects appear to far outnumber those affecting T cells, phagocytic cells, or complement proteins. It has been estimated that agammaglobulinemia occurs with a frequency of 1:50,000 and severe combined immunodeficiency with a frequency of 1:40,000 to 1:100,000 live births. Selective absence of serum and secretory IgA is the most common defect, with reported incidences ranging from 1:333 to 1:700 (6,7). Primary immunodeficiency is seen more often in infants and children than in adults.

MOLECULAR GENETICS OF PRIMARY IMMUNODEFICIENCY

Until 1993, there was little insight into the fundamental problems underlying a majority of human primary immunodeficiency disorders. It is impressive that the un-

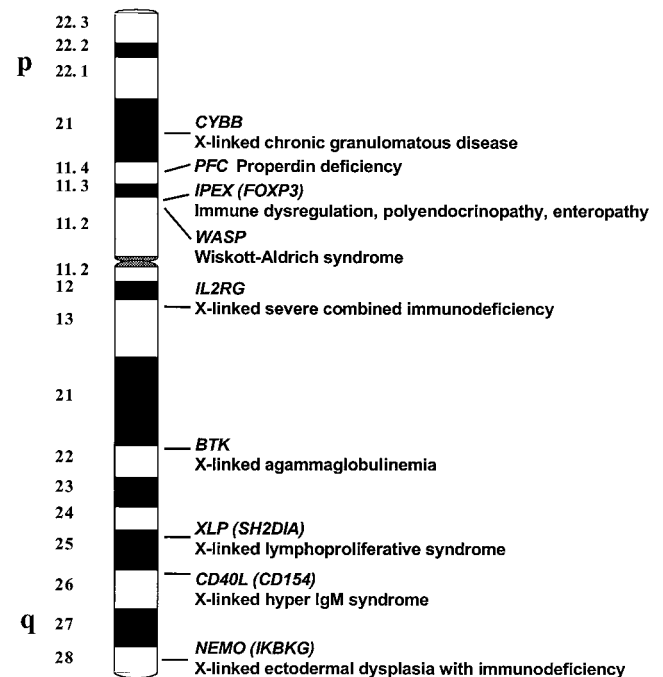
derlying genetic defects have now been identified in more than 150 of these diseases (Table 46.1) (4). Within the last decade and a half the molecular bases of seven X-linked immunodeficiency disorders have been discovered (Figure 46.1, Table 46.1): X-linked agammaglobulinemia (8,9),


FIGURE 46.1 Locations of the X-linked immunodeficiency disease loci. Correspondence with the cytogenetic map of the X chromosome is indicated on the left. Most of these defects have been discovered over the last decade.

▌**TABLE 46.2 Mutated Immune System Genes with Variable Phenotypic Expression**

Mutated Gene	Normal Gene Product	Classic Syndrome	Variant Syndrome
RAG1	Recombinase activating gene 1	SCID	1. Omenn's syndrome 2. Oligoclonal γ/δ T cells, autoimmune disease, and CMV infection
BTK	Bruton tyrosine kinase	Agammaglobulinemia	Polysaccharide antibody deficiency
WASP	Wiskott-Aldrich syndrome protein	Wiskott-Aldrich syndrome	X-linked thrombocytopenia

CMV, cytomegalovirus; SCID, severe combined immunodeficiency. From Buckley RH. Variable phenotypic expression of mutations in genes of the immune system. *J Clin Invest*. 2005;115(11):2974, with permission.

X-linked immunodeficiency with hyper IgM (10,11), the Wiskott-Aldrich syndrome (12,13), X-linked severe combined immunodeficiency (14,15), X-linked lymphoproliferative disease (16,17), immune dysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX) syndrome (18), and nuclear factor of κB essential modulator (NEMO) deficiency (19,20) (Table 46.1). The abnormal gene in X-linked chronic granulomatous disease (CGD) had been identified several years earlier (21), and the gene encoding properdin (mutated in properdin deficiency) has also been cloned (22).

In addition to these X-linked defects, the underlying bases for numerous autosomal recessive immunodeficiencies have also been identified (Table 46.1) (4). The rapidity of these advances suggests that there will soon be many more. The discovery and cloning of the genes for these diseases have obvious implications for the potential of gene therapy (23). A committee of the World Health Organization has published several versions of a classification of primary immunodeficiency diseases over the last three decades, most recently in 2007 (3). Table 46.1 lists some of the numerous conditions for which the molecular bases are known (4).

Discovery of mutated genes that cause primary immunodeficiencies has significantly advanced our understanding of the pathogenesis of these diseases and of the functions of normal gene products. However, it is apparent that seemingly identical clinical conditions are caused by mutations in different immune system genes and that some conditions that used to be considered a single disease now must be defined as a syndrome. Examples of this are severe combined immunodeficiency, which is now known to be caused by mutations in 12 different genes; hyper IgM syndrome, which can result from mutations in any one of at least 6 different genes; Omenn's syndrome, which can

be caused by mutations in at least 4 different genes; and common variable immunodeficiency (CVID), which can be caused by mutations in any one of at least 10 different genes, although the molecular basis for most common form of CVID is unknown. To make matters even more complicated, it is becoming abundantly clear that the phenotypic presentation of mutations in a single gene can be quite different even within the same family, depending on the location and type of mutation but also probably on other genetic factors and environmental influences (Table 46.2) (24).

DEFECTS CHARACTERIZED BY ANTIBODY DEFICIENCY

X-Linked Agammaglobulinemia

Most boys afflicted with X-linked agammaglobulinemia (XLA), also known as Bruton's agammaglobulinemia (2), remain well during the first 6 to 9 months of life by virtue of maternally transmitted IgG antibodies (25). Thereafter, they repeatedly acquire infections with extracellular pyogenic organisms such as pneumococci, streptococci, and *Haemophilus* unless given prophylactic antibiotics or γ-globulin therapy. Chronic fungal infections are not usually present, and *Pneumocystis jiroveci* pneumonia rarely occurs unless there is an associated neutropenia (26). Viral infections are also usually handled normally, with the notable exceptions of the hepatitis viruses and the enteroviruses (27). In addition to septic arthritis, patients with this condition may have joint inflammation similar to that seen in rheumatoid arthritis (25). Infections with *Ureaplasma urealyticum* and viral agents such as echoviruses, coxsackie viruses, and adenovirus have been

identified from joint fluid cultures of patients even on intravenous immune globulin (IVIG) replacement therapy. These observations suggest a primary role for antibody, particularly secretory IgA, in host defense against this group of viruses, because normal T cell numbers and function are present in X-linked agammaglobulinemia. Concentrations of immunoglobulins of all isotypes are very low, and circulating B cells are usually absent. Pre-B cells are present in reduced numbers in the bone marrow. Tonsils are usually very small, and lymph nodes are rarely palpable due to absence of germinal centers from these lymphoid tissues. Thymus architecture, including Hassall's corpuscles, is normal, as are the thymus-dependent areas of spleen and lymph nodes.

In 1993, two groups of investigators independently and almost simultaneously discovered the mutated gene in XLA (8,9). Because XLA had been precisely mapped to position Xq22 (Figure 46.1), one group successfully used the technique of positional cloning to identify an abnormal gene in patients with this defect (Table 46.1) (9). For other reasons, the second group sought and found a B cell–specific tyrosine kinase important in murine B lymphocyte signaling (8); the kinase was found to be encoded by a gene on the mouse X chromosome. When the human gene counterpart was cloned, it was found to reside at Xq22, and the gene product was identical to that found by the first group. This intracellular signaling tyrosine kinase has been named Bruton tyrosine kinase (or Btk) in honor of O. C. Bruton. Btk is a member of the Tec family of cytoplasmic protein tyrosine kinases (28). It is expressed at high levels in all B-lineage cells, including pre-B cells. This kinase appears to be necessary for pre-B cell expansion and maturation into surface Ig-expressing B cells, but it probably has a role at all stages of B cell development (8,9). It has not been detected in any cells of T lineage, but it has been found in cells of the myeloid series (8). Thus far, all males with known XLA (by family history) have had low or undetectable Btk mRNA and kinase activity.

Female carriers of XLA can be identified by the finding of nonrandom X chromosome inactivation in their B cells or by the detection of the mutated gene (if known in the family) (29). Prenatal diagnosis of affected or nonaffected male fetuses has also been accomplished by detection of the mutated gene in chorionic villous or amniocentesis samples. Studies of Btk protein enzymatic activity or mRNA have also permitted identification of X-linked inheritance in some agammaglobulinemic boys with no family history. The fact that Btk is also expressed in cells of myeloid lineage is of interest in light of the occurrence of intermittent neutropenia in boys with XLA, particularly at the onset of an acute infection (26). It is conceivable that Btk is only one of several signaling molecules participating in myeloid maturation and that neutropenia would be observed in XLA only when rapid production of such cells is needed. XLA has also been reported in association with

growth hormone deficiency in nine cases (30) and with sensorineural hearing loss in three cases (31).

A mutation at position 28 of the murine *btk* gene has been shown to be the basis for the B cell defect in CBA/N mice (32). Because such mice have a much milder antibody deficiency than boys with XLA have, speculation had been that humans with mutations in the non–kinase-encoding part of the *Btk* gene might have a less severe immunodeficiency. However, many different mutations of the human *Btk* gene (more than 550) have been described (33), encompassing most parts of the coding portions of the gene, and there has not been any clear correlation between the location of the mutation and the clinical phenotype.

Autosomal Recessive Agammaglobulinemia

Autosomal recessive conditions that resemble XLA phenotypically are caused by mutations in the genes that encode immunoglobulin heavy or light chains or their associated signaling molecules, leading to a- or hypogammaglobulinemia (Table 46.1). In μ chain (34), $\lambda5/14.1$ (surrogate light chain) (35), Igα (B cell antigen receptor signaling molecule) (36), and B cell linker (*BLNK*) gene mutations (37), circulating B cells are absent. In the case of other heavy-chain gene mutations, deficiencies of individual immunoglobulin classes or subclasses are seen, and circulating B cells are present (38). Mutations in the κ-chain gene result in molecules with only λ light chains.

Immunodeficiency with Elevated IgM

The hyper IgM syndrome is characterized by defective class switch recombination (39) resulting in very low serum IgG, IgA, and IgE levels but either a normal or a markedly elevated concentration of polyclonal IgM. Patients with this syndrome resemble agammaglobulinemics in their susceptibility to encapsulated bacterial infections (40). The hyper IgM syndrome may be caused by mutations in at least six different genes (41). Thus far, two X-linked and four autosomal recessive defects have been found to cause this syndrome, and there are likely to be more. Distinctive clinical features permit presumptive recognition of the type of mutation in these patients, thereby aiding proper choice of therapy (Table 46.3). However, all such patients should undergo molecular analysis to ascertain the affected gene for purposes of genetic counseling, carrier detection, and definitive therapy.

X-Linked Hyper IgM Due to CD154 (CD40 Ligand) Deficiency (HIGM1)

Like boys with XLA, those with X-linked hyper IgM (HIGM1) may become symptomatic during the first or second year of life with recurrent pyogenic infections. However, they also are highly prone to have *Pneumocystis*

▌ **TABLE 46.3 Hyper Immunoglobulin M (HIGM) Syndrome: Clinical Features of the Different Molecular Types**

HIGM Type	PJ Pneumonia	Neutropenia	Lymphadenopathy	Early Death
HIGM1 (CD40L Def)	Yes	Yes	No	Yes
NEMO	No	No	No	Unknown
HIGM2 (AICDA Def), HIGM5 (UNG Def)	No	No	Yes	No
HIGM3 (CD40 Def)	Yes	Yes	No	Unknown
HIGM4 (molecular defect unknown)	No	No	Yes	No

jiroveci pneumonia and to have profound neutropenia (40,42). Normal numbers of B lymphocytes are usually present in the circulation of these patients.

Until 1993 this condition was classified as a B cell defect because only IgM is produced. However, B cells from HIGM1 patients were shown more than two decades ago to have the capacity to synthesize IgM, IgA, and IgG normally when cocultured with a "switch" T cell line, suggesting that in those patients the defect lay in T lineage cells (43). This was puzzling because routine tests of T cell function were usually normal in such patients. In 1993, the abnormal gene in HIGM1 was localized to Xq26 (Figure 46.1) and identified by five groups almost simultaneously (10,44–46). The gene product is a surface molecule known as CD154 (or CD40 ligand) on the surfaces of activated helper T cells (47), which interacts with CD40 molecules on B cells (Figure 46.2) (10). Cross-linking of CD40 on either normal or HIGM1 B cells with a monoclonal antibody to CD40 or with soluble CD154 in the presence of cytokines (interleukin [IL]-2, IL-4, or IL-10) causes the B cells (which are intrinsically normal in HIGM1) to undergo proliferation and isotype switching and to secrete various types of immunoglobulins. CD154 is a type II integral membrane glycoprotein with significant sequence homology to tumor necrosis factor (TNF); it is found only on activated T cells, primarily of the CD4 phenotype (Figure 46.2) (47). Mutations in the gene encoding CD154 on HIGM1 patients' T cells result in a lack of signaling of their normal B cells when their T cells are activated. Therefore, HIGM1 B cells fail to undergo isotype switching and produce only IgM, and there is an absence of CD27$^+$ memory B cells (48). Lymph node histology shows only abortive germinal center formation and a severe depletion and phenotypic abnormalities of follicular dendritic cells. Of further importance to effective immune responses, the lack of stimulation of CD40 also results in these patients' B cells not upregulating CD80 and CD86. The latter are important costimulatory molecules that interact with CD28/CTLA4 on T cells (49). The failure of interaction of the molecules of those pathways results in a propensity for tolerogenic T cell signaling and defective recognition of tumor cells.

Many distinct point mutations or deletions in the gene encoding CD154 have been identified, giving rise to frame shifts, premature stop codons, and single amino acid substitutions, most of which were clustered in the TNF homology domain located in the carboxy-terminal region (39).

In a retrospective study of 56 European patients with HIGM1, 13 (23.3%) had died, and the mean age at death was 11.7 years (42). In addition to opportunistic infections such as *Pneumocystis jiroveci* pneumonia, there is an increased incidence of cryptosporidial enteritis and
FIGURE 46.2 The role of the CD40 ligand (CD154) in B cell class switching. The *CD154* gene is mutated in X-linked hyper immunoglobulin M (IgM) syndrome. Thus, this is a T cell, not a B cell, defect. IL, interleukin. (From Allen RC, Armitage RJ, Conley ME, et al. CD40 ligand gene defects responsible for X-linked hyper IgM syndrome. *Science*. 1993;259:990, with permission.)

subsequent liver disease in this syndrome. There is also an increased risk of malignancy. Because of the poor prognosis, the treatment of choice is an HLA-identical sibling bone marrow transplant at an early age (50). Treatment for this condition also includes monthly IVIG infusions (51). In patients with severe neutropenia, the use of granulocyte colony-stimulating factor has been beneficial.

X-Linked Hyper IgM Due to Nuclear Factor κB Essential Modulator (NEMO or I$\kappa\kappa\gamma$) Deficiency

This condition is characterized most often clinically as anhidrotic ectodermal dysplasia with associated immunodeficiency (EDA-ID) in males and incontinentia pigmenti in females (19,20). It results from mutations in the *IKBKG* gene at position 28q on the X chromosome (Figure 46.1), which encodes nuclear factor of κB (NFκB) essential modulator (NEMO). NEMO is a regulatory protein that serves as a scaffold for two kinases necessary for activation of the transcription factor NFκB. Activation of NFκB by proinflammatory stimuli normally leads to increased expression of genes involved in inflammation, such as TNFα and IL-12. B cells from patients with NEMO deficiency fail to undergo class switch recombination, and their antigen-presenting cells fail to produce TNFα and IL-12 (20). Germline loss-of-function mutations cause the X-linked dominant condition incontinentia pigmenti and are lethal in male fetuses. Mutations in the coding region of *IKBKG* are associated with EDA-ID.

The immunodeficiency has been variable, with most EDA-ID patients showing impaired antibody responses to polysaccharide antigens (19). However, two patients with EDA-ID presented with hyper IgM (20). Pharmacologic inhibitors of NFκB activation have been shown to downregulate CD154 mRNA and protein levels, suggesting the mechanism of hyper IgM in this condition (52). Stop codon mutations in *IKBKG* are associated with osteopetrosis, lymphedema, EDA, and immunodeficiency (OL-EDA-ID). Neither type of mutation abolishes NFκB signaling entirely. OL-EDA-ID patients' immune cells respond poorly to lipopolysaccharide, IL-1, IL-18, TFNα, and CD154, accounting for the seriousness of their infections. Although most hyper IgM patients with this defect should be easily recognizable because of the presence of ectodermal dysplasia, some have presented with immunodeficiency but no ectodermal dysplasia (53).

Autosomal Recessive Hyper IgM

Autosomal Recessive Hyper IgM Due to Activation-induced Cytidine Deaminase Deficiency (HIGM2)

It has been known for some time that not all males with hyper IgM have a mutation in the gene encoding CD154, and there are many examples in females (54), indicating

that this condition has more than one genetic cause. As in HIGM1, concentrations of serum IgG, IgA, and IgE are very low in this autosomal recessive form of hyper IgM. However, in contrast to X-linked CD40L deficiency, where the IgM level is normal or only slightly elevated, the serum IgM concentration in patients with autosomal recessive hyper IgM is often markedly elevated and polyclonal (55). Patients with autosomal recessive hyper IgM are generally older at age of onset of infections, do not have susceptibility to *Pneumocystis jiroveci* pneumonia, often do have isohemagglutinins, and are less likely to have anemia, neutropenia, or thrombocytopenia (Table 46.3) (55). Normal numbers of B lymphocytes are usually present in the circulation of these patients. However, in further contrast to HIGM1 patients, B cells from patients with autosomal hyper IgM are not able to switch from IgM-secreting to IgG-, IgA-, or IgE-secreting cells, even when cocultured with monoclonal antibodies to CD40 and a variety of cytokines (39). Thus, in these patients, the condition truly is a B cell defect.

The defect in many patients with autosomal recessive hyper IgM has been identified as mutations in a gene on chromosome 12p13 that encodes an activation-dependent cytidine deaminase (AICDA), an RNA- and DNA-editing enzyme specifically expressed in germinal center B cells (55,56). A deficiency of AICDA results in impaired terminal differentiation of B cells and a failure of isotype switching, and there is a lack of immunoglobulin gene somatic hypermutation (Figure 46.3). Unlike HIGM1 patients, who have minimal lymphoid tissue, patients with this defect have lymphoid hyperplasia because they have enhanced although defective germinal center formation. Nearly all such patients have markedly elevated polyclonal serum IgM levels, and, when their B cells are cultured *in vitro*, they spontaneously secrete large amounts of IgM. This IgM secretion is not further augmented by the addition of IL-4 or anti-CD40 with IL-4 or other cytokines. Their B cells are positive for CD27 (56).

With early diagnosis and treatment with IVIG (51), as well as good management of infections with antibiotics, patients with AICDA mutations generally have a more benign course than do those with HIGM1 (Table 46.3).

Autosomal Recessive Hyper IgM Due to Uracil-DNA Glycosylase Deficiency (HIGM5)

AICDA deaminates cytosine into uracil in targeted DNA, followed by uracil removal by uracil-DNA glycosylase (UNG). Three patients with hyper IgM were found to have mutations in the gene encoding UNG (57). Their B cells had profoundly impaired class switch recombination and a partial defect in somatic hypermutation. They had clinical characteristics similar to those of patients with AICDA deficiency, that is, susceptibility to bacterial infections, lymphoid hyperplasia, and elevated serum concentrations of

Germ line *IgH* locus
FIGURE 46.3 Schematic representation of the generation of antibody repertoires. Rearrangement of antigen receptor genes from their germline configuration occurs through the actions of the products of recombinase activating genes (RAGs) 1 and 2 without antigen encounter to generate a primary antibody repertoire composed of immunoglobulin M (IgM) antibodies. However, class switch recombination and somatic hypermutation requires the action of activation-induced cytidine deaminase (AID) following antigen encounter. The *AID* gene is mutated in one autosomal recessive form of hyper IgM. Thus, this is truly a B cell defect because the B cells are unable to generate a secondary repertoire. (From Neuberger MS, Scott J. RNA editing AIDS antibody diversification? *Science*. 2000;289:1705, with permission.)

IgM with profoundly decreased serum IgG and IgA concentrations (Table 46.3).

Autosomal Recessive Hyper IgM Due to Mutations in CD40 (HIGM3)

CD40 is a type I integral membrane glycoprotein encoded by a gene on chromosome 20 and belonging to the TNF and nerve growth factor receptor superfamily. It is expressed on B cells, macrophages, dendritic cells, and a few other types of cells (Figure 46.2). Three patients with autosomal recessive hyper IgM were identified who failed to express CD40 on their B cell surfaces (58). Their clinical presentations were similar to those with XHIM due to CD40L deficiency (Table 46.3). Sequence analysis of their CD40 genomic DNA showed that one patient carried a homozygous silent mutation at the fifth base pair position of exon 5, involving an exonic splicing enhancer and leading to exon skipping and premature termination; the other two patients showed a homozygous point mutation in exon 3, resulting in a cysteine-to-arginine substitution. These findings show that mutations of the CD40 gene can also cause an autosomal recessive form of hyper IgM that is clinically indistinguishable from HIGM1 due to CD40L deficiency (58).

X-Linked Lymphoproliferative Disease

X-linked lymphoproliferative disease (XLP), also referred to as Duncan's disease (after the original kindred in which it was described), is a recessive trait characterized by an inadequate immune response to infection with Epstein-Barr virus (EBV), resulting in (usually) fatal malignant or nonmalignant immune cell proliferation or in immunodeficiency syndromes (59,60). Affected boys are apparently healthy until they experience infectious mononucleosis (59). There are three major clinical phenotypes: (a) fulminant, often fatal, infectious mononucleosis (FIM) (50% of cases), (b) lymphomas, predominantly involving B lineage cells (25%), and (c) acquired hypogammaglobulinemia (25%) (59). The mononucleosis is fatal primarily because of extensive liver necrosis caused by polyclonally activated CD8+ cytotoxic T cells that recognize EBV-infected autologous B cells. The mean age at presentation is less than 5 years. Most patients surviving the primary infection develop lymphomas or hypogammaglobulinemia. Natural killer (NK) function is also markedly depressed (61).

The defective gene in XLP was localized to the Xq26-q27 region and cloned; it is now known officially as *SH2D1A* (Figure 46.1, Table 46.1) (16,17,62). The gene encodes a novel T cell–specific adaptor protein composed of a single SH2 domain. It functions as an inhibitory adaptor protein for a high-affinity self-ligand called signaling lymphocyte activation molecule (SLAM) present on the surfaces of T and B cells. The adaptor protein, called SAP (for SLAM-associated protein) or SH2D1A, normally serves to inhibit signal transduction by SLAM so that T cell proliferation does not continue unchecked in response to EBV and possibly other types of infections. Boys who have mutations in SH2D1A fail to inhibit this signaling. The SH2D1A protein also associates with 2B4 on NK cells (61). Ligation of 2B4 on NK cells from a SAP- deficient XLP patient failed to initiate cytotoxicity. Despite this, CD2- or CD16-induced cytotoxicity of SAP-deficient NK cells was similar to that of normal NK cells. Thus, selective impairment of 2B4-mediated NK cell activation may contribute to the immunopathology of XLP (61).

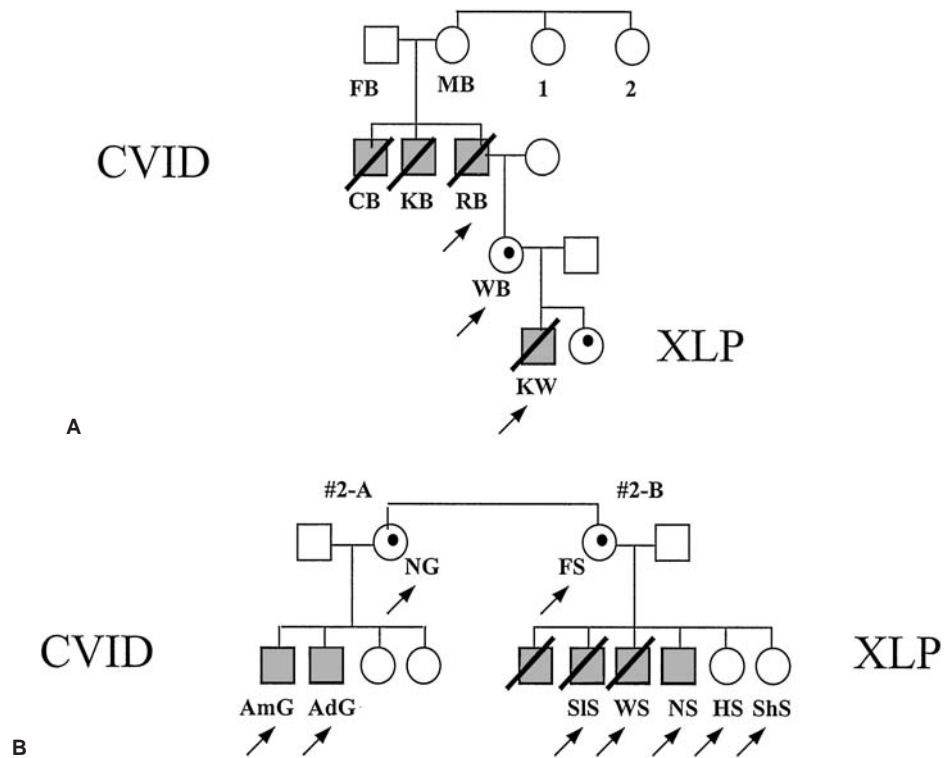
Two pedigrees have been reported in which boys in one arm of each pedigree had been diagnosed with common variable immunodeficiency (CVID), whereas those in the other arms had FIM (Figure 46.4) (63). The family members with CVID never gave a history of infectious mononucleosis. However, all of affected members of each pedigree had the same distinct *SH2D1A* mutation, despite the different clinical phenotypes. Because the *SH2D1A* mutation was the same but the phenotype varied in these families, XLP should be considered in all males with a diagnosis of CVID, particularly if there is more than one male family member with this phenotype. A patient with an *SH2D1A* mutation was recently reported who developed systemic


FIGURE 46.4 **A, B:** Two pedigrees in which boys in one arm of each had the clinical phenotype of common variable immunodeficiency (CVID) and in the other fulminating infectious mononucleosis, leading to a diagnosis of X-linked lymphoproliferative disease (XLP). The pedigree-unique mutations in *SH2DIA* were the same in those with CVID as in those with XLP. Thus, boys with CVID should be screened for this mutation. (From Morra M, Silander O, Calpe-Flores S, et al. Alterations of the X-linked lymphoproliferative disease gene *SH2DIA* in common variable immunodeficiency syndrome. *Blood*. 2001;98(5):1321–1325, with permission.)

vasculitis, hypogammaglobulinemia, and hemophagocytic lymphohistiocytosis (64).

XLP overall has an unfavorable prognosis: 70% of affected boys die by age 10 years. Only two XLP patients are known to have survived beyond 40 years. Approximately half of the limited number of patients with XLP given HLA-identical related or unrelated unfractionated bone marrow transplants are surviving without sign of the disease (50).

Common Variable Immunodeficiency

CVID is a syndrome characterized by hypogammaglobulinemia with B cells. Most patients have no known molecular diagnosis, but it is highly likely that this syndrome consists of many different genetic defects. Also known as "acquired" hypogammaglobulinemia because of a generally later age of onset of infections, the patients may appear similar clinically to those with XLA in the kinds of infections experienced and bacterial etiologic agents involved (3,65). In comparing the two defects, it is noted that in CVID there is an almost equal sex distribution, a tendency to autoantibody formation, normal-sized or enlarged tonsils and lymph nodes, and splenomegaly in approximately 25% of those affected. Lymphoid interstitial pneumonia, pseudolymphoma, amyloidosis, and noncaseating granulomata of the lungs, spleen, skin, and liver have also been seen. There is a 438-fold increase in lymphomas in affected women in the fifth and sixth decades (66).

The serum immunoglobulin and antibody deficiencies in CVID may be as profound as in XLA. Despite normal numbers of circulating immunoglobulin-bearing B lymphocytes and the presence of lymphoid cortical follicles, blood B lymphocytes from CVID patients do not differentiate into immunoglobulin-producing cells when stimulated with PWM *in vitro*, even when cocultured with normal T cells. From these observations, it was believed that the defect(s) in this syndrome are intrinsic to the B cell. However, B cells from some CVID patients can be stimulated to both isotype-switch and synthesize and secrete immunoglobulin when stimulated with anti-CD40 plus IL-4 or IL-10 (67). T cells and T cell subsets are usually present in normal percentages, but a dominance of T cells has been observed in some patients, and depressed T cell function has been reported in others. Tonsils and lymph nodes are either normal sized or enlarged, and splenomegaly occurs in approximately 25% of patients with CVID. In addition, there is a tendency to autoantibody formation, and there are now several cases of lupus erythematosus converting to CVID (68). Rarely, CVID has been reported to resolve transiently or permanently when some such patients acquired HIV infection (69).

Because this disorder occurs in first-degree relatives of patients with selective IgA deficiency (A Def) and some patients with A Def become panhypogammaglobulinemic, it has long been suspected that these diseases have a common genetic basis (70). The high incidences of abnormal immunoglobulin concentrations, autoantibodies,

autoimmune disease, and malignancy in families of both types of patients also suggested a shared hereditary influence. This concept is supported by the finding of a high incidence of C4-A gene deletions and C2 rare gene alleles in the class III major histocompatibility complex (MHC) region in individuals with either A Def or CVID, suggesting that there is a susceptibility gene in this region on chromosome 6 (71). However, the abnormal gene has not yet been identified. These studies also have shown that a small number of HLA haplotypes are shared by individuals affected with CVID and A Def, with at least one of two particular haplotypes being present in 77% of those affected (71). In one large family with 13 members, 2 had A Def and 3 had CVID (70). All of the immunodeficient patients in the family had at least one copy of an MHC haplotype shown to be abnormally frequent in A Def and CVID: HLA-DQB1*0201, HLA-DR3, C4B-Sf, C4A-deleted, G11-15, Bf-0.4, C2a, HSP70-7.5,TNF-5, HLA-B8 and HLA-A1. However, four immunologically normal members of the pedigree also possessed this haplotype, indicating that its presence alone is not sufficient for expression of the defects (70). Environmental factors, particularly drugs such as phenytoin, have been suspected as providing the triggers for disease expression in individuals with the permissive genetic background.

The foregoing notwithstanding, it is clear that CVID is still best thought of as a syndrome that includes many different genetic defects. Most cases of CVID are sporadic or follow an autosomal dominant pattern of inheritance for which the underlying genetic defect(s) have not been discovered. As noted, however, two pedigrees have been reported in which boys in one arm of each pedigree had CVID, whereas those in the other had FIM (Figure 46.4) (63). Thus, the *SH2D1A, Btk*, and *CD154* genes should be studied in male CVID patients because patients with these mutations may present clinically with CVID. In addition, both males and females should be evaluated for mutations in the *AID, UNG*, and *CD40* genes for the same reason. Four other known causes of this syndrome are discussed below.

Inducible Costimulator Deficiency in Autosomal Recessive CVID

In the Black Forest of Germany, patients with CVID have been found who have an autosomal recessive pattern of inheritance and who lack the "inducible costimulator" (ICOS), a surface protein on activated T cells (72). Binding of ICOS to its ligand induces a significant increase in T cell proliferation and cytokine production, especially of IL-10, which has been implicated in the differentiation of B cells to plasma cells. Nine such patients from six families have been found to have identical homozygous large genomic deletions of the *ICOS* gene, suggesting a founder effect. Thus far, no examples of ICOS deficiency have been found in the United States.

B Cell Signaling Defects in CVID

Other patients with a clinical presentation of CVID have recently been identified with mutations involving intermediates in B cell signaling and developmental pathways (65). Specifically, mutations in CD19, B cell–activating factor of the TNF family receptor (BAFF-R), and transmembrane activator, calcium-modulator, and cyclophilin ligand interactor (TACI) genes have been identified in such patients (73–75). BAFF and APRIL serve as ligands for BAFF-R, TACI, and B cell maturation antigen (BCMA). It is postulated that the patients with mutations in BAFF-R or TACI most likely lack the necessary B cell signaling provided through interaction with BAFF and APRIL to promote proper maturation and generation of a diverse antibody repertoire. These findings further emphasize the known heterogeneity of CVID. As the molecular bases of more and more primary immunodeficiency syndromes are being identified, it will be important to consider a variety of genetic mutations that can lead to the hypogammaglobulinemia seen in CVID.

The treatment of patients with CVID is essentially the same as that for XLA (51). Anaphylactic reactions caused by IgE antibodies to IgA are always a possibility in patients with CVID; thus, caution should be used when therapy is initiated with IVIG preparations containing IgA (76). Nonanaphylactic adverse reactions to IVIG infusions in patients with CVID (usually those with chronic lung or sinus disease) have been associated with elevated plasma TNFα levels. The prognosis for patients with CVID is reasonably good unless severe autoimmune disease or malignancy develops.

Selective IgA Deficiency

An isolated absence or near-absence (i.e., less than 10 mg/dL) of serum and secretory IgA is believed to be the most common well-defined immunodeficiency disorder, with a frequency of 1:333 being reported among some blood donors (6). Although this disorder has been observed in apparently healthy individuals (6), it is commonly associated with ill health. As would be expected when there is a deficiency of the major immunoglobulin of external secretions, infections occur predominantly in the respiratory, gastrointestinal, and urogenital tracts (65). Bacterial agents responsible are essentially the same as in other types of antibody deficiency syndromes. There is no clear evidence that patients with this disorder have an undue susceptibility to viral agents. Similar to CVID, there is a frequent association of A Def with collagen-vascular and autoimmune diseases. In further similarity to patients with CVID, there is an increased incidence of malignancy.

Serum concentrations of other immunoglobulins are usually normal in patients with A Def, although IgG2 subclass deficiency has been reported, and IgM (usually elevated) may be monomeric. Children with A Def vaccinated with killed poliovirus intranasally produced local IgM and

IgG antibodies. Of possible etiologic and great clinical significance is the presence of antibodies to IgA in the sera of as high as 44% of patients with A Def (6). A number of A Def patients have had severe or fatal anaphylactic reactions after intravenous administration of blood products containing IgA, and anti-IgA antibodies [particularly IgE anti-IgA antibodies (76)] have been implicated. For this reason, only five-times washed (in 200-mL volumes) normal donor erythrocytes or blood products from other IgA-absent individuals should be administered to these patients. Patients with A Def also frequently have IgG antibodies against cow milk and ruminant serum proteins (77). These antiruminant antibodies often falsely detect "IgA" in immunoassays that employ goat (but not rabbit) antisera (7). A high incidence of autoantibodies has also been noted.

The basic defect leading to A Def is unknown. *In vitro* cultures of B cells from some IgA-deficient patients could be stimulated to produce IgA by the combination of anti-CD40 and IL-10. Treatment with Dilantin, sulfasalazine (78), *d*-penicillamine, or gold has been suspected as being the cause of A Def; the condition has also been known to remit following discontinuation of Dilantin therapy or spontaneously. Usually when this happens the remission is permanent. The occurrence of A Def in both males and females and in families is consistent with autosomal inheritance; in most families this appears to be dominant with variable expressivity (70). As noted, this defect occurs in pedigrees with CVID patients, some patients with IgA deficiency have gone on to develop CVID, and recent studies suggest that the susceptibility genes for these two defects may reside in the MHC class III region as an allelic condition on chromosome 6 (Table 46.1) (70,71).

Immunodeficiency with Thymoma

Patients with immunodeficiency with thymoma are adults who almost simultaneously develop recurrent infections, panhypogammaglobulinemia, deficits in cell-mediated immunity, and benign thymoma (3). They may also have eosinophilia or eosinopenia, aregenerative or hemolytic anemia, agranulocytosis, thrombocytopenia, or pancytopenia. Antibody formation is poor, and progressive lymphopenia develops, although percentages of Ig-bearing B lymphocytes are usually normal. The thymomas are predominantly of the spindle cell variety, but other types of benign and malignant thymic tumors have been seen.

IgG Subclass Deficiencies

A number of patients have been reported to have deficiencies of one or more subclasses of IgG, despite normal or elevated total IgG serum concentrations (79). IgG_2 deficiency would be suspected if patients had repeated problems with encapsulated bacterial pathogens, because a majority of the antipolysaccharide antibody molecules are of the IgG_2 isotype. Most of those with absent or very low

concentrations of IgG_2 have been patients with A Def. However, not all A Def patients who have recurrent infections have IgG_2 deficiency, and some A Def patients have defective antipolysaccharide antibody responses despite normal levels of IgG_2. Similarly, patients with the Wiskott-Aldrich syndrome, who have a profound antipolysaccharide antibody deficiency, have normal levels of IgG_2. Marked deficiencies of antipolysaccharide antibodies have also been noted in other non–Wiskott-Aldrich children and adults with recurrent infections who had normal concentrations of IgG_2, as well as normal concentrations of all of the other immunoglobulin isotypes (80). Conversely, a number of healthy children have been described who had low levels of IgG_2 but normal responses to polysaccharide antigens when immunized. In other patients with IgG_2 deficiency, continued follow-up revealed an evolving pattern of immunodeficiency (such as into CVID), suggesting that the presence of IgG subclass deficiency may be a marker for more general immune dysfunction (81). Thus, the more relevant question to ask is "What is the capacity of the patient to make specific antibodies to protein and polysaccharide antigens?" It is, therefore, difficult to know the biological significance of the multiple moderate deficiencies of IgG subclasses that have been reported, particularly when completely asymptomatic individuals have been described who totally lacked IgG_1, IgG_2, IgG_4, and IgG_1 due to gene deletion (Table 46.1) (38).

CELLULAR IMMUNODEFICIENCY

In general, patients with partial or absolute defects in T cell function have infections or other clinical problems for which there is no effective treatment or which are of a more severe nature than those with antibody deficiency disorders. It is also rare that such individuals survive beyond infancy or childhood.

Thymic Hypoplasia (DiGeorge's Syndrome)

Thymic hypoplasia results from dysmorphogenesis of the third and fourth pharyngeal pouches during early embryogenesis, leading to hypoplasia or aplasia of the thymus and parathyroid glands (82). Other structures forming at the same age are also frequently affected, resulting in anomalies of the great vessels (right-sided aortic arch), esophageal atresia, bifid uvula, upper limb malformations, congenital heart disease (conotruncal, atrial and ventricular septal defects), a short philtrum of the upper lip, hypertelorism, an antimongoloid slant to the eyes, mandibular hypoplasia, and low-set, often notched ears (82). A variable degree of hypoplasia of the thymus and parathyroid glands (partial DiGeorge's syndrome) is more frequent than total aplasia (83). Those with complete DiGeorge's syndrome are susceptible to infections with opportunistic pathogens and to graft-versus-host disease (GVHD) from nonirradiated

blood transfusions. There are many clinical similarities among DiGeorge's syndrome, the velocardiofacial syndrome, the fetal alcohol syndrome, and retinoic acid toxicity.

Patients with DiGeorge's syndrome are usually only mildly lymphopenic (83). However, the percentage of CD3$^+$ T cells is variably decreased. Immunoglobulin concentrations are usually normal, although sometimes IgE is elevated and IgA may be low (83). Responses of blood lymphocytes after mitogen stimulation have been absent, reduced, or normal, depending on the degree of thymic deficiency (83). Thymic tissue, when found, does contain Hassall's corpuscles and a normal density of thymocytes; corticomedullary distinction is present. Lymphoid follicles are usually present, but lymph node paracortical areas and thymus-dependent regions of the spleen show variable degrees of depletion.

DiGeorge's syndrome has occurred in both males and females. It is rarely familial, but three cases of apparent autosomal dominant inheritance have been reported. Microdeletions of specific DNA sequences from chromosome 22q11.2 (the DiGeorge chromosomal region) have been shown in a majority of patients, and several candidate genes have been identified in this region (82). There appears to be an excess of 22q11.2 deletions of maternal origin (84). Another deletion associated with DiGeorge's and velocardiofacial syndromes has been identified on chromosome 10p13 (85).

No immunologic treatment is needed for the partial form. If patients with the partial DiGeorge syndrome do not have a severe cardiac lesion, they have few clinical problems, except that some experience seizures and developmental delay. Transplantation of cultured, mature thymic epithelial explants has successfully reconstituted the immune function of several infants with the complete DiGeorge syndrome (86).

COMBINED IMMUNODEFICIENCY DISORDERS

Severe Combined Immunodeficiency

Severe combined immunodeficiency (SCID) is a fatal syndrome of diverse genetic cause characterized by profound deficiencies of T and B cell (and sometimes NK cell) function (87–90). Affected infants present in the first few months of life with frequent episodes of diarrhea, pneumonia, otitis, sepsis, and cutaneous infections. Persistent infections with opportunistic organisms such as *Candida albicans*, *Pneumocystis jiroveci*, varicella-zoster virus, parainfluenza 3 virus, respiratory syncytial virus, adenovirus, cytomegalovirus, Epstein-Barr virus, and bacillus Calmette-Guérin lead to death. These infants also lack the ability to reject foreign tissue and are, therefore,

at risk for GVHD from maternal T cells that cross into the fetal circulation while the SCID infant is *in utero* or from T lymphocytes in nonirradiated blood products or allogeneic bone marrow (50).

Infants with SCID are lymphopenic (87,88,91). They have an absence of lymphocyte proliferative responses to mitogens, antigens, and allogeneic cells *in vitro*, even on samples collected *in utero* or from the cord blood (92). Therefore, physicians caring for newborns need to be aware of what the normal range for the cord blood absolute lymphocyte count is (2,000 to 11,000/mm^3) and arrange for T cell phenotypic and functional studies to be performed on blood from neonates with values below this range (87,91–93). Even though all forms of SCID could be diagnosed at birth by detecting lymphopenia or an absence of T cells, there is currently no newborn screening for this syndrome anywhere in the world. The normal absolute lymphocyte count is much higher at 6 to 7 months of age, when most SCIDs are diagnosed, so that any count below 4,000/mm^3 at that age is lymphopenic (94). Serum immunoglobulin concentrations are diminished to absent, and no antibody formation occurs after immunization. Typically, all SCID patients have very small thymuses (usually less than 1 g), which fail to descend from the neck, contain no thymocytes, and lack corticomedullary distinction and Hassall's corpuscles. However, the thymic epithelium is normal, and results of bone marrow stem cell transplantation have shown that these tiny thymuses are capable of supporting normal T cell development (95). Thymus-dependent areas of the spleen are depleted of lymphocytes in SCID patients, and lymph nodes, tonsils, adenoids, and Peyer's patches are absent or extremely underdeveloped.

In the more than 50 years since the initial description of SCID (1), it has become evident that the genetic origins of this condition are quite diverse (Table 46.4) (88,96). X-linked SCID (SCID-X1) is the most common form, accounting for approximately 46% of U.S. cases

	Ligase 4 deficient

ADA, adenosine deaminase; IL-7Rα, interleukin-7 receptor α chain; Jak3, Janus kinase-3; RAG, recombination activating gene.

FIGURE 46.5 Diagram showing that Janus kinase 3 (Jak3) is the major signal transducer for the common γ chain shared by multiple cytokine receptors. Mutations in the *IL2RG* gene cause X-linked severe combined immunodeficiency (X-SCID), whereas mutations in the *JAK3* gene result in a form of autosomal recessive SCID that mimics X-SCID in lymphocyte phenotype (i.e., T⁻B⁺NK⁻). Mutations in the alpha chain of the IL-7 receptor also cause SCID, but unlike X-linked and Jak3-deficient SCID, IL-7Rα chain–deficient SCID infants have both B and NK cells (i.e., are T⁻B⁺NK⁺). (From Buckley RH. Primary cellular immunodeficiencies. *J Allergy Clin Immunol.* 2002;109(5):747, with permission.)

(Figure 46.7) (88,96). Mutated genes on autosomal chromosomes have been identified in 11 genetic types of SCID: adenosine deaminase (ADA) deficiency, Janus kinase 3 (Jak3) deficiency, IL-7 receptor α-chain deficiency (IL-7Rα), recombination-activating gene (*RAG-1* or *RAG-2*) deficiencies, *Artemis* deficiency, CD3 α-, ε-, and ζ-chain deficiencies, and CD45 deficiency; and there are likely other causes yet to be discovered (Table 46.1) (88,96).

X-Linked Recessive Severe Combined Immunodeficiency Disease (SCID-X1)

Despite the uniformly profound lack of T or B cell function, patients with SCID-X1 usually have few or no T or NK cells but a normal or elevated number of B cells (Table 46.5) (87,91,93). However, SCID-X1 B cells do not produce immunoglobulin normally, even after T cell reconstitution by bone marrow transplantation (91). The abnormal gene in SCID-X1 was mapped to the Xq13 region and identified as the gene encoding a common gamma chain (γc) shared by several cytokine receptors, including those for IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21 (Figures 46.1, 46.5) (14,15,97). Of the first 136 patients studied, 95 distinct mutations spanning all eight *IL2RG* exons were identified, most of them consisting of small changes at the level of one to a few nucleotides (Figure 46.6) (98). These mutations resulted in abnormal γc's in two thirds of the cases and absent γc protein in the remainder. The finding that the mutated gene results in faulty signaling through several cytokine receptors explains how multiple cell types can be affected by a mutation in a single gene (97,99,100).

Autosomal Recessive Severe Combined Immunodeficiency Disease Caused by Adenosine Deaminase Deficiency

An absence of the enzyme adenosine deaminase (ADA) has been observed in approximately 16% of patients with SCID (Figure 46.7) (87,88,91). The gene encoding ADA

is on chromosome 20q13-ter and was cloned and sequenced more than a decade ago (101). There are certain distinguishing features of ADA deficiency, including the presence of multiple skeletal abnormalities of chondroosseous dysplasia on radiographic examination; these occur predominantly at the costochondral junctions, at the apophyses of the iliac bones, and in the vertebral bodies (causing a "bone-in-bone" effect) (101). ADA deficiency results in pronounced accumulations of adenosine, 2′-deoxyadenosine, and 2′-*O*-methyladenosine (101). The latter metabolites directly or indirectly lead to apoptosis of thymocytes and circulating lymphocytes, which causes the immunodeficiency. As a consequence, ADA-deficient infants usually have a much more profound lymphopenia than those with other types of SCID, with mean absolute lymphocyte counts of less than 500/mm³ and deficiencies of all types of lymphocytes (Table 46.5) (88,91). As with other types of SCID, ADA deficiency can be cured by HLA-identical or haploidentical T cell–depleted bone marrow transplantation, which is the treatment of choice (50,88,91). Enzyme replacement therapy with polyethylene glycol–modified bovine ADA (PEG-ADA) administered subcutaneously once weekly has resulted in both clinical and immunologic improvement in more than 100 ADA-deficient patients (102). However, the immunocompetence achieved is not nearly so great as with bone marrow

IL2RG MUTATIONS IN 87 FAMILIES WITH X-LINKED SCID

FIGURE 46.6 *IL2RG* cDNA map showing exons, cDNA numbers corresponding to the first coding nucleotide of each exon, protein domains, and sites of mutations found in 87 unrelated families with X-linked severe combined immunodeficiency (X-SCID). Identical mutations found in unrelated patients are surrounded by shaded boxes. (From Puck JM, Pepper AE, Henthorn PS, et al. Mutation analysis of IL2RG in human X-linked severe combined immunodeficiency. *Blood*. 1997;89:1968, with permission.)

transplantation (103). In view of this, PEG-ADA therapy should not be initiated if bone marrow transplantation is contemplated because it will confer graft-rejection capability on the infant. After T cell function is effected

FIGURE 46.7 Relative frequencies of the different genetic types of severe combined immunodeficiency among 194 patients seen consecutively by the author over three and a half decades. by bone marrow transplantation (without pretransplantation chemotherapy), infants with ADA deficiency generally have B cell function.

Autosomal Recessive Severe Combined Immunodeficiency Disease Caused by Janus Kinase 3 Deficiency

SCID patients with autosomal recessive SCID caused by Janus kinase 3 (Jak3) deficiency resemble all other types in their susceptibility to infection and to graft-versus-host disease from allogeneic T cells. However, they have lymphocyte characteristics most closely resembling those of patients with X-linked SCID, including an elevated percentage of B cells and very low percentages of T and NK cells (Table 46.5) (88,104). Because Jak3 is the only signaling molecule known to be associated with γc, it's gene was a candidate for mutations leading to autosomal recessive SCID of unknown molecular type (Table 46.4, Figure 46.6) (105). Thus far, more than 30 patients who lack Jak3 have been identified (Figure 46.6) (88,104,106). Like SCID-X1 patients, they have very low or no NK cells (88). Even after successful immune reconstitution by bone marrow transplantation, they fail to develop NK cells (50). Moreover, as

with SCID-X1 patients, they often fail to develop normal B cell function after transplantation despite their high numbers of B cells. Their failure to develop NK cells or B cell function is believed to be due to the defective function of the multiple cytokine receptors that share γc.

Autosomal Recessive Severe Combined Immunodeficiency Caused by Interleukin 7 Receptor α-Chain Deficiency

Because mice whose genes for either the α chain of the IL-7 receptor or of IL-7 itself have been mutated are profoundly deficient in T and B cell function but have normal natural killer cell function, naturally occurring mutations in these genes were sought in some of the author's patients who had T$^-$B$^+$NK$^+$ SCID and who had previously been shown not to have either γc or Jak3 deficiency. Mutations in the gene for IL-7Rα on chromosome 5p13 have been found in 22 of the author's patients, making it the third-most-common cause of SCID (Figure 46.7) (88,107). These findings imply that the T cell but not the NK cell defect in SCID-X1 and Jak3-deficient SCID results from an inability to signal through the IL-7 receptor (Figure 46.6). The fact that these patients developed normal B cell function after nonablative haploidentical bone marrow stem cell transplantation despite lacking donor B cells also suggests that the B cell defect in SCID-X1 is not due to failure of IL-7 signaling.

Autosomal Recessive Severe Combined Immunodeficiency Caused by Recombination-Activating Gene (RAG-1 or RAG-2) Deficiencies

Infants with autosomal recessive SCID caused by mutations in recombination activating genes *RAG-1* and *RAG-2* resemble all others in their infection susceptibility and complete absence of T or B cell function. However, their lymphocyte phenotype differs from those of patients with SCID caused by γc, Jak3, IL-7Rα, or ADA deficiencies in that they lack both B and T lymphocytes and have primarily NK cells in their circulation (T$^-$B$^-$NK$^+$ SCID, Table 46.5) (88). This particular phenotype suggested a possible problem with their antigen receptor genes, leading to the discovery of mutations in *RAG-1* and *RAG-2* in some (but not all) such SCID infants (108–110). These genes, on chromosome 11p13, encode proteins necessary for somatic rearrangement of antigen receptor genes on T and B cells. The proteins recognize recombination signal sequences (RSSs) and introduce a DNA double-stranded break, permitting V, D, and J gene rearrangements. *RAG-1* or *RAG-2* mutation results in a functional inability to form antigen receptors through genetic recombination.

Patients with Omenn's syndrome also have mutations in *RAG1* or *RAG2* genes, resulting in partial and impaired V(D)J recombinational activity (109,110). Omenn's syndrome is characterized by the development soon after birth of a generalized erythroderma and desquamation, diarrhea, hepatosplenomegaly, hypereosinophilia, and markedly elevated serum IgE levels. The latter are caused by circulating activated, oligoclonal T lymphocytes that do not respond normally to mitogens or antigens *in vitro* (111). Circulating B cells are not found, and lymph node architecture is abnormal due to a lack of germinal centers. The condition is fatal unless corrected by bone marrow transplantation (50).

Autosomal Recessive Severe Combined Immunodeficiency Caused by Deficiencies of the Artemis Gene

SCID may also be caused by a deficiency of a novel V(D)J recombination/DNA repair factor that belongs to the metallo-β-lactamase superfamily. It is encoded by a gene on chromosome 10p called *Artemis* (110,112). A deficiency of this factor results in an inability to repair DNA after double-stranded cuts have been made by *RAG1* or *RAG2* gene products in rearranging antigen receptor genes from their germline configuration. Similar to *RAG1*- and *RAG2*-deficient SCID, this defect results in another form of T$^-$B$^-$NK$^+$ SCID, also called Athabascan SCID (Table 46.5). In addition, there is increased radiation sensitivity of both skin fibroblasts and bone marrow cells of those affected with this type of SCID (110,112).

Autosomal Recessive Severe Combined Immunodeficiency Caused by Deficiencies of the Ligase 4 Gene Product

Another recently described cause of radiation-sensitive T$^-$B$^-$NK$^+$ SCID (Tables 46.4, 46.5) is mutation in the *Ligase 4* gene (113). The gene product is necessary for catalyzing the ligation step in the nonhomologous end-joining (NHEJ) pathway of DNA double-strand break (DSB) repair. Sequencing analysis of the *LIG4* gene in a female Turkish infant with T$^-$B$^-$NK$^+$ SCID (Table 46.5) who was not microcephalic and who had normal development revealed the presence of a homozygous deletion of three nucleotides CAA at nucleotide positions 5333 to 5335 (National Center for Biotechnology Information [NCBI] AF479264). Deletion of these three nucleotides resulted in deletion of glutamine Q433 in the protein (NCBI NP_996820). *LIG4* transcripts were present, but the absence of detectable LIG4 protein suggested that this mutation affects protein stability. The mutations in *LIG4* that had been previously reported were hypomorphic and resulted in radiosensitivity and leukemia in two patients or

in pancytopenia, micro-cephaly, and developmental and growth delay—collec-tively called the LIG4 syndrome—in eight other patients (114,115).

Autosomal Recessive Severe Combined Immunodeficiency Caused by CD45 Deficiency

Another molecular defect causing SCID is a mutation in the gene encoding the common leukocyte surface protein CD45 (116,117). This hematopoietic cell–specific trans-membrane protein tyrosine phosphatase functions to reg-ulate Src kinases required for T and B cell antigen receptor signal transduction. A 2-month-old male infant presented with a clinical picture of SCID and was found to have a very low number of T cells but a normal number of B cells. The T cells failed to respond to mitogens, and serum immunoglobulins diminished with time. He was found to have a large deletion at one *CD45* allele and a point muta-tion causing an alteration of the intervening sequence 13 donor splice site at the other (116). A second case of SCID due to CD45 deficiency has been reported (117), and the au-thor and her associates have recently evaluated yet a third case (unpublished observations) confirming that the lym-phocyte phenotype is $T^-B^+NK^+$ SCID (Table 46.5). Figure 46.7 shows the frequency of the various genetic forms of SCID that I have evaluated over the last three and a half decades.

Autosomal Recessive Severe Combined Immunodeficiency Caused by Mutations in Genes Encoding Chains of the CD3 Complex

Dadi et al. (118) discovered in 2003 that mutations in the gene encoding the δ chain of the CD3 complex caused SCID. Later, de Saint Basile et al. (119) studied three fami-lies with fetuses/infants who had SCID of unknown molec-ular type. All of the fetuses/infants had the $T^-B^+NK^+$ lym-phocyte phenotype (Table 46.5), that is, they had no T cells but did have phenotypically normal B cells and natu-ral killer (NK) cells, the same phenotype as in the SCID infants reported by Dadi et al. (118). Mutations in the gene encoding the CD3δ chain were found in only two of the families. In the third family, the investigators found a homozygous mutation in the CD3ε gene that created a premature stop codon near the start of the extracellu-lar domain, resulting in the absence of CD3 expression in those individuals affected. The author has evaluated a sim-ilar patient. More recently, mutations in the CD3 ζ-chain gene were found by the author and her associates to also result in $T^-B^+NK^+$ SCID (Table 46.5) (120). In the lat-ter case, the infant had CD16$^+$ NK cells but no CD56$^+$ NK cells.

Hypomorphic mutations in the CD3ε gene had been previously reported in a 4-year-old boy who had had re-current *Haemophilus influenzae* pneumonia early in life

but was later healthy (121). His T cells had low expres-sion of the CD3 complex but did respond to antigens. Defective expression of the T cell receptor CD3 com-plex was also reported in two male siblings in a Spanish family who were found to have mutations in the CD3γ gene (122). One of the siblings died at age 31 months with autoimmune hemolytic anemia and viral pneumo-nia, but the other was healthy. Both had very low expres-sion of CD3 on their T cells, but they were capable of making antigen-specific responses and had IgG$_2$ subclass deficiency.

Treatment and Prognosis

SCID is a pediatric emergency (87,88,91,92). Replacement therapy with IVIG fails to halt the progressively down-hill course (51). Unless bone marrow transplantation from HLA-identical or haploidentical donors can be performed, death usually occurs before the patient's first birthday and almost invariably before the second. On the other hand, transplantation in the first 3.5 months of life offers a greater than 96% chance of survival (88,91,92). Therefore, early diagnosis is essential. Recent studies have shown that the immune reconstitution effected by stem cell trans-plants is due to thymic education of the transplanted al-logeneic stem cells (95). The thymic output appears to oc-cur sooner and to a greater degree in those infants trans-planted in the neonatal period than in those transplanted after that time (92). There are more than 500 SCID patients surviving worldwide as a result of successful bone marrow transplantation (50).

ADA deficiency was the first genetic defect in which gene therapy was attempted; these early efforts were unsuccess-ful (23). However, within the last decade, normal γc cDNA was successfully transduced into autologous marrow cells of nine infants with SCID-X1 in France by retroviral gene transfer, with subsequent full correction of their T and NK cell defects (123). Thus the efficacy of gene therapy in con-ferring immune function in those infants with SCID-X1 seemed to be superior to that of allogeneic hematopoi-etic stem-cell transplantation. Tragically, however, serious adverse events occurred in four of them, who developed leukemia-like processes, with expanded clonal populations of T cells (124). The leukemias are considered to have been induced by the retroviral gene therapy by a process called insertional mutagenesis. More recently, this complication also occurred in a SCID-X1 patient treated in England, but it has not occurred in eight ADA-deficient patients success-fully treated with gene therapy in Italy (125). In view of the early successes with gene therapy in SCID-X1 and ADA deficiency (23), the hope is that in the future those and other primary immunodeficiencies for which the molecu-lar defects have been identified will be correctable by gene therapy.

Reticular Dysgenesis

This condition was first described in 1959 in identical twin male infants who exhibited a total lack of both lymphocytes and granulocytes in their peripheral blood and bone marrow. Seven of the eight infants thus far reported with this defect died between 3 and 119 days of age from overwhelming infections; the eighth underwent complete immunologic reconstitution from a bone marrow transplant. Recombinant granulocyte colony-stimulating factor was not successful in the treatment of an infant with this condition. The thymuses have all weighed less than 1 g, no Hassall's corpuscles have been present, and few or no thymocytes have been seen. The molecular basis of this autosomal recessive disorder is unknown (3).

Combined Immunodeficiency

The term combined immunodeficiency (CID) is used to distinguish patients with low but not absent T cell function from those with SCID. Several examples will be given.

Purine Nucleoside Phosphorylase Deficiency

More than 40 patients with CID have been found to have purine nucleoside phosphorylase (PNP) deficiency (101,126). Deaths have occurred from generalized vaccinia, varicella, lymphosarcoma, and graft-versus-host disease mediated by T cells from nonirradiated allogeneic blood or bone marrow. Two thirds of patients have had neurologic abnormalities ranging from spasticity to mental retardation. One third of patients developed autoimmune diseases, the most common of which is autoimmune hemolytic anemia. Most patients have normal or elevated concentrations of all serum immunoglobulins. PNP-deficient patients are as profoundly lymphopenic as those with ADA deficiency, with absolute lymphocyte counts usually less than 500/mm^3. T cell function is low but not absent and is variable with time. The gene encoding PNP is on chromosome 14q13.1, and it has been cloned and sequenced. A variety of mutations have been found in the PNP gene in patients with PNP deficiency (101). Unlike ADA deficiency, serum and urinary uric acid are deficient because PNP is needed to form the urate precursors hypoxanthine and xanthine. Prenatal diagnosis is possible. PNP deficiency is invariably fatal in childhood unless immunologic reconstitution can be achieved. Bone marrow transplantation is the treatment of choice but has been successful in only six such patients (50,127,128).

Ataxia-Telangiectasia

Ataxia-telangiectasia (AT) is a complex combined immunodeficiency syndrome with associated neurologic, endocrinologic, hepatic, and cutaneous abnormalities (129,130). The most prominent features are progressive cerebellar ataxia, oculocutaneous telangiectasias, chronic sinopulmonary disease, a high incidence of malignancy, and variable humoral and cellular immunodeficiency (131). The ataxia typically becomes evident soon after the child begins to walk and progresses until he or she is confined to a wheelchair, usually by 10 to 12 years of age. The telangiectasias develop at between 3 and 6 years of age. Recurrent, usually bacterial, sinopulmonary infections occur in roughly 80% of these patients. Fatal varicella occurred in one patient, and transfusion-associated graft-versus-host disease has also been reported. Selective IgA deficiency is found in from 50% to 80% of those affected (131). IgE concentrations are usually low, and IgG2 or total IgG may be decreased. Specific antibody titers may be decreased or normal. The percentages of CD3$^+$ and CD4$^+$ T cells are only modestly low, and *in vitro* tests of lymphocyte function have generally shown moderately depressed proliferative responses to T and B cell mitogens. The thymus is hypoplastic, exhibits poor organization, and is lacking in Hassall's corpuscles. Cells from patients, as well as those of heterozygous carriers, have increased sensitivity to ionizing radiation, defective DNA repair, and frequent chromosomal abnormalities (131). The malignancies reported in this condition usually have been of the lymphoreticular type, but adenocarcinoma and other forms also have been seen; there is also an increased incidence of malignancy in unaffected relatives.

Inheritance of AT follows an autosomal recessive pattern. The mutated gene (*ATM*) responsible for this defect was mapped by restriction fragment length polymorphism analysis to the long arm of chromosome 11 (11q22–23) and was cloned (130,132). The gene product is a DNA-dependent protein kinase localized predominantly to the nucleus and believed to be involved in mitogenic signal transduction, meiotic recombination, and cell cycle control (130). Of the mutations identified, a majority were expected to completely inactivate the ATM protein by truncating it, by abolishing correct initiation or termination of translation, or by deleting large segments (130). No satisfactory definitive treatment has been found (131). The prognosis is exceedingly poor for patients with this condition, although a number have reached adulthood. The most common causes of death are lymphoreticular malignancy and progressive neurologic disease.

Immunodeficiency with Thrombocytopenia and Eczema (Wiskott-Aldrich Syndrome)

The Wiskott-Aldrich syndrome (WAS) is an X-linked recessive syndrome characterized by eczema, thrombocytopenic purpura with normal-appearing megakaryocytes but small defective platelets, and undue susceptibility to infection (13,89,133). Patients usually present during infancy with prolonged bleeding from the circumcision

site, bloody diarrhea, or excessive bruising. Atopic dermatitis and recurrent infections usually also develop during the first year of life. Infections are usually those produced by pneumococci and other encapsulated bacteria, resulting in otitis media, pneumonia, meningitis, or sepsis. Later, infections with opportunistic agents such as *Pneumocystis jiroveci* and the herpesviruses become more problematic. Autoimmune cytopenias and vasculitis are common in those who live beyond infancy. Survival beyond the teens is rare; infections and bleeding may cause death, and there is also a 12% incidence of fatal malignancy in this condition (13,133).

Patients with WAS have an impaired humoral immune response to polysaccharide antigens, as evidenced by absent or greatly diminished isohemagglutinins and poor or absent antibody responses to polysaccharide antigens (13). In addition, antibody titers to protein antigens fall with time. Most often there is a low serum IgM, elevated IgA and IgE, and a normal or slightly low IgG concentration. Flow cytometry of blood lymphocytes has shown a moderately reduced percentage of T cells, and lymphocyte responses to mitogens are moderately depressed (13).

The mutated gene responsible for this defect was mapped to Xp11.22–11.23 and isolated in 1994 by Derry et al. (12). It was found to be limited in expression to lymphocytic and megakaryocytic lineages (12). The gene product, a 501–amino acid, proline-rich protein that lacks a hydrophobic transmembrane domain, was designated WAS protein (WASP). It has been shown to bind CDC42H2 and rac, members of the Rho family of GTPases, which are important in actin polymerization (13,134). A large and varied number of mutations in the *WASP* gene have been identified in WAS patients, with some correlation of the site of the mutation with severity of infection susceptibility or other problems in one series (135) but not in others. Mutations in the *WASP* gene have been shown to affect not only platelet (136) and T cell function but also dendritic cell and B cell adhesion, homing, and function (137,138) and NK cell cytotoxicity (139). Isolated X-linked thrombocytopenia is also caused by mutations in the *WASP* gene, as are some cases of severe congenital neutropenia (140). Carriers can be detected by the finding of nonrandom X chromosome inactivation in several hematopoietic cell lineages or by detection of the mutated gene (if known in the family). Prenatal diagnosis of WAS can also be made by chorionic villous sampling or amniocentesis if the mutation is known in that family. Two families with apparent autosomal inheritance of a clinical phenotype similar to WAS have been reported (141,142), and in one case a girl was shown to have this as an X-linked defect (143).

Numerous patients with WAS have had complete corrections of both the platelet and the immunologic abnormalities by HLA-identical sibling bone marrow transplants after being conditioned with irradiation or busulfan and cyclophosphamide (50). Success has been minimal with T cell–depleted haploidentical stem cell transplants in WAS, primarily because of the requirement for pretransplant immunosuppression to permit engraftment, the long time course to immunoreconstitution when T cells are depleted, resistance to engraftment, and a high mortality from preexisting opportunistic infections in that setting (50). However, success has been achieved in the treatment of WAS with matched unrelated donor transplants when done in children younger than 5 years of age (144). It is likely that matched related or unrelated cord blood transplants will be similarly successful because in both cases T cells can be left in the donor cell suspension. Several patients who required splenectomy for uncontrollable bleeding had impressive rises in their platelet counts and did well clinically while being administered prophylactic antibiotics and IVIG (145). Based on success in *in vitro* transfection studies (146), the first gene therapy trials for this condition are underway (147). The most common cause of death in WAS patients is EBV-induced lymphoreticular malignancy (133).

Cartilage-hair Hypoplasia

In 1965, an unusual form of short-limbed dwarfism with frequent and severe infections was reported among the Pennsylvania Amish; non-Amish cases have since been described (148). These patients have short and pudgy hands with redundant skin, metaphyseal chondrodysplasia, hyperextensible joints of hands and feet but an inability to extend the elbows completely, and fine, sparse light hair and eyebrows. These features led to the name cartilage-hair hypoplasia (CHH). Radiographically the bones show scalloping and sclerotic or cystic changes in the metaphyses. In contrast to ADA deficiency, in which the predominant changes are in the apophyses of the iliac bones, the ribs, and vertebral bodies, the chondrodysplasia in CHH principally affects the limbs. Severe and often fatal varicella infections, progressive vaccinia, and vaccine-associated poliomyelitis have been observed. Associated conditions include deficient erythrogenesis, Hirschsprung's disease, and an increased risk of malignancies.

Three patterns of immune dysfunction have emerged: defective antibody-mediated immunity, defective cellular immunity (most common form), and severe combined immunodeficiency. NK cells, however, are increased in number and function.

CHH is an autosomal recessive condition, and the defective gene was mapped to chromosome 9p21-p13 in Amish and Finnish families. Numerous mutations have been found in the untranslated *RMRP* gene that cosegregates with the CHH phenotype (149). The gene product, endoribonuclease RNase MRP (mitochondrial RNA processing), consists of an RNase molecule bound to several proteins. It has at least two functions: cleavage of RNA

in mitochondrial DNA synthesis and nucleolar cleaving of pre-RNA. Mutations in *RMRP* cause CHH by disrupting a function of RNase MRP RNA that affects multiple organ systems (149). Bone marrow transplantation has resulted in immunologic reconstitution in some cartilage-hair hypoplasia patients with the SCID phenotype (91). Those with milder types of immune deficiency have lived to adulthood, some even to old age.

Nijmegen Breakage Syndrome

This is a rare autosomal recessive condition in which the immunologic, cytogenetic, and radiation-sensitivity findings are almost identical to those in ataxia-telangiectasia (150,151). However, the patients are quite distinct from those with ataxia-telangiectasia clinically in that they have short stature, a "birdlike" facies, and microcephaly from birth. They lack the classic clinical features of ataxia-telangiectasia, including ataxia and telangiectasia, and they have normal serum α-fetoprotein levels. Intelligence can vary from normal to moderate mental retardation. The immunodeficiency appears to be more severe than in ataxia-telangiectasia. Most patients have recurrent respiratory infections. The tendency to express rearrangements of chromosomes 7 and 14 and to develop a malignancy is much higher than in ataxia-telangiectasia. More than 40 patients from approximately 30 families have been reported, and most are of eastern European origin (150,151). Complementation studies have indicated that patients with this syndrome are genetically distinct from those with ataxia-telangiectasia. The abnormal gene in this condition has been mapped to chromosome 8q21 (Table 46.1) (152).

Defective Expression of Major Histocompatibility Complex Antigens

There are two main forms: (a) class I MHC antigen deficiency (bare lymphocyte syndrome) and (b) class II MHC antigen deficiency.

MHC Class I Antigen Deficiency

An isolated deficiency of MHC class I antigens is rare, and the resulting immunodeficiency is milder than that in SCID, contributing to a later age of presentation (153). Sera from affected individuals contain normal quantities of class I MHC antigens and β_2-microglobulin, but class I MHC antigens are not detected on any cells in the body. There is a deficiency of CD8$^+$ but not of CD4$^+$ T cells. Mutations have been found in two genes within the MHC locus on chromosome 6 that encode the peptide transporter proteins TAP1 and TAP2 (Table 46.1) (153–155). TAP proteins function to transport peptide antigens from the cytoplasm across the Golgi apparatus membrane to join the α chain of MHC class 1 molecules and β_2-microglobulin. The complex can then move to the cell surface; if the assembly of the complex cannot be completed because there is no peptide antigen, the MHC class I complex is destroyed in the cytoplasm.

MHC Class II Antigen Deficiency

Many individuals affected with this autosomal recessive syndrome are of North African descent.. More than 70 patients have been identified. They present in infancy with persistent diarrhea, often associated with cryptosporidiosis; bacterial pneumonia; pneumocystis; septicemia; and viral or monilial infections. Nevertheless, their immunodeficiency is not as severe as in SCID, as evidenced by their failure to develop BCGosis or GVHD from nonirradiated blood transfusions (156). MHC class II–deficient patients have a very low number of CD4$^+$ T cells but normal or elevated numbers of CD8$^+$ T cells. Lymphopenia is only moderate. The MHC class II antigens HLA-DP, -DQ, and -DR are undetectable on blood B cells and monocytes. The patients have impaired antigen-specific responses caused by the absence of these antigen-presenting molecules. In addition, MHC antigen–deficient B cells fail to stimulate allogeneic cells in mixed leukocyte culture. Lymphocytes respond normally to mitogens but not to antigens. The thymus and other lymphoid organs are severely hypoplastic. The lack of class II molecules results in abnormal thymic selection because recognition of HLA molecules by thymocytes is central to both positive and negative selection. The latter results in circulating CD4$^+$ T cells that have altered CDR3 profiles. The associated defects of both B and T cell immunity and of HLA expression emphasize the important biological role for HLA determinants in effective immune cell cooperation.

Four different molecular defects resulting in impaired expression of MHC class II antigens have been identified (Table 46.1) (156). In one, there is a mutation in the gene on chromosome 1q that encodes a protein called RFX5, a subunit of RFX, a multiprotein complex that binds the X box motif of MHC II promoters (157). A second form is caused by mutations in a gene on chromosome 13q that encodes a second, 36-kDa subunit of the RFX complex called RFX-associated protein (RFXAP) (158). The most recently discovered and most common cause of MHC class II defects are mutations in RFXANK, the gene encoding a third subunit of RFX (159). In a fourth type, there is a mutation in the gene on chromosome 16p13 that encodes a novel MHC class II transactivator (CIITA), a non–DNA-binding coactivator that controls the cell-type specificity and inducibility of MHC II expression (160). All of these defects cause impairment in the coordinate expression of MHC class II molecules on the surface of B cells and macrophages (156).
FIGURE 46.8 T cell signal transduction pathway. The T cell receptor (TCR) spans the plasma membrane in association with CD3 and ζ, CD4 or CD8, CD28, and CD45. Cytoplasmic protein tyrosine kinases (PTKs) associated with the TCR are activated on antigen binding to the TCR. These PTKs include Lck, Fyn, ζ-chain–associated protein-70 (ZAP-70), and Syk. PTK activation results in the phosphorylation of phospholipase Cγ1 (PLCγ1) and the activation of other signaling molecules. Distal signaling events, including PKC activation and Ca^{2+} mobilization, result in the transcription of genes encoding interleukin-2 (IL-2) and other proteins, culminating in T cell activation, differentiation, and proliferation. Ionomycin and phorbol myristate acetate (PMA) can be used to mimic distal signaling events. Mutations in the gene encoding ZAP-70 result in markedly impaired T cell activation, in addition to abnormal thymic selection resulting in CD8 deficiency. AP-1, activated protein; DAG, diacylglycerol; IP$_3$, inositol phosphate 3; MAP, mitogene-activated protein kinase; NFAT, nuclear factor of activated T cells; PIP$_2$, phosphatidyl inositol 2; PL-3, phospholipase 3. (Modified from Elder ME. Severe combined immunodeficiency due to a defect in the tyrosine kinase ZAP-70. *Pediatr Res*. 1996;39:743, with permission.)

CD8 Deficiency Due to a Mutation in the CD8α Gene

Another cause for CD8 deficiency (in addition to ζ-chain–associated protein-70 deficiency and MHC class I antigen deficiency) was discovered in a 25-year-old Spanish man with a history of recurrent respiratory infections since childhood. Immunoglobulins and antibodies were normal, as were T cell proliferation studies and NK cell function. However, he was found to have a complete absence of CD8$^+$ T cells. Molecular studies revealed a missense mutation in both alleles of the immunoglobulin domain of the CD8α gene in the patient and in two of his sisters (161,162).

T CELL ACTIVATION DEFECTS

These conditions are characterized by the presence of normal or elevated numbers of blood T cells that appear phenotypically normal but fail to proliferate or produce cytokines in response to stimulation with mitogens, antigens, or other signals delivered to the T cell antigen receptor (TCR) due to defective signal transduction from the TCR to intracellular metabolic pathways (Figure 46.8) (163). This condition can be caused mutations in genes for a variety of cell surface molecules or signal transduction molecules. These patients have problems similar to those of other T cell–deficient individuals, and some with severe T cell activation defects may resemble SCID patients clinically. Two examples are described.

Defective Ca^{2+} Release–Activated Ca^{2+} Channels

Two male infants born to consanguineous parents had SCID-like infection susceptibility despite phenotypically normal blood lymphocytes. However, their T cells were unable to produce IL-2, IFNγ, IL-4, and TNFα. Electrophoretic mobility shift assays were used to examine

the DNA binding of AP-1, Oct, CREB, SP1, NFκB, and NF-AT, and the binding of all but NF-AT was normal (164). This problem was subsequently shown to be secondary to defective store-operated Ca^{2+} entry and calcium release–activated calcium (CRAC) channel function. The molecular defect responsible for this was recently discovered (165). It was found that the infants are homozygous for a single missense mutation in the gene that encodes a novel protein called Orai1. The protein contains four putative transmembrane segments. Expression of wild-type Orai1 in SCID T cells restored store-operated Ca^{2+} influx and the CRAC current. The authors propose that Orai1 is an essential component or regulator of the CRAC channel complex.

CD8 Lymphocytopenia Due to ζ-Chain–Associated Protein-70 Deficiency

Patients with CD8 lymphocytopenia caused by ζ-chain–associated protein-70 (ZAP-70) deficiency present during infancy with severe, recurrent, sometimes fatal infections similar to those in SCID patients; however, they often live longer and present later than SCID patients (163). More than eight cases have been reported, and a majority were Mennonites (163,166,167). They have normal, low, or elevated serum immunoglobulin concentrations and normal or elevated numbers of circulating CD4$^+$ T lymphocytes but essentially no CD8$^+$ cells. These CD4$^+$ T cells fail to respond to mitogens or to allogeneic cells *in vitro* or to generate cytotoxic T lymphocytes. By contrast, NK activity is normal. The thymus of one patient exhibited normal architecture; there were normal numbers of CD4:CD8 double-positive thymocytes but an absence of CD8 single-positive thymocytes. This condition has been attributed to mutations in the gene encoding ZAP-70, a non–src family protein tyrosine kinase important in T cell signaling (Figure 46.8) (163). The gene is on chromosome 2 at position q12. ZAP-70 has been shown to have an essential role in both positive and negative selection in the thymus (Table 46.1) (166). The hypothesis as to why there are normal numbers of CD4$^+$ T cells is that thymocytes can use the other member of the same tyrosine kinase family, Syk, to facilitate positive selection of CD4$^+$ cells. In addition, there is a stronger association of Lck with CD4$^+$ than with CD8$^+$ cells. Syk is present at fourfold-higher levels in thymocytes than in peripheral T cells, possibly accounting for the lack of normal responses by the CD4$^+$ blood T cells.

AUTOIMMUNE AND LYMPHOPROLIFERATIVE SYNDROMES

Immune Dysregulation, Polyendocrinopathy, Enteropathy, X-Linked Syndrome (IPEX)

IPEX syndrome is a fatal, X-linked recessive immunologic disorder characterized by multisystem autoimmunity, most commonly in the form of early-onset type 1 diabetes mellitus, severe enteropathy with watery, often bloody diarrhea associated with eosinophilic inflammation and an eczematous dermatitis, and moderate to severe recurrent infections caused by *Enterococcus and Staphylococcus* species. The condition is due to mutations in the forkhead box P3 (*FOXP3*) gene on Xp11.23 (Figure 46.1), which encodes a forkhead domain–containing protein, FOXP3 (168). *FOXP3* is predominantly expressed in the CD4$^+$CD25^{high} subset of regulatory T cells (Tregs), and studies in mutant mice indicate that FOXP3 is essential for the development of Tregs. The number and phenotype of CD4$^+$CD25^{high} T cells appears to be normal in IPEX patients, but there is either no FOXP3 protein in these cells or mutant protein with abnormal regulatory function (169). The findings demonstrate a key role for FOXP3 in the maintenance of self-tolerance and in the prevention of autoimmune and allergic diseases.

Autoimmune Polyendocrinopathy-Candidiasis Ectodermal Dysplasia (APCEP)

Patients with this syndrome present with chronic mucocutaneous candidiasis and polyendocrinopathy, usually affecting the parathyroid or adrenal glands and less frequently the thyroid, liver, and skin. Autoimmune polyendocrinopathy-candidiasis ectodermal dysplasia, or autoimmune polyendocrinopathy syndrome type I (APS1), is due to a mutation in the autoimmune regulator (*AIRE*) gene (170,171). The gene product, AIRE, is expressed at high levels in purified human thymic medullary stromal cells and is believed to regulate the cell surface expression of tissue-specific proteins such as insulin and thyroglobulin. Expression of these self-proteins allows for the negative selection of autoreactive T cells during their development. Failure of negative selection results in organ-specific autoimmune destruction. The overall significance of AIRE in the establishment and maintenance of T cell self-tolerance is not well understood.

Autoimmune Lymphoproliferative Syndrome (ALPS)

Autoimmune lymphoproliferative syndrome (ALPS) is a disorder of apoptosis in which the inability of lymphocytes to die leads to nonmalignant massive lymphadenopathy, hypersplenism, and autoimmune cytopenias of childhood onset (172). Consistent immunologic findings include polyclonal hypergammaglobulinemia and an expansion of T cells lacking either CD4 or CD8 on their surfaces (double-negative T cells). The most frequent genetic cause of ALPS is germline dominant, heterozygous mutations in the tumor necrosis factor receptor superfamily member 6 (*TNFRSF6*) gene (ALPS type Ia), which encodes CD95 (also known as Fas), a mediator of apoptosis. Somatic

mutations in the gene have also been found. Other causes are mutations in genes encoding either the CD95 ligand (ALPS type Ib), caspase 10 (ALPS type IIa), or caspase 8 (ALPS type IIb). Major determinants of morbidity and mortality in ALPS are the severity of the autoimmune disease, hypersplenism, and the risk of Hodgkin's or non-Hodgkin's lymphoma (173). Penetrance and range of disease manifestations in ALPS are highly variable, even among family members who share the same dominant *TNFRSF6* mutation (172). Although most episodes of cytopenias respond to courses of conventional immunomodulatory agents, some ALPS patients with massive splenomegaly may require splenectomy and/or ongoing immunosuppressive treatment. This disorder underscores the critical role played by cell surface receptor–mediated apoptosis in eliminating redundant proliferating lymphocytes with autoreactive and oncogenic potential.

Interleukin 2 Receptor α Chain (IL-2Rα, CD25) Mutation

A male infant born of a consanguineous union presented at 6 months of age with cytomegalovirus pneumonia, persistent oral and esophageal candidiasis, adenoviral gastroenteritis, and failure to thrive. He developed lymphadenopathy, hepatosplenomegaly, and chronic inflammation of his lungs and mandible. Biopsies revealed extensive lymphocytic infiltration of his lung, liver, gut, and bone. Serum IgG and IgM were elevated, but IgA was low. He had a T cell lymphocytopenia, with an even CD4:CD8 ratio. The T cells responded poorly to anti-CD3, phytohemagglutinin and other mitogens, and IL-2. He was found to have a truncated mutation of the IL-2R α chain (CD25) (Table 46.1) (174). He could not reject an allogeneic skin graft. He was given a successful allogeneic bone marrow transplant following cytoreduction.

Young mutant mice lacking the IL-2R α chain have phenotypically normal T and B cell development (175). However, as adults, they develop massive lymphoid organ enlargement and polyclonal T and B cell expansion attributed to defective apoptosis. They also develop autoimmune disorders, including hemolytic anemia and inflammatory bowel disease. Similarly, gene targeted mice lacking the IL-2R β chain develop exhaustive differentiation of B cells into plasma cells, elevated IgG1 and IgE, and autoantibodies that cause hemolytic anemia (176). Their T cells did not respond to polyclonal or antigen-specific activators. It is known that IL-2 programs murine $\alpha\beta$ T lymphocytes for apoptosis (177). From these observations, it is deduced that both IL-2R α and β chains play an important role in influencing the activation programs of T cells, the balance between clonal expansion and cell death following lymphocyte activation, and the prevention of autoimmunity.

DEFECTS IN INNATE IMMUNITY

Leukocyte Adhesion Deficiencies 1 and 2

Leukocyte Adhesion Deficiency-1 (LAD-1)

This condition is attributable to mutations in the gene on chromosome 21 at position q22.3 encoding CD18, a 95-kDa β subunit shared by three adhesive heterodimers: LFA-1 on B, T, and NK lymphocytes; complement receptor type 3 (CR3) on neutrophils, monocytes, macrophages, eosinophils, and NK cells; and p150,95 (another complement receptor) (Table 46.1) (178). The α chains of these three molecules (encoded by genes on chromosome 16) are not expressed because of the abnormal β chain. Those so affected have histories of delayed separation of the umbilical cord, omphalitis, gingivitis, recurrent skin infections, repeated otitis media, pneumonia, septicemia, ileocolitis, peritonitis, perianal abscesses, and impaired wound healing (178). Life-threatening bacterial and fungal infections account for the high mortality. Affected people do not have increased susceptibility to viral infections or malignancy. Blood neutrophil counts are usually significantly elevated even when no infection is present because of an inability of the cells to adhere to vascular endothelium and migrate out of the intravascular compartment. All cytotoxic lymphocyte functions are considerably impaired because of a lack of the adhesion protein LFA-1; deficiency of LFA-1 also interferes with immune cell interaction and immune recognition. CR3 binds fixed iC3b fragments of C3 and β-glucans; its absence causes abnormal phagocytic cell adherence and chemotaxis and a reduced respiratory burst with phagocytosis. Deficiencies of these glycoproteins can be screened for by flow cytometry with monoclonal antibodies to CD18 or to CD11a, b, or c. Because the CD18 gene has been cloned and sequenced, this disorder is another potential candidate for gene therapy (23).

Leukocyte Adhesion Deficiency-2 (LAD-2)

LAD-2 is attributable to the absence of neutrophil sialyl-Lewis^X, a ligand of E-selectin on vascular endothelium (178). This disorder was discovered in two unrelated Israeli boys 3 and 5 years of age, each the offspring of consanguineous parents. Both had severe mental retardation, short stature, a distinctive facial appearance, and the Bombay (hh) blood phenotype, and both were secretor- and Lewis-negative. They both had had recurrent severe bacterial infections similar to those seen in patients with LAD-1, including pneumonia, peridontitis, otitis media, and localized cellulitis. Similar to that in patients with LAD-1, their infections were accompanied by pronounced leukocytosis (30,000 to 150,000/mm^3) but an absence of pus formation at sites of recurrent cellulitis. *In vitro* studies revealed a pronounced defect in neutrophil motility. Because the genes for the red blood cell H

antigen and for the secretor status encode for distinct $\alpha_{1,2}$-fucosyltransferases and the synthesis of Sialyl-Lewis^X requires an $\alpha_{1,3}$-fucosyltransferase, it was postulated that a general defect in fucose metabolism is the basis for this disorder. It was subsequently found that GDP-L-fucose transport into Golgi vesicles was specifically impaired (179), and then missense mutations in the GDP-fucose transporter cDNA of three patients with LAD II were discovered. Thus, GDP-fucose transporter deficiency is a cause of LAD-2 (180).

Interferon-γ Receptor-1 and 2 Mutations

Disseminated BCG infections occur in infants with SCID or with other severe T cell defects. However, in approximately half of the cases no specific host defect has been found. One possible explanation for this predilection was found in a 2.5-month-old Tunisian female infant who had fatal idiopathic disseminated BCG infection (181) and in four children from Malta who had disseminated atypical mycobacterial infection in the absence of a recognized immunodeficiency (182). In the case of all five children, there was consanguinity in their pedigrees. All affected were found to have a functional defect in the upregulation of TNFα production by their blood macrophages in response to stimulation with IFNγ. Furthermore, all lacked expression of IFNγR's on their blood monocytes or lymphocytes, and each was found to have a mutation in the gene on chromosome 6q22-q23 that encodes IFNγR1. Of interest, these children did not appear to be susceptible to infection with agents other than mycobacteria. Th1 responses appeared to be normal in these patients. The susceptibility of these children to mycobacterial infections thus apparently results from an intrinsic impairment of the IFNγ pathway response to these particular intracellular pathogens, showing that IFNγ is obligatory for efficient macrophage antimycobacterial activity. Since the initial discoveries of IFNγR1-deficient humans, many more examples have been found, and IFNγR2-deficient individuals have been found as well (183,184).

IL-12 and IL-12 Receptor β1 Mutations

IL-12 is produced by activated antigen-presenting cells (dendritic cells, macrophages) (183). It promotes the development of Th1 responses and is a powerful inducer of IFNγ production by T and NK cells (184). A child with BCG and *Salmonella enteritidis* infection was found to have a large homozygous deletion within the IL-12 p40 subunit gene, precluding expression of functional IL-12 p70 cytokine by activated dendritic cells and phagocytes. As a result, IFNγ production by the child's lymphocytes was markedly impaired (185). This suggested that IL-12 is essential for protective immunity to intracellular bacteria such as mycobacteria and *Salmonella*. In further support

of this, T and NK cells from seven unrelated patients who had severe idiopathic mycobacterial and *Salmonella* infections failed to produce IFNγ when stimulated with IL-12 (186,187). The patients were otherwise healthy. They were found to have mutations in the IL-12 receptor β1 chain, resulting in premature stop codons in the extracellular domain, resulting in unresponsiveness to this cytokine, again demonstrating IL-12's crucial role in host defense (186,187).

Germline STAT 1 Mutation

Interferons induce the formation of two transcriptional activators: gamma-activating factor (GAF) and interferon-stimulated gamma factor 3 (ISGF3). A natural heterozygous germline STAT1 mutation associated with susceptibility to mycobacterial but not viral disease was found in two unrelated patients with unexplained mycobacterial disease (188). This mutation caused a loss of GAF and ISGF3 activation but was dominant for one cellular phenotype and recessive for the other. It impaired the nuclear accumulation of GAF but not of ISGF3 in cells stimulated by interferons, implying that the antimycobacterial but not the antiviral effects of human interferons are mediated by GAF. More recently, two patients have been identified with homozygous *STAT-1* mutations who developed both post–BCG vaccination disseminated disease and lethal viral infections. The mutations in these patients caused a complete lack of STAT-1 and resulted in a lack of formation of both GAF and ISGF3 (189).

Il-1R–Associated Kinase 4 Deficiency

Members of interleukin-1 receptor and the Toll-like receptor superfamily share an intracytoplasmic Toll-IL-1 receptor (TIR) domain, which mediates recruitment of the interleukin-1 receptor–associated kinase (IRAK) complex via TIR-containing adapter molecules (190). Three unrelated, otherwise healthy children with recurrent pyogenic infections due to pneumococci and staphylococci had normal immunocompetence by standard immune studies. They had normal titers of antipneumococcal antibodies. However, their blood and fibroblast cells did not activate nuclear factor κB and mitogen-activated protein kinase and failed to induce downstream cytokines in response to any of the known ligands of TIR-bearing receptors. Each was found to have an inherited deficiency of IRAK-4. Thus, the TIR-IRAK signaling pathway appears to be crucial for protective immunity against specific bacteria but is redundant against most other microorganisms (190).

Chediak-Higashi Syndrome

This rare disease is characterized by oculocutaneous albinism and susceptibility to recurrent respiratory tract and other types of infections (191). The hallmark of the

disease is giant lyosomal granules, not only in neutrophils, but also in most of the other cells of the body, including melanocytes, neural Schwann cells, renal tubular cells, gastric mucosa, pneumatocytes, hepatocytes, Langerhans cells of the skin, and adrenal cells (191). The granules in neutrophils are positive for peroxidase, acid phosphatase, and esterase. The abnormal lysosomes are unable to fuse with phagosomes, so that ingested bacteria cannot be lysed normally. In addition, there is nearly complete absence of cytotoxic T lymphocyte and NK cell activity as a result of abnormal lysosomal granule function (191). Abnormal chemotaxis has also been reported, and there is evidence of a profound alteration of the cytoskeleton of the neutrophils. There are reports of a decreased number of centriole-associated microtubules and abnormalities in tubulin tyrosinolation.

The fundamental defect in this autosomal recessive disorder was recently found to be caused by mutations in a gene on human chromosome 1 at position q42-43 (Table 46.1) (192,193). This gene is similar to the one mutated in the murine beige defect (192). The gene product is postulated to function with other proteins as components of a vesicle membrane–associated signal transduction complex that regulates intracellular protein trafficking (192).

Approximately 85% of the patients develop an "accelerated phase" of the disease, with fever, jaundice, hepatosplenomegaly, lymphadenopathy, pancytopenia, bleeding diathesis, and neurologic changes (194). Once the accelerated phase occurs, the disease is usually fatal within 30 months unless successful treatment with an unfractionated HLA-identical bone marrow transplant following cytoreductive conditioning can be accomplished (50,195).

HYPERIMMUNOGLOBULINEMIA E SYNDROME

The hyperimmunoglobulinemia E (hyper IgE) syndrome is a relatively rare primary immunodeficiency syndrome characterized by recurrent severe staphylococcal abscesses of the skin, lungs, and viscera and greatly elevated levels of serum IgE (196,197). I first reported the disorder in two young boys in 1972 (196). Since then I have evaluated more than 40 patients with the condition, and many other examples have been reported (197). These patients all have histories of staphylococcal abscesses involving the skin, lungs, joints, and other sites from infancy; persistent pneumatoceles develop as a result of their recurrent pneumonias. The pruritic dermatitis that occurs is not typical atopic eczema, and it does not always persist; respiratory allergic symptoms are usually absent. I noted coarse facial features in the first two patients (196), and this has been a consistent feature of all of the patients I have evaluated with this syndrome. Hyper IgE syndrome patients look very different from their nonaf-

fected family members. Distinctive facial characteristics were again pointed out recently by Grimbacher et al. (198). Among the findings reported were a prominent forehead, deep-set eyes, a broad nasal bridge, a wide, fleshy nasal tip, mild prognathism, facial asymmetry, and hemihypertrophy. They also found that the mean nasal interalar distance in these patients was above the 98th percentile ($p < 0.001$). These findings were present in all patients in that study by age 16 years (198). High incidences of scoliosis and hyperextensible joints were also noted. An interesting observation in that group of patients that had not been previously reported was a 72% incidence of failure or delayed shedding of the primary teeth, owing to lack of root resorption (198). Unexplained osteopenia is also present in most patients with the hyper IgE syndrome, many of whom have problems with recurrent fractures from even minor trauma (198,199).

Laboratory features include exceptionally high serum IgE; elevated serum IgD; usually normal concentrations of IgG, IgA, and IgM; pronounced blood and sputum eosinophilia; abnormally low anamnestic antibody responses to booster immunizations; and poor antibody-mediated and cell-mediated responses to neoantigens. *In vitro* studies have shown normal percentages of all lymphocytes. Most patients have normal lymphocyte-proliferative responses to mitogens but very low or absent responses to antigens or allogeneic cells from family members. Blood, sputum, and histologic sections of lymph nodes, spleen, and lung cysts show striking eosinophilia. Hassall's corpuscles and normal thymic architecture were observed at postmortem examination of one patient. Phagocytic cell ingestion, metabolism, killing, and total hemolytic complement activity have been normal in all patients. Variable defects of mononuclear or polymorphonuclear chemotaxis have been present in some but not all patients and hence are not the basic problem in these patients (197).

The fundamental problem in this condition was recently discovered and found to be due to mutations in the STAT 3 gene. I have observed a decreased percentage of T cells of the memory (CD45RO) phenotype in the blood of these patients, and such a decrease possibly is related to these patients' impaired anamnestic antibody responses, impaired antigen-specific T cell responses, and abnormal mixed leukocyte responses (201,202). Paradoxically, B cells from these patients do not produce as much IgE as normal or atopic B cells do when they are cultured with IL-4 and anti-CD40 *in vitro* (200). The latter indicates that the B cells may have already been exposed to IL-4 *in vivo* and were no longer sensitive to it because they had already isotype-switched *in vivo*. Because of the very short half-life of IL-4, serum levels cannot be detected; therefore it has been difficult to prove that the condition is caused by excessive IL-4 production. The presence of increased numbers of eosinophils in blood, sputum, and tissues

suggests that some of the pathology seen may be eosinophil mediated. The fact that both men and women have been affected, just as members of succeeding generations have, is consistent with an autosomal dominant form of inheritance with incomplete penetrance.

The most effective management for this condition is long-term therapy with a penicillinase-resistant penicillin or cephalosporin, with the addition of other antibiotics or antifungal agents as required for specific infections, and appropriate thoracic surgery for superinfected pneumatoceles or those persisting beyond 6 months. Interferon-γ therapy has been tried but had no clinical benefit, and neither did bone marrow transplantation. If the diagnosis is made early and antistaphylococcal antibiotic therapy is rendered in treatment doses continuously, the prognosis is good. Three patients are known to have died of lymphoreticular malignancy, and three experienced cryptococcal meningitis.

CONCLUSION

Since the discovery of X-linked agammaglobulinemia more than five decades ago, more than 200 genetically determined immunodeficiencies have been identified, and the list is rapidly growing. Recent research has led to major breakthroughs in the definition of the molecular bases of a large number of these disorders, and, undoubtedly, this will soon be the case for many others. This information will obviously be of great value in clarifying variant forms of these diseases, in carrier detection, in prenatal diagnosis, and, it is hoped, eventually in permitting gene therapy for many of these conditions.

In addition to the knowledge gained about the immune system from studying the clinical and immunologic features of these rare patients, even greater information about the functioning of the immune system should come from the integrated and comparative study of immune abnormalities in patients and those in gene-targeted mutant mice deficient. Moreover, these studies should lead to the design of more specific and effective therapies.

Although treatment of these rare defects has not advanced quite as rapidly as the discovery of new primary immunodeficiency diseases and the fundamental causes of a large number of them, major therapeutic advances have been made over the last three decades. These include (a) the development of safe intravenous forms of human immunoglobulin that make it possible to deliver high quantities of missing antibodies to antibody-deficient patients, (b) the development of T cell depletion techniques that permit the use of half-matched parents as donors of corrective stem cells for human infants with SCID, and (c) the recent success in achieving successful gene therapy in both X-linked and ADA-deficient SCID. The creation of human chimeras by nonablative allogeneic bone marrow stem cell transplantation has also made it possible to study early human T, B, and NK cell ontogeny, tolerance induction, and MHC restriction mechanisms (i.e., "thymic education") in a manner heretofore not possible. In the next few years, humans with genetically determined immunodeficiency diseases, as well as artificially created immunodeficient animals, will undoubtedly provide many more insights into the normal workings of the immune system.

FIGURE 2.4 Organization of the spleen white pulp. **Top panel:** Immunofluorescent staining of a white pulp unit in the mouse spleen. T cells (anti-CD4$^+$anti-CD8$^+$, red) are localized around the central arteriole. B cells (anti-IgM, green) are localized in follicles around the T cell area, surrounded by a layer of metalophillic macrophages (labeled with monoclonal antibody-MOMA-1) and a more peripheral layer of marginal zone macrophages (labeled with monoclonal antibody ERTR9, orange). The marginal zone (MZ) is located between the metalophillic macrophage and the MZ macrophage layers (not shown) (307). **Bottom panel:** Structure of the marginal sinus in a thick (100 micrometer) frozen section of mouse spleen with targeted insertion of the *LacZ* gene into the ephrin B2 locus. Eprhrin B2 is expressed at high levels in the central arteriole, in radial branches of the central arteriole, and in the marginal sinus. LacZ is visualized by staining with FITC-labeled anti-LacZ antibody. Note the transition from discrete arteriolar vessels to a network of flattened vessels at the transition to the marginal sinus plexus (C. Zindl, University of Alabama at Birmingham, Birmingham, AL). From Chaplin (308), with permission.

FIGURE 4.2 Ribbon diagram of a complete IgG1 crystal (1 hzh in PDB from data of Harris et al [190]). The major regions of the immunoglobulin are illustrated. The heavy-chain constant regions (green) also include the hinge (yellow) between the first two domains. CH2 is glycosylated (also seen in yellow). The heavy- and light-chain variable regions (red and dark blue, respectively) are N terminal to the heavy-(green) and light-chain (light blue) constant regions. CDR loops in the heavy- and light-chain variable regions (yellow and white) are illustrated as well.

FIGURE 4.6 The structure of an Fab. The antigen binding site is formed by the H and L chain B-C, C′-C″, and F-G loops. Each loop encodes a separate complementarity determining region, or CDR. The location of CDRs H1, H2, H3, L1 L2, and L3 are shown. The opposing H and L chain C-C′ strands and loop help stabilize the interaction between VH and VL. This C-C′ structure is encoded by the second V framework region, FR2. The inclusion of this structure permits the V domains to interact in a head-to-head fashion. The E-F strands and loop are encoded by the FR3 region and lie directly below the antigen binding site. The A-B strands and loop encode FR1 and lie between the C_H1 and CL domains and the rest of the Vs. The beta sheet strands of the C_H1 and CL domains rest crosswise to each other. The illustration is modified from (191).

FIGURE 4.12 A comparison of an x-ray and neutron-solution-scattering theoretical model (human IgA1) and x-ray crystal (murine IgG1 and IgG2a) structures. Light chains (yellow), heavy chains (red and dark blue), and glycosylation (light blue) are illustrated. The extended length of IgA1 over that of IgG can be seen along with extensive glycosylation that characterizes this isotype. (From Boehm et al. [192], with permission.)

FIGURE 10.6 Ribbon diagrams of the T cell receptor (TCR) structures. This shows the structures of the 2CαβTCR (150) versus the G8γδ TCR (153). The TCRβ and the TCRγ chains are in cyan, and the TCRα and γ chains are in vermillion. The CDRs of both are in yellow. The very long TCRδCDR3 in G8, which binds the T10/T22 ligands, is very apparent here but are shorter in most other γδ TCRs. Note the different C region interactions with these TCRs and the deviations from the classic "β barrel" structure in both Cα and Cδ. The prominent Cβ loop to the left is also unusual and may mediate interactions with CD3 or other molecules on the T cell surface. (Figure courtesy of Dr. K. C. Garcia.)

FIGURE 10.9 T cell receptor (TCR)-peptide/major histocompatibility complex (MHC) crystal structure of a TCR-peptide/MHC complex. Peptide and complementary-determining regions are portrayed in different colors (150).

FIGURE 10.10 CDR3 movement in αβ T cell receptor (TCR) binding. In most cases where there is a structure for an αβ TCR as well as for one (or more) for that TCR in complex with a peptide-MHC, there is a marked movement of one or the other of the Vα or Vβ CDR3s. This example from Mallissen et al. (209) shows a particularly large (14 Å) movement of CDR3β with binding. This meshes well with thermodynamic data showing an "induced fit" binding mechanism for most TCRs (173,211).

FIGURE 10.12 Crystal structure of a T cell receptor (TCR) β/superantigen (SAg) complex. Fields et al. (253) crystallized TCR-SAg complexes and from the structure of the same superantigens with a class II major histocompatibility complex (MHC) molecule and were able to deduce the relative spatial arrangement of the three molecules. This model suggests that TCR does not contact the MHC very strongly, which is consistent with the relative peptide insensitivity of SAg activation.

FIGURE 10.14 The T22 structure and the interaction with the G8 γδ TCR. **A:** The structure of a T22 molecule, a nonclassical class I MHC that is missing half of an alpha helix and does not bind peptides (270). **B, C:** The intersection with the G8 TCR, where the long TCR δ CDR3 accounts for almost all of the contact residues (153).

FIGURE 10.15 Conserved TCRδ CDR3 sequences correlate with T10/T22 specificity in $\gamma\delta$ T cells. Sequence data from Shin et al. (290) showing that both established cell lines (G8 and KNG) and $\gamma\delta$ T cells from clonal cultures that are specific for the T10/T22 share highly conserved TCRδ CDR3 sequences. These are largely derived from the Dδ2 gene segment and from the structural data (Adams et al., color plate 4, 153). These conserved sequences constitute the main interaction between these $\gamma\delta$ T cell receptors and their ligand.

FIGURE 12.1 Subsets of T cell precursors: normal development versus development without TCR gene rearrangement. The major subsets of cells discussed in this chapter are shown in a typical flow cytometric analysis. Top panels (**A** and **B**) show normal thymocytes, and bottom panels (**C** and **D**) show thymocytes from RAG-deficient mice, which cannot rearrange any TCR genes. Cells are stained with fluorescent antibodies against CD4 and CD8 (**A** and **C**), and the DN cells (boxed in **A**) are further analyzed with fluorescent antibodies against CD44 and CD25 (**B** and **D**). The axes show increasing levels of these surface molecules on a 4-decade logarithmic scale (10^4-fold range) of staining intensity. The main populations discussed in Figure 12.2 are indicated (DN, DP, CD4 SP, CD8 SP) (**A**), and the DN cells are subdivided into DN1, DN2, DN3, and DN4 (**B**). The recombinase-deficient thymocytes are developmentally arrested in the DN stages (**C;** cf. **A**), and these DN cells accumulate in the DN3 state and are blocked from progressing forward to the DN4 state (**D;** cf. **B**). RAG-deficient thymocytes also accumulate to only about 1/100 as many cells per thymus as wild-type ($\sim 4 \times 10^6$ versus $\sim 3 \times 10^8$).

FIGURE 16.4 Crystal structures of NK cell receptors in complex with their ligands. **A:** Mouse Ly49A bound to H2D^d at site 1 (PDB ID = 1QO3) (170). Site 2 interaction is not shown. **B:** Mouse Ly49C bound to H2K^b at site 2 (PDB ID = 1P1Z) (193). Ly49A interaction with site 1 of H2D^d is very similar (170). **C:** Human LILRB1 (LIR1, ILT2) bound to HLA-A2 (PDB ID = 1P7Q) (266). Figures were produced using the UCSF Chimera package from the Resource for Biocomputing, Visualization, and Informatics at the University of California, San Francisco (www.cgl.ucsf.edu/chimera) *(776)*. The structures are viewed from the side with the NK cell positioned at the top of the figure and the target cell surface at the bottom. The MHC molecules are oriented similarly.

FIGURE 16.5 Additional structures of NK cell receptors in complex with their ligands. **A:** Human KIR2DL2 with HLA-Cw3 (PDB ID = 1EFX) (236). Two KIR molecules are apparent in the crystal structure with only one molecule (KIR A) contacting the HLA molecule. In this view, the D2 domain of the KIR A obscures the D1 domain behind it. **B:** Human NKG2D with MICA (PDB ID = 1HYR) (412). The figures were produced and oriented as described in Figure 16.4.

FIGURE 17.5 Structural determinants of ligand recognition. Left: The rearranged TCR α chain of NKT cells exclusively use Jα18, shown as a thick tube in the structure of the human Vα24-Jα18/Vβ11 TCR. The CDR3α of the NKT TCRs are nearly identical in amino acid sequence between mouse and human and provide most of the contact points with CD1d complexed with an α-galactosylceramide ligand (99a). Right: $\gamma\delta$ T cells specific for the H-2T22 MHC class I molecule use a conserved amino acid motif (W.EGYEL) in their CDR3δ loop, shown as a thick tube in the structure of the G8 $\gamma\delta$ TCR in complex with H-2T22. These amino acids, which are encoded by the germline V region and D segments, contribute most of the contact points with H-2T22 (7). (Courtesy of Erin Adams, University of Chicago, Chicago, IL, USA.)

FIGURE 19.6 Structure of HLA-A*0201. **A:** Ribbon representation of HLA-A2 heavy chain (green), β2m light chain (cyan), and bound peptide (yellow). **B:** Ribbon representation of the peptide-binding groove. **C:** Surface representation of the binding groove, with pockets labeled. **D:** Surface representation of binding groove with peptide shown in stick illustration. Figure generated from protein data bank (*508*) structure 2BSV using PyMol (*509*).

FIGURE 19.7 Color ribbon representation of HLA-DR1. **A:** Side view; α chain is in green, β chain is in blue, peptide in stick representation is in yellow. **B:** Top view. **C:** Top view with bound peptide (PKYVKQNTLKLAT) visualized. The illustration was made with PyMol (*509*) based on the protein data bank (*508*) coordinates of 1DLH.
FIGURE 19.8 Superposition of the α-carbon backbones of an MHC-I [PDB (*508*)], 3HLA (*363*), and an MHC-II [1DLH (*383*)] molecule. The backbone tracings were displayed and superposed with QUANTA 97 (Molecular Simulations, Inc). MHC-I is shown in blue, MHC-II in red. Amino termini are labeled N.

FIGURE 19.9 Location of polymorphic amino acid residues in MHC-I and MHC-II molecules. Variability plots were calculated according to the method of Kabat and Wu (*382*) and the level of variability illustrated on ribbon diagrams. Generated in QUANTA 2000 (Accelrys) of 3HLA (*363*) (HLA-class I), 1DLH (*383*) (HLA-DR), and 1JK8 (*510*) (HLA-DQ), where greatest variability is red, intermediate is green, and least is blue.

FIGURE 19.10 Location of pockets in HLA-DR1 based on the cocrystal of HLA-DR1 with a peptide derived from the influenza hemagglutinin. The surface representation of the molecule, looking into the cleft, is shown colored based on electrostatics—red, acidic; blue, basic. Numbering of the major binding pockets of HLA-DR1 is according to (383).
FIGURE 19.11 Ribbon diagram of the structure of HLA-DR1 showing the dimer of dimers and the individual domains of the protein. α chains are in blue and I, β chains are in red and green. Peptide is in red. The illustration was generated from 1DLH (383) in MOLSCRIPT (*511*) and rendered in RASTER3D (*512*).
FIGURE 19.12 Comparison of the α-carbon backbone tracings and size of the potential peptide-bindng cleft of MHC-I molecule H2-K^b, MHC-II HLA-DR1, and MHC-Ib molecules CD1d, and FcRn. (From (*397*), with permission.)
FIGURE 19.13 Shape, size, and charge of the binding groove of CD1d compared with those of several other MHC molecules and with a lipid-transport protein. Surface representation of the ligand-bindng cleft is displayed with acidic regions in red, basic regions in blue, and hydrophobic regions in green. (From (*397*), with permission.)

FIGURE 19.14 Structural differences between the binding grooves of CD1b and CD1d. **A:** Orthogonal views for CD1b. **B:** Orthogonal views for CD1d. The hydrophobic groove and key side chains for CD1b and CD1d are in blue and green, respectively. Position of alkyl chains and detergent visualized in CD1b are colored with respect to the binding channels they occupy: A′ (red), C′ (yellow), F′ (pink), and T′ (violet). (From (*398*), with permission.)

FIGURE 19.15 Structure of the FcRn complexed with Fc. Ribbon diagram of the FcRn (purple), β2m (green) interacting with the Fc (magenta and brown) heterodimer consisting of the wild-type (wt) and nonbinding (nb) engineered chain. For comparison, the homodimer of the nbFc is shown on the right. These are PDB (*508*) files, 1I1A and 1I1C (*513*), respectively. (From (*513*), with permission.)

FIGURE 19.16 Structure of the MHC-Iv molecule, m144 (27), is shown. Heavy chain is in magenta, β2m light chain is in blue.

FIGURE 19.17 Structure of an MHC-I/peptide/TCR complex. H2-K^b bound to the peptide dEV8 (EQYKFYSV) in complex with the 2C TCR is shown. The TCR α and β chains (magenta and light blue) as well as H2-K^b (green) and peptide (yellow) are shown. Complementarity-determining regions (CDRs) of the TCR, colored in contrasting colors, and labeled 1, 2, and 3, are also indicated. (From (*429*), with permission.)
FIGURE 19.18 Footprint of CDRs. The structure of the H2-K^b/dEV8/2CTCR complex (2TCR) was displayed in PyMol (*509*). **(A)** shows the full complex, **(B)** a close-up of the TCR/MHC/peptide interface, and **(C)** shows the surface of the MHC (magenta)/peptide (yellow) complex with the CDR loops of the TCR Vα (green) and Vβ (blue) shown and labeled.
FIGURE 19.19 CDR3 plasticity. Backbone tracings of the KB5-C20 TCR CDR loops free or bound to the MHC/peptide complex are superposed. The unliganded forms are in lighter colors. (From (*430*), with permission.)
FIGURE 19.20 MHC-I–binding site for CD8$\alpha\alpha$ homodimer lies beneath the peptide-binding groove. HLA-A2 heavy chain, red, β2m, orange, and peptide (ball-and-stick) are shown in complex with the CD8$\alpha\alpha$ homodimer (red and blue). MOLSCRIPT (*511*) illustration based on the PDB (*508*) file 1AKJ (*82*).
FIGURE 19.21 Model of TCR/MHC-II/peptide complex interacting with CD4. Superposition of MHC-II/CD4 D1D2 structure with that of a complete D1-D4 CD4 structure results in this model suggesting how MHC-II may contribute to multimerization of a TCR/CD4 complex. (From (78), with permission.)
FIGURE 19.22 Interactions of KIR2D molecules with their HLA-Cw ligands. KIR2DL2 **(A, C)** and KIR2DL1 **(B, D)** are shown (magenta) in complex with their respective HLA-Cw3 and HLA-Cw4 ligands. (From (13), with permission.)
FIGURE 19.23 H2-D^d interactions with the C-type lectinlike receptor, Ly49A. The crystallographic determination of two distinct sites of H2-D^d interacting with the Ly49A homodimer is shown. Extensive mutagenesis and binding studies suggest that the functional site of interaction is site 2. (From (13), with permission.)

FIGURE 34.3 Killing in action. This cytotoxic cell appears to contact two targets (red); however, the granules (green) are polarized to the left-hand target. The cell exhibits the characteristic blebbing of apoptosis. The other target seems unaffected. Figure provided by Dr. I.S. Goping, University of Alberta.

FIGURE 31.5 Segregated cell distribution in the PPs. CD4$^+$ T cells (green) are mainly present in the intrafollicular regions (IFRs) and B cells (red) are located in the subepithelial dome (SED) and follicle (FO) regions. DCs (blue) are distributed in the SED and IFRs. GCs are enriched in B cells with small numbers of T cells and DCs for the creation of a cellular environment for the efficient generation of IgA-committed B cells.
