Sources: *Dietary Reference Intakes for Calcium, Phosphorus, Magnesium, Vitamin D, and Fluoride* (1997); *Dietary Reference Intakes for Thiamin, Riboflavin, Niacin, Vitamin B₆, Folate, Vitamin B₁₂, Pantothenic Acid, Biotin, and Choline* (1998); *Dietary Reference Intakes for Vitamin C, Vitamin E, Selenium, and Carotenoids* (2000); *Dietary Reference Intakes for Vitamin A, Vitamin K, Arsenic, Boron, Chromium, Copper, Iodine, Iron, Manganese, Molybdenum, Nickel, Silicon, Vanadium, and Zinc* (2001); *Dietary Reference Intakes for Water, Potassium, Sodium, Chloride, and Sulfate* (2005); and *Dietary Reference Intakes for Calcium and Vitamin D* (2011). These reports may be accessed via www.nap.edu.

***Note:** This table (taken from the DRI reports, see www.nap.edu) presents Recommended Dietary Allowances (RDAs) in **boldface type** and Adequate Intakes (AIs) in **lightface type** followed by an asterisk (*). An RDA is the average daily dietary intake level; sufficient to meet the nutrient requirements of nearly all (97-98%) healthy individuals in a group. It is calculated from an Estimated Average Requirement (EAR). If sufficient scientific evidence is not available to establish an EAR, and thus calculate an RDA, an AI is usually developed. For healthy breastfed infants, an AI is the mean intake. The AI for other life stage and gender groups is believed to cover the needs of all healthy individuals in the groups, but lack of data or uncertainty in the data prevent being able to specify with confidence of the percentage of individuals covered by this intake.

^aAs retinol activity equivalents (RAEs). 1 RAE = 1 mcg of retinol, 12 mcg of β-carotene, 24 mcg of α-carotene, or 24 mcg of β-cryptoxanthin. The RAE for dietary provitamin A carotenoids is twofold greater than retinol equivalents (REs), whereas the RAE for preformed vitamin A is the same as the RE for vitamin A.

^bAs cholecalciferol. 1 mcg of cholecalciferol = 40 IU of vitamin D.

^cUnder the assumption of minimal sunlight.

^dAs α-tocopherol. α-Tocopherol includes RRR-α-tocopherol, the only form of α-tocopherol that occurs naturally in foods, and the 2*R*-stereoisomeric forms of α-tocopherol (RRR-, RSR-, RRS-, and RSS-α-tocopherol) that occur in fortified foods and supplements. It does not include the 2*S*-stereoisomeric forms of α-tocopherol (SSR-, SSR-, SRS-, and SSS-α-tocopherol), also found in fortified foods and supplements.

^eAs niacin equivalents (NEs). 1 mg of niacin = 60 mg of tryptophan; 0-6 months = preformed niacin (not NE).

^fAs dietary folate equivalents (DFEs). 1 DFE = 1 mcg of food folate = 0.6 mcg of folic acid from fortified food or as a supplement consumed with food = 0.5 mcg of a supplement taken on an empty stomach.

^gAlthough AIs have been established for choline, there are few data to assess whether a dietary supply of choline is needed at all stages of the life cycle, and it may be that the choline requirement can be met by endogenous synthesis at some of these stages.

^hBecause 10% to 30% of older people may malabsorb food-bound B₁₂, it is advisable for those older than 50 years to meet their RDA mainly by consuming foods fortified with B₁₂ or a supplement containing B₁₂.

ⁱIn view of evidence linking folate intake with neural tube defects in the fetus, it is recommended that all women capable of becoming pregnant consume 400 mcg from supplements or fortified foods in addition to intake of food folate from a varied diet.

^jIt is assumed that women will continue consuming 400 mcg from supplements or fortified food until their pregnancy is confirmed and they enter prenatal care, which ordinarily occurs after the end of the periconceptual period—the critical time for formation of the neural tube.

Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

*This 14th edition is dedicated to the students, professors and practitioners
who use this text and consider it their “nutrition bible.”
We are most grateful to them for their learning, writing, and insights
and dedication to the field of nutrition and dietetic practice.*

—The Authors, 14th Edition

and

*To Robert who is always there for me with love and a humorous perspective,
to Carly and Justin for their loving energy, to Ana who has known the "book"
her whole life, and to Ailey and Kiera, my grandchildren who bring such joy.*

—Kathleen

*To my parents who are both now deceased. My father, George Raymond, DDS,
sparked my interest in nutrition through his interest in it. And my mother
Betty Raymond, a woman who could whip up delicious foods in minutes and
who was making her own yogurt and sprouting beans when I was a teenager.
Thank you for the inspiration.*

—Janice

FOREWORD

“We’re not just a textbook; we’re your connection to the leaders in nutrition.” This statement has been true since the first edition of *Krause’s Food and the Nutrition Care Process* was published in 1952. The reason this nutrition and diet therapy textbook became and has remained the go-to book for teaching about food and the nutrition care process is the editors have been in the forefront of dietetics practice. In addition, the editors have selected authors who not only have expertise on the topic of their chapter, but also are engaged in cutting-edge practice in the specific area that is being addressed.

With each edition, one thinks it cannot get better, but it does. The well-known and highly respected editors of this 14th edition, Kathleen Mahan and Janice Raymond, as well as the authors, read like a who’s who of dietetics practice. Both editors have been and are authors of chapters in this and prior editions, Kathleen for more than 35 years. Early on one author could cover one or more topics. With the ever-increasing explosion of information, it often takes two or three authors to cover a topic. The editors have done an excellent job selecting authors who are clinical specialists with the specific expertise to address each of the topics – writers, researchers, and practitioners who have provided in-depth coverage with many practical and evidence-based recommendations. The authors, at the request of the editors, have taken an integrative approach to nutrition care.

The comprehensiveness of the book continues in this edition with a new chapter on “Inflammation and the Physiology of Chronic Disease,” which underlies so much of the therapy, including nutrition, of chronic disease. This edition also includes the 2015 Dietary Guidelines for Americans, more visuals, and highlighted *Focus On* boxes, *Clinical Insights*, and *Clinical Case Studies* that help translate scientific knowledge into practical patient care.

The editors and authors are also leaders in the dietetics profession. They are often selected to make presentations at national meetings. It is exciting for students and young professionals, who have been exposed to the latest information in the Krause textbook, to attend national meetings and hear presentations by the authors who provide even newer and more exciting information on their topic for which they have extensive expertise. It is even more exciting to be able to meet and talk with them.

This remarkable food and nutrition textbook has been in existence throughout my almost 50 years in the dietetics profession. I fully expect it to be a leading textbook for the next 50 years!

Sonja L. Connor, MS, RD, LD, FAND
Research Associate Professor
Oregon Health & Science University
Portland, Oregon

President, Academy of Nutrition and Dietetics 2014–2015

Over its 14 editions this classic text has continued to change in response to the ever-dynamic field of nutrition. And because it remains the most comprehensive nutrition text book available it is the reference students take into their internships and careers.

AUDIENCE

Scientific knowledge and clinical information is presented in a form that is useful to students in dietetics, nursing, and other allied health professions in an interdisciplinary setting. It is valuable as a reference for other disciplines such as medicine, dentistry, child development, physical and occupational therapy, health education, and lifestyle counseling. Nutrient and assessment appendices, tables, illustrations, and clinical insight boxes provide practical hands-on procedures and clinical tools for students and practitioners alike.

This textbook accompanies the graduating student into clinical practice as a treasured shelf reference. The popular features remain: having basic information on nutrition in the life cycle all the way through to protocols for clinical nutrition practice in one place, clinical management algorithms, focus boxes that give “nice-to-know” detailed insight, sample nutrition diagnoses for clinical scenarios, useful websites, and extensive appendices for patient education. All material reflects current evidence-based practice as contributed by authors, experts in their fields. This text is the first choice in the field of dietetics for students, interns, educators, and clinicians.

ORGANIZATION

This edition follows the Conceptual Framework for Steps of the Nutrition Care Process (see inside of back cover). All nutritional care process components are addressed to enhance or improve the nutritional well-being of individuals, their families, or populations. The chapters flow according to the steps of assessment, nutrition diagnosis, intervention, monitoring, and evaluation with the separation of the pediatric medical nutrition therapy (MNT) chapters into their own section to assist with that specialty practice.

Part 1, Nutrition Assessment, organizes content for an effective assessment. Chapters here provide an overview of the digestive system, as well as calculation of energy requirements and expenditure, macronutrient and micronutrient needs, nutritional genomics, and food intake. A thorough review of biochemical tests, acid-base balance issues, and medications promote the necessary insight for provision of excellent care. A new approach for this edition is a chapter titled “Inflammation and the Pathophysiology of Chronic Disease,” which addresses the latest knowledge about inflammation as a cause of chronic disease and the necessity of assessing for it. The final chapter in this section addresses the behavioral aspects of an individual’s food choices within the community, a safe food supply, and available resources for sufficient food access.

Part 2, Nutrition Diagnosis and Intervention, describes the critical thinking process from assessment to selection of relevant, timely, and measurable nutrition diagnoses. These nutrition

diagnoses can be resolved by the dietitian nutritionist (RDN) or trained health professional. The process is generally used for individuals but can be applied when helping families, teaching groups, or evaluating the nutritional needs of a community or a population. A nutrition diagnosis requires an intervention, and interventions relate to food and nutrient delivery (including nutrition support), use of bioactive substances and integrative medical nutrition, education, counseling, and referral when needed.

Part 3, Nutrition in the Life Cycle, presents in-depth information on the nutrition for life stages from conception and nutrition in the womb and pregnancy and through lactation and infancy. There is a chapter on nutrition in adolescence and another that deals with the nutrition issues and chronic disease that usually start appearing in adulthood. Finally, nutrition and the aging adult is discussed in detail because much of the employment of nutrition professionals in the future is going to be in providing nutrition services to this rapidly expanding percentage of the population.

Part 4, Nutrition for Health and Fitness, provides nutrition concepts for the achievement and maintenance of health and fitness, as well as the prevention of many disease states. Weight management, problems with eating disorders, dental health, bone health, and sports nutrition focus on the role of nutrition in promoting long-term health.

Part 5, Medical Nutrition Therapy, reflects evidence-based knowledge and current trends in nutrition therapies. All of the chapters are written and reviewed by experts in their fields who present nutritional aspects of conditions such as cardiovascular disorders; diabetes; liver disease; renal disease; pulmonary disease; HIV; endocrine disorders, especially thyroid disease; and rheumatologic, neurologic, and psychiatric disorders.

Part 6, Pediatric Specialties, describes the role of nutrition therapies in childhood. Chapters provide details for low-birth-weight, neonatal intensive-care conditions, genetic metabolic disorders, and developmental disabilities.

NEW TO THIS EDITION

- Provides the most current content throughout, including the 2015 Dietary Guidelines for Americans, due to be finalized in 2016.
- Includes a new chapter titled “Inflammation and the Pathophysiology of Chronic Disease.”
- Worksheets on calculating parenteral and enteral nutrition needs are included in Chapter 12: “Food and Nutrient Delivery: Nutrition Support Methods.”
- Standards of Care recommendations have been incorporated throughout the book as appropriate.
- The latest recommendations from the National Institutes of Health are discussed in Chapter 33: “Medical Nutrition Therapy for Cardiovascular Disease.”
- Now includes detailed Clinical Case Studies and Clinical Applications boxes designed to help translate academic knowledge into practical patient care.
- New Appendix on The Anti-inflammatory Diet.
- Many new content highlight boxes such as “Nutrition and the Affordable Care Act” and “Human Milk Banking and Vending Machine Labeling Law.”

PEDAGOGY

- **UNIQUE!** Pathophysiology algorithms present the cause, pathophysiology, and the medical nutrition management for a variety of disorders and conditions. They equip the reader with an understanding of the illness as background for providing optimal nutritional care.
- *Clinical Insight* boxes expand on clinical information in the text and highlight areas that may go unnoticed. These boxes contain information on studies and clinical resources for the student and practitioner.
- *New Directions* boxes suggest areas for further research by spotlighting emerging areas of interest within the field
- *Focus On* boxes provide thought-provoking information on key concepts for well-rounded study and the promotion of further discussion within the classroom.
- Useful Websites direct the reader to online resources that relate to the chapter topics.
- Sample Nutrition Diagnosis boxes present a problem, its etiology, and its signs and symptoms, before concluding with a sample nutrition diagnosis, providing both students and practitioners with “real-life” scenarios they may encounter in practice.
- Key Terms are defined at the beginning of each chapter and bolded within the text where they are discussed in more detail.
- Chapter References: References are current and extensive, with the purpose of giving the student and instructor lots of opportunity for further reading and understanding.

ANCILLARIES

Accompanying this edition is the Evolve website, which includes updated and invaluable resources for instructors and students. These materials can be accessed by going to <http://evolve.elsevier.com/Mahan/nutrition/>.

INSTRUCTOR RESOURCES

- PowerPoint presentations: More than 900 slides to help guide classroom lectures.
- Image Collection: Approximately 200 images from the text are included in the PowerPoint presentations, as well as more illustrations that can be downloaded and used to develop other teaching resources.
- Audience Response System Questions (for use with iClicker and other systems): Three to five questions per chapter help aid incorporation of this new technology into the classroom.
- Test Bank: Each chapter includes NCLEX-formatted questions with page references specific to that chapter’s content to bring you more than 900 multiple-choice questions.
- Animations: Animations have been developed to visually complement the text and the processes described.
- Nutrition Care Process Tools: Consisting of assessment and monitoring tools and intervention tools, this information can be used by the new student and practitioner in teaching and guiding the client in his or her specific nutritional care.

STUDENT RESOURCES

- Study Exercises with Answers: With more than 600 questions, these exercises give instant feedback on questions related to the chapter’s content.

We strive to create a text that is current, relevant and interesting to read.

L. Kathleen Mahan, MS, RDN, CD
Janice L. Raymond, MS, RDN, CD, CSG

ACKNOWLEDGMENTS

We sincerely thank the reviewers and especially contributors for this edition who have devoted hours and hours of time and commitment to researching the book's content for accuracy, reliability, and practicality. We are greatly in debt to them and realize that we could not continue to produce this book without them. Thank you!

We also wish to acknowledge the hard work of Kristin Geen, Director of Traditional Education, who keeps the vision, and Danielle Frazier, Senior Developmental Editor, who can get the "hot off the press" items we'd like included, and Alex Kluesner, Project Manager at Graphic World, who amazingly keeps the manuscript moving forward as he juggles between us and all others. Thank you!

Nutrition Assessment

Food provides energy and building materials for countless substances that are essential for the growth and survival of every human being. This section opens with a brief overview of the digestion, absorption, transportation, and excretion of nutrients. These remarkable processes convert myriads of complex foodstuffs into individual nutrients ready to be used in metabolism. Macronutrients (proteins, fats, and carbohydrates) each contribute to the total energy pool, but ultimately the energy they yield is available for the work of the muscles and organs of the body. The way nutrients become integral parts of the body and contribute to proper functioning depends heavily on the physiologic and biochemical processes that govern their actions. It is now known that these metabolic processes are altered in the presence of acute and chronic inflammation. Understanding the biomarkers and other indicators of inflammation are a critical component of nutrition assessment.

For the health provider, nutrition assessment is the first step in the nutrition care process. To implement a successful nutrition plan, the assessment must include key elements of the patient's clinical or medical history, current situation, anthropometric measurements, biochemical and laboratory values, information on medication and herbal supplement use for potential food-drug interactions, plus a thorough food and nutrition intake history. Genetic research is rapidly clarifying how genes and nutrition are interrelated. Nutrigenomics is the study of the effects of foods and nutrients on gene expression and thus nutritional requirements. Thus, the chapters in Part 1 provide an organized way to develop the skills needed to make an assessment in the nutrition care process.

Intake: Digestion, Absorption, Transport, and Excretion of Nutrients

One of the primary considerations for a complete nutrition assessment is to consider the three-step model of “ingestion, digestion, and utilization.” In this model, consideration is given to each step to identify all areas of inadequacy or excess. If there is any reason why a step is altered from physical, biochemical, or behavioral-environmental causes, the astute nutrition provider must select an appropriate nutrition diagnosis for which intervention is required. Intake and assimilation of nutrients should lead to a desirable level of nutritional health.

THE GASTROINTESTINAL TRACT

Assessment of the function of the gastrointestinal tract (GIT) is essential to the nutrition care process. For the nutrition care process, several nutrition diagnoses can be identified when assessing GIT function. Common or possible nutrition diagnoses related to digestion or metabolism include:

- Altered gastrointestinal function
- Imbalance of nutrient intake
- Altered nutrient utilization
- Altered nutrition biomarkers
- Inadequate or excessive fluid intake
- Food-drug interaction

The GIT is designed to (1) digest the macronutrients protein, carbohydrates, and lipids from ingested foods and beverages; (2) absorb fluids, micronutrients, and trace elements; (3) provide a physical and immunologic barrier to pathogens,

foreign material, and potential antigens consumed with food or formed during the passage of food through the GIT; and (4) provide regulatory and biochemical signaling to the nervous system, often involving the intestinal microbiota, via a pathway known as the **gut-brain axis**.

The human GIT is well suited for digesting and absorbing nutrients from a tremendous variety of foods, including meats, dairy products, fruits, vegetables, grains, complex starches, sugars, fats, and oils. Depending on the nature of the diet consumed, 90% to 97% of food is digested and absorbed; most of the unabsorbed material is of plant origin. Compared with ruminants and animals with a very large cecum, humans are considerably less efficient at extracting energy from grasses, stems, seeds, and other coarse fibrous materials. Humans lack the enzymes to hydrolyze the chemical bonds that link the molecules of sugars that make up plant fibers. However, fibrous foods and any undigested carbohydrates are fermented to varying degrees by bacteria in the human colon; this process can contribute 5% to 10% of the energy needed by humans.

The GIT is one of the largest organs in the body, has the greatest surface area, has the largest number of immune cells, and is one of the most metabolically active tissues in the body (Figure 1-1). The unique structure of the GIT enables ample processing capacity in healthy humans. The human GIT is about 9 m long, extending from the mouth to the anus and including the oropharyngeal structures, esophagus, stomach, liver and gallbladder, pancreas, and small and large intestine. The lining of this hollow tube, called the mucosa, is configured in a pattern of folds, pits, and fingerlike projections called **villi**. The villi are lined with epithelial cells and even smaller, cylindrical

Sections of the chapter were written by Peter L. Beyer, MS, RD, for previous editions of this text.

FIGURE 1-1 The digestive system.

extensions called **microvilli**. The result is a tremendous increase in surface area compared with that expected from a smooth, hollow cylinder. The cells lining the intestinal tract have a life span of approximately 3 to 5 days, and then they are sloughed into the lumen and “recycled,” adding to the pool of available nutrients. The cells are fully functional only for the last 2 to 3 days as they migrate from the crypts to the distal third of the villi.

The health of the body depends on a healthy, functional GIT. Because of the unusually high turnover rate and metabolic requirements of the GIT, the cells lining it are more susceptible than most tissues to micronutrient deficiencies, protein-energy malnutrition, and damage resulting from toxins, drugs, irradiation, food allergy reactions, or interruption of its blood supply. Approximately 45% of the energy requirement of the small intestine and 70% of the energy requirement of cells lining the colon are supplied by nutrients passing through its lumen. After only a few days of starvation or intravenous feeding (parenteral nutrition), the GIT atrophies (i.e., the surface area decreases and secretions, synthetic functions, blood flow, and absorptive capacity are all reduced). Resumption of food intake, even with less-than-adequate calories, results in cellular proliferation and return of normal GI function after only a few days. Optimum function of the human GIT seems to depend on a constant supply of foods rather than on consumption of large amounts of foods interrupted by prolonged fasts. This knowledge justifies the clinical practice of feeding an individual orally and/or

enterally (via tube), as opposed to intravenously (or parenterally) when adequate GIT function is present (see Chapter 13).

BRIEF OVERVIEW OF DIGESTIVE AND ABSORPTIVE PROCESSES

The sight, smell, taste, and even thought of food starts the secretions and movements of the GIT. In the mouth, chewing reduces the size of food particles, which are mixed with salivary secretions that prepare them for swallowing. A small amount of starch is degraded by **salivary amylase**, but digestion in the mouth is minimal. The esophagus transports food and liquid from the oral cavity and pharynx to the stomach. In the stomach, food is mixed with acidic fluid and proteolytic and lipolytic enzymes. Small amounts of lipid digestion take place, and some proteins are changed in structure or partially digested to large peptides. When food reaches the appropriate consistency and concentration, it is now called **chyme** and passes from the stomach into the small intestine, where most digestion takes place.

In the first 100 cm of small intestine, a flurry of activity occurs, resulting in the digestion and absorption of most ingested food (Figure 1-2). Here the presence of food stimulates the release of hormones which stimulate the production and release of powerful enzymes from the pancreas as well as bile from the gallbladder. Starches and proteins are reduced to smaller-molecular-weight carbohydrates and small to medium-size peptides. Dietary fats are reduced from visible globules of fat to microscopic droplets of

FIGURE 1-2 Sites of secretion, digestion, and absorption.

triglycerides, then to free fatty acids and monoglycerides. Enzymes from the brush border of the small intestine further reduce the remaining carbohydrates to monosaccharides and the remaining peptides to single amino acids, dipeptides, and tripeptides. Large volumes of fluid are used to digest and absorb nutrients. Together with salivary and gastric secretions, secretions from the pancreas, small intestine, and gallbladder secrete 7 L of fluid into the GIT lumen each day—far more than the 2 L ingested through dietary intake each day. All but 100 mL of the total fluid entering the lumen is reabsorbed: about 7 L in the small intestine and about 2 L in the large intestine.

Along the remaining length of the small intestine, almost all the macronutrients, minerals, vitamins, trace elements, and

fluid are absorbed before reaching the colon. The colon and rectum absorb most of the remaining fluid delivered from the small intestine. The colon absorbs electrolytes and only a small amount of remaining nutrients. The movement of ingested and secreted material in the GIT is regulated primarily by hormones, nerves, and enteric muscles.

Most nutrients absorbed from the GIT enter the portal vein for transport to the liver where they may be stored, transformed into other substances, or released into circulation. End products of most dietary fats are transported into the bloodstream via the lymphatic circulation.

Nutrients reaching the distal small intestine and large intestine, most notably dietary fiber and resistant starches, are fermented by the microbiota located within the lumen of the ileum and large intestine. Fermentation produces short-chain fatty acids (SCFAs) and gas. SCFAs provide a preferred fuel source for cells of the intestine, stimulate intestinal cell renewal and function, enhance immune function, and regulate gene expression. In addition, some carbohydrates have “prebiotic” functions that induce the growth and activity of beneficial microbes within the intestinal microbiota. The large intestine also provides temporary storage for waste products. The distal colon, rectum, and anus control defecation.

Enzymes in Digestion

Digestion of food is accomplished by enzymatic hydrolysis. Cofactors such as hydrochloric acid, bile, and sodium bicarbonate facilitate the digestive and absorptive processes. Digestive enzymes synthesized in specialized cells of the mouth, stomach, and pancreas are released into the GIT lumen, whereas digestive enzymes synthesized in enterocytes of the small intestine remain embedded within the brush border membrane. Except for fiber and resistant carbohydrates, digestion and absorption of intake is completed essentially in the small intestine. [Table 1-1](#) summarizes digestive enzymes and their functions within the GIT.

Regulators of Gastrointestinal Activity: Neural and Hormonal Mechanisms

GIT movement, including contraction, mixing, and propulsion of luminal contents, is the result of the coordinated movement of smooth muscle and the activity of the enteric nervous system, enteroendocrine hormones, and smooth muscle. The enteric nervous system is integrated throughout the lining of the GIT. Mucosal receptors sense the composition of chyme and distention of the lumen (i.e., fullness) and send impulses that coordinate the processes of digestion, secretion, absorption, and immunity.

Neurotransmitters and neuropeptides with small molecular weights signal nerves to contract or relax muscles, increase or decrease fluid secretions, or change blood flow. The GIT then largely regulates its own motility and secretory activity. However, signals from the central nervous system can override the enteric system and affect GIT function. Hormones, neuropeptides, and neurotransmitters in the GIT not only affect intestinal function but also have an effect on other nerves and tissues in many parts of the body. Some examples of neurotransmitters released from enteric nerve endings are listed in [Table 1-2](#). In people with gastrointestinal disease (e.g., infections, inflammatory bowel disease, irritable bowel syndrome), the enteric nervous system may be overstimulated, resulting in abnormal secretion, altered blood flow, increased permeability, and altered immune function.

TABLE 1-1 Summary of Enzymatic Digestion and Absorption

Secretion and Source	Enzymes	Substrate	Action and Resulting Products	Final Products Absorbed	
Saliva from salivary glands in mouth	α -amylase	Starch (α -linked polysaccharides)	Hydrolysis to form dextrins and maltose	—	
	Lingual lipase	Triglyceride	Hydrolysis to form diglyceride and free fatty acids	—	
Gastric secretion from gastric glands in stomach mucosa	Pepsin (activated from pepsinogen in the presence of hydrochloric acid)	Protein	Hydrolysis of peptide bonds to form peptides and amino acids	—	
	Gastric lipase	Triglyceride	Hydrolysis to form diglyceride and free fatty acids	—	
Exocrine secretions from pancreatic acinar cells, acting in duodenum	Lipase	Fat (in the presence of bile salts)	Hydrolysis to form monoglycerides and fatty acids; incorporated into micelles	Fatty acids into mucosal cells; reesterified as triglycerides	
	Cholesterol esterase	Sterols (such as cholesterol)	Hydrolysis to form esters of cholesterol and fatty acids; incorporated into micelles	Cholesterol into mucosal cells; transferred to chylomicrons	
	α -Amylase	Starch and dextrins	Hydrolysis to form dextrins and maltose	—	
	Trypsin (activated trypsinogen)	Proteins and polypeptides	Hydrolysis of interior peptide bonds to form polypeptides	—	
	Chymotrypsin (activated chymotrypsinogen)	Proteins and peptides	Hydrolysis of interior peptide bonds to form polypeptides	—	
	Carboxypeptidase (activated pro-carboxypeptidase)	Polypeptides	Hydrolysis of terminal peptide bonds (carboxyl end) to form amino acids	Amino acids	
	Ribonuclease and deoxyribonuclease	Ribonucleic acids (RNA) and deoxyribonucleic acids (DNA)	Hydrolysis to form mononucleotides	Mononucleotides	
	Elastase	Fibrous protein (elastin)	Hydrolysis to form peptides and amino acids	—	
	Small intestine enzymes (embedded in the brush border membrane)	Enterokinase	Trypsinogen	Activates trypsin	Dipeptides and tripeptides
		Aminopeptidase and dipeptidase (also located within the enterocyte cytosol)	Polypeptides	Cleavage of amino acids from the amino terminus of protein (N-terminus) or peptide substrates	Amino acids
Sucrase		Sucrose	Hydrolysis to form glucose and fructose	Glucose and fructose	
α -Dextrinase (isomaltase)		Dextrin (isomaltose)	Hydrolysis to form glucose	Glucose	
Maltase		Maltose	Hydrolysis to form glucose	Glucose	
Lactase		Lactose	Hydrolysis to form glucose and galactose	Glucose and galactose	
Nucleotidases		Nucleic acids	Hydrolysis to form nucleotides and phosphates	Nucleotides	
Nucleosidase and phosphorylase		Nucleosides	Hydrolysis to form purines, pyrimidines, and pentose phosphate	Purine and pyrimidine bases	

Autonomic innervation is supplied by the sympathetic fibers that run along blood vessels and by the parasympathetic fibers in the vagal and pelvic nerves. In general, sympathetic neurons, which are activated by fear, anger, and stress, tend to slow transit of intestinal contents by inhibiting neurons affecting muscle contraction and inhibiting secretions. The parasympathetic nerves innervate specific areas of the alimentary tract and contribute to certain functions. For example, the sight or smell of food stimulates vagal activity and subsequent secretion of acid from **parietal cells** within the stomach. The enteric nervous system also sends signals to the central nervous system that are perceived as pain, nausea, urgency or gastric fullness, or gastric emptiness by way of

the vagal and spinal nerves. Inflammation, dysmotility, and various types of intestinal damage may intensify these perceptions.

Gastrointestinal Hormones

Regulation of the GIT involves numerous hormones that are secreted by enteroendocrine cells located within the epithelium lining of the GIT. These regulators can regulate function of the cell from which they were secreted (autocrine), on neighboring cells (paracrine), or distant cells by traveling through the blood to their target organs (endocrine). More than 100 peptide hormones and hormone-like growth factors have been identified. Their actions are often complex and extend well beyond the

TABLE 1-2 Examples of Neurotransmitters and their Actions

Neurotransmitter	Site of Release	Primary Action
GABA	Central nervous system	Relaxes lower esophageal sphincter
Norepinephrine	Central nervous system, spinal cord, sympathetic nerves	Decreases motility, increases contraction of sphincters, inhibits secretions
Acetylcholine	Central nervous system, autonomic system, other tissues	Increases motility, relaxes sphincters, stimulates secretion
Neurotensin	GI tract, central nervous system	Inhibits release of gastric emptying and acid secretion
Serotonin (5-HT)	GI tract, spinal cord	Facilitates secretion and peristalsis
Nitric oxide	Central nervous system, GI tract	Regulates blood flow, maintains muscle tone, maintains gastric motor activity
Substance P	Gut, central nervous system, skin	Increases sensory awareness (mainly pain), and peristalsis

5-HT, 5-hydroxytryptamine; GABA, α -aminobutyric acid; GI, gastrointestinal.

GIT. Some of the hormones (e.g., of the **cholecystokinin [CCK]** and somatostatin family) also serve as neurotransmitters between neurons.

The GIT secretes more than 30 hormone families, making it the largest hormone-producing organ in the body (Rehfeld, 2014). Gastrointestinal hormones are involved in initiating and terminating feeding, signaling hunger and satiety, pacing movements of the GIT, governing gastric emptying, regulating blood flow and permeability, priming immune functions, and stimulating the growth of cells (within and beyond the GIT). **Ghrelin**, a neuropeptide secreted from the stomach, and **motilin**, a related hormone secreted from the duodenum, send a “hungry” message to the brain. Once food has been ingested, hormones PYY 3-36, CCK, glucagon-like peptide-1 (GLP-1), oxyntomodulin, pancreatic polypeptide, and gastrin-releasing polypeptide (bombesin) send signals to decrease hunger and increase satiety (Rui, 2013). Some of the GI hormones, including some of those that affect satiety, also tend to slow gastric emptying and decrease secretions (e.g., somatostatin). Other GI hormones (e.g., motilin) increase motility.

The signaling agents of the GIT also are involved in several metabolic functions. Glucose-dependent insulinotropic polypeptide (GIP) and GLP-1 are called incretin hormones because they help lower blood sugar by facilitating insulin secretion, decreasing gastric emptying, and increasing satiety. Several of these hormones and analogs are used in management of obesity, inflammatory bowel disease, diarrhea, diabetes, GI malignancies, and other conditions. This area of research is critically important.

Some functions of the hormones that affect gastrointestinal cell growth, deoxyribonucleic acid (DNA) synthesis, inflammation, proliferation, secretion, movement, or metabolism have not been fully identified. Knowledge of major hormone functions becomes especially important when the sites of their secretion or action are diseased or removed in surgical procedures, or when hormones and their analogs are used to suppress or enhance some aspect of gastrointestinal function. **Glucagon-like peptide-2 (GLP-2)** is an example of a hormone secreted from the distal GIT that increases intestinal surface area and enhances nutrient processing capacity. An analog of GLP-2, named teduglutide, recently has become available for treatment of patients with short bowel syndrome who are dependent on parenteral nutrition to meet their nutrient and fluid requirements (Seidner et al, 2013; see the Clinical Insight box in Chapter 28). The key GIT hormones are summarized in Table 1-3.

Gastrin, a hormone that stimulates gastric secretions and motility, is secreted primarily from endocrine “G” cells in the

antral mucosa of the stomach. Secretion is initiated by (1) impulses from the vagus nerve, such as those triggered by the smell or sight of food; (2) distention of the antrum after a meal; and (3) the presence of secretagogues in the antrum, such as partially digested proteins, fermented alcoholic beverages, caffeine, or food extracts (e.g., bouillon). When the lumen gets more acidic, feedback involving other hormones inhibits gastrin release (Chu and Schubert, 2013). Gastrin binds to receptors on parietal cells and histamine-releasing cells to stimulate gastric acid, to receptors on chief cells to release pepsinogen, and to receptors on smooth muscle to increase gastric motility.

Secretin, the first hormone to be named, is released from “S” cells in the wall of the proximal small intestine into the bloodstream. It is secreted in response to gastric acid and digestive end products in the duodenum, wherein it stimulates the secretion of pancreatic juice and inhibits gastric acid secretion and emptying (the opposite of gastrin). Neutralized acidity protects the duodenal mucosa from prolonged exposure to acid and provides the appropriate environment for intestinal and pancreatic enzyme activity. The human receptor is found in the stomach and ductal and acinar cells of the pancreas. In different species, other organs may express secretin, including the liver, colon, heart, kidney, and brain (Chey and Chang, 2014).

Small bowel mucosal “I” cells secrete **CCK**, an important multifunctional hormone released in response to the presence of protein and fat. Receptors for CCK are in pancreatic acinar cells, pancreatic islet cells, gastric somatostatin-releasing D cells, smooth muscle cells of the GIT, and the central nervous system. Major functions of CCK are to (1) stimulate the pancreas to secrete enzymes, bicarbonate, and water; (2) stimulate gallbladder contraction; (3) increase colonic and rectal motility; (4) slow gastric emptying; and (5) increase satiety. CCK is also widely distributed in the brain and plays a role in neuronal functioning (Dockray, 2012).

Motilin is released by endocrine cells in the duodenal mucosa during fasting to stimulate gastric emptying and intestinal migrating contractions. Erythromycin, an antibiotic, has been shown to bind to motilin receptors; thus analogs of erythromycin and motilin have been used as therapeutic agents to treat delayed gastric emptying (De Smet et al, 2009).

Somatostatin, released by “D” cells in the antrum and pylorus, is a hormone with far-reaching actions. Its primary roles are inhibitory and antisecretory. It decreases motility of the stomach and intestine and inhibits or regulates the release of several gastrointestinal hormones. Somatostatin and its analog, octreotide, are being used to treat certain malignant diseases, as well as numerous gastrointestinal disorders such as diarrhea,

TABLE 1-3 Functions of Major Gastrointestinal Hormones

Hormone	Site of Release	Stimulants for Release	Organ Affected	Effect on Target Organ
Gastrin	G cells of gastric mucosa and duodenum	Peptides, amino acids, caffeine Distention of the antrum Some alcoholic beverages, vagus nerve	Stomach, esophagus, GIT in general	Stimulates secretion of HCl and pepsinogen Increases gastric antral motility Increases lower esophageal sphincter tone
			Gallbladder Pancreas	Weakly stimulates contraction of gallbladder Weakly stimulates pancreatic secretion of bicarbonate
Secretin	S cells of duodenum	Acid in small intestine	Pancreas	Increases output of H ₂ O and bicarbonate; increases enzyme secretion from the pancreas and insulin release
			Duodenum	Decreases motility Increases mucus output
CCK	I cells of duodenum	Peptides, amino acids, fats, HCl	Pancreas	Stimulates secretion of pancreatic enzymes
			Gallbladder	Causes contraction of gallbladder
			Stomach	Slows gastric emptying
			Colon	Increases motility May mediate feeding behavior
GIP	K cells of duodenum and jejunum	Glucose, fat	Stomach	Reduced intestinal motility
Motilin	M cells of duodenum and jejunum	Interdigestive periods, alkaline pH in duodenum	Stomach, small bowel, colon	Promotes gastric emptying and GI motility
GLP-1	L cells of small intestine and colon (density increases in distal GIT)	Glucose, fat, short-chain fatty acids	Stomach	Prolongs gastric emptying
			Pancreas	Inhibits glucagon release; Stimulates insulin release
GLP-2	L cells of small intestine and colon (density increases in distal GIT)	Glucose, fat, short-chain fatty acids	Small intestine, colon	Stimulates intestinal growth and nutrient digestion and absorption

CCK, Cholecystokinin; GI, gastrointestinal; GIP, glucose-dependent insulinotropic polypeptide; GIT, gastrointestinal tract; GLP-1, glucagon-like peptide-1; GLP-2, glucagon-like peptide-2; H₂O, water; HCl, hydrochloric acid.

short bowel syndrome, pancreatitis, dumping syndrome, and gastric hypersecretion (Van Op den Bosch et al, 2009; see Chapters 27 and 28).

Digestion in the Mouth

In the mouth, the teeth grind and crush food into small particles. The food mass is simultaneously moistened and lubricated by saliva. Three pairs of salivary glands – the parotid, submaxillary, and sublingual glands – produce approximately 1.5 L of saliva daily. Enzymatic digestion of starch and lipid is initiated in the mouth due to the presence of amylase and **salivary lipase**, respectively, in saliva. This digestion is minimal, and the salivary amylase becomes inactive when it reaches the acidic contents of the stomach. Saliva also contains mucus, a protein that causes particles of food to stick together and lubricates the mass for swallowing.

The masticated food mass, or bolus, is passed back to the pharynx under voluntary control, but throughout the esophagus, the process of swallowing (deglutition) is involuntary. **Peristalsis** then moves the food rapidly into the stomach (see Chapter 40 for detailed discussion of swallowing).

Digestion in the Stomach

Food particles are propelled forward and mixed with gastric secretions by wavelike contractions that progress forward from the upper portion of the stomach (fundus), to the midportion (corpus), and then to the antrum and pylorus. In the stomach, gastric secretions are mixed with food and

beverages. An average of 2000 to 2500 ml of fluid is secreted daily in the stomach. These gastric secretions contain hydrochloric acid (secreted by the parietal cells), pepsinogen, gastric lipase, mucus, intrinsic factor (a glycoprotein that facilitates vitamin B₁₂ absorption in the ileum), and gastrin. The protease, **pepsin**, is secreted in an inactive form, pepsinogen, which is converted by hydrochloric acid to its active form. Pepsin is active only in the acidic environment of the stomach and primarily changes the shape and size of some of the proteins found in a normal meal.

An acid-stable lipase is secreted into the stomach by chief cells. Although this lipase is considerably less active than pancreatic lipase, it contributes to the overall processing of dietary triglycerides. Gastric lipase is more specific for triglycerides composed of medium- and short-chain fatty acids, but the usual diet contains few of these fats. Lipases secreted in the upper portions of the GIT may have a relatively important role in the liquid diet of infants; however, when pancreatic insufficiency occurs, it becomes apparent that lingual and gastric lipases are not sufficient to prevent lipid malabsorption. In the process of gastric digestion, most of the food becomes semi-liquid chyme, which is 50% water. When food is consumed, significant numbers of microorganisms are also consumed. The stomach pH is low, ranging from about 1 to 4. The combined actions of hydrochloric acid and proteolytic enzymes result in a significant reduction in the concentration of viable microorganisms. Some microbes may escape and enter the intestine if consumed in sufficient concentrations or if achlorhydria,

gastrectomy, gastrointestinal dysfunction or disease, poor nutrition, or drugs that suppress acid secretions are present. This may increase the risk of pathogenic infection in the intestine.

The lower esophageal sphincter (LES), which lies above the entrance to the stomach, prevents reflux of gastric contents into the esophagus. The pyloric sphincter in the distal portion of the stomach helps regulate the exit of gastric contents, preventing backflow of chyme from the duodenum into the stomach. Obesity, certain food, gastrointestinal regulators, and irritation from nearby ulcers may alter the performance of sphincters. Certain foods and beverages may alter LES pressure, permitting reflux of stomach contents back into the esophagus (see Chapter 27).

The stomach continuously mixes and churns food and normally releases the mixture in small quantities into the small intestine through the pyloric sphincter. The amount emptied with each contraction of the antrum and pylorus varies with the volume and type of food consumed, but only a few milliliters are released at a time. The presence of acid and nutrients in the duodenum stimulate the regulatory hormone, GIP, to slow gastric emptying.

Most of a liquid meal empties within 1 to 2 hours, and most of a solid meal empties within 2 to 3 hours. When eaten alone, carbohydrates leave the stomach the most rapidly, followed by protein, fat, and fibrous food. In a meal with mixed types of foods, emptying of the stomach depends on the overall volume and characteristics of the foods. Liquids empty more rapidly than solids, large particles empty more slowly than small particles, and energy-dense foods empty more slowly than those containing less energy. These factors are important considerations for practitioners who counsel patients with nausea, vomiting, diabetic gastroparesis, or weight management concerns (see Chapters 27, 30, and 21).

Digestion in the Small Intestine

The small intestine is the primary site for digestion of foods and nutrients. The small intestine is divided into the duodenum, the jejunum, and the ileum (Figure 1-2). The duodenum is approximately 0.5 m long, the jejunum is 2 to 3 m, and the ileum is 3 to 4 m. Most of the digestive process is completed in the duodenum and upper jejunum, and the absorption of most nutrients is largely complete by the time the material reaches the middle of the jejunum. The acidic chyme from the stomach enters the duodenum, where it is mixed with secretions from the pancreas, gallbladder, and duodenal epithelium. The sodium bicarbonate contained within these secretions neutralizes the acidic chyme and allows the digestive enzymes to work more effectively at this location.

The entry of partially digested foods, primarily fats and protein, stimulates the release of CCK, secretin, and GIP, which, in turn, stimulate the secretion of enzymes and fluids and affect gastrointestinal motility and satiety. Bile, which is predominantly a mixture of water, bile salts, and small amounts of pigments and cholesterol, is secreted from the liver and gallbladder. Through their surfactant properties, the bile salts facilitate the digestion and absorption of lipids, cholesterol, and fat-soluble vitamins. Bile acids are also regulatory molecules; they activate the vitamin D receptor and cell-signaling pathways in the liver and GIT that alter gene expression of enzymes involved in the regulation of energy metabolism (Hylemon et al, 2009). Furthermore, bile acids play an important role in hunger and satiety.

The pancreas secretes potent enzymes capable of digesting all of the major nutrients, and enzymes from the small intestine help complete the process. The primary lipid-digesting enzymes secreted by the pancreas are **pancreatic lipase** and colipase. **Proteolytic enzymes** include trypsin and chymotrypsin, carboxypeptidase, aminopeptidase, ribonuclease, and deoxyribonuclease. Trypsin and chymotrypsin are secreted in their inactive forms and are activated by enterokinase (also known as enteropeptidase), which is bound within the brush border membrane of enterocytes within the small intestine. **Pancreatic amylase** eventually hydrolyzes large starch molecules into units of approximately two to six sugars. Disaccharidase enzymes bound in the enterocyte brush border membrane further break down the carbohydrate molecules into monosaccharides before absorption. Varying amounts of resistant starches and most ingested dietary fiber escape digestion in the small intestine and may add to fibrous material available for fermentation by colonic microbes.

Intestinal contents move along the small intestine at a rate of approximately 1 cm per minute, taking from 3 to 8 hours to travel through the entire intestine to the ileocecal valve; along the way, remaining substrates continue to be digested and absorbed. The ileocecal valve, like the pyloric sphincter, paces the entry of chyme into the colon and limits the amount of material passed back and forth between the small intestine and the colon. A damaged or nonfunctional ileocecal valve results in the entry of significant amounts of fluid and substrate into the colon and increases the chance for microbial overgrowth in the small intestine (see Chapter 28).

THE SMALL INTESTINE: PRIMARY SITE OF NUTRIENT ABSORPTION

The primary organ of nutrient and water absorption is the small intestine, which has an expansive absorptive area. The surface area is attributable to its extensive length, as well as to the organization of the mucosal lining. The small intestine has characteristic folds in its surface called *valvulae conniventes*. These convolutions are covered with fingerlike projections called *villi* (Figure 1-3), which in turn are covered by enterocytes that contain microvilli, or the **brush border membrane**. The combination of folds, villous projections, and microvillous border creates an enormous absorptive surface of approximately 200 to 300 m² - a surface area equivalent to a tennis court. The villi rest on a supporting structure called the *lamina propria*. Within the lamina propria, which is composed of connective tissue, the blood and lymph vessels receive the products of digestion.

Each day, on average, the small intestine absorbs 150 to 300 g of monosaccharides, 60 to 100 g of fatty acids, 60 to 120 g of amino acids and peptides, and 50 to 100 g of ions. The capacity for absorption in the healthy individual far exceeds the normal macronutrient and energy requirements. Approximately 95% of the bile salts secreted from the liver and gallbladder are reabsorbed as bile acids in the distal ileum. Without recycling bile acids from the GIT (enterohepatic circulation), synthesis of new bile acids in the liver would not keep pace with needs for adequate digestion. Bile salt insufficiency becomes clinically important in patients who have resections of the distal small bowel and diseases affecting the small intestine, such as Crohn's disease, radiation enteritis, and cystic fibrosis. The distal ileum is also the site for vitamin B₁₂ (with intrinsic factor) absorption.

FIGURE 1-3 Structure of the human intestine showing crypt-villus architecture and blood and lymph vessels.

Absorptive and Transport Mechanisms

Absorption is a complex process involving many distinct pathways for specific nutrients and/or ions. However, the two basic transport mechanisms used are active and passive transport. The primary differences between the two are whether (1) energy in the form of ATP is required and (2) the nutrient being transported is moving with or against a concentration gradient.

Passive transport does not require energy, and nutrients move from a location of high concentration to low concentration. With passive transport a transport protein may or may not be involved. If the nutrient moves through the brush border membrane without a transport protein, this is termed **passive**

diffusion, or simple passive transport. However, in cases in which a transport protein assists the passage of the nutrient across the brush border membrane, this process is termed **facilitated diffusion** (Figure 1-4).

Active transport is the movement of molecules across cell membranes in the direction *against* their concentration gradient and therefore requires a transporter protein and energy in the form of ATP. Some nutrients may share the same transporter and thus compete for absorption. Transport or carrier systems also can become saturated, slowing the absorption of the nutrient. A notable example of such a carrier is intrinsic factor, which is responsible for the absorption of vitamin B₁₂ (see Chapter 27).

FIGURE 1-4 Transport pathways through the cell membrane, as well as basic transport mechanisms. *ATP*, Adenosine triphosphate.

THE LARGE INTESTINE

The large intestine is approximately 1.5 m long and consists of the cecum, colon, rectum, and anal tract. Mucus secreted by the mucosa of the large intestine protects the intestinal wall from excretion and bacterial activity and provides the medium for binding the feces together. Bicarbonate ions secreted in exchange for absorbed chloride ions help to neutralize the acidic end products produced from bacterial action. Approximately 2 L of fluids are taken from food and beverages during the day, and 7 L of fluid is secreted along the GIT. Under normal circumstances, most of that fluid is absorbed in the small intestine, and approximately 2 L of fluid enters the large intestine. All but 100 to 150 ml of this fluid is absorbed; the remainder is excreted in the feces.

The large intestine is also the site of bacterial fermentation of remaining carbohydrates and amino acids, synthesis of a small amount of vitamins (particularly vitamin K), storage, and excretion of fecal residues. Colonic contents move forward slowly at a rate of 5 cm/h, and some remaining nutrients may be absorbed.

Defecation, or expulsion of feces through the rectum and anus, occurs with varying frequency, ranging from three times daily to once every 3 or more days. Average stool weight ranges from 100 to 200 g, and mouth-to-anus transit time may vary from 18 to 72 hours. The feces generally consist of 75% water and 25% solids, but the proportions vary greatly. Approximately two thirds of the contents of the wet weight of the stool is bacteria, with the remainder coming from gastrointestinal secretions, mucus, sloughed cells, microbiota, and undigested foods. A diet that includes abundant fruits, vegetables, legumes, and whole grains typically results in a shorter overall GIT transit time, more frequent defecation, and larger and softer stools.

Intestinal Microbiota: The Microbiome

The intestinal **microbiota**, also called the **microbiome**, is a dynamic mixture of essential microbes that develops under key influences of genetics, environment, diet, and disease. Bacterial population profiles differ along the gastrointestinal tract, from the lumen to the mucosa, and among individuals. The total microbiota population outnumbers the cells in the human body by a factor of 10 and accounts for 35% to 50% of the volume of the

colonic content. Key physiologic functions of the commensal microbiota include (1) protective effects exerted directly by specific bacterial species, (2) control of epithelial cell proliferation and differentiation, (3) production of essential mucosal nutrients, such as short-chain fatty acids and amino acids, (4) prevention of overgrowth of pathogenic organisms, (5) stimulation of intestinal immunity, and (6) development of the gut-brain axis (Kostic et al, 2014; see Chapter 41). Reduced abundance or changes in the relative proportions of these beneficial bacteria, a state called **dysbiosis**, is associated with various diseases in both children and adults (Buccigrossi et al, 2013; Figure 1-5).

Normally, relatively few bacteria remain in the stomach or small intestine after meals because bile, hydrochloric acid, and pepsin work as germicides. However, decreased gastric secretions can increase the risk of inflammation of the gastric mucosa (*gastritis*), increase the risk of bacterial overgrowth in the small intestine, or increase the numbers of microbes reaching the colon. An acid-tolerant bacterium is known to infect the stomach (*Helicobacter pylori*) and may cause gastritis and ulceration in the host (see Chapter 27).

Bacterial action is most intense in the distal small intestine and the large intestine. After a meal, dietary fiber, resistant starches, remaining bits of amino acids, and mucus sloughed from the intestine are fermented by the microbes present. This process of fermentation produces gases (e.g., hydrogen, carbon dioxide, nitrogen, and, in some individuals, methane) and SCFAs (e.g., acetic, propionic, butyric, and some lactic acids). During the process, several nutrients are formed by bacterial synthesis, such as vitamin K, vitamin B₁₂, thiamin, and riboflavin.

Strategies to stabilize and fortify the beneficial microbes within the microbiota in an attempt to maintain or improve health include the consumption of prebiotics, probiotics, and synbiotics.

Probiotics are live microorganisms, which, when administered in adequate amounts, provide a health benefit to the host. Probiotics can be found within fermented food products (such as miso or sauerkraut) or as a nutritional supplement (Hill et al, 2014). Knowledge of their role in preventing and treating a host of gastrointestinal and systemic disorders has expanded tremendously (Tappenden and Deutsch, 2007; Floch, 2014) in recent years. However, when recommending a probiotic,

FIGURE 1-5 Factors affecting stability and complexity of intestinal microbiota in health and disease. (Redrawn from Kostic AD et al: The microbiome in inflammatory bowel disease: current status and the future ahead, *Gastroenterology* 146:1489, 2014.)

practitioners must ensure that the specific microbial species has been shown in properly controlled studies to provide benefits to health (see Chapter 12).

Prebiotics are nondigestible food ingredients that have a specific stimulatory effect upon selected populations of GIT bacteria. Prebiotics typically require the following three attributes to benefit “beneficial” microbes such as *Lactobacilli* and *Bifidobacteria* spp.: (1) be able to escape digestion in the upper GIT, (2) be able to be fermented by the microbiota to SCFA(s), and (3) be able to increase the abundance and/or relative proportion of bacteria known to contribute to human health. Good dietary sources of prebiotic carbohydrates are vegetables, grains, and legumes, chicory, Jerusalem artichokes, soybeans, and wheat bran. Strong evidence exists for the use of specific prebiotics in reducing the extent of diarrhea and immune stimulation, and improving mineral bioavailability (Rastall and Gibson, 2014). **Synbiotics** are a synergistic combination of probiotics and prebiotics in the same food or supplement.

Colonic Salvage of Malabsorbed Energy Sources and Short-Chain Fatty Acids

Normally, varying amounts of some small-molecular-weight carbohydrates and amino acids remain in the chyme after leaving the small intestine. Accumulation of these small molecules could become osmotically important were it not for the action of bacteria in the colon. The disposal of residual substrates through production of SCFAs is called **colonic salvage**. SCFAs produced in fermentation are rapidly absorbed and take water with them. They also serve as fuel for the colonocytes and the microbiota, stimulate colonocyte proliferation and differentiation, enhance the absorption of electrolytes and water, and reduce the osmotic load of malabsorbed sugars. SCFAs also may help slow the movement of GI contents and participate in several other regulatory functions.

The ability to salvage carbohydrates is limited in humans. Colonic fermentation normally disposes of 20 to 25 g of carbohydrate over 24 hours. Excess amounts of carbohydrate and fermentable fiber in the colon can cause increased gas production, abdominal distention, bloating, pain, flatulence, decreased colonic pH, and diarrhea. Over time, adaptation occurs in individuals consuming

diets high in fiber. Current recommendations are for the consumption of approximately 14 g of dietary fiber per 1000 kcal consumed each day. This recommendation can be met by consuming ample fruits, vegetables, legumes, seeds, and whole grains and is aimed to (1) maintain the health of the colonic epithelium, (2) prevent constipation, and (3) support stable, health-promoting microbiota.

Digestion and Absorption of Specific Types of Nutrients Carbohydrates and Fiber

Most dietary carbohydrates are consumed in the form of starches, disaccharides, and monosaccharides. Starches, or polysaccharides, usually make up the greatest proportion of carbohydrates. Starches are large molecules composed of straight or branched chains of sugar molecules that are joined together, primarily in alpha 1-4 or 1-6 linkages. Most of the dietary starches are *amylopectins*, the branching polysaccharides, and *amylose*, the straight chain-type polymers.

Dietary fiber also is made largely of chains and branches of sugar molecules, but in this case the hydrogens are positioned on the beta (opposite) side of the oxygen in the link instead of the alpha side. Humans have significant ability to digest starch but not most fiber; this exemplifies the “stereospecificity” of enzymes.

In the mouth, the enzyme salivary amylase operates at a neutral or slightly alkaline pH and starts the digestive action by hydrolyzing a small amount of the starch molecules into smaller fragments (Figure 1-6). Amylase deactivates after contact with hydrochloric acid. If digestible carbohydrates remained in the stomach long enough, acid hydrolysis could eventually reduce most of them into monosaccharides. However, the stomach usually empties before significant digestion can take place. By far, most carbohydrate digestion occurs in the proximal small intestine.

Pancreatic amylase breaks the large starch molecules at the 1-4 linkages to create maltose, maltotriose, and “alpha-limit” dextrans remaining from the amylopectin branches. Enzymes from the brush border of the enterocytes further break the disaccharides and oligosaccharides into monosaccharides. For example, **maltase** located at the enterocyte brush border membrane breaks down the disaccharide maltose into two molecules

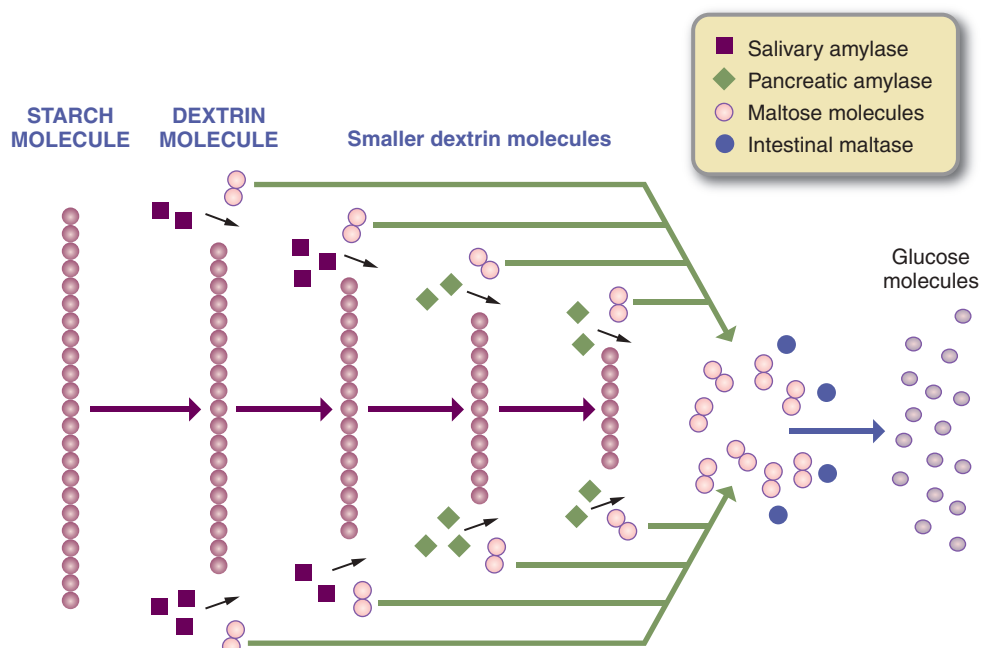

FIGURE 1-6 The gradual breakdown of large starch molecules into glucose by digestion enzymes.

FIGURE 1-7 Starch, sucrose, maltotriose, and galactose are digested to their constituent sugars. Glucose and galactose are transported through the apical brush border membrane of the enterocyte by a sodium-dependent transporter, glucose (galactose) cotransporter; fructose is transported by glucose transporter 5 (GLUT5). Glucose, fructose, and galactose are transported across the serosal membrane by the sodium-independent transporter, GLUT2.

of glucose. The brush border membrane also contains the enzymes **sucrase**, **lactase**, and isomaltase, which act on sucrose, lactose, and isomaltose, respectively (Figure 1-7).

The resultant monosaccharides (i.e., glucose, galactose, and fructose) pass through the enterocytes and into the bloodstream via the capillaries of the villi, where they are carried by the portal vein to the liver. At low concentrations, glucose and galactose are absorbed by active transport, primarily by a sodium-dependent active transporter called the sodium-glucose cotransporter (SGLT1). At higher luminal concentrations of glucose, the facilitative transporter GLUT2 becomes a primary route for transport of glucose from the lumen into the enterocyte. Fructose is absorbed from the intestinal lumen across the brush border membrane using the facilitative transporter, GLUT5. All three monosaccharides—glucose, galactose, and fructose—exit the basolateral membrane of the enterocyte into portal circulation using the facilitative transporter, GLUT2.

The active transporter, SGLT1, is key to the ability of the small intestine to absorb 7 L of fluid each day and provides the basis for why oral rehydration solutions, rather than water or sugary drinks, should be used to treat hydration. In addition to transporting sodium and glucose, SGLT1 functions as a molecular water pump. For each molecule of glucose absorbed by SGLT1, two molecules of sodium and 210 molecules of water also are absorbed. Given that this is a major pathway for water absorption in the small intestine, to facilitate water absorption, sodium and glucose also must be present in the right amounts. This explains why the most effective oral rehydration solutions often include both sugar and salt, in addition to water (see Chapters 6 and 23).

Some forms of carbohydrates (i.e., cellulose, hemicellulose, pectin, gum, and other forms of fiber) cannot be digested by humans because neither salivary nor pancreatic amylase has the ability to split the linkages connecting the constituent sugars. These carbohydrates pass relatively unchanged into the colon, where they are partially fermented by bacteria in the colon. However, unlike humans, cows and other ruminants can subsist on high-fiber food because of the bacterial digestion of these carbohydrates that takes place in the rumen. Other resistant starches and sugars are also less well digested or absorbed by humans; thus their consumption may result in

significant amounts of starch and sugar in the colon. These resistant starches and some types of dietary fiber are fermented into SCFAs and gases. Starches resistant to digestion tend to include plant foods with a high protein and fiber content such as those from legumes and whole grains. One form of dietary fiber, lignin, is made of cyclopentane units and is neither readily soluble nor fermentable.

Proteins

Protein intake in the Western world ranges from approximately 50 to 100 g daily, and a good deal of the protein consumed is from animal sources. Additional protein is added all along the GIT from gastrointestinal secretions and sloughed epithelial cells. The GIT is one of the most active synthetic tissues in the body, and the life span of enterocytes migrating from the crypts of the villi until they are shed is only 3 to 4 days. The number of cells shed daily is in the range of 10 to 20 billion. The latter accounts for an additional 50 to 60 g of protein that is digested and “recycled” and contributes to the daily supply. In general, animal proteins are more efficiently digested than plant proteins, but human physiology allows for very effective digestion and absorption of large amounts of ingested protein sources.

Protein digestion begins in the stomach, where some of the proteins are split into proteoses, peptones, and large polypeptides. Inactive pepsinogen is converted into the enzyme pepsin when it contacts hydrochloric acid and other pepsin molecules. Unlike any of the other proteolytic enzymes, pepsin digests collagen, the major protein of connective tissue. Most protein digestion takes place in the upper portion of the small intestine, but it continues throughout the GIT. Any residual protein fractions are fermented by colonic microbes.

Contact between chyme and the intestinal mucosa allows for the action of the brush border-bound **enterokinase**, an enzyme that transforms inactive pancreatic **trypsinogen** into active **trypsin**, the major pancreatic protein-digesting enzyme. Trypsin, in turn, activates the other pancreatic proteolytic enzymes. Pancreatic trypsin, chymotrypsin, and carboxypeptidase break down intact protein and continue the breakdown started in the stomach until small polypeptides and amino acids are formed.

Proteolytic peptidases located on the brush border also act on polypeptides, breaking them down into amino acids, dipeptides, and tripeptides. The final phase of protein digestion takes place in the brush border, where some of the dipeptides and tripeptides are hydrolyzed into their constituent amino acids by peptide hydrolases.

End products of protein digestion are absorbed as both amino acids and small peptides. Several transport molecules are required for the different amino acids, probably because of the wide differences in the size, polarity, and configuration of the different amino acids. Some of the transporters are sodium or chloride dependent, and some are not. Considerable amounts of dipeptides and tripeptides also are absorbed into intestinal cells using a peptide transporter, a form of active transport (Wuensch et al, 2013). Absorbed peptides and amino acids are transported to the liver via the portal vein for metabolism by the liver and are released into the general circulation.

The presence of antibodies to many food proteins in the circulation of healthy individuals indicates that immunologically significant amounts of large intact peptides escape hydrolysis and can enter the portal circulation. The exact mechanisms that cause a food to become an allergen are not entirely clear, but these foods tend to be high in protein, to be relatively resistant to complete digestion, and to produce an immunoglobulin response (see Chapter 26). With new technology, it is possible to map and characterize allergenic peptides; this eventually will lead to better diagnosis and development of safe immunotherapy treatments (Melioli et al, 2014).

Almost all protein is absorbed by the time it reaches the end of the jejunum, and only 1% of ingested protein is found in the feces. Small amounts of amino acids may remain in the epithelial cells and are used for synthesis of new proteins, including intestinal enzymes and new cells.

Lipids

Approximately 97% of dietary lipids are in the form of triglycerides, and the rest are found as phospholipids and cholesterol. Only small amounts of fat are digested in the mouth by lingual lipase and in the stomach from the action of gastric lipase. **Gastric lipase** hydrolyzes some triglycerides, especially short-chain triglycerides (such as those found in butter), into fatty acids and glycerol. However, most fat digestion takes place in the small intestine as a result of the emulsifying action of bile salts and hydrolysis by pancreatic lipase. As in the case of carbohydrates and protein, the capacity for digestion and absorption of dietary fat is in excess of ordinary needs.

Entrance of fat and protein into the small intestine stimulates the release of CCK, secretin, and GIP, which inhibit gastric secretions and motility, thus slowing the delivery of lipids. As a result, a portion of a large, fatty meal may remain in the stomach for 4 hours or longer. In addition to its many other functions, CCK stimulates biliary and pancreatic secretions. The combination of the peristaltic action of the small intestine and the surfactant and emulsification action of bile reduces the fat globules into tiny droplets, thus making them more accessible to digestion by the most potent lipid-digesting enzyme, pancreatic lipase.

Bile is a liver secretion composed of bile acids (primarily conjugates of cholic and chenodeoxycholic acids with glycine or taurine), bile pigments (which color the feces), inorganic salts, some protein, cholesterol, lecithin, and many compounds such as detoxified drugs that are metabolized and secreted by the liver. From its storage organ, the gallbladder, approximately 1 L

of bile is secreted daily in response to the stimulus of food in the duodenum and stomach.

Emulsification of fats in the small intestine is followed by their digestion, primarily by pancreatic lipase, into free fatty acids and monoglycerides. Pancreatic lipase typically cleaves the first and third fatty acids, leaving a single fatty acid esterified to the middle glycerol carbon. When the concentration of bile salts reaches a certain level, they form **micelles** (small aggregates of fatty acids, monoglycerides, cholesterol, bile salts, and other lipids), which are organized with the polar ends of the molecules oriented toward the watery lumen of the intestine. The products of lipid digestion are solubilized rapidly in the central portion of the micelles and carried to the intestinal brush border (Figure 1-8).

At the surface of the **unstirred water layer (UWL)**, the slightly acidic and watery plate that forms a boundary between the intestinal lumen and the brush border membranes, the lipids detach from the micelles. Remnants of the micelles return to the lumen for further transport. The monoglycerides and fatty acids thus are left to make their way across the lipophobic UWL to the more lipid-friendly membrane cells of the brush border. Upon release of the lipid components, luminal bile salts are reabsorbed actively in the terminal ileum and returned to the liver to reenter the gut in bile secretions. This efficient recycling process is known as the **enterohepatic circulation**. The pool of bile acids may circulate from 3 to 15 times per day, depending on the amount of food ingested.

The cellular mechanism(s) whereby fatty acids traverse the brush-border membrane include both passive diffusion (a form of transport that does not require energy), and active transport processes. Traditionally, the absorption of lipid was thought to be passive, wherein lipid molecules would solubilize through the brush border membrane in a manner driven by diffusion down the concentration gradient into the enterocyte. The inwardly directed concentration gradient was thought to be maintained in the fed state by the high concentration of fatty acids within the intestinal lumen and the rapid scavenging of free fatty acids for triglyceride reformation once inside the enterocyte. Current theories indicate that passive diffusion and carrier-mediated mechanisms contribute to lipid absorption. At low fatty acid concentrations, carrier-mediated mechanisms take precedence with little passive diffusion occurring. However, when free fatty acid concentration in the intestinal lumen is high, absorption of fatty acids via passive diffusion becomes quantitatively important.

In the enterocyte, the fatty acids and monoglycerides are reassembled into new triglycerides. Others are further digested into free fatty acids and glycerol and then reassembled to form triglycerides. These triglycerides, along with cholesterol, fat-soluble vitamins, and phospholipids, are surrounded by a lipoprotein coat, forming chylomicrons (see Figure 1-8). The lipoprotein globules pass into the lymphatic system instead of entering portal blood and are transported to the thoracic duct and emptied into the systemic circulation at the junction of the left internal jugular and left subclavian veins. The chylomicrons then are carried through the bloodstream to several tissues, including liver, adipose tissue, and muscle. In the liver, triglycerides from the chylomicrons are repackaged into very low-density lipoproteins and transported primarily to the adipose tissue for metabolism and storage.

Under normal conditions approximately 95% to 97% of ingested fat is absorbed into lymph vessels. Because of their shorter length and thus increased solubility, fatty acids of 8 to 12 carbons (i.e., medium-chain fatty acids) can be absorbed directly into colonic mucosal cells without the presence of bile and micelle formation. After entering mucosal cells, they are

FIGURE 1-8 Summary of fat absorption.

able to go directly without esterification into the portal vein, which carries them to the liver.

Increased motility, intestinal mucosal changes, pancreatic insufficiency, or the absence of bile can decrease the absorption of fat. When undigested fat appears in the feces, the condition is known as steatorrhea (see Chapter 28). Medium-chain triglycerides (MCTs) have fatty acids 8 to 12 carbons long; MCTs are clinically valuable for individuals who lack necessary bile salts for long-chain fatty acid metabolism and transport. Supplements for clinical use normally are provided in the form of oil or a dietary beverage with other macronutrients and micronutrients.

Vitamins and Minerals

Vitamins and minerals from foods are made available as macronutrients and are digested and absorbed across the mucosal layer, primarily in the small intestine (Figure 1-9). Besides adequate passive and transporter mechanisms, various factors affect the bioavailability of vitamins and minerals, including the presence or absence of other specific nutrients, acid or alkali, phytates, and oxalates. The liters of fluid that are secreted each day from the GIT serve as a solvent, a vehicle for chemical reactions, and a medium for transfer of several nutrients.

At least some vitamins and water pass unchanged from the small intestine into the blood by passive diffusion, but several

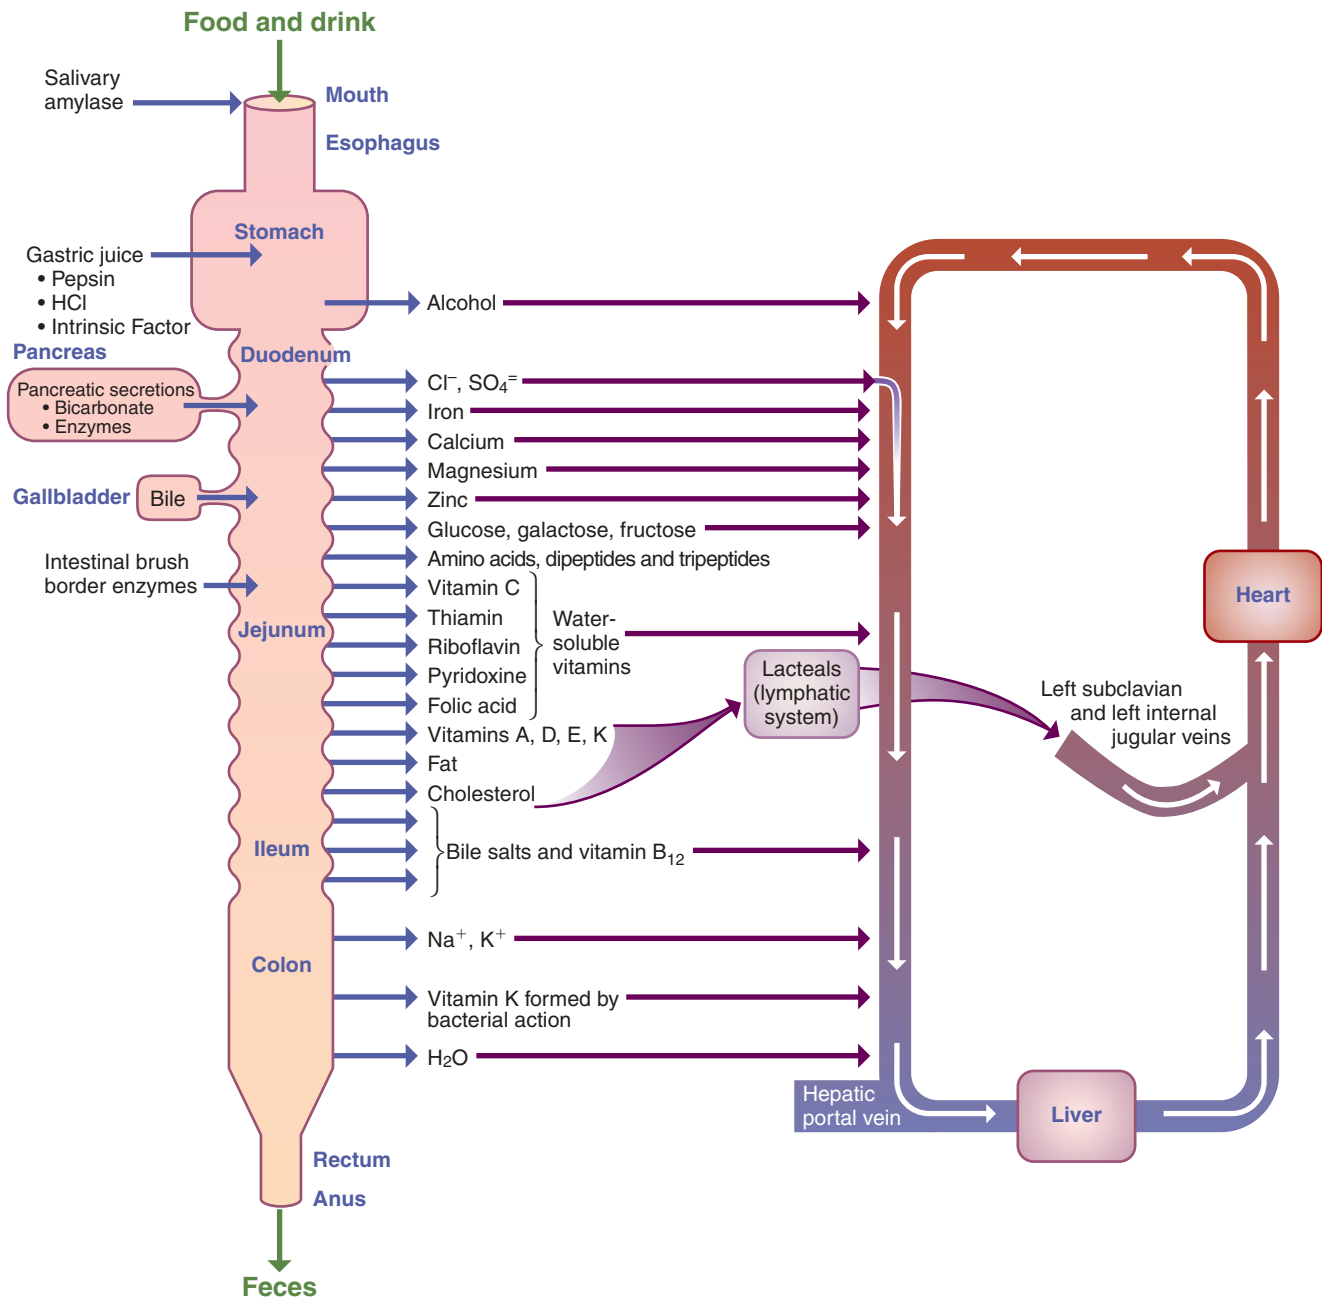

FIGURE 1-9 Sites of secretion and absorption in the gastrointestinal tract.

different mechanisms may be used to transport individual vitamins across the mucosa. Drugs are absorbed by a number of mechanisms but often by passive diffusion. Thus drugs may share or compete with mechanisms for the absorption of nutrients into intestinal cells (see Chapter 8).

Mineral absorption is more complex, especially the absorption of the cation minerals. These cations, such as selenium, are made available for absorption by the process of **chelation**, in which a mineral is bound to a ligand—usually an acid, an organic acid, or an amino acid—so that it is in a form absorbable by intestinal cells.

Iron and zinc absorption share several characteristics in that the efficiency of absorption partly depends on the needs of the host. They also use at least one transport protein, and each has mechanisms to increase absorption when stores are inadequate. Because

phytates and oxalates from plants impair the absorption of iron and zinc, absorption is better when animal sources are consumed. The absorption of zinc is impaired with disproportionately increased amounts of magnesium, calcium, and iron. Calcium absorption into the enterocyte occurs through channels in the brush border membrane, where it is bound to a specific protein carrier for transportation across the basolateral membrane. The process is regulated by the presence of vitamin D. Phosphorus is absorbed by a sodium phosphorus cotransporter, which also is regulated by vitamin D or low phosphate intake.

The GIT is the site of important interactions among minerals. Supplementation with large amounts of iron or zinc may decrease the absorption of copper. In turn, the presence of copper may lower iron and molybdenum absorption. Cobalt absorption is increased in patients with iron deficiency, but cobalt

and iron compete and inhibit one another's absorption. These interactions are probably the result of an overlap of mineral absorption mechanisms.

Minerals are transported in blood bound to protein carriers. The protein binding is either specific (e.g., transferrin, which binds with iron, or ceruloplasmin, which binds with copper) or general (e.g., albumin, which binds with a variety of minerals). A fraction of each mineral also is carried in the serum as amino acid or peptide complexes. Specific protein carriers are usually not completely saturated; the reserve capacity may serve as a buffer against excessive exposure. Toxicity from minerals usually results only after this buffering capacity is exceeded.

KEY TERMS

activity thermogenesis (AT)

basal energy expenditure (BEE)

basal metabolic rate (BMR)

calorie

direct calorimetry

estimated energy requirement (EER)

excess postexercise oxygen consumption (EPOC)

facultative thermogenesis

fat-free mass (FFM)

high-metabolic-rate organ (HMRO)

indirect calorimetry (IC)

kilocalorie (kcal)

lean body mass (LBM)

metabolic equivalents (METs)

nonexercise activity thermogenesis (NEAT)

obligatory thermogenesis

physical activity level (PAL)

resting energy expenditure (REE)

resting metabolic rate (RMR)

respiratory quotient (RQ)

thermic effect of food (TEF)

total energy expenditure (TEE)

Energy may be defined as “the capacity to do work.” The ultimate source of all energy in living organisms is the sun. Through the process of photosynthesis, green plants intercept a portion of the sunlight reaching their leaves and capture it within the chemical bonds of glucose. Proteins, fats, and other carbohydrates are synthesized from this basic carbohydrate to meet the needs of the plant. Animals and humans obtain these nutrients and the energy they contain by consuming plants and the flesh of other animals.

The body makes use of the energy from dietary carbohydrates, proteins, fats, and alcohol; this energy is locked in chemical bonds within food and is released through metabolism. Energy must be supplied regularly to meet needs for the body’s survival. Although all energy eventually takes the form of heat, which dissipates into the atmosphere, unique cellular processes first make possible its use for all of the tasks required for life. These processes involve chemical reactions that maintain body tissues, electrical conduction of the nerves, mechanical work of the muscles, and heat production to maintain body temperature.

ENERGY REQUIREMENTS

Energy requirements are defined as the dietary energy intake that is required for growth or maintenance in a person of a defined age, gender, weight, height, and level of physical activity. In children and pregnant or lactating women, energy requirements include the needs associated with the deposition of tissues or the secretion of milk at rates consistent with good health. In ill or injured people, the stressors have an effect by increasing or decreasing energy expenditure.

Body weight is one indicator of energy adequacy or inadequacy. The body has the unique ability to shift the fuel mixture of carbohydrates, proteins, and fats to accommodate energy needs. However, consuming too much or too little energy over time results in body weight changes. Thus body weight reflects adequacy of energy intake, but it is not a reliable indicator of macronutrient or micronutrient adequacy.

In addition, because body weight is affected by body composition, a person with a higher lean mass to body fat mass or body fat mass to lean mass may require differing energy intakes compared with the norm or “average” person. Obese individuals have higher energy needs as a result of an increase in body fat mass and lean body mass (Kee et al, 2012).

COMPONENTS OF ENERGY EXPENDITURE

Energy is expended by the human body in the form of **basal energy expenditure (BEE)**, **thermic effect of food (TEF)**, and **activity thermogenesis (AT)**. These three components make up a person’s daily **total energy expenditure (TEE)**.

Basal and Resting Energy Expenditure

BEE, or **basal metabolic rate (BMR)**, is the minimum amount of energy expended that is compatible with life. An individual’s BEE reflects the amount of energy used during 24 hours while physically and mentally at rest in a thermoneutral environment that prevents the activation of heat-generating processes, such as shivering. Measurements of BEE should be done before an individual has engaged in any physical activity (preferably on awakening from sleep) and 10 to 12 hours after the ingestion of any food, drink, or nicotine. The BEE remains remarkably constant on a daily basis.

Resting energy expenditure (REE), or **resting metabolic rate (RMR)**, is the energy expended in the activities necessary to sustain normal body functions and homeostasis. These activities include respiration and circulation, the synthesis of organic compounds, and the pumping of ions across membranes. REE, or RMR, includes the energy required by the central nervous system and for the maintenance of body temperature. It does not include thermogenesis, activity, or other energy expenditure and is higher than the BEE by 10% to 20% (Ireton-Jones, 2010). The terms *REE* and *RMR* and *BEE* and *BMR* can be used interchangeably, but *REE* and *BEE* are used in this chapter.

Factors Affecting Resting Energy Expenditure

Numerous factors cause the REE to vary among individuals, but body size and composition have the greatest effect. See Chapter 7 for discussion of methods used to determine body composition.

Age. Because REE is highly affected by the proportion of **lean body mass (LBM)**, it is highest during periods of rapid growth, especially the first and second years of life. Growing infants may store as much as 12% to 15% of the energy value of their food in the form of new tissue. As a child becomes older, the energy requirement for growth is reduced to approximately 1% of TEE. After early adulthood there is a decline in REE of 1% to 2% per kilogram of **fat-free mass (FFM)** per decade (Keys et al, 1973). Fortunately, exercise can help maintain a higher LBM and a higher REE. Decreases in REE with increasing age may be partly related to age-associated changes in the relative size of LBM components (Cooper et al, 2013).

Body composition. FFM, or LBM, makes up the majority of metabolically active tissue in the body and is the primary predictor of REE. FFM contributes to approximately 80% of the variations in REE (Bosy-Westphal et al, 2004). Because of their greater FFM, athletes with greater muscular development have an approximately 5% higher resting metabolism than nonathletic individuals. Organs in the body contribute to heat production (Figure 2-1). Approximately 60% of REE can be accounted for by the heat produced by **high-metabolic-rate organs (HMROs)**: the liver, brain, heart, spleen, intestines, and kidneys (McClave and Snider, 2001). Indeed, differences in FFM between ethnic groups may be related to the total mass of these as well as musculature (Gallagher et al, 2006). Relatively small individual variation in the mass of the liver, brain, heart, spleen, and kidneys, collectively or individually, can significantly affect REE (Javed et al, 2010). As a result, estimating the percentage of energy expenditure that appendages (arms and legs) account for in overall daily energy expenditure is difficult, although it is presumably a small amount.

Body size. Larger people generally have higher metabolic rates than smaller people, but tall, thin people have higher metabolic rates than short, stocky people. For example, if two people weigh the same but one person is taller, the taller person

FIGURE 2-1 Proportional contribution of organs and tissues to calculated resting energy expenditure. (Modified and used with permission from Gallagher D et al: Organ-tissue mass measurement allows modeling of REE and metabolically active tissue mass, *Am J Physiol Endocrinol Metab* 275:E249, 1998. Copyright American Physiological Society.)

has a larger body surface area and a higher metabolic rate. The amount of LBM is highly correlated with total body size. For example, obese children have higher REEs than nonobese children, but, when REE is adjusted for body composition, FFM, and fat mass, no REE differences are found (Byrne et al, 2003). This provides a conundrum for the practitioner when using the BMI to assess health (see Chapter 7).

Climate. The REE is affected by extremes in environmental temperature. People living in tropical climates usually have REEs that are 5% to 20% higher than those living in temperate areas. Exercise in temperatures greater than 86°F imposes a small additional metabolic load of approximately 5% from increased sweat gland activity. The extent to which energy metabolism increases in extremely cold environments depends on the insulation available from body fat and protective clothing (Dobratz et al, 2007).

Gender. Gender differences in metabolic rates are attributable primarily to differences in body size and composition. Women, who generally have more fat in proportion to muscle than men, have metabolic rates that are approximately 5% to 10% lower than men of the same weight and height. However, with aging, this difference becomes less pronounced (Cooper et al, 2013).

Hormonal status. Hormones affect metabolic rate. Endocrine disorders, such as hyperthyroidism and hypothyroidism, increase or decrease energy expenditure, respectively (see Chapter 31). Stimulation of the sympathetic nervous system during periods of emotional excitement or stress causes the release of epinephrine, which promotes glycogenolysis and increased cellular activity. Ghrelin and peptide YY are gut hormones involved in appetite regulation and energy homeostasis (Larson-Meyer et al, 2010). The metabolic rate of women fluctuates with the menstrual cycle. During the luteal phase (i.e., the time between ovulation and the onset of menstruation), metabolic rate increases slightly (Ferraro et al, 1992). During pregnancy, growth in uterine, placental, and fetal tissues, along with the mother's increased cardiac workload, contributes to gradual increases in BEE (Butte et al, 2004).

Temperature. Fevers increase REE by approximately 7% for each degree of increase in body temperature above 98.6° F or 13% for each degree more than 37° C, as noted by classic studies (Hardy and DuBois, 1937).

Other factors. Caffeine, nicotine, and alcohol stimulate metabolic rate. Caffeine intakes of 200 to 350 mg in men or 240 mg in women may increase mean REE by 7% to 11% and 8% to 15%, respectively (Compher et al, 2006). Nicotine use increases REE by approximately 3% to 4% in men and by 6% in women; alcohol consumption increases REE in women by 9% (Compher et al, 2006). Under conditions of stress and disease, energy expenditure may increase or decrease, based on the clinical situation. Energy expenditure may be higher in people who are obese (Dobratz et al, 2007) but depressed during starvation or chronic dieting and in people with bulimia (Sedlet and Ireton-Jones, 1989).

Thermic Effect of Food

The **thermic effect of food (TEF)** is the increase in energy expenditure associated with the consumption, digestion, and absorption of food. The TEF accounts for approximately 10% of TEE (Ireton-Jones, 2010). The TEF may also be called diet-induced thermogenesis, specific dynamic action, or the specific effect of food. TEF can be separated into obligatory and facultative

(or adaptive) subcomponents. **Obligatory thermogenesis** is the energy required to digest, absorb, and metabolize nutrients, including the synthesis and storage of protein, fat, and carbohydrate. Adaptive or **facultative thermogenesis** is the “excess” energy expended in addition to the obligatory thermogenesis and is thought to be attributable to the metabolic inefficiency of the system stimulated by sympathetic nervous activity.

The TEF varies with the composition of the diet, with energy expenditure increasing directly after food intake, particularly after consumption of a meal higher in protein compared with a meal higher in fat (Tentolouris et al, 2008). Fat is metabolized efficiently, with only 4% waste, compared with 25% waste when carbohydrate is converted to fat for storage. The macronutrient oxidation rate is not different in lean and obese individuals (Tentolouris et al, 2008). Although the extent of TEF depends on the size and macronutrient content of the meal, TEF decreases after ingestion over 30 to 90 minutes, so effects on TEE are small. For practical purposes, TEF is calculated as no more than an additional 10% of the REE. Spicy foods enhance and prolong the effect of the TEF. Caffeine, capsaicin, and different teas such as green, white, and oolong tea also may increase energy expenditure and fat oxidation and suppress hunger (Hursel and Westerterp-Plantenga, 2010; Reinbach et al, 2009). The role of TEF in weight management is discussed in Chapter 21.

Enteral nutrition (tube feeding) as well as parenteral nutrition exert a thermic effect on energy expenditure, which should be considered in patients receiving nutrition support. Leuck and colleagues found that energy expenditure of patients receiving enteral nutrition intermittently vs. continuously was increased at night and increased in association with each intermittent feeding (Leuck et al, 2013). A case study of a long-term home parenteral nutrition patient showed an increase in energy expenditure when the intravenous nutrition was being infused (Ireton-Jones, 2010). These are important considerations when predicting overall energy needs for patients receiving enteral or parenteral nutrition (see Chapter 13).

Activity Thermogenesis

Beyond REE and TEF, energy is expended in physical activity, either exercise-related or as part of daily work and movement. This is referred to as **activity thermogenesis**. **Activity thermogenesis (AT)** includes **nonexercise activity thermogenesis (NEAT)**, the energy expended during activities of daily living, and the energy expended during sports or fitness exercise. (Levine and Kotz, 2005).

The contribution of physical activity is the most variable component of TEE, which may be as low as 100 kcal/day in sedentary people or as high as 3000 kcal/day in athletes. NEAT represents the energy expended during the workday and during leisure-type activities (e.g., shopping, fidgeting, even gum chewing), which may account for vast differences in energy costs among people (Levine and Kotz, 2005; see Appendix 20). TEE reflects REE, TEF, and energy expended for exercise, as depicted in Figure 2-2.

Individual AT varies considerably, depending on body size and the efficiency of individual habits of motion. The level of fitness also affects the energy expenditure of voluntary activity because of variations in muscle mass. AT tends to decrease with age, a trend that is associated with a decline in FFM and an increase in fat mass. In general, men have greater skeletal muscle

FIGURE 2-2 The components of total energy expenditure: activity, thermic effect of food (TEF), and basal or resting metabolic rate.

than women, which may account for their higher AT. The measurement of physical activity is very difficult whether related to children, adolescents, or adults (Mindell et al, 2014). However, this remains an important component of the overall energy intake recommendation suggesting that low-cost quantitative assessment methods are needed (e.g., heart rate monitoring) along with the typical questionnaire and estimate.

Additional Considerations in Energy Expenditure

Excess postexercise oxygen consumption (EPOC) is influenced by the duration and magnitude of physical activity. In a study of high-intensity intermittent exercise, there was an increase in energy expenditure during activity, although the effect on metabolic rate post-activity was minor (Kelly et al, 2013). Habitual exercise does not cause a significantly prolonged increase in metabolic rate unless FM is decreased and FFM is increased, and then this increase in energy expenditure is mostly during the activity itself.

Amputations resulting from trauma, wounds, or disease processes affect body size; presumably then, they would affect activity energy expenditure. However, a study of energy expenditure related to level of amputation (partial foot to transfemoral) at various speeds of walking was done in unilateral amputees, and no differences in energy expenditure were found between levels of amputation or speed when walking (Göktepe et al, 2010).

Measurement of Energy Expenditure

The standard unit for measuring energy is the **calorie**, which is the amount of heat energy required to raise the temperature of 1 ml of water at 15°C by 1°C. Because the amount of energy involved in the metabolism of food is fairly large, the kilocalorie (kcal), 1000 calories, is used to measure it. A popular convention is to designate kilocalorie by Calorie (with a capital C). In this text, however, kilocalorie is abbreviated kcal. The **joule (J)** measures energy in terms of mechanical work and is the amount of energy required to accelerate with a force of 1 Newton (N) for a distance of 1 m; this measurement is widely used in countries other than the United States. One kcal is equivalent to 4.184 kilojoules (kJ).

Because various methods are available to measure human energy expenditure, it is important to gain an understanding of the differences in these methods and how they can be applied in practical and research settings.

Direct Calorimetry

Direct calorimetry is possible only with specialized and expensive equipment. An individual is monitored in a room-type structure (a whole-room calorimeter) that permits a moderate amount of activity. It includes equipment that monitors the amount of heat produced by the individual inside the chamber or room. Direct calorimetry provides a measure of energy expended in the form of heat, but provides no information on the kind of fuel being oxidized. The method also is limited by the confined nature of the testing conditions. Therefore the measurement of TEE using this method is not representative of a free-living (i.e., engaged in normal daily activities) individual in a normal environment, because physical activity within the chamber is limited. High cost, complex engineering, and scarcity of appropriate facilities around the world also limit the use of this method.

Indirect Calorimetry

Indirect calorimetry (IC) is a more commonly used method for measuring energy expenditure. An individual's oxygen consumption and carbon dioxide production are quantified over a given period. The Weir equation (1949) and a constant respiratory quotient value of 0.85 are used to convert oxygen consumption to REE. The equipment varies but usually involves an individual breathing into a mouthpiece (with nose clips), a mask that covers the nose and mouth, or a ventilated hood that captures all expired carbon dioxide (Figure 2-3). Ventilated hoods are useful for short- and long-term measurements.

IC measurements are achieved using equipment called a metabolic measurement cart or an indirect calorimeter. There are various types of metabolic measurement carts, varying from larger equipment that measures oxygen consumption and carbon dioxide production only, to equipment that also has the capability of providing pulmonary function and exercise testing parameters. These larger carts are more expensive because of the expanded capabilities, including measurement interface for IC measurements of hospitalized patients who are ventilator dependent. Metabolic carts often are used at hospitals to assess

energy requirements and are found most typically in the intensive care unit (Iretton-Jones, 2010). Individuals and patients who are breathing spontaneously may have their energy expenditure measured with smaller “handheld” indirect calorimeters designed specifically for measuring oxygen consumption while using a static value for carbon dioxide production. These have easy mobility and are relatively low cost (Hipskind et al, 2011).

A strict protocol should be followed before performing IC measurement. For healthy people, a minimum of a 5-hour fast after meals and snacks is recommended. Caffeine should be avoided for at least 4 hours, and alcohol and smoking for at least 2 hours. Testing should occur no sooner than 2 hours after moderate exercise; after vigorous resistance exercise, a 14-hour period is advised (Compher et al, 2006). To achieve a steady-state measurement, there should be a rest period of 10 to 20 minutes before the measurement is taken. An IC measurement duration of 10 minutes, with the first 5 minutes deleted and the remaining 5 minutes having a coefficient of variation less than 10%, indicates a steady-state measurement (Compher et al, 2006). When the measurement conditions listed here are met and a steady state is achieved, energy expenditure can be measured at any time during the day.

Energy expenditure can be measured for ill or injured individuals as well (Cooney and Frankenfield, 2012). Equipment used for the patient who is ventilator dependent may be different from that used for the ambulatory individual; however, a protocol specifying the conditions of measurement should be used for these patients as well (Iretton-Jones, 2010). When these conditions are met, IC can be applied for measuring the energy expenditure of acute or critically ill inpatients, outpatients, or healthy individuals.

Respiratory Quotient

When oxygen consumption and carbon dioxide production are measured, the **respiratory quotient (RQ)** may be calculated as noted in the following equation. The RQ indicates the fuel mixture being metabolized. The RQ for carbohydrate is 1 because the number of carbon dioxide molecules produced is equal to the number of oxygen molecules consumed.

FIGURE 2-3 **A:** Measuring resting energy expenditure using a ventilated hood system. (Courtesy MRC Mitochondrial Biology Unit, Cambridge, England.) **B:** Measuring resting energy expenditure using a handheld system. (Courtesy Korr.)

RQ = volume of CO expired/volume of O₂ consumed (VO₂/VCO₂)

RQ values:

1 = carbohydrate

0.85 = mixed diet

0.82 = protein

0.7 = fat

≤0.65 = ketone production

RQs greater than 1 are associated with net fat synthesis, carbohydrate (glucose) intake, or total caloric intake that is excessive, whereas a very low RQ may be seen under conditions of inadequate nutrient intake (McClave et al, 2003). Although RQ has been used to determine the efficacy of nutrition support regimens for hospitalized patients, McClave found that changes in RQ failed to correlate to percent calories provided or required, indicating low sensitivity and specificity that limits the efficacy of RQ as an indicator of overfeeding or underfeeding. However, use of RQ is appropriate as a marker of test validity (to confirm measured RQ values are in physiologic range) and a marker for respiratory tolerance of the nutrition support regimen.

Other Methods of Measuring Energy Expenditure

Alternative methods of measuring energy expenditure remain in the research setting because of the need for specialized equipment and expertise.

Doubly labeled water. The doubly labeled water (DLW) technique for measuring TEE is considered the gold standard for determining energy requirements and energy balance in humans. The DLW method is based on the principle that carbon dioxide production can be estimated from the difference in the elimination rates of body hydrogen and oxygen. After an oral loading dose of water labeled with deuterium oxide (²H₂O) and oxygen-18 (H₂¹⁸O)—hence the term doubly labeled water—is administered, the ²H₂O is eliminated from the body as water, and the H₂¹⁸O is eliminated as water and carbon dioxide. The elimination rates of the two isotopes are measured for 10 to 14 days by periodic sampling of body water from urine, saliva, or plasma. The difference between the two elimination rates is a measure of carbon dioxide production. Carbon dioxide production then can be equated to TEE using standard IC techniques for the calculation of energy expenditure.

The caloric value of AT can be estimated by using the DLW method in conjunction with IC and also can be used to determine adherence to recommended intake and body composition longitudinally (Wong et al, 2014). The DLW technique is most applicable as a research tool; the stable isotopes are expensive, and expertise is required to operate the highly sophisticated and costly mass spectrometer for the analysis of the isotope enrichments. These disadvantages make the DLW technique impractical for daily use by clinicians.

Measuring Activity-Related Energy Expenditure

Triaxial monitors. A triaxial monitor has also been used to measure energy related to activity. It more efficiently measures multidirectional movement by employing three uniaxial monitors. In a review of numerous articles, Plasqui and Westerterp (2007) found that a triaxial monitor correlated with energy expenditure measured using DLW technique. Application of an easily accessible and useable monitor allows determination of real activity levels, thereby reducing errors related to

overreporting or underreporting of actual energy expenditure for weight management.

Physical Activity Questionnaire

Physical activity questionnaires (PAQs) are the simplest and least expensive tools for gaining information about an individual's activity level (Winters-Hart et al, 2004). Reporting errors are common among PAQs, which can lead to discrepancies between calculated energy expenditure and that determined by DLW (Neilson et al, 2008). For healthy individuals, this may account for slowed weight loss or gain and, as such, a need to modify caloric intake.

ESTIMATING ENERGY REQUIREMENTS

Equations for Estimating Resting Energy Expenditure

Over the years several equations have been developed to estimate the REE. Equations are available that allow the estimation of REE as derived from measurement using IC in adults. Until recently, the Harris-Benedict equations were some of the most widely used equations to estimate REE in normal and ill or injured individuals (Harris and Benedict, 1919). The Harris-Benedict formulas have been found to overestimate REE in normal weight and obese individuals by 7% to 27% (Frankenfield et al, 2003). A study comparing measured REE with estimated REE using the Mifflin-St. Jeor equations, Owen equations, and Harris-Benedict equations for males and females found that the Mifflin-St. Jeor equations were most accurate in estimating REE in both normal weight and obese people (Frankenfield et al, 2003). The Mifflin-St Jeor equations were developed from measured REE using IC in 251 males and 247 females; 47% of these individuals had a body mass index (BMI) between 30 and 42 kg/m² (Mifflin et al, 1990). Mifflin-St. Jeor equations are used today to estimate energy expenditure of healthy individuals and in some patients and are as follows:

$$\begin{aligned} \text{Males: kcal/day} &= 10 (\text{wt}) + 6.25 (\text{ht}) - 5 (\text{age}) + 5 \\ \text{Females: kcal/day} &= 10 (\text{wt}) + 6.25 (\text{ht}) - 5 (\text{age}) - 161 \\ \text{Weight} &= \text{actual body weight in kilograms} \\ \text{Height} &= \text{centimeters; age} = \text{years} \end{aligned}$$

Although the Harris-Benedict equations have been applied to ill and injured people, these equations, as well as those of Mifflin, were developed for use in healthy individuals, and their application to any other population is questionable. In addition, the database from which the Harris-Benedict equations were developed no longer reflects the population, and therefore use of these equations is not recommended.

Energy expenditure of ill or injured patients also can be estimated or measured using IC. For energy requirements for critically ill patients, see Chapter 38.

Determining TEE

The equations for estimating or measuring energy expenditure begin with resting energy expenditure or REE. Additional factors for TEF and activity must be added. As stated previously, the TEF may be considered as an overall additive factor within activity thermogenesis in calculations of TEE. A simplified way of predicting physical activity additions to REE is through the use of estimates of the level of physical activity, which are then multiplied by the measured or predicted REE. To estimate TEE

for minimal activity, increase REE by 10% to 20%; for moderate activity, increase REE by 25% to 40%; for strenuous activity, increase REE by 45% to 60%. These levels are ranges used in practice and can be considered “expert opinion” rather than evidence based at this time.

Estimating Energy Requirements from Energy Intake

Traditionally, recommendations for energy requirements were based on self-recorded estimates (e.g., diet records) or self-reported estimates (e.g., 24-hour recalls) of food intake. However, these methods do not provide accurate or unbiased estimates of an individual’s energy intake. The percentage of people who underestimate or underreport their food intake ranges from 10% to 45%, depending on the person’s age, gender, and body composition. This occurs in the compromised patient population as well (Ribeiro et al, 2014). See Chapter 4.

Many online programs are available in which an individual can enter the food and quantity consumed into a program that estimates the macronutrient and micronutrient content. These programs allow users to enter data and receive a summary report, often with a detailed report provided to the health professional as well. Widely available programs include Food Prodigy and the MyPlate Tracker from the United States Department of Agriculture (see Chapter 4).

Other Prediction Equations

The National Academy of Sciences, Institute of Medicine (IOM), and Food and Nutrition Board, in partnership with Health Canada, developed the estimated energy requirements for men, women, children, and infants and for pregnant and lactating women (IOM, 2005). The **estimated energy requirement (EER)** is the average dietary energy intake predicted to maintain energy balance in a healthy adult of a defined age, gender, weight, height, and level of physical activity consistent with good health. In children and pregnant and lactating women, the EER is taken to include the energy needs associated with the deposition of tissues or the secretion of milk at rates consistent with good health. Table 2-1 lists average dietary reference intake (DRI) values for energy in healthy, active people of reference height, weight, and age for each life-stage group (IOM, 2002; 2005).

Supported by DLW studies, prediction equations have been developed to estimate energy requirements for people according to their life-stage group. Box 2-1 lists the EER prediction equations for people of normal weight. TEE prediction equations also are listed for various overweight and obese groups, as well as for weight maintenance in obese girls and boys. All equations have been developed to maintain current body weight (and promote growth when appropriate) and current levels of physical activity for all subsets of the population; they are not intended to promote weight loss (IOM, 2002; 2005).

The EER incorporates age, weight, height, gender, and level of physical activity for people ages 3 years and older. Although variables such as age, gender, and feeding type (i.e., breast milk, formula) can affect TEE among infants and young children, weight has been determined as the sole predictor of TEE needs (IOM, 2002; 2005). Beyond TEE requirements, additional calories are required for infants, young children, and children ages 3 through 18 to support the deposition of tissues needed for growth, and for pregnant and lactating women. Thus the EER among these subsets of the population is the sum of TEE plus the caloric requirements for energy deposition.

TABLE 2-1 Dietary Reference Intake Values for Energy for Active Individuals

Life-Stage Group	Criterion	ACTIVE PAL EER (kcal/day)	
		Male	Female
Infants			
0-6 mo	Energy expenditure + Energy deposition	570	520 (3 mo)
7-12 mo	Energy expenditure + Energy deposition	743	676 (9 mo)
Children			
1-2 yr	Energy expenditure + Energy deposition	1046	992 (24 mo)
3-8 yr	Energy expenditure + Energy deposition	1742	1642 (6 yr)
9-13 yr	Energy expenditure + Energy deposition	2279	2071 (11 yr)
14-18 yr	Energy expenditure + Energy deposition	3152	2368 (16 yr)
Adults			
>18 yr	Energy expenditure	3067 [†]	2403 [†] (19 yr)
Pregnant Women			
14-18 yr Adolescent female EER + Change in TEE + Pregnancy energy deposition			
First trimester			2368 (16 yr)
Second trimester			2708 (16 yr)
Third trimester			2820 (16 yr)
19-50 yr Adult female EER + Change in TEE + Pregnancy energy deposition			
First trimester			2403 [†] (19 yr)
Second trimester			2743 [†] (19 yr)
Third trimester			2855 [†] (19 yr)
Lactating Women			
14-18 yr Adolescent female EER + Milk energy output – Weight loss			
First 6 mo			2698 (16 yr)
Second 6 mo			2768 (16 yr)
19-50 yr Adult female EER + Milk energy output – Weight loss			
First 6 mo			2733 [†] (19 yr)
Second 6 mo			2803 [†] (19 yr)

From Institute of Medicine of The National Academies: *Dietary reference intakes for energy, carbohydrate, fiber, fat, fatty acids, cholesterol, protein, and amino acids*. Washington, DC, 2002/2005, The National Academies Press.

EER, Estimated energy requirement; PAL, physical activity level; TEE, total energy expenditure.

*For healthy active Americans and Canadians at the reference height and weight.
[†]Subtract 10 kcal/day for men and 7 kcal/day for women for each year of age above 19 years.

The prediction equations include a physical activity (PA) coefficient for all groups except infants and young children (see Box 2-1). PA coefficients correspond to four **physical activity level (PAL)** lifestyle categories: sedentary, low active, active, and very active. Because PAL is the ratio of TEE to BEE, the energy spent during activities of daily living, the sedentary lifestyle

category has a PAL range of 1 to 1.39. PAL categories beyond sedentary are determined according to the energy spent by an adult walking at a set pace (Table 2-2). The walking equivalents that correspond to each PAL category for an average-weight adult walking at 3 to 4 mph are 2, 7, and 17 miles per day, for low active, active and very active (IOM, 2002; 2005). All equations

BOX 2-1 Estimated Energy Expenditure* Prediction Equations at Four Physical Activity Levels†

EER for Infants and Young Children 0 to 2 Years (Within the 3rd to 97th Percentile for Weight-for-Height)

EER = TEE[‡] Energy deposition

0-3 months (89 × Weight of infant [kg] – 100) + 175 (kcal for energy deposition)

4-6 months (89 × Weight of infant [kg] – 100) + 56 (kcal for energy deposition)

7-12 months (89 × Weight of infant [kg] – 100) + 22 (kcal for energy deposition)

13-35 months (89 × Weight of child [kg] – 100) + 20 (kcal for energy deposition)

EER for Boys 3 to 8 Years (Within the 5th to 85th Percentile for BMI)[§]

EER = TEE[‡] Energy deposition

EER = 88.5 – 61.9 × Age (yr) + PA × (26.7 × Weight [kg] + 903 × Height [m]) + 20 (kcal for energy deposition)

EER for Boys 9 to 18 Years (Within the 5th to 85th Percentile for BMI)

EER = TEE Energy deposition

EER = 88.5 – 61.9 × Age (yr) + PA × (26.7 × Weight [kg] + 903 × Height [m]) + 25 (kcal for energy deposition)

in which

PA = Physical activity coefficient for boys 3-18 years:

PA = 1 if PAL is estimated to be ≥ 1 < 1.4 (Sedentary)

PA = 1.13 if PAL is estimated to be ≥ 1.4 < 1.6 (Low active)

PA = 1.26 if PAL is estimated to be ≥ 1.6 < 1.9 (Active)

PA = 1.42 if PAL is estimated to be ≥ 1.9 < 2.5 (Very active)

EER for Girls 3 to 8 Years (Within the 5th to 85th Percentile for BMI)

EER = TEE Energy deposition

EER = 135.3 – 30.8 × Age (yr) + PA × (10 × Weight [kg] + 934 × Height [m]) + 20 (kcal for energy deposition)

EER for Girls 9 to 18 Years (Within the 5th to 85th Percentile for BMI)

EER = TEE + Energy deposition

EER = 135.3 – 30.8 × Age (yr) + PA × (10 × Weight [kg] + 934 × Height [m]) + 25 (kcal for energy deposition)

in which

PA = Physical activity coefficient for girls 3-18 years:

PA = 1 (Sedentary)

PA = 1.16 (Low active)

PA = 1.31 (Active)

PA = 1.56 (Very active)

EER for Men 19 Years and Older (BMI 18.5 to 25 kg/m²)

EER = TEE

EER = 662 – 9.53 × Age (yr) + PA × (15.91 × Weight [kg] + 539.6 × Height [m])

in which

PA = Physical activity coefficient:

PA = 1 (Sedentary)

PA = 1.11 (Low active)

PA = 1.25 (Active)

PA = 1.48 (Very active)

EER for Women 19 Years and Older (BMI 18.5 to 25 kg/m²)

EER = TEE

EER = 354 – 6.91 × Age (yr) + PA × (9.36 × Weight [kg] + 726 × Height [m])

in which

PA = Physical activity coefficient:

PA = 1 (Sedentary)

PA = 1.12 (Low active)

PA = 1.27 (Active)

PA = 1.45 (Very active)

EER for Pregnant Women

14-18 years: EER = Adolescent EER + Pregnancy energy deposition

First trimester = Adolescent EER + 0 (Pregnancy energy deposition)

Second trimester = Adolescent EER + 160 kcal (8 kcal/wk × 20 wk) + 180 kcal

Third trimester = Adolescent EER + 272 kcal (8 kcal/wk × 34 wk) + 180 kcal

19-50 years: = Adult EER + Pregnancy energy deposition

First trimester = Adult EER + 0 (Pregnancy energy deposition)

Second trimester = Adult EER + 160 kcal (8 kcal/wk × 20 wk) + 180 kcal

Third trimester = Adult EER + 272 kcal (8 kcal/wk × 34 wk) + 180 kcal

EER for Lactating Women

14-18 years: EER = Adolescent EER + Milk energy output – Weight loss

First 6 months = Adolescent EER + 500 – 170 (Milk energy output – Weight loss)

Second 6 months = Adolescent EER + 400 – 0 (Milk energy output – Weight loss)

19-50 years: EAR = Adult EER + Milk energy output – Weight loss

First 6 months = Adult EER + 500 – 70 (Milk energy output – Weight loss)

Second 6 months = Adult EER + 400 – 0 (Milk energy output – Weight loss)

Weight Maintenance TEE for Overweight and At-Risk for Overweight Boys 3 to 18 Years (BMI >85th Percentile for Overweight)

TEE = 114 – 50.9 × Age (yr) + PA × (19.5 × Weight [kg] + 1161.4 × Height [m])

in which

PA = Physical activity coefficient:

PA = 1 if PAL is estimated to be ≥ 1.0 < 1.4 (Sedentary)

PA = 1.12 if PAL is estimated to be ≥ 1.4 < 1.6 (Low active)

PA = 1.24 if PAL is estimated to be ≥ 1.6 < 1.9 (Active)

PA = 1.45 if PAL is estimated to be ≥ 1.9 < 2.5 (Very active)

Weight Maintenance TEE for Overweight and At-Risk for Overweight Girls 3-18 Years (BMI >85th Percentile for Overweight)

TEE = 389 – 41.2 × Age (yr) + PA × (15 × Weight [kg] + 701.6 × Height [m])

in which

PA = Physical activity coefficient:

PA = 1 if PAL is estimated to be ≥ 1 < 1.4 (Sedentary)

PA = 1.18 if PAL is estimated to be ≥ 1.4 < 1.6 (Low active)

PA = 1.35 if PAL is estimated to be ≥ 1.6 < 1.9 (Active)

PA = 1.60 if PAL is estimated to be ≥ 1.9 < 2.5 (Very active)

From Institute of Medicine, Food and Nutrition Board: *Dietary reference intakes for energy, carbohydrate, fiber, fat, fatty acids, cholesterol, protein, and amino acids*, Washington, DC, 2002, The National Academies Press, www.nap.edu.

BMI, Body mass index; EER, estimated energy requirement; PA, physical activity; PAL, physical activity level; TEE, total energy expenditure. EER is the average dietary energy intake that is predicted to maintain energy balance in a healthy adult of a defined age, gender, weight, height, and level of physical activity consistent with good health. In children and pregnant and lactating women, the EER includes the needs associated with the deposition of tissues or the secretion of milk at rates consistent with good health.

¹PAL is the physical activity level that is the ratio of the total energy expenditure to the basal energy expenditure.

²TEE is the sum of the resting energy expenditure, energy expended in physical activity, and the thermic effect of food.

³BMI is determined by dividing the weight (in kilograms) by the square of the height (in meters).

TABLE 2-2 Physical Activity Level Categories and Walking Equivalence*

PAL Category	PAL Values	Walking Equivalence (Miles/Day at 3-4 mph)
Sedentary	1-1.39	
Low active	1.4-1.59	1.5, 2.2, 2.9 for PAL = 1.5
Active	1.6-1.89	3, 4.4, 5.8 for PAL = 1.6
Very active	1.9-2.5	5.3, 7.3, 9.9 for PAL = 1.75
		7.5, 10.3, 14 for PAL = 1.9
		12.3, 16.7, 22.5 for PAL = 2.2
		17, 23, 31 for PAL = 2.5

From Institute of Medicine, The National Academies: *Dietary reference intakes for energy, carbohydrate, fiber, fat, fatty acids, cholesterol, protein, and amino acids*, Washington, DC, 2002/2005, The National Academies Press.

PAL, Physical activity level.

*In addition to energy spent for the generally unscheduled activities that are part of a normal daily life. The low, middle, and high miles/day values apply to relatively heavy-weight (120-kg), midweight (70-kg), and lightweight (44-kg) individuals, respectively.

are only estimates and individual variations may be wide and unexpected (O’Riordan et al, 2010).

Estimated Energy Expended in Physical Activity

Energy expenditure in physical activity can be estimated using either the method shown in Appendix 20, which represents energy spent during common activities and incorporates body weight and the duration of time for each activity as variables, or using information in Figure 2-3, which represents energy spent by adults during various intensities of physical activity—energy

that is expressed as **metabolic equivalents (METs)** (IOM, 2002; 2005).

Estimating Energy Expenditure of Selected Activities Using Metabolic Equivalents

METs are units of measure that correspond with a person’s metabolic rate during selected physical activities of varying intensities and are expressed as multiples of REE. A MET value of 1 is the oxygen metabolized at rest (3.5 ml of oxygen per kilogram of body weight per minute in adults) and can be expressed as 1 kcal/kg of body weight per hour. Thus the energy expenditure of adults can be estimated using MET values (1 MET = 1 kcal/kg/hr). For example, an adult who weighs 65 kg and is walking moderately at a pace of 4 mph (which is a MET value of 4.5) would expend 293 calories in 1 hour (4.5 kcal × 65 kg × 1 = 293) (Table 2-3).

Estimating a person’s energy requirements using the Institute of Medicine’s EER equations requires identifying a PAL value for that person. A person’s PAL value can be affected by various activities performed throughout the day and is referred to as the change in physical activity level (Δ PAL). To determine Δ PAL, take the sum of the Δ PALs for each activity performed for 1 day from the DRI tables (IOM, 2002; 2005). To calculate the PAL value for 1 day, take the sum of activities and add the BEE (1) plus 10% to account for the TEF (1 + 0.1 = 1.1). For example, to calculate an adult woman’s PAL value, take the sum of the Δ PAL values for activities of daily living, such as walking the dog (0.11) and vacuuming (0.14) for 1 hour each, sitting for 4 hours doing light activity (0.12), and then performing moderate to vigorous activities such as

TABLE 2-3 Intensity and Effect of Various Activities on Physical Activity Level in Adults*

Physical Activity	METs*	ΔPAL/10 min [†]	Δ PAL/hr [‡]
Daily Activities			
Lying quietly	1	0	0
Riding in a car	1	0	0

Modified from Institute of Medicine of The National Academies: *Dietary reference intakes for energy, carbohydrate, fiber, fat, fatty acids, protein, and amino acids*, Washington, DC, 2002, The National Academies Press.

MET, Metabolic equivalent; PAL, physical activity level.

*PAL is the physical activity level that is the ratio of the total energy expenditure to the basal energy expenditure.

†METs are multiples of an individual's resting oxygen uptakes, defined as the rate of oxygen (O₂) consumption of 3.5 ml of O₂/min/kg body weight in adults.

‡The Δ PAL is the allowance made to include the delayed effect of physical activity in causing excess postexercise oxygen consumption and the dissipation of some of the food energy consumed through the thermic effect of food.

walking for 1 hour at 4 mph (0.20) and ice skating for 30 minutes (0.13) for a total of 0.7. To that value add the BEE adjusted for the 10% TEF (1.1) for the final calculation:

$$0.7 + 1.1 = 1.8$$

For this woman, the PAL value (1.8) falls within an active range. The PA coefficient that correlates with an active lifestyle for this woman is 1.27.

To calculate the EER for this adult woman, age 30, use the EER equation for women 19 years and older (BMI 18.5-25 kg/m²); see [Box 2-1](#). The following calculation estimates the EER for a

30-year-old active woman who weighs 65 kg, is 1.77 m tall, with a PA coefficient (1.27):

$$\text{EER} = 354 - 6.91 \times \text{Age (yr)} + \text{PA} \times (9.36 \times \text{Weight [kg]} + 726 \times \text{Height [m]})$$

$$\text{EER} = 354 - (6.91 \times 30) + 1.27 \times [(9.36 \times 65) + [726 \times 1.77]]$$

$$\text{EER} = 2551 \text{ kcal}$$

Energy spent during various activities and the intensity and impact of selected activities also can be determined for children and teens (see [Box 2-1](#)).

Physical Activity in Children

CALCULATING FOOD ENERGY

The total energy available from a food is measured with a bomb calorimeter. This device consists of a closed container in which a weighed food sample, ignited with an electric spark, is burned in an oxygenated atmosphere. The container is immersed in a known volume of water, and the rise in the temperature of the water after igniting the food is used to calculate the heat energy generated.

Not all of the energy in foods and alcohol is available to the body's cells, because the processes of digestion and absorption are not completely efficient. In addition, the nitrogenous portion of amino acids is not oxidized but is excreted in the form of urea. Therefore, the biologically available energy from foods and alcohol is expressed in values rounded off slightly below those obtained using the calorimeter. These values for protein, fat, carbohydrate, and alcohol ([Figure 2-4](#)) are 4, 9, 4, and 7 kcal/g, respectively. Fiber is an "unavailable carbohydrate" that resists digestion and absorption; its energy contribution is minimal.

Although the energy value of each nutrient is known precisely, only a few foods, such as oils and sugars, are made up of a single nutrient. More commonly, foods contain a mixture of protein, fat, and carbohydrate. For example, the energy value of one medium (50 g) egg calculated in terms of weight is derived from protein (13%), fat (12%), and carbohydrate (1%) as follows:

$$\text{Protein: } 13\% \times 50 \text{ g} = 6.5 \text{ g} \times 4 \text{ kcal/g} = 26 \text{ kcal}$$

$$\text{Fat: } 12\% \times 50 \text{ g} = 6 \text{ g} \times 9 \text{ kcal/g} = 54 \text{ kcal}$$

$$\text{Carbohydrate: } 1\% \times 50 \text{ g} = 0.05 \text{ g} \times 4 \text{ kcal/g} = 2 \text{ kcal}$$

$$\text{Total} = 82 \text{ kcal}$$

The energy value of alcoholic beverages can be determined using the following equation:

$$\text{Alcohol kcal} = \text{amount of beverage (oz)} \times \text{proof} \times .8 \text{ kcal/proof/oz.}$$

Proof is the proportion of alcohol to water or other liquids in an alcoholic beverage. The standard in the United States defines 100-proof as equal to 50% of ethyl alcohol by volume. To determine the percentage of ethyl alcohol in a beverage, divide the proof value by 2. For example, 86-proof whiskey contains 43% ethyl alcohol. The latter part of the equation—0.8 kcal/proof/1 oz—is the factor that accounts

FIGURE 2-4 Energy value of food.

for the caloric density of alcohol (7 kcal/g) and the fact that not all of the alcohol in liquor is available for energy. For example, the number of kilocalories in 1½ oz of 86-proof whiskey would be determined as follows:

$$1\frac{1}{2} \text{ oz} \times 86\% \text{ proof} \times 0.8 \text{ kcal/proof/1 oz} = 103 \text{ kcal}$$

See Appendix 32 for the caloric content of alcoholic beverages.

Energy values of foods based on chemical analyses may be obtained from the U.S. Department of Agriculture (USDA) Nutrient Data Laboratory website or from *Bowes and Church's Food Values of Portions Commonly Used* (Pennington and Spungen, 2009).

Many computer software programs that use the USDA nutrient database as the standard reference are also available and many online websites can be used. See Chapter 4.

Recommendations for macronutrient percentages vary based on the goal of the client and any underlying or overriding disease process. This is discussed in other chapters.

Inflammation and the Pathophysiology of Chronic Disease

Diana Noland, MPH, RD, CCN, LD

KEY TERMS

allostasis	genesis of disease	prostaglandins
adipokines	glutathione	reactive oxygen species (ROS)
antecedents	health continuum	resolvins
autophagy	hyperinsulinemia	quercetin
biochemical individuality	inflammation	sarcopenia
body fluid viscosity	interleukin-6 (IL-6)	sedimentation rate
C-reactive protein- hs	leukotrienes	smoldering disease
coenzyme Q-10	lipoic acid	specialized pro-resolving mediators (SPM)
conditionally essential	lipoxigenases (LOX)	systems biology
curcumin	long-latency nutrient insufficiencies	TNF-alpha
cyclooxygenases (COX)	mediators	total inflammatory load
cytochrome P450 enzymes	metabolic syndrome	triage theory
cytokines	“new-to-nature” molecules	triggers
delta-6-desaturase	nutrient-partner principle	visceral adipose tissue (VAT)
eicosanoid cascade	nutrition transition	xenobiotics
enteroimmunology	prolonged inflammation	

EPIDEMIC OF CHRONIC DISEASE

Now that the biochemical and lifestyle components of chronic disease have become more evident, the question of how to change the lifelong diet and lifestyle habits of people, as well as a food industry, an agricultural industry, the political climate, and a culture became the challenge we face today.

Sydney Baker, MD, 2009

Chronic disease in the twenty-first century is a recent phenomenon in the history of the human race (Murray et al, 2012; UN, 2011; World Health Organization [WHO], 2011; Yach, 2004). Its recognition began after World War II at the same time the very significant **nutrition transition** began to occur, first in industrialized countries, then globally. The nutrition transition includes technology that enables synthesis of “**new-to-nature**” **molecules** (Bland, 1998, 2007), rapid increases in environmental toxin exposure, and decreased physical activity. New behavior patterns have promoted a decrease in home cooking along with increases in convenience food consumption and eating out. All of these changes are accompanied by the increased use of processed, less nutrient-dense food, decreased intake of whole fruits and vegetables, and increased consumption of sugar and high-sugar-containing foods. These components of the nutrition transition do not appear to have been beneficial

to the human race, because the effects are rapidly and globally increasing the risk of being overweight and obese, along with producing epidemic levels of chronic diseases at earlier ages (Hruby and Hu, 2014; Olshansky, 2005). (see *New Directions: Is Chronic Disease an Epidemic?*).

Despite the fact that the United States spends more money on health care than any other country, according to a report by

NEW DIRECTIONS

Is Chronic Disease an Epidemic?

- If the current trend continues, 1 out of 3 U.S. adults will have diabetes by 2050 (CDC, 2011).
- 70% of U.S. deaths are from chronic disease (CDC, 2015).
- Global cancer rates could increase by 70% 2015 to 2035 (WHO, 2015).
- Two of three U.S. adults are overweight or obese.
- One third of cancer deaths are due to the five leading behavioral and dietary risks (WHO, 2015).
- Younger Americans will likely face a greater risk of mortality throughout life than previous generations (related to obesity) (Olshansky, 2005).
- The three most preventable risk factors are unhealthy diet, smoking, and physical inactivity (CDC, 2014).

the Centers for Disease Control and Prevention (CDC), 86% of the health care dollars in the United States are spent on chronic disease management (CDC, 2015). As people are living longer, the number of years spent living with disability has increased. The fact of the growing incidence of chronic disease has driven the global civilian and governmental health care systems to seek new answers to this nearly universal challenge.

The global effort to improve understanding of this chronic disease phenomenon is bringing the realization that these chronic diseases have long incubation periods (years to decades), thus they may not be observable during their early stages and may be present in an otherwise healthy-looking person. Focus on preventive care with earlier detection of signs, symptoms, and biomarkers that were previously thought insignificant allows for a chance of reversing the disease process before it becomes a serious affliction. The new phenotype of “fat, fatigued, and painful” in combination with associated conditions is descriptive of many chronic disease states considered to be preventable “lifestyle” diseases. The genotype, or genetic makeup, of a person may increase the propensity toward a chronic disease, but lifestyle—what one eats and thinks and where one lives—may be the most powerful cause of these “lifestyle” chronic diseases (CDC, 2015; Elwood et al, 2013).

CONCEPTS OF CHRONIC DISEASE PATHOPHYSIOLOGY

An understanding of the following basic concepts is essential when addressing the newly identified characteristics of chronic disease pathophysiology: systems biology, allostasis, autophagy, the health continuum, genesis of disease, long-latency nutrient insufficiencies, and nutrient-partner principle.

Systems Biology

The emerging new paradigm of systems biology (Aderem et al, 2011; Potthast, 2009) is the basis for a broader understanding of chronic disease. **Systems biology** encompasses viewing the whole person, the whole organism, and all systems working together interdependently. It provides a working model for assessing and monitoring the whole person. Chronic disease is complex and never involves just one organ or organ system. It involves underlying physiologic systems affecting the whole organism. With use of a systematic examination of an individual’s physiologic imbalances that include mind, body, and spirit, a more robust identification of metabolic priorities can be achieved by members of the health care team.

The global movement in health care toward systems biology and personalized medicine is expanding. The registered dietitian nutritionist (RDN), as a member of the health care team, has a larger role to improve the nutritional status of each individual with dietary and lifestyle modifications as a foundational component of addressing chronic disease.

Allostasis

This is a condition of metabolic stability with adjustments for environmental influences and stresses through physiologic changes. **Allostasis** will be established even under inflammatory conditions but not always for optimal function. The maintenance of allostatic changes over a long period of time can lead to wear and tear of the system and body. Inflammation may be initiated for tissue adaptation and yet may involve collateral

damage. Inflammation is particularly relevant to obesity and its associated adverse health conditions, such as type 2 diabetes, cardiovascular disease, and cancer. The ensuing systemic low-grade inflammation promotes a multitude of pathologic and self-perpetuating events, such as insulin resistance, endothelial dysfunction, and activation of oncogenic pathways (Baffy and Loscalzo, 2014).

For the nutritionist in clinical practice, the challenge is assessing metabolism and levels of inflammation at the cellular-molecular level available indirectly by using improved laboratory testing technology and scientific discovery of biochemical markers. For example, the biomarker **C-reactive protein-high sensitivity (CRP-hs)** has been shown to be the strongest univariate predictor of the risk of cardiovascular events (Ridker, 2000). It is a systemic marker of inflammation related most often to bacterial infection, trauma, and neoplastic activity with acute and chronic expression. Strong evidence indicates that the omega-3 fat EPA from fish oil has a powerful antiinflammatory effect and suppresses CRP-hs. Its measurement shows if the nutrients are balanced and working to create an allostatic microenvironment of wellness, or if there are imbalances that must be identified and restored (Baffy and Loscalzo, 2014).

Autophagy

Autophagy, or “self-eating,” results in the lysosomal degradation of organelles, unfolded proteins, or foreign extracellular material. It is a survival mechanism required for maintaining cellular homeostasis after infection, mitochondrial damage, or endothelial reticulum stress. Defects in autophagy have been shown to result in pathologic inflammation (Abraham and Medzhitov, 2011; Prado et al, 2014).

Health Continuum

Health is a continuum from birth to death. “Health is the perfect, continuing adjustment of an organism to its environment” (Wyle, 1970). Chronic disease management for an individual must include considering the entire **health continuum** history to determine which factors along the way relate to one’s current health condition. When collecting the patient’s history during the assessment, clinicians should think of a life timeline to put the health continuum in perspective (see Figure 7-9).

Genesis of Disease

Triggers, antecedents, and mediators are critical terms that are part of the **genesis of disease** that underlies the patient’s signs and symptoms, illness behaviors, and demonstrable pathology. **Triggers** are the distinct entities or events that provoke disease or its symptoms. They are usually insufficient for disease formation; host response is an essential component (Jones, 2005). **Antecedents** are congenital or developmental aspects of the individual that can include gender, family history, and genomics. These act to set the stage for the body’s response to the trigger. **Mediators** are intermediates that are the primary drivers of disease; these are biochemical (Di Gennaro, 2012) but can be influenced by psychosocial factors such as smoking or stress (Avitsur et al, 2015; see Figure 7-9).

Long-Latency Nutrient Insufficiencies

Long-latency nutrient insufficiencies (i.e., subclinical [below-optimum] or deficient nutrient pools resulting from chronic poor intake and genotype) contribute over time to development of chronic disease. New tools have to be included in nutrition

practice to expand beyond just detection of overt clinical deficiencies (Heaney, 2012). There must be further identification of biomarkers, usually biochemical and phenotypic, which are indicative of early chronic disease and are evidence based.

The nutrient deficiencies defined in the early 1900s are the end-stage and the result of specific index diseases. An example of this is the discovery that vitamin C deficiency caused scurvy in British sailors. Scurvy produces obvious clinical symptoms and death within months of the absence of vitamin C intake. In contrast, a more recent discovery is that years of subclinical vitamin C deficiency (without classic scurvy symptoms) can cause a less recognizable form of scorbutic progression in the form of periodontal gum disease (periodontitis) (Alagl and Bhat, 2015; Japatti et al, 2013; Popovich et al, 2009). Many other functions of vitamin C are compromised because of this “subclinical” deficiency (see Figure 7-2).

Nutrient-Partner Principle

Nutrient balance is the foundation of nutrition science, and this concept is expanding to appreciate the principle that, besides all macronutrients requiring balance, there are known partner nutrients involved in an individual’s nutrition and inflammatory status. An example of application of the **nutrient partner principle** is the common recommendation for adults to take calcium supplements along with vitamin D. Another example is calcium and magnesium. For years, no attempt was made to routinely assess an individual’s intake of magnesium, even though the NHANES studies showed that 70% to 80% of the U.S. population had magnesium intakes below the RDA for magnesium. With recent recognition of this calcium-magnesium partnership, many calcium supplements now contain magnesium in a 2:1 or 1:1 Ca:Mg ratio, and nutrition guidelines include the consumption of more vegetables and greens containing magnesium and calcium. The principle of nutrients as well as metabolic systems having synergistic relationships are seen in Box 3-1.

Triage Theory

The concept of nutrient **triage theory** states that “during poor dietary supply, nutrients are preferentially utilized for functions that are important for survival.” This infers that some tissues

may be lacking during times of insufficiency. This may be chronic in the person with an inadequate diet week after week, month after month, year after year, and often for decades (Ames 2010; McCann and Ames, 2011). To summarize (Heaney, 2014; Maggio, 2014):

- Most tissues need most nutrients.
- Inadequate intakes of most nutrients impair the function of most systems.
- The classical deficiency diseases occur at only the extremes of “inadequacy” (see Figure 7-2).
- The role of nutritional status as a key factor of successful aging is very well recognized (McCann and Ames, 2011).
- “Adequate” adult nutrition can be best conceptualized as preventive maintenance.

INFLAMMATION: COMMON DENOMINATOR OF CHRONIC DISEASE

Inflammation is the natural healthy reaction of the immune system as it responds to injury or infection, or flight or fright scenarios. See Box 3-2 for a classic description of inflammation.

The immune system’s response to physiologic and metabolic stress is to produce pro-inflammatory molecules such as **adipokines** and **cytokines** - cell-signaling molecules that aid cell-to-cell communication and stimulate the movement of cells toward sites of inflammation in conditions of infection and injury. Thus immune system responses and the resulting inflammation are intimately connected.

Inflammation is the complex biological response of vascular tissue to harmful stimuli such as pathogens, damaged cells or irritants that consists of both vascular and cellular responses. Inflammation is a protective attempt by the organism to remove the injurious stimuli and initiate the healing process and to restore both structure and function. Inflammation may be local or systemic. It may be acute or chronic.

Undurti N. Das, MD

Molecular Basis of Health and Disease (2011)

Optimally, the immune system’s function is to keep the body healthy, responding appropriately with an inflammatory response to environmental influences, such as short-lived infection and injury, and then returning the body to an alert system of defense. This function depends on the body’s ability to recognize “self” and “non-self.” When the immune response is successful, the tissue returns to a state of wellness, or metabolic stability described as **allostasis**. If many areas of the body’s defense system, such as the gastrointestinal barrier, stomach acidity, skin, or various orifices (e.g., eye, ear, nose, lung, vagina, uterus), are compromised, there is diminishing recognition of “self” and

BOX 3-1 Nutrient and System Partner Principles

Nutrient Partners

- Calcium – Zinc – Copper
- Omega 6 GLA/DGLA - Arachidonic Acid – Omega 3 EPA/DHA
- Sodium chloride – potassium - calcium
- B Complex (B1-B2-B3-B5-B6-B9 (folate)-B12-Biotin-Choline)
- Antioxidants – reactive oxygen species (ROS)
- Albumin – globulin

System Partners and Rhythm Cycles:

- Autonomic Nervous System: sympathetic – parasympathetic
- Circadian Rhythm: 24 hour balanced rhythm
- Acid-Base Balance
- Microbiome: oral, nasal, skin, lung, vaginal, gastrointestinal
- Hormones-biochemistry
 - Cortisol - insulin - glucose
 - Estrogen – progesterone -testosterone
 - T4-T3 (total and free forms)
 - HPTA axis – Hippocampus – Pituitary – Thyroid - Adrenal

BOX 3-2 The five classic signs of inflammation, first described and documented by Aulus Cornelius Celsus (ca 25 BC-ca 50), a Roman physician and encyclopaedist

- **Dolor** - “pain”
- **Calor** - “heat”
- **Rubor** - “redness”
- **Tumor** - “swelling”
- **Functio laesa** - “injured function” or “loss of function”

“non-self” until the body is repaired. The longer the physiologic injury continues, the greater the loss of the ability to recognize “self” and “non-self” (Fasano, 2012; Wu et al, 2014).

If the underlying cause is not resolved, the immune response can get “stuck” in a state of **prolonged inflammation**. Locked into this state for a while, the immune system loses its ability to recognize “self” and “non-self,” a critical survival skill and the core of immunology (Paul, 2010; Queen, 1998).

Prolonged Inflammation

Prolonged inflammation, known as chronic inflammation, sustained inflammation, or non-resolving inflammation, leads to a progressive shift in the type of cells present at the site of inflammation and is characterized by simultaneous destruction and healing of the tissue from the inflammatory process. Multiple studies have suggested that prolonged inflammation plays a primary role in the pathogenesis of chronic diseases (e.g., arthritis), when the immune response is to increase the ratio of proinflammatory to antiinflammatory cytokines (Bauer et al, 2014; Franceschi and Campisi, 2014).

One of the most fundamental characteristics of all chronic diseases is the initiation and continuation of a prolonged inflammation over all or part of the lifespan, leading to clinical chronic disease (Bauer et al, 2014). In the chronology of chronic disease progression, inflammation is at first subclinical, often referred to as “silent inflammation.” This insidious inflammation remains below the threshold of clinical diagnosis. Cellular and tissue damage occurs in the body for years before being noticed. It is like a “smoldering” fire with a small whiff of smoke and heat being evident before it finally bursts into a flame. Some refer to early chronic disease as a “**smoldering disease**” (Noland, 2013). Chronic disease inflammation is described as:

Low-grade, chronic, systemic inflammation may be defined as a 2- to 3-fold elevation of circulating inflammatory mediators, usually associated with the innate arm of the

immune system. It is a state that develops slowly (in contrast to pathological acute inflammatory responses, to sepsis for example), and its origin cannot be easily identified (in contrast to chronic inflammatory diseases such as rheumatoid arthritis and inflammatory bowel disease, where additional symptoms identify local dysregulated inflammation). This makes it difficult to develop appropriate therapeutic strategies that target both cause and symptom (inflammation) in a concerted fashion (Calcada et al, 2014).

Of grave concern is the initiation of prolonged inflammation in utero from the maternal inflammatory environment, thereby programming the fetus for a lifetime of chronic disease (Barker, 1998; Delisle, 2002; European Foundation for the Care of Newborn Infants [EFCNI], 2015; Fisher et al, 2012; Fleisch et al, 2012; see Chapter 15).

Clinical elevations of inflammatory biomarkers, such as **high-sensitivity C-reactive protein (CRP-hs)** (plasma), **sedimentation rate**, **interleukin-6 (IL-6)**, and **TNF-alpha**, represent systemic markers of inflammation that are exacerbated by insulin resistance (IR) and hyperinsulinemia (Das, 2012, 2014; see Table 3-1). Diseases well characterized by these markers include heart disease, diabetes, autoimmune diseases, and possibly cancer and Alzheimer’s disease (Birch et al, 2014; Wu, 2013).

There are other common physiologies shared by these inflammatory conditions that include changes in nutrient tissue pools, plasma, and RBC membrane composition of polyunsaturated fatty acids and antioxidants. This multifactorial syndrome (often referred to as metabolic syndrome) is related to obesity, and more importantly, insulin resistance and central adiposity evidenced by the presence of **visceral adipose tissue (VAT)**. (See Chapters 7 and 30 for discussion of the metabolic syndrome). However, the expression of the prolonged inflammation is individual, and all individuals need not necessarily have all the characteristics described above.

TABLE 3-1 Biomarkers of Prolonged Inflammation

Test	Reference	Association
Blood Speciman		
8-hydroxy-2-deoxyquanosine	< 7.6 ng/ml	DNA increased ROS and cell proliferation*
Asymmetric dimethylarginine (ADMA)	<18 years: not established ≥18 years: 63-137 ng/mL	Inhibitor of Larginine (Arg)-derived nitric oxide (NO)
C-reactive protein hi sensitivity	≤3.0 mg/L	Systemic inflammation related to bacterial infection, trauma, VAT, neoplastic activity
CA-125	0-35 U/mL	Inflammation in abdomen Ovarian cancer Uterine fibroids
CA 15-3/CA 27-29	<32 U/mL	Breast Cancer, advanced
CA-19-9	<55 U/mL	Pancreatic cancer
Carbohydrate Ag 19-9 (screening test)	Up to 20% of individuals do not express CA 19-9.	Infections in your liver, gallbladder, and pancreas.
CEA (other specimens also)	12-100 years: 0-5.0 ng/mL	Cancer
CD4 Lymphocyte		HIV infections, autoimmune
CD4 percent		
CD8 Count		Infections Lymphoma
Ceruloplasmin (bound copper/ acute phase reactant)	18-46 mg/dL	Acute Phase Reactant Cancer (elevated) Wilson’s Disease (low) Menkes syndrome (low)

Continued

TABLE 3-1 Biomarkers of Prolonged Inflammation—cont'd

Test	Reference	Association
Eosinophils	1-4%	Elevated inflammatory marker of Allergies/ sensitivities, helminthic, parasites, autoimmune, neoplasms
Ferritin (storage iron)	Males \geq 5 years: 24-150 ng/mL Females \geq 5 years: 12-150 ng/mL	Acute Phase Reactant Hemochromatosis (genetic) Iron Toxicity
Fibrinogen / Platelets	150-450 mg/dL / 150-450 billion/L	Disseminated intravascular coagulation (DC) Liver disease
Homocysteine (Hcy)	0-15 umol/L	Block in homocysteine metabolism to cystothionine relate to B ₆ , B ₁₂ , folate, betaine co-factors
IgA Total or IgA specific	50-350 mg/dl	Elevated in lymphoproliferative disorders; chronic infections; autoimmune; celiac disease.
IgE Total or IgE specific	800-1500 mg/dl	Elevated immediate-response inflammatory allergic disorders; parasitic infections;
IgG Total or IgG specific	800-1500 mg/dl	Elevated inflammation marker of delayed sensitivities; chronic infections.
Interleukin-1 (IL-1)	<3.9 pg/mL	Bone formation, insulin secretion, appetite regulation, fever reduction, neuronal development
Interleukin 8 (IL-8)	<17.4 pg/mL < or = 5 pg/mL (2014)	Neoplasms /promotes angiogenesis Obesity Oxidative Stress
Insulin (Korkmaz 2014)	2.0-12.0 uIU/ml	Elevated inflammatory insulin resistance.
Lipid Peroxides	<2.60 nmol/ml	Inflammatory elevation when risk of oxidative stress/ elevated triglycerides.
Liver enzyme: ALT	0-35/U/L	Inflammatory elevation in liver disease
Liver enzyme: AST	0-35 U/L	Inflammatory elevation with liver, kidney, muscle infection or injury.
Liver enzymes: Alk Phos	30-120 U/L	Inflammatory elevation related to liver, bone, placenta
Liver enzyme: GGT	0-30 U/L	Elevated inflammatory marker of liver disease, neoplasms, toxicity
Liver enzyme: LDH	50-150 U/L	
Prostate Specific Antigen (PSA)	Total PSA \leq 4.0 ng/mL % Free PSA $>$ 25 % (calc)	Prostate inflammation Prostate cancer
Rheumatoid factor (RF)	Less than 40-60 u/mL Less than 1:80 (1 to 80) titer	Rheumatoid Arthritis Sjorgrens Autoimmune disease
Sedimentation Rate/ ESR Westergren	Male <50 years old:<15 mm/hr Male>50 years old:<20 mm/hr Female<50years old:<20 mm/hr Female >50 years old:<30 mm/hr	Systemic inflammation marker related to autoimmune; viral infections; rouleaux; carcinoid influence.
Total Protein	60-80g/L. 6.0-8.0g/dl),	Total Protein in serum
Albumin	35 - 50 g/L (3.5 - 5.0 g/dL) (half-life ~ 20 days)	Acute Phase Reactant
Globulin	2.6-4.6 g/dL.	Chronic inflammation, low albumin levels and other disorders
TH17	0.0 – 1.9 pg.ml	Fungal, bacterial, viral infections, autoimmune conditions
Interlukin 17 (IL-17)		
TNF-a	1.2-15.3 pg/mL	Systemic inflammation Acute Phase Reactant Alzheimer's, infection, depression, IBD, cancer
Uric Acid	2-7 mg/dl	Antioxidant, elevated in abnormal urate cycle exacerbated by protein in diet, gout, other.
VEGF	31-86 pg/mL	Cancer, angiogenesis
White blood cell count	4.5- 11 x10E3/uL	(elevated) Leukocytosis , bacterial infections, anemia, cigarette smoking (Low) Cancer, radiation, severe infection
Stool Specimen		
Calprotectin	2–9 years 166 μ g/g of feces 10–59 years 51 μ g/g of feces \geq 60 years 112 μ g/g of feces	Inflammatory Bowel Disease Intestinal inflammation Neoplasms
Lactoferrin	Negative	Intestinal inflammation
Pancreatic elastase I	> 200 mcg/g	Exocrine pancreatic function
Urine		
5-hydroxyindoleacetate (5-HIAA)	1.6-10.9 mcg/ml creatinine	Elevated with inflammatory breakdown of serotonin.
p-hydroxyphenyllactate (HPLA)	<1.45 mcg/ml creatinine	Inverse relationship to depletion of ascorbic acid

*Normal value ranges may vary slightly among different labs

For the nutritionist to incorporate the related factors of prolonged inflammation into the nutrition assessment, it is useful to conceptualize an overview of a person's **total inflammatory load** (see Figure 3-1). It is a compilation of every factor in the patient's history or story that contributes to the inflammation that a person carries.

As various factors are identified within diet, lifestyle, environment, and genetics, the pattern of where the most inflammatory risk is being generated becomes clear and gives a basis of how to intervene with a plan for medical nutrition therapy (MNT).

Antigens

Antigens are a source of inflammation that become chronic with chronic exposure (see Chapter 26). During assessment of the total inflammatory load of an individual, the “antigenic load” is important. Antigens usually are thought to come from foods to which one is either allergic or sensitive, but also can be derived from cosmetics, clothing, inhalants, furniture, household building materials, and other substances in the environment. Antigens from food are much more likely to be significant when a person has lost gut barrier integrity and a situation of intestinal permeability, sometimes referred to as “leaky gut” exists (Fasano, 2012). This condition provides access of larger molecules into the internal microenvironment, setting off a cascade of immunologic responses (see Chapters 26 and 28).

Genomics

Predictive genomic testing, family history, and personal history are gathered as the practitioner hears the patient's story during an assessment. This information helps to paint a picture of biochemical individuality (Williams, 1956), which influences the response to inflammation. Since the completion of the Human Genome Project (2003), the rapid development of genomic testing for clinical application has greatly enhanced the toolbox of the nutrition practitioner. Nutrigenomics, nutrigenetics, and epigenetics are new fields of study about the way the individual metabolically interacts with their environment (Dick, 2015; see Chapter 5).

Body Composition

Chronic diseases are related directly to increased body fat exacerbated by physical inactivity, poor diet, lack of restorative

sleep, and immune stress, all of which drive increased inflammation. Of equal importance with increased body fat percentage is the fat distribution. Central adiposity at all ages is the most serious health concern. **Visceral adipose tissue (VAT)** has been discovered to have endocrine functions with the secretion of several known inflammatory adipokines, such as resistin, leptin, and adiponectin, and tumor necrosis-factor-alpha (TNF-alpha)—all contributing to the systemic total inflammatory load (Hughes-Austin et al, 2014). **Sarcopenia** results from a wasting of lean body mass from the ongoing inflammatory burden and is exacerbated by decreased physical activity. Most often the sarcopenia is accompanied by increased body fat percentage, especially the deposit of VAT with increasing waist circumference.

Body composition can be assessed (see Chapter 7), and if found to be abnormal based on an individual's lean body mass (LBM) and fat mass (FM), it should be considered a primary marker for monitoring prolonged inflammation (Biolo et al, 2015; Juby, 2014; Stenholm et al, 2008).

Obesity today stands at the intersection between inflammation and metabolic disorders causing an aberration of immune activity, and resulting in increased risk for diabetes, atherosclerosis, fatty liver, and pulmonary inflammation to name a few.

Khan et al, 2014a

In addition to assessing those who are overweight, obese, and have VAT, it is important to assess those with normal or low BMIs. However, body composition phenotypes cannot be determined based solely on BMI (Roubenoff, 2004). See Chapter 7 for assessment of body composition (see *Clinical Insight: Sarcopenic Obesity*).

Energy Dysregulation

Another underlying physiologic system involved in inflammation is compromised mitochondrial production of adenosine triphosphate (ATP) (Cherry and Piantadosi, 2015). Assessment of mitochondrial function focuses on structure and function by considering co-nutrients such as coenzyme Q10 and alpha-lipoic acid (already produced by the body) and their protective effects against oxidative stress. Quelling systemic prolonged inflammation promotes a healthier microenvironment for improved mitochondrial function and energy production.

Mitochondrial disease or dysfunction is an energy production problem. Almost all cells in the body have mitochondria, which are tiny “power plants” that produce a body's essential energy. Mitochondrial disease means the power plants in cells do not function properly. When that happens, some functions in the body do not work normally. It is as if the body has a power failure: there is a gradation of effects, like a “brown out” or a “black out.”

The ratios of carbohydrate, fat, and protein affect mitochondrial function, primarily affecting glucose-insulin regulation. During each assessment, determination of the most favorable macronutrient ratios and individual nutrient requirements provides the foundation for the most effective interventions for restoring mitochondrial health and general wellness. The complaint of “fatigue” is the most common phenotypic expression of mitochondrial dysfunction (<http://mitochondrialdiseases.org/mitochondrial-disease/>, 2013. Accessed 02.07.15.) (see *New Directions: Inflammaging*).

CLINICAL INSIGHT

Sarcopenic Obesity

Clinical Insight: Sarcopenic Obesity

Body composition Phenotypes

In this figure, body composition is depicted by a spectrum of ASMI and FMI (low to high). On the basis of the Baumgartner model (Waters and Baumgartner, 2011), these phenotypes can be depicted as follows:

LA-HM = low adiposity with high muscle mass (individuals with low FMI and high ASMI)

HA-HM = high adiposity with high muscle mass (individuals with high FMI and ASMI)

LA-LM = low adiposity with low muscle mass (individuals with low ASMI and FMI)

HA-LM = high adiposity with low muscle mass (individuals with high FMI and low ASMI).

Those with **LA-HM** would be the least healthiest.

Cutoffs were defined according to the following deciles:

LA-HM (ASMI: 50–100; FMI: 0–49.99)

HA-HM (ASMI: 50–100; FMI: 50–100)

LA-LM (ASMI: 0–49.99; FMI: 0–49.99)

HA-LM (ASMI: 0–49.99; FMI: 50–100).

ASMI, appendicular skeletal muscle mass index; **FMI**, fat mass index

tract, and nose/lung) and reveal data that exceed expectations. The total number of genes in the human microbiome exceeds the human genome tenfold. When the delicate microbiome community in and on the body is disturbed and altered from healthy baseline, it becomes a factor in promoting prolonged inflammation and affects the way food is used. The loss of microbiome diversity and the presence of specific undesirable or virulent bacteria appears to be a common finding related to various diseases (Fasano, 2012; Viladomiu, 2013).

The cause of these changes in the patterns of microbiota from “healthy” to dysfunctional appears to be influenced by genetics, diet, exposure to environmental toxins, and antibiotic use (National Institutes of Health [NIH], 2014). After pathology has been determined, the systems biology-based practitioner often uses the functional Comprehensive Digestive Stool Analysis (CDSA) testing to provide more quantitative and specific information regarding the condition of the gut environment and microbiology. The CDSA tests for inflammatory markers such as calprotectin, lactoferrin, and pancreatic elastase 1 in the gut, much like sedimentation rate or C-reactive protein-ultra sensitive (CRP_{us}) and IgA are markers of inflammation in the blood (Gommerman, 2014). Because the GI tract contains about 70% of the immune system, it is important to assess the condition of the GI tract—from the mouth to the anus—as part of the total inflammatory load of an individual (Underwood, 2014). A new field of study regarding diseases that are related to disturbances in the gut environment and the immune system is called **enteroimmunology** (Lewis, 2014; see Figure 3–2).

Hypercoagulation

With inflammation comes an increasingly unhealthy degree of coagulation within body fluids. At some point, the microenvironment becomes too sluggish and congested, facilitating the development of chronic diseases such as cancer, cardiovascular disease, and infectious diseases (Karabudak et al, 2008). This increase in **body fluid viscosity** promotes secretion of more pro-inflammatory immune cytokines and chemokines that can set the stage for any of the chronic disease conditions. Autophagy is the normal response to raise the level of proteolytic enzymes to “clean up” the cell debris and prepare it for recycling or elimination (Gottlieb and Mentzer, 2010; Gurkar et al, 2013; Wallace et al, 2014).

Dietary factors helping to maintain healthy fluid viscosity are hydration, vitamin E with significant gamma-tocopherol, polyunsaturated fatty acids (PUFAs), monounsaturated fats (MUFAs), and avoidance of any chronic subclinical infections and foods or substances that may act as antigens (see Chapter 26). Common biomarkers of increased body fluid viscosity are blood fibrinogen with platelets, and urinalysis measurements of specific gravity and the presence of “cloudiness” or mucus.

Infection

Acute infections are easily recognized and diagnosed because of their blatant signs and symptoms such as fever, leukocytosis, pus, and tachycardia. Subclinical infection processes, on the contrary, may go unnoticed for years or decades while promoting a “smoldering,” under-the-radar, inflammatory condition

NEW DIRECTIONS

Inflammaging

Aging is a ubiquitous complex phenomenon that results from environmental, stochastic, genetic, and epigenetic events in different cell types and tissues and their interactions throughout life. A pervasive feature of aging tissues and most if not all age-related diseases is chronic inflammation. “Inflammaging” describes the low-grade, chronic, systemic inflammation in aging, in the absence of overt infection (“sterile” inflammation) and is a highly significant risk factor for morbidity and mortality in the elderly (Franceschi and Campisi, 2014).

Microbiome

After the Human Genome Project, the National Institutes of Health (NIH) launched studies for genomic identification and characterization of the microorganisms associated with healthy and diseased humans. The exciting findings focus on five body sites (mouth, skin, vagina, gastrointestinal (GI)

FIGURE 3-2 Enteroimmunology

that wears away at the integrity of the body cells and tissues. Good examples are hepatitis C virus (HCV), which begins as an acute infection but persists as a chronic infection in the liver (Vescovo et al, 2014), and human papilloma virus (HPV), which becomes chronic in cervical tissue and may lead to cervical cancer.

All chronic infections raise the level of immune response to produce inflammatory mediators and are exacerbated by nutrient insufficiencies and deficiencies and imbalances between prooxidant and antioxidant conditions (Cokluk et al, 2015). Other nutrients, when insufficient for optimum function, are involved in permitting chronic infections to persist over decades include vitamin D, vitamin C, and methylation nutrients such as folate, B₁₂, B₆, and B₂, which act as co-nutrients in inflammation and immune-control mechanisms (Ames, 2010). In addition, the health of the microbiome in the gastrointestinal tract, the skin, and other body orifices plays a critical role in inflammation and immune strength or weakness.

Stress

Stress is inflammatory. The sources of metabolic stress may include injury, infection, musculoskeletal misalignment, lack of sleep, emotions, unhealthy diet, smoking, quality of life challenges, or lack or excess of physical activity. Whatever the source, stress can increase nutrient requirements contributing to depletion and the level of oxidative stress risks of damage to body cells and tissues.

NUTRIENT MODULATORS OF INFLAMMATION

For the prostaglandins formed from the eicosanoid cascade, there are vitamin, mineral, and antioxidant nutrients that act as rate-limiting cofactors for the shared delta-5 and delta-6 desaturase and the elongase enzymes required for conversion of the essential fatty acids (EFA) and polyunsaturated fatty acids (PUFAs) to **prostaglandins**. These co-nutrients, listed in Figure 3-3, have the important ability to modulate the fatty acids and their antiinflammatory products

S.P.M. = Specialized pro-resolving mediators
 COX = Cyclooxygenase
 LOX = Lipoxygenase

FIGURE 3-3 Mechanisms of essential fatty acids and Eicosanoid metabolites in modulating inflammation Inflammatory biological responses are driven by a balance between feedback loops, much like a “toggle” switch, influenced by messages from hormones, lifestyle and nutrient co-factors (see primary enzyme nutrient-co-factors listed in diagram). The Eicosanoid biological cascade responses receive environmental messages from diet, lifestyle, infection and trauma. From the essential fatty acids (LA, ALA), downstream metabolites are produced dependent on hormonal messages, genotype and adequate nutrient co-factors of enzymatic conversion activity. Acute inflammatory triggers to initiate a healing response from infection or trauma are then resolved to homeostasis by specialized proresolving mediators (SPM) in healthy subjects. This complex dance of biochemical activity is handicapped by interfering conditions (see (circle with X in it) noted in the diagram above). Nutrition status from regular intake over the lifespan of essential fatty acids and nutrient dense whole foods build the foundation for healthy Eicosanoid management of acute and prolonged inflammation.

that have key roles in the pathophysiology of chronic disease and systemic inflammation that contributes to its progression.

Nutrient insufficiencies and imbalances that accompany prolonged inflammation initially can go unrecognized. Along with possible insufficient dietary intake of nutrients, there can potentially be imbalances of the body nutrient reservoirs. Various stressors or genomic single nucleotide polymorphisms (SNPs) (see Chapter 5) can also cause increased nutrient requirements to meet metabolic needs, and those depleted nutrients become “**conditionally essential**” for an individual. Dr. Robert P. Heaney has provided a simplified conceptual diagram called the sigmoid curve to illustrate the concepts of dynamic varied nutrient needs of the physiologic “nutrient needs spectrum.” (see Figure 3-4).

Nutriture is the state of nutrition. This skill of assessing the *nutriture* condition of body tissues relies on evidence-based research, physiologic science-based, individual nutrient therapy skills, and the awareness that no nutrient functions in isolation but has extensive interaction with other molecular compounds (e.g., hormones, nutrients, ROS). Manipulating biologic function with nutrition always must include consideration of the “rate limiting” restrictions on a biochemical system. Like a food recipe, if any “ingredient” in the “biology of life recipe” is depleted or missing, the final product is flawed (see <http://blogs.creighton.edu/heaney/2013/06/25/some-rules-for-studies-evaluating-nutrient-effects/>).

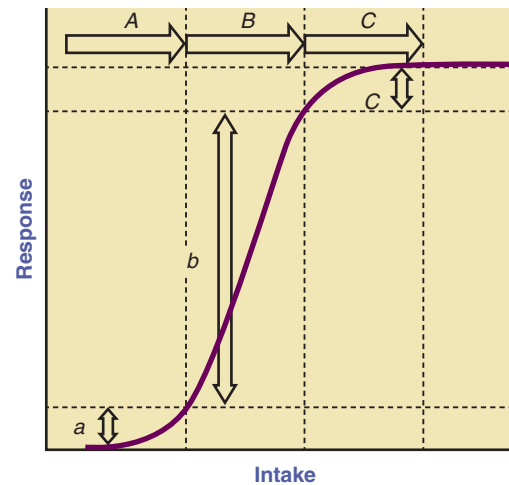

Examples of some critical nutrient-partner balances are omega-6 and omega-3 fatty acids, vitamin D and vitamin A, magnesium and calcium, and folate, B₆, B₂, and B₁₂. In whole or unprocessed foods, these nutrients naturally exist in balance, such as vitamin A and D in cod liver oil, in liver, and in eggs (see Box 3-1).

The nutrient partners most strongly associated with influencing prolonged inflammation are discussed below.

Omega-6 Linoleic Acid and Omega-3 Alpha-Linolenic Acid (Essential Fatty Acids)

Fish ingestion several times a week has been associated with reduced risk of chronic disease, especially cardiac disease. It is a characteristic of the Mediterranean Diet (Pallauf et al, 2013), the Asian Diet (Kruk, 2014), and the more recently studied Nordic or Viking Diet described in the Systems Biology in Controlled Dietary Interventions and Cohort Studies (SYSDIET) (Kolehmainen, 2015; Uusitupa et al, 2013). The human metabolism of oils in fish and their bioactive mediators provide important factors in inflammatory processes. The relationship of diet to inflammatory biochemistry supports a strong position for the nutritionist to develop individualized interventions to ensure adequate balance of the eicosanoid-producing foods that decrease inflammation.

Three main groups of prostaglandin metabolites are formed from the two initial essential fatty acids in the eicosanoid cascade (linoleic acid [LA] and alpha-linolenic acid [ALA]): prostaglandin 1 (PGE1) (omega 6 di-homo gamma-linoleic acid [DGLA]-derived antiinflammatory), prostaglandin 2 (PGE2) (omega 6-arachidonic-derived pro-inflammatory), and prostaglandin 3 (PGE3) (omega 3-derived antiinflammatory). These metabolites are precursors for a wide range of bioactive lipid mediators influencing inflammation within the body. Again, like making a recipe in the kitchen, the nutritionist

Typical sigmoid curve showing physiological response as a function of nutrient intake. Depicted are the expected responses from *equal* increments in intake, starting from a low basal intake, and moving to progressively higher starting levels. Intake increments A, B, and C produce responses, a, b, and c, respectively. Only intakes in the B region produce responses large enough adequately to test the hypothesis that the nutrient concerned elicits the response in question. (Copyright Robert P. Heaney, MD., 2010. FIGURE 3-4 Sigmoid Curve (Heaney 2010) PERMISSION BY ROBERT HEANEY Heaney RP: The Nutrient Problem, *Nutr Rev* 70:165, 2012.

can assess and then develop an individualized intervention “recipe” to return the individual’s metabolic balance in these three groups of metabolites of the eicosanoid series toward wellness for the individual. The most accurate way to assess fatty acid status is to evaluate dietary fat intake (see Table 3-2), absorptive capacity (bile adequacy, pancreatic function), and red blood cell (RBC) fatty acids (Kelley, 2009). Collecting this nutrition data for an individual during assessment can reveal important underlying physiologic imbalances. (See Chapters 4 and 7.)

The balance between the two eicosanoid pathways, omega-3 and omega-6, exert inflammatory control in response to the metabolic environment (Gil et al, 2015). Prostaglandins contribute to the regulation of vascular tone, platelet function, and fertility (Ricciotti and FitzGerald, 2011; Stipanuk and Caudill, 2013). They also play key roles as inflammatory mediators and modulators of tumor biology and are major regulators of growth and transport in epithelial cells (Varga et al, 2014). Although technically hormonal in function (autocrine/paracrine), because they do not have a specific organ of secretion, they are not often referred to as such.

The prostaglandins formed as downstream metabolites are the primary metabolic control for acute and chronic inflammation. The seminal observation that omega-3 EPA could modulate eicosanoid biosynthesis to suppress arachidonic acid biosynthesis, an omega-6 fatty acid, was first made in 1962 (Machlin) and 1963 (Mohrhauer and Holman) and initiated the plethora of research on the use of fish oil supplements to calm inflammation.

TABLE 3-2 Fat-Oil Dietary Intake Survey

Fats and Oils

Please indicate how many times PER WEEK you eat the following fats/oils.

OMEGA 9 (stabilizer)

~50% of daily fat calories

Oleic Fatty Acid

- Almond Oil
- Almonds/Cashews
- Almond butter
- Avocados
- Peanuts
- Peanut butter (natural/soft)

- Olives
- Olive Oil
- Sesame Seeds/Tahini
- Hummus (tahini oil)
- Macadamia Nuts
- Pine Nuts

OMEGA 6 (controllers)

Essential Fatty Acid Family

~30% of daily fat calories

LA→GLA→DGLA→AA

- Eggs (whole), organic (AA)
- Meats (commercial) (AA)
- Meats (grass-fed, org) (AA)
- Brazil nuts (raw)
- Pecan (raw)
- Hazelnuts/Filberts (raw)
- Hemp Seeds

- Evening Primrose (GLA)
- Black Currant Oil (GLA)
- Borage Oil (GLA)
- Hemp Oil
- Grapeseed Oil
- Sunflower Seeds (raw)
- Pumpkin seeds (raw)

OMEGA 3 (fluidity/communicators)

Essential Fatty Acid Family

~10% of daily fat calories

ALA→EPA→DHA

- Fish Oil capsule: ↑DHA
- Fish Oil capsule: ↑TEPA
- Fish (salmon/fin-fish)
- Fish (shellfish)
- Flax seeds/meal

- Flax Oil
- UDO's DHA Oil
- Algae
- Greens Powder w/algae
- Chia seeds

BENEFICIAL SATURATED (structure)

~10% of daily fat calories

Short Chain/Medium-chain Triglycerides

- Coconut Oil
- Butter, organic
- Ghee (clarified butter)
- Dairy, raw & organic

- Meats, grass-fed
- Wild game
- Poultry, organic
- Eggs, whole organic

DAMAGED FATS/OILS (promoting stress to cells & tissues)

Should be <5% (try to avoid)

Trans Fats

Acrylamides

Odd-Chain Fatty Acids

VLCFA/damaged

- Margarine
- Reg. vegetable oils (corn, sunflower, canola)
- Mayonnaise (Commercial)
- Hydrogenated Oil (as an ingredient)
- "Imitation" cheeses
- Tempura

- Doughnuts (fried)
- Deep-fried foods
- Chips fried in oil
- Regular salad dressing
- Peanut Butter (JIF, etc)
- Roasted nuts/seeds
- Products with hydrogenated fats

©2004, Diana Noland MPH RDCCN

An interesting molecule is formed from the eicosanoid cascade, omega-3 DHA, a C22 with antiinflammatory effects (Shichiri et al, 2014), collaborating with the omega-3 EPA. EPA and DHA are found in fish oil, and they are biochemically reversible, meaning they can be metabolized from one molecule to the other. DHA is a critical component of many body tissues such as the eye and brain, and it contributes to modulation of metabolic inflammation. It illustrates the enormous capacity of the body to have redundant and multiple systems to provide essential molecules for metabolism.

The key eicosanoid metabolic intersections in the eicosanoid cascade are omega-6 gamma-linolenic acid (GLA), di-homo-gamma linolenic acid (DGLA), and arachidonic acid (AA) co-existing with omega-3 eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). As the knowledge of the functions of these eicosanoid metabolites has matured over the past 50 years, their synergistic relationships and the need to keep them in homeostatic balance is now appreciated (Das, 2011). The omega-6 and omega-3 eicosanoids share the same desaturase and elongase enzymes, so there is a competition between the two, ready to move in response to the environment and availability of cofactor nutrients (Reed, 2014).

Today, knowledge that fatty acid intake can change physiologic responses by modification of eicosanoid metabolism to favor synthesis of antiinflammatory prostaglandins and **leukotrienes** (produced by the oxidation of arachidonic acid) can help manage chronic inflammation (Arm et al, 2013). As more RCT studies are

available, it is hoped this will result in an improved model for study of nutrient synergistic influences on metabolism. Wergeland and colleagues designed a multivariable study of a combination of fatty acid therapies that showed a suppression of inflammation in multiple sclerosis described as "beneficial disease-modifying effect of increased intake of polyunsaturated fatty acids (PUFAs)" (Wergeland et al, 2012). Even as far back as 1993, Berth-Jones hypothesized that "since both $\omega 6$ and $\omega 3$ essential fatty acids may possess this property [anti-inflammatory], it is possible that giving both together will have a synergistic effect" (1993).

Metabolically the five primary eicosanoids (GLA, DGLA, AA, EPA, DHA) collaborate and compete for shared enzymes in forming the prostaglandin groups: prostaglandin 1 (PGE1), prostaglandin 2 (PGE2), and prostaglandin 3 (PGE3) series (see Figure 3-3). Each plays a critical role in the control of inflammatory conditions. Until the research interest in the 1990s of the dynamic influence omega-3 EPA has on elevated omega-6 AA, dietary intake of the essential fatty acids was the main determinant of the levels of these fatty acids in tissue composition.

However, as awareness of omega-3 and its function increased, a large portion of the U.S. population is now adding omega-3 fatty acids to their regular nutraceutical intake. This has resulted in some individuals who take more than 500 mg EPA and/or DHA daily with the result that arachidonic acid and gamma-linolenic acid (GLA) biosynthesis is suppressed with the potential to unbalance the levels of these two molecules (Horribin, 2000). Nutrient partners require balance for optimum metabolic function. A nutrition assessment

should consider the fatty acid supplements a client is taking and for how long, in addition to the amount in the diet to assess the potential for imbalance. If laboratory testing of fatty acid parameters is available, it can add a quantitative evaluation to the assessment (Djousse et al, 2012; Guo et al, 2010; Mouglos et al, 1995) (see Chapter 7).

Prostaglandin 1 Series (PGE1): Antiinflammatory

PGE1 metabolites are part of the balancing act between prostaglandin groups to manage inflammation, with a primary anti-inflammatory effect on the tissue microenvironment. PGE1 is particularly important for the effects of GLA and its conversion to DGLA in managing inflammation. GLA not only attenuates intracellular inflammation by converting to DGLA (Arm et al, 2013) but also reduces inflammation in the extracellular matrix present in diabetic nephropathy (Kim et al, 2012). Evidence suggests skin integrity and other inflammatory conditions have a “conditionally essential” (Kendler, 2006) need for GLA (Harbige, 2003; Muggli, 2005).

Another physiologic function of the fatty acids is that GLA, DGLA, EPA, and DHA, if kept in balance, can function as inhibitors of tumor cell proliferation and migration in in-vitro and in-vivo conditions (Rahman et al, 2013; Wang et al, 2012; Yao et al, 2014).

Prostaglandin 2 Series (PGE2): Pro-inflammatory When in Excess

PGE2's ability to increase tissue inflammation is part of the cause of inflammation with pain, swelling, fever, redness, and constriction of blood vessels that lead to loss of function. Arachidonic acid (AA) increases with acute injury to bring inflammation and increased healing blood flow, but with chronic disease's prolonged character, AA can get “stuck” in an elevated state and continue to damage tissue and encourage degeneration. The neoplastic disease overproduction of PGE2 in the tumor environment has been found to simulate the growth and formation of a substantial number of carcinomas (Goodwin, 2010).

AA can become dangerously elevated, especially when dietary intake has deficient levels of omega-3 ALA, EPA, and DHA to act as an AA counterbalance. The United States and most industrialized countries' populations live with high AA levels because of low intake of omega-3 oils and large intakes of highly processed PUFAs and trans fats.

With all the reporting over the past 20 years of elevated AA being the generator of the fire of chronic disease, AA function in a healthy human must be acknowledged for its positive contribution to stable cell membranes and inflammation control. AA has essential functions in platelet aggregation and vasoconstriction, for example. Targeted nutrition therapy must have a goal of healthy homeostasis requiring monitoring to ensure omega-3 supplementation does not cause AA levels to fall too low (Khan et al, 2014).

Prostaglandin 3 Series (PGE3): Antiinflammatory

Another aspect of antiinflammatory action lies in the PGE3 group and their metabolites, leukotriene-5 series and others, which promote suppression of AA, GLA, and DGLA. They are most studied in relation to cardiovascular pathologies such as vascular and coagulation health, but often the suppression of GLA goes unnoticed and unappreciated.

Lipoxygenases (LOX)

Lipoxygenases (LOX) are intermediates that produce inflammatory leukotrienes-4 (PGE2) or antiinflammatory leukotrienes-5 (PGE3). LOX-4 and LOX-5 molecules can modulate inflammation,

mostly as mediators of cell signaling and as modifiers of cell membrane structures. Practical examples of structural changes are in red blood cell maturation, modification of lung barrier function to improve bronchial function in asthma conditions, and others. The LOX molecules also act as a substrate in the mobilization of fatty acids in membranes involving beta-oxidation metabolism of fatty acids. The LOX are expressed more intensely under physiologic stress (Brash, 1999; Allaj, 2013).

Cyclooxygenases (COX)

Another group of eicosanoid metabolites, the **cyclooxygenase (COX)** products, have an important role in reproduction and in the inflammatory response with inflammatory COX (PGE2) molecules and antiinflammatory COX (PGE1 and PGE3).

Specialized Pro-resolving Mediators (SPM)

More recent recognition of further downstream metabolites of a different class are called SPM derived from both w3 and w6 PUFA. These SPM lipid molecules are capable of initiating a resolution phase of inflammation to return metabolism to homeostasis. These SPMs are lipoxins, resolvins, protectins and maresins (See Fig 3-3). These mediators appear to explain some of the anti-inflammatory effects of PGE1, PGE2 and PGE3 metabolites (Calder, 2009).

REDUCING INFLAMMATION IN THE BODY

Modern research of essential fatty acids (EFA) and their metabolites has been concerned mainly with the therapeutic impact on the inflammatory process. However, as with all systems in the body, there are opposing mediators in the body's regulation of these systems to achieve homeostasis or allostasis to promote survival. Among the primary mediators of inflammation are biogenic amines, such as histamine and serotonin, cytokines, prostaglandins, thromboxanes, and leukotrienes. The PGE1 and PGE3 antiinflammatory action oppose and balance the PGE2 inflammatory systems. Both are required for healthy metabolism. For instance, derivatives of the omega-6 GLA and DGLA acids regulate the inflammatory process through their opposed activity and synergism with EPA, by directing formation at the crossroads to the antiinflammatory PGE1, or the inflammatory PGE2 molecules. In parallel metabolism the derivatives of the omega-3 ALA, EPA, DHA, and others form the antiinflammatory PGE3 metabolites, while at the same time inhibiting the transformation of AA to leukotrienes and conversion of DGLA to the PGE1 molecules. This antiinflammatory action of the omega-3 eicosanoids is most researched because of their powerful suppression of AA associated with cardiovascular disease (Tousoulis et al, 2014).

It is important to understand the enzymes responsible for healthy metabolic conversions from the essential fatty acids, LA and ALA, and how to target them with foods and nutrients. These enzymes are illustrated on the eicosanoid cascade (see Figure 3-3). The desaturase enzymes (delta-5 and delta-6) and the elongase enzymes are shared and are in competition between the omega-6 and omega-3 pathways. **Delta-6-desaturase** transforms LA into GLA and ALA to EPA by making additional double bonds. Of all the endogenous conversion steps in the eicosanoid cascade, the one driven by delta-6-desaturase is the least efficient and not biochemically equipped to handle the conversion of high dietary intake of LA found in the standard American diet (Kurotani et al, 2012). In the competition for the

enzyme between the omega-6 and omega-3 metabolites, a preference has been shown toward the omega-3s. However, these enzyme systems are affected by the adequacy of nutrient cofactors such as zinc, vitamin B₆, and magnesium and other physiologic and pathologic factors, such as hyperglycemia, that can lead to GLA deficiency.

This is seen often in type 2 diabetes related to the hyperglycemia in the early stages of that disease. GLA supplementation has been shown to bypass the inefficient rate-limiting delta-6-desaturase system in the formation of LA to GLA and then DGLA, and which pathway it will follow—either antiinflammatory PG1 or inflammatory AA-PG2 and their derivatives. EPA has been shown in the omega-3 pathway to bypass the delta-6-desaturase conversion of ALA to EPA (Innis, 2014; see Figure 3-3). The biology of essential fatty acids and particularly the role of GLA is important as part of the quelling of excessive prolonged inflammation (Dobryniewski, 2007; Miyake, 2009).

A targeted approach using dietary, nutraceutical, or enteral and parenteral lipids directs PUFAs to shift the metabolism of eicosanoids toward homeostasis, thereby attributing potent antiinflammatory effects (Triana et al, 2014; Waitzberg, 2014; see Chapter 13). There are promising data out of Europe, where olive oil–based intravenous lipids have been used for a decade, which indicate that by using different intravenous fat sources, inflammation can be reduced.

Short-term and long-term inflammatory stimulation influence COX pathways in shifting them to the “less inflammatory” COX (PGE3 and thromboxane [TX]-3), and the **resolvins** derived from EPA and DHA polyunsaturated fatty acids (LC PUFAs) through Cox-2 enzymatic epoxidation (5-lipoxygenase), thereby offering protection against inflammation (Kahn SA, 2014; Uddin 2011).

Dietary therapies to improve balance and promote adequate GLA to DGLA conversion that directs DGLA toward conversion to the PGE1 prostanoids include weight management, improving insulin sensitivity, and adequate nutrient stores of vitamin D, EPA, zinc, magnesium, B₆, and others. Nutraceuticals studied include GLA-rich plant oils from evening primrose, black currant, and borage (Pickens et al, 2014).

The nutritionist who is skilled in assessing an individual’s fatty acid balance, by first performing a dietary intake survey (see Table 3-2), and more specifically by obtaining an RBC fatty acid analysis, can more accurately target interventions to see improved outcomes in managing inflammation. With the information from a RBC fatty acid test, one can calculate an Omega-3 Index, a prognostic indicator of cardiovascular disease (CVD) (Harris et al, 2004; von Schacky, 2014; see Figure 3-5).

These assessment parameters provide a roadmap that is able to guide individualized lipid interventions. With this information, the levels of lipids in the body can be manipulated toward a healthy composition, restoring a degree of optimum inflammation-immune response in all systems of the body. Targeted

nutrient therapy using dietary supplements, functional foods, or therapeutic herbal compounds can be mediators of these metabolic enzyme systems and help take advantage of the membrane and tissue malleability affected by dietary and lifestyle changes. These therapies usually require 2 to 12 months of nutrient therapy to achieve successful outcomes.

Cytochrome P450 Enzymes

Cytochrome P450 (CYP450) enzymes are essential for the production of cholesterol, steroids, prostacyclins, and thromboxane A₂. They are also involved in the first pass hydroxylation of endogenous and exogenous toxic molecules in the detoxification transport of toxins for elimination via the feces and bile, urine, and sweat. If the enzyme function is suppressed by poor integrity of the enzyme structure, abnormal pH microenvironment, hepatic inflammation, altered availability of nutrient cofactors, or CYP450 genotype, then there is a backup of toxins and an increase in an individual’s toxic load. These CYP450 enzymes are expressed primarily in the liver, but they also occur in the small intestine, kidneys, lungs, and placenta.

More tools for assessment of all the systems of the body’s metabolism are becoming available. Testing for the CYP450 single nucleotide polymorphisms (SNP), for instance, allows recognition of a person’s metabolic strengths and weaknesses that can influence nutritional interventions (see Chapter 5). The increased availability of nutrigenomic testing is supporting clinical application of a person’s genome to provide more detail in understanding the patient’s story and the foods and nutrients that enable these biochemical and genomic systems to function.

Vitamin D

Vitamin D (cholecalciferol) actually functions as a prohormone with multiple roles, including hormone and immune modulation, antiinflammatory and antitumor effects, and apoptosis support (Alele and Kamen, 2010; Maruotti and Cantatore, 2010). This suggests that vitamin D is able to physiologically contribute to the regulation of all immune responses, by means of the vitamin D receptor (VDR) expressed in the nucleus of these cells. Epidemiologic, genetic, and basic studies indicate a potential role of vitamin D in the pathogenesis of certain systemic and organ-specific autoimmune diseases (Agmon-Levin et al, 2013).

Vitamin D is made in the skin upon exposure to UV sunlight or artificial rays (therapeutically used in northern and southern extreme latitudes), as well as obtained by dietary sources (fatty fish, fish eggs or caviar, organ meats, egg yolk, and mushrooms; see Appendix 51). The past decade has spotlighted attention on an apparent global epidemic of low vitamin D status without a known cause. Many chronic diseases are associated with increased prevalence of lowered vitamin D levels as vitamin D 25-OH vit D levels fall below 30 ng/ml (75 nmol/L) (see Chapter 7). Recommendations to test for 25-OH vit D and supplement vitamin D are becoming more common to increase blood levels to a goal of 40 to 50 ng/ml (90 to 100 nmol/L). A serum 25(OH) vit D level of approximately 52 ng/ml has been shown to be associated with a reduction by 50% in the incidence of breast cancer (Krishnan et al, 2012). An estimate is that for each additional 1000 IU/day of vitamin D intake, the serum 25(OH) vit D may increase by 4 to 5 ng/ml (10 to 20 nmol/L) (Stipanuk and Caudill, 2013).

Vitamin D is well evidenced to exhibit antiinflammatory effects (Khan, 2014; Krishnan et al, 2012; Krishnan et al, 2013).

FIGURE 3-5 HS-Omega-3 Index® Target Zones

Also, as a nutrient partner, the vitamin A (retinol/retinyl palmitate) relationship with vitamin D lies in the sharing of the RXR nuclear receptor with the vitamin D receptor (VDR), establishing a synergistic effect between the two. In nature vitamins A and D are always found together (e.g., liver, egg yolk; see Appendix 41). Because of the close proximity to this RXR nuclear receptor in all cells, there is a synergistic relationship. If one is too high or too low, it can affect the function of the other. Vitamin A (retinol) has been shown to relate to vitamin D function, so prudent testing of vitamin A retinol and 25(OH) vit D when investigating a person's vitamin D status is recommended before supplementation (Schmutz et al, 2015).

Minerals

Magnesium

Magnesium is involved with more than 300 identified enzyme systems in metabolism. It is a key partner as the counterpart of calcium: magnesium being the “relaxing” parasympathetic promoting partner with the “contracting” and sympathetic promoting calcium. They function in balance in a healthy metabolism. Magnesium is inversely related to the systemic inflammatory C-reactive protein blood values (Dibaba et al, 2015). The potential beneficial effect of magnesium intake on chronic disease may be, at least in part, explained by its inhibition of inflammation (Dibaba et al, 2015).

The NHANES 1999-2000 study revealed that 60% of the U.S. population consumed inadequate dietary magnesium from low vegetable and whole grain intake. Low dietary magnesium intake has been related to several health outcomes, including those related to metabolic and inflammatory processes such as hypertension, metabolic syndrome (He et al, 2006; Rayssiguier et al, 2006; Song et al, 2005), type 2 diabetes (Song et al, 2004), cardiovascular diseases (Liu and Chacko, 2013; Stevanovic et al, 2011), osteoporosis, and some cancers (e.g., colon, breast) (Nielsen, 2010).

Magnesium requires the microenvironment of other essential nutrients, especially its nutrient-partners, calcium and zinc. Dietary intake of chlorophyll-rich vegetables, nuts, and seeds and whole grains provides adequate magnesium if digestion and absorption are functioning well (see Appendix 50). Recently, López-Alarcón and colleagues, in their study linking low-grade inflammation with obesity in children, looked at several inflammation-related biomarkers and concluded that the most significant determinants of inflammation were a magnesium-deficient diet and central obesity (López-Alarcón et al, 2014).

Zinc

Zinc is a primary cofactor for more than 300 enzymes, many of which are involved in inflammatory processes. See Appendix 53 for food sources of zinc. Intracellular zinc is required for cell signaling within the intestinal tissue triggered by the inflammatory cytokine TNF-alpha (Ranaldi et al, 2013). Zinc deficiency leads to thymic atrophy and decreased function. The thymus gland is responsible for the production of T-lymphocytes, a critical part of immunity.

Zinc is the nutrient partner to copper, so when assessing zinc status, copper also should be considered. Gibson (2008) has described loss of taste (especially in the elderly) with zinc deficiency, and this should be noted when taking a history from an individual. Also, as a metabolic “hint,” because alkaline phosphatase (Alk Phos) is a zinc-dependent/zinc sensitive enzyme, its measurement may suggest further investigation for zinc insufficiency.

Currently, zinc status assessment includes only dietary intake data because there are no reliable functional zinc status tests. However, useful indicators are copper status, the erythrocyte zinc/copper ratio, and hair mineral testing (Stipanuk and Caudill, 2013). In a nutrition-focused physical exam, white spots under the nails (if injury has been ruled out), loss of appetite, anorexia nervosa, loss of normal taste sensation, alopecia, hyperkeratinization of skin, dermatitis, and reproductive abnormalities can indicate possible zinc deficiencies. (Stipanuk and Caudill, 2013; see Appendices 21 and 22).

Methylation

Methylation is universal throughout metabolism, and methyl factor nutrients are one of the primary promoters of healthy methylation. The B complex vitamins work synergistically and are critical to the methylation process. Folate, B₆, B₂ and B₁₂ have been shown to be the most rate-limiting when insufficient. More recent research has identified various advantages of vitamin forms when used as dietary supplement therapy to manage inflammation of chronic disease. This is true, for example, with the SNPs MTHFR 677C or MTHFR 1298C when the 5-MTHF form of folate rather than the synthetic folic acid is used (Bailey, 2010; Manshadi, 2014; Miller, 2010; Vollset, 2014) (see *Clinical Insight: Synthetic and Bioactive B-Complex Vitamins*).

CLINICAL INSIGHT

Synthetic and Bioactive B-Complex Vitamins

B-Complex Vitamins	Synthetic form/ common name	Bioactive Natural Form in Foods
B1	Thiamin mononitrate Thiamin hydrochloride	Thiamin (benfotiamine)
B2	Riboflavin	Riboflavin-5-phosphate
B3	Nicotinic acid Niacin (generic term)	Nicotinamide adenine dinucleotide (NAD) NAD phosphate (NADP) Niacinamide
B5	Pantothenic acid D-pantothenate Panthenol	Pantothenate
B6	Pyridoxine-HCl	Pyridoxine-5-phosphate (P5P)
B12	Cyanocobalamin	Methylcobalamin Hydroxycobalamin Adenocobalamin
B9	Folic Acid	Folinic Acid 5-Methyltetrahydrofolate 5-Formyltetrahydrofolate
B7	Biotin	Biotin (Biocytin)

To date, the methylation system most associated with inflammation of chronic disease is the methylation of DNA, which is especially sensitive. Chronic diseases related to methylation from epigenetic influences from the environment relate to potential development and promotion of cancer (Ehrlich, 2002), inflammatory bowel disease such as Crohn's disease (Karatzas et al, 2014), cognitive function, mood disorders (Hing et al, 2014), and cardiovascular disease (Delbridge, 2015).

The mechanisms supporting this methylation have important implications in inflammation and immune responses

(Kominsky et al, 2010). These mechanisms rely on B vitamin cofactors and the role they play in the methylation metabolism involving folate and homocysteine (Nazki et al, 2014), as well as the eicosanoid cascade producing the inflammation-controlling prostaglandins. These methyl factors are involved in upregulating gene expression concerned with neurotransmitters, nitric oxide (eNO), and methionine metabolism, precursors to antiinflammatory compounds that protect from oxidative stress damage, and other mechanisms (Das, 2007).

CLINICAL INSIGHT

Understanding the Eicosanoid Cascade

A primary nutrient group involved in the control of inflammation is the essential fatty acids, omega-3 alpha-linolenic acid (ALA) and omega-6 linoleic acid (LA), and their downstream metabolites described as the eicosanoid cascade (see Figure 3-3). A nutrition assessment skill for managing prolonged inflammation of chronic disease is a thorough working knowledge of the eicosanoid cascade pathway and the enzymes and nutrient cofactors involved. The polyunsaturated fatty acid (PUFA) metabolites of the essential fatty acids and their hormone-like prostaglandins respond like on/off switches that react to the internal and external environment stimulating anti- or pro-inflammatory signals. In chronic diseases, the switches become dominated by the pro-inflammatory signals. Imbalances in the metabolism of eicosanoid prostaglandin metabolites produced by the essential fatty acids linoleic and alpha-linolenic acids hold particular significance in determining the onset of prolonged inflammation and are influenced by dietary intake.

The methylation genes are currently the most studied of the single nucleotide polymorphisms (SNPs) and able to provide data for clinical application. Most national laboratories provide testing for these genes MTHFR C667T, MTHFR 1298C, and COMT. Others are available at specialty labs (see Chapter 5 and Figure 3-6).

Flavonoids and Antioxidant Nutrients

Flavonoids or bioflavonoids are phytonutrients associated with the varied colors found in fruits and vegetables. These phytonutrients provide antiinflammatory antioxidant functions beneficially messaging the immune system (Grimble, 1994; Jeena et al, 2013). They provide protection against free radical and reactive oxygen species (ROS) activity that cause inflammation, and they modulate epigenetic effects by collaborating with the fatty acid and prostaglandin status of a person.

When the antioxidant and flavonoid status is inadequate to protect cells and tissues, accelerated damage occurs, promoting degeneration, and depleting the health of the individual. The most studied flavonoid compound researched to date is **curcumin**, a component of the spice turmeric (Agrawal, 2015; Tuorkey, 2014). Another example is **quercetin**, a component of citrus pulp, apples, and onions, which is a yellow flavonoid with antiinflammatory action towards mast cells. Quercetin-rich foods are helpful in quelling allergic or sensitivity reactions (Kim et al, 2014; Lee, 2013). Both of these flavonoid compounds, as well as others, are also available in supplemental form for targeted nutritional therapy when indicated (see Box 3-3).

FIGURE 3-6 Methylation Mechanism

BOX 3-3 Selected Flavonoid Antioxidants

Alpha Lipoic Acid	Glutathione
Astaxanthin	Lutein
Citrus Bioflavonoids	Lycopene
CoQ10	Quercetin
Curcumin	Reseveratrol
Epigallocatechin 3 Gallate (EGCG)	Zeaxanthin

Several antioxidant systems are involved in protection against these ROS—especially within the electron transport system in the mitochondria. Among the 80 or more known antioxidants, ascorbate (vitamin C) has been shown to react with other biologic antioxidants referred to as the “antioxidant network.” Ascorbate acts as a central reducing agent regenerating other biologic antioxidants (Stipanuk and Caudill, 2013). Ascorbate interacts with the vitamin E complex to provide protection to water- and lipid-soluble surfaces in membranes. Other key members of the antioxidant network are **glutathione**, another water-soluble antioxidant that is synthesized in all cells and which supports the central role of ascorbate and vitamin E; **lipoic acid** with its water and lipid molecular components and sometimes considered the “universal antioxidant”; and **coenzyme Q-10** that functions in protecting lipid structures, especially in cardiac muscle and mitochondrial membranes. Antioxidants work synergistically to quell ROS activity. These nutrients are natural metabolites in healthy individuals and can be used as supplements for health-compromised individuals if indicated.

Gut Ecology and the Microbiome

The gastrointestinal tract has many functions in the health of an individual, and one of them is in immune integrity. This is because the largest immune organ is located within the gastrointestinal tract as gut-associated lymphoid tissue (GALT) and mucosa-associated lymphoid tissue (MALT) containing innate and acquired immune systems as well as about 3 pounds of symbiotic microbial organisms. The condition of

the gut lymphoid tissue and the microbial ecology has a large influence on the body's inflammatory state (Lewis, 2014). The inverse relationship of gut barrier integrity and ecology with organ specific or systemic inflammation is well documented (Goldman and Schafer, 2012; Hold et al, 2014; Kinnebrew and Pamer, 2012; Pastorelli, 2013; Ruth, 2013).

Medical nutrition therapy recommendations for increasing fermented foods, lowering intake of processed foods, avoiding gastrointestinal irritating foods and any known antigens for an individual, are basic to improving the microbial ecology. Therapeutic use of functional foods (Abuajah, 2015), pre- and probiotics (Isolauri and Salminen, 2015), and supplements can sometimes be indicated to restore optimum gut function and reduce inflammation (Luoto et al, 2013; see chapters 26 and 28).

Lifestyle

Chronic diseases are known as “lifestyle diseases,” and total inflammation management requires lifestyle factors be addressed for improved outcomes. Modifications of lifestyle factors such as sleep, physical activity, and smoking cessation have been widely disseminated from public health agencies. More recently, recommendations for environmental toxin exposure protection, stress management, and community relationships have been identified as significantly influencing factors in chronic disease and inflammation (Tay, 2013; Umberson, 2010).

Sleep: Circadian Rhythm

The CDC targets sleep insufficiency as an important public health challenge with 50 to 70 million U.S. adults diagnosed with sleep disorders (CDC, 2014a). Sleep quality and duration, “feeling refreshed” and vital upon awaking, and having good energy throughout the day until bedtime are the signs of adequate sleep. Sleep specialists report that sleep is one of the “most anti-inflammatory” activities (Lombardo, 2005). That is a profound statement. Common habits of TV watching right before bed, and sometimes in bed, produce penetrating light that reduces the body's production of melatonin (the natural sleep hormone responding to darkness). Sleep apnea, snoring disturbing spousal sleep, and stimulant drinks during the day and evening contribute to poor sleep quality. Without quality sleep, the body does not get quality parasympathetic healing time (Ayurveda and Chinese Medicine philosophies) that calms the inflammation of the day.

The cumulative effects of poor sleep affect metabolic activities that lead to weight gain, mood disorders, stressful emotions, and increased nutrient requirements (Heaney, 2012). Sleep problems can contribute to diseases such as hypertension, heart disease, depression, and diabetes, and they add stress and inflammation to already hectic lives. Sleep affects the balance of the 24-hour circadian rhythm involving hormone, mood, immune, organ, and digestive balance. Poor sleep can affect all of those systems and affect the degree of prolonged inflammation and nutrient status (Lopresti et al, 2013).

Physical Activity

Exercise physiology research is revealing new guidelines on the effect physical activity has on inflammation in the body. Too much exercise for too long can produce high levels of **reactive oxygen species (ROS)**, a normal byproduct of metabolism of oxygen. When ROS levels rise too high, they cause oxidative

stress damage to cell structures. Current recommendations are for intermittent activity throughout the day, with mild to moderate activity. Strenuous exercise should be for only those who have trained to avoid the damaging effects of the free radicals generated (Lopresti et al, 2013). Nutrition assessment of antioxidant status can provide identification of metabolic excess activity of ROS and guidance for dietary antioxidant protection as part of the investigation into the total inflammatory load of a person (Akil et al, 2015; Mankowski et al, 2015; see Chapter 7).

Stress of Life

Some health professionals and researchers in human body stress state that prolonged unresolved stress on the body is one of the worst promoters of early aging and chronic disease. The unresolved state of stress, whether emotional, physical, or perceived, or from infection or injury, triggers the immune system to respond with more inflammatory cytokines. The analogy used to describe unrelenting stress is getting ready for the “fright or flight” response, with nowhere to run. If animals or humans are frightened they run away and work out the metabolic inflammatory chemicals. When safe, they come to a rest to restore balance (Sapolsky, 1998). That cannot happen with unrelenting chronic stress.

Toxin Load

Toxins are endogenous and exogenous **xenobiotics**, toxic substances within a biologic organism, that damage the metabolism.

In the modern world, since WWII, there have been 80,000 or more synthetic chemicals and many toxic metals released into the environment, increasing the exposure of plant and animal life to an unprecedented level (NRDC 2010, 2015). Although many historical compounds such as smoking are toxic (Adams, 2015; Jin, 2008), many toxic compounds are “new-to-nature” molecules not before present in the environment (Aris and Leblanc, 2011; Bland, 1998). An example is trans fatty acids (Ganguly and Pierce, 2015).

The metabolisms of plants and animals usually have difficulty providing the systems to process and eliminate these toxins when incorporated into the organism. Industrial and food industry pressures have challenged attempts at governmental regulation of these toxic compounds. The result has been increasing tissue levels of some of these toxins when tissue testing is performed. Examples of these increased levels are shown in the Environmental Working Group (EWG) (<http://www.ewg.org>) studies of newborn cord blood, which have found more than 260 known-toxic substances present in 100% of U.S. newborns (EWG, 2005).

Another example is studies of toxic cadmium and lead metals in Korean populations residing near abandoned metal mines. A study of more than 5000 Koreans found notably higher toxic metal levels in those residing within a 2-km radius of the mines than in the general population in Korea and other countries (Park et al, 2014). Cadmium and lead are known carcinogens and are related to CNS disturbances and cardiovascular and renal diseases with accompanying prolonged inflammation.

A study on hermetic (low-level) exposure to cadmium and arsenic related to clinical symptoms found that low dietary protein intake affected enzyme activity such that depressed

biologic systems and long-term adaptations were inadequate. (Dudka et al, 2014). Lack of dietary vegetable micronutrient and phytonutrient intake has repeatedly been shown to be a potentially significant marker of inflammatory effects of toxins such as toxic metals, chemicals, and pesticides (Bakırcı et al, 2014, Jeena et al, 2013). In summary, there is beneficial protection against toxic damage when there is adequate macro- and micronutrient intake and nutrient bioavailability provided to the human organism, from a high intake of vegetables and adequate protein.

Assessment and Reducing Prolonged Inflammation in Chronic Diseases

The Patient's Story

Nutrition assessment includes gathering information about the whole person and begins by hearing the patient's story and forming the therapeutic relationship that is foundational for the most effective outcomes. It is a type of detective work partnering with the client to uncover root causes of underlying physiological imbalances that frame the intervention.

The **patient's story** is a term inclusive of the whole of the patient's history and the current state of their health; it is a collection of all data that potentially can contribute to the individual's metabolic health. In the therapeutic encounter the data is collected from the personal interview, study of medical records, family history, clinical observation and current laboratory records. Collection of family history is gathered best by requesting an intake form for health histories of the two previous generations to be completed before an assessment session. Most often a pattern suggesting metabolic genotypes can be recognized. Examples like cardiovascular, autoimmune or neurological events repeated in family members, especially at young ages or in multiple relatives, should prompt the nutritionist to investigate possible metabolic mechanisms and single nucleotide polymorphisms (SNPs). Quantitative laboratory or clinical confirmation of an altered metabolism may be appropriate before planning an intervention.

Personal health history starting with an individual's gestational history and place of birth, and developing a timeline can give insight into recognizing patterns that lead to a better understanding of the individual's current metabolic nutritional health. For example, infants not breastfed are found to have more difficulty in maintaining healthy gut microbiota, and increased incidence of allergies and asthma. These infants may benefit from probiotic supplementation (Prescott 2011, Ip 2007).

Medical History and Data

The common denominator of prolonged inflammation is identifiable in every chronic disease. Most evidence of this phenotype among humans, centers around various aspects of the **metabolic syndrome** described as presenting with a cluster of risk factors including insulin resistance (IR)/**hyperinsulinemia**, increased VAT (increased body fat percentage, waist circumference), elevated blood triglycerides (TG)/lowered high-density cholesterol (HDL-cholesterol), hypertension, and raised fasting glucose (dysglycemia) (Watson, 2014). An additional biomarker is seen commonly as elevated CRP-hs blood values greater than

1.0. Increased understanding of dysregulation of glucose metabolism and its various causes helps define the complex condition of prolonged inflammation (Alberti et al, 2009; Grundy et al, 2005).

Biochemical markers also can be important factors in personalizing an individual's "total inflammatory load." In 2004 it became clear that slow increases in inflammatory markers such as sedimentation rate (blood) were significant in the progression of chronic disease degenerative processes (see Table 3-1).

Predictive genomic testing has provided new tools for personalizing assessment of individual metabolism. The use of SNP testing is currently in a preliminary stage as far as clinical application, but growing at a rapid pace. Integrative and functional medicine practitioners currently are adding SNP testing to their assessment as part of the patient's story to guide effective interventions. It is important to appreciate the SNP as a "predictive" value and not as a "diagnostic" tool. An example of use of an SNP with breast cancer is the vitamin D receptor (VDR genes such as CDX2 and BGL) that currently suggest an association (Khan MI, 2014). The VDR gene may influence risks of some cancers and their prognosis. This encourages closer monitoring of vitamin D status in cancer patients (Mun, 2015). Current consensus for cancer prevention recommends maintaining 25(OH)vit D in the range of 30 to 80 ng/ml (90 to 110 nmol/L) (Mohr, 2014).

Vitamin D is involved in enhancing the management of metabolic inflammation because of its almost "pro-hormone" immune and hormone modulating effects. This comprehensive candidate-gene analysis demonstrates that the risk of multiple VDR polymorphisms results in lower VDR mRNA levels. Polymorphisms of the vitamin D receptor gene (VDR) have been shown to be associated with several complex diseases, including osteoporosis. This could affect the vitamin D signaling efficiency and may contribute to the increased fracture risk observed for these risk haplotype alleles (Fang et al, 2005).

Gathering the patient's story and combining it with other data like anthropometrics, medical history, and the nutrition focused physical exam (see Appendix 21) allows a pattern to emerge of nutritional and metabolic priorities. This provides the clinician with important information to develop a nutrition intervention to promote optimal health and wellness.

PROLONGED INFLAMMATION EXPRESSION SPECIFIC TO MAJOR CHRONIC DISEASES

Heart Disease/Cardiometabolic Syndrome

Atherosclerosis is a chronic inflammatory disease. The term most used to describe the multi-factored physiologic condition including all chronic diseases in some form is **metabolic syndrome (MetS)**. Cardiovascular disease (CVD) and diabetes are associated most closely, but increasing connections with the other major chronic diseases are occurring (see Chapters 30 and 33). MetS involves the cardiovascular system and the immune response of building atherosclerotic plaque on the vascular walls. In the 1970s, it was recognized that the atherosclerotic plaque was the result of a highly inflammatory process involving sometimes infection, but always macrophages and

BOX 3-4 Cardiometabolic Specific Inflammatory Markers

- Increased body fat%, most often with elevated BMI and VAT.
 - BMI,
 - Waist Circumference
 - Waist/Height Ratio
 - Waist/Hip Ratio
 - Body fat % (bioelectric impedance, Air or water displacement plethysmograph, DEXA, calipers)
- Blood Biomarkers of prolonged inflammation in CVD/cardiometabolic syndrome with Diabetes
 - Hyperlipidemia/Hypertriglyceridemia
 - Total Cholesterol/HDL Ratio
 - Fasting Glucose/Fasting Insulin
 - HgbA1C
 - C-Reactive Protein-hi sensitivity (CRPhs or CRP-cardio)
 - Homocysteine
- Imaging: Coronary calcium scan
- Myeloperoxidase (blood)
- Other associations for CVD/cardiometabolic syndrome /diabetes:
 - Sympathetic dominant metabolism (metabolic stress)
 - Stress (biochemical, glandular, emotional, environmental, smoking)
 - Poor sleep
 - Apnea

foam cells cementing with free calcium and cholesterol. Other factors of MetS are hypertension, strokes, infections, and stress. The most common biomarkers of inflammation related to metabolic syndrome and CVD are lipids, homocysteine, CRP-hs, myeloperoxidase, and ferritin—all acute phase reactants synonymous with inflammation (Smith, 2010; see Box 3-4 and Table 7-6).

Cancer

Cancer can be considered a cousin of cardiometabolic syndrome sharing many of the same characteristics of prolonged inflammation. Cancer deaths occur because of metastatic growth of a tumor and malnutrition. Metastases of solid tumors require new increased blood supply with neo-vascularization (angiogenesis) to thrive (Albini, 2011; see Chapter 36). Angiogenesis is essential to adult tissue remodeling and regeneration, solid tumor growth, and coronary artery disease (Bingling et al, 2014). This awareness has brought a research focus to food, herbs and medications that can inhibit angiogenesis (Bodai, 2015; Kunnumakkara et al, 2008).

When assessing the metabolic and nutritional status of a cancer patient, the clinician should use the same factors listed for metabolic syndrome and add cancer-specific markers (see Box 3-5).

Autoimmune Conditions

Autoimmune conditions share the fundamental processes of cardiometabolic disease with a stronger genetic component. Conditions such as rheumatoid arthritis, celiac disease, inflammatory bowel disease, lupus, Sjögren syndrome, and others have identified genetic susceptibilities. All have specific inflammatory markers particular to the disease process. They are exacerbated by obesity, chronic infections, antigenic exposures, and stress (Table 3-3).

BOX 3-5 Cancer Specific Inflammatory Markers

- Various metabolic markers measuring inflammatory hallmarks of cancer
 - Adhesion: Fibrinogen and platelets (blood)
 - Metastasis promoters:
 - Copper (Cu): Zinc Ratio 1.0 or less (rate limiting to metastatic enzymes)
 - Ceruloplasmin (contributes to the total Cu load)
 - Angiogenesis promoters (Bingling, 2014): VEGF, adhesion factors.
- Tumor-promoting inflammation: Specific type of cancer markers (examples: ovarian cancer CA 125, breast cancer CA 15-3), prostate cancer PSA). Various proinflammatory cytokines and chemokines: TNF- α , IL-8, IL-6, etc.
 - Glycolysis (Warburg Effect: (sugar is primary fuel of cancer cells))
 - Growth factors
 - Genome instability/mitochondrial DNA
 - Loss of apoptosis / cell immortality

Neurologic Conditions

Neurologic conditions range from mitochondrial dysfunction diseases such as Parkinson's disease and Alzheimer's disease (AD) (Hroudová et al, 2014) to mood disorders associated with altered methylation pathways from variations in the MTHFR and COMT genes to nutrient insufficiencies. Inflammation and the cardiometabolic parameters are present with naming of AD as type 3 diabetes (de la Monte and Wands, 2008). The neurologic system appears to be more vulnerable to toxic exposures because of the fact that 90% of toxins are lipophilic, fat-loving, and neurons and the central nervous system (CNS) are high-fat cells and tissues (see Table 3-4).

Endocrine Abnormalities

Endocrine (non-cancer) abnormalities seem to be increasing in the population. For example, infertility has increased globally with 10% of women facing this challenge (CDC, 2015; Inhorn and Patrizio, 2015). Inflammatory conditions of endometriosis, PCOS, and unexplained infertility are the most common related diseases worldwide (Gupta, 2014). Oxidative stress and its accompanying inflammation are postulated as the most important pathways in female infertility. All of the cardiometabolic markers suffice in assessing endocrine risks of chronic disease along with markers specific to the condition. Other conditions such as “estrogen dominance” carry inflammatory problems as in uterine fibroids, fibrocystic breasts, hypothyroid or autoimmune thyroiditis, diabetes type 1 and type 2, and adrenal stress (see Table 3-5).

Developmental Inflammatory-Related Conditions

Developmental inflammatory-related conditions bring a focus to the uterine environment, where there is recognition of the importance of preprogramming the fetus for a lifetime phenotype. The epigenetic messages to the fetal genotype are powerful modulators of the life expression. In the infant and toddler years brain development and behavioral wellness, including self-esteem and forming of relationships are vulnerable. If the fetus and young child do not grow in a healthy environment, the inflammatory processes of chronic disease take root and will challenge the individual lifelong.

TABLE 3-3 Autoimmune Specific Inflammatory Markers

Biomarker Test	Reference Range	Specimen	Association
Sedimentation Rate (ESR)	men: 0-15 mm/h women: 0-20 mm/h	Blood serum	Collagen diseases Inflammatory diseases Infections Toxicity, heavy metals
C-Reactive Protein-hs (CRP-hs)	<1.0 mg/dl	blood	Systemic inflammation Metabolic Syndrome
Rheumatoid Factor (RF)	0-39 IU/ml non-reactive 40-79 IU/ml weakly reactive >80 reactive	blood	Rheumatoid arthritis Sjogren's syndrome Joint pain Rheumatoid conditions
Anti-gliadin Antibody Deamidated Gliadin Antibody, IgA, IgG	0-19 Negative 20-30 Weak Positive >30 Moderate to Strong positive	Blood serum	Celiac disease Dermatitis herpatiforme Non-Celiac gluten sensitivity
Endomysial antibody test (IgA-EMA)	Negative normal individuals Negative Gluten-free diet		Dermatitis herpetiforme, celiac disease
Tissue Transglutaminase IgA/IgG (tTG-IgA)	<4.0 U/mL (negative) 4.0-10.0 U/mL (weak positive) >10.0 U/mL (positive)	Blood serum	Celiac disease (indicates Rx biopsy, gene HLA_DQ2/DQ8) Dermatitis herpetiforme
SS-A Sjorgrens/Ro IgG	Reference values apply to all ages. <1.0 U (negative) > or =1.0 U (positive)	blood	Villi Atrophy Connective tissue disease (Systemic lupus erythematosus, Sjorgrens, Rheumatoid arthritis)
SS-B Sjorgrens	Reference values apply to all ages. <1.0 U (negative) > or =1.0 U (positive)	blood	Connective tissue disease, including Sjogren syndrome, systemic lupus erythematosus (SLE).
ANA antibody titer	Reference values apply to all ages. <1:40 normal (or < 1/0 IU) is negative.	Blood serum	Multiple autoimmune conditions, systemic lupus erythematosus (SLE).
Anti-dsDNA Test IgG	<30.0 IU/mL (negative) 30.0-75.0 IU/mL (borderline) >75.0 IU/mL (positive) Negative is considered normal. Reference values apply to all ages.	blood	
Cyclic Citrullinated Peptide Antibody (Anti-CCP)	<20.0 U (negative) 20.0-39.9 U (weak positive) 40.0-59.9 U (positive) > or =60.0 U (strong positive) Reference values apply to all ages.	blood	Rheumatoid arthritis Arthritis
Anti-Desmoglein 1/3 IgG antibody Blister biopsy	negative	Blood Skin tissue	Pemphigus vulgaris Pemphigus foliaceus Epidermolysis bullosa acquisita

TABLE 3-4 Neurological Specific Inflammatory Markers

Biomarker Test	Reference	Specimen	Association
RBC Fatty Acid Analysis	Mean +/- SD	Blood	Membrane integrity
Lipid Panel			
Triglycerides	170-200 mg/dL	Blood	
Total Cholesterol	50-80 mg/dL		
HDL	Men: 37-40 mg/dL Women: 40-85 mg/dL	Blood	CHD risk
LDL	Adult <130 mg/dL or <3.4 mmol/L Child <110 mg/dL or <2.8 mmol/L	Blood	Adult: CHD risk Child: abnormal cholesterol metabolism
Creatine Kinase			
Creatinine	0.76-1.27 mg/dL	Blood	Kidney Function
BUN	8-27 mg/dL		
GFR	>60 mL/min/BSA		
Glucose, fasting	65-99 mg/dL	Blood, urine	Glucose status
Insulin, fasting	2.0-19.6 μ U/mL	Blood	Insulin status
HgbA1C	4.8%-6.4%	Blood	Average BS over 120 days
25OH vit D	30-150 ng/ml	Blood, saliva	Vitamin D status

TABLE 3-5 Endocrine (non-cancer) Specific Inflammatory Markers

Biomarker Test (Mother)	Reference	Specimen	Association
RBC Fatty Acid Analysis	Mean +/- SD	Blood	Membrane integrity
Lipid Panel		Blood	CHD
Total Cholesterol	170-200 mg/dL		Cholesterol/lipid metabolism
HDL-cholesterol	Men: 37-40 mg/dL Women: 40-85 mg/dL		Liver stress
LDL-cholesterol	Adult <130 mg/dL or <3.4 mmol/L Child <110 mg/dL or <2.8 mmol/L		CHD risk
Triglycerides	<150 mg/dL		CHD risk
Celiac Panel			Abnormal cholesterol
tTG IgG/IgA	<4 U/mL no antibody detected		Metabolic syndrome
Anti-Gliadin antibody	<20 Units antibody not detected		Carnitine insufficiency
tissueTransglutaminase IgG/IgA			High simple sugar/alcohol diet
Antigen (Food IgG/IgE)			CHD risk
Insulin, fasting	Per lab 2.0-19.6 μ U/mL	Blood	Insulin status
HgbA1C	4.8%-6.4%	Blood	Average BS over 120 days
TSH	Adult 0.2-5.4 mU/L blood	Blood	Thyroid function
Vitamin D25-OH	30-150 ng/ml	Blood, saliva	Vitamin D status

SUMMARY

Chronic disease is an epidemic that is affected by diet and lifestyle, and chronic disease pathophysiology is the result of genetics and epigenetic influences. Sustained inflammation is the common denominator of all chronic disease. Nutrition and lifestyle are modulators of sustained inflammation (see Box 3-6).

The nutritionist has an important role in the interdisciplinary management of chronic disease. The skills to recognize the early signs and symptoms of smoldering inflammation enable the nutritionist to identify nutritional priorities and individual strategies to reduce inflammation and restore health and well-being.

Whole foods, “functional foods,” targeted dietary supplements when indicated, and lifestyle changes can be foundational in achieving wellness. The nutritionist, with an understanding of the inflammation and immune response of chronic disease pathophysiology, possesses the capability for more effective nutrition assessment and intervention.

for Standard Reference (SR)

Nutrition status reveals the degree to which physiologic nutrient needs are met for an individual. Assessment of nutrition status is the foundation of nutritional care; it is the important base for personalizing an individual's nutritional care in the context of the cause, prevention, or management of disease or promotion of health. Chronic diseases, including heart disease, stroke, diabetes, and osteoporosis, as well as many gastrointestinal disorders and most cancers, are influenced by the underlying nutritional status. In addition, an individual's nutritional status affects gene expression and vice versa, with implications for many disorders (see Chapter 5). In promotion of health, regular assessment can detect a nutritional insufficiency in the early stages, allowing dietary intake and lifestyle to be improved through nutrition support and counseling before a more severe deficiency and functional change develops.

Nutrition assessment often begins with collection of **dietary intake data**, the information on the food, drink, and supplements consumed. This personal dietary intake is influenced by factors such as economic situation, availability of food, eating behavior, emotional climate, cultural background, effects of disease, and the ability to acquire and absorb nutrients. Once the dietary intake data are collected, they are analyzed for nutrient and phytonutrient content. This is compared with dietary recommendations and requirements particular to that individual (Figure 4-1). These requirements depend on age, gender, periods of growth such as pregnancy or adolescence, presence of chronic disease or inflammation, coexistence of stressors such as injury or psychologic trauma, and medical treatments or medications.

Nutritional well-being and the continuum of nutritional health are essential concepts to understand. Figure 4-2 illustrates the general sequence of steps leading to nutritional decline and

the development of a nutritional deficiency, as well as areas in which an assessment can identify problems.

Screening and assessment are integral parts of the nutrition care process (NCP), which has four steps: (1) assessment of nutrition status; (2) identification of nutritional diagnoses; (3) interventions such as food and nutrient delivery, education, counseling, coordination of care; and (4) monitoring and evaluation of the effectiveness of the interventions (Academy of Nutrition and Dietetics [AND], 2013; see Chapter 10).

NUTRITION SCREENING

Nutrition risk is determined through a nutrition screening process. Factors to consider in determining whether an individual is at nutritional risk are listed in Table 4-1. They include food, nutrient, and botanicals intake patterns; psychosocial and economic factors; physical conditions; abnormal laboratory findings; and medication and treatment regimens.

Ideally, everyone should undergo periodic nutrition screening throughout life. Just as a health care provider conducts an annual health examination, a trained nutrition provider can conduct regular nutritional evaluations. To provide cost-effective nutrition services in today's health care environment, it is important first to screen patients to find those who are at nutritional risk. The purpose of a nutrition screen is to quickly identify individuals who are malnourished or at nutritional risk and determine whether a more detailed assessment is warranted. Nutrition screening is defined as "the process of identifying patients, clients, or groups who may have a nutrition diagnosis and benefit from nutrition assessment and intervention by a

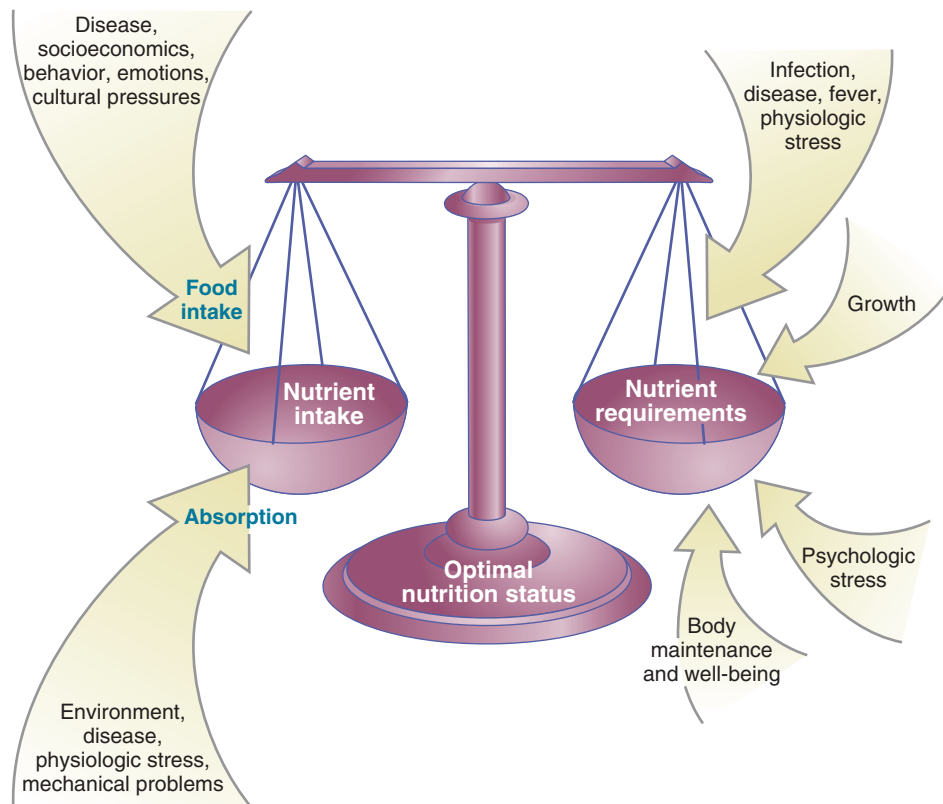

FIGURE 4-1 Optimal nutrition status: a balance between nutrient intake and nutrient requirements.

DEVELOPMENT OF DEFICIENCY

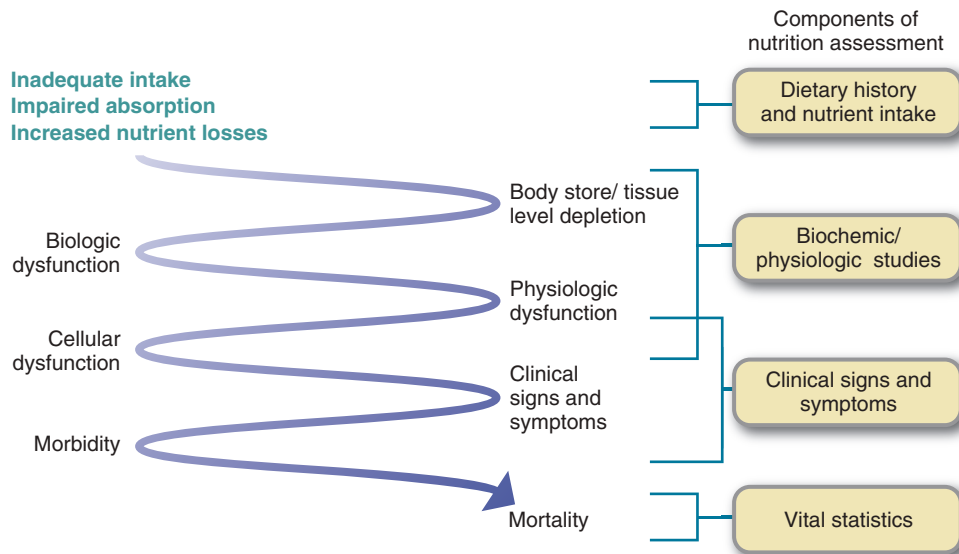

FIGURE 4-2 Development of clinical nutritional deficiency with corresponding dietary, biochemical, and clinical evaluations.

registered dietitian nutritionist (RDN).” Key considerations for nutrition screening include:

1. Tools should be quick, easy to use, and able to be conducted in any practice setting.
2. Tools should be valid and reliable for the patient population or setting.
3. Tools and parameters are established by RDNs, but the screening process may be performed by dietetic technicians, registered, or other trained personnel.
4. Screening and rescreening should occur within an appropriate time frame for the setting (AND, 2013a; Skipper et al, 2012).

TABLE 4-1 Nutritional Risk Factors

Category	Factors
Food and nutrient intake patterns	<ul style="list-style-type: none"> • Calorie and protein intake greater or less than that required for age and activity level • Vitamin and mineral intake greater or less than that required for age • Swallowing difficulties • Gastrointestinal disturbances • Unusual food habits (e.g., pica) • Impaired cognitive function or depression • Nothing by mouth for more than 3 days • Inability or unwillingness to consume food • Increase or decrease in activities of daily living • Misuse of supplements • Inadequate transitional feeding, tube feeding or parenteral nutrition, or both • Bowel irregularity (e.g., constipation, diarrhea) • Restricted diet • Feeding limitations
Psychologic and social factors	<ul style="list-style-type: none"> • Low literacy • Language barriers • Cultural or religious factors • Emotional disturbances associated with feeding difficulties (e.g., depression) • Limited resources for food preparation or obtaining food and supplies • Alcohol or drug addiction • Limited or low income • Lack of ability to communicate needs • Limited use or understanding of community resources
Physical conditions	<ul style="list-style-type: none"> • Extreme age: adults older than 80 years, premature infants, very young children • Pregnancy: adolescent, closely spaced, or three or more pregnancies • Alterations in anthropometric measurements: marked overweight or underweight for height, age, or both; head circumference less than normal; depressed somatic fat and muscle stores; amputation • Fat or muscle wasting • Obesity or overweight • Chronic renal or cardiac disease and related complications • Diabetes and related complications • Pressure ulcers or altered skin integrity • Cancer and related treatments • Acquired immune deficiency syndrome • Gastrointestinal complications (e.g., malabsorption, diarrhea, digestive or bowel changes) • Catabolic or hypermetabolic stress (e.g., trauma, sepsis, burns, stress) • Immobility • Osteoporosis, osteomalacia • Neurologic impairments, including impairment in sensory function • Visual impairments
Abnormal laboratory values	<ul style="list-style-type: none"> • Visceral proteins (e.g., albumin, transferrin, prealbumin) • Lipid profile (cholesterol, high-density lipoproteins, low-density lipoproteins, triglycerides) • Hemoglobin, hematocrit, and other hematologic tests • Blood urea nitrogen, creatinine, and electrolyte levels • Fasting serum blood glucose level • Other laboratory indexes as indicated
Medications	<ul style="list-style-type: none"> • Chronic use • Multiple and concurrent administration (polypharmacy) • Drug-nutrient interactions and side effects

Adapted from the Council on Practice, Quality Management Committee: Identifying patients at risk: ADA's definitions for nutrition screening and nutrition assessment, *J Am Diet Assoc* 94:838, 1994.

The most common screening criteria include history of weight loss, current need for nutrition support, presence of skin breakdown, poor dietary intake, and chronic use of modified or unusual diets. Further information collected during a nutrition screen depends on (1) the setting in which the information is obtained (e.g., home, clinic, hospital, long-term care facility), (2) the life stage or disease type, (3) the available data, and (4) a definition of risk priorities. Regardless of the information gathered, the goal of screening is to identify individuals who are at nutritional risk, those likely to become at nutritional risk, and those who need further assessment. For example, being 85 years or older, having low nutrient intake, losing the ability to eat independently, having swallowing and chewing difficulties, becoming bedridden,

having pressure ulcers or a hip fracture or dementia, and suffering from two or more chronic illnesses are factors of concern in a nutritional screen.

Nutrition Screening Tools

Commonly used nutrition screening tools were evaluated by the AND. The results can be found in the Evidence Analysis Library (EAL) (AND, 2013b; AND, 2015). A screen that is simple to use is the **Malnutrition Screening Tool (MST)** by Ferguson (1999). The parameters include recent weight loss and recent poor dietary intake. The tool is useful for the acute hospitalized adult population and was the only one of the 11 evaluated by the EAL shown to be *valid* and *reliable* for identifying problems in acute care and hospital-based ambulatory care settings (AND, 2013b; Box 4-1).

BOX 4-1 Malnutrition Screening Tool (MST)

Question	Score
Have you lost weight recently without trying?	
No	0
Unsure	2
If yes, how much weight (kilograms) have you lost?	
1-5	1
6-10	2
11-15	3
>15	4
Unsure	2
Have you been eating poorly because of a decreased appetite?	
No	0
Yes	1
Total score:	

Score of 2 or more = patient at risk of malnutrition.

From Ferguson M et al: Development of a valid and reliable malnutrition screening tool from adult acute hospital patients, *Nutrition* 15:458, 1999, p 461.

Another screening tool is the **Malnutrition Universal Screening Tool (MUST)** developed by **Stratton and colleagues (2004)** to assess for malnutrition rapidly and completely; it is designed to be used by professionals of different disciplines (AND, 2015; **Figure 4-3**). Three independent criteria are used: (1) current weight and height with determination of body mass index (BMI), (2) unintentional weight loss using specific cutoff points, and (3) the effect of acute disease on dietary and nutrition intake for more than 5 days.

These three components work better together to predict outcome rather than the individual components separately. Once the scores are added, the overall risk of malnutrition can be determined using three categories: 0 = low risk, 1 = medium risk, and 2 and above = high risk. Nutritional management guidelines can then be put into place (**Stratton et al, 2004**).

The **Nutrition Risk Screening (NRS 2002)** is a screening tool that is useful for medical-surgical hospitalized patients (AND, 2015). This tool contains the nutritional components of the MUST and a grading of disease severity as reflected by increased nutritional requirements. Screening parameters for this tool include recent weight loss percentage, body mass index (BMI), severity of disease, consideration of >70 years of age, and food intake/eating problems and skipping of meals (AND, 2013b; **Table 4-2**).

The **Mini Nutritional Assessment (MNA) Short Form** is a rapid and reliable screening method for the subacute and ambulatory elderly populations. Nutrition screening parameters include recent dietary intake, recent weight loss, mobility, recent acute disease or psychologic stress, neuropsychologic problems, and body mass index (ANDb, 2013; **Figure 4-4**).

NUTRITION ASSESSMENT

Nutrition assessment is a comprehensive evaluation carried out by an RDN using medical and health, social, dietary and nutritional, medication, and supplement and herbal use histories; physical examination; anthropometric measurements; and laboratory data. Nutrition assessment interprets data from the

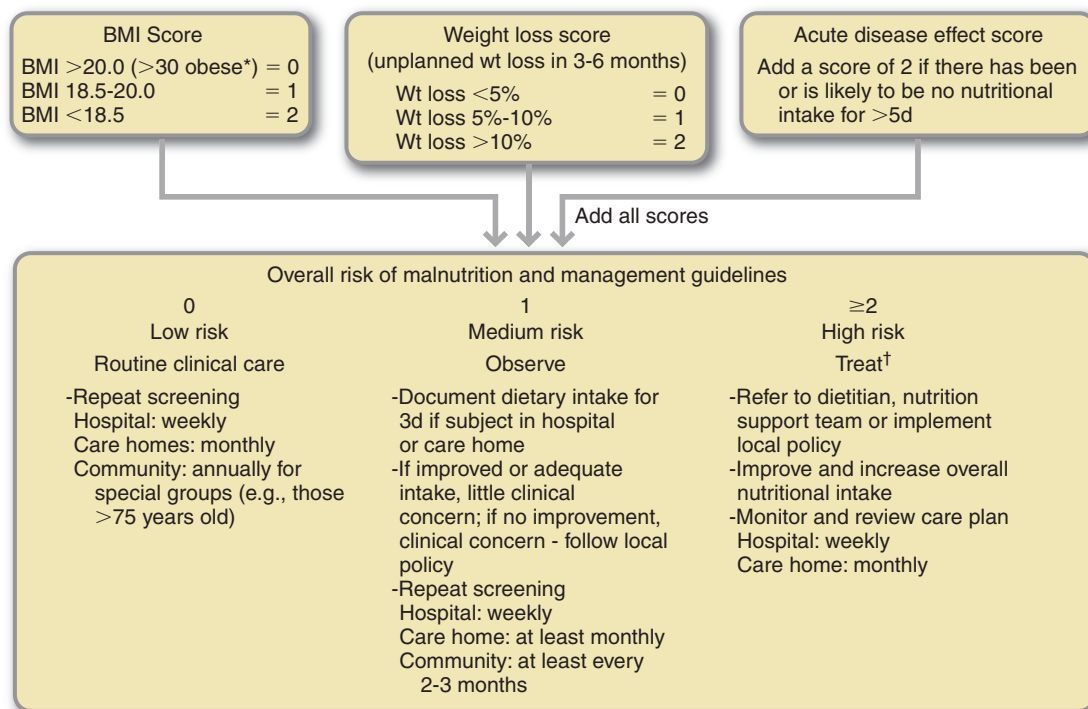

FIGURE 4-3 The Malnutrition Universal Screening Tool (MUST) for adults. Record malnutrition risk category, presence of obesity and/or need for special diets and follow local policy for those identified at risk. If unable to obtain height and weight, alternative measurements and subjective criteria are provided (Elia, 2003).

*In the obese, underlying acute conditions are generally controlled before treatment of obesity.

†Unless detrimental or no benefit is expected from nutritional support (e.g., imminent death).

nutrition screen and incorporates additional information. It is the first step in the nutrition care process (see Chapter 7).

The purpose of assessment is to gather adequate information in which to make a professional judgment about nutrition status. The nutrition assessment is defined as a systematic approach to collect, record, and interpret relevant data from patients, clients, family members, caregivers, and other individuals and groups. It is an ongoing, dynamic process that involves initial data collection and continued reassessment and analysis of nutritional status in comparison to specific criteria (Table 4-3).

The information gathered depends on the particular setting, the present health status of the individual or group, how data are related to particular outcomes, whether it is an initial or follow-up assessment, and recommended practices. Once the nutrition assessment process is complete and a nutrition diagnosis made, the plan of care can be developed (see Chapter 10).

Tools for Assessment of Nutritional Status

Several tools are available for the assessment of nutritional status. The **Subjective Global Assessment (SGA)** is a tool that uses weight history, diet history data, stress level, and primary diagnosis along with physical symptoms to assess nutritional status (Mueller et al, 2011). The **Mini Nutrition Assessment (MNA) Long Form** tool evaluates independence, medication therapy, pressure sores, number of full meals consumed per day, protein intake, consumption of fruits and vegetables, fluid intake, mode of feeding, self-view of nutritional status, comparison with peers, and mid-arm and calf circumferences (Figure 4-5) (Bauer et al, 2008; Guigoz, 2006).

Histories

The information collected about individuals or populations is used as part of the nutrition status assessment. Frequently the information is in the form of histories—health and medical, social, medication and herbal use, and dietary and nutritional.

Medical or Health History

The medical or health history usually includes the following information: chief complaint, present and past illness, current health, allergies, past or recent surgeries, family history of disease, psychosocial data, and a review of problems—by body system—from the patient's perspective (Hammond, 2006). These histories usually provide much insight into nutrition-related problems. Alcohol and drug use, increased metabolic

needs, increased nutritional losses, chronic disease, recent major surgery or illness, disease or surgery of the gastrointestinal tract, and recent significant weight loss may contribute to malnutrition. In older patients, additional review is recommended to detect mental deterioration, constipation or incontinence, poor eyesight, hearing or taste sensation, slowed reactions, major organ diseases, effects of prescription and over-the-counter drugs, and physical disabilities.

Medication and Herbal Use History

Various foods, medications, and herbal supplements can interact in many ways that affect nutrition status and drug therapy effectiveness; thus a medication and herbal history is an important part of any nutrition assessment. Those who are older, are chronically ill, have a history of marginal or inadequate nutritional intake, or are receiving multiple drugs for a long time are susceptible to drug-induced nutritional deficiencies. The effects of medication therapy can be altered by specific foods, the timing of food and meal consumption, and use of herbal products (see Chapter 8 and Appendix 23).

Social History

Social aspects of the medical or health history also may affect nutrition intake. Socioeconomic status, the ability to purchase food independently, whether the person is living alone, physical or mental handicaps, smoking, drug or alcohol addiction, confusion caused by environmental changes, unsuitable housing conditions, environmental toxins, lack of socialization at meals, psychologic problems, or poverty may add to the risks for inadequate nutrition intake. Knowledge of various cultures is also important in assessing diverse groups of clients. Cultural factors include religious beliefs, rituals, symbols, language, dietary practices, education, communication style, views on health, wellness, and illness, and racial identity. See Chapter 11 for more guidance on nutrition and cultural competency.

Nutrition or Diet History

Inadequate dietary intake and nutritional inadequacy can result from anorexia, **ageusia** (loss of the sense of taste), **dysgeusia** (diminished or distorted taste), **anosmia** (loss of smell), excessive alcohol intake, fad dieting, chewing or swallowing problems, frequent eating of highly processed foods, adverse food and drug interactions, cultural or religious restrictions of diet, an inability

TABLE 4-3 Nutrition Care Process: Step 1: Nutrition Assessment

Data sources/tools for assessment	Screening or referral form. Patient/client interview. Medical or health records. Consultation with other caregivers, including family members. Community-based surveys and focus groups. Statistical reports, administrative data, and epidemiologic studies.
Types of data collected	Food- and nutrition-related history. Anthropometric measurements. Biochemical data, medical tests, and procedures. Nutrition-focused physical examination findings. Client history.
Nutrition assessment components	Review data collected for factors that affect nutrition and health status. Cluster individual data elements to identify a nutrition diagnosis as described in diagnosis reference sheets. Identify standards by which data will be compared.
Critical thinking	Determine appropriate data to collect. Determine the need for additional information. Select assessment tools and procedures that match the situation. Apply assessment tools in valid and reliable ways. Distinguish relevant from irrelevant data. Distinguish important from unimportant data. Validate data.
Determination for continuation of care	If on completion of an initial or reassessment it is determined that the problem cannot be modified by further nutrition care, discharge or discontinuation from this episode of nutrition care may be appropriate.

From Writing Group of the Nutrition Care Process/Standardized Language Committee: Nutrition care process and model part 1: the 2008 update, *J Am Diet Assoc* 108:1113, 2008.

to eat for more than 7 to 10 days, intravenous fluid therapy alone for more than 5 days, or the need for assistance with eating. Problems faced by older adults include ill-fitting dentures and poor dentition, changes in taste and smell, long-established poor food habits, poverty and food insecurity, and inadequate knowledge of nutrition (see Chapter 20). Self-prescribed therapies, including use of megadoses of vitamins and minerals, use of various herbs, macrobiotic diets, probiotics, and fatty acid or amino acid supplements, also must be addressed because they affect a person's nutritional and overall health.

A **diet history** is perhaps the best means of obtaining dietary intake information and refers to a review of an individual's usual patterns of food intake and the food selection variables that dictate the food intake. See **Box 4-2** for the kind of information collected from a dietary history. **Dietary intake data** may be assessed either by collecting retrospective intake data (e.g., a 24-hour recall or food frequency questionnaire) or by summarizing prospective intake data (e.g., a food record kept for a number of days by an individual or the caretaker). Each method has specific purposes, strengths, and weaknesses. Any self-reported method of obtaining data can be challenging because it is difficult for people to remember what they ate, the content, and the amounts (**Thompson et al, 2010**). The choice of data collection depends on the purpose and setting, but the goal is to determine the food and nutrient intake that is typical for that individual.

A daily food record, or **food diary**, involves documenting dietary intake as it occurs and is often used in outpatient clinic settings. The food diary is usually completed by the individual client (**Figure 4-6**). A food diary or record is usually most accurate if the food and amounts eaten are recorded at the time of consumption, minimizing error from incomplete memory or attention. The individual's nutrient intake is then calculated and averaged at the end of the desired period, usually 3 to 7 days, and compared with dietary reference intakes (DRIs) (see inside front cover), government dietary guidelines as in the MyPlate guide (Chapter 11), or personalized dietary recommendations for disease management or prevention.

With the current emphasis on self-management, electronic food diaries and records are gaining in popularity, including mobile applications (apps) that store food intake data along with allowing the sharing of reports with friends or health professionals. (see **Focus On: Does Your App Know What You are Eating?**).

FOCUS ON

Does Your App Know What You are Eating?

In addition, a variety of nutrition apps can be downloaded to smartphones to further assist in assessing nutrient intake. Using an app, an individual can self-monitor their nutrition and exercise lifestyle. They can record calorie and nutrient intake as well as energy expenditure in exercise. Electronic diaries can be more accurate and useful compared with handwritten entries. With some apps it is also possible for the client to share this information with a dietitian or other health professional and receive feedback on changes or improvements that can be made. Many of these apps support access from a personal computer, a mobile phone, or other hand-held device as well as search in a food database and create graphs from food intake data (**Rusin, 2013**). Recording electronic devices can link a kitchen scale used to weigh food eaten directly to a computer, making recording of portion sizes more accurate.

Mobile devices can be used to photograph meals and document portion sizes. This process can either be active (i.e., the user takes an image before and after a meal) or passive (i.e., a wearable camera takes images during daily activities, including mealtime). These options can assist with more accurate reporting of intake, which previously relied completely on recall. However, if images are not of satisfactory quality, or if they do not provide a reference point to judge portion size, they may underestimate intake (**Gemming et al, 2015**). Other apps use a bar code reader to transmit data from food labels to a food record (**Six et al, 2011; Thompson et al, 2010**). Some of the popular apps are:

- Lose It!
- MyFitnessPal
- Meal Snap
- Fooducate

LaGesse D: Lose weight with your phone. <<http://www.aarp.org/health/fitness/info-04-2011/lose-weight-with-your-phone.1.html>>, 2011. Accessed February 10, 2015.

Mini Nutritional Assessment MNA[®]

Last name:		First name:		
Sex:	Age:	Weight, kg:	Height, cm:	Date:

Complete the screen by filling in the boxes with the appropriate numbers. Add the numbers for the screen. If score is 11 or less, continue with the assessment to gain a Malnutrition Indicator Score.

Screening	
A Has food intake declined over the past 3 months due to loss of appetite, digestive problems, chewing or swallowing difficulties? 0 = severe decrease in food intake 1 = moderate decrease in food intake 2 = no decrease in food intake	<input type="checkbox"/>
B Weight loss during the last 3 months 0 = weight loss greater than 3kg (6.6lbs) 1 = does not know 2 = weight loss between 1 and 3kg (2.2 and 6.6 lbs) 3 = no weight loss	<input type="checkbox"/>
C Mobility 0 = bed or chair bound 1 = able to get out of bed / chair but does not go out 2 = goes out	<input type="checkbox"/>
D Has suffered psychological stress or acute disease in the past 3 months? 0 = yes 2 = no	<input type="checkbox"/>
E Neuropsychological problems 0 = severe dementia or depression 1 = mild dementia 2 = no psychological problems	<input type="checkbox"/>
F Body Mass Index (BMI) (weight in kg) / (height in m²) 0 = BMI less than 19 1 = BMI 19 to less than 21 2 = BMI 21 to less than 23 3 = BMI 23 or greater	<input type="checkbox"/>
Screening score (subtotal max. 14 points) 12-14 points: Normal nutritional status 8-11 points: At risk of malnutrition 0-7 points: Malnourished For a more in-depth assessment, continue with questions G-R	<input type="checkbox"/> <input type="checkbox"/> <input type="checkbox"/> <input type="checkbox"/>
Assessment	
G Lives independently (not in nursing home or hospital) 1 = yes 0 = no	<input type="checkbox"/>
H Takes more than 3 prescription drugs per day 0 = yes 1 = no	<input type="checkbox"/>
I Pressure sores or skin ulcers 0 = yes 1 = no	<input type="checkbox"/>
J How many full meals does the patient eat daily? 0 = 1 meal 1 = 2 meals 2 = 3 meals	<input type="checkbox"/>
K Selected consumption markers for protein intake <ul style="list-style-type: none"> • At least one serving of dairy products (milk, cheese, yoghurt) per day yes <input type="checkbox"/> no <input type="checkbox"/> • Two or more servings of legumes or eggs per week yes <input type="checkbox"/> no <input type="checkbox"/> • Meat, fish or poultry every day yes <input type="checkbox"/> no <input type="checkbox"/> 0.0 = if 0 or 1 yes 0.5 = if 2 yes 1.0 = if 3 yes	<input type="checkbox"/> <input type="checkbox"/> <input type="checkbox"/> <input type="checkbox"/>
L Consumes two or more servings of fruit or vegetables per day? 0 = no 1 = yes	<input type="checkbox"/>
M How much fluid (water, juice, coffee, tea, milk...) is consumed per day? 0.0 = less than 3 cups 0.5 = 3 to 5 cups 1.0 = more than 5 cups	<input type="checkbox"/> <input type="checkbox"/> <input type="checkbox"/> <input type="checkbox"/>
N Mode of feeding 0 = unable to eat without assistance 1 = self-fed with some difficulty 2 = self-fed without any problem	<input type="checkbox"/>
O Self view of nutritional status 0 = views self as being malnourished 1 = is uncertain of nutritional state 2 = views self as having no nutritional problem	<input type="checkbox"/>
P In comparison with other people of the same age, how does the patient consider his / her health status? 0.0 = not as good 0.5 = does not know 1.0 = as good 2.0 = better	<input type="checkbox"/> <input type="checkbox"/> <input type="checkbox"/> <input type="checkbox"/>
Q Mid-arm circumference (MAC) in cm 0.0 = MAC less than 21 0.5 = MAC 21 to 22 1.0 = MAC 22 or greater	<input type="checkbox"/> <input type="checkbox"/> <input type="checkbox"/> <input type="checkbox"/>
R Calf circumference (CC) in cm 0 = CC less than 31 1 = CC 31 or greater	<input type="checkbox"/>
Assessment (max. 16 points)	<input type="checkbox"/> <input type="checkbox"/> <input type="checkbox"/> <input type="checkbox"/>
Screening score	<input type="checkbox"/> <input type="checkbox"/> <input type="checkbox"/> <input type="checkbox"/>
Total Assessment (max. 30 points)	<input type="checkbox"/> <input type="checkbox"/> <input type="checkbox"/> <input type="checkbox"/>

Malnutrition Indicator Score	
24 to 30 points	<input type="checkbox"/> normal nutritional status
17 to 23.5 points	<input type="checkbox"/> at risk of malnutrition
Less than 17 points	<input type="checkbox"/> malnourished

FIGURE 4-5 Mini Nutritional Assessment Long Form. (Permission by Nestlé Healthcare Nutrition.)

BOX 4-2 Diet History Information

Category

Allergies, intolerances, or food avoidances	Foods avoided and reason for avoidance Length of avoidance Description of problems caused by foods
Appetite	Good, poor, any changes Factors that affect individual's appetite Changes in taste or smell perception
Attitude toward food and eating	Disinterest in food Irrational ideas about food, eating, or body weight Parental interest in child's eating
Chronic disease, treatments, and medications	Treatments or medications Length of treatment time Length of medication use Dietary modification: self-imposed or physician prescribed, date of modification Past nutrition and diet education, compliance with diet
Culture and background	Influence of culture on eating habits Religious practices, holiday rituals Educational background Health beliefs
Dental and oral health	Problems with chewing Foods that cannot be eaten Problems with swallowing, salivation, choking, food sticking
Economics	Income: frequency and steadiness of employment Amount of money for food each week or month Individual's perception of food security Eligibility for SNAP Public aid assistance status
Gastrointestinal factors	Problems with heartburn, bloating, gas Problems with diarrhea, vomiting, constipation, distention Frequency of problems Use of OTC medications Use of herbal or home remedies Antacid, laxative, or other drug use
Home life and meal patterns	Number in household (eat together?) Who does shopping Who does cooking Food storage and cooking facilities (e.g., stove, refrigerator) Type of housing (e.g., home, apartment, room) Ability to shop and prepare foods, disabilities
Supplements, herbal remedies	Vitamin and mineral supplements: frequency of use, type, amount Other nutraceuticals (e.g., coenzyme CoQ10, omega-3 fats): frequency of use, type, and amount Medications: type, amount, frequency of administration, length of time on medication Herbal remedies: type, amount, purpose
Nutritional problems	Concerns as perceived by patient and family Referrals from physician, nurse, other therapist, agency
Physical activity, stress, leisure time	Occupation: type, hours/week, shift, energy expenditure Exercise: type, amount, frequency (seasonal?) Sleep: hours/day (uninterrupted?) Stress: amount, frequency, chronic? Relaxation and leisure activities: type, amount, frequency Handicaps
Weight pattern and history	Loss or gain: how many pounds and over what length of time? Intentional or nonvolitional % Usual weight; healthy weight; desirable weight
Environment and toxin exposure	Exposure to known toxins: when, amount, length of time Possible exposure to toxins: when Sequelae

The **food frequency questionnaire** is a retrospective review of intake based on frequency (i.e., food consumed per day, per week, or per month). For ease of evaluation, the food frequency chart organizes foods into groups that have common nutrients. Because the focus of the food frequency questionnaire is the frequency of consumption of food groups without portion sizes, the information obtained is general, not specific, and cannot be applied to certain nutrients. During illness, food consumption patterns can change, depending on the stage of illness. Therefore it is helpful to complete food frequency questionnaires for the period immediately before hospitalization or before illness to obtain a complete and accurate history. **Box 4-3** shows a food frequency questionnaire. Another more specific, quantified questionnaire is online at <http://sharedresources.fhrc.org/content/ffq-sample-booklets>.

The **24-hour recall** method of data collection requires individuals to remember the specific foods and amounts of foods they consumed in the past 24 hours. The nutrition professional asks the person to recall his or her intake using a specific set of questions to gain as much detailed information as possible. For example, when told that the person had cereal for breakfast, the nutritionist may ask, "What kind of cereal?" The next question may be, "How much did you have?" at the same time that the person is being shown a bowl or measuring cup to jog the memory on portion size.

Problems commonly associated with this method of data collection include (1) an inability to recall accurately the kinds and amounts of food eaten, (2) difficulty in determining whether the day being recalled represents an individual's typical intake or was exceptional, and (3) the tendency for persons to exaggerate low intakes and underreport high intakes of foods. Concurrent use of food frequency questionnaires with 24-hour recalls or food diaries (i.e., doing a cross-check) improves the accuracy of dietary intake data.

Reliability and validity of dietary recall methods are important issues. When attention is directed toward the diet, people may consciously or unconsciously alter their intake either to simplify recording or impress the interviewer, thus decreasing the information's validity. The validity of dietary recall information from obese individuals is often questionable, because they tend to underreport their intakes. The same can be true for patients with eating disorders, those who are critically ill, those who abuse drugs or alcohol, individuals who are confused, and those whose intake is unpredictable. **Table 4-4** describes the advantages and disadvantages of the various methods used to obtain accurate dietary intake data.

Nutrient Intake Analysis

A **nutrient intake analysis (NIA)** also may be referred to as a nutrient intake record analysis or calorie count, depending on the information collected and the analysis done. The NIA is a tool used in various inpatient settings to identify nutritional inadequacies by monitoring intakes before deficiencies develop. Information about actual intake is collected through direct observation or an inventory of foods eaten based on observation of what remains on the individual's tray or plate after a meal. In many cases, photographs taken by smartphones are useful in documenting amount of food consumed (**LaGessee, 2011**). Intake from enteral and parenteral tube feedings is also recorded.

Food Diary: DAY _____

MEAL	Foods (list)	AMOUNT EATEN	HOW PREPARED	WHERE EATEN (home, work, etc.)
Breakfast:				
Snack:				
Lunch:				
Dinner:				
Snack:				

Food Supplements Cans/Day: _____ Name: _____
 Vitamins/Mineral Supplement: _____

FIGURE 4-6 Food diary format.

BOX 4-3 General Food Frequency Questionnaire*

To determine the frequency of food consumption, the following pattern of questions may be useful. However, questions may have to be modified based on information from the 24-hour recall. For instance, if a woman states that she drank a glass of milk the day before, do not ask, "Do you drink milk?" Rather, ask, "How much milk do you drink?" Record answers with the appropriate time frame designated (e.g., 1/day, 1/wk, 3/mo) or as accurately as possible. The frequency may have to be recorded as "occasionally" or "rarely" if the patient cannot be more specific.

1. Do you drink milk? If so, how much? What kind? Whole Skim Low-fat
2. Do you use fat? If so, what kind? How much? Butter Oil Other
3. How often do you eat meat? Eggs? Cheese? Beans?
4. Do you eat snack foods? If so, which ones? How often? How much?
5. Which vegetables (in each group) do you eat? How often?
 - a. Broccoli Cauliflower Brussels sprouts Kale
 - b. Tomatoes or tomato juice Raw cabbage Green peppers
 - c. Asparagus Beets Green peppers Corn Cooked cabbage Celery Peas Lettuce
 - d. Cooked greens Sweet potatoes Yams Carrots
6. Which fruits do you eat? How often?
 - a. Apples or applesauce Apricots Bananas Berries Cherries Grapes or grape juice Peaches Pears Pineapple Plums Prunes Raisins
 - b. Oranges, orange juice Grapefruit, grapefruit juice Lemons, lemon juice

7. Bread and cereal products

Do you eat bread? What kind? Whole wheat? High fiber? White? Gluten-free? How much per day?

Do you eat cereal? (daily? weekly?) What type? Cooked Dry

How often do you eat foods such as macaroni, spaghetti, and noodles?

Do you eat crackers or chips? How often? What kind?
8. Do you use salt? Do you salt your food before tasting it? Do you cook with salt? Do you crave salt or salty foods?
9. How many teaspoons of sugar do you use daily? Include sugar on cereal, fruit, toast, and in beverages such as coffee and tea.
10. Do you eat desserts? How often?
11. Do you drink sugar-containing beverages such as soda pop or sweetened juice drinks? How often? How much?
12. How often do you eat candy or cookies?
13. Do you drink water? How often during the day? How much each time? How much water do you drink each day?
14. Do you use sugar substitutes in packet form or in drinks? What type do you use? How often?
15. Do you drink alcohol? Which type: beer, wine, liquor? How often? How much?
16. Do you drink caffeinated beverages such as coffee, tea, or energy drinks? How often? How much per day?

A NIA should be recorded for at least 72 hours to reflect daily variations in intake. Complete records for this period usually accurately reflect an average intake for most individuals. If the record is incomplete, it may be necessary to extend the duration of the recorded intake. Eating habits or meals consumed during the weekend and during the week may differ, so ideally a weekend day is included.

ANALYSIS OF DIETARY INTAKE DATA

Once all data has been collected, the record of total intake can be analyzed for its nutrient content using one of several available computerized methods. Several database choices for estimation of intake vary by the nutrients analyzed, other data factored in, and how the data are presented. For example,

TABLE 4-4 Methods for Obtaining Dietary Intake Data

Method	Advantages	Disadvantages
Inpatient nutrient intake analysis (NIA)	Allows actual observation of food intake in clinical setting for good reliability Weight of foods measured before and after meals allows for most accurate analysis of intake	Does not reflect intake of free-living individual
Daily food record or diary	Provides daily record of food consumption Can provide information on quantity of food, how food is prepared, and timing of meals and snacks Inclusion of weekend days and weekdays results in more accurate analysis of intake More days recorded results in more accurate analysis of intake	Depends on variable literacy skills of participants Requires ability to measure or judge portion size Actual food intake possibly influenced by the recording process Reliability of records is questionable
Food frequency questionnaire	Easily standardized Can be beneficial when considered in combination with usual daily intake Provides overall picture of intake	Requires literacy skills Does not provide meal pattern data
24-hour recall	Quick and easy	Relies on patient's memory Requires knowledge of portion sizes May not represent usual intake Requires nutrition professional to have interviewing skills

besides the amounts of various nutrients, are the data presented for each day in addition to an average for the week? Is information on the individual's gender, height, weight, and age factored in so that the data can be compared with the DRI (see inside cover) for that individual? Or are the food intake data general (as from a completed food frequency questionnaire) and can be compared only with MyPlate.com or other general guidelines?

Nutrient Databases

The **USDA National Nutrient Database for Standard Reference (SR)**, which is maintained by the Agricultural Research Service (ARS) of the U.S. Department of Agriculture, is updated annually. The SR is the major source of food composition data in the United States, and, as of this writing, is at version SR27 (USDA ARS, 2014; Pennington, 2007).

The **Food and Nutrient Database for Dietary Studies (FNDDS)**, also maintained by the ARS, is a database of foods, their nutrient values, and weights for typical food portions. It includes 10 data files, plus comprehensive documentation and a user's guide for ease of use. The FNDDS is used to analyze data from the survey "*What We Eat in America*," the dietary intake component of the National Health and Nutrition Examination Survey (NHANES).

The **FDA Total Diet Study Database** includes 280 core foods. It provides analytical data for dietary minerals, folic acid, heavy metals, radionuclides, pesticide residues, industrial chemicals, and chemical contaminants.

The **Dietary Supplements Database** from the NIH Office of Dietary Supplements offers information on dietary supplements via its website and its My Dietary Supplements (MYDS) mobile application. The **Nutrient Data System for Research** from the University of Minnesota provides ongoing updates for generic and branded products, as well as a dietary supplement assessment module. The **ProNutra** database, from VioCare, Inc., is designed for research diets controlled in many nutrients. It includes customizable calculation algorithms, with research kitchen outputs (Viocare, 2009).

Food and nutrition management software systems such as Computrition or CBORD are designed for institutional

use and typically include extensive nutrient databases. These systems may regularly import data from the SR. Other food database software programs designed and priced for individual use are available; however, their cost and their comprehensiveness vary. Only certain software programs are approved for use in the USDA School Meals program (Stein, 2011).

CASE STUDY

Laverne, a 66 year-old woman, has contacted you to set up an outpatient nutrition screening appointment. She works full time and lives by herself. She has type 2 diabetes, hypertension, and a history of colon cancer. She is 5 ft, 8 in tall and weighs 203 lb. Her current medications are glyburide and a diuretic. (She does not know its name.) She tells you that she eats throughout the day and sometimes gets up during the night for a snack. She finds eating fast-food a convenience with her busy schedule and tends to frequent these type of restaurants three to four times per week. She does not have an exercise routine and is usually too tired to exercise after her long day at work and commute.

Nutrition Diagnostic Statement

Overweight/obesity related to poor food choices as evidenced by a BMI of 31.

Nutrition Care Questions

1. What would you include in a nutrition screening for Laverne?
2. What would you include in a nutrition assessment for Laverne?
3. How could you identify her medications?
4. What additional information is needed for assessment of her dietary and nutrient intake?
5. If you need more details, what questions would you ask her physician?

BMI, Body mass index.

KEY TERMS

allele	genomic imprinting	nutrigenomics
autosomal dominant	genomics	nutritional genomics
autosomal recessive	genotype	pedigree
autosome	haplotype	penetrance, reduced penetrance
bioactive food components	heterozygous	peroxisome proliferator-activated receptor (PPAR)
bioinformatics	histone	pharmacogenomics
chromosome	homozygous	phenotype
coding region	Human Genome Project	polymerase chain reaction (PCR)
codon	inborn errors of metabolism (IEM)	polymorphism
copy number variant	insertions	posttranscriptional processing
CpG island	inversions	promoter region
deletion	International HapMap Project	proteomics
deoxyribonucleic acid (DNA)	intervening sequences	recessive
DNA code	intron	recombinant DNA
DNA methylation	karyotype	regulatory region
DNA sequencing	junk DNA	response element
dominant	ligand	restriction endonuclease (restriction enzyme)
Encyclopedia of DNA Elements (ENCODE)	meiosis	RNA interference (RNAi)
environmental factors	mendelian inheritance	sex chromosome
epigenetics	messenger RNA (mRNA)	sex linked
epigenetic code	metabolomics	signal transduction
epigenetic gene silencing	methylome	silent mutation
epigenetic inheritance	microarray technology (DNA “chips”)	single nucleotide polymorphism (SNP)
epigenetic marks	microbiomics	small interfering RNA (siRNA)
epigenome	microRNAs (miRNA)	transcription
epigenomics	mitochondrial DNA (mtDNA)	transcription factor
exon	mitochondrial (maternal) inheritance	transgenerational epigenetic inheritance
gene	mitosis	translation
gene X environment (GxE)	model system	translocation
genetic code	mutation	xenobiotics
genetics	National Human Genome Research Institute	X-linked dominant
Genetic Information Nondiscrimina- tion Act (GINA)	nucleosome	X-linked recessive
genetic variation/gene variant	nucleotide	Y-linked inheritance
genome	nutritional epigenetics	
genome-wide association studies (GWAS)	nutrigenetics	

Imagine being able to factor into the medical nutrition therapeutic intervention a client's genetic susceptibilities and environmental influences so that therapy could be targeted to optimizing health and minimizing disease. Does such an approach sound a bit like science fiction? For the immediate future, perhaps, but not for the long term. The prevalence of

chronic disorders, such as heart disease, cancer, diabetes, and obesity, has been rising steadily throughout the world, accompanied by a decreasing quality of life for individuals and a soaring economic burden for the countries in which they live. Chronic disease is lifestyle disease, the result of lifelong inappropriate daily choices, particularly nutrition, interacting

with each individual's genetic makeup, their **deoxyribonucleic acid (DNA)**. These disease-promoting habits typically begin in early childhood and, for many, prenatally. Delivering effective lifestyle therapy will be a major focus of clinical nutrition in the decades ahead and will involve knowledge, skills, and tools that target the molecular, biochemical, physiologic, and social aspects of health and disease.

The success of the **Human Genome Project** in identifying the nucleotide building blocks of human DNA has elevated substantially our knowledge of the importance of understanding how chronic disease occurs at the molecular level. At this level common variations in DNA interact with a multitude of **environmental factors**, such as the foods consumed, to influence physiologic outcomes (i.e., a tendency toward wellness or illness). Health care for individuals with chronic conditions has focused on managing disease, primarily through the use of medications. Insight into the root causes of these disorders and identification of the underlying mechanisms responsible for the development and perpetuation of chronic disorders is providing new approaches that bring the promise of restoring health to those with chronic disease and, ultimately, preventing its development.

Nutrition research is focused increasingly on the mechanisms that underlie these interactions and on projecting how this understanding can be translated into clinical interventions for more effective chronic disease management and prevention. Health is a continuum that spans wellness at one end and illness at the other. Genes are an important component in determining at which end of this continuum we find ourselves; they determine our unique signature of susceptibility to being well or ill. However, research into chronic disease is teaching us that environmental factors such as diet and other lifestyle choices made on a daily basis strongly influence who among the susceptible will actually develop dysfunction and disease. Food choices, physical activity habits, sleep patterns, thoughts and emotions, and systems of meaning—relationships with self and others and one's sense of purpose in life—affect cellular function at the molecular, biochemical, and physiologic levels. The influence of these environmental factors is modifiable through daily choices and, when appropriate to the genetic makeup, has the potential for changing the health trajectory from a poor quality of life filled with disease and disability to one of thriving and flourishing.

This understanding of the key role of choices regarding these modifiable lifestyle factors is enabling clinicians to drill down to the root cause of chronic disease, to identify the molecular and biochemical mechanisms that underlie symptoms, and to tailor therapy to the individual's uniqueness. As a result, the promise of the molecular era is not only to manage chronic disease more effectively but also to restore health and, ultimately, to prevent chronic disease from developing. The interactions among genes, diet and other lifestyle factors, and their influence on health and disease are the focus of **nutritional genomics**. This emerging subdiscipline of clinical nutrition provides the tools for identifying genetic variations that portend increased susceptibility to developing chronic disease and the knowledge for modifying lifestyle choices to promote health rather than disease.

Considerable research is needed to realize the full potential of nutrition to prevent disease and promote health, from building a deep foundation of scientific knowledge to developing new technologies and tools, to applying targeted interventions in the clinic. Nutritional genomics is an important assessment tool that provides the ability to (1) identify the

genetic signature of each individual, (2) assess the health and disease susceptibilities of that individual, and (3) project, for each modifiable lifestyle factor that influences health, which choices are most likely to promote health and prevent disease throughout the lifespan.

THE HUMAN GENOME PROJECT AND THE “OMIC” DISCIPLINES

Nutritional genomics has been an active research area within the genetics community for decades. However, this discipline has come to the forefront only recently as a result of the success of the Human Genome Project and the resultant widespread understanding that genetic makeup directly relates to state of health and disease. Fifty years after the elucidation of the structure of DNA, the genetic material, and its clues as to how information is encoded and translated into proteins, the Human Genome Project identified the sequence of nucleotide building blocks in the DNA and projected an estimate of approximately 19,000 genes, the sequences of nucleotides that encode each protein's structural information.

The “Omics”

The Human Genome Project was completed in 2003 but was just the beginning of the move to integrate genetic principles into health care. From this multinational effort has come numerous new disciplines (often called the “omics”), technologies, and tools applicable to health care. The sum of an organism's genetic material is its **genome**. Within the genome are the individual **genes**, stretches of DNA that contain the information for synthesizing a protein and the regulatory sequences that control expression of this information and thus the synthesis of these proteins.

Genomics is the study of genomes, their composition, organization, and function. Interest in the human genome and how this knowledge can improve health care is paramount at this time, but the genomes of numerous animals and plants also are being sequenced. This work has provided the opportunity to compare the size, nucleotide sequence, and organizational complexity of the human genome with other organisms, from bacteria to plants to mammals. Many aspects of the genome have been conserved across species, which provides useful information as to which regions of the genome are critical to life. Because of this genetic homogeneity, it has been possible to develop a variety of model systems whose genes can be manipulated experimentally and the influence on function determined. In this way **model systems**, such as the laboratory mouse, whose genome is similar to that of humans, have served as valuable sources of information about human health and disease at the molecular and biochemical levels.

The Human Genome Project has ended, but it has spawned a host of new projects, disciplines, and technologies, which are discussed briefly in this chapter. The **Encyclopedia of DNA Elements (ENCODE)** is a follow-up to the Human Genome Project. Whereas the Human Genome Project focused on defining genes within the total genome, the ENCODE project's goal is to investigate the nongene sequences, which make up approximately 99% of the human genome. Originally thought to be “**junk DNA**” because a substantial proportion of this DNA does not code for proteins, these nongene sequences appear to be critical to regulating the expression of genes and their encoded proteins. For additional information see <http://ghr.nlm.nih.gov/handbook/genomicresearch/encode>.

Among the disciplines spawned by the Human Genome Project are proteomics, metabolomics, microbiomics, and **bioinformatics**. This latter is an important tool for managing the vast amount of data generated by the various “omic” disciplines. **Proteomics** focuses on identifying the protein encoded within each gene in an organism’s genome and on determining its function. **Metabolomics** is concerned with identifying metabolites that are produced in all aspects of metabolism, typically as a result of the action of proteins. **Microbiomics** is a relatively new discipline that recognizes the importance of the microbial ecology (the microbiome) of the digestive tract and other body cavities, such as the mouth and vagina. Beneficial and pathogenic microbes colonize these cavities. The contributions of these microbes and their metabolites to human health and disease are currently under investigation.

DNA sequencing analysis is used to identify pathogenic organisms and is replacing rapidly the time-consuming growth assays used in the clinical laboratory to identify which microbial strains are present in a patient’s digestive tract, for example, along with the relative concentrations of each strain. In this way antimicrobial therapy can be initiated quickly. For the beneficial microbes, researchers are investigating which strains help to promote human health and how diet and lifestyle choices can support their vitality and successful colonization within the body.

The vast amount of data generated by these disciplines has led to rapid growth in the field of **bioinformatics**, a field that sits at the crossroads of computer science, information science, biology, and medicine. The development of sophisticated computers that can organize, store, and retrieve massive amounts of data has been integral to the rapid advances of the genomics era. Researchers around the world are able to share data and compare various “omic” profiles across a variety of microbes, plants, and animals.

For a more complete explanation of these fields and their nomenclature and associated technologies, see current genetics and molecular biology texts as well as the online resources available through the **National Human Genome Research Institute** (www.genome.gov).

Clinical Applications

These “omic” disciplines that have arisen from the Human Genome Project increasingly are being integrated into clinical applications. The earliest application has been in **pharmacogenomics**, which involves using genomics to analyze the genetic variations in the genes that direct the synthesis of the drug-metabolizing enzymes and using this information to predict a patient’s response to a drug. Genetic variability can lead to differing function in these enzymes, which explains why a drug may have the intended effects for one person, be ineffective for another, and be harmful to a third. Examples of drugs for which genetic testing is being incorporated before initiation of therapy include warfarin (the *CYP2C9* and *VKORC1* genes) (Johnson, 2014) and clopidogrel (the *CYP2C19* gene) (Goswami, 2012; Mega, 2009).

Additional clinical applications in current use involve assisting with diagnosis and selection of therapeutic interventions. Knowing the gene associated with a particular disease and the gene’s DNA sequence, its protein product, and the function of the protein in promoting health or disease provides the basis for diagnostic assays and effective interventions. Oncologists routinely use genetic profiling for screening and therapy. Tumors that appear pathologically identical can be distinguished by

their genetic profiles. This distinction is important for effective therapy because different types of tumors respond to different therapeutic approaches. Oncologists also have been using genomic analysis to monitor therapeutic response and to project which individuals are most likely to experience treatment failure early in the therapy so that they can be switched to another therapy as quickly as possible.

Beyond diagnosis, intervention, and monitoring, genomic analysis can be used to detect dysfunction in those without symptoms. This aspect is particularly important to health promotion because it allows for assessment of genetic susceptibilities and early intervention before disease symptoms become apparent.

Metabolomics, coupled to genomics, is expected to enhance treatment efficacy. Genomic analysis can provide information about an individual’s genetic susceptibilities but does not provide insight as to where on the spectrum between illness and wellness the individual currently falls nor the efficacy of the therapeutic intervention being followed. **Metabolomics** is useful in filling in these gaps by measuring which metabolites are present and at what concentrations. This information reflects how functional the gene variant’s protein product is, which in turn can be helpful in projecting how well an individual will function in a particular environment. **Epigenomics** enhances genomics further through its focus on the interactions between the genome and the information coming in from the environment. Each of these disciplines is part of the larger picture of increasing focus of nutrition therapy at the molecular and biochemical levels.

For these technologies to be helpful in the clinic, clients must be comfortable with their use. Of particular concern to clients has been whether their information would be used for their benefit and not lead to discrimination in obtaining employment and insurance. These concerns thus far have not been realized. From the beginning of the Human Genome Project attention has been given to addressing the ethical, legal, and social implications of genetic research and technology to protect against just such concerns. The passage of the **Genetic Information Nondiscrimination Act (GINA)** in 2008 is seen as an important milestone in ensuring that Americans will not be discriminated against with respect to employment and health insurance.

Nutritional Genomics

Among the “omic” disciplines of particular importance to nutrition professionals are nutritional genomics and epigenetics. Nutritional genomics is the field itself, and includes nutrigenetics, nutrigenomics, and epigenetics. **Nutritional genomics** focuses on diet- and lifestyle-related disorders that result from the interaction between the genome and environmental factors, such as nutrients and other bioactives in food, toxins and other xenobiotics (new-to-nature molecules), physical activity, sleep, and stress.

Nutritional genomics is conceptually similar to pharmacogenomics in that, like drugs, food requires enzymatic processing into nutrients before absorption and circulation in the body’s tissues and cells. Changes in the genes that encode the proteins involved can lead to changes in nutrient availability at the cellular level. This emerging field incorporates the various “omic” disciplines in multiple ways, such as identifying an individual’s genetic susceptibilities by virtue of the gene variants in his or her genome (genomics), analyzing the influence of these variants on the expression of the proteins encoded by the gene

variants and the functioning of the expressed proteins (proteomics), and detecting the metabolites produced and their concentration (metabolomics).

Nutrigenetics is concerned with how an individual's set of genetic variations affects function. For example, an often-cited illustration of nutrigenetics involves the 5,10-methylenetetrahydrofolate reductase (*MTHFR*) gene. Human beings have two copies of this gene. **Mutations** (changes to the DNA) in this gene can result in a substantial decrease in enzymatic activity, which is responsible for converting dietary folate or folic acid into 5-methyl folate, the active form. Individuals with such a mutation in both copies of the *MTHFR* gene require the active form of folate for optimal health. **Nutrigenomics**, in contrast, is the study of the interaction of genes and environmental factors that result in a change in gene expression. In the *MTHFR* example, mutation in even a single nucleotide within the region of the gene that controls gene expression could result in insufficient reductase enzyme production, which essentially mimics the outcome of having two copies of an altered *MTHFR* gene. This individual also would need the activated form of folate for optimal health. In addition, the frequency of particular genetic variations differs among populations. For example, the frequency of occurrence of the most common *MTHFR* gene variant is low in African Americans, moderate in Caucasians, and relatively high in Hispanics. Clinicians alert to this type of information are particularly diligent about assessing folate status of pre-conception Hispanic females to forestall complications such as miscarriages and neural tube defects (see Chapter 15).

Epigenetics provides an additional influence on functional outcomes beyond those at the genomic level by controlling whether genes can be expressed, which in turn determines whether nutrigenetic or nutrigenomic influences can occur. The *epi-* prefix is from the Greek meaning “above,” in this case meaning “above the genome.” By attaching chemical groups to the DNA or its associated proteins, epigenetic processes allow or disallow gene expression in a heritable fashion but without changing the nucleotide sequence of the DNA. Each different cell type, whether a liver, heart, or brain cell, has the complete set of genetic information, yet only a portion of the total genome is expressed once the cell has differentiated. The control of gene expression is the result of the **epigenetic marks** on the genetic material of that cell, the “epigenetic signature” of that cell type. The genome has not changed; the DNA is the same from cell type to cell type. What is different, and what results in the differential gene expression, is the unique set of epigenetic “marks” or “tags” of each cell type (the total of all the epigenetic markings in that cell type is the **epigenome**). In this way cells become specialized and perform roles unique to the needs of a specific type of tissue. A bone cell does not need to produce insulin but the beta-cells of the pancreas do. Epigenetic markings control which regions of a cell's genome are translated into the needed proteins. Further, the timing of gene expression is critical during fetal development and is orchestrated exquisitely.

Epigenetics research is of increasing importance with respect to chronic disease management and prevention, because the composition of the epigenome in various cell types is influenced by our lifelong diet-and-lifestyle choices (i.e., “environmental factors”). Thus the potential exists for these choices to be modified by the individual in ways that will promote health rather than disease. The main emphasis of research to date has centered around epigenetics and cancer, and the role of diet and lifestyle modification (Supic et al, 2013). The main categories of

environmental factors in this regard are nutrition, physical activity, sleep and recovery, thoughts and emotions and the stress they induce, and relationships and sense of life purpose. Technically each of the modifiable lifestyle factors has its own subdiscipline of epigenetics that describes how a specific type of environmental factor “talks” to the DNA through chemical modification, such as **nutritional epigenetics**, behavioral epigenetics, and so on. However, in practice epigenetics embraces this whole study of how the environment communicates with an organism's DNA to modulate gene expression and what this interaction portends for one's health status. Ultimately, diet and other lifestyle choices are expected to be geared toward the particular variants of each individual to provide the most appropriate support for that individual's unique genome. (See Waterland, 2014 for an overview of the emerging field of epigenetics.)

Epigenetics is a significant enhancement to our understanding of the role of genes in living organisms. Traditional theory was that genes contain information that, when translated into proteins, determines an organism's functional ability, and that this situation was permanent for life. Instead, genes can be thought of as the organism's hardware; the environmental factors washing over the genes throughout a lifetime supply the software that provides the functional outcomes. That is, it is not just our genes; it is the interaction of our genes with lifestyle choices throughout life that determines function. Identical twins, who have the same DNA nucleotide sequence, provide an excellent descriptive example of the influence of epigenetics. These siblings appear to be identical in looks and function when they are young but, as they age, distinctions gradually begin to emerge in a variety of characteristics, from physical appearance to disease conditions. It is not unusual for one identical twin to develop a disease and for the other twin to remain healthy. Studies of identical twins have been a mainstay of genetic research and will continue to help us understand the physiologic consequences of changes at the molecular level, particularly how environmental factors change gene expression and therefore health outcomes.

GENOTYPE AND NUTRITION ASSESSMENT

The application expected to have the most dramatic effect on clinical nutrition professionals is the ability to associate a unique genotype with that person's susceptibility to particular diseases. This advance is an important enhancement in the nutrition assessment, diagnosis, and intervention phases of the nutrition care process. As understanding of how genotype influences the ability to function within a particular environment and how environmental factors influence gene expression progresses, nutrition protocols will be developed. Specific counseling and nutrient recommendations will be guided increasingly by the client's genetic profile.

Nutrition professionals must be able to translate client genotypes to develop appropriate interventions. If nutrition professionals are going to be prepared for the era of genomic-directed health care, they must develop a foundation in genetics, biochemistry, molecular biology, metabolism, and other fundamental sciences of twenty-first-century nutrition.

GENETIC FUNDAMENTALS

Genetics is the science of inheritance and forms the foundation of the disciplines of genomics, epigenomics, pharmacogenomics,

and nutritional genomics. Historically genetic research focused on identifying the mechanisms by which traits were passed from parent to child, such as physical traits or certain rare diseases that appeared within extended families. Genetic diseases were considered to be a separate category of disease that were limited to those rare heritable disorders that resulted either from changes to a single gene that produced a detectable change in function or alterations at the chromosomal level, which affected multiple genes and often had a devastating effect on the functional ability of the individual. Today it is recognized that, directly or indirectly, all disease is connected to the information in the genes and how that information is translated into functional ability. Furthermore, depending on the role of the protein encoded by a gene; where within a gene a change occurs; and the extent of its impact on the ability of the protein to fulfill its role, there is a continuum in terms of the extent of dysfunction that occurs. Whereas particular changes in some genes have a devastating effect on function and that dysfunction is identified readily as a disease, changes in other genes may be silent or have a much less drastic functional impact. Even within the cystic fibrosis transmembrane conductance regulator gene (*CFTR*) associated with the development of cystic fibrosis, more than 1000 different changes (mutations) have been detected in that one gene (<http://ghr.nlm.nih.gov/gene/CFTR>). Some changes are associated with severe cystic fibrosis and others with much milder disease (see Chapter 34). For additional exploration, the National Coalition for Health Professional Education in Genetics website provides a good overview of characteristics of this gene and the physiologic effects of different mutations within this gene (<http://www.nchpeg.org/nutrition/index.php>).

Again, what is observed (the **phenotype**) is a continuum of physiologic outcomes reflecting which mutation is involved. This realization has contributed to the shift away from the concept of “genetic disease” being distinct and rare and to an understanding that each different change within a gene’s nucleotide structure has the potential to affect physiologic outcomes differently. Some are so devastating that dysfunction (disease) is readily detectable whenever that change is present, whereas others are mild or even silent unless triggered by an environmental factor. The latter is particularly important with respect to chronic disease in which an individual may have the genetic susceptibility but not manifest disease unless exposed to an inappropriate environment. A well-established example is celiac disease, in which a genetic change results in the inability to fully digest to single amino acids a protein common to wheat, barley, and rye. When exposed to these foods, the individual with celiac disease develops an immune reaction to the incompletely digested protein, an inflammatory response within the digestive tract, erosion of the lining of the gut, and resultant disruption of essential digestive and absorptive processes. However, if the environment is changed—in this case eliminating exposure to the offending protein—the pathology characteristic of celiac disease can be avoided, even though the individual still has the genetic potential to react to this type of protein and trigger celiac symptoms.

These examples highlight the value of knowing the client’s genetic makeup, the underlying mechanisms involved, and the appropriate nutritional therapy that can prevent disease from occurring and potentially can restore health in those who already have developed disease. For nutrition professionals to maximize the potential of nutrition genomics,

however, it is helpful to have a solid command of genetics and genomics, from the fundamentals to current research into chronic disease and its underlying **gene X environment interaction (GxE)**. This chapter briefly reviews the basic principles of genetics at the molecular and chromosomal levels, modes of inheritance, mechanisms of disease, and then addresses the newer discipline of epigenetics and epigenomics, which is of particular importance to chronic disease, and a summary of how nutritional genomics is being used in various diseases. For a more in-depth exploration of these topics, there are numerous resources for learning foundational genetics and genomics, from current textbooks to online resources, such as the Genetics Home Reference site (<http://ghr.nlm.nih.gov/handbook>) and the National Human Genome Research Institute (www.genome.gov), as well as various resources from the Online Genetics Education Resources (<http://www.genome.gov/10000464>). Please see the **Useful Websites** list at the end of this chapter for additional recommended resources.

Genetic Basics

Genetics as a discipline historically developed from the observation that physical traits could be inherited among generations, first in plants and later in humans and other mammals. In time the inheritance patterns for human traits were explained by the distribution of chromosomes during egg and sperm formation and the reconstitution of the diploid state at fertilization. The later discovery that DNA was the essential chromosomal component responsible for inheritance led to the molecular era in which genes, mutations, proteins, function, and dysfunction came to be understood. Extensive research over the past six decades has revealed many of the details of these processes and their relationship to each other, such as the chemical makeup of the genetic material DNA, how it stores information and how that information is retrieved and translated into proteins that do the work of the cells, and how those proteins contribute to the individual’s functional ability.

Deoxyribonucleic acid (DNA) is the genetic material of all living organisms. In higher organisms the DNA is housed within the nucleus of cells. The molecule is a double helix consisting of two strands of **nucleotide** subunits held together by hydrogen bonds. The human genome contains approximately 3 billion nucleotides. Each nucleotide contains the sugar deoxyribose, the mineral phosphorus, and one of four nitrogenous bases: adenine (A), thymine (T), guanine (G), or cytosine (C). The nucleotides are arranged side by side, and this linear arrangement determines the particular information encoded in a stretch of DNA that results in the synthesis of a protein.

The large amount of genetic material in the nucleus is distributed among multiple **chromosomes**, which are a combination of DNA and specific proteins called **histones**. Human beings have 23 pairs of chromosomes, 22 autosomes, and 2 sex chromosomes. One copy of each member of a pair comes from the mother and the other copy from the father. Females have two X chromosomes; males have one X and one Y chromosome. The nucleus of each human cell contains all 46 chromosomes, which are typically in a highly condensed state to fit all the genetic material into the nucleus. Condensation is achieved by the DNA winding around core structures of eight histone proteins. The combination of DNA wrapped around histone structures forms the **nucleosome**.

To be useful to the cells, information in the DNA first must be decoded and translated into proteins, which perform the work of the organism at the cellular level. A sequence of DNA nucleotides that encodes the information for synthesizing a protein is called a **gene**. There are approximately 19,000 genes. Each gene has a location or “address” at a specific site on a particular chromosome. Long stretches of nucleotides often are found between one gene and the next along the chromosome. Such sequences are called **intervening sequences** and compose the majority of the DNA in humans. These sequences do not code for proteins, but they are not “junk DNA.” Instead, they perform structural and regulatory functions, such as controlling when, where, and how much of a protein is produced.

To initiate the process of decoding the DNA, the condensed chromosomes housing the genes first must open (decondense) to allow access to the information in the DNA nucleotide sequence. A common mechanism employed is the covalent attachment of acetyl groups to the histone proteins associated with the chromosomes. This action relaxes the DNA and makes it accessible to the transcription (decoding) process. Information decoding involves **transcription** by RNA polymerase into **messenger RNA** (mRNA) and subsequent **translation** of mRNA into the amino acid sequence of the protein according to a universal **genetic code**. The architecture of a gene typically includes a **promoter region**, where the RNA polymerase attaches and a **coding region** (also called a “structural region”) that contains the encoded information for the structure of a protein. Within the coding region are sequences of nucleotides (**exons**) that correspond to the order of the amino acids in the gene’s protein product. The coding region also contains **introns** (sequences that are interspersed between exons and do not code for amino acids needed for synthesizing proteins).

Upstream from the promoter region is the **regulatory region** that controls the ability of the polymerase to attach to the promoter, thereby influencing whether transcription occurs. Within this region are **response elements**, DNA sequences that serve as binding sites for regulatory proteins such as **transcription factors** and their bound **ligands**. The binding of transcription factors triggers the recruitment of additional proteins to form a protein complex that in turn changes the expression of that gene by changing the conformation of the promoter region, increasing or decreasing the ability of RNA polymerase to attach and transcribe (express) the gene. The array of response elements within the promoter region can be complex, allowing for the binding of multiple transcription factors that in turn fine-tune the control of gene expression. It is through the binding of transcription factors to response elements that environmental factors such as the bioactive components in food essentially “talk” to a gene, conveying information that more or less of its protein product is needed.

Once transcribed, the mRNA must be processed (**posttranscriptional processing**) so that the introns are removed before the protein is synthesized. At this point, each set of three nucleotides in the transcribed and processed exon makes up a **codon**, which in turn specifies a particular amino acid and its position within the protein. Some proteins need further posttranslational processing before they are active, such as occurs with glycoproteins, proenzymes, and prohormones that must be enzymatically processed before becoming active.

The regulation of transcription (i.e., gene expression) is complex. The need to first decondense the chromosomes that contain the genes is one step in the control of gene expression.

A second level of control of gene expression is epigenetic control, which occurs at the level of the DNA. A common control mechanism involves the attachment of methyl groups to the DNA within the regulatory region of a gene. When methyl groups are attached, transcription is impeded and gene expression is silenced. Alternatively, removal of the methyl groups permits gene expression to take place.

In addition to the information in the nucleotide sequence of DNA (the “**DNA code**”), there are two other sources of information: the **epigenetic code** and the environmental factors to which cells are exposed. Epigenetics is nature’s “pen-and-pencil set” (Gosden and Feinberg, 2007). Acetyl or methyl groups, covalently attached to histone proteins associated with DNA or to the DNA itself, respectively, affect whether DNA is accessible for decoding. These groups can be added and removed as needed and are influenced by exposure to various environmental factors such as traditional nutrients, phytochemicals, cytokines, toxins, hormones, and drugs. These environmental factors communicate information as to the state of the environment and ultimately influence when and whether particular genes are expressed. The majority of these environmental factors are lifestyle factors and modifiable based on the individual’s choices. The science of **nutritional genomics** is concerned particularly with the interactions between dietary factors and DNA, their influence on health outcomes, and how nutrition therapy can be used to optimize health and minimize disease. **Figures 5-1 through 5-6** review these fundamental genetic principles.

The proteins coded for by the genes provide the metabolic machinery for the cells, such as enzymes, receptors, transporters, antibodies, hormones, and communicators. Changes within a gene can alter the amino acid sequence of the protein. Such changes are called **mutations**, which historically have been associated with the concept of severely impairing the function of that protein and creating dysfunction within the cells and, ultimately, the organism. A single nucleotide change may be all that is needed to cause a debilitating disease. For example, in those with sickle cell disease, a single nucleotide change causes a

FIGURE 5-1 Cells are the fundamental working units of every living system. All the instructions needed to direct their activities are contained within the chemical deoxyribonucleic acid. (From U.S. Department of Energy, Human Genome Program: www.ornl.gov/hgmis/.)

DNA Replication Prior to Cell Division

FIGURE 5-2 Each time a cell divides into two daughter cells, its full genome is duplicated; for humans and other complex organisms, this duplication occurs in the nucleus. During cell division the deoxyribonucleic acid (DNA) molecule unwinds, and the weak bonds between the base pairs break, allowing the strands to separate. Each strand directs the synthesis of a complementary new strand, with free nucleotides matching up with their complementary bases on each of the separated strands. Strict base-pairing rules are adhered to (i.e., adenine pairs only with thymine [an A-T pair] and cytosine with guanine [a C-G pair]). Each daughter cell receives one old and one new DNA strand. The cells' adherence to these base-pairing rules ensures that the new strand is an exact copy of the old one. This minimizes the incidence of errors (mutations) that may greatly affect the resulting organism or its offspring. (From U.S. Department of Energy, Human Genome Program: www.ornl.gov/hgmis.)

DNA Genetic Code Dictates Amino Acid Identity and Order

FIGURE 5-3 All living organisms are composed largely of proteins. Proteins are large, complex molecules made up of long chains of subunits called *amino acids*. Twenty different kinds of amino acids are usually found in proteins. Within the gene, each specific sequence of three deoxyribonucleic acid bases (codons) directs the cells protein-synthesizing machinery to add specific amino acids. For example, the base sequence ATG codes for the amino acid methionine. Because three bases code for one amino acid, the protein coded by an average-sized gene (3000 bp) contains 1000 amino acids. The genetic code is thus a series of codons that specify which amino acids are required to make up specific proteins. A, adenine; bp, base pairs; C, cytosine; G, guanine; T, thymine. (From U.S. Department of Energy, Human Genome Program: www.ornl.gov/hgmis.)

DNA Sequence Variation in a Gene Can Change the Protein Produced by the Genetic Code

Gene A from person 1	CGT	TCT	CTA	TTA	ACA	Protein products
	Ala	Arg	Asp	Asn	Cys	
	1	2	3	4	5	
Gene A from person 2 (Codon made no difference in amino acid sequence)	CGC	TCT	GAT	TTA	ACA	
	Ala	Arg	Asp	Asn	Cys	
	1	2	3	4	5	
Gene A from person 3 (Codon resulted in a different amino acid at position 2)	CGT	TTT	GAT	TTA	ACA	Or
	Ala	Lys	Asp	Asn	Cys	
	1	2	3	4	5	

FIGURE 5-4 Some variations in a person's genetic code will have no effect on the protein that is produced; others can lead to disease or an increased susceptibility to a disease. (From U.S. Department of Energy, Human Genome Program: www.ornl.gov/hgmis.)

Health or Disease?

	DNA Sequence	
Person 1	A A A T T T	Normal protein
	↑	
Person 2	A A T T T T	
	↑	Low or nonfunctioning protein
Person 3	A A C T T T	

FIGURE 5-5 Human beings differ from each other in only an estimated 0.1% of the total sequence of nucleotides that compose deoxyribonucleic acid. These variations in genetic information are thought to be the basis for the physical and functional differences between individuals. (From U.S. Department of Energy, Human Genome Program: www.ornl.gov/hgmis.)

single amino acid change in the hemoglobin molecule, resulting in severe anemia (see Chapter 32).

Changes in the DNA are the basis for evolution; thus clearly not all mutations are harmful. Some changes actually improve function, and many **silent mutations** have no effect. The effect of the mutation on the functioning of the encoded protein is what determines the outcome, from debilitating disease to no effect at all. All changes to the DNA are technically mutations. However, at this point in the development of genomics and its lexicon, the term **mutation** tends to be applied to those changes that sufficiently influence function such that a measurable outcome results. In contrast, the term **genetic variation** (or **gene**

FIGURE 5-6 Epigenetic regulation of gene expression through histone modification and DNA methylation.

variant) is reserved for those mutations with an effect on function that is not strong enough to lead to a disease or other measurable outcome by itself. Nutritional genomics is concerned primarily with those variations that interact with dietary and other environmental factors.

Thus a gene can exist in slightly different forms as a result of a seemingly minor change, such as a substitution of a single nucleotide with another (e.g., guanine can replace cytosine). The term for the different forms of a gene is an **allele** or **polymorphism**. As a result, genes have protein products with differing amino acid sequences (isoforms) and often different functions. Polymorphism (allelism) is an important concept because it explains why human beings, although 99.9% alike genetically, are distinctly different. The 0.1% difference is sufficient to explain the obvious physical variations among humans. It is also the basis for more subtle differences that may not be readily observable, such as in the functional ability of a key metabolic enzyme to catalyze its reaction. Such variations likely underlie many of the inconsistencies observed in therapeutic outcomes and in nutritional intervention research.

The **single nucleotide polymorphism (SNP)** is the structural variant best studied and by far the most common change in DNA. As the name for this genetic variation suggests, the change involves a single nucleotide within DNA. Depending on where in the gene the change occurs and the effect on the encoded protein's function, the nucleotide alteration may result in no change in function, improved change in function, or dysfunction and disease susceptibility. A major ongoing research effort is to identify the SNPs that exist within the human genome and to associate each with their effect on function, particularly with respect to health and disease.

The rate of progress of nutritional genomics in terms of clinical applications is associated strongly with progress in identifying SNPs associated with disease so that diagnostic tests and appropriate diet and lifestyle interventions can be developed and tested for efficacy. The **International HapMap Project** is a multicountry collaboration designed to catalog in the DNA of human beings common patterns of genetic variants that are associated with health and disease. The HapMap Project figures prominently in the efforts to develop a deep scientific foundation upon which to base nutritional genomics-related diagnosis and therapy. "HapMap" is short for haplotype.

A **haplotype** occurs when several SNPs are clustered together in the same region of a chromosome, which typically results in their being inherited as a group. Because the human genome contains approximately 10 million SNPs, studying each one is not practical at this time, but studying haplotypes allows for large-scale studies of SNPs (called **genome-wide association studies**, or **GWAS**) and their association to human disease across multiple populations. Remember that each gene pool (i.e., population) has its own signature set of SNPs, slightly different from any other population. This feature is important to keep in mind in reference to the application of nutrition therapy because what is appropriate for one human population is not necessarily appropriate for all other populations because of the differences in gene pools. For additional information on the HapMap Project, see the Project's website at <http://hapmap.ncbi.nlm.nih.gov/abouthapmap.html>.

Ongoing analysis of the human genome suggests that, in addition to SNPs, other structural variations also may play an important role in the genotypic and phenotypic variation among humans. Loss or gain of one or more nucleotides (**deletions** and **insertions**, respectively), duplication of nucleotide sequences, **copy number variants**, and restructuring of regions within a chromosome (**inversions** and **translocations**) also have important consequences to function. A chromosome may contain thousands of genes and the order of the nucleotides must remain intact to produce the proteins encoded in each gene's original nucleotide sequence. Whereas a single nucleotide may result in no effect or even an improved effect on function, changes in multiple genes tend to be lethal.

Understanding the prevalence and significance of genetic variation is a primary focus of twenty-first century nutrition, which represents a major departure from nutrition research and therapy to date. Each person is susceptible to a different set of diseases, handles environmental toxins differently, metabolizes molecules somewhat differently, and has slightly unique nutritional requirements. These exciting discoveries are revolutionizing the way clinicians think about the clinical aspects of medicine, pharmacology, and nutrition. Personalized therapy using individualized dietary requirements will become increasingly common in nutrition therapy.

Control of Gene Expression

The control of gene expression occurs at two levels: genomic and epigenomic. Genomic control takes place within the regulatory region of genes, upstream from the promoters. Transcription factors, specialized proteins that have one site for binding DNA and one for binding a small molecular weight ligand, bind to the DNA and regulate whether the RNA polymerase can attach to the promoter and initiate transcription. Factors that influence binding are mutations within the nucleotides that make up the DNA binding site and ligands. Mutations and ligands can promote or inhibit transcription, depending on the gene involved. Among the numerous ligands identified are bioactive food components such as the omega-3 and omega-6 fatty acids, derivatives of vitamin A, vitamin D, and numerous phytonutrients. These molecules bind to transcription factors to form an active complex that directs the conformation of the DNA, which in turn influences the facility with which the RNA polymerase can bind to the promoter and initiate transcription.

From a nutrition therapy perspective, a fruitful research approach has been to investigate whether changing the nature of the ligand can potentially influence transcription and therefore

physiologic outcomes. A variety of bioactive components in food (**bioactive food components**) have been tested, particularly for the ability to attenuate inflammation as an important underlying mechanism in the development of cancer (see Chapter 36). The majority of the work to date is either laboratory or animal based. Numerous food bioactives can alter gene expression and interfere with the expression of proinflammatory genes, a central underlying mechanism in cancer and other chronic diseases. In addition to omega-3 and omega-6 fatty acids, vitamin D, and conjugated linoleic acid from dairy products, the phytonutrients curcumin from the spice turmeric, sulforaphane from cruciferous vegetables, resveratrol from purple grapes, genistein from soybeans, quercetin from onion and garlic, (-)-epigallocatechin-3-gallate (EGCG) from green tea, luteolin from celery, broccoli, and numerous other plants have been shown to inhibit proinflammatory transcription factors such as tumor necrosis factor alpha, interleukin-1 beta, interleukin-6, and nuclear factor kappa B, which in turn decreases the expression of proinflammatory genes (Gupta and Prakash, 2014; Ong et al, 2012; see Chapter 3).

Epigenetic control can occur at the level of histone modification or DNA modification and is discussed in the section titled Epigenetic Inheritance. **Epigenetic marks** control the availability of DNA for transcription and translation. Because gene expression changes are critical in normal development and disease progression, epigenetics is widely applicable to many aspects of biological research. The influences of nutrients and bioactive food components on epigenetic phenomena, such as DNA methylation and various types of histone modifications, have been investigated extensively. An individual's epigenetic patterns are established during early pregnancy and are personalized further through the interaction with various environmental factors over his or her lifetime. Epigenetics is, understandably, critically important during development. Alterations of genome-wide DNA methylation have been observed during adulthood, which has led to the hypothesis that epigenetics is also relevant to the aging process as well as the emergence of diseases such as cancer, obesity, diabetes, and cardiovascular disease (Brunet and Berger, 2014; Chaturvedi and Tyagi, 2014; Choi et al, 2013). Of importance to nutrition professionals is the understanding that diet and lifestyle exposure throughout the lifespan are key modifiers of the epigenetic patterns that, in turn, influence long-term health (Jiménez-Chillarón JC et al, 2012; Lillycrop and Burdge, 2012; Milagro et al, 2013).

Modes of Inheritance

Traits are transmitted from one generation to the next in three ways: mendelian inheritance, mitochondrial inheritance, and epigenetic inheritance.

Mendelian Inheritance

Each cell's nucleus contains a complete set of genetic material (**genome**), divided among 22 pairs of chromosomes (called **autosomes**) and 2 **sex chromosomes** for a total of 46 chromosomes. During cell division (**mitosis**) all 46 chromosomes are duplicated and distributed to each new cell. During **meiosis**, one member of each of the autosome and sex chromosome pairs is distributed to each egg or sperm; the full set of 46 chromosomes then is restored to the diploid state upon fertilization.

Because genes are carried on chromosomes, the rules governing the distribution of chromosomes during mitosis and meiosis govern the distribution of genes and any changes

(mutations, variations) they contain. These rules describe the **mendelian inheritance** of a gene, named after Gregor Mendel, who first deduced that the inheritance of traits was governed by a predictable set of rules. It is possible to track a mutation through multiple generations by knowing these rules of inheritance. This transmission is depicted typically as a **pedigree** and can be used to predict the probability of a genetic change being inherited by a particular family member. When the change causes a disease, a pedigree can be helpful in predicting the probability that another family member will inherit the disease. The Family History Initiative, implemented by the U.S. Surgeon General, helps people construct their family pedigree (www.cdc.gov/genomics/famhistory).

Mendelian transmission can be autosomal or **sex linked**, dominant or recessive. There are five classic modes of mendelian inheritance: autosomal dominant, autosomal recessive, X-linked dominant, X-linked recessive, and Y-linked. An individual's **genotype** obeys the laws of inheritance, but the **phenotype** (the observable/measurable expression of the genotype) may not. Each gene in an individual is present in two copies (alleles), one on each chromosome. When the alleles are the same (either both are the common or usual version or both are the mutant or variant form), the individual is said to be **homozygous**. If the alleles are different, the individual is **heterozygous** (also called a *carrier*).

Dominance and recessiveness refer to whether a trait is expressed (can be measured, observed) in a heterozygous individual who has one common allele and one variant allele. If a trait is expressed when only a single copy of a variant allele is present, the allele is said to be **dominant** (i.e., the phenotype of the variant allele is the predominant one). Alleles that do not dominate the genotype when only a single copy is present are called **recessive**. The variant allele is present in the genome, but the trait is not expressed unless two copies of the variant allele are present.

Further confounding the nomenclature is the concept of **penetrance**. Even when a pedigree suggests that a gene is present that should lead to the individual displaying a certain phenotype, the disease may not be evident. Such a gene is said to have reduced penetrance, meaning that not everyone who has the gene expresses it in a measurable form. "Measurable form" very much depends on what is able to be measured. Many alleles thought to be recessive 50 years ago can be detected today as the result of new and more sensitive technologies. Penetrance is of interest to nutrition professionals because it reflects the inability of a genetic variation to impair function and cause disease unless the individual is exposed to specific environmental triggers, such as diet and lifestyle factors. Modifying these factors potentially can improve outcomes for those with such variants. Expect the terminology to continue to be updated as understanding advances.

Mitochondrial Inheritance

In addition to genetic material in the nucleus, the mitochondria in each cell also contain DNA that codes for a limited number of proteins. The majority of these genes are involved in maintenance of the mitochondrion and its energy-producing activities. As with nuclear DNA, changes in **mitochondrial DNA (mtDNA)** can lead to disease. Traits resulting from mitochondrial genes have a characteristic inheritance pattern; they are non-mendelian because mitochondria and their genetic material typically pass from mother to child, called **mitochondrial**

or **maternal inheritance**. This biologic principle has become the basis for anthropological studies that trace lineage and population migration patterns through the centuries. It also has provided a way to trace familial diseases caused by changes in mtDNA. However, as with other biologic processes, occasional mistakes occur; reports exist of some mtDNA being passed from father to child.

Epigenetic Inheritance, Genomic Imprinting

Epigenetic inheritance illustrates another mechanism by which genetic information is passed between generations. Epigenetics provides an additional set of instructions beyond that contained in the DNA nucleotide sequence. It affects gene expression but does not change the nucleotide sequence (Villagra et al, 2009). At least three mechanisms are involved: histone modification, DNA modification, and RNA interference (RNAi). Like DNA nucleotide inheritance, the epigenetic “marks” (“tags”) also can be passed down through the generations. Just how far the reach extends is not yet known but there is a clear pattern at least from grandparents to children to grandchildren. The importance here to nutrition professionals is that what grandparents ate has the potential to influence the functioning of their grandchildren.

Histones are proteins associated with DNA that assist the chromosome to condense. Units of histone proteins form a scaffolding around which DNA is wrapped, which creates the nucleosome, similar to thread wrapped around a spool. Similar in concept to condensing data on a hard drive, this mechanism helps to fit the large amount of DNA into the small space of the nucleus. When DNA is condensed, it is not available for transcribing into mRNA. The attachment and removal of acetyl groups is an important mechanism for controlling whether DNA is relaxed and available for transcription to proceed or condensed and closed to transcription, respectively.

Similarly, DNA itself can be modified by the covalent attachment and removal of functional groups, such as methyl groups. In somatic (body) cells, **DNA methylation** takes place at cytosine residues that occur within CpG islands found near a gene’s promoter region. **CpG islands** (the *p* refers to the phosphodiester bond between [C]cytosine and [G] guanine nucleotides) are DNA sequences enriched in cytosine and guanine that, when methylated, interfere with transcription and therefore gene expression. In general, methylation silences gene expression and demethylation promotes gene expression.

DNA methylation and histone modification can contribute to genomic imprinting and affect gene expression. **Genomic imprinting** is an unusual phenomenon in which only one of the two alleles (version) of a gene is expressed, either the allele contributed by the mother or by the father. If each allele contains a different mutation that leads to a measurable phenotype, the individual’s phenotype differs depending on whether the mother’s or the father’s allele is the one expressed. Prader-Willi syndrome and Angelman syndrome involve DNA on chromosome 15 and provide examples of genomic imprinting. When the father’s allele is expressed, the child develops Prader-Willi syndrome. When the mother’s allele is expressed, the child develops Angelman syndrome. Both syndromes are characterized by intellectual disabilities, but individuals with Prader-Willi also experience a lack of perception of satiety, which leads to overeating and morbid obesity. The suspected underlying basis for the phenotypic differences is the different pattern of epigenetic markings (either histone acetylation or DNA methylation)

between the two parents rather than differences in the DNA sequence itself. Genomic imprinting represents epigenetic erasure and reestablishment of the epigenetic marks in the germline and has important implications for health and disease, with documented metabolic, neurologic, and behavioral effects (Adalsteinsson and Ferguson-Smith, 2014; Giradot et al, 2012; Peters, 2014).

The third mechanism, **RNA interference (RNAi)**, is the subject of considerable research. Two types of small (21 to 23 nucleotides) RNA molecules, **microRNAs** (miRNA) and **small interfering RNAs** (siRNA), are transcribed from noncoding DNA that formerly was thought to be “junk DNA.” If the RNA is complementary to the DNA of a gene’s promoter region, increased transcription can occur, but more commonly these RNAs attach to the transcribed messenger RNA and interfere with gene expression by preventing translation of the gene into its encoded protein. Alternatively, attaching to DNA leads to silencing of whole regions of chromosomes, a phenomenon called **epigenetic gene silencing**, which is the basis for X-inactivation in mammalian females in which one of the two X chromosomes is silenced. In this way the amount of information contributed by the X chromosome is equalized between females and males, the latter having only a single X chromosome. The details of these processes are beyond the scope of this chapter, but readers should be aware that diet and other environmental factors are suspected of being primary influencers of epigenetic mechanisms. Therefore expect that in time, understanding epigenetic mechanisms will be essential for the development of effective nutrition therapy in the clinic.

In a landmark study using the mouse as a mammalian model system for dissecting this complex process, Waterland and Jirtle (2003) selected a strain of mice with a mutation in the *agouti* gene. The wild-type (usual, “normal”) *agouti* allele causes the mouse’s coat color to be brown. The A^{vy} mutation (*agouti viable yellow* allele) causes the coat color to be yellow and, because this allele is dominant, all mice with at least one copy of A^{vy} have the potential to develop the yellow coat color. The researchers bred genetically identical female mice with brown coats (two copies of the usual *agouti* allele) with genetically identical males that had two copies of the A^{vy} mutation and had yellow coats. On a standard mouse chow diet, the coat color of the mothers would be brown, that of the fathers would be yellow, and the coat color of the offspring, who have one *agouti* allele and one A^{vy} allele, would be yellow because the A^{vy} allele is dominant. Waterland and Jirtle asked whether diet could make a difference in coat color by feeding half of the females the usual mouse chow diet and half a methyl-rich diet in which methyl donors such as folate, vitamin B₁₂, choline, and betaine were added to the chow. Most of the unsupplemented mothers had offspring with yellow coats. Most of the offspring from the mothers on the methyl-rich diet, however, had a mottled coat with a mix of brown and yellow (called *pseudoagouti*). Remember that ALL the offspring had one copy of the normal allele and one copy of the A^{vy} allele. Clearly, the mother’s diet affected the coat color of the offspring and this effect persisted into adulthood. An investigation into what may be causing the difference in phenotype among genotypically identical siblings detected a correlation between mottled coat and degree of methylation of the *agouti* gene, which suggested that the methyl-rich diet led to epigenetic silencing of the A^{vy} allele.

Furthermore, this effect of diet could be inherited. In subsequent experiments (Cropley et al, 2006) found that feeding the

females of the “grandmother” generation a methyl-rich diet but not enriching the daughter offspring’s diet with methyl donors still produced a number of second generation (“grandchildren”) offspring with mottled brown coats, suggesting that the effect the diet had on coat color could be transmitted between generations. Diet and possibly other environmental factors may have a transgenerational effect through their influence on epigenetic markings that affect gene expression without altering the DNA sequence (Jiménez-Chillarón et al, 2012). To transpose the significance of these results to humans, this type of gene-diet epigenetic mechanism could explain why identical twins, although having the exact same genotype, typically do not have identical phenotypes and that the extent of the differences appear to increase as the twins age. This observation in human identical twins has baffled researchers for a long time and now is believed to be due to epigenetics and the influence of diet and other environmental factors. In a series of studies focused on overfeeding-induced phenotypes, studies with rodents suggest that epigenetic inheritance can be sustained for at least two to three generations. In male rats, overfeeding led to impaired glucose and insulin metabolism and altered gene expression in the female offspring over the next two generations (Ng et al, 2014). In mice, feeding males a high-fat diet and then mating them to females fed the usual diet was correlated with heritable impairment of insulin secretion and blood glucose disposition in the daughters as a result of changes in pancreatic beta-cell gene expression (Pentinat et al, 2010). In female mice fed a high-fat diet, the effect was detected into the third generation and was passed from the male line, which suggests that genomic imprinting is involved (Dunn and Bale, 2009; Dunn and Bale, 2011).

A retrospective cohort study in humans also supports the possibility of **transgenerational epigenetic inheritance**. The Dutch Hunger Winter Families Study investigated the offspring of mothers who were pregnant during the Dutch Hunger Winter famine that followed World War II (Bygren, 2013). Female but not male offspring of these mothers had dyslipidemia compared with unexposed same-sex females from mothers not exposed to the famine. The children subsequently born to these females with dyslipidemia had greater neonatal adiposity and a higher prevalence of metabolic disease compared with controls born to unaffected females. Other environmental factors beyond nutrition also have been shown to be associated with heritable epigenetic markings. These studies, however, have been conducted in animal models and have yet to be substantiated for humans. The molecular mechanisms underlying transgenerational epigenetic inheritance are not yet known but may include mechanisms beyond DNA methylation and histone modification. Heard and Martienssen (2014) provide a current understanding of transgenerational epigenetic inheritance.

Inheritance and Disease

Changes to the genetic material, whether to the chromosomal DNA, mtDNA, or even a single nucleotide, have the potential to alter one or more proteins that may be critical to the operation of the cells, tissues, and organs of the body. There are important consequences from changes to the genetic material at each of these levels.

Disease at the Chromosomal Level

Change in the number of chromosomes, or the arrangement of the DNA within a chromosome, is almost always detrimental

and often fatal to the individual. Chromosomal disorders are detected by means of a **karyotype**, a visualization of all the chromosomes in picture form. An example of a nonfatal chromosomal abnormality is trisomy 21 (Down syndrome), which results from an addition of genetic material to chromosome 21.

Some syndromes are caused by the loss of a portion of a chromosome (a partial deletion). In Beckwith-Wiedemann syndrome (a chromosome 11 deletion), changes are characterized by organ overgrowth, including an oversized tongue, which leads to feeding difficulties and hypoglycemia. Nutrition professionals play an important role in the therapy of those with chromosomal disorders, because these individuals often have oral-motor problems that affect their nutritional status and cause growth problems in early life. Later in development, obesity may become an issue, and nutrition therapy is helpful in controlling weight, diabetes, and cardiovascular complications. In people with such chromosomal abnormalities, varying degrees of mental retardation often complicate therapy. A knowledgeable nutrition professional can mitigate the detrimental effects of these disorders on nutritional status (see Chapter 43).

Disease at the Mitochondrial Level

Mitochondria are subcellular organelles that are thought to have originated from bacteria and function primarily to produce adenosine triphosphate (ATP). Human **mtDNA** codes for 13 proteins, 2 ribosomal RNAs, and 22 transfer RNAs to synthesize these proteins; the remainder of the proteins are coded for by nuclear DNA. In contrast to nuclear DNA, mtDNA is small (16,569 base pairs), circular, and exists in hundreds to thousands of copies in each mitochondrion. As noted earlier, mtDNA typically is passed from the mother to her offspring.

Not surprisingly, alterations in mtDNA are frequently degenerative and affect tissues primarily with a high demand for oxidative phosphorylation. They also have varied clinical manifestations because of the multiple copies of mtDNA, not all of which may contain the genetic change. Mutations in mtDNA can manifest at any age and include neurologic diseases, cardiomyopathies, and skeletal myopathies. For example, Wolfram syndrome, a form of diabetes with associated deafness, was one of the earliest disorders to be traced to mtDNA. More than 60 diseases that result from changes in mtDNA have been identified thus far. See MITOMAP, a human mitochondrial genome database, for specifics on human mitochondrial DNA variants (www.mitomap.org).

Disease at the Molecular Level

The majority of disease conditions associated with nutritional genomics involve changes at the molecular level. Changes to the DNA typically involve a single nucleotide change or several nucleotides within a single gene through substitutions, additions, or deletions. Further, larger-scale changes involving the deletion or addition of multiple nucleotides also can occur in the regulatory or protein coding regions of a gene. Alterations in the regulatory region may increase or decrease the quantity of protein produced or alter the ability of the gene to respond to environmental signals. Alterations in the coding region may affect the amino acid sequence of the protein, which in turn can affect the conformation and function of the protein and thereby the functioning of the organism. Because the majority of human genes reside on nuclear chromosomes, gene variations are transmitted according to mendelian inheritance and are subject to modification from epigenetic markings.

Autosomal dominant single-gene disorders that have nutritional implications include several that may result in oral-motor problems, growth problems, susceptibility to weight gain, and difficulties with constipation. Examples include Albright hereditary osteodystrophy, which commonly results in dental problems, obesity, hypocalcemia, and hyperphosphatemia; chondrodysplasias, which often result in oral-motor problems and obesity; and Marfan syndrome, which involves cardiac disease, excessive growth, and increased nutritional needs. Familial hypercholesterolemia results in a defective low-density lipoprotein (LDL) receptor, elevated levels of cholesterol, and susceptibility to atherosclerosis.

Autosomal recessive disorders are much more common and include metabolic disorders of amino acid, carbohydrate, and lipid metabolism. Traditionally these disorders were detected because the mutation had a detrimental effect on the newborn infant that led to serious developmental consequences or death. These disorders were heritable, ultimately associated with a particular mutation, and designated **inborn errors of metabolism (IEM)**.

IEM disorders are the earliest known examples of nutritional genomics, and dietary modification is the primary treatment modality (see Chapter 43). A brief overview of IEM from a genetic perspective is included here to emphasize the important role of the nutrition professional in restoring health to these individuals and to contrast IEM with chronic disorders, which result from the same type of genetic change but affect function less severely.

Currently the United States has no uniform guidelines for newborn screening; some states test for a handful of conditions and other states test for 30 or more conditions. With the belief that the early detection of IEM allows earlier initiation of therapy, which results in better health prospects of the child, and at the request of the Health Services and Research Administration (HRSA), in 2011 the American College of Medical Genetics submitted a proposed set of uniform guidelines for consideration.

A classic example of an IEM of amino acid metabolism is phenylketonuria (PKU). PKU results from a mutation in the gene coding for the enzyme phenylalanine hydroxylase, leading to an inability to convert phenylalanine to tyrosine. Lifelong dietary restriction of phenylalanine enables individuals with PKU to live into adulthood and enjoy a quality life (see Chapter 43). In maple syrup urine disease (MSUD), the metabolic defect is branched-chain alpha-keto acid decarboxylase, an enzyme complex encoded by six genes. A mutation in any one of these genes can result in accumulation of alpha-keto acids in the urine, which produces an odor somewhat similar to maple syrup. Failure to limit branched-chain amino acid intake can lead to mental retardation, seizures, and death in individuals with MSUD (see Chapter 43).

Hereditary fructose intolerance (HFI) is an example of an autosomal recessive IEM of carbohydrate metabolism (see Table 43-1). A mutation in the *ALDOB* gene encoding aldolase B (fructose-1,6-biphosphate aldolase) impairs the catalytic activity of the enzyme and prevents fructose from being converted to glucose. Breast-fed infants are typically asymptomatic until fruit is added to the diet. Nutrition therapy involves the elimination of fructose and the fructose-containing disaccharide sucrose as well as sorbitol. In the absence of understanding the presence of this genetic lesion and the need to eliminate these sweeteners from the diet, the individual typically proceeds

to develop hypoglycemia, vomiting, and ultimately kidney failure, leading to death.

This disease is a good example of the power of understanding the underlying genetic lesion when developing nutrition therapeutic approaches (see Chapter 43). First, the family history may give a hint that HFI is present. Second, although the genetic lesion (genotype) is permanent, the phenotype is not. In spite of an individual having the *ALDOB* mutation, eliminating the exposure to these sweeteners essentially keeps the disease susceptibility silent, and the infant will enjoy normal development. Often it is the nutrition professional that detects the problem and recommends the appropriate therapy sufficiently early to prevent disease symptoms from manifesting.

An example of an autosomal recessive disorder of lipid metabolism is the deficiency of medium-chain acyl-coenzyme A (acyl-CoA) dehydrogenase, which prevents medium-chain fatty acids from being oxidized to provide energy during periods of fasting. Nutrition therapy focuses on preventing the accumulation of toxic fatty acid intermediates that, when not controlled, can lead to death (see Chapter 43).

The **X-linked dominant** fragile X syndrome also affects nutritional status. Fragile X syndrome is characterized by developmental delays, mental impairment, and behavioral problems. The lesion occurs within the *FMR1* gene on the X chromosome in which a CGG segment is repeated more times than the usual number for human beings. The multiple repeats of this trinucleotide make the X chromosome susceptible to breakage. Another X-linked dominant disorder is a form of hypophosphatemic rickets. This disorder is found in males and females, is resistant to vitamin D therapy, and is characterized by bone anomalies, which include dental malformations and resultant feeding challenges.

X-linked recessive conditions include nephrogenic diabetes insipidus, adrenoleukodystrophy, and Duchenne muscular dystrophy (DMD) disorders. Individuals with X-linked recessive nephrogenic diabetes insipidus are unable to concentrate urine and exhibit polyuria and polydipsia. This disorder usually is detected in infancy and can manifest as dehydration, poor feeding, vomiting, and failure to thrive. X-linked recessive adrenoleukodystrophy results from a defect in the enzyme that degrades long-chain fatty acids. These fats accumulate and lead to brain and adrenal dysfunction and ultimately motor dysfunction. X-linked recessive DMD is characterized by fatty infiltration of muscles and extreme muscle wasting. Children typically are confined to a wheelchair by the time they reach their teens and need assistance with feeding.

Y-linked inheritance disorders involve male sex determination and physiologic “housekeeping functions.” No nutrition-related disorders have been assigned conclusively to the Y chromosome.

In summary, any gene potentially can undergo mutation, which can affect the function of its protein and the health of the individual. Its location within the nuclear or mtDNA determines its mode of inheritance.

Genetic Technologies

Progressing beyond knowing the chromosomal location of a disease trait to associating the disease with a particular mutation and understanding its functional consequences has required the development of sophisticated molecular genetic technologies. One of the most critical technologic advances occurred in the early 1970s with the introduction of **recombinant DNA** technology, which

allowed major progress in terms of studying genes, their functions, and the regulation of their expression. Using bacteria-derived **restriction endonucleases (restriction enzymes)**, researchers could cut the DNA in precise, reproducible locations along the nucleotide chain, isolate the fragments and, using **polymerase chain reaction (PCR)** technology, make unlimited copies of the DNA for various applications. This basic approach has been the cornerstone of many routine techniques, such as genetic engineering and the production of therapeutic proteins such as insulin and growth hormone as well as new genetic strains of crops and food for animal consumption. See Focus On: *GMO or Genetically Engineered (GE) Foods* in chapter 26.

Recombinant DNA technology is the basis for detecting variations in DNA sequences that can be used to identify individuals for forensic and paternity purposes and to predict disease susceptibilities. This technology also paved the way for DNA sequencing, which is used to identify the sequence of nucleotides within a gene, pinpoint the exact location of any change, and identify each of the nucleotides in an individual's genome. DNA sequencing technology has evolved rapidly, from a labor- and time-intensive process to one of high-throughput sequencing techniques that have lowered significantly the cost of sequencing whole genomes. The benefit for health care is the expectation that it will soon be inexpensive to sequence the human genome to detect large numbers of genetic susceptibilities in one analysis, which can provide individuals with their genetic signature.

One of the outgrowths of these earlier technologies is **DNA microarray technology**. Microarrays, also called DNA “chips,” are used to determine which genes are expressed at a particular time under particular conditions, such as during the different stages of fetal development. They also can be used to determine which genes are turned on in response to environmental factors, such as nutrients. A useful clinical application is the comparison of gene expression between normal and diseased cells, with important implications for cancer therapeutics.

Another type of genetic technology involves interfering with a gene's expression to determine the function of that gene and its encoded protein. The concept originally was exploited in model systems involving transgenic animals, particularly the laboratory mouse (“knockout mouse”). In the knockout mouse, a gene is altered (“knocked out”) so that the normal protein is no longer made. Alternatively, a gene can be altered so that it expresses too much or too little of its product. Regulatory sequences can be altered so that a gene no longer responds appropriately to environmental signals. In these ways the normal function of a gene can be determined, the effects of overexpressing or underexpressing a gene can be studied, and details of the communication process between signals outside the organism and the genetic material inside the organism can be determined. Transgenic mice are particularly valuable for studying gene-diet interactions. A recent application of this concept involves RNAi. Short sequences of RNA bind to mRNA and interfere with translation of the mRNA into protein (“knock down”). By measuring the outcome of a decrease in a particular protein, researchers can gain insight into the role of the protein and its contribution to the organism's function.

The combination of the data available from the Human Genome Project and the HapMap Project coupled with the new technologies that have been developed as a result of these projects made it possible to conduct GWAS. Such studies allow more rapid analysis of whole-genome sequences for the

presence of genetic variations and their association with various traits and disease states. Two groups of subjects are studied, those with the disease of interest and those without. A set of SNPs is analyzed in both groups and if certain ones are found more frequently in those with the disease, these SNPs are proposed to be associated with the disease, which helps to pinpoint the region of the human genome where the culprit genes are located.

The SNPs themselves may be a causative factor or they simply may be located near the causal variants. Typically researchers sequence the regions where the associated SNPs are located to identify the specific genetic changes associated with the disease. Until a genetic region detected in a GWAS study has been mapped to a definitive locus (location on a chromosome) and the gene identified, its location is referred to as a Quantitative Trait Locus (QTL). One of the more notable nutrition-related GWAS successes has been the detection of the *FTO* (fat mass and obesity-associated) gene, which is the most common gene variant to be associated definitively with obesity and across multiple populations (Frayling et al, 2007; Harbron et al, 2014).

The final key technology that has become essential is DNA methylation profiling to detect the epigenetic state of the individual, often referred to as the **methyloome**. Various techniques are currently in use. The methyl group is attached covalently to the cytosine residues of CpG islands, which makes it possible to distinguish between methylated and unmethylated cytosines. The total methylation load can be determined and compared between samples, or specific regions of the genome can be analyzed and compared.

GENETICS AND NUTRITION THERAPY

Chromosomal or single-gene mutations can alter nutritional status and are helpful in illustrating the importance of nutrition therapy for health. The rapid development of molecular nutrition and nutritional genomics expands the role of the nutrition professional beyond rare disorders and into more prevalent chronic diseases such as cardiovascular disease (CVD), cancer, diabetes, inflammatory disorders, osteoporosis, and obesity. Typically these disorders are managed at best, yet diet-and-lifestyle therapy potentially can restore the individual's health.

Nutritional genomics is unique in its focus on how the interactions between genetic variations and environmental factors influence the genetic potential of individuals and populations, the GxE premise. Nutrition professionals play a critical role in this transition to health promotion and disease prevention.

Nutrigenetic Influences on Health and Disease

The interplay between nutrition and genetics varies from being straightforward to being highly complex. The most straightforward is the direct correlation between a faulty gene, a defective protein, a deficient level of a metabolite, and a resultant disease state passed on through mendelian inheritance and is responsive to nutrition therapy. The IEM already discussed are good examples of such interactions. IEM are characterized as rare mutations that result in protein dysfunction, which leads to metabolic disorders. In actuality they are on the far end of the personal health continuum, on the dysfunction/illness end of this spectrum. Far more common are the mutations that occur frequently, have less severe consequences on function, and thus fall on the function/wellness end. The effect of these mutations is far more subtle, which makes detection more challenging for

the health care professional, yet no less important if the individual is to make appropriate lifelong choices in terms of the environmental factors that promote health and prevent disease.

All humans have mutations that result in protein dysfunction that leads to metabolic disease. The human species requires certain amino acids, fatty acids, vitamins, and minerals, and mutations limit the ability to synthesize these important nutrients. The diet must supply them to prevent dysfunction and disease. For example, humans lack the gene for the enzyme gulonolactone oxidase and cannot synthesize vitamin C. If dietary vitamin C intake is below needed levels, individuals are at risk for developing scurvy, which can be fatal.

New is the understanding of the genetic basis for nutrient requirements, the realization that nutrition therapy can circumvent genetic limitations by supplying the missing nutrients, and that each individual may require a different level of nutrient because of his or her particular set of genetic variations. In a seminal paper in 2002, Ames and colleagues called attention to this fact by detailing more than 50 metabolic reactions that involve enzymes with decreased affinities for their cofactors and that require high levels of a nutrient to restore function (Ames et al, 2002). Many of the supplementation levels are well in excess of the usual recommended nutrient levels, which highlights the importance of remembering that each individual is genetically unique and has distinct metabolic needs.

Although generalized guidelines for recommended nutrient levels are helpful, individuals may have genetic variations that require them to consume significantly more or less of certain nutrients than the general recommendation. Nutritional genomics has changed the thinking about global dietary recommended intakes, from an age- and sex-related orientation to incorporating nutrigenetic makeup and its influence on protein function. Nutrition assessment, then, is a critical tool for compensating for changes in the DNA that can lead to increased risk of disease (see Chapter 7).

The inborn error of amino acid metabolism classic homocystinuria is of particular interest because it led to the realization that an elevated blood level of homocysteine may be an independent risk factor for CVD. A defect in the vitamin B₆-requiring enzyme cystathionine beta-synthase prevents the conversion of homocysteine to cystathionine. Homocysteine accumulates, appears to promote atherogenesis, and forms the dipeptide homocystine, which leads to abnormal collagen crosslinking and osteoporosis. Nutrition therapy is multipronged, depending on the specific genetic defect. Some individuals have an enzyme defect that requires a high concentration of the vitamin B₆ cofactor for activity. Others are not responsive to B₆ and need a combination of folate, vitamin B₁₂, choline, and betaine to convert homocysteine to methionine. Others must limit their methionine intake. At least three forms of homocystinuria exist, each requiring a different nutritional approach. The ability to use genetic analysis to distinguish these similar disorders has been a useful technological advance (see Chapters 7, 32, and 33).

The consequences of genetic variation in the *MTHFR* gene were discussed earlier and provide an excellent example of nutrigenetics as well as how genetic variation can influence nutrient requirements. Specific variants of this gene can influence the body's ability to supply the active form of the B vitamin folate. Enzymatic impairment also results in insufficient conversion of homocysteine to S-adenosylmethionine, a critical methyl donor to numerous metabolic reactions, including

those involved in synthesizing and repairing nucleic acids (see Chapters 32 and 33). A common variation in the *MTHFR* gene is the 677C>T gene variant, which involves substitution of thymine (T) for cytosine (C) at nucleotide position 677 within the coding region of the *MTHFR* gene. The resultant enzyme has reduced activity, which leads to decreased production of active folate and accumulation of homocysteine. Elevated homocysteine levels often can be lowered through supplementation with one or more of the B vitamins, folate, B₂, B₆, and B₁₂, and key mineral cofactors. However, the genotype of the individual is an important factor in exactly which concentration of nutrients at which level is needed to elicit this response, which supports the need for tailoring nutrient recommendations.

In addition to the increased risk of CVD, elevated serum homocysteine increases the risk of neural tube defects in developing fetuses. As a result of these risks, in the United States cereal grains now are fortified with folic acid to ensure adequate levels in women of childbearing age (see Chapter 15). This public policy response brings to our attention the importance of having nutrition professionals knowledgeable about nutritional genomics in positions of influence at the policy-making level. If folate/folic acid is the primary supplier of methyl groups for epigenetic regulation of gene expression via DNA methylation, and excessive methylation of DNA leads to the silencing of gene expression, how do we determine a safe level sufficient to ensure folate levels are high enough to prevent neural tube defects, but low enough not to silence inappropriately genes that are critical to development, the effects of which may not show up until adulthood?

Disease-causing changes also can occur in genes coding for other types of proteins, such as transport proteins, structural proteins, membrane receptors, hormones, and transcription factors. Mutations that increase the transport of iron (hereditary hemochromatosis) or copper (Wilson's disease) to higher-than-normal levels have nutritional implications (see Chapter 32). Mutations in vitamin D receptors are associated with deleterious effects on bone health and throughout the body, because vitamin D is a hormone involved in hundreds of metabolic and regulatory processes. Changes in the gene coding for insulin can result in structural changes in the insulin hormone and lead to dysglycemia, as can mutations in the insulin receptor. Many proteins such as kinases, cytokines, and transcription factors that are involved in critical signaling cascades are subject to mutational changes, altered activities, and health consequences.

Nutrigenomic Influences on Health and Disease

In addition to compensating for metabolic limitations, nutrients and other bioactive components in food can influence gene expression, as seen in studies with lower organisms, such as is seen with the *lac* and *trp* operons of bacteria. In these situations the organism "senses" the presence of a nutrient in its external environment and alters its gene expression accordingly. In the case of lactose, the proteins required to use lactose as an energy source are induced by transcriptional regulation of the genes that code for the lactose transport system and for the enzyme that cleaves lactose into its monosaccharides. The opposite occurs when tryptophan is present in the environment: the organism inhibits the endogenous biosynthesis of tryptophan by inhibiting transcription of the genes that encode tryptophan biosynthetic proteins. Gene X environment interactions, such as monitoring and responding to environmental signals by

changing gene expression, are fundamental processes of living systems, allowing them to use resources efficiently.

Higher organisms such as humans have similar mechanisms by which they monitor the environment that bathes their cells and alter cellular or molecular activities as needed. An example is the response of cells to the presence of glucose. Insulin is secreted and binds to its receptor on the surface of skeletal muscle cells and initiates a stepwise biochemical signaling cascade (**signal transduction**). Signaling results in the translocation of glucose transporter type 4 (GLUT4), a receptor involved in glucose entry into cells, from the interior of the cell to the cell surface. Exercise also promotes the translocation of GLUT4, which helps in controlling blood sugar levels. A drop in blood sugar triggers the release of epinephrine and glucagon that, in turn, bind to cell surface receptors in the liver and skeletal muscle and, through signal transduction, stimulate glycogen breakdown to glucose to restore blood sugar levels.

Nutrients and other bioactive food components also can serve as ligands, molecules that bind to specific nucleotide sequences (response elements) within a gene's regulatory region. Binding results in a change in gene expression through the regulation of transcription. Examples of such food components are the polyunsaturated omega-3 fatty acids. These fats decrease inflammation by serving as precursors for the synthesis of anti-inflammatory eicosanoids and by decreasing the expression of genes that lead to the production of inflammatory cytokines, such as the tumor necrosis factor- α and the interleukin-1 genes (Calder, 2015; see Chapter 3).

The omega-3 and omega-6 fatty acids also have been found to serve as ligands for the **peroxisome proliferator-activated receptor (PPAR)** family of transcription factors. The PPARs function as lipid sensors and regulate lipid and lipoprotein metabolism, glucose homeostasis, adipocyte proliferation and differentiation, and the formation of foam cells from monocytes during atherogenic plaque formation. They are important components in the sequence of events by which a high-fat diet promotes insulin resistance and obesity (Christodoulides and Vidal-Puig, 2010).

To influence the expression of the genes under its control, a PPAR transcription factor must complex with a second transcription factor, the retinoic X receptor (RXR). Each has its ligand attached—polyunsaturated fatty acid and a derivative of vitamin A—respectively. The PPAR-RXR complex then can bind to the appropriate response element within the regulatory region of a gene under its control. Binding results in a conformational change in the structure of the DNA molecule that allows RNA polymerase to bind and transcribe the PPAR-regulated genes, leading to a host of lipogenic and pro-inflammatory activities. A large number of transcription factors have been identified and the mechanisms of action are under investigation.

The bioactive components that serve as ligands for these transcription factors are either provided by the diet or made endogenously. Examples are omega-3 and omega-6 fatty acids, cholesterol, steroid hormones, bile acids, **xenobiotics** (foreign chemicals, or “new-to-nature” molecules), the active form of vitamin D, and numerous phytonutrients, to name just a few. In all cases these bioactives must communicate their presence to the DNA sequestered within the nucleus. Depending on their size and lipid solubility, some bioactives can penetrate the various membrane barriers and interact directly with the DNA, as in the fatty acid example discussed previously. Others,

including phytochemicals found in the cruciferous vegetables, may not be able to cross the cell membrane and instead interact with a receptor on the cell surface and set into motion the cascade of signal transduction events that results in a transcription factor being translocated to the nucleus.

Identification of the genetic and biochemical mechanisms underlying health and disease provides the basis for developing individualized intervention and prevention strategies. In the case of the omega-3 fatty acids, researchers are actively seeking conditions under which dietary omega-3s can be used to decrease inflammation and increase insulin sensitivity. An understanding of the mechanisms by which gene expression is controlled is also helpful in developing drugs that can target various aspects, including gene expression. For example, the thiazolidinedione class of antidiabetes drugs targets the PPAR mechanism described previously to improve insulin sensitivity.

Identifying bioactive components in fruits, vegetables, and whole grains that are responsible for positive health effects and the mechanisms by which they influence gene expression is of considerable interest. Small-molecular-weight lipophilic molecules can penetrate the cellular and nuclear membranes and serve as ligands for transcription factors that control gene expression. Depending on the gene and the particular bioactive, expression may be turned on or off or increased or decreased in magnitude in keeping with the information received. Examples include resveratrol from purple grape skins; along with a large number of flavonoids such as the catechins found in tea, dark chocolate, and onions and the isoflavones genistein and daidzein from soy. The potential therapeutic use of phytonutrients is being investigated for a variety of chronic disorders (Grabacka et al, 2014; Gupta and Prakash, 2014; Lee et al, 2014; Ong et al, 2011; see *Focus On: Epigenetics and Colorful Eating*).

For bioactive phytochemicals that are too large or too hydrophilic to penetrate the cell's membrane barriers, communication occurs by means of signal transduction. The bioactive interacts with a receptor protein at the cell surface and initiates a cascade of biochemical reactions that ultimately results in one or more transcription factors interacting with DNA and modulating gene expression. Examples of this type of indirect communication are seen with the organosulfur compounds such as sulforaphane and other glucosinolates from the cabbage family vegetables. As a result of the signaling pathway, transcription factors (e.g., *nrf*) are activated and increase transcription of the glutathione-S-transferases needed for phase II detoxification,

FOCUS ON

Epigenetics and Colorful Eating

It can be challenging to communicate the specifics of phytonutrients to consumers because they do not think in terms of the food they eat containing bioactive substances. Attempts have been made to simplify the message, such as focusing on thinking of food in terms of its dominant color and understanding that each color contributes different valuable phytonutrients. For example, eating one to two servings from a wide variety of fruits, vegetables, legumes, grains, nuts, and seeds within the red, orange, yellow, green, purple, and white color categories daily supplies a variety of health-promoting phytonutrients. Individuals with particular disease susceptibilities or environmental challenges should increase the number of servings within a particular category to meet their specific health needs. Practitioners can provide a valuable service by translating these research findings into practical food solutions for consumers (Gupta and Prakash, 2014; see Table 36-1).

which helps to protect against cancer. Flavonoids such as naringenin, found in citrus fruits, and quercetin from onions and apples activate signaling pathways, leading to increased apoptosis of cancer cells (see Chapter 36).

Nutritional Genomics and Chronic Disease

Chronic disorders (e.g., CVD, cancer, diabetes, osteoporosis, inflammatory disorders) are typically more complex than single-gene disorders, in which the change in the DNA is known, the abnormal protein can be identified and analyzed, and the resulting phenotype is defined clearly. Either the influence on function of a particular genetic variation is subtle or even silent and/or multiple genes and their genetic variations contribute in small ways to the overall chronic condition rather than a single variant having a dramatic effect. The genes involved with chronic disease are influenced by environmental factors in addition to the genetic variation. An individual may have gene variants that predispose to a particular chronic disorder, but the disorder may or may not develop. Obviously this situation is challenging because of its complexity but nonetheless must be factored into the nutrition assessment and diagnosis if therapeutic interventions are to be successful.

Genetic Variability

Given the genetic variability among individuals in a population, the high degree of variability in client response to nutrition therapy should not be surprising. Although a change in a gene—including diet- and lifestyle-related genes—can affect function severely enough to cause disease outright, the majority of these genetic variations appear to affect the magnitude of response and do not pose a life-threatening situation. They confer an increased susceptibility to dysfunction and disease but not a sure bet. Many are responsive to diet and lifestyle changes, providing the opportunity to minimize their effect through informed lifestyle choices.

The major focus of nutritional genomics research is on identifying (1) gene-disease associations, (2) the dietary components that influence these associations, (3) the mechanisms by which dietary components exert their effects, and (4) the genotypes that benefit most from particular diet and lifestyle choices. The practical applications of this research include a new set of tools that nutrition professionals can use. The growing body of knowledge supports strategies for disease prevention and intervention that are targeted specifically to the underlying mechanisms.

The following section takes a brief look at some of the key diet-related genes, their known variants, and how these variants affect a person's response to diet. Chronic disease involves complex interactions among genes and bioactive food components. Unraveling the details requires population and intervention studies large enough to have the statistical power needed to draw meaningful conclusions.

Cardiovascular Disease

Cardiovascular disease (CVD) remains the number one disease plaguing developed countries. Not surprisingly, a major focus of nutritional genomics has been to identify gene-diet associations for CVD and to study the influence of diet and exercise parameters in managing and preventing this chronic disease. Nutrition professionals who work with clients with dyslipidemia know firsthand the high degree of individual variability of responses to standard dietary interventions. These therapies are

used primarily to lower elevated blood levels of LDL cholesterol (LDL-C), raise high-density lipoprotein cholesterol (HDL-C), and lower triglycerides (TGs). Until recently the standard approach is a diet low in saturated fat, with increased content of polyunsaturated fats (PUFAs). Response across a population varies, ranging from reduced LDL-C levels and TGs in some to decreased HDL-C levels or elevated TGs in others. Furthermore, some have had their LDL-C levels respond dramatically to dietary oat bran and other soluble fibers, whereas others have had more modest responses. In some a low-fat diet has caused a shift to a lipid pattern that is more atherogenic than the original. Genotype is an important factor; dietary interventions must be matched to genotypes to accomplish the intended lipid-lowering response (see Chapter 33).

A number of contributing genes already have been identified and include those involved with postprandial lipoprotein and triglyceride response, homocysteine metabolism, hypertension, blood-clotting, and inflammation. Gene-diet interactions have been reported for those that code for apolipoprotein E (*APOE*), apolipoprotein A-1 (*APOA1*), cholesterol esteryl transport protein (*CETP*), hepatic lipase (*LIPC*), lipoxigenase-5 (*ALOX5*), *MTHFR*, angiotensinogen (*AGT*), angiotensin-converting enzyme (*ACE*), the interleukin-1 family (*IL1*), interleukin-6 (*IL6*), and tumor necrosis factor-alpha (*TNF*). Among the more recently discovered interactions are those involving the monoglyceride lipase (*MGLL*) gene, omega-3 fatty acids, and LDL cholesterol levels and LDL particle size (Ouellette et al, 2014). Work with the omega-6 fatty acids and gene-diet-cardiovascular disease associations have involved variants in the fatty acid synthase (*FADS*) gene and their effect on heart health (Li et al, 2013) as well as gene variants that lead to increased arachidonic acid metabolism to proinflammatory, vasoconstrictive, and platelet-aggregating family of eicosanoids (Chilton et al, 2014). Examining haplotypes of the sterol regulatory element binding protein-1 (*SREBP1*) gene in postmenopausal women, consumption of omega-6 PUFAs but not omega-3 PUFAs was associated with the progression of atherosclerosis, as measured by decreased arterial diameter (Kalantarian et al, 2014).

An additional link of carbohydrate metabolism to heart health has been reported (Ortega-Azorin et al, 2014). The *MLXIPL* (Max-like protein X interacting protein-like) gene encodes the carbohydrate response element binding protein. These researchers found that those with one or more copies of the rs3812316 variant had lower blood levels of triglyceride and decreased incidence of myocardial infarcts when consuming a Mediterranean-style diet compared with a control diet and compared with subjects who had no copies of the variant.

The possibilities for nutritional intervention are numerous, with the Mediterranean-style diet being of particular interest in terms of heart health (Gotsis et al, 2015). However, this type of diet is beneficial for some individuals but not for others. Researchers continue to probe potential mechanisms that explain the heart-healthy outcomes of this type of diet and why there are interindividual differences in response to the diet. They also recommend developing sound guidelines for dietary intervention for dyslipidemic conditions (Corella and Ordovas, 2014).

CVD is, at its basis, an inflammatory disorder (Rocha and Libby, 2009), and variants of *TNF*, *IL1*, and *IL6* are being investigated for their effect on CVD susceptibility. Further, cardiovascular disease and other chronic disorders tend to involve multiple comorbidities, which makes it increasingly critical that practitioners become aware of the underlying, intersecting

mechanisms and the need for effective interventions for management and prevention. Knowing the genotype of clients provides additional important information as to how they are likely to respond to particular dietary interventions.

In summary of the current state of knowledge of nutritional genomics with respect to cardiovascular disease, considerable research is being conducted globally. The identification of numerous gene variants with associations to different aspects of cardiovascular health suggests that progress is being made in identifying susceptibility variants that can be modulated through judicious diet and lifestyle choices (Merched and Chan, 2013).

Inflammatory Disorders

Inflammation now is recognized as an underlying factor in chronic disorders, from heart disease to cancer to diabetes to obesity to more traditional inflammatory disorders such as arthritis and the inflammatory bowel disorders. Inflammation is a normal and desirable response to insult by the body. Typically inflammation is an acute phase response; once the threat has passed, inflammation subsides and healing ensues. Certain genetic variations predispose individuals to be in a chronic inflammatory state, making them more reactive to proinflammatory triggers and extending the inflammation phase so that inflammation becomes a chronic state. The regular assault of proinflammatory mediators such as the cytokines and eicosanoids on tissues leads to oxidative stress and cellular degeneration rather than the healing that is characteristic of the acute phase (see Chapter 3).

Among the genes known to be of particular importance to the inflammatory response are the proinflammatory cytokine genes *IL1*, which encodes the interleukin-1 β cytokine (also known as IL-1F2), *IL6* (encoding the interleukin-6 cytokine), and *TNF* (produces the tumor necrosis factor cytokine). Variants in each of these genes have been discovered that increase the susceptibility of humans to be in a proinflammatory state, which in turn increases the risk of developing one or more chronic disorders. Certain diet and lifestyle approaches can minimize susceptibility and dampen existing inflammation. Examples include the inclusion of fish and foods that contain omega-3 fatty acids and plant foods rich in various polyphenols. Currently the role of the microbiome in chronic inflammation and immunity is receiving increased attention (Belkaid and Hand, 2014). The hypothesis is that current diets and lifestyles may be decreasing the benefits of the symbiotic relationship between humans and the microbes that colonize the digestive tract and may be at least in part responsible for the increase in inflammatory and autoimmune disorders seen in developed countries (see Chapters 3 and 26).

Immune Health and Cancer

The relationship of gene variants and gene-diet interactions to immune health and cancer is of considerable interest to researchers around the world (Trottier et al, 2010; Villagra et al, 2009). One of the key mechanisms by which the body protects against cancer is detoxification, the process of neutralizing potentially harmful molecules (see *Focus On: Eating to Detoxify* in Chapter 19). Among the better-characterized genes involved in various aspects of detoxification are the cytochrome P450 isozymes (*CYPs*), glutathione S-transferases (*GSTs*), and superoxide dismutases (*SOD1*, *SOD2*, *SOD3*). The *CYP* and *GST* genes

are part of the phase I and phase II detoxification system, respectively, found in the liver and the gut. The *SOD* genes code for proteins that dismantle the reactive oxygen species superoxide. Each of these genes has nutritional implications, and variants have been identified that result in decreased detoxification. Nutritional genomics provides the basis for directing nutrition therapy to protect against cancer by augmenting endogenous detoxification activity and by identifying genetic variants that can decrease phase I or phase II activity and including foods that can help compensate for the decreased activity.

Epidemiologic studies have suggested that consuming plant foods is cancer protective. Numerous dietary factors play a role in protecting against cancer (see Chapter 36). Examples include curcumin from the spice turmeric, resveratrol from purple grape skins, glucosinolates in cruciferous vegetables, epigallocatechin gallate catechins from green tea, isoflavones from soybeans, folic acid, and vitamin D. Numerous labs are investigating the underlying mechanisms by which these phytochemicals exert their protective effects (see reviews by Gupta and Prakash [2014], Howes and Simmonds [2014], Lee et al [2011], Martin et al [2013], Ong et al [2011]). See Table 36-1.

Blood Sugar Regulation

Glucose is the preferred source of energy for the body's cells. Accordingly, blood glucose levels are controlled carefully through an intricate system of checks and balances. When glucose levels are higher than normal (hyperglycemia), the hormone insulin is secreted from the beta-cells of the pancreas, glucose is taken up by the cells, and a normal blood sugar level (euglycemia) is restored. When blood glucose levels fall (hypoglycemia), the hormone glucagon is secreted by the liver, glycogen is hydrolyzed to glucose, and euglycemia is again restored. When this process goes awry, the stage is set for the chronic conditions of insulin resistance, metabolic syndrome, and, ultimately, T2DM (see Chapter 30).

Identification of gene variants that lead to T2DM would allow individuals with this susceptibility to be identified early in the lifespan so that intervention could be initiated. A few rare mutations have been associated with the development of T2DM, but they do not explain the high prevalence of the disease. It is likely that multiple gene variants contribute to the development of this condition. One promising variant is the transcription factor 7-like 2 (*TCF7L2*) identified by Grant and colleagues (2006). The variant occurs frequently within multiple populations. Evidence suggests the gene is involved in insulin secretion from pancreatic beta-cells (Villareal et al, 2010).

Bone Mineralization and Maintenance

Healthy bone tissue depends on a balance between the action of the osteoblasts that synthesize new bone tissue and resorption by osteoclasts. Important components in this dynamic balance are vitamin D, calcium, other nutrients, and hormones such as parathyroid hormone and estrogen. When resorption predominates, bones become fragile, are subject to fracture, and osteoporosis results. Osteoporosis can occur in men and women as they age; it is prevalent among older postmenopausal women (see Chapter 24).

Numerous genes and their protein products are involved in the overall process. In fact, more than 60 loci are being investigated for their association with bone health and disease (Mitchell and Stretten, 2013). The gene VDR, which codes for the vitamin D receptor present on the surface of many cell

types, is an obvious candidate. Vitamin D has multiple roles in metabolism, but its control of the absorption of dietary calcium from the digestive tract truly affects bone health. Four *VDR* variants have been studied over several years (*Apal*, *BsmI*, *FokI*, and *TaqI*), but no clear association has emerged (Horst-Sikorska et al, 2013). Further research regarding gene variants and risk of osteoporosis is imperative given the aging of the global population and the growing prevalence of osteoporosis.

Weight Management

The ability to maintain a healthy weight is another challenge for modern society. As with the other chronic disorders, the regulation of body weight is a complex process and offers multiple points at which a gene variant can give rise to an impaired protein that, when combined with the appropriate environmental trigger, promotes body fat storage. Similar to T2DM, variations in single genes have been associated with excess weight, but these genetic changes are not likely the basis for the rapid rise in prevalence of excess body weight during the past several generations (Hetherington and Cecil, 2010).

A variant in the *FTO* gene has been identified and found to occur frequently among multiple populations (Chu et al, 2008; Dina et al, 2007). An SNP in the *FTO* gene is associated with increased risk of obesity, and the effect was correlated directly with the number of copies of the SNP. That is, those with one copy of the risk allele weighed more than those with no copies, and those with two copies weighed the most of the three groups (Frayling et al, 2007). In 2009 two large genome-wide association studies found the *FTO* variant to be associated with BMI (Thorleifsson et al, 2009; Willer et al, 2009). Harbron and colleagues (2014) provide a useful overview of the current status of *FTO* and its variants in terms of association with several environmental factors that contribute to susceptibility to overweight and obesity. A number of other gene variants have been implicated in weight management, including *ADRB3*, *FABP2*, *POMC*, and *PPARG*, but none so dramatically as *FTO*. The *FTO* variant also may increase risk for T2DM and CVD through its effect on susceptibility to increased body fat.

Adipose tissue is dynamic tissue that is highly vascularized and produces hormones, inflammatory peptides (cytokines), and new adipocytes in addition to storing excess calories as triglycerides and hydrolyzing them as energy is needed. The multistep process of transporting free fatty acids into the adipocyte, esterifying them into triglycerides, and mobilizing the triglycerides potentially provides many proteins that could be affected by genetic variation such that fat is stored more readily or mobilized more slowly than normal. Adipocytes have cell surface receptors that respond to various environmental factors, such as catecholamines produced during exercise, to mobilize stored fat. An example is the receptor encoded by the *ADRB2* gene, which has a greater propensity to store dietary fat as body fat. Individuals with either of these variants will find it more challenging to maintain a healthy weight and may need to restrict their dietary fat intake or engage in regular, vigorous exercise to achieve and maintain a healthy weight.

Ethnicity is an additional confounder in maintaining a healthy weight. Joffe and colleagues extensively investigated novel dietary fat-inflammatory gene interactions in black and in white South African women and detected complex interrelationships linking obesity, inflammation, serum lipids, dietary fat intake and ethnicity (Joffe et al, 2010, 2011, 2012, 2013). This extensive work points up the influence of genetic variation on

dietary response and could suggest that nutrition professionals proceed with caution in extrapolating findings from one population to another. Obesity is a state of low-grade inflammation, which likely contributes to some populations being more susceptible to becoming obese but also to developing other chronic conditions in addition to obesity. The interconnectedness of obesity, inflammation, insulin resistance, dyslipidemia, and nonalcoholic fatty liver disease and suggest potential common mechanisms (Jung and Choi, 2014).

Other Chronic Diseases

Candidate genes, gene variants, and diet-gene interactions are being investigated for many chronic disorders. Populations differ in the types and frequencies of the gene variants; dietary approaches that are most appropriate vary accordingly. As gene variants and their health implications are identified, attention also is being paid to examining the frequency of particular variants among populations so that guidelines can be developed that take into account the most frequently occurring genetic susceptibilities within specific populations.

ETHICAL, LEGAL, AND SOCIAL IMPLICATIONS

If nutritional genomics is to realize its potential as a valuable tool, genetic testing is an essential component of identifying the variations in each individual. Such testing is not, however, without controversy. Consumers worry that genetic testing for any purpose could be used against them, primarily to deny insurance coverage or employment; they are particularly uncomfortable with insurers and employers having access to their personal genetic information (Genetics & Public Policy Center, 2010).

Although theoretically possible, according to existing case law such discrimination rarely has occurred. Furthermore, identifying gene variants that increase susceptibility to diet- and lifestyle-related diseases that can be addressed through readily available diet and lifestyle measures may also lead to legal debate. Many legislators and legal experts believe the Americans with Disabilities Act sufficiently protects against discrimination, but, as an added measure of protection, GINA was passed by Congress and went into effect on November 21, 2009. GINA defines genetic testing and genetic information, bans discrimination based on genetic information, and penalizes those who violate the provisions of this law. Consumers and health care professionals can feel comfortable in adopting this new service.

Consumers and health care professionals should ask critical questions before consent for genetic testing. The laboratory itself should have the appropriate credentials and state licensing, if required (at a minimum, Clinical Laboratory Improvement Amendment (CLIA) certification according to the CLIA of 1988) and should have an appropriately credentialed health professional available for assistance in interpreting the test results. The laboratory should have written, readily available policies concerning how it will protect the privacy of the individual being tested and whether the DNA sample will be retained by the laboratory or destroyed after testing. Transparency in each of these areas increases consumer comfort.

A second concern on the part of consumers and health care professionals is that nutritional genomics is elitist by nature, in that only the wealthy will be able to benefit. At this early stage in its development, the cost of nutritional genomics testing precludes its use as a public health measure and effectively

BOX 5-1 Discussion Points Related to Genetic Testing

Which laboratory will analyze the deoxyribonucleic acid?
 What measures are in place in that laboratory to protect privacy?
 What is the total cost of the test?
 Which gene variants are tested?
 Is there a lifestyle action that can be taken for each variant?
 Has the test been scientifically validated for accuracy and reliability?
 When will the test results be received?
 How and to whom will the test results be presented?
 Who should be tested?
 Should individuals be tested for a disease for which there is no cure?
 Do parents have the right to have their minor children tested for a genetic susceptibility?
 Do parents have the right to withhold the results from the children?
 Should gene therapy be allowed on reproductive cells so that any corrected genes can be inherited by subsequent generations?
 Should human cloning be allowed?
 What is the best way to educate those who are already in practice as health care professionals?
 What changes are needed so that future health care practitioners can be educated properly?

restricts access to those with sufficient disposable income. However, like any other new technology, as the sales volume increases, the cost will decrease.

Numerous additional issues must be discussed thoroughly in the course of integrating genetic technologies into health care. [Box 5-1](#) lists key questions to be answered in the development of nutritional genomics practices. These and other ethical, legal, and social issues relating to nutritional genomics in particular have been explored. One particular question is whether nutritional genomics may be used for “nutrition-based doping” in athletic competition, and it is recommended that international sports organizations begin to consider such a situation ([Bragazzi, 2013](#)).

SUMMARY

The steady rise in chronic disease globally is fueling the need for health care to shift from a focus on acute care to one of managing and, ultimately, preventing chronic disorders. The decreasing quality of life and soaring economic burden of escalating chronic disease is untenable and unsustainable. Chronic disease is diet-and-lifestyle disease, the result of inappropriate daily choices over a lifetime interacting with each individual’s DNA.

Nutrition therapy increasingly will have to address chronic disease management and prevention from a new perspective. Among the key drivers of chronic disease are such environmental factors as food choices, whether an individual chooses to exercise, the quality and quantity of sleep and relaxation, how effectively a person manages stress and thoughts and emotions in general, the extent of toxicity of the environment, and the relationships with one’s self and others along with a sense of purpose in life. These key drivers contribute to each person’s unique health spectrum that spans wellness to illness. Where someone falls on that spectrum is the result of interactions among genes and the environment that bathes the genes throughout a lifetime. When these factors are inappropriate for meeting needs, over time the foundation for health erodes. Normal function (health) cannot be maintained and dysfunction (disease) emerges at some point along the lifespan. Fortunately each of these key factors is modifiable through behavioral change. As health care professionals are well aware, behavioral

change is a slow, steady process requiring excellent counseling skills coupled with the specific guidance needed for each modifiable lifestyle factor.

Increasingly the field of nutrition is recognizing the need to take a whole systems approach to the use of food as a therapeutic intervention. Nutritional genomics is expected to provide a greater understanding of how to use nutrition therapy to promote health and prevent disease. This subdiscipline of nutrition focuses on how genetic makeup influences the ability to digest, absorb, and use the nutrients in food and on how food and other environmental factors influence the expression of genes. As the understanding grows that it is not just genes that contribute to our disease potential but the interaction between genes and environmental factors, it has become important to identify the changes in genes that provide the increased potential for being susceptible to chronic disease. Changes in genes can lead to changes in the information encoded with the genes, which in turn can lead to changes in functional ability. These changes can be inherited from one generation to the next but may lie dormant in their influence on function unless triggered by the interaction with particular environmental factors, such as food. Being able to identify changes within genes that result in altered proteins and function or in the control of the expression of a gene and its encoded protein gives the practitioner insight into potential disease susceptibility and thereby an idea of how to correct the metabolic imbalances that ensue.

Aspects of nutritional genomics have been applied to clinical nutrition for decades. Changes to single genes that cause sufficient dysfunction as to manifest as disease in the individual have been known for a long time. This situation describes the molecular, biochemical, and physiologic basis for the inborn errors of metabolism, which result from errors in single genes and occur rarely. Nutrition professionals have long used food and particular nutrients to address the nutrient imbalances that result. Today nutritional genomics has a far greater reach by being able to detect changes within genes that result in increased susceptibility to chronic disease and provide insight into effective management and preventive interventions.

It is not enough to simply manage chronic disease. Nutrition professionals can and must take the lead in preventing chronic disease and in restoring health to those in whom chronic disease already exists. To do so will entail making use of the extensive scientific training of nutrition professionals to understand the molecular, biochemical, physiologic, and psychosocial mechanisms that underlie chronic disease and provide the targets against which nutrition therapy can be directed effectively. This comprehensive, whole systems biology approach to the functioning of the human organism will form the basis for more effective clinical interventions.

Studies over the past decade have suggested that most nutrition professionals are in the early stage of preparedness regarding nutritional genomics. Most recently registered dietitians in Quebec were surveyed ([Cormier et al, 2014](#)), and the majority were not yet comfortable in their knowledge of nutritional genomics and had questions about the clinical validity and utility of nutrigenetic testing. The Academy of Nutrition and Dietetics has provided recommendations in its position paper on nutritional genomics ([Camp and Trujillo, 2014](#)). Although cautionary regarding nutrigenetic testing not being ready for clinical application as yet, the Academy supports preparing appropriately for the new opportunities that nutritional genomics affords nutrition professionals.

The nutrition profession will be pivotal in this new era of health promotion and disease prevention. The role includes assessing disease susceptibilities and then recommending preventive therapy and lifestyle approaches. Increasingly, genotyping must be incorporated into the nutrition assessment and recommendations customized to the genetic uniqueness of individuals. Such a pivotal role requires that the nutrition professional be well versed in the molecular and biochemical bases for health. Appropriately trained individuals will be able to converse with physicians in their language, which increasingly will involve therapies targeted to underlying molecular, biochemical, and physiologic mechanisms involved in the disease process (see Chapters 3 and 7). Remember that the nutrients and other bioactive components in food are critical players in these underlying mechanisms. The nutrition professional will be able to recommend therapeutic interventions in which food can be used to target the specific underlying mechanisms of complex disease processes and to ensure that negative interactions with other therapies, such as drugs and medical procedures, are minimized. Further, the translation of the medical therapies into practical applications for the patients and the coaching of patients as they modify their lifestyle choices is a primary role of the nutrition professional that will become increasingly important for the success of patient outcomes.

CLINICAL CASE STUDY

Jared and Matthew are identical twins who grew up together but have lived apart since college. Jared lives in New York City and is a certified public accountant in a high-profile accounting firm, working long hours in a stressful environment. Matthew attended college in California, where he studied nutrition and exercise physiology and now manages the wellness program at a large fitness center. At age 30 the two brothers are noticeably different in weight and body shape. Jared has a body mass index of 29 compared with Matthew's 23. Jared has developed central obesity, hypertension, and problems with blood sugar regulation, all signs of a tendency toward developing type 2 diabetes. In contrast, Matthew is lean and has normal blood pressure and normal blood sugar levels.

Nutrition Diagnostic Statement

Overweight related to possible genetic susceptibility, limited physical activity, overeating with snacks and consumption of large meals as evidenced by diet history, central obesity, and body mass index

Nutrition Care Questions

1. Because they are identical twins, would you have expected the two brothers to have similar health profiles?
2. How would you expect their diets to be different?
3. What is going on? Does Matthew not have the same genetic susceptibilities that Jared has? If not, why not? If so, why doesn't Matthew exhibit the same phenotype as Jared? This question is complex: think about the twins' deoxyribonucleic acid but also their environmental influences and their epigenetic markings.
4. How could you confirm your suspicion that Jared is genetically predisposed to type 2 diabetes?
5. What would you advise Jared to do to decrease his genetic susceptibility to diabetes?
6. As part of the nutrition assessment, Jared is found to be homozygous for IL1 -511C>T and heterozygous for IL6 -174G>C. These genes code for the proinflammatory cytokines interleukin-1 and interleukin-6 and these particular single nucleotide polymorphisms have been strongly associated with chronic inflammation. What would you discuss with Jared about the implications of these genotype findings and his susceptibility to chronic disease?

Clinical: Water, Electrolytes, and Acid-Base Balance

Mandy L. Corrigan, MPH, RD, CNSC, FAND

KEY TERMS

acid-base balance
acidemia
alkalemia
anion gap
buffer
contraction alkalosis
corrected calcium
edema
electrolytes
extracellular fluid (ECF)

extracellular water
insensible water loss
intracellular fluid (ICF)
metabolic acidosis
metabolic alkalosis
metabolic water
Na/K-ATPase pump
oncotic pressure (colloidal osmotic pressure)
osmolality

osmolarity
osmotic pressure
renin-angiotensin system
respiratory acidosis
respiratory alkalosis
sensible water loss
“third space” fluid
vasopressin
water intoxication

Fluid, electrolyte, and acid-base management is complex and requires an understanding of the functions and homeostatic mechanisms the body uses to maintain an optimal environment for cell function. Alterations in fluid, electrolyte, and acid-base balance are commonly seen in hospitalized patients and can affect homeostasis both acutely and chronically. If untreated these imbalances have consequences with varying degrees of severity including death. Understanding the function and regulation of fluid and electrolytes lends the ability to prevent and treat these imbalances in patients across any disease state.

The volume, composition, and distribution of body fluids have profound effects on cell function. A stable internal environment is maintained through a sophisticated network of homeostatic mechanisms, which are focused on ensuring that water intake and water loss are balanced. Protein-energy malnutrition, disease, trauma, and surgery can disrupt fluid, electrolyte, and **acid-base balance** and alter the composition, distribution, or amount of body fluids. Even small changes in pH, electrolyte concentrations, and fluid status can adversely affect cell function. If these derangements are not corrected, severe consequences or death can ensue.

BODY WATER

Water is the largest single component of the body. At birth, water accounts for approximately 75% to 85% of total body weight; this proportion decreases with age and adiposity. Water accounts for 60% to 70% of total body weight in the lean adult but only 45% to 55% in the obese adult. Metabolically active cells of the muscle and viscera have the highest concentration of water; calcified tissue cells have the lowest. Total body water

is higher in athletes than in nonathletes and decreases with age and diminished muscle mass (Figure 6-1). Although the proportion of body weight accounted for by water varies with gender, age, and body fat, there is little day-to-day variation in an individual (Cheuvront et al, 2010).

Functions

Water makes solutes available for cellular reactions, regulates body temperature, maintains blood volume, transports nutrients, and is involved with digestion, absorption, and excretion (Armstrong 2005, Whitmire 2010). Loss of 20% of body water (**dehydration**) may cause death; loss of only 10% may lead to damage to essential body systems (Figure 6-2). Even mild dehydration (loss of 1% to 2%) can lead to loss of cognitive function and alertness, an increase in heart rate, and a decrease in exercise performance (Armstrong, 2005; Maughan et al, 2007). Healthy adults can live up to 10 days without water, and children can live up to 5 days, whereas a person can survive for several weeks without food.

Distribution

Total body water (TBW) is mainly distributed in the **intracellular fluid (ICF)** and **extracellular fluid (ECF)**. The transcellular fluid is comprised of 3% of TBW and is the small amount of fluid making up cerebral spinal, pericardial, and pleural fluids as well as fluid surrounding the eye (Whitmire 2008, Rhoda 2011). **ICF** is contained within cells and accounts for two thirds of total body water. **ECF** accounts for the remaining one third of total body water. **ECF** is the water and dissolved substances in the plasma, lymph, and also includes interstitial fluid (the fluid around the cells in tissues) (Kingley 2005, Lanley 2012, Whitmire 2008). While the distribution of body water varies under different circumstances, the total amount in the body remains relatively constant. Water intake of foods and beverages is balanced by water lost through urination, perspiration, feces,

Portions of this chapter were written by Pamela Charney, PhD, RD

FIGURE 6-1 Distribution of body water as a percentage of body weight.

FIGURE 6-2 Adverse effects of dehydration.

CLINICAL INSIGHT

Edema

Edema is the abnormal accumulation of fluid in the “third space,” including intercellular tissue spaces or body cavities. Fluid in the “third space” is isolated and therefore does not contribute to the functional duties of body water within the body. Edema is graded based on severity (grades 1, 2, 3, 4+) and can be classified as pitting or nonpitting. If pressure is applied by a finger or thumb to an area with edema, it is classified as pitting edema when an impression or “pit” remains after the finger is removed.

The causes of edema can be multifactorial and have four main causes. Circulating plasma proteins decrease as part of the acute phase response to injury or inflammation. Circulating proteins normally draw water into the vascular space, but with less circulating proteins there is a decrease in oncotic pressure (the pressure at the capillary membrane). To compound the issue, there is an increase in the permeability of the capillaries, which allows protein leaks into the interstitial space, thereby attracting more water out of the vascular space.

Edema also can occur when there is an increase in hydrostatic pressure as seen in disease states such as cirrhosis, congestive heart failure, and pulmonary edema. The force from the increased pressure pushes fluid into the interstitial space. Lymph edema is the final type and usually is localized to specific areas of the body when there is an obstruction of the lymphatic vessels. It occurs when fluid and protein cannot return to circulation, and the trapped protein-rich lymph fluid attracts water. Lymph edema can be seen in cancer patients who have had surgery for lymph node dissection.

and respiration. Edema is the abnormal accumulation of fluid in the “third space,” including intercellular tissue spaces or body cavities. Fluid in the “third space” is isolated and therefore does not contribute to the functional duties of body water within the body.

Water Balance

Water movement is dictated by hydrostatic pressure, diffusion, osmosis, and active transport. Water moves in and out of the ICF and ECF based on the osmolarity (ability for osmotic pressure

to move fluid between compartments) to obtain equilibrium. Osmotic pressure is directly proportional to the number of particles in the solution and usually refers to the pressure at the cell membrane. The sodium-potassium adenosine triphosphatase pump (Na/K-ATPase pump) plays a key role in regulating water balance. In simple terms, osmotic pressure of the ICF is a function of its potassium content because potassium is the predominant intracellular cation. The osmotic pressure of ECF is relative to the sodium content because sodium is the major

TABLE 6-1 Content of Common Intravenous Fluids

Fluid	Dextrose (g/L)	Sodium (mEq/L)	Chloride (mEq/L)	Additional Components (mEq/L)
0.45% NaCl (half normal saline)	0	77	77	n/a
0.9% NaCl (normal saline)	0	154	154	n/a
3% Saline	0	513	513	n/a
5% Dextrose in water (D ₅ W)	50	0	0	n/a
D ₅ 0.45% NaCl	50	77	77	n/a
D ₅ 0.9% NaCl	50	154	154	n/a
10% Dextrose	100	0	0	n/a
Lactated Ringer's (LR)	0	130	109	Potassium 4 Calcium 3 Lactate 28
D ₅ LR	50	130	109	Potassium 4 Calcium 3 Lactate 28

extracellular cation. Although variations in the distribution of sodium and potassium ions are the principal causes of water shifts between the various fluid compartments, chloride and phosphate also are involved with water balance.

Osmolality is a measure of the osmotically active particles per kilogram of the solvent in which the particles are dispersed (Langley 2012, Whitmire 2008, Rhoda 2011). The average sum of the concentration of all the cations in serum is approximately 150 mEq/L. The cation concentration is balanced by 150 mEq/L of anions, yielding a total serum osmolality of approximately 300 mOsm/L. Osmolality or tonicity are words used interchangeably in clinical practice. Normal osmolality or tonicity is 280-300 mOsm and values above or below this range are termed hypotonic (typically a sign of water excess) or hypertonic (often a sign of water deficit).

Shifts in water balance can have adverse consequences. Homeostatic regulation by the gastrointestinal (GI) tract, kidneys, and brain keeps body water content fairly constant. In general, the amount of water intake is approximately equivalent to output each day.

Mechanisms to maintain water equilibrium come from a number of hormones including antidiuretic hormone (aka vasopressin), aldosterone, angiotensin II, cortisone, norepinephrine, and epinephrine (Kingley 2005, Rhoda 11, Whitmire 08, Whitmire 03). Increased serum osmolality or decreased blood volume lead to the release of antidiuretic hormone which signals the kidneys to conserve water. In the presence of low ECF volume, the kidneys release renin to produce angiotensin II (the **renin-angiotensin system**). Angiotensin II has several functions, including stimulation of vasoconstriction and the thirst centers (whitmire 2008, Langley 2012, Harrisons).

Water Intake

Thirst is regulated by the hypothalamus and controls water intake in healthy individuals. Sensitivity to thirst is decreased in older individuals, chronically or acutely ill patients, infants, and athletes leading to a higher potential for water deficits. Sources of water include fluids (oral, enteral tube feeding, parenteral fluids), food, and oxidative metabolism (Tables 6-1 and 6-2). The oxidation of foods in the body produces **metabolic water** as an end product. The oxidation of 100 g of fat, carbohydrate,

TABLE 6-2 Percentage of Water in Common Foods

Food	Percentage
Lettuce, iceberg	96
Celery	95
Cucumbers	95
Cabbage, raw	92
Watermelon	92

or protein yields 107, 55, or 41 g of water, respectively, for a total of approximately 200 to 300 ml/day (Whitmire, 2008).

Tonicity of body fluids can be measured (serum osmolality) or estimated from the following formula:

$$\text{Osmolality (mOsm)} = (2 \times \text{Serum sodium mEq/L}) + (\text{BUN mg/dL}) + (\text{Blood glucose mg/dL})$$

CLINICAL INSIGHT**Osmotic Forces**

Osmotic pressure is directly proportional to the number of particles in solution and usually refers to the pressure at the cell membrane. It is convenient (although not entirely accurate) to consider the osmotic pressure of intracellular fluid as a function of its potassium content because potassium is the predominant cation there. In contrast, the osmotic pressure of extracellular fluid may be considered relative to its sodium content because sodium is the major cation present in extracellular fluid. Although variations in the distribution of sodium and potassium ions are the principal causes of water shifts between the various fluid compartments, chloride and phosphate also influence water balance. Proteins cannot diffuse because of their size and thus also play a key role in maintaining osmotic equilibrium. **Oncotic pressure**, or **colloidal osmotic pressure**, is the pressure at the capillary membrane. It is maintained by dissolved proteins in the plasma and interstitial fluids. Oncotic pressure helps to retain water within blood vessels, preventing its leakage from plasma into the interstitial spaces. In patients with an exceptionally low plasma protein content, such as those who are under physiologic stress or have certain diseases, water leaks into the interstitial spaces, causing edema or third spacing, thus the fluid is called **"third space" fluid**.

Osmoles and Milliosmoles

Concentrations of individual ionic constituents of extracellular or intracellular fluids are expressed in terms of milliosmoles per liter (mOsm/L). One mole equals the gram molecular weight of a substance; when dissolved in 1 L of water, it becomes 1 osmole (osm). One milliosmole (mOsm) equals 1/1000th of an osmole. The number of milliosmoles per liter equals the number of millimoles per liter times the number of particles into which the dissolved substance dissociates. Thus 1 mmol of a nonelectrolyte (e.g., glucose) equals 1 mOsm; similarly, 1 mmol of an electrolyte containing only monovalent ions (e.g., sodium chloride [NaCl]) equals 2 mOsm. One mOsm dissolved in 1 L of water has an osmotic pressure of 17 mm Hg.

Osmolality is a measure of the osmotically active particles per kilogram of the solvent in which the particles are dispersed. It is expressed as milliosmoles of solute per kilogram of solvent (mOsm/kg). **Osmolarity** is the term formerly used to describe concentration—milliosmoles per liter of the entire solution; but osmolality is now the measurement for most clinical work. However, in reference to certain conditions such as hyperlipidemia, it makes a difference whether osmolality is stated as milliosmoles per kilogram of solvent or per liter of solution.

The average sum of the concentration of all the cations in serum is about 150 mEq/L. The cation concentration is balanced by 150 mEq/L of anions, yielding a total serum osmolality of about 300 mOsm/L. An osmolar imbalance is caused by a gain or loss of water relative to a solute. *An osmolality of less than 285 mOsm/L generally indicates a water excess; an osmolality of greater than 300 mOsm/L indicates a water deficit.*

Water Intoxication

Water intoxication occurs as a result of water intake in excess of the body's ability to excrete water. The increased **intracellular fluid** volume is accompanied by osmolar dilution. The increased volume of intracellular fluid causes the cells, particularly the brain cells, to swell, leading to headache, nausea, vomiting, muscle twitching, blindness, and convulsions with impending stupor. If left untreated, water intoxication can be fatal. Water intoxication is not commonly seen in normal, healthy individuals. It may be seen in endurance athletes who consume large amounts of electrolyte-free beverages during events, individuals with psychiatric illness, or as a result

of water drinking contests (Goldman, 2009; Rogers and Hew-Butler, 2009; Adetoki 2013.)

Water Elimination

Water loss normally occurs through the kidneys as urine and through the GI tract in the feces (measurable, **sensible water loss**), as well as through air expired from the lungs and water vapor lost through the skin (nonmeasurable, **insensible water loss**). The kidney is the primary regulator of sensible water loss. Under normal conditions the kidneys have the ability to adjust to changes in body water composition by either decreasing or increasing water loss in the urine. Natural diuretics are substances in the diet that increase urinary excretion, such as alcohol and caffeine.

Insensible water loss is continuous and usually unconscious. High altitude, low humidity, and high temperatures can increase insensible fluid loss through the lungs and through sweat. Athletes can lose 3 to 4 lb from fluid loss when exercising in a temperature of 80° F and low humidity or even more at higher temperatures.

The GI tract can be a major source of water loss. Under normal conditions the water contained in the 7 to 9 L of digestive juices and other extracellular fluids secreted daily into the GI tract is reabsorbed almost entirely in the ileum and colon, except for about 100 ml that is excreted in the feces. Because this volume of reabsorbed fluid is about twice that of the blood plasma, excessive GI fluid losses through diarrhea may have serious consequences, particularly for very young and very old individuals.

Choleric diarrhea is responsible for the loss of many lives in developing countries and can be successfully corrected without intravenous fluids. Oral rehydration solution, an isotonic fluid, is a simple mixture of water, sugar, and salt is highly effective in improving hydration status (Kelly 2004). Other abnormal fluid losses may occur as a result of emesis, hemorrhage, fistula drainage, burn and wound exudates, gastric and surgical tube drainage, and the use of diuretics.

When water intake is insufficient or water loss is excessive, healthy kidneys compensate by conserving water and excreting more concentrated urine. The renal tubules increase water reabsorption in response to the hormonal action of vasopressin. However, the concentration of the urine made by the kidneys has a limit: approximately 1400 mOsm/L. Once this limit has been reached, the body loses its ability to excrete solutes. The ability of the kidneys to concentrate urine may be compromised in older individuals or in young infants, resulting in increased risk of developing dehydration or hypernatremia, especially during illness.

Signs of dehydration include headache, fatigue, decreased appetite, lightheadedness, poor skin turgor (although this may be present in well-hydrated older persons), skin tenting on the forehead, concentrated urine, decreased urine output, sunken eyes, dry mucous membranes of the mouth and nose, orthostatic blood pressure changes, and tachycardia (Armstrong, 2005). In a dehydrated person the specific gravity, a measure of the dissolved solutes in urine, increases above the normal levels of 1.008 to 1.030, and the urine becomes remarkably darker (Shirreffs, 2003).

High ambient temperature and dehydration adversely affect exercise performance; changes may be mediated by serotonergic and dopaminergic alterations in the central nervous system (Maughan et al, 2007). Fluids of appropriate composition in

appropriate amounts are essential (see *Clinical Insight: Water Requirements: When Eight Is Not Enough*).

Clinical Assessment of Fluid Status

A variety of methods to estimate fluid requirements are based on age, caloric intake, and weight. Obesity has led to challenges with using weight-based calculations for fluid requirements as water accounts for only 45% to 55% of body weight for patients with lower proportions of lean body mass. In clinical practice fluid estimations should be individualized to each patient, especially those with cardiac, liver, or renal failure, and in the presence of ongoing high-volume GI losses.

Unfortunately there is no gold standard to assess hydration status. Clinicians must carefully assess data from a variety of sources, including physical examination by the medical team, nutrition-focused physical examinations, imaging reports (e.g., identifying abnormal fluid collections within the lungs, ascites), laboratory studies, subjective report of symptoms from patients, sudden weight changes, medications, and vital signs. In clinical settings it is important to acknowledge all sources of fluid delivery (oral, enteral feeding tube, intravenous fluids, parenteral nutrition, and intravenous fluids given with medications) and all sources of fluid losses (urine, diuretic medications, and GI secretions (e.g., emesis, gastric secretions, surgical drains, stool, fistulas) (Popkin et al, 2010).

CLINICAL INSIGHT

Water Requirements: When Eight is Not Enough

The body has no provision for water storage; therefore the amount of water lost every 24 hours must be replaced to maintain health and equilibrium. Under ordinary circumstances, a reasonable allowance based on recommended caloric intake is 1 ml/kcal for adults and 1.5 ml/kcal for infants. This translates into approximately 35 ml/kg of usual body weight in adults, 50 to 60 ml/kg in children, and 150 ml/kg in infants.

In most cases a suitable daily allowance for water from all sources, including foods, is approximately 3.7 L (15.5 cups) for adult males and 2.7 L (11+ cups) for adult females, depending on body size (Institute of Medicine [IOM] Food and Nutrition Board, 2004). Because solid food provides 19% of total daily fluid intake, this equals 750 ml of water or approximately 3 cups daily. When this is added to the 200 to 300 ml (about 1 cup) of water contributed by oxidative metabolism, men should consume about 11.5 cups and women need 7 cups of fluids daily. Although the annual consumption of bottled water in the United States equals about 1 cup (8 fl oz) of water daily, this volume alone is not sufficient (Campbell, 2007). Total fluid intake comes from drinking water, other liquids, and food; the AIs for water are for total daily water intake and include all dietary water sources.

Infants need more water because of the limited capacity of their kidneys to handle a large renal solute load, their higher percentage of body water, and their large surface area per unit of body weight. A lactating woman's need for water also increases, approximately 600 to 700 mL (2.5 to 3 cups) per day, for milk production.

Thirst is a less effective signal to consume water in infants, heavily exercising athletes, sick individuals, and older adults who may have a diminished thirst sensation. Anyone sick enough to be hospitalized, regardless of the diagnosis, is at risk for water and electrolyte imbalance. Older adults are particularly susceptible because of factors such as impaired renal concentrating ability, fever, diarrhea, vomiting, and a decreased ability to care for themselves. In situations involving extreme heat or excessive sweating, thirst may not keep pace with the actual water requirements of the body.

ELECTROLYTES

Electrolytes are minerals with electric charges that dissociate in a solution into positive or negatively charged ions. Electrolytes can be simple inorganic salts of sodium, potassium, or magnesium, or complex organic molecules; they play a key role in a host of normal metabolic functions (see Table 6-3). One milliequivalent (mEq) of any substance has the capacity to combine chemically with 1 mEq of a substance with an opposite charge. For univalent ions (e.g., Na⁺) 1 millimole (mmol) equals 1 mEq; for divalent ions (e.g., Ca⁺⁺) 1 mmol equals 2 mEq (see Appendix 2 for conversion guidelines).

The major **extracellular** electrolytes are sodium, calcium, chloride, and bicarbonate. Potassium, magnesium, and phosphate are the major **intracellular** electrolytes. These elements, which exist as ions in body fluids, are distributed throughout all body fluids. Electrolytes are responsible for maintenance of physiologic body functions, cellular metabolism, neuromuscular function, and osmotic equilibrium. Although oral intake varies, the homeostatic mechanisms regulate the concentrations of electrolytes throughout the body.

Changes in either intracellular or extracellular electrolyte concentrations can have a major impact on bodily functions. The **Na/K-ATPase pump** closely regulates cellular electrolyte contents by actively pumping sodium out of cells in exchange for potassium. Other electrolytes follow ion gradients.

Calcium

Although approximately 99% of the body's calcium (Ca⁺⁺) is stored in the skeleton (bones and teeth) the remaining 1% has important physiologic functions. Ionized calcium within the vascular compartment is a cation, with a positive charge. Approximately half of the calcium found in the intravascular compartment is bound to the serum protein albumin. Thus, when serum albumin levels are low, total calcium levels decrease because of hypoalbuminemia. The **corrected calcium** formula, often used in renal disease, is:

$$\text{Serum calcium} + 0.8 (4 - \text{Serum albumin})$$

The binding ability of calcium and its ionized content in blood have implications for normal homeostatic mechanisms.

TABLE 6-3 Normal Electrolyte Concentration of Serum

Electrolyte	Normal Range	Location
Cations		
Sodium	136-145 mEq/L	Extracellular cation
Potassium	3.5-5 mEq/L	Intracellular cation
Calcium	4.5-5.5 mEq/L (9-11 mg/dl)	Extracellular cation
Magnesium	1.5-2.5 mEq/L (1.8-3 mg/dl)	Intracellular cation
Anions		
Chloride	96-106 mEq/L	Extracellular Anion
CO ₂	24-28.8 mEq/L	Extracellular Anion
Phosphorus (inorganic)	3-4.5 mg/dl (1.9-2.85 mEq/L as HPO ₄ ²⁻)	Intracellular Anion

Blood tests for calcium levels often measure total and ionized calcium levels. This is because ionized (or free, unbound calcium) is the active form of calcium and is not affected by hypoalbuminemia. In healthy adults, normal levels for serum total calcium are about 8.5 to 10.5 mg/dl, whereas normal levels for ionized calcium are 4.5 to 5.5 mEq/L.

Functions

Calcium serves as an extracellular cation that regulates nerve transmission, muscle contraction, bone metabolism, and blood pressure regulation and is necessary for blood clotting. Calcium is regulated by parathyroid hormone (PTH), calcitonin, vitamin D, and phosphorus. Through a complex system of regulation among multiple organs, including the kidney, GI tract, and bone, calcium absorption can be enhanced to increase calcium reabsorption to maintain homeostasis. When serum calcium levels are low, PTH causes release of calcium from the bones and stimulates increased absorption from the GI tract. Calcitonin works in the opposite direction, shutting off the release of calcium from the bone and decreasing GI absorption. Vitamin D stimulates while phosphorus inhibits calcium absorption in the GI tract.

In the setting of hypoalbuminemia, serum calcium levels are not accurate because nearly 50% of calcium is protein bound. An ionized calcium level is the most accurate assay for calcium because it is the active form and is not affected by protein levels. In healthy adults, normal levels for serum total calcium are approximately 8.5 to 10.5 mg/dl, whereas normal levels for ionized calcium are 4.5 to 5.5 mEq/L. When ionized calcium levels are not available, a simple formula may be used. The corrected calcium formula accounts for a 0.8 mg/dl decrease in calcium for each 1 g/dl decrease in serum albumin below 4 g/dl. The corrected calcium formula is

$$([4 - \text{Serum albumin (g/dL)}] \times 0.8) + \text{Measured calcium (mg/dL)}$$

Ionized calcium levels are altered inversely by changes in acid-base balance; as serum pH rises, calcium binds with protein, leading to decreased ionized calcium levels. As pH is lowered, the opposite occurs. Because calcium has an important role in cardiac, nervous system, and skeletal muscle function, hypocalcemia and hypercalcemia can become life threatening.

Common causes of hypercalcemia are cancer with the presence of bone metastases or hyperparathyroidism, when there is a large amount of calcium moved into the ECF. Symptoms of hypercalcemia include lethargy, nausea, vomiting, muscle weakness, and depression. Treatment usually is directed at treating the underlying cause of the problem, discontinuation of calcium containing medications, and increasing the excretion of calcium through the kidneys (by delivery of intravenous fluids followed by diuretic medications).

Hypocalcemia often is marked with numbness or tingling, hyperactive reflexes, tetany, lethargy, muscle weakness, confusion, and seizures. Causes of hypocalcemia include low serum phosphorus or magnesium levels, medications that cause calcium losses, hypoalbuminemia, vitamin D deficiency, or hypoparathyroidism. Oral calcium supplements are most often the first-line therapy in the absence of symptoms. Because other hormones, electrolytes, and vitamins are involved in calcium regulation, these are assessed in the setting of true hypocalcemia. Low phosphorus and magnesium levels must be repleted before calcium levels can be corrected (Rhoda, 2011).

Absorption and Excretion

Approximately 20% to 60% of dietary calcium is absorbed and is tightly regulated because of the need to maintain steady serum calcium levels in the face of fluctuating intake. The ileum is the most important site of calcium absorption. Calcium is absorbed via passive transport and through a vitamin D–regulated transport system.

The kidney is the main site of calcium excretion. The majority of serum calcium is bound to proteins and not filtered by the kidneys; only about 100 to 200 mg is excreted in the urine in normal adults.

Sources

Dairy products are the main source of calcium in the American diet, with some green vegetables, nuts, canned fish including bones, and calcium-enriched tofu having moderate amounts of calcium. Food manufacturers fortify many foods with additional calcium that may have some bioavailability.

Recommended Intakes

Recommended intakes of calcium range from 1000 to 1300 mg/day, depending on age and gender. An upper limit for calcium intake has been estimated to be approximately 2500 to 3000 mg/day (see inside cover).

Sodium

Sodium (Na^+) is the major cation of extracellular fluid with a normal range of 135 to 145 mEq/L. Secretions such as bile and pancreatic juice contain substantial amounts of sodium. Gastric secretions and diarrhea also contain sodium, but contrary to common belief sweat is hypotonic and contains a relatively small amount of sodium. Approximately 35% to 40% of the total body sodium is in the skeleton and the remainder is in body fluids.

Functions

As the predominant ion of the extracellular fluid, sodium thus regulates extracellular and plasma volume. Sodium is also important in neuromuscular function and maintenance of acid-base balance. Maintenance of serum sodium levels is vital, because severe hyponatremia can lead to seizures, coma, and death.

Extracellular sodium concentrations are much higher than intracellular levels (normal serum sodium is around 135 mEq/L, whereas intracellular levels are around 10 mEq/L). The sodium-potassium ATP pump is an active transport system that works to keep sodium outside the cell through exchange with potassium. The sodium-potassium ATP pump requires carriers for sodium and potassium along with energy for proper function. Exportation of sodium from the cell is the driving force for facilitated transporters, which import glucose, amino acids, and other nutrients into the cells.

Hyponatremia. Assessing hyponatremia or hypernatremia takes into consideration sodium's role in regulating fluid balance and requires evaluation of overall hydration status. Hyponatremia is one of the most common electrolyte disorders among hospitalized patients and occurs in 25% of inpatients. When hyponatremia is below 125 mEq/L, symptoms generally become apparent. Patients may display signs of headache, lethargy, restlessness, decreased reflexes, seizures, or coma in extreme cases. There are three basic causes for hyponatremia. Hypertonic hyponatremia is due to excess delivery of mannitol or hyperglycemia, which causes serum sodium to increase by

1.6 mEq for every 100 mg/dl rise in serum glucose. Isotonic hyponatremia occurs in the presence of hyperlipidemia or hyperproteinemia, because the aqueous component that sodium is dissolved in results in a falsely low value (this is mainly a laboratory artifact and is not often seen in clinical practice). The final type is hypotonic hyponatremia. Evaluation depends on fluid status to evaluate the three subtypes.

Isovolemic hyponatremia can be caused by malignancies, adrenal insufficiency, or the syndrome of inappropriate antidiuretic hormone secretion (SIADH). SIADH can result from central nervous system disorders, pulmonary disorders, tumors, and certain medications. The treatment is usually water restriction. Hypervolemic hypotonic hyponatremia is characterized by excess TBW and sodium (overall higher excess water than sodium) because of reduced excretion of water or excess free water administration. Cardiac, renal, or hepatic failure is often a contributing factor, and patients have edema or ascites on physical examination. The treatment is fluid restriction or diuretics to aid in decreasing TBW, and oral sodium restriction also may be beneficial. The final type is hypovolemic hypotonic hyponatremia, characterized by a deficit in TBW and sodium that requires treatment with fluid replacement. Often fluid losses leading to hypovolemia hyponatremia include excessive vomiting, excessive sweating (marathon athletes), diarrhea, wound drainage/burns, high-volume gastrointestinal secretions, or excessive diuretic use. Equations to calculate fluid deficits can be used to replace half of the fluid deficit in the first 24 hours. Correcting sodium levels must be done slowly (max of 8 to 12 mEq in 24 hours) to prevent osmotic demyelinating syndrome that is seen with rapid correction (Rhoda et al, 2011).

Hypernatremia. A serum sodium level greater than 145 mEq/L is classified as hypernatremia, and there are various types. Hypovolemic hypernatremia is caused by a loss of sodium and TBW when water losses exceed sodium losses. It is important to identify the cause of the fluid losses so that they can be corrected and prevented in the future. The treatment is to slowly replace fluid volume with a hypotonic fluid solution. Hypervolemic hypernatremia is caused by excessive intake of sodium resulting in higher sodium gain than water gains. The treatment is to restrict sodium (especially in intravenous fluids) and possibly the use of diuretics. Isovolemic hypernatremia is seen with disease states such as diabetes insipidus. Signs of hypernatremia include lethargy, thirst, hyperreflexia, seizures, coma, or death. Formulas for calculating a water deficit are helpful to guide fluid replacement. Free water deficit is calculated as follows (Kingley, 2005):

$$[0.6 \times \text{Weight (kg)}] \times 1 - [140 / \text{Na mEq/L}]$$

Absorption and Excretion

Sodium is absorbed readily from the intestine and carried to the kidneys, where it is filtered and returned to the blood to maintain appropriate levels. The amount absorbed is proportional to the intake in healthy adults.

About 90% to 95% of normal body sodium loss is through the urine; the rest is lost in feces and sweat. Normally the quantity of sodium excreted daily is equal to the amount ingested. Sodium excretion is maintained by a mechanism involving the glomerular filtration rate, the cells of the juxtaglomerular apparatus of the kidneys, the renin-angiotensin-aldosterone system, the sympathetic nervous system, circulating catecholamines, and blood pressure.

Sodium balance is regulated in part by aldosterone, a mineralocorticoid secreted by the adrenal cortex. When blood sodium levels rise, the thirst receptors in the hypothalamus stimulate the thirst sensation. Ingestion of fluids returns sodium levels to normal. Under certain circumstances sodium and fluid regulation can be disrupted, resulting in abnormal blood sodium levels. The syndrome of inappropriate antidiuretic hormone secretion (SIADH) is characterized by concentrated, low-volume urine and dilutional hyponatremia as water is retained. SIADH can result from central nervous system disorders, pulmonary disorders, tumors, and certain medications.

Estrogen, which is slightly similar to aldosterone, also causes sodium and water retention. Changes in water and sodium balance during the menstrual cycle, during pregnancy, and while taking oral contraceptives are attributable partially to changes in progesterone and estrogen levels.

Dietary Reference Intake

The dietary reference intakes (DRI) give an upper limit of 2.3 g of sodium per day (or 5.8 g sodium chloride per day). The mean daily salt intake in Western societies is approximately 10 to 12 g (4 to 5 g of sodium), which is in excess of the adequate intake for sodium of 1.2 to 1.5 g per day, depending on age, with lower amounts recommended for the elderly (see Table 6-4).

Healthy kidneys are usually able to excrete excess sodium intake; however, persistent excessive sodium intake has been implicated in development of hypertension. In addition to its role in hypertension, excessive salt intake has been associated with increased urinary calcium excretion, kidney stones, and some cases of osteoporosis (Teucher 2003; He 2010, Caudarella et al, 2009). Higher sodium consumption has been associated with higher weight status, and a positive relationship has been observed between sodium intake and obesity independent of energy intake (Song et al, 2013; Yoon 2013; Zhu 2014). In addition, a positive association has been identified between sodium intake and increased circulation of leptin (secreted by fat cells and influences inflammatory response and sodium excretion) and tumor necrosis factor alpha (plays a role in inflammation) (Zhu et al, 2014).

Sources

The major source of sodium is sodium chloride, or common table salt, of which sodium constitutes 40% by weight. Protein foods generally contain more naturally existing sodium than do

TABLE 6-4 Dietary Reference Intakes for Sodium, Potassium, and Chloride Daily Intake

Age	Sodium	Potassium	Chloride	Salt (Sodium Chloride)
Adult	1.5 g	4.7 g	2.3 g	3.8 g
19-49	(65 mmol)	(120 mmol)	(65 mmol)	(65 mmol)
Adult	1.3 g	4.7 g	2.0 g	3.2 g
50-70	(55 mmol)	(120 mmol)	(55 mmol)	(55 mmol)
Adult 71	1.2 g	4.7 g	1.8 g	2.9 g
	(50 mmol)	(120 mmol)	(50 mmol)	(50 mmol)
UL	2.3 g	n/a	3.6 g	na
	(100 mmol)		(100 mmol)	

Institute of Medicine, Food and Nutrition Board: *Dietary reference intakes for water, potassium, sodium, chloride, and sulfate*, Washington, DC, 2004, National Academies Press.

UL, Tolerable upper intake level.

vegetables and grains, whereas fruits contain little or none. The addition of table salt, flavored salts, flavor enhancers, and preservatives during food processing accounts for the high sodium content of most convenience and fast-food products. For instance ½ cup of frozen vegetables prepared without salt contains 10 mg of sodium, whereas ½ cup of canned vegetables contains approximately 260 mg of sodium. Similarly, 1 ounce of plain meat contains 30 mg of sodium, whereas 1 ounce of luncheon meat contains approximately 400 mg of sodium. The larger portion sizes offered by dining establishments to consumers are increasing the sodium intake even more.

Magnesium

Magnesium is the second most prevalent intracellular cation. Approximately half of the body's magnesium is located in bone, whereas another 45% resides in soft tissue; only 1% of the body's magnesium content is in the extracellular fluids. Normal serum magnesium levels are about 1.6 to 2.5 mEq/L; however, about 70% of serum magnesium is free or ionized. The remainder is bound to proteins and is not active.

Function

Magnesium (Mg^{2+}) is an important cofactor in many enzymatic reactions in the body and is also important in bone metabolism as well as central nervous system and cardiovascular function. Many of the enzyme systems regulated by magnesium are involved in nutrient metabolism and nucleic acid synthesis, leading to the body's need to carefully regulate magnesium status.

As with calcium, severe hypo- or hypermagnesemia can have life-threatening sequelae. Physical symptoms of magnesium abnormalities are similar to those observed with other electrolyte deficiencies, and the challenges with serum measurements discussed earlier make assessment of magnesium status difficult. Symptoms of hypomagnesemia include muscle weakness, tetany, ataxia, nystagmus, and in severe cases ventricular arrhythmia. Frequent causes of hypomagnesemia include excessive stool losses (as seen in short bowel syndrome or malabsorption), inadequate magnesium in the diet (oral, enteral, or parenteral nutrition), intracellular shifts during refeeding syndrome, acute pancreatitis, burns, alcoholism, diabetic ketoacidosis, and medications causing increased magnesium losses via the urine. Long-term use of proton pump inhibitors also may be a rare cause.

Often hypomagnesemia is treated with oral supplementation if no physical symptoms are noted. However, dietitians should monitor cautiously for diarrhea with oral magnesium supplements if they are not given in divided doses (such as magnesium oxide), which often can increase magnesium losses through the stool. Increased losses through the stool is avoided with supplementation from salts such as magnesium gluconate or magnesium lactate. Intravenous repletion with magnesium is required with symptomatic signs of deficiency or if serum levels are below 1 mg/dl.

Hypermagnesemia, a serum value greater than 2.5 mg/dl, can be due to excess supplementation or magnesium containing medications, severe acidosis, or dehydration. Treatment options include omission of magnesium-containing medications and correction of the fluid imbalance.

Absorption/Excretion

Approximately 30-50% of magnesium ingested from the diet is absorbed (within the jejunum and ileum through passive and active transport mechanisms). Magnesium is regulated by the

intestine, kidney, and bone. Magnesium absorption is regulated to maintain serum levels; if levels drop, more is absorbed and if levels increase, less is absorbed. The kidney is the major regulator of magnesium excretion, but some magnesium is also lost via the stool. As magnesium is a cofactor for the Na-K ATPase pump, low magnesium levels should be evaluated and corrected especially when hypokalemia is refractory to repletion. Additionally, the kidneys increase potassium excretion in light of hypomagnesemia (Kraft, Langley 2012, Rhoda 2011).

Sources

Magnesium is found in a variety of foods, making an isolated magnesium deficiency unlikely in otherwise healthy individuals. Highly processed foods tend to have lower magnesium content, whereas green leafy vegetables, legumes, and whole grains are thought to be good sources. The high magnesium content of vegetables helps to alleviate some concerns about the potential for phytate binding. Intakes of magnesium, potassium, fruits, and vegetables have been associated with higher alkaline status and a subsequent beneficial effect on bone health; enhanced mineral-water consumption may be an easy, inexpensive way to reduce the onset of osteoporosis (Wynn et al, 2010).

Dietary Reference Intakes

The recommended intake of magnesium ranges from 310 to 420 mg/day, depending on age and gender (see inside cover).

Phosphorus

Phosphorus is the primary intracellular anion and its role in adenosine triphosphate (ATP) is vital in energy metabolism. In addition, phosphorus is important in bone metabolism. About 80% of the body's phosphorus is found in bones. Normal levels for serum phosphorus are between 2.4 and 4.6 mg/dl.

Functions

Large amounts of free energy are released when the phosphate bonds in ATP are split. In addition to this role, phosphorus is vital for cellular function in phosphorylation and dephosphorylation reactions, as a buffer in acid-base balance, and in cellular structure as part of the phospholipid membrane. Because of the vital role that phosphorus plays in energy production, severe hypophosphatemia can be a life-threatening event. This is seen most often clinically in refeeding syndrome and occurs with the increased use of phosphorus for the phosphorylation of glucose (Skipper, 2012; Rhoda 2011; Kraft 2005). In addition to intracellular shifts, hypophosphatemia can be medication related (insulin, epinephrine, dopamine, erythropoietin, phosphorus-binding medications). Severe and symptomatic hypophosphatemia (<1 mg/dl) can be critical and includes impaired cardiac function, reduced contractions of the diaphragm leading to a weakened respiratory state, confusion, reduced oxygen delivery to tissues, coma, and even death.

Absorption and Excretion

Phosphorus absorption is dependent on serum levels and vitamin D status. Around 80% of phosphorus intake is absorbed in the small bowel when hypophosphatemia is present. The kidney is the major site of phosphorus excretion and regulates phosphorus absorption based on parathyroid hormone and acid base status. Phosphorus absorption decreases when vitamin D deficiency occurs or with certain medications that bind

phosphorus (certain antacids or phosphate binders used in patients with chronic kidney disease).

Sources

Phosphorus is found mainly in animal products, including meats and milk; some dried beans are also good sources.

Dietary Reference Intakes

The recommended intake of phosphorus is approximately 700 mg per day, depending on age and gender, with an upper limit of 3500 to 4000 mg (see inside cover).

Potassium

With approximately 98% of Potassium (K^+) in the intracellular space, K^+ is the major cation of intracellular fluid. The normal serum potassium concentration is 3.5 to 5 mEq/L.

Functions

With sodium, potassium is involved in maintaining a normal water balance, osmotic equilibrium, and acid-base balance. In addition to calcium, K^+ is important in the regulation of neuromuscular activity. Concentrations of sodium and potassium determine membrane potentials in nerves and muscle. Potassium also promotes cellular growth. The potassium content of muscle is related to muscle mass and glycogen storage; therefore, if muscle is being formed, an adequate supply of potassium is essential. Potassium has an integral role in the Na/K-ATPase pump.

Hypokalemia and hyperkalemia can have devastating cardiac implications. When hypokalemia is less than 3 mEq/L, symptoms are more apparent and critical. Symptoms of hypokalemia include muscle weakness, cramping in the extremities, vomiting, and weakness. Clinically, hypokalemia occurs with large volume losses of gastrointestinal fluids that contain potassium, insulin delivery, excessive losses through the urine caused by certain medications (diuretics), and diabetic ketoacidosis. Guidelines exist for the treatment of hypokalemia (oral or intravenous medications) and are adjusted in renal impairment because potassium is excreted by the kidneys.

Hyperkalemia can be critical, especially when levels exceed 6.5 mEq/L and are accompanied by symptoms of muscle weakness, paralysis, respiratory failure, and arrhythmias/ECG changes. Causes of hyperkalemia in a clinical setting include hemolysis causing falsely elevated laboratory results, kidney disease impairing K^+ excretion, medications such as potassium-sparing diuretics, gastrointestinal hemorrhage, rhabdomyolysis, catabolism, metabolic acidosis, or overzealous K^+ supplementation.

Absorption and Excretion

Potassium is absorbed readily from the small intestine. Approximately 80% to 90% of ingested potassium is excreted in the urine; the remainder is lost in the feces. The kidneys maintain normal serum levels through their ability to filter, reabsorb, and excrete potassium under the influence of aldosterone. In the setting of hypokalemia, aldosterone secretions are lower and the kidneys shift to reabsorb potassium and excrete sodium.

Sources

Potassium-rich food sources include fruits, vegetables, fresh meat, and dairy products. Salt substitutes commonly contain potassium. [Box 6-1](#) categorizes select foods according to their

potassium content. When evaluating potassium sources and losses, clinicians must consider other nonfood sources of potassium, such as intravenous fluids with added potassium, certain medications containing potassium, and medications that may cause the body to excrete potassium.

Dietary Reference Intakes

The adequate intake level for potassium for adults is 4700 mg per day. No upper limit has been set. Potassium intake is inadequate in a large number of Americans, as many as 50% of adults. The reason for the poor potassium intakes is simply inadequate consumption of fruits and vegetables. Insufficient potassium intakes have been linked to hypertension and cardiac arrhythmia.

ACID-BASE BALANCE

An acid is any substance that tends to release hydrogen ions in solution, whereas a base is any substance that tends to accept hydrogen ions in solution. The hydrogen ion concentration [H^+] determines acidity. Because the magnitude of hydrogen ion concentration is small compared with that of other serum electrolytes, acidity is expressed more readily in terms of pH units. A low blood pH indicates a higher hydrogen ion concentration and greater acidity, whereas a high pH value indicates a lower hydrogen ion concentration and greater alkalinity.

Acid-base balance is the dynamic equilibrium state of hydrogen ion concentration. Maintaining the arterial blood pH level within the normal range of 7.35 to 7.45 is crucial for many physiologic functions and biochemical reactions. Regulatory mechanisms of the kidneys, lungs, and buffering systems enable the body to maintain the blood pH level despite the enormous acid load from food consumption and tissue metabolism. A disruption of the acid-base balance occurs when acid or base losses or gains exceed the body's regulatory capabilities or when normal regulatory mechanisms become ineffective. These regulatory disturbances may develop in association with certain diseases, toxin ingestion, shifts in fluid status, and certain medical and surgical treatments ([Table 6-5](#)). If a disrupted acid-base balance is left untreated, multiple detrimental effects ranging from electrolyte abnormalities to death can ensue.

Acid Generation

The body produces a large amount of acids daily through routine processes such as metabolism and oxidation of food, endogenous production of acid from tissue metabolism, and ingestion of acid precursors. The main acid is carbon dioxide (CO_2), termed a volatile acid, which is produced from the oxidation of carbohydrates, amino acids, and fat. Nonvolatile or fixed acids, including phosphoric and sulfuric acids, are produced from the metabolism of phosphate-containing compounds to form phosphates and phosphoric acid and sulfur-containing amino acids (such as the metabolism of methionine and cystine). Organic acids, such as lactic, uric, and keto acids, come from the incomplete metabolism of carbohydrates and fats. These organic acids typically accumulate only during exercise, acute illness, or fasting. Under normal conditions, the body is able to maintain normal acid-base status through a wide range of acid intake from foods.

Regulation

Various regulatory mechanisms maintain the pH level within very narrow physiologic limits. At the cellular level, [buffer](#)

BOX 6-1 Classification of Select Foods by Potassium Content

Low (0-100 mg/serving)*	Medium (100-200 mg/serving)*	High (200-300 mg/serving)*	Very High (>300 mg/serving)*
Fruits	Fruits	Fruits	Fruits
Applesauce	Apple, 1 small	Apricots, canned	Avocados, ¼ small
Blueberries	Apple juice	Grapefruit juice	Banana, 1 small
Cranberries	Apricot nectar	Kiwi, ½ medium	Cantaloupe, ¼ small
Lemon, ½ medium	Blackberries	Nectarine, 1 small	Dried fruit, ¼ cup
Lime, ½ medium	Cherries, 12 small	Orange, 1 small	Honeydew melon, ⅛ small
Pears, canned	Fruit cocktail	Orange juice	Mango, 1 medium
Pear nectar	Grape juice	Peach, fresh, 1 medium	Papaya, ½ medium
Peach nectar	Grapefruit, ½ small	Pear, fresh, 1 medium	Prune juice
Vegetables	Grapes, 12 small	Vegetables	Vegetables
Cabbage, raw	Mandarin oranges	Asparagus, fresh, cooked, 4 spears	Artichoke, 1 medium
Cucumber slices	Peaches, canned	Beets, fresh, cooked	Bamboo shoots, fresh
Green beans, frozen	Pineapple, canned	Brussels sprouts	Beet greens, ¼ cup
Leeks	Plum, 1 small	Kohlrabi	Corn on the cob, 1 ear
Lettuce, iceberg, 1 cup	Raspberries	Mushrooms, cooked	Chinese cabbage, cooked
Water chestnuts, canned	Rhubarb	Okra	Dried beans
Bamboo shoots canned	Strawberries	Parsnips	Potatoes, baked, ½ medium
	Tangerine, 1 small	Potatoes, boiled or mashed	Potatoes, French fries, 1 oz
	Watermelon, 1 cup	Pumpkin	Spinach
	Vegetables	Rutabagas	Sweet potatoes, yams
	Asparagus, frozen	Miscellaneous	Swiss chard, ¼ cup
	Beets, canned	Granola	Tomato, fresh, sauce, or juice; tomato paste, 2 tbsp
	Broccoli, frozen	Nuts and seeds, 1 oz	Winter squash
	Cabbage, cooked	Peanut butter, 2 tbsp	Miscellaneous
	Carrots	Chocolate, 1.5-oz bar	Bouillon, low sodium, 1 cup
	Cauliflower, frozen		Cappuccino, 1 cup
	Celery, 1 stalk		Chili, 4 oz
	Corn, frozen		Coconut, 1 cup
	Eggplant		Lasagna, 8 oz
	Green beans, fresh, raw		Milk, chocolate milk, 1 cup
	Mushrooms, fresh, raw		Milkshakes, 1 cup
	Onions		Molasses, 1 tbsp
	Peas		Pizza, 2 slices
	Radishes		Salt substitutes, ¼ tsp
	Turnips		Soy milk, 1 cup
	Zucchini, summer squash		Spaghetti, 1 cup
			Yogurt, 6 oz

*One serving equals ½ cup unless otherwise specified.

TABLE 6-5 Four Major Acid-Base Imbalances

Acid-base Imbalance	pH	Primary Disturbance	Compensation	Possible Causes
Respiratory				
Respiratory acidosis	Low	Increased pCO ₂	Increased renal net acid excretion with resulting increase in serum bicarbonate	Emphysema; COPD; neuromuscular disease where respiratory function is impaired; excessive retention of CO ₂
Respiratory alkalosis	High	Decreased pCO ₂	Decreased renal net acid excretion with resulting decrease in serum bicarbonate	Heart failure, pregnancy, sepsis, meningitis, anxiety, pain, excessive expiration of CO ₂
Metabolic				
Metabolic acidosis	Low	Decreased HCO ₃ ⁻	Hyperventilation with resulting low pCO ₂	Diarrhea; uremia; ketoacidosis from uncontrolled diabetes mellitus; starvation; high-fat, low-carbohydrate diet; drugs, alcoholism, kidney disease
Metabolic alkalosis	High	Increased HCO ₃ ⁻	Hypoventilation with resulting increase in pCO ₂	Diuretics use; increased ingestion of alkali; loss of chloride; vomiting/nasogastric tube suction

FIGURE 6-3 Generation of NaHCO_3 and clearance of H^+ by the three buffer systems that function in the kidney. *HA*, Any acid in the body.

systems composed of weak acids or bases and their corresponding salts minimize the effect on pH of the addition of a strong acid or base. The buffering effect involves formation of a weaker acid or base in an amount equivalent to the strong acid or base that has been added to the system (Figure 6-3).

Proteins and phosphates are the primary intracellular buffers, whereas the bicarbonate and carbonic acid system is the primary extracellular buffer. The acid-base balance also is maintained by the kidneys and lungs. The kidneys regulate hydrogen ion (H^+) secretion and bicarbonate resorption. The kidneys regulate the pH of the urine by excreting H^+ or HCO_3^- and can make bicarbonate. The kidneys are the slowest responding mechanism to maintain acid-base balance. The lungs control H^+ through the amount of CO_2 that is exhaled. When more CO_2 is exhaled, it reduces the H^+ concentration in the body. The respiratory system responds quickly to alter either the depth or rate of air movement in the lungs.

ACID-BASE DISORDERS

Acid-base disorders can be differentiated based on whether they have metabolic or respiratory causes. The evaluation of acid-base status requires analysis of serum electrolytes and arterial blood gas (ABG) values (Table 6-6). There are four main acid-base abnormalities: metabolic acidosis, metabolic alkalosis, respiratory acidosis and respiratory alkalosis. It is important to

TABLE 6-6 Normal Arterial Blood Gas Values

Clinical Test	ABG Value
pH	7.35-7.45
pCO_2	35-45 mm Hg
pO_2	80-100 mm Hg
HCO_3^- (bicarbonate)	22-26 mEq/L
O_2 saturation	>95%

ABG, Arterial blood gas.

characterize the type of acid-base disorder because this will dictate the treatment and response or “compensation” mechanism enacted by the body. Metabolic acid-base imbalances result in changes in bicarbonate (i.e., base) levels, which are reflected in the total carbon dioxide (TCO_2) portion of the electrolyte profile. TCO_2 includes bicarbonate (HCO_3^-), carbonic acid (H_2CO_3) and dissolved carbon dioxide; however, all but 1 to 3 mEq/L is in the form of bicarbonate. Thus, for ease of interpretation, TCO_2 should be equated with bicarbonate. Respiratory acid-base imbalances result in changes in the partial pressure of dissolved carbon dioxide (pCO_2). This is reported in the arterial blood gas values in addition to the pH, which reflects the overall acid-base status.

Metabolic Acidosis

Metabolic acidosis results from increased production or accumulation of acids or loss of base (i.e., bicarbonate) in the extracellular fluids. Simple, acute metabolic acidosis results in a low blood pH (or **acidemia**), low HCO_3^- and normal pCO_2 . Examples of metabolic acidosis include diabetic ketoacidosis, lactic acidosis, toxin ingestion, uremia, and excessive bicarbonate loss via the kidneys or intestinal tract. Multiple deaths previously have been attributed to lactic acidosis caused by administration of parenteral nutrition devoid of thiamin. In patients with metabolic acidosis, the anion gap is calculated to help determine cause and appropriate treatment. An **anion gap** is the measurement of the interval between the sum of “routinely measured” cations minus the sum of the “routinely measured” anions in the blood. The anion gap is

$$(\text{Na}^+ + \text{K}^+) - (\text{Cl}^- + \text{HCO}_3^-)$$

where Na^+ is sodium, K^+ is potassium, Cl^- is chloride, and HCO_3^- is bicarbonate. Normal is 12 to 14 mEq/L.

Anion gap metabolic acidosis occurs when a decrease in bicarbonate concentration is balanced by increased acid anions other than chloride. This causes the calculated anion gap to exceed the normal range of 12 to 14 mEq/L. This normochloremic metabolic acidosis may develop in association with the following conditions, represented by the acronym **MUD PILES** (Wilson, 2003):

Methanol ingestion	Paraldehyde ingestion
Uremia	lntrogenic
Diabetic ketoacidosis	Lactic acidosis
	Ethylene glycol or ethanol ingestion
	Salicylate intoxication

Nongap metabolic acidosis occurs when a decrease in bicarbonate concentration is balanced by an increase in chloride concentration, resulting in a normal anion gap. This hyperchloremic

metabolic acidosis may develop in association with the following, represented by the acronym *USED CARP* (Wilson, 2003):

Ureterosigmoidostomy	Carbonic anhydrase inhibitor
Small bowel fistula	Adrenal insufficiency
Extra chloride ingestion	Renal tubular acidosis
Diarrhea	Pancreatic fistula

Metabolic Alkalosis

Metabolic alkalosis results from the administration or accumulation of bicarbonate (i.e., base) or its precursors, excessive loss of acid (e.g., during gastric suctioning), or loss of extracellular fluid containing more chloride than bicarbonate (e.g., from villous adenoma or diuretic use). Simple, acute metabolic alkalosis results in a high blood pH, or **alkalemia**. Metabolic alkalosis also may result from volume depletion; decreased blood flow to the kidneys stimulates reabsorption of sodium and water, increasing bicarbonate reabsorption. This condition is known as **contraction alkalosis**. Alkalosis also can result from severe hypokalemia (serum potassium concentration <2 mEq/L). As potassium moves from the intracellular to the extracellular fluid, hydrogen ions move from the extracellular to the intracellular fluid to maintain electroneutrality. This process produces intracellular acidosis, which increases hydrogen ion excretion and bicarbonate reabsorption by the kidneys.

Respiratory Acidosis

Respiratory acidosis is caused by decreased ventilation and consequent carbon dioxide retention. Simple, acute respiratory acidosis results in a low pH, normal HCO_3^- and elevated pCO_2 . Acute respiratory acidosis can occur as a result of sleep apnea, asthma, aspiration of a foreign object, or acute respiratory distress syndrome (ARDS). Chronic respiratory acidosis is associated with obesity hypoventilation syndrome, chronic obstructive pulmonary disease (COPD) or emphysema, certain neuromuscular diseases, and starvation cachexia. Prevention of overfeeding is prudent as it can worsen acidosis (Ayers 2012).

Respiratory Alkalosis

Respiratory alkalosis results from increased ventilation and elimination of carbon dioxide. The condition may be mediated centrally (e.g., from head injury, pain, anxiety, cerebrovascular accident, or tumors) or by peripheral stimulation (e.g., from pneumonia, hypoxemia, high altitudes, pulmonary embolism, congestive heart failure, or interstitial lung disease). Simple, acute respiratory alkalosis results in a high pH, (or alkalemia), normal HCO_3^- , and decreased pCO_2 .

Compensation

When an acid-base imbalance occurs, the body attempts to restore the normal pH by developing an opposite acid-base imbalance to offset the effects of the primary disorder, a response known as compensation. For example, the kidneys of a patient with a primary respiratory acidosis (decreased pH) compensate by increasing bicarbonate reabsorption, thereby creating a metabolic alkalosis. This response helps to increase the pH. Similarly, in response to a primary metabolic acidosis (decreased pH), the lungs compensate by increasing ventilation and carbon dioxide elimination, thereby creating a respiratory

alkalosis. This compensatory respiratory alkalosis helps to increase pH.

Respiratory compensation for metabolic acid-base disturbances occurs quickly—within minutes. In contrast, renal compensation for respiratory acid-base imbalances may take 3 to 5 days to be maximally effective (Ayers et al, 2015). Compensation does not always occur; and when it does, it is not completely successful (i.e., does not result in a pH of 7.4). The pH level still reflects the underlying primary disorder. Clinicians must distinguish between primary disturbances and compensatory responses because treatment always is directed toward the primary acid-base disturbance and its underlying cause. As the primary disturbance is treated, the compensatory response corrects itself. Predictive values for compensatory responses are available to differentiate between primary acid-base imbalances and compensatory responses (Whitmire 2002). Clinicians also may use tools such as clinical algorithms.

Acid Base Balance: Rules of Thumb and Applications to Dietetics Practice

Acid-base balance is a complicated topic that requires a high-level understanding of many complex processes. Table 6-5 displays the anticipated ABG alterations and compensation mechanisms. A few rules of thumb may be helpful to understanding this topic. In uncompensated and simple acid base disorders, pH and pCO_2 move in opposite directions in respiratory disorders. In uncompensated and simple acid base disorders, pH and HCO_3^- move in the same direction. When mixed acid base disorders occur, pCO_2 and HCO_3^- generally move in opposite directions. Regardless of the disorder, the medical team directs the treatment at the underlying cause and uses supporting information from the medical history, current clinical condition, medications, laboratory values, intake and output records, and physical examination to determine the cause. Dietetics professionals play an important role in understanding the physiologic process and how it relates to regulation of electrolyte and fluid balance. Adjustments to the nutrition care plan related to acid-base balance can include shifting chloride and acetate salts in Parenteral Nutrition, manipulation of macronutrients to prevent overfeeding, or adjustments in fluid and electrolytes.

Nutrition assessment may be completed within the context of a traditional medical model or a functional integrative medical model. Clinicians must demonstrate critical thinking skills to observe, interpret, analyze, and infer data to detect new nutrition diagnoses or determine that nutrition-related issues have resolved (Charney et al, 2013). The three sources of information—biochemical data, physical attributes, and functional changes—are viewed in the context of each other, and the trends of data over time are useful to identify patterns consistent with nutrition and medical diagnoses (Figure 7-1).

Health care reforms are changing the practice of dietetics specific to nutrition assessment in several ways. First, the practice of ordering diets is changing to allow RDNs the privilege of writing diet orders within the parameters set by the governing body of the health care organization. Second, the practice of ordering routine laboratory tests is changing and health care providers must justify the need for each laboratory test ordered. Third, the use of evidence-based medical guidelines is reshaping the types and frequency of biochemical testing, physical assessments, and functional tests ordered. These changes augment the value of physical and functional assessment as pivotal components of nutrition assessment.

Practitioners should assess patients from a global perspective, requesting necessary tests, and not be limited by the history of reimbursement for testing. Also, many consumers are seeking health care services that are not covered currently by traditional insurance and government-funded health care programs. The nutrition professional can determine the validity and usefulness of these requests for testing. Before recommending a biochemical test to be performed, the dietitian should consider, “How will the test results change my intervention?”

BIOCHEMICAL ASSESSMENT OF NUTRITION STATUS

Laboratory tests are ordered to diagnose diseases, support nutrition diagnoses, monitor effectiveness of nutrition preventions, evaluate medication effectiveness, and evaluate NCP interventions or medical nutrition therapy (MNT). Acute illness, surgery, or injury can trigger dramatic changes in laboratory test results, including rapidly deteriorating nutrition status. However, chronic diseases that develop slowly over time also influence these results, making them useful in preventive care.

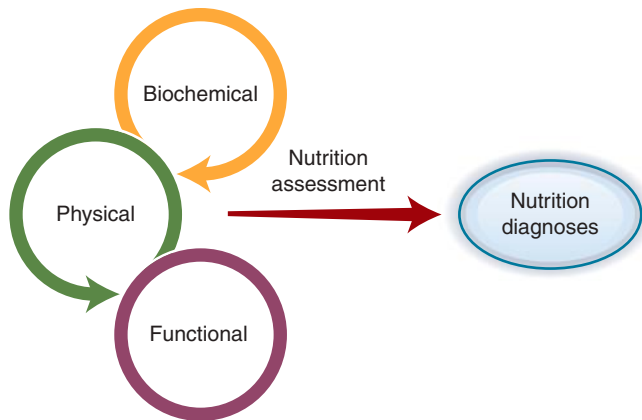

FIGURE 7-1 Interrelationship of biochemical data, physical attributes, and functional status.

Definitions and Applications of Laboratory Test Results

Laboratory assessment is a stringently controlled process. It involves comparing control samples with predetermined substance or chemical constituent (**analyte**) concentrations with every patient specimen. The results obtained must compare favorably with predetermined acceptable values before the patient data can be considered valid. Laboratory data are the only *objective data* used in nutrition assessment that are “controlled”—that is, the validity of the method of its measurement is checked each time a specimen is assayed by also assaying a sample with a known value.

Laboratory-based nutrition testing, used to estimate nutrient concentration in biologic fluids and tissues, is critical for assessment of clinical and subclinical nutrient deficiencies. As shown in [Figure 7-2](#), the size of a nutrient pool can vary continuously from a frank deficit to insufficiency to adequate to toxic. Most of these states can be assessed in the laboratory so that nutritional intervention can occur before a clinical or anthropometric change or a frank deficiency occurs ([Litchford, 2015](#)). Single test results must be evaluated in light of the patient’s current medical condition,

nutrition-focused physical assessment data, medications, lifestyle choices, age, hydration status, fasting status at the time of specimen collection, and reference standards used by the clinical laboratory. Single test results may be useful for screening or to confirm an assessment based on changing clinical, anthropometric, and dietary status. Comparison of current test results to historic baseline test results from the same laboratory is desirable when available. It is vital to monitor trends in test results and patterns of results in the context of genetic and environmental factors. Changes in laboratory test results that occur over time are often an objective measure of nutrition or pharmacologic interventions and modified lifestyle choices.

Specimen Types

Ideally, the specimen to be tested reflects the total body content of the nutrient to be assessed. However, the best specimen may not be readily available. The most common specimens for analysis of nutrients and nutrient-related substances include the following:

- Whole blood: Collected with an anticoagulant if entire content of the blood is to be evaluated; none of the elements are removed; contains red blood cells (RBCs), white blood cells (WBCs), and platelets suspended in plasma
- Serum: The fluid obtained from blood after the blood has been clotted and then centrifuged to remove the clot and blood cells
- Plasma: The transparent (slightly straw-colored) liquid component of blood, composed of water, blood proteins, inorganic electrolytes, and clotting factors
- Blood cells: Separated from anticoagulated whole blood for measurement of cellular analyte content
- Erythrocytes: RBCs
- Leukocytes: WBCs and leukocyte fractions
- Blood spots: Dried whole blood from finger or heel prick that is placed on paper and can be used for selected hormone tests and other tests such as infant phenylketonuria screening
- Other tissues: Obtained from scrapings or biopsy samples
- Urine (from random samples or timed collections): Contains a concentrate of excreted metabolites

FIGURE 7-2 The size of a nutrient pool can vary continuously from frankly deficient, to adequate, to toxic.

- Feces (from random samples or timed collections): Important in nutritional analyses when nutrients are not absorbed and therefore are present in fecal material or to determine composition of gut flora or microbiota
Less commonly used specimens include the following:
- Breath tests: Noninvasive tool to evaluate nutrient metabolism and malabsorption, particularly of sugars
- Hair and nails: Easy-to-collect tissue for determining exposure to selected toxic metals
- Saliva: Noninvasive medium with a fast turnover; currently is used to evaluate functional adrenal and other hormone levels
- Sweat: Electrolyte test used to detect sweat chloride levels to determine presence of cystic fibrosis
- Hair and nails specimens have significant drawbacks, including lack of standardized procedures for processing, assay, and quality control and there is potential environmental contamination. Nutrient levels or indices may be less than the amounts that can be measured accurately. Hair can be used for deoxyribonucleic acid (DNA) testing and may be useful in the future as a noninvasive methodology to predict genetic predisposition to disease and effectiveness of medical nutrition therapy (see Chapter 5). Considerable research is being done to improve the

usefulness of noninvasive and easy-to-collect specimens that are not routinely ordered.

NUTRITION INTERPRETATION OF ROUTINE MEDICAL LABORATORY TESTS

Clinical Chemistry Panels

Historically the majority of laboratory tests were ordered as panels or groupings; however, the current practice is that the professional ordering the test must justify the medical need for each test ordered. The bundling or grouping of laboratory tests is changing as health care reforms reshape medical practices to be more cost effective. The most commonly ordered groups of tests are the **basic metabolic panel (BMP)** and the **comprehensive metabolic panel (CMP)** that include groups of laboratory tests defined by the Centers for Medicare and Medicaid Services for reimbursement purposes. The BMP and CMP require the patient to fast for 10 to 12 hours before testing. The BMP includes eight tests used for screening blood glucose level, electrolyte and fluid balance, and kidney function. The CMP includes all the tests in the BMP and six additional tests to evaluate liver function. [Table 7-1](#) explains these tests (see Appendix 22).

TABLE 7-1 Constituents of the Basic Metabolic Panel and Comprehensive Metabolic Panel

Analytes	Reference Range*	Purpose	Significance
Basic Metabolic Panel (BMP) (All Tests Reflect Fasting State)			
Glucose	70-99 mg/dl; 3.9-5.5 mmol/L (fasting)	Used to screen for diabetes and to monitor patients with diabetes. Individuals experiencing severe stress from injuries or surgery have hyperglycemia related to catecholamine release	Fasting glucose >125 mg/dl indicates DM (oral glucose tolerance tests are not needed for diagnosis); fasting glucose >100 mg/dl is indicator of insulin resistance Monitor levels along with triglycerides in those receiving total parenteral nutrition for glucose intolerance
Total calcium	8.5-10.5 mg/dl; 2.15-2.57 mmol/L Normal dependent on albumin level	Reflects the calcium levels in the body that are not stored in bones. Used to evaluate parathyroid hormone function, calcium metabolism and monitor patients with renal failure, renal transplant, and some cancers	Hypercalcemia associated with endocrine disorders, malignancy, and hypervitaminosis D Hypocalcemia associated with vitamin D deficiency and inadequate hepatic or renal activation of vitamin D, hypoparathyroidism, magnesium deficiency, renal failure, and nephrotic syndrome
Na ⁺	135-145 mEq/L [†]	Reflects the relationship between total body sodium and extracellular fluid volume as well as the balance between dietary intake and renal excretory function	When serum albumin is low, ionized calcium is measured Used in monitoring various patients, such as those receiving total parenteral nutrition or who have renal conditions, uncontrolled DM, various endocrine disorders, ascitic and edematous symptoms, or acidotic or alkalotic conditions; water dysregulation, and diuretics. Increased with dehydration and decreased with overhydration
K ⁺	3.6-5 mEq/L [†]	Levels often change with sodium levels. As sodium increases, potassium decreases and vice versa. Reflects kidney function, changes in blood pH, and adrenal gland function	Used in monitoring various patients, such as those receiving total parenteral nutrition or who have renal conditions, uncontrolled DM, various endocrine disorders, ascitic and edematous symptoms, or acidotic or alkalotic conditions; decreased K ⁺ associated with diarrhea, vomiting, or nasogastric aspiration, water dysregulation, some drugs, licorice ingestion, and diuretics; increased K ⁺ associated with renal diseases, crush injuries, infection, and hemolyzed blood specimens.
Cl ⁻	101-111 mEq/L [†]	Reflects acid-base balance, water balance, and osmolality	Used in monitoring various patients, such as those receiving total parenteral nutrition or who have renal conditions, chronic obstructive pulmonary disease, diabetes insipidus, acidotic or alkalotic conditions; increased with dehydration and decreased with overhydration
HCO ₃ ⁻ (or total CO ₂)	21-31 mEq/L [†]	Used to assess acid-base balance and electrolyte status	Used in monitoring various patients, such as those receiving total parenteral nutrition or who have renal conditions, chronic obstructive pulmonary disease, uncontrolled DM, various endocrine disorders, ascitic and edematous symptoms, or acidotic or alkalotic conditions

TABLE 7-1 Constituents of the Basic Metabolic Panel and Comprehensive Metabolic Panel—cont'd

Analytes	Reference Range*	Purpose	Significance
Basic Metabolic Panel (BMP) (All Tests Reflect Fasting State)			
BUN or urea	5-20 mg urea nitrogen/dl 1.8-7 mmol/L	Used to assess excretory function of kidney and metabolic function of liver	Increased in those with renal disease and excessive protein catabolism and overhydration; decreased in those with liver failure and negative nitrogen balance and in females who are pregnant
Creatinine	0.6-1.2 mg/dl; 53-106 μ mol/L (males) 0.5-1.1 mg/dl; 44-97 μ mol/L (females)	Used to assess excretory function of kidney	Increased in those with renal disease and after trauma or surgery; and decreased in those with malnutrition (i.e., BUN/creatinine ratio >15:1)
Comprehensive Metabolic Panel (CMP) (All Tests Reflect Fasting State and Includes All of the Tests in the BMP and Six Additional Tests)			
Albumin	3.5-5 mg/dl; 30-50 g/L	Reflects severity of illness, inflammatory stress and serves as marker for mortality	Decreased in those with liver disease or acute inflammatory disease and overhydration. Increases with dehydration. It is not a biomarker of protein status
Total protein	6.4-8.3 g/dl; 64-83 g/L	Reflects albumin and globulin in blood	Not a useful measure of nutrition or protein status
ALP	30-120 units/L; 0.5-2 μ Kat/L	Reflects function of liver; may be used to screen for bone abnormalities	Increased in those with any of a variety of malignant, muscle, bone, intestinal, and liver diseases or injuries
ALT	4-36 units/L at 37° C; 4-36 units/L	Reflects function of liver	Used in monitoring liver function in those receiving parenteral nutrition
AST	0-35 IU/L; 0-0.58 μ Kat/L	Reflects function of liver; may be used to screen for cardiac abnormalities	Used in monitoring liver function in those receiving parenteral nutrition
Bilirubin	Total bilirubin 0.3-1 mg/dl; 5.1-17 μ mol/L Indirect bilirubin 0.2-0.8 mg/dl; 3.4-12 μ mol/L Direct bilirubin 0.1-0.3 mg/dl; 1.7-5.1 μ mol/L	Reflects function of liver; also used to evaluate blood disorders, and biliary tract blockage	Increased in association with drugs, gallstones, and other biliary duct diseases; intravascular hemolysis and hepatic immaturity; decreased with some anemias
Phosphorous (phosphate)	3-4.5 mg/dl; 0.97-1.45 mmol/L		Hyperphosphatemia associated with hypoparathyroidism and hypocalcemia; hypophosphatemia associated with hyperparathyroidism, chronic antacid ingestion, and renal failure
Total cholesterol	<200 mg/dl; 5.20 mmol/L		Decreased in those with malnutrition, malabsorption, liver diseases, and hyperthyroidism
Triglycerides	<100 mg/dl; <1.13 mmol/L (age and gender dependent)		Increased in those with glucose intolerance (e.g., in those receiving parenteral nutrition who have combined hyperlipidemia) or in those who are not fasting

*Reference ranges may vary slightly among laboratories.

[†]mEq/L = 1 mmol/L.

ALP, Alkaline phosphate; ALT, alanine aminotransferase; AST, aspartate aminotransferase; BUN, blood urea nitrogen; Cl⁻, chlorine; CO₂, carbon dioxide; DM, diabetes mellitus; HCO₃⁻, bicarbonate; K⁺, potassium; Na⁺, sodium; PEM, protein-energy malnutrition.

Complete Blood Count

The **complete blood count (CBC)** provides a count of the cells in the blood and description of the RBCs. A hemogram is a CBC with a white blood cell **differential count** (often called a *differential* or *diff*). Table 7-2 provides a list of the basic elements of the CBC and differential, with reference ranges and explanatory comments.

Stool Testing

Mucosal changes in the gastrointestinal (GI) tract are indicated by problems such as diarrhea and bloody or black stool. Tests may be done on a stool sample and can reveal excessive amounts of fat (an indication of malabsorption), the status of the GI flora, and the amounts and types of bacteria present in the gut. Fecal samples may be tested for the presence of blood, pathogens, and gut flora. The fecal occult blood test is ordered routinely for adults older than age 50 and younger adults with unexplained anemia. Stool culture testing may be ordered in patients with prolonged diarrhea, especially if foodborne illness is suspected. If pathogenic bacteria are isolated in stool culture,

appropriate pharmacologic interventions are initiated. Patients with chronic GI symptoms such as maldigestion or unexplained weight loss or gain may benefit from gut flora testing to identify pathologic flora or an imbalance of physiologic flora. In addition, stool tests may be helpful to evaluate the gut microbiota and the effectiveness of probiotic, prebiotic, and synbiotic use.

Urinalysis

The **urinalysis** test is used as a screening or diagnostic tool to detect substances or cellular material in the urine associated with different metabolic and kidney disorders. Some urinalysis data have broader medical and nutritional significance (e.g., glycosuria suggests abnormal carbohydrate metabolism and possibly diabetes). The full urinalysis includes a record of (1) the appearance of the urine, (2) the results of basic tests done with chemically impregnated reagent strips (often called dipsticks) that can be read visually or by an automated reader, and (3) the microscopic examination of urine sediment. Table 7-3 provides a list of the chemical tests performed in a urinalysis and their significance.

TABLE 7-2 Constituents of the Hemogram: Complete Blood Count and Differential

Analytes	Reference Range*	Significance
Red blood cells	4.7-6.1 × 10 ⁶ /μl (males); 4.7-6.1 10 ¹² /L 4.2-5.4 × 10 ⁶ /μl (females); 4.2-5.4 10 ¹² /L	In addition to nutritional deficits, may be decreased in those with hemorrhage, hemolysis, genetic aberrations, marrow failure, or renal disease or who are taking certain drugs; not sensitive for iron, vitamin B ₁₂ , or folate deficiencies
Hemoglobin concentration	14-18 g/dl; 8.7-11.2 mmol/L (males) 12-16 g/dl; 7.4-9.9 mmol/L (females) >11 g/dl; >6.8 mmol/L (pregnant females) 14-24 g/dl; 8.7-14.9 mmol/L (newborns)	In addition to nutritional deficits, may be decreased in those with hemorrhage, hemolysis, genetic aberrations, marrow failure, or renal disease or who are taking certain drugs
Hematocrit	42%-52% (males) 35%-47% (females) 33% (pregnant females) 44%-64% (newborns)	In addition to nutritional deficits, may be decreased in those with hemorrhage, hemolysis, genetic aberrations, marrow failure, or renal disease or who are taking certain drugs
MCV	80-99 fl 96-108 fl (newborns)	Somewhat affected by hydration status Decreased (microcytic) in presence of iron deficiency, thalassemia trait and chronic renal failure; normal or decreased in anemia of chronic disease; increased (macrocytic) in presence of vitamin B ₁₂ or folate deficiency and genetic defects in DNA synthesis; neither microcytosis nor macrocytosis sensitive to marginal nutrient deficiencies
MCH	27-31 pg/cell 23-34 pg (newborns)	Causes of abnormal values similar to those for MCV
MCHC	32-36 g/dl; 32-36% 32-33 g/dl; 32-33% (newborns)	Decreased in those with iron deficiency and thalassemia trait; not sensitive to marginal nutrient deficiencies
WBC	5-10 × 10 ⁹ /L; 5,000-10,000/mm ³ (2 yr-adult) 6-17 × 10 ⁹ /L; 6,000-17,000/mm ³ (<2 yr) 9-30 × 10 ⁹ ; 9,000-30,000/mm ³ (newborns)	Increased (leukocytosis) in those with infection, neoplasia; stress decreased (leucopenia) in those with malnutrition, autoimmune diseases, or overwhelming infections or who are receiving chemotherapy or radiation therapy
Differential	55%-70% neutrophils 20-40% lymphocytes 2-8% monocytes 1%-4% eosinophils 0.5%-1% basophils	<i>Neutrophilia</i> : Ketoacidosis, trauma, stress, pus-forming infections, leukemia <i>Neutropenia</i> : malnutrition, aplastic anemia, chemotherapy, overwhelming infection <i>Lymphocytosis</i> : Infection, leukemia, myeloma, mononucleosis <i>Lymphocytopenia</i> : Leukemia, chemotherapy, sepsis, AIDS <i>Eosinophilia</i> : Parasitic infestation, allergy, eczema, leukemia, autoimmune disease <i>Eosinopenia</i> : Increased steroid production <i>Basophilia</i> : Leukemia <i>Basopenia</i> : Allergy

AIDS, Acquired immune deficiency syndrome; DNA, deoxyribonucleic acid; MCH, mean corpuscular hemoglobin; MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume.

*Reference ranges may vary slightly among laboratories.

TABLE 7-3 Chemical Tests in a Urinalysis

Analyte	Expected Value	Significance
Specific gravity	1.010-1.025	Can be used to test and monitor the concentrating and diluting abilities of the kidney and hydration status; low in those with diabetes insipidus, glomerulonephritis, or pyelonephritis; high in those with vomiting, diarrhea, sweating, fever, adrenal insufficiency, hepatic diseases, or heart failure
pH	4.6-8 (normal diet)	Acidic in those with a high-protein diet or acidosis (e.g., uncontrolled DM or starvation), during administration of some drugs, and in association with uric acid, cystine, and calcium oxalate kidney stones; alkaline in individuals consuming diets rich in vegetables or dairy products and in those with a urinary tract infection, immediately after meals, with some drugs, and in those with phosphate and calcium carbonate kidney stones
Protein	2-8 mg/dl	Marked proteinuria in those with nephrotic syndrome, severe glomerulonephritis, or congestive heart failure; moderate in those with most renal diseases, preeclampsia, or urinary tract inflammation; minimal in those with certain renal diseases or lower urinary tract disorders
Glucose	Not detected (2-10 g/dl in DM)	Positive in those with DM; rarely in benign conditions
Ketones	Negative	Positive in those with uncontrolled DM (usually type 1); also positive in those with a fever, anorexia, certain GI disturbances, persistent vomiting, or cachexia or who are fasting or starving
Blood	Negative	Indicates urinary tract infection, neoplasm, or trauma; also positive in those with traumatic muscle injuries or hemolytic anemia
Bilirubin	Not detected	Index of unconjugated bilirubin; increase in those with certain liver diseases (e.g., gallstones)
Urobilinogen	0.1-1 units/dl	Index of conjugated bilirubin; increased in those with hemolytic conditions; used to distinguish among hepatic diseases
Nitrite	Negative	Index of bacteriuria
Leukocyte esterase	Negative	Indirect test of bacteriuria; detects leukocytes

DM, Diabetes mellitus; GI, gastrointestinal.

ASSESSMENT OF HYDRATION STATUS

Assessment of hydration status is vital because water dysregulation can be associated with other imbalances such as electrolyte imbalance. Types of water dysregulation include volume depletion or extracellular fluid contraction, dehydration or sodium intoxication, and overhydration or excessive fluid shift into interstitial-lymph fluid compartment. **Dehydration** often is due to excessive loss of water and electrolytes from vomiting, diarrhea, excessive laxative abuse, diuretics, fistulas, GI suction, polyuria, fever, excessive sweating, decreased intake caused by anorexia, nausea, depression, or limited access to fluids. Characteristics include rapid weight loss, decreased skin turgor, dry mucous membranes, dry and furrowed tongue, postural hypotension, a weak and rapid pulse, slow capillary refill, a decrease in body temperature (95° to 98° F), decreased urine output, cold extremities, or disorientation. See Figure 6-2 in Chapter 6.

Volume depletion is a state of vascular instability resulting from blood loss, GI bleeding, burns, vomiting, and diarrhea. Volume depletion may occur with hyponatremia, hypernatremia, or normal serum sodium levels.

Edema (overhydration), occurs when there is an increase in the extracellular fluid volume. The fluid shifts from the extracellular compartment to the interstitial fluid compartment (see Chapter 6). Overhydration is caused by an increase in capillary hydrostatic pressure or capillary permeability, or a decrease in colloid osmotic pressure. It often is associated with renal failure, congestive heart failure, cirrhosis of the liver, Cushing syndrome, excess use of sodium-containing intravenous fluids, and excessive intake of sodium-containing food or medications. Characteristics include rapid weight gain, peripheral edema, distended neck veins, slow emptying of peripheral veins, a bounding and full pulse, rales in the lungs, polyuria, ascites, and pleural effusion. Pulmonary edema may occur in severe cases.

Laboratory measures of hydration status include serum sodium, blood urea nitrogen (elevated out of proportion to serum creatinine), serum osmolality, and urine specific gravity. Although the laboratory tests are important, decisions regarding hydration should only be made only in conjunction with other information from physical examination, nutrition-focused physical assessment, and the clinical condition of the patient. In addition, many other labs may be affected by overhydration or dehydration, and accurate interpretation of laboratory results is critical in assessing patients (see Table 7-1).

Inflammation and Biochemical Assessment

Inflammation is a protective response by the immune system to infection, acute illness, trauma, toxins, many chronic diseases, and physical stress. Biochemical indices are affected by inflammation primarily by redirection to synthesis of acute phase reactants. Inflammatory conditions trigger the immune response to release eicosanoids and cytokines, which mobilize nutrients required to synthesize **positive acute-phase reactants** (which increase in response to inflammation) and leukocytes. Cytokines (interleukin-1beta [IL-1 β], tumor necrosis factor-alpha [TNF- α], interleukin-6 [IL-6]) and eicosanoids (prostaglandin E2 [PGE2]) influence whole-body metabolism, body composition, and nutritional status. Cytokines reorient hepatic synthesis of plasma proteins and increase the breakdown of muscle protein to meet the demand for protein and energy during the inflammatory response. Moreover, there is a redistribution of albumin to the interstitial compartment, resulting in

edema. Declining values of the **negative acute-phase** reactants (i.e., serum albumin, prealbumin, and transferrin) also reflect the inflammatory processes and severity of tissue injury. In the acute inflammatory state, negative acute phase reactant values do not reflect current dietary intake or protein status (Friedman and Fadem, 2010).

Cytokines impair the production of erythrocytes and reorient iron stores from hemoglobin and serum iron to ferritin. During infection IL-1 β inhibits the production and release of transferrin while stimulating the synthesis of ferritin. Therefore laboratory test results used to predict the risk of nutritional anemias (see Chapter 32) are not useful in assessing the patient with an inflammatory response. Refer to Chapter 3 for more information on the effects of cytokines on organ systems.

As the body responds to acute inflammation, TNF- α , IL-1 β , IL-6, and PGE2 increase to a set threshold, then IL-6 and PGE2 inhibit TNF- α synthesis and IL-1 β secretion, creating a negative feedback cycle. Hepatic synthesis of positive acute-phase reactants diminishes, and synthesis of negative acute-phase reactants increases. Albumin shifts from the interstitial compartment to the extravascular space. Iron stores shift from ferritin to transferrin and hemoglobin.

Markers of Inflammation

Biochemical markers of inflammation include positive acute phase reactants and negative acute phase reactants. In the presence of inflammation, the hepatic synthesis of positive acute phase reactants is *increased* while the synthesis of the negative acute phase reactants is *depressed*. See Table 7-4 for acute phase reactants.

Positive Acute Phase Reactants

C-Reactive Protein

C-reactive protein (CRP) is a nonspecific marker of inflammation that may help to estimate and monitor the severity of illness. **High-sensitivity CRP (hs-CRP)** is a more sensitive measure of chronic inflammation seen in patients with atherosclerosis and other chronic diseases (Bajpai et al, 2010). Although the exact function of CRP is unclear, it increases in the initial stages of acute stress—usually within 4 to 6 hours of surgery or other trauma. Furthermore, its level can increase as much as 1000-fold, depending on the intensity of the stress response. When the CRP level begins to decrease, the patient has entered the anabolic period of the inflammatory response and the beginning of recovery when more intensive nutrition

TABLE 7-4 Acute Phase Reactants

Positive Acute-Phase Reactants	Negative Acute-Phase Proteins
C-reactive protein	Albumin
α -1 antichymotrypsin	Transferrin
α -antitrypsin	Prealbumin (transthyretin)
Haptoglobins	Retinol-binding protein
Ceruloplasmin	
Serum amyloid A	
Fibrinogen	
Ferritin	
Complement and components C3 and C4	
Orosomuroid	

therapy may be beneficial. Ongoing assessment and follow-up are required to address changes in nutrition status.

Ferritin

Ferritin is a positive acute-phase protein, meaning that synthesis of ferritin increases in the presence of inflammation. Ferritin is not a reliable indicator of iron stores in patients with acute inflammation, uremia, metastatic cancer, or alcoholic-related liver diseases. Cytokines and other inflammatory mediators can increase ferritin synthesis, ferritin leakage from cells, or both. Elevations in ferritin occur 1 to 2 days after the onset of the acute illness and peak at 3 to 5 days. If iron deficiency also exists, it may not be diagnosed because the level of ferritin would be falsely elevated.

Negative Acute Phase Reactants

Albumin

Albumin is responsible for the transport of major blood constituents, hormones, enzymes, medications, minerals, ions, fatty acids, amino acids, and metabolites. Its major purpose is to maintain colloidal osmotic pressure, providing approximately 80% of colloidal osmotic pressure of the plasma. When serum albumin levels decrease, the water in the plasma moves into the interstitial compartment and edema results. This loss of plasma fluid results in hypovolemia, which triggers renal retention of water and sodium.

Albumin has a half-life of 18 to 21 days. Levels of albumin remain nearly normal during uncomplicated starvation as redistribution from the interstitium to the plasma occurs. Levels of albumin fall precipitously in inflammatory stress and often do not improve with aggressive nutrition support. Serum levels reflect the severity of illness but do not reflect current protein status or the effects of nutrient-dense supplemental nutrition. For these reasons, a well-nourished but stressed patient may have low levels of albumin and the hepatic transport proteins, whereas a patient who has had significant weight loss and undernutrition may have normal or close to normal levels. Albumin is very sensitive to hydration status, and the practitioner must be aware and document the true cause of an elevated or depressed albumin level.

Albumin is synthesized in the liver and is a measure of liver function. When disease affects the liver, the synthesis of albumin, by the hepatocytes, is impaired. Because of the half-life of albumin, significant changes in liver function are not immediately apparent.

Prealbumin (Transthyretin)

Prealbumin (PAB), officially **transthyretin (TTHY)**, is a hepatic protein transported in the serum as a complex of retinol-binding protein and vitamin A. It transports the thyroid hormones triiodothyronine and thyroxine (T_4), along with T_4 -binding globulin. It has a short half-life ($t_{1/2}$ = 2 days), and currently it is considered a marker of inflammation. Levels of PAB plummet in inflammatory stress and often do not improve with aggressive nutrition support. Moreover, serum levels decrease with malignancy and protein-wasting diseases of the intestines or kidneys. Serum levels do not reflect protein status or the effects of refeeding in the individual with depleted protein reserves. Serum levels also decrease in the presence of a zinc deficiency because zinc is required for hepatic synthesis and secretion of PAB. Consider zinc status from dietary intake and medical history,

in addition to inflammation, when interpreting low plasma PAB levels.

PAB levels are often normal in starvation-related malnutrition but decreased in well-nourished individuals who have undergone recent stress or trauma. During pregnancy, the changed estrogen levels stimulate PAB synthesis and serum levels may increase. In nephrotic syndrome, PAB levels also may be increased. Proteinuria and hypoproteinemia are common in nephrotic syndrome, and because PAB is synthesized rapidly, a disproportionate percentage of PAB can exist in the blood, whereas other proteins take longer to produce (Litchford, 2015).

Retinol-Binding Protein

The hepatic protein with the shortest half-life ($t_{1/2}$ = 12 hr) is **retinol-binding protein (RBP)**, a small plasma protein that does not pass through the renal glomerulus because it circulates in a complex with PAB. As implied by its name, RBP binds **retinol**, and transport of this vitamin A metabolite seems to be its exclusive function. RBP is synthesized in the liver and released with retinol. After RBP releases retinol in peripheral tissue, its affinity for PAB decreases, leading to dissociation of the PAB-RBP complex and filtration of apoprotein (apo)-RBP by the glomerulus.

The plasma RBP concentration has been shown to decrease in starvation-related malnutrition. However, RBP levels also fall in the presence of inflammatory stress and may not improve with refeeding. RBP may not reflect protein status in acutely stressed patients. It may even be elevated with renal failure because the RBP is not being catabolized by the renal tubule.

RBP4 is an adipocyte-derived peptide of RBP that influences glucose homeostasis and may play a role in lipoprotein metabolism. Human clinical trials have demonstrated increased RBP4 levels in obesity, insulin resistance, gestational diabetes, proliferative diabetic retinopathy, and nondiabetic stage 5 chronic kidney disease, suggesting a possible relationship between these conditions. Larger clinical trials are needed to define this relationship (Klein et al, 2010; Li et al, 2010).

Transferrin

Transferrin is a globulin protein that transports iron to the bone marrow for production of hemoglobin (Hgb). The plasma transferrin level is controlled by the size of the iron storage pool. When iron stores are depleted, transferrin synthesis increases. It has a shorter half-life ($t_{1/2}$ = 8 days) than albumin. Levels diminish with acute inflammatory reactions, malignancies, collagen vascular diseases, and liver diseases. Transferrin levels reflect inflammation and are not useful as a measure of protein status.

Immunocompetence

Inflammation-related malnutrition is associated with impaired immunocompetence, including depressed cell-mediated immunity, phagocyte dysfunction, decreased levels of complement components, reduced mucosal secretory antibody responses, and lower antibody affinity. Assessing immunocompetence is also useful in the patient who is being treated for allergies (see Chapter 26).

There is no single marker for immunocompetence except for the clinical outcome of infection or allergic response. Laboratory markers with a high degree of sensitivity include vaccine-specific serum antibody production, delayed-type

hypersensitivity response, vaccine-specific or total secretory immunoglobulin A in saliva, and the response to attenuated pathogens. Less sensitive markers include natural killer cell cytotoxicity, oxidative burst of phagocytes, lymphocyte proliferation, and the cytokine pattern produced by activated immune cells. Using a combination of markers is currently the best approach to measuring immunocompetence.

ASSESSMENT FOR NUTRITIONAL ANEMIAS

Anemia is a condition characterized by a reduction in the number of erythrocytes per unit of blood volume or a decrease in the Hgb of the blood to below the level of usual physiologic need. By convention, anemia is defined as Hgb concentration below the 95th percentile for healthy reference populations of men, women, or age-grouped children. Anemia is not a disease but a symptom of various conditions, including extensive blood loss, excessive blood cell destruction, or decreased blood cell formation. It is observed in many hospitalized patients and is often a symptom of a disease process; its cause should be investigated. Clinical nutritionists must distinguish between anemia caused by nutritional inadequacies and that caused by other factors (i.e., dehydration masking falsely low blood values). See Chapter 32 for discussion of the management of anemias.

Classification of Anemia

Nutritional deficits are a major cause of decreased Hgb and erythrocyte production. The initial descriptive classification of anemia is derived from the hematocrit (Hct) value or CBC as explained in Table 7-2. Anemias associated with a mean RBC volume of less than 80 fl (femtoliters) are microcytic; those with values of 80 to 99 fl are normocytic; those associated with values of 100 fl or more are macrocytic. (See Chapter 32.) Data from the CBC are helpful in identifying nutritional causes of anemia. **Microcytic anemia** is associated most often with iron deficiency, whereas **macrocytic anemia** generally is caused by either folate- or vitamin B₁₂-deficient erythropoiesis. However, because of the low specificity of these indexes, additional data are needed to distinguish between the various nutritional causes and nonnutritional causes, such as thalassemia trait and chronic renal insufficiency. Normocytic anemia is associated with the **anemia of chronic and inflammatory disease (ACD)**. This type of anemia is associated with autoimmune diseases, rheumatic diseases, chronic heart failure, chronic infection, Hodgkin disease and other types of cancer, inflammatory bowel disease and other chronic inflammatory conditions, severe tissue injury, and multiple fractures. ACD does not respond to iron supplementation.

Other information from the CBC that helps to differentiate the nonnutritional causes of anemia includes leukocyte, reticulocyte, and platelet counts. When these levels are low, marrow failure is indicated and elevated counts are associated with anemia caused by leukemia or infection. Erythrocyte sedimentation rate testing is ordered when symptoms are nonspecific and if inflammatory autoimmune diseases are suspected. Reticulocytes are large, nucleated, immature RBCs that are released in small numbers with mature cells. When RBC production rates increase, reticulocyte counts also increase. Any time anemia is accompanied by a high reticulocyte count, elevated erythropoietic activity in response to bleeding should be considered. In such cases, stool specimens can be tested for occult blood to

rule out chronic GI blood loss. Other causes of a high reticulocyte count include intravascular hemolysis syndromes and an erythropoietic response to therapy for iron, vitamin B₁₂, or folic acid deficiencies.

Normocytic or microcytic anemia may be caused by chronic or acute blood loss, such as from recent surgery, injury, or from the GI tract as indicated by a positive occult stool test. Note that in those with hemolytic anemias and early iron deficiency anemia, the RBC size may still be normal. Macrocytic anemias include folate deficiency and vitamin B₁₂ deficiency. The presence of macrocytic RBCs requires evaluation of folate and vitamin B₁₂ status. DNA synthesis is affected negatively by deficiencies of folic acid and vitamin B₁₂, resulting in impaired RBC synthesis and maturation of RBCs. These changes cause large, nucleated cells to be released into the circulation. Although vitamin B₁₂-related anemia is categorized as a macrocytic normochromic anemia, approximately 40% of the cases are normocytic.

Markers of Iron Deficiency Anemias

Hematocrit or Packed Cell Volume and Hemoglobin

Hct and Hgb are part of a routine CBC and are used together to evaluate iron status. Hct is the measure of the percentage of RBCs in total blood volume. Usually the Hct percentage is three times the Hgb concentration in grams per deciliter. The Hct value is affected by an extremely high WBC count and hydration status. Individuals living in high altitudes often have increased values. It is common for individuals older than age 50 to have slightly lower levels than younger adults.

The Hgb concentration is a measure of the total amount of Hgb in the peripheral blood. It is a more direct measure of iron deficiency than Hct because it quantifies total Hgb in RBCs rather than a percentage of total blood volume. Hgb and Hct are below normal in the four types of nutritional anemias and always should be evaluated in light of other laboratory values and recent medical history (see Chapter 32).

Serum Ferritin

Ferritin is the storage protein that sequesters the iron normally gathered in the liver (reticuloendothelial system), spleen, and marrow. As the iron supply increases, the intracellular level of ferritin increases to accommodate iron storage. A small amount of this ferritin leaks into the circulation. This ferritin can be measured by assays that are available in most clinical laboratories. In individuals with normal iron storage, 1 ng/ml of serum ferritin equals approximately 8 mg of stored iron. In healthy adults, the measurement of ferritin that has leaked into the serum is an excellent indicator of the size of the body's iron storage pool.

ACD is the primary condition in which ferritin fails to correlate with iron stores. ACD, a common form of anemia in hospitalized patients, occurs in those with cancer or inflammatory or infectious disorders. It occurs during inflammation because red cell production decreases as the result of inadequate mobilization of iron from its storage sites. In those with arthritis, depletion of stored iron develops partly because of reduced absorption of iron from the gut. Also the regular use of nonsteroidal antiinflammatory drugs can cause occult GI blood loss. ACD has many forms and must be distinguished from iron deficiency anemia so that inappropriate iron supplementation is not initiated.

Serum Iron

Serum iron measures the amount of circulating iron that is bound to transferrin. However, it is a relatively poor index of iron status because of large day-to-day changes, even in healthy individuals. Diurnal variations also occur, with the highest concentrations occurring midmorning (from 6 AM to 10 AM), and a nadir, averaging 30% less than the morning level, occurring mid afternoon. Serum iron should be evaluated in light of other laboratory values and recent medical history to assess iron status.

Total Iron-Binding Capacity and Transferrin Saturation

Total iron-binding capacity (TIBC) is a direct measure of all proteins available to bind mobile iron and depends on the number of free binding sites on the plasma iron-transport protein transferrin. Intracellular iron availability regulates the synthesis and secretion of transferrin (i.e., transferrin concentration increases in those with iron deficiency).

Transferrin saturation reflects iron availability to tissues (bone marrow erythropoiesis). It is determined by the following equation:

$$\% \text{ Transferrin saturation} = (\text{Serum Fe} / \text{TIBC}) \times 100$$

In addition, when the amount of stored iron available for release to transferrin decreases and dietary iron intake is low, saturation of transferrin decreases.

There are exceptions to the general rule that transferrin saturation decreases and TIBC increases in patients with iron deficiency. For example, TIBC increases in those with hepatitis. It also increases in people with hypoxia, women who are pregnant, or those taking oral contraceptives or receiving estrogen replacement therapy. On the other hand, TIBC decreases in those with malignant disease, nephritis, and hemolytic anemias. Furthermore, the plasma level of transferrin may be decreased in those with protein energy malnutrition (PEM), fluid overload, and liver disease. Thus, although TIBC and transferrin saturation are more specific than Hct or Hgb values, they are not perfect indicators of iron status.

An additional concern about the use of serum iron, TIBC, and transferrin saturation values is that normal values persist until frank deficiency actually develops. Thus these tests cannot detect decreasing iron stores and iron insufficiencies.

Tests for Macrocytic Anemias from B Vitamin Deficiencies

Macrocytic anemias include folate deficiency and vitamin B₁₂ deficiency. The nutritional causes of macrocytic anemia are related to the availability of folate and vitamin B₁₂ in the bone marrow and require evaluation of both nutrient levels. Both nutrients decrease DNA synthesis by preventing the formation of thymidine monophosphate. Folate and vitamin B₁₂ are used at different steps of the synthetic pathway. Impaired RBC synthesis occurs and large, nucleated RBCs then are released into the circulation (see Chapter 32).

Assessing Folate and Vitamin B₁₂ Status

Evaluation for macrocytic anemia includes static measurement of folate and vitamin B₁₂ deficiency in blood. They can be assayed using tests of the ability of the patient's blood specimen to support the growth of microbes that require either folate or vitamin B₁₂, or radiobinding assays, or immunoassays.

Serum Homocysteine. Folate and vitamin B₁₂ are required for the synthesis of S-adenosylmethionine (SAM), the biochemical precursor involved in the transfer of one-carbon (methyl) groups during many biochemical syntheses. SAM is synthesized from the amino acid methionine by a reaction that includes the addition of a methyl group and the purine base adenine (from adenosine triphosphate, or ATP). For example, when SAM donates a methyl group for the synthesis of thymidine, choline, creatine, epinephrine, and protein and DNA methylation, it is converted to S-adenosylhomocysteine. After losing the adenosyl group, the remaining homocysteine can be converted either to cysteine by the vitamin B₆-dependent transsulfuration pathway or back to methionine in a reaction that depends on adequate folate and vitamin B₁₂.

When either folate or vitamin B₁₂ is lacking, the homocysteine-to-methionine reaction is blocked, causing homocysteine to build up in the affected tissue and spill into the circulation. The vitamin B₆-dependent transsulfuration pathway can metabolize excess homocysteine. Homocysteine has been shown to be sensitive to folate and vitamin B₁₂ deficiency.

Therefore an elevated homocysteine level indicates either genetic defects involved in the enzymes that catalyze these reactions, or a deficiency in folate, vitamin B₁₂, or vitamin B₆. Research indicates that several folate gene polymorphisms affecting the methylation of folate and B₁₂ contribute risk for several chronic cardiovascular and neurologic disorders (Fan et al, 2010; see Chapters 5 and 41).

Folate Assessment. Folate most often is measured simultaneously in whole blood with its combined amount from plasma and blood cells, and in the serum alone. The difference between whole-blood folate and serum folate levels then is used to calculate total RBC folate concentration. RBC folate concentration is a better indicator of folate status than serum folate, because folate is much more concentrated in RBCs than in the serum. RBC folate measurement more closely reflects tissue stores and is considered the most reliable indicator of folate status. Folate is absorbed in the jejunum, and its malabsorption has several causes, but a specific test for folate absorption is not available. The presence and extent of deficiency should be assessed in patients with celiac disease, those who have had bariatric surgery, those with a history of long-term use of medications such as anticonvulsants and sulfasalazine, those with chronic alcohol consumption, those with methyltetrahydrofolate reductase (MTHFR) genetic polymorphisms, and those with rheumatoid arthritis taking methotrexate (see Chapters 5 and 8).

Vitamin B₁₂ Assessment. Vitamin B₁₂ is measured in the serum, and all indications are that the serum level gives as much information about vitamin B₁₂ status as does the RBC level. If vitamin B₁₂ status is compromised, intrinsic factor antibodies (IFAB) and parietal cell antibodies are measured; the presence of antibodies suggests the main cause of macrocytic anemia. Historically the Schilling test was used to detect defects in vitamin B₁₂ absorption; it rarely is used today because the test requires that the patient be given radioactive vitamin B₁₂ (see Chapter 32). **Methylmalonic acid (MMA)** levels in serum or urine are more useful to assess B₁₂ status.

Vitamin B₁₂ and Methylmalonic Acid. Once a genetic or autoimmune cause is ruled out, the most straightforward biochemical method for differentiating between folate and vitamin B₁₂ deficiencies is by measuring the serum or urinary MMA level. MMA is formed during the degradation of the amino acid valine and odd-chain fatty acids. MMA is the side product in

this metabolic pathway that increases when the conversion of methylmalonic coenzyme A (CoA) to succinyl CoA is blocked by lack of vitamin B₁₂, a coenzyme for this reaction. Therefore deficiency leads to an increase in the MMA pool, which is reflected by the serum or urinary MMA level. The urinary MMA test is more sensitive than the serum B₁₂ test because it indicates true tissue B₁₂ deficiency. The serum MMA test may give falsely high values in renal insufficiency and intravascular volume depletion. The urinary MMA test is the only B₁₂ deficiency assay that has been validated as a screening tool. Homocysteine and MMA tend to detect impending vitamin deficiencies better than the static assays. This is especially important when assessing the status of certain patients such as vegans or older adults, who could have vitamin B₁₂ deficiency associated with central nervous system impairment.

FAT-SOLUBLE VITAMINS

Fat malabsorption often results in impaired absorption of vitamins A, E, D, and K. Factors including low luminal pH, bile salts below the critical micellar concentration, and inadequate triglyceride hydrolysis can interfere with normal bile salt micelle formation, causing impaired absorption of fat-soluble vitamins. Individuals with fat malabsorptive disorders, including those who have had bariatric surgery, are at greatest risk of deficiencies of fat-soluble vitamins. See Appendix 22 for further discussion of tests for assessing specific vitamin adequacy.

Vitamin A

Vitamin A status can be estimated using serum retinol, and the normal level in adults is 30 to 80 mcg/dl. A primary deficiency of vitamin A can result from inadequate intake, fat malabsorption, or liver disorders. A secondary deficiency of vitamin A may be due to decreased bioavailability of provitamin A carotenoids or interference with vitamin A absorption, storage, or transport (e.g., celiac disease, cystic fibrosis, pancreatic insufficiency, malabsorptive weight loss surgery, or bile duct obstruction). Vitamin A deficiency is common in prolonged malnutrition and reported a year or longer after gastric bypass surgery and biliopancreatic weight loss surgery (Ledoux et al, 2006; Maden et al, 2006; Zalesin et al, 2011). The oxidative stress associated with major surgeries, including gastric bypass surgery, also may interfere with vitamin A absorption and use. Because of shared absorptive mechanisms with vitamin D, serum retinol always should be assessed in the presence of vitamin D supplementation.

Acute or chronic vitamin A toxicity is defined as retinol levels greater than 100 mcg/dl. Hypervitaminosis A has been reported in almost 50% of patients taking 150% of the RDA for vitamin A, in the form of retinol, between 6 to 12 months after laparoscopic sleeve gastrectomy (Aarts, 2011). Chronic vitamin A toxicities are associated with loss of hair; dry mucous membranes; dry, rough skin; and even cortical bone loss and fractures. See Appendix 22.

Vitamin D

Individual vitamin D status can be estimated by measuring plasma 25-hydroxy vitamin D (25-[OH]D₃) levels. Current clinical practice reference ranges have been updated by the IOM (IOM, 2011). Traditional levels defining vitamin D sufficiency have been based on the lowest threshold value for plasma 25-(OH)D₃ (approximately 80 nmol/L or 32 ng/ml) that

prevents secondary hyperparathyroidism, increased bone turnover, bone mineral loss, or seasonal variations in plasma parathyroid hormone. The IOM review concluded that individuals are at risk of deficiency at serum 25(OH)D₃ levels below 30 nmol or 12 ng/ml and that practically all persons have sufficient serum levels at 50 nmol or 20 ng/ml. The American Geriatric Society (AGS) published a new consensus statement on vitamin D and calcium supplementation for reduction of falls and fractures in adults 65 years and older and for high-risk populations with malabsorption syndromes, those using medications that accelerate vitamin D metabolism, the obese, and those with minimal sun exposure (AGS, 2014).

Vitamin D sufficiency is defined as 25(OH)D₃ at 75 nmol/L, or 30 ng/mL (AGS, 2014). Serum levels even higher at 90 to 100 nmol/L (36 to 40 ng/ml) are recommended by some (Bischoff-Ferrari, 2014). Optimal levels of 25(OH)D₃ have not been defined, and the measurement of serum levels lacks standardization and calibration.

A vitamin D deficiency may be due to inadequate dietary intake, inadequate exposure to sunlight, or malabsorption. Deficiency of vitamin D also can lead to secondary malabsorption of calcium. Calcium malabsorption occurs in chronic renal failure because renal hydroxylation is required to activate vitamin D, which promotes synthesis of a calcium-binding protein in intestinal absorptive cells (see Chapter 35). Vitamin D toxicity is rare, but it has been reported in a few patients taking megadoses of vitamin D. Reported adverse effects include hypercalcemia, hyperphosphatemia, suppressed parathyroid-hormone levels, and hypercalciuria (Klontz and Acheson, 2007).

Vitamin E

Vitamin E status can be estimated by measuring serum alpha-tocopherol or the ratio of serum alpha-tocopherol to total serum lipids. A low ratio suggests vitamin E deficiency. Deficiencies are uncommon in the developed world except in individuals with fat malabsorption syndromes. The main symptoms of a vitamin E deficiency include mild hemolytic anemia and nonspecific neurologic effects. In adults, alpha-tocopherol levels is less than 5 µg/ml (<11.6 µmol/L) are associated with a deficiency. In adults with hyperlipidemia, a low ratio of serum alpha-tocopherol to lipids (<0.8 mg/g total lipid) is the most accurate indicator.

Vitamin E toxicity is uncommon, but intakes of vitamin E greater than 1000 mg/d may result in a significant bleeding risk, especially if the individual is taking anticoagulation medications. Although adverse effects are rarely observed even in individuals taking very high dosages of vitamin E, a meta-analysis showed a possible increase in mortality at dosages of 400 IU/d and higher (alpha-tocopherol only) (Miller et al, 2005).

Vitamin K

Vitamin K status can be estimated using prothrombin time (PT). PT is used to evaluate the common pathway of blood clotting. The synthesis of clotting factors II, VII, IX, and X are vitamin K dependent. Osteocalcin or bone G1a protein (BGP), a bone turnover marker, may also be used to assess vitamin K status. The production of BGP is stimulated by 1,25 dihydroxy vitamin D (1,25[OH]2D₃) and depends on vitamin K. Vitamin K increases the carboxylation of osteocalcin or BGP, but it does not increase its overall rate of synthesis. A reduced vitamin K status is associated with reduced BGP or serum osteocalcin levels. This relationship may explain the pathophysiologic

findings of vitamin K–deficiency osteoporosis. The function of osteocalcin is unclear; however, it may exist as a deposition site for hydroxyapatite crystals or it also may affect energy metabolism via the production and action of insulin (Hammami, 2014).

WATER-SOLUBLE VITAMINS AND TRACE MINERALS

Ascorbic Acid

Ascorbic acid or vitamin C is a water-soluble vitamin and also an antioxidant. Vitamin C status can be determined by measuring blood ascorbic acid levels. Values less than 6 mg/dl (<34 micromol/L) suggest insufficiency and values less than 2 mg/dl (<11 micromol/L) suggest a deficiency. Deficiencies are rare in developed countries unless self-imposed dietary intake is highly restrictive. Symptoms of a deficiency include bleeding gums, loose teeth, poor wound healing, and perifollicular hemorrhages. Toxicities have been reported in individuals taking more than 2 g/d for an extended period of time.

Vitamin B₁₂ and folate are the most common water-soluble vitamin deficiencies reported in adults. Frank deficiencies of other water-soluble vitamins and trace minerals are uncommon in populations that consume a variety of whole foods and fortified foods. Thiamin deficiency has been reported in individuals who chronically consume high levels of alcohol with inadequate thiamin intake, in those with persistent vomiting, when someone is on high doses of diuretics and has poor intake, in those with impaired absorption because of disease or surgery as well as individuals on long-term PN without adequate vitamin added. To assess thiamin status, thiamin diphosphate in whole blood is measured because plasma and serum levels reflect recent dietary changes and may be misleading. Subclinical deficiencies of water-soluble vitamins and other trace minerals may be present in some individuals. However, the current methodologies for evaluating nutritional status of these components are expensive and controversial. See Appendix 22 for further discussion of tests for assessing specific vitamin and trace mineral adequacy.

Markers of Body Composition

Creatinine

Creatinine is formed from creatine, found almost exclusively in muscle tissue. Serum creatinine is used along with BUN to assess kidney function (see Chapter 35). Urinary creatinine has been used to assess somatic (muscle) protein status. Creatine is synthesized from the amino acids glycine and arginine with addition of a methyl group from the folate- and cobalamin-dependent methionine–SAM–homocysteine cycle. Creatine phosphate is a high-energy phosphate buffer that provides a constant supply of ATP for muscle contraction. When creatine is dephosphorylated, some of it is converted spontaneously to creatinine by an irreversible, nonenzymatic reaction. Creatinine has no specific biologic function; it is released continuously from the muscle cells and excreted by the kidneys with little reabsorption.

The use of urinary creatinine to assess somatic protein status is confounded by omnivorous diets. Because creatine is stored in muscle, muscle meats are rich sources. The creatinine formed from dietary creatine cannot be distinguished from endogenously produced creatinine. When a person follows a meat-restricted diet, the size of the somatic (muscle) protein pool is directly proportional to the amount of creatinine excreted.

Therefore men generally have higher serum levels and excrete larger amounts of creatinine than women, and individuals with greater muscular development have higher serum levels and excrete larger amounts than those who are less muscular. Total body weight is not proportional to creatinine excretion, but muscle mass is. Creatinine excretion rate is related to muscle mass and is expressed as a percentage of a standard value as shown by the following equation for creatinine-height index (CHI):

$$\text{CHI} = \frac{24\text{-hr urine creatinine (mg)} \times 100}{\text{Expected 24-hr urine creatinine/cm height}}$$

Calculated CHI greater than 80% is normal, 60% to 80% suggests mild skeletal muscle depletion, 40% to 60% suggests moderate depletion, and less than 40% suggests severe depletion (Blackburn et al, 1977).

Daily creatinine excretion varies significantly within individuals, probably because of losses in sweat. In addition, the test is based on 24-hour urine collections, which are difficult to obtain. Because of these limitations, urinary creatinine concentration as a marker of muscle mass has limited use in health care settings and is used typically only in research (Table 7-5).

Nitrogen Balance

Nitrogen balance studies are used primarily in research studies to estimate the balance between exogenous nitrogen intake (orally, enterally, or parenterally) and removal of nitrogen-containing compounds (urinary, fecal, wound), and other nitrogen sources. These studies are not a measure of protein anabolism and catabolism because true protein turnover studies require consumption of labeled (stable isotope) protein to track protein use. Even if useful, nitrogen balance studies are difficult because valid 24-hour urine collections are tedious unless the patient has a catheter. In addition, changes in renal function are common in patients with inflammatory metabolism, making standard nitrogen balance calculations inaccurate without calculation of nitrogen retention (Gottschlich et al, 2001). Clinicians using nitrogen balance to estimate protein

TABLE 7-5 Expected Urinary Creatinine Excretions for Adults Based on Height

ADULT MALES*		ADULT FEMALES†	
Height (cm)	Creatinine (mg)	Height (cm)	Creatinine (mg)
157.5	1288	147.3	830
160.0	1325	149.9	851
162.6	1359	152.9	875
165.1	1386	154.9	900
167.6	1426	157.5	925
170.2	1467	160.0	949
172.7	1513	162.6	977
175.3	1555	165.1	1006
177.8	1596	167.6	1044
180.3	1642	170.2	1076
182.9	1691	172.7	1109
185.4	1739	175.3	1141

190.5	1831	180.3	1206
193.0	1891	182.9	1240

*Creatinine coefficient males 23 mg/kg "ideal" body weight.

†Creatinine coefficient females 18 mg/kg "ideal" body weight.

flux in critically ill patients must remember the limitations of these studies and that positive nitrogen balance may not mean that protein catabolism has decreased, particularly in inflammatory (disease and trauma) conditions.

CHRONIC DISEASE RISK ASSESSMENT

Lipid Indices of Cardiovascular Risk

The American College of Cardiology (ACC) and American Heart Association (AHA) released new practice guidelines for the assessment of cardiovascular risk (Stone et al, 2014). These guidelines are referred to as the Adult Treatment Panel 4 (ATP 4) and replace the Adult Treatment Panel 3 (ATP 3). Four high-risk groups are identified:

- Adults with atherosclerotic cardiovascular disease
- Adults with diabetes, aged 40 to 75 years, with low-density lipoprotein (LDL) levels 70 to 189 mg/dl
- Adults with LDL cholesterol levels of at least 190 mg/dl
- Adults aged 40 to 75 years who have LDL levels 70 to 189 mg/dl and at least 7.5% 10-year risk of atherosclerotic cardiovascular disease

Ten-year risk of atherosclerotic cardiovascular disease is determined using the Framingham 10-year general cardiovascular disease risk equations. Risk factors include age, gender, total cholesterol, HDL cholesterol, smoking status, systolic blood pressure, and current treatment for high blood pressure (Box 7-1). The new ACC/AHA Guidelines deemphasize use of

any markers other than LDL cholesterol and HDL cholesterol. Emerging risk markers for atherosclerotic cardiovascular disease (ACVD) that are not recommended in ATP 4 include differentiating subparticles of LDL by size and grouping by pattern, apolipoprotein B (apoB), and apolipoprotein E (apoE) phenotype. The Cholesterol Expert Panel determined that these markers are not independent markers for risk and do not add to prediction equations. Other researchers propose mathematical models that predict the risk of plaque formation for combined levels of LDL and HDL (Hao and Friedman, 2014). See Chapter 33 for further discussion of the lipid profile and cardiovascular risk.

The National Lipid Association (NLA) Expert Panel presents somewhat different treatment goals from the ATP 4. The NLA includes treatment goals for non-HDL cholesterol, LDL cholesterol, and apolipoprotein B (Jacobson et al, 2014; see Chapter 33).

Patients undergoing lipid assessments should be fasting for 12 hours at the time of blood sampling. Fasting is necessary primarily because triglyceride levels rise and fall dramatically in the postprandial state, and LDL cholesterol values are calculated from measured total serum cholesterol and high-density lipoprotein cholesterol concentrations. This calculation, based on the Friedewald equation, is most accurate when triglyceride concentrations are less than 400 mg/dl. The Friedewald equation gives an estimate of fasting LDL cholesterol levels that is generally within 4 mg/dl of the true value when triglyceride concentrations are less than 400 mg/dl.

Hemoglobin A1C and Diabetes

In adults with normal glucose control, approximately 4% to 6% of the total Hgb is glycosylated. The percent of this glycohemoglobin or **hemoglobin A1C (Hgb A1C)** in the blood is related directly to the average blood glucose levels for the preceding 2 to 3 months and does not reflect more recent changes in glucose levels. It is useful in differentiating between short-term hyperglycemia in individuals under stress or who have had an acute myocardial infarction and those with diabetes. It has been added as a diagnostic criteria for diagnosis of diabetes mellitus once the initial value is confirmed by a repeat Hgb A1C above 6.5%, or plasma glucose above 200 mg/dl (11 mmol/L). Hgb A1C is not used as a diagnostic criterion for gestational diabetes because of changes in red cell turnover (American Diabetes Association [ADA], 2011).

Hgb A1C can be correlated with daily mean plasma glucose. Each 1% change in Hgb A1C represents approximately 35 mg/dl change in mean plasma glucose. Test results are useful to provide feedback to patients about changes they have made in their nutritional intakes (ADA, 2011). See Chapter 30 for further discussion of Hgb A1C and diabetes management.

Markers of Oxidative Stress and Inflammation

Biomarkers of oxidative stress status and inflammation have been associated with many chronic conditions and risk factors (see Chapter 3). Aging and many diseases, including rheumatoid arthritis, Parkinson disease, Alzheimer disease, cardiovascular disease, and cancer, are initiated, in part, by oxidative stress as evidenced by free radical oxidation of lipids, nucleic acids, or proteins. An indirect way of assessing the level of oxidative stress is to measure the levels of antioxidant compounds present in body fluids. Oxidative stress is related to levels of the following:

- Antioxidant vitamins (tocopherols and ascorbic acid)
- Dietary phytochemicals with antioxidant properties (e.g., carotenoids)

BOX 7-1 Lipid and Lipoprotein Atherosclerotic Cardiovascular Risk Factors

Laboratory test cutpoints used to calculate 10-year risk of ACVD

Total cholesterol: >200 mg/dl

HDL: <40 mg/dl

LDL: >131 mg/dl

In selected high-risk individuals, these laboratory test cutpoints may be considered:

hs-CRP cutpoints used to assign risk

- <1.0 mg/L = low risk
- 1.1-3.0 mg/L = average risk
- 3.1-9.9 mg/L = high risk
- ≥ 10 mg/L = very high risk
- If initial value is >3.0 but <10 mg/L, repeat in 2 weeks

Lipoprotein-associated phospholipase A₂ (Lp-PLA₂): used in conjunction with hs-CRP with intermediate or high risk

Apolipoprotein A-1: May be used in addition to LDL-C monitoring as a non-HDL-C marker in patients with serum triglycerides ≥ 200 mg/dl; decreased level is atherogenic

Apolipoprotein B/A ratio: May be used in addition to LDL-C monitoring as a non-HDL-C marker in patients with serum triglycerides ≥ 200 mg/dl

Other laboratory test results associated with cardiovascular risk, but not recommended in ATP 4

VLDL density: Remnants are atherogenic

Lp(a): Elevated levels are atherogenic

Serum homocysteine: Increased = greater risk

RBP4: Elevated levels may identify early insulin resistance and associated cardiovascular risk factors

Adapted from Stone NJ et al: 2013 ACC/AHA guideline on the treatment of blood cholesterol to reduce atherosclerotic cardiovascular risk in adults: a report of the American College of Cardiology/American Heart Association Task Force on practice guidelines, *Circulation* 129 (25 Suppl 2):S1, 2014.

HDL, High-density lipoprotein; hs-CRP, high-sensitivity C-reactive protein; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; Lp(a), lipoprotein little a; RBP4, retinol-binding protein 4; VLDL, very low density lipoprotein.

- Minerals with antioxidant roles (e.g., selenium)
- Endogenous antioxidant compounds and enzymes (e.g., superoxide dismutase, glutathione)

More precisely, the concentration of these compounds correlates with the balance between their intake and production, and their use during the inhibition of free radical compounds produced by oxidative stress.

Measurement of intracellular antioxidant thiols such as glutathione can be estimated using the free oxygen radical test via spectrophotometric techniques on specimens obtained from finger sticks. However, further standardization of protocols for assays and methods of combining and integrating multiple panels of biomarkers of oxidative stress and inflammation are needed to facilitate evaluation of biomarkers for risk factor prediction. Although some intervention studies examining the effects of dietary supplements, diet, and exercise on biomarkers of oxidative stress and inflammation have been done, the data have been inconclusive, and more studies are needed to understand the underlying mechanisms.

The most commonly used chemical markers of oxidative stress are presented in Table 7-6. Some tests measure the presence of one class of free radical products, and others measure the global antioxidant capacity of plasma or a plasma fraction. For example, one noninvasive test measures antioxidant capacity by using Raman spectroscopy with a laser scanner to measure the amount of carotenoids at the cellular level. (See [New Directions: Raman Spectroscopy Used to Measure Antioxidant Capacity](#).) These tests have been promoted on the assumption that knowledge of the total antioxidant capacity of the plasma or plasma fraction may be more useful than knowledge of the individual concentrations of free radical markers or antioxidants. This total antioxidant activity is determined by a test that assesses the combined antioxidant capacities of the constituents. Unfortunately, the results of these tests include the antioxidant capacities of compounds such as uric acid and albumin, which are not compounds of interest. In other words, no one type of assay is likely to provide a global picture of the oxidative stress to which an individual is exposed.

TABLE 7-6 Advantages and Disadvantages of Various Biomarkers of Oxidative Stress

Biomarker	Advantages	Disadvantages	Comments
IsoPs (isoprostanes)	Can be detected in various samples (serum, urine) and has been shown to be elevated in the presence of a range of CV risk factors	Current methods of quantification are impractical for large-scale screening.	No evidence linking this biomarker to clinical outcomes yet. F ₂ -IsoPs show most potential.
MDA (malondialdehyde)	Technically easy to quantify spectrophotometrically using the TBARS assay ELISA kits to detect MDA also have good performance Studies show MDA can predict progression of CAD and carotid atherosclerosis at 3 years	TBARS assay is nonspecific (can detect aldehydes other than MDA) and sample preparation can influence results.	Shows promise as a clinical biomarker; however does not have a functional impact on the pathophysiology of CVD
Nitrotyrosine (3-NO ₂ -tyr)	Human studies have demonstrated association with CAD independent of traditional risk factors	Circulating levels are not equivalent to tissue levels. Current detection methods are expensive and impractical.	Nitrotyrosine formation on particular cardiovascular proteins has direct effect on function
S-glutathionylation	S-glutathionylation of SERCA, eNOS and Na ⁺ -K ⁺ pump demonstrated as biomarkers as well as role in pathogenesis	Detection of S-glutathionylation prone to methodological artifact Access to tissue (myocardium, vasculature), where modification occurs presents a clinical obstacle	Modified hemoglobin currently being investigated as biomarker
Myeloperoxidase (MPO)	Commercial assays available. An enzyme abundant in granules in inflammatory cells. Strong evidence that MPO correlates with CVD risk	Influenced by sample storage and time to analysis	MPO is a promising biomarker for CVD risk prediction.
Oxidized LDL cholesterol (OxLDL)	Forms and occurs in vascular walls as foam cells and stimulates production of proinflammatory cytokines by endothelial cells. Elevated in CAD, increasing OxLDL correlates with increasing clinical severity. Also is predictive of future CAD in healthy population. Good reproducibility from frozen samples	Reduction in OxLDL by antioxidant pharmacotherapy has not been matched by reduction in CVD severity.	ELISAs for OxLDL detection readily available
ROS-induced changes to gene expression	The expression of several genes involved in regulating oxidative stress may be measured simultaneously using microarray technology, potentially increasing the power of this biomarker	Microarray technology can be manually and computationally expensive	It is unclear if expression profiles of cells in biologic samples reflect that in cardiovascular tissues
Serum antioxidant capacity	Activity of antioxidant enzymes such as glutathione peroxidase 1 (GPX-1) and superoxide dismutase (SOD) are demonstrated to be inversely proportional to CAD. Commercial kits available to measure antioxidant capacity. Reproducibly quantified despite frozen sample storage	Antioxidant activity in serum may not reflect that of the cells that are important to the pathogenesis of CVD	Clinical relevance of antioxidant quantification to CVD risk needs further investigation

CAD, Coronary artery disease; CV, cardiovascular; CVD, cardiovascular disease; ELISA, enzyme-linked immunosorbent assay; TBARS, thiobarbituric acid (TBA) reacting substances; eNOS, endothelial nitric oxide synthase; GPX-1, glutathione peroxidase-1, ROS, reactive oxygen species; SERCA, sarcoplasmic reticulum Ca²⁺-ATPase; SOD, superoxide dismutase.

NEW DIRECTIONS

Raman Spectroscopy Used to Measure Antioxidant Capacity

Noninvasive measurements of clinical parameters are always preferable to those requiring blood, urine, or tissue. Raman spectroscopy, or resonance Raman spectroscopy (RRS) is just such a measurement technique, and is being used to measure the antioxidant capacity of an individual. It measures the antioxidant capacity by measuring the amount of skin carotenoids. Carotenoids are powerful antioxidants, and because they are part of the “antioxidant network,” a measure of their presence can give a good assessment of the antioxidant capacity of the cell and thus the individual.

A laser light is pointed toward the skin (usually the fat pad of the palm). As the laser light penetrates the skin, the amount of skin carotenoids (all-trans-beta-carotene, lycopene, alpha-carotene, gamma-carotene, phytoene, phytofluene, senebiero-beta-carotene, dihydro-beta-carotene, astaxanthin, canthaxanthin, zeaxanthin, lutein, violaxanthins, and rhodoxanthin) is measured because carotenoids have a carbon backbone with alternating carbon double and single bonds, and the vibration of these bonds can be detected with RRS.

Serum carotenoids as measured by high performance liquid chromatography (HPLC) significantly correlate with skin carotenoids, as measured using RSS. (Ermakov and Gellerman, 2015, Aguilar et al, 2014, Nguyen et al, 2015). The measurement of skin carotenoids, or the RRS score, also correlates with reported fruit and vegetable and dietary carotenoid intake; the greater the intake of fruits and vegetables, the higher the score. (Jahns et al, 2014). This was found in both adults and children. (Nguyen et al, 2015). The use of skin carotenoid status can be used as an objective biomarker of change in fruit and vegetable based intervention studies or clinical dietary protocols (Mayne et al, 2013, Jahns et al, 2014).

This score, or the numeric result from this scan, can also be used to determine how well a person is processing the consumed carotenoid antioxidants, and whether the antioxidants are reaching the cell where they exert their protective functions. The RRS score is higher in those with

optimal health, and besides increasing with greater consumption of fruits and vegetables, it also increases with consumption of carotenoid-containing nutritional supplements, smoking cessation, and loss of excess body fat (Carlson et al., 2006). It has also been found to be lower in those with an ongoing oxidative stress such as with metabolic syndrome (Holt et al, 2014). RRS has also been used to assess carotenoids in precancerous skin lesions, and to assess early stages of macular degeneration in the retina (Carlson et al., 2006).

With the development of portable scanners, RRS measurement is quick, easy, and inexpensive, making it a possible nutritional assessment tool for professionals in the future.

Despite this lack of correlation or specificity of assays of oxidative stress, three assays seem promising. One is the immunoassay myeloperoxidase used in conjunction with CRP to predict CVD mortality risk (Heslop et al, 2010). The second assay is the measurement of the compounds F₂ isoprostanes either in plasma or urine (Harrison and Nieto, 2011). This test measures the presence of a continuously formed free radical compound that is produced by free radical oxidation of specific polyunsaturated fatty acids. Isoprostanes are prostaglandin-like compounds that are produced by free radical mediated peroxidation of lipoproteins. Elevated isoprostane levels are associated with oxidative stress, and clinical situations of oxidative stress such as hepatorenal syndrome, rheumatoid arthritis, atherosclerosis, and carcinogenesis (Roberts and Fessel, 2004). The third test is urinary 8-hydroxy-2' deoxyguanosine (8-OH-d-g), in which elevated levels are associated with inadequate intake of carotenoids and antioxidant-rich foods (see Table 7-6).

PHYSICAL ASSESSMENTS

Anthropometry

Anthropometry involves obtaining physical measurements of an individual, comparing them to standards that reflect the growth and development of that individual, and using them for evaluating overnutrition, undernutrition, or the effects of nutrition preventions over a period of time. Accurate and consistent measurements require training in the proper techniques using calibrated instruments. Measurements of accuracy can be established by several clinicians taking the same measurement and comparing results. Valuable anthropometric measurements

include height, weight, and girth measurements. Skinfold thicknesses and circumference measurements are used in some settings but are associated with a higher rate of inconsistency. Head circumference and length are used in pediatric populations. Birth weight and ethnic, familial, and environmental factors affect these parameters and should be considered when anthropometric measures are evaluated.

Interpretation of Height and Weight in Children and Teens

Currently, reference standards are based on a statistical sample of the U.S. population. The WHO international growth standards are based on data from multiple countries and ethnic populations and have been adopted for use in numerous countries. In the United States, the expert review panel of WHO and CDC growth charts recommend the WHO growth standards for children aged less than 24 months and the CDC growth charts for children aged 24 months to 18 years.

Height and weight measurements of children are recorded as percentiles, which reflect the percentage of the total population of children of the same sex who are at or below the same height or weight at a certain age. Children's growth at every age can be monitored by mapping data on growth curves, known as **height-for-age**, **length-for-age**, **weight-for-age**, and **weight-for-length curves**. Appendices 4 through 11 provide pediatric growth charts and percentile interpretations.

Length and Height

The methodology used for determining the length or height of children is determined by the age of the child. Recumbent length measurements are used for infants and children younger

FIGURE 7-3 Measurement of the length of an infant.

than 2 or 3 years of age. Ideally these young children should be measured using a length board as shown in [Figure 7-3](#). Recumbent lengths in children ages 2 and younger should be recorded on the birth to 24-month growth grids. Standing height is determined in children using a measuring rod, or **statiometer**, and should be recorded on the 2- to 20-year growth grids, as in Appendices 6, 7, 10, and 11. Sitting heights may be measured in children who cannot stand (see [Figure 44-1](#)). Recording on the proper growth grids provides a record of a child's gain in height over time and compares the child's height with that of other children of the same age. The rate of length or height gain reflects long-term nutritional adequacy.

Weight

Weight in children and teens is a more sensitive measure of nutritional adequacy than height, because it reflects more recent nutritional intake and provides a rough estimate of overall fat and muscle reserves. For children who are obese or have edema, weight alone makes it difficult to assess overall nutritional status. Weight should be recorded on the age- and gender-appropriate growth grid.

Body weight is interpreted using various methods, including **body mass index (BMI)**, usual weight, and actual weight. BMI is used as a screening tool to identify overweight and obese children and teens. Although the calculation of BMI is the same for adults and children, the interpretation of BMI is different in children and teens. BMI is plotted on the CDC BMI-for-age growth charts from which a percentile ranking can be determined. These percentiles are the most commonly used indicator to assess the size and growth patterns of children and teens aged 2 to 20 years in the United States (see Appendices 7 and 11). BMI-for-age weight status categories are noted in [Box 7-2](#).

Interpretation of Height and Weight in Adults

In adults, height and weight measurements are also useful for evaluating nutrition status. Both should be measured because the tendency is to overestimate height and underestimate weight, resulting in an underestimation of the relative weight or BMI. In addition, many adults are losing height as a result of osteoporosis, joint deterioration, and poor posture, and this should be documented ([Box 7-3](#)).

BOX 7-2 Interpretation of BMI-for-Age Percentiles in Children and Teens

Percentile Range	Interpretation
Less than 5th percentile	Underweight
5th percentile to less than 85th percentile	Healthy weight
85th percentile to less than the 95th percentile	Overweight
Equal to or greater than the 95th percentile	Obese

BOX 7-3 Using Height and Weight to Assess a Hospitalized Patient's Nutritional Status

- Measure. Do not just ask a person's height.
- Measure weight (at admission, current, and usual).
- Determine percentage of weight change over time (weight pattern).
- Determine percentage above or below usual or ideal body weight.

Measurements of height can be obtained using a direct or an indirect approach. The direct method involves a stadiometer, and the adult must be able to stand or recline flat. Indirect methods, including knee-height measurements, arm span, or recumbent length using a tape measure, may be options for those who cannot stand or stand straight, such as individuals with scoliosis, kyphosis (curvature of the spine), cerebral palsy, muscular dystrophy, contractures, paralysis, or who are bedridden (see Appendix 15). Recumbent height measurements made with a tape measure while the person is in bed may be appropriate for individuals in institutions who are comatose, critically ill, or unable to be moved. However, this method can be used only with patients who do not have musculoskeletal deformities or contractures.

Ideal weight for height reference standards such as the Metropolitan Life Insurance Tables from 1959 and 1983 or the National Health and Nutrition Examination Survey percentiles are no longer used. A commonly used method of determining ideal body weight is the Hamwi Equation ([Hamwi, 1964](#)). It does not adjust for age, race, or frame size and its validity is questionable. Nonetheless, it is in widespread use by clinicians as a quick method for estimation of ideal weight:

Men: 106 lb for first 5 feet of height and 6 lb per inch over 5 feet; or 6 lb subtracted for each inch under 5 feet

Women: 100 lb for first 5 feet of height and 5 lb per inch over 5 feet; or 5 lb subtracted for each inch under 5 feet

Using the Hamwi method a female who is 5 feet 5 inches tall would have an ideal weight of 125 pounds.

Actual body weight is the weight measurement obtained at the time of examination. This measurement may be influenced by changes in the individual's fluid status. Weight loss can reflect dehydration but also can reflect a pattern of suboptimal food intake. The percentage of weight loss is highly indicative of the extent and severity of an individual's illness. The Characteristics of Malnutrition defined by the Academy of Nutrition and Dietetics (AND) and ASPEN serve as a benchmark for evaluating weight loss ([White et al, 2012](#)):

- Significant weight loss: 5% loss in a month, 7.5% loss in 3 months, 10% loss in 6 months
- Severe weight loss: >5% weight loss in a month, >7.5% weight loss in 3 months, >10% weight loss in 6 months

$$\text{Percentage weight loss} = \frac{\text{Usual wt} - \text{Actual wt}}{\text{Usual wt}} \times 100$$

- For example if a person's usual weight is 200 lb and he now weighs 180 lb, that is a weight loss of 20 lb.

$$200 \text{ to } 180 = 20\text{lb}/200\text{lb} = 0.10 \text{ or } 10\%$$

- If this person has lost this 10% in 2 months, that would be more than 7.5% in 3 months and considered SEVERE weight loss.

Another method for evaluating the percentage of weight loss is to calculate an individual's current weight as a percentage

of usual weight. **Usual body weight (UBW)** is a more useful parameter than **ideal body weight (IBW)** for those who are experiencing involuntary weight loss. However, one problem with using UBW is that it may depend on the patient's memory.

Body Mass Index

The Quetelet index (W/H^2) or the BMI is used to determine whether an adult's weight is appropriate for height and can indicate overnutrition or undernutrition. BMI accounts for differences in body composition by defining the level of adiposity and relating it to height, thus eliminating dependence on frame size (Stensland and Margolis, 1990). The BMI has the least correlation with body height and the highest correlation with independent measures of body fat for adults. The BMI is an indirect measure of body fat and correlates with the direct body fat measures such as underwater weighing and dual x-ray absorptiometry (Keys et al, 1972; Mei et al, 2002). BMI is calculated as follows:

Metric : $BMI = \text{Weight (kg)} \div \text{Height (m)}^2$

English: $BMI = \text{Weight (lb)} \div \text{Height (in)}^2 \times 703$

Nomograms are also available to calculate BMI, as are various charts (see Appendix 18). The **Clinical Insight box: Calculating BMI and Determining Appropriate Body Weight** gives an example of the BMI calculation.

Standards classify a BMI of less than 18.5 for an adult as underweight, a BMI between 25 and 29 as overweight, and a BMI greater than 30 as obese. A healthy BMI for adults is considered between 18.5 and 24.9 (CDC, 2014). Although a strong correlation exists between total body fat and BMI, individual variations must be recognized before making conclusions regarding appropriate body fatness (Mueller, 2012).

Differences in race, sex, and age must be considered when evaluating the BMI. BMI values tend to increase with age, yet the relationship between BMI and mortality appears to be U-shaped in adults aged 65 and older. The risk of mortality increased in older adults with a BMI of less than 23 (Winter, 2014; see Chapter 20).

Body Composition

Body composition is a critical component of nutrition assessment and medical status. It is used concurrently with other assessment factors to differentiate the estimated proportions of fat mass, soft tissue body mass, and bone mass. For example, muscular athletes may be classified as overweight because of excess

muscle mass contributing to increased weight rather than excessive adipose tissue. Older adults tend to have lower bone density and reduced lean body mass and therefore may weigh less than younger adults of the same height and yet have greater adiposity. Variation in body composition exists among different population groups as well as within the same group. The majority of body composition studies that were performed on whites may not be valid for other ethnic groups. There are differences and similarities between blacks and whites relative to fat-free body mass, fat patterning, and body dimensions and proportions; blacks have greater bone mineral density and body protein compared with whites (Wagner and Heyward, 2000). In addition, optimal BMIs for Asian populations must be in the lower ranges of "normal" for optimal health to reflect their higher cardiovascular risks (Zheng et al, 2009). These factors must be considered to avoid inaccurate estimation of body fat and interpretation of risk.

Imaging techniques such as dual-energy x-ray absorptiometry (DXA) and magnetic resonance imaging (MRI) are used in research and clinical settings to assess body composition. The focus of the research on different imaging methodologies is to quantify characteristics of lean soft tissue (LST) that predicts clinical risk and nutrition status. Areas of greatest research are to assess for sarcopenia, sarcopenic obesity, and osteosarcopenic obesity (Prado, 2014).

Subcutaneous Fat in Skinfold Thickness

In research studies and selected health care settings, fat-fold or skinfold thickness measurements may be used to estimate body fat in an individual. Skinfold measurement assumes that 50% of body fat is subcutaneous. Because of limitations with accuracy and reproducibility, these measurements are not used routinely in clinical settings.

Circumference Measurements

Circumference measurements may be useful in health care settings in which these measurements are recorded periodically (e.g., monthly or quarterly) and tracked over time to identify trends and potential risk factors for chronic conditions. However, in acutely ill individuals with daily fluid shifts measures of arm circumference and TSF measurements usually are not performed. (See **New Directions: Measuring the Neck: What Can it Mean?**)

Circumference Measurements in Children

Head circumference measurements are useful in children younger than 3 years of age, primarily as an indicator of non-nutritional abnormalities. Undernutrition must be very severe to affect head circumference; see **Box 7-4**.

Measuring Head Circumference

Midarm circumference (MAC) is measured in centimeters halfway between the acromion process of the scapula and the olecranon process at the tip of the elbow. MAC should be measured when assessing for nutritional status of children and compared with the standards developed by WHO for children aged 6 to 59 months of age (de Onis et al, 1997). It is an independent anthropometric assessment tool in determining malnutrition in children.

Circumference Measurements in Adults

MAC is measured the same way in adults as in children. Combining MAC with TSF measurements allows indirect determination of the arm muscle area (AMA) and arm fat area. Because of

CLINICAL INSIGHT

Calculating BMI and Determining Appropriate Body Weight

Example: Woman who is 5'8" (68 in) tall and weighs 185 pounds (lb)

Step 1: Calculate current BMI:

Formula: (Metric) $\text{Weight (kg)} 84 \text{ kg} \div \text{Height (m)}^2 (1.72 \text{ m}) \times (1.72 \text{ m}) = 84 \div 2.96 \text{ m}^2 = \text{BMI} = 28.4 = \text{overweight}$

Step 2: Appropriate weight range to have a BMI that falls between 18.5 and 24.9

18.5 $(18.5) \times (2.96) = 54.8 \text{ kg} = 121 \text{ pounds}$

24.9 $(24.9) \times (2.96) = 73.8 \text{ kg} = 162 \text{ pounds}$

Appropriate weight range = 121 – 162 lb or 54.8 – 73.8 kg

Formula (English) $\text{Weight (lb)} \div (\text{Height (in)} \times \text{Height (in)}) \times 703 = \text{BMI}$

BMI, Body mass index.

NEW DIRECTIONS

“Measuring the Neck: What Can it Mean?”

Neck circumference (NC) is an emerging marker of overweight, obesity, and associated disease risk in children and adults. Its measurement is a novel, noninvasive screening tool that is easy to do without the privacy concerns associated with waist and hip circumference measurements. Neck circumference is measured on bare skin between the midcervical spine and midanterior neck just below the laryngeal prominence (the Adam’s apple) with the head in the Frankfurt plane (looking straight ahead). The tape should be as close to horizontal as anatomically feasible (i.e., the tape line in the front of the neck will be at the same height as the tape line in the back of the neck) (Arnold, 2014).

Studies of adults report that neck circumference is associated highly with waist circumference, weight, BMI, and percent body fat. Findings

from study of a predominantly African American cohort include significant correlations between serum insulin, triglycerides, and LDL cholesterol levels, and neck circumference (Arnold, 2014).

Neck circumference can be used as a reliable tool to identify adolescents with high body mass indexes (Androutsos, 2010). The Canadian Health Measures Survey has published reference data for interpretation of neck circumference measurements in Canadian children (Katz, 2014). More research is needed to determine cutoff points for identifying children at risk of central obesity-associated conditions associated with disease risk. In children and adults study is needed to establish possible neck circumference predictors for obesity-related chronic disease.

Androutsos O et al: Neck circumference: a useful screening tool of cardiovascular risk in children. *Pediatric Obesity* Jun;7(3):187, 2010.

Arnold TJ et al: Neck and waist circumference biomarkers of cardiovascular risk in a cohort of predominantly African-American college students: a preliminary study. *J Acad Nutr Dietetics* 114(1):107, 2014.

Katz S et al: Creation of a reference dataset of neck sizes in children: standardizing a potential new tool for prediction of obesity-associated diseases? *BMC Pediatr* 21;14:159, 2014.

limitations with accuracy and reproducibility, these measurements are rarely used to assess adult nutrition status.

Waist and Hip Circumference, Waist-to-Hip Ratio, and Waist-to-Height Ratio

Selected circumference measurements may be useful in determining estimated risk for chronic diseases and assessing changes in body composition. **Waist circumference (WC)** is obtained by measuring the distance around the narrowest area of the waist between the lowest rib and iliac crest and above the umbilicus using a nonstretchable tape measure. Hip circumference is measured at the widest area of the hips at the greatest protuberance of the buttocks. Because fat distribution is an indicator of risk, circumferential or girth measurements may be used. The

presence of excess body fat around the abdomen out of proportion to total body fat is a risk factor for chronic diseases associated with obesity and the metabolic syndrome. A WC of greater than 40 inches (102 cm) for men and greater than 35 inches (88 cm) for women is an independent risk factor for disease (CDC, 2014; Stone, 2013). These measurements may not be as useful for those less than 60 inches tall or with a BMI of 35 or greater (CDC, 2014). WC is used as a risk indicator supplementary to BMI.

To determine the waist-to-hip ratio (WHR), divide the waist measurement by the hip measurement. The WHO defines the ratios of greater than 9.0 in men and greater than 8.5 in women as one of the decisive benchmarks for metabolic syndrome and is consistent with findings of research predicting all cause and cardiovascular disease mortality (Srikanthan et al, 2009; Welborn and Dhaliwal, 2007).

Figure 7-4 shows the proper location to measure waist (abdominal) circumference.

The **waist-to-height ratio (WHtR)** is defined as the waist circumference divided by the measured height. WHtR is a measure of the distribution of adipose tissue. Generally speaking, the higher the values of WHtR, the greater the risk of metabolic syndrome and obesity-related atherosclerotic cardiovascular diseases (Schneider et al, 2010). Desirable ratios are less than 0.5 in adults 40 years and younger, between 0.5 and 0.6 in adults aged 40 to 50 years, and 0.6 or less in adults over 50. These targets apply to both males and females and a variety of ethnic groups. For example, a BMI of 25 is equivalent to a WHtR of 0.51. Table 7-7 provides a guide to interpreting WHtR by gender.

Some experts have concluded that WHtR is a superior measure of cardiovascular disease than BMI (Ashwell et al, 2012). However WHtR is not identified as a risk marker in the ACC/AHA ATP 4.

Researchers have proposed A Body Shape Index (ABSI) based on WC, height, and weight as a complementary health risk indicator to be used in conjunction with BMI. More research is needed to validate this methodology (Krakauer and Krakauer, 2012).

BOX 7-4 Measuring Head Circumference

Indications

- Head circumference is a standard measurement for serial assessment of growth in children from birth to 36 months and in any child whose head size is in question.

Equipment

- Paper or metal tape measure (cloth can stretch) marked in tenths of a centimeter because growth charts are listed in 0.5-cm increments

Technique

- The head is measured at its greatest circumference.
- The greatest circumference is usually above the eyebrows and pinna of the ears and around the occipital prominence at the back of the skull.
- More than one measurement may be necessary because the shape of the head can affect the location of the maximum circumference.
- Compare the measurement with the National Center for Health Statistics standard curves for head circumference (see Appendices 5 and 9).

Data from Hockenberry MJ, Wilson D: *Wong’s nursing care of infants and children*, ed 9, St Louis, 2015, Mosby.

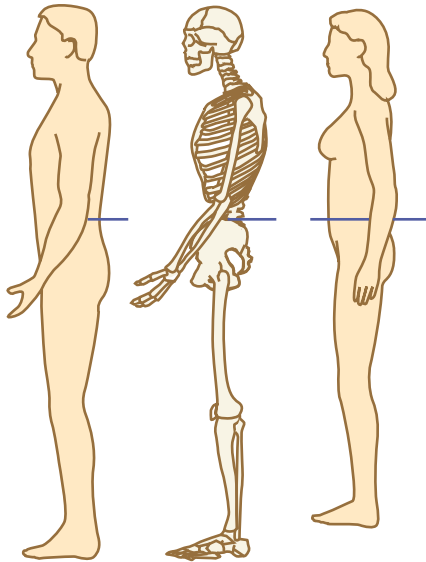

FIGURE 7-4 Measuring tape position for waist circumference.

FIGURE 7-5 A patient undergoing a dual-energy x-ray absorptiometry scan. (Courtesy the Division of Nutrition, University of Utah.)

TABLE 7-7 Interpretation of Waist-to-Height Ratio by Gender

Females	Males	Interpretation
WHtR < 0.35	WHtR < 0.35	Underweight
0.35-0.42	0.35-0.43	Slim
0.42-0.49	0.43-0.53	Healthy
0.49-0.54	0.53-0.58	Overweight
0.54-0.58	0.58-0.63	Obese
> 0.58	> 0.63	Very obese

WHtR, Weight-to-height ratio.

Other Methods of Measuring Body Composition

Dual-Energy X-Ray Absorptiometry

Dual-energy x-ray absorptiometry (DXA) measures fat, bone mineral, and fat-free soft tissue. The energy source in DXA is an x-ray tube that contains an energy beam. The amount of energy loss depends on the type of tissue through which the beam passes; the result can be used to measure mineral, fat, and lean tissue compartments (Russell, 2007). DXA is easy to use, emits low levels of radiation, and is available in the hospital setting, making it a useful tool. Generally, it is found to be a reliable measurement of percentage body fat; however, the patient must remain still for more than a few minutes, which may be difficult for older adults and those in chronic pain. Measurements are influenced by the thickness of tissues and hydration status (Prado and Heymsfield, 2014). Figure 7-5 illustrates a DXA scan.

Air Displacement Plethysmogram

Air displacement plethysmogram (ADP) relies on measurements of body density to estimate body fat and fat-free masses. Performing an ADP with the BOD-POD device is a

FIGURE 7-6 The BOD-POD measures body fat and fat-free mass. (Courtesy COSMED USA, Inc., Concord, CA.)

densitometry technique found to be an accurate method to measure body composition. ADP appears to be a reliable instrument in body composition assessment; it is of particular interest with obese individuals. ADP does not rely on body water content to determine body density and body composition, which makes it potentially useful in those adults with end-stage renal disease (Flakoll et al, 2004; Figure 7-6).

Bioelectrical Impedance Analysis

Bioelectrical impedance analysis (BIA) is a body composition analysis technique based on the principle that, relative

FIGURE 7-7 Image reproduced with permission of ImpediMed Limited.

to water, lean tissue has a higher electrical conductivity and lower impedance than fatty tissue because of its electrolyte content. BIA has been found to be a reliable measurement of body composition (fat-free mass and fat mass) compared with BMI or skinfold measurements or even height and weight measurements. The BIA method is safe, noninvasive, portable, and rapid (Figure 7-7). For accurate results the patient should be well hydrated; have not exercised in the previous 4 to 6 hours; and have not consumed alcohol, caffeine, or diuretics in the previous 24 hours (see Appendix 22). If the person is dehydrated, a higher percentage of body fat than really exists is measured. Fever, electrolyte imbalance, and extreme obesity also may affect the reliability of measurements.

NUTRITION-FOCUSED PHYSICAL ASSESSMENT

Nutrition-focused physical assessment (NFPA) is one of the components of nutrition assessment in the nutrition care process model. Data gathered in the NFPA are used in conjunction with food and nutrition history, laboratory and diagnostic test results, physical measurements, and client history to accurately make one or more nutrition diagnoses. The *International Dietetics & Nutrition Terminology Reference Manual* (IDNT) (AND, 2013) defines nutrition-focused physical examination as “findings from an evaluation of body systems, muscle and subcutaneous fat wasting, oral health, suck, swallow/breathe ability, appetite and affect.” Unlike a comprehensive clinical examination that reviews all body systems, NFPA is a focused assessment that addresses specific signs and symptoms by reviewing selected body systems.

Approach

A systems approach is used when performing the NFPA, which should be conducted in an organized, logical way to ensure efficiency and thoroughness (Litchford, 2013). Body systems include the following:

- Overall appearance
- Vital signs
- Skin
- HEENT (head, ears, eyes, nose, and throat)
- Cardiopulmonary system
- Extremities, muscles, and bones
- Digestive system
- Nerves and cognition

Equipment

The extent of the NFPA dictates the necessary equipment. Any or all of the following may be used: examination gloves, a stethoscope, a penlight or flashlight, a tongue depressor, scales, calipers, a tape measure, a blood pressure cuff, and a watch with a second hand.

Examination Techniques and Findings

Four basic physical examination techniques are used during the NFPA. These techniques include inspection, palpation, percussion, and auscultation (Table 7-8). Appendix 21 discusses NFPA in more detail.

Interpretation of data collected in each component of an NFPA requires critical thinking skills and the following steps in clinical reasoning:

- Identify abnormal findings or symptoms.
- Localize the findings anatomically.
- Interpret findings in terms of probable process.
- Make a hypothesis about the nature of the patient’s problem.
- Test the hypothesis by collaborating with other medical professionals and establish a working nutrition diagnosis.
- Develop a plan agreeable to the patient following all the steps of the NCP model (Bickley, 2009). See Chapter 10.

Guidelines for Assessing Malnutrition in Children

Definitions and guidelines to identify malnutrition in children are evolving. Pediatric malnutrition is defined as an imbalance between nutrient requirements and dietary intake that results in deficits of energy, protein, and micronutrients stores, resulting in impaired growth and development. Pediatric malnutrition is either related to an illness or injury or caused by an environmental circumstance or behavioral factor (Mehta et al, 2014). Specific parameters for determining pediatric undernutrition and malnutrition are being standardized (Becker et al, 2014).

Guidelines for Assessing Malnutrition in Adults

The Academy and the ASPEN Consensus Statement: Characteristics Recommended for the Identification and Documentation of Adult Malnutrition provides a standardized and measurable set of criteria for all health professionals to use to

TABLE 7-8 Physical Examination Techniques

Technique	Description
Inspection	General observation that progresses to a more focused observation using the senses of sight, smell, and hearing; note appearance, mood, behavior, movement, facial expressions, most frequently used technique
Palpation	Gentle tactile examination to feel pulsations and vibrations; assessment of body structures, including texture, size, temperature, tenderness, and mobility
Percussion	Assessment of sounds to determine body organ borders, shape, and position; not always used in a nutrition-focused physical examination
Auscultation	Use of the naked ear or bell or diaphragm of stethoscope to listen to body sounds (e.g., heart and lung sounds, bowel sounds, blood vessels)

Adapted from Litchford MD: *Nutrition focused physical assessment: making clinical connections*, Greensboro, NC, 2013, CASE Software & Books.

identify malnutrition (White et al, 2012). It uses a cause-based nomenclature that reflects the current understanding of the role of inflammatory response on the incidence, progression, and resolution of adult malnutrition. Moreover, malnutrition syndromes are defined by patient settings, including acute illness or surgery, chronic disease, and environmental or social circumstances. In addition, the presence and degree of inflammation further differentiates types of malnutrition as nonsevere and severe. Nonsevere does not mean not urgent; it means mild to moderate malnutrition or undernutrition (Figure 7-8).

No single parameter defines malnutrition. The Consensus guidelines identify six characteristics of malnutrition. From

these, the clinician must identify a minimum of two characteristics that relate to the context of the concurrent medical condition for a nutrition diagnosis of malnutrition. The characteristics of nonsevere and severe malnutrition are noted in Table 7-9.

Measures of Functionality

Loss of functionality and mobility has a ripple effect on achieving activities of daily living (ADLs) and nutrition-related ADLs. An emerging component of nutrition-focused assessment is assessment for muscle strength and functionality. Clinicians may work collaboratively with rehabilitation therapists to assess this and identify strategies to improve physical strength and mobility using diet and exercise.

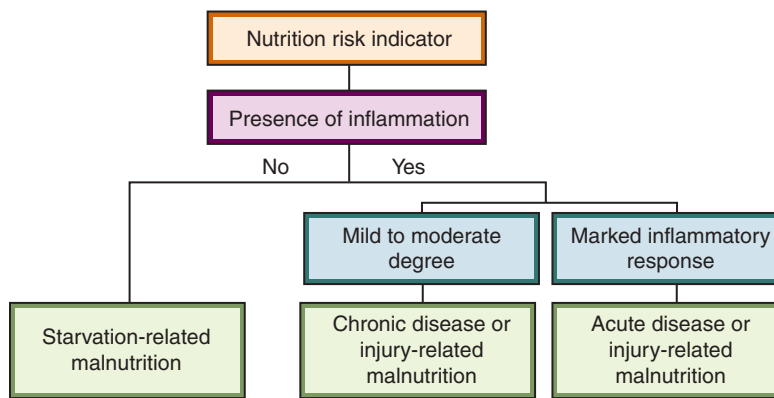

FIGURE 7-8 Cause-based malnutrition. (Adapted from White JV et al: Consensus statement of the Academy of Nutrition and Dietetics/American Society for Parenteral and Enteral Nutrition: characteristics recommended for the identification and documentation of adult malnutrition (undernutrition), *J Acad Nutr Diet* 112(5):730, 2012.)

TABLE 7-9 Characteristics of Adult Malnutrition

ACUTE ILLNESS OR INJURY		CHRONIC ILLNESS		SOCIAL OR ENVIRONMENTAL CIRCUMSTANCES	
Nonsevere	Severe	Nonsevere	Severe	Nonsevere	Severe
Interpretation of Weight Loss for Malnutrition by Cause					
1-2% in 1 wk	>2% in 1 wk	5% in 1 wk	>5% in 1 wk	>5% in 1 wk	>5% in 1 wk
5% in 1 mo	>5% in 1 mo	7.5% in 3 mo	>7.5% in 3 mo	>7.5% in 3 mo	>7.5% in 3 mo
7.5% in 3 mo	>7.5% in 3 mo	10% in 6 mo	>10% in 6 mo	>10% in 6 mo	>10% in 6 mo

Physical Activity Assessment

Inclusion of a physical activity assessment is part of a comprehensive nutrition assessment because lifestyle and behavioral factors play a role in the cause and prevention of chronic diseases. Electronic tracking of physical activity through smartphones and other wearable fitness and health tracking devices are useful in collecting, compiling and preparing summary reports useful to clinicians and patients. **Box 7-5** provides a series of questions that can be asked to identify the current levels and interest in future activity levels for ambulatory patients and clients.

Measures of Strength

With aging, the balanced cycle of muscle synthesis and degradation shifts toward more breakdown than synthesis of muscle tissue (See Chapter 20). The consequence is atrophy of muscle mass and loss of strength and power. Handgrip dynamometry can provide a baseline nutritional assessment of muscle function by measuring grip strength and endurance and is useful in serial measurements. Measurements of handgrip dynamometry are compared with reference standards provided by the manufacturer. Decreased grip strength is an important sign of frailty and is one of the characteristics of severe malnutrition (White, 2012). Low grip strength is associated consistently with a greater likelihood of premature mortality, the development of disability, and an increased risk of complications or prolonged length of stay after hospitalization or surgery in middle-aged and older adults (McLean, 2014).

Rehabilitation therapists use a number of evidence-based measures of upper and lower extremity physical function and performance that include muscle resistance testing, walking tests, stair climbing, rising from a chair, and balance. A score is determined for each test and summed for interpretation (Ha, 2010). Working collaboratively with rehabilitation therapists allows for a better understanding of functional measures of performance and how they relate to nutritional status.

Functional Medicine

Functional medicine is an evolving, evidence-based discipline that sees the body with its mutually interactive systems as a whole, rather than as a set of isolated signs and symptoms. The Institute of Functional Medicine (IFM) promotes an evaluation process that recognizes the biochemical, genetic, and environmental individuality of each person. The focus is patient centered, not just disease centered. Lifestyle and health-promoting factors include nutrition, exercise, adequate sleep, healthy relationships, and a positive mind-body-belief system.

The **Functional Nutrition Assessment (FNA)** approach identifies root causes of chronic disease by integrating traditional dietetic practice with nutritional genomics (see Chapter 3, the restoration of gastrointestinal function, the quelling of chronic inflammation (see Chapter 3), and the interpretation of nutritional biomarkers. The functional nutrition practitioner organizes the data collected from ingestion, digestion, and utilization (IDU) factors, leading to identification of the root causes for each individual within the framework of the nutrition care process (NCP). See **Table 7-10** and **Figure 7-9**.

BOX 7-5 Physical Activity Assessment Questionnaire

To be considered physically active, you must get at least:

- 30 minutes of moderate physical activity on 5 or more days a week, OR
- 20 minutes of vigorous physical activity on 3 or more days a week

How physically active do you plan to be over the next 6 months? (Choose the best answer.)

___ I am not currently active and do not plan to become physically active in the next 6 months.

___ I am thinking about becoming more physically active.

___ I intend to become more physically active in the next 6 months.

___ I have been trying to get more physical activity.

___ I am currently physically active and have been for the last 1 to 5 months.

___ I have been regularly physically active for the past 6 months or more.

Compared with how physically active you have been over the last 3 months, how would you describe the last 7 days: (Check one)

___ More active ___ Less active ___ About the same

Recall your participation in activities or in sedentary behaviors, over the past 24 hours:

- Reading, watching TV, or computer time ___ minutes/day
- Fast walking ___ minutes/day
- Physical activity (swimming, tennis, racquetball, similar) ___ minutes/day
- Other physical activity (describe _____) ___ minutes/day

What are the 3 most important reasons why you would consider increasing your physical activity?

Improve my health Control my weight Lower my stress

TABLE 7-10 Selected Components of Functional Nutrition Assessment

Ingestion	Digestion	Utilization—Cellular and Molecular Functional Relationships
Food, fiber, water, supplements, medication	Adequate microflora	Antioxidants: water-soluble vitamin C, phytonutrients
Intake patterns affected by emotional or disordered eating	Allergies	Methylation and acetylation: dependence on adequate B complex vitamins and minerals
Toxins entering the body via food, skin, inhalants, water, environment (including pesticides and chemicals)	Genetic enzyme deficits	Oils and fatty acids: prostaglandin balance, cell membrane function, vitamin E function
	Hydration	Protein metabolism: connective tissue, enzymes, immune function, etc.
	Infection/inflammatory response	Vitamin D in concert with functional metabolic partner nutrients vitamins A and K
	Lifestyle: sleep, exercise, stressors

FIGURE 7-9 Functional Medicine Matrix Model.

CLINICAL CASE STUDY

Winifred, a 38 year old F, is seen at City Hospital emergency department (ED). She has a history of hypertension, obesity and unsuccessful weight loss attempts. She loves fried foods, soft drinks, beer and pretzels. She has a history of binge eating. Winifred is required to have a yearly physical by her employer, but has put off scheduling the appointment until she can lose some weight. She fell down some stairs in a work-related accident and was sent to the ED for observation. The emergency department doctor determined that Winifred has no broken bones, but is concerned about her elevated blood pressure, 185/98. The doctor orders laboratory tests and Winifred is admitted to the hospital. Her medical profile today is:

Age	38 years old	Normal
Height	5'1"	
Weight	285 lb	
Glucose	142 mg/dL; 7.8 mmol/L	
Calcium	9.1 mg/dL; 2.27 mmol/L	
Sodium	140 mEq/L; 140 mmol/L	
Potassium	3.6 mEq/L; 3.6 mmol/L	
CO ₂	25 mEq/L; 25 mmol/L	
Chloride	96 mEq/L; 96 mmol/L	
BUN	30 mg/dL; 10.7 mmol/L	
Creatinine	0.9 mg/dL; 79.6 μmol/L	
Albumin	3.8 g/dL; 38 g/L	
Total protein	8.0 g/dL; 80 g/L	
ALP	35 U/L; 0.5 μkat/L	
ALT	28 units/L; 28 units/L	
AST	23 units/L; 0.38 μkat/L	
Bilirubin, total	1.5 mg/dL; 25.65 μmol/L	
RBC	5.1 × 10 ⁶ mL; 5.1 × 10 ¹² L	
Hgb	11 g/dL; 7 mmol/L	
Hct	30%; 0.30	
MCV	78 mm ³ ; 78 fL	
MCH	23 pg	
MCHC	40 g/dL; 40%	
WBC	8 × 10 ⁹	
Total cholesterol	245 mg/dL	
LDL	145 mg/dL	
HDL	30 mg/dL	
Triglycerides	210 mg/dL	

Winifred is referred for medical nutrition therapy. NFPA indicates a robust female, with excessive fat stores, normal muscular development and no fluid accumulation. Assess her nutrition status using the data provided.

Nutrition Diagnostic Statement

Altered laboratory values related to disordered eating pattern as evidenced by signs of nutritional anemia and dyslipidemia.

Nutrition Care Questions

1. Estimate Winifred's energy and protein needs based on her anthropometric data.
2. Considering Winifred's medical history, what does her laboratory report for hemoglobin, hematocrit, mean corpuscular volume, mean corpuscular hemoglobin, and mean corpuscular hemoglobin concentration suggest?
3. What does her laboratory report for total cholesterol, LDL, HDL and triglycerides values suggest?
4. What does her laboratory report for sodium, blood urea nitrogen and glucose suggest?
5. What additional laboratory tests would be helpful for a comprehensive nutrition assessment?

ALP, Alkaline phosphatase; ALT, alanine aminotransferase; AST, aspartate aminotransferase; BUN, blood urea nitrogen; CO₂, carbon dioxide; Hct, hematocrit; Hgb, hemoglobin; MCH, mean corpuscular hemoglobin; MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume; RBC, red blood cell; WBC, white blood cell.

Progression in the fields of medicine and pharmacology have led to the development of a wide variety of medications for various disease states and conditions. Drugs, by definition, are any chemicals that can affect living processes. Interactions between drugs and food can range from inconsequential to life-threatening. Toxicity can be related to alterations in drug levels within the body, leading to either increased or decreased efficacy.

The terms *drug-nutrient interaction* and *food-drug interaction* often are used interchangeably. In actuality, drug-nutrient interactions are a subsection of the many possible food-drug interactions. **Drug-nutrient interactions** include specific changes to the activity of a drug caused by a nutrient or nutrients, or changes to the kinetics of a nutrient caused by a drug. **Food-drug interaction** is a broader term that also includes the effects of a medication on nutritional status. For example, nutritional status may be affected by the side effects of a medication such as gastrointestinal effects (eg. dry mouth, stomatitis), appetite changes, metabolic effects (blood glucose or lipid abnormalities), or renal or urinary effects (retention, frequency, or acute renal failure).

For clinical, economic, and legal reasons, it is important to recognize and anticipate food-drug interactions. Food-drug interactions that reduce the efficacy of a drug can result in longer or repeated stays in health care facilities, disease progression and increased morbidity and mortality. **Polypharmacy**, or the use of four or more medications during a single time period, can potentiate the risks for food-drug interactions. See **Box 8-1** for other situations that put individuals at risk.

Medical team members should be aware of the positive and negative food-drug interactions, and being diligent to review medications and nutrients during every hospital admission,

outpatient office visit, and encounter with the patient. See **Box 8-2** for some potential benefits of minimizing drug interactions over time.

PHARMACOLOGIC ASPECTS OF FOOD-DRUG INTERACTIONS

Pharmacology is the study of drugs and their interactions with systems. Drugs are administered to produce a pharmacologic effect in a target organ or tissue. To achieve this goal, the drug must move from the site of administration into the bloodstream and eventually to the site of drug action. In due course, the drug may be changed to active or inactive metabolites, and ultimately is eliminated from the body. An interaction between the drug and food, a food component, or a nutrient can alter this process at any point.

Food-drug interactions are divided into two broad types: (1) pharmacodynamic interactions, which affect the activity at the site of action in the body; and (2) pharmacokinetic interactions, which affect the absorption, distribution, metabolism, and excretion of the drug.

Pharmacodynamics is the study of the biochemical and physiologic effects of a drug. The mechanism of action of a drug may include the binding of the drug molecule to a receptor, enzyme, or ion channel, resulting in the observable physiologic response. This response may be enhanced or attenuated by the addition of other substances with similar or opposing actions.

Pharmacokinetics is the study of the time course of a drug in the body involving the absorption, distribution, metabolism (biotransformation), and excretion of the drug, otherwise known as drug disposition, or “ADME” (**Figure 8-1**).

Absorption is the process of the movement of the drug from the site of administration to the bloodstream. This process depends on (1) the route of administration, (2) the

Sections of this chapter were written by Zaneta M. Pronsky, MS, RD, LDN, FADA and Sr. Jeanne P. Crowe, PharmD, RPh, RPI for previous editions of this text.

BOX 8-1 Individuals at Risk for Drug-Nutrient Interactions

Persons considered at higher risk for drug-nutrient interactions include:

- Those who have a poor diet
- Those who have serious health problems
- Growing children
- Pregnant women
- Older adults
- Patients taking two or more medications at the same time
- Those using prescription and over-the-counter medications together at the same time
- Patients not following medication directions
- Patients taking medications for long periods of time
- Those who drink alcohol or smoke excessively

From Hermann J: *Drug-nutrient interactions*, Oklahoma Cooperative Extension Service (website): <http://pods.dasnr.okstate.edu/docushare/dsweb/Get/Document-2458/T-3120web.pdf>. Accessed January 14, 2015.

BOX 8-2 Benefits of Minimizing Drug Interactions

- Medications achieve their intended effects.
- Patients do not discontinue their drug.
- The need for additional medication is minimized.
- Fewer caloric or nutrient supplements are required.
- Adverse side effects are avoided.
- Optimal nutritional status is preserved.
- Accidents and injuries are avoided.
- Disease complications are minimized.
- The cost of health care services is reduced.
- There is less professional liability.
- Licensing agency requirements are met.
- Prevention of nutrient deficiencies with long term use.

From Pronsky ZM et al: *Food-medication interactions*, ed 18, Birchrunville, PA, 2015, Food-Medication Interactions.

chemistry of the drug and its ability to cross biologic membranes, and (3) the rate of gastric emptying (for orally administered drugs) and gastrointestinal (GI) motility. Food, food components, and nutrition supplements can interfere with the absorption process, especially when the drug is administered orally.

Distribution occurs when the drug leaves the systemic circulation and travels to various regions of the body. Distribution varies based on the chemistry of the drug molecule. The rate and extent of blood flow to an organ or tissue strongly affect the amount of drug that reaches the sites. Many drugs are bound to plasma proteins such as albumin. The bound fraction of drug does not leave the vasculature and therefore does not produce a pharmacologic effect. Only the **unbound fraction**, medication that is not bound to plasma proteins, is able to produce an effect at a target organ (Figure 8-2).

A drug is eliminated from the body as either an unchanged drug or a metabolite of the original compound. The major organ of metabolism, or **biotransformation**, in the body is the liver, although other sites, such as the intestinal membrane, kidneys, and lungs, contribute to variable degrees of metabolism. One of the more important enzyme systems that facilitates drug metabolism is the **cytochrome P-450 enzyme system**. This is a multi-enzyme system in the smooth endoplasmic reticulum of numerous tissues that is involved in phase I of liver detoxification (see Focus On Box on Detoxification Chapter 19). Food or dietary supplements may either induce or inhibit the activity of this enzyme system, which can significantly alter the rate or extent of drug metabolism. The general tendency of the process of metabolism is to transform a drug from a lipid-soluble to a more water-soluble compound that can be handled more easily by the kidneys and excreted in the urine.

FIGURE 8-1 The four basic pharmacokinetic processes. Dotted lines represent membranes that must be crossed as drugs move throughout the body. (From Lehne et al: *Pharmacology of nursing care*, ed 8, St Louis, Missouri, 2012, Elsevier.)

FIGURE 8-2 Drug movement across the blood-brain barrier. Tight junctions between cells that compose the walls of capillaries in the CNS prevent drugs from passing between cells to exit the vascular system. Consequently, to reach sites of action within the brain, a drug must pass directly through cells of the capillary wall. To do this, the drug must be lipid soluble or be able to use an existing transport system. (From Lehne et al: *Pharmacology of nursing care*, ed 8, St Louis, 2012, Elsevier.)

Renal **excretion** is the major route of elimination for drugs and drug metabolites either by glomerular filtration or tubular secretion. To a lesser extent drugs may be eliminated in feces, bile, tears, breast milk, and other body fluids. Under certain circumstances, such as a change in urinary pH, drugs that have reached the renal tubule may pass back into the bloodstream. This process is known as **tubular reabsorption**. The recommended dose of a drug generally assumes normal liver and kidney function, although drug references have sections dedicated to medications that require dosage adjustments based on alterations in kidney function. The dose and dosing interval of an excreted drug or

active metabolite must be adjusted to meet the degree of renal and hepatic dysfunction in patients with kidney disease or hepatic disease (see Chapters 29 and 35; [Figure 8-3](#)).

RISK FACTORS FOR FOOD-DRUG INTERACTIONS

Patients must be assessed individually for the effect of food on drug action and nutrition status. Interactions can be caused or complicated by a multitude of patient specific variables, including polypharmacy, nutrition status, genetics, underlying illness, diet, nutrition supplements, herbal or phytonutrient products,

FIGURE 8-3 Factors that determine the intensity of drug responses. (From Lehne et al: *Pharmacology of nursing care*, ed 8, St Louis, 2012, Elsevier.)

FIGURE 8-4 As a result of the increased potential for illness with aging, older adults often take multiple drugs, both prescription and over-the-counter preparations. This places them at increased risk for drug-drug and food-drug interactions.

alcohol intake, drugs of abuse, gut microbiome, excipients in drugs or food, allergies, and intolerances. Poor patient compliance and physicians' prescribing patterns further complicate the risk. Drug-induced malnutrition occurs most commonly during long-term treatment for chronic disease (see [Focus On: Polypharmacy in Older Adults](#); [Figure 8-4](#)).

Existing malnutrition places patients at greater risk for drug-nutrient interactions. Protein alterations and changes in body composition secondary to malnutrition can affect drug disposition by altering protein binding and drug distribution. Patients

FOCUS ON

Polypharmacy in Older Adults

Older patients are more likely to take multiple drugs, prescription and over-the-counter, than are younger patients. They have a higher risk of food-drug interactions because of physical changes related to aging, such as the increase in the ratio of fat tissue to lean body mass, a decrease in liver mass and blood flow, and impairment of kidney function. Illness, cognitive or endocrine dysfunction, and ingestion of restricted diets also increase this risk. Malnutrition and dehydration affect drug kinetics. The use of herbal or phytonutrient products has increased significantly in all developed countries, including use by older adults. Drugs of abuse or excessive alcohol intake often are missed in the older patient.

Central nervous system side effects of drugs can interfere with the ability or desire to eat. Drugs that cause drowsiness, dizziness, ataxia, confusion, headache, weakness, tremor, or peripheral neuropathy can lead to nutritional compromise, particularly in older patients. Recognition of these problems as a drug side effect rather than a consequence of disease or aging can be overlooked.

Care must be taken to evaluate intake of interacting nutrients (in the oral diet, supplements, or tube feedings) when specific drugs are used. Examples are vitamin K with warfarin (Coumadin); calcium and vitamin D with tetracycline; and potassium, sodium, and magnesium with loop diuretics such as furosemide (Lasix). Patients with Parkinson disease may be concerned with the amount and timing of protein intake because of interaction with levodopa (Sinemet, Dopar). The interdisciplinary team, which includes the physician, pharmacist, nurse, and dietitian, must work together to plan and coordinate the medication regimen and diet and nutritional supplements to preserve optimal nutrition status and minimize food-drug interactions.

with active cancer or human immunodeficiency virus (HIV) infection who have significant anorexia and wasting are at special risk because of the high prevalence of malnutrition and reduced dietary intake. Treatment modalities such as chemotherapy and radiation also may exacerbate nutritional disturbances. For example, cisplatin (Platinol-AQ) and other cytotoxic agents commonly cause mouth sores, nausea, vomiting, diarrhea, anorexia, and thus reduced food intake. Many drugs have loss of appetite as a side effect. Drug disposition can be affected by alterations in the GI tract, such as vomiting, diarrhea, hypochlorhydria, mucosal atrophy, and motility changes. Malabsorption caused by intestinal damage from cancer, celiac disease, inflammatory bowel disease, or surgical removal of intestinal tissue for various reasons, creates greater potential for food-drug interactions. Body composition is another important consideration in determining drug response. In obese or older patients, the proportion of adipose tissue to lean body mass is increased. In theory, accumulation of fat-soluble drugs such as the long-acting benzodiazepines (e.g., diazepam [Valium]) is more likely to occur. Accumulation of a drug and its metabolites in adipose tissue may result in prolonged clearance and increased toxicity. In older patients this interaction may also be complicated by decreased hepatic and/or renal clearance of the drug.

The developing fetus, infant, and pregnant woman are also at high risk for drug-nutrient interactions. Many drugs have not been tested on these populations, making it difficult to assess the risks of negative drug effects, including food-drug interactions. Medications should be assessed for risk versus benefit with regard to the developing fetus.

Pharmacogenomics

Gene-nutrient interactions reflect the genetic heterogeneity of humans with diverse physiologies, in combination with unique environmental factors and dietary chemicals. Because the efficacy and safety disparity of drugs varies according to race and genetic variants, pharmacogenetic knowledge is important for the interpretation and prediction of drug interaction-induced adverse events.

Pharmacogenomics involves genetically determined variations that are revealed solely by the effects of drugs and can be a driver for nutrigenomics, as discussed in Chapter 5. Food-drug interaction ramifications are seen in glucose-6-phosphate dehydrogenase (G6PD) enzyme deficiency, slow inactivation of isoniazid (Nydrazid) or phenelzine (Nardil), and warfarin (Coumadin) resistance. Warfarin resistance affects individual requirements for and response to warfarin.

Slow inactivation of isoniazid, used in tuberculosis (TB), represents the effect of slow **acetylation**, a conjugation reaction that metabolizes and inactivates amines, hydrazines, and sulfonamides. "Slow acetylators" are persons who metabolize these drugs more slowly than average because of inherited lower levels of the hepatic enzyme acetyl transferase. Therefore unacetylated drug levels remain higher for longer periods in these persons than in those who are "rapid acetylators." For example, the **half-life** (the period of time required for the concentration or amount of drug in the body to be reduced to one-half of a given concentration or amount) of isoniazid for fast acetylators is approximately 70 minutes, compared to more than 3 hours for slow acetylators. A dose of drug prescribed normally for fast acetylators can be toxic for slow acetylators. Elevated blood levels of affected drugs in slow acetylators increase the potential

for food-drug interactions. Slow inactivation of isoniazid increases the risk of pyridoxine deficiency and peripheral neuropathy. Slow inactivation of phenelzine, a monoamine oxidase inhibitor (MAOI), increases the risk for hypertensive crisis if foods high in tyramine are consumed. See Chapter 26.

Deficiency of G6PD is an X-chromosome–linked deficiency of G6PD enzyme in red blood cells that can lead to neonatal jaundice, hemolytic anemia, or acute hemolysis. Most common in African, Middle Eastern, and Southeast Asian populations, it is also called *favism*. Intake of fava beans (broad beans), aspirin, sulfonamides, and antimalarial drugs can cause hemolysis and acute anemia in G6PD-deficient persons. The potential exists for food-drug interactions in G6PD deficiency resulting from the ingestion of fava beans, as well as vitamin C or vitamin K.

Another factor that affects drug metabolism is genetic variation of activity of the cytochrome P450 (CYP) enzymes. These enzymes are a group of 12 enzyme families that function in the metabolism of drugs. Therapeutic proteins affect the disposition of drugs that are metabolized by these enzymes (Lee et al, 2010). “Slow metabolizers” may have less of a specific enzyme or their enzymes may be less active. Such individuals have a higher risk of adverse drug effects, as there is an increase in the amount of unbound or active drug. Slow CYP2D6 metabolizers make up approximately 5% to 10% of whites, whereas approximately 20% of Asians are CYP2C19 poor metabolizers (Fohner et al, 2013). The nomenclature of CYP-Number-Letter-Number represents the various enzyme families. Tests are now available

to analyze the client’s DNA to determine variations in the activity of these two enzymes. The CYP2D6 and CYP2C19 enzyme systems are responsible for metabolizing approximately 25% of all drugs, including many antipsychotics, antidepressants, and narcotics. Slow metabolizers achieve a higher drug blood level with usual doses of such drugs, whereas fast metabolizers may have an unpredictable response as a result of rapid metabolism of the drug (Medical Letter, 2005).

Drug response genotyping helps to determine which drugs will be effective, depending on an individual’s genetic makeup (see Chapter 5). The ability to predict response to specific drugs determines more effective treatments for cancer, mental illness, and even pain management. Genotyping helps reduce adverse drug reactions, including food-medication interactions. This is a rapidly growing field, which will change the way medicine is practiced in the future, leading to the development of patient specific medications based on genotypes.

EFFECTS OF FOOD ON DRUG THERAPY

Drug Absorption

The presence of food and nutrients in the stomach or intestinal lumen may alter the absorption of a drug. **Bioavailability** describes the fraction of an administered drug that reaches the systemic circulation (Figure 8-5). If a medication is administered intravenously, its bioavailability is 100%, whereas bioavailability decreases with oral administration as absorption

FIGURE 8-5 Movement of drugs after GI absorption. All drugs absorbed from sites along the GI tract—stomach, small intestine, and large intestine (but not the oral mucosa or distal rectum)—must go through the liver, via the portal vein, on their way to the heart and then the general circulation. For some drugs, passage is uneventful. Others undergo extensive hepatic metabolism. Still others undergo *enterohepatic recirculation*, a repeating cycle in which a drug moves from the liver into the duodenum (via the bile duct) and then back to the liver (via the portal blood). As discussed in the text under *Enterohepatic Recirculation*, the process is limited to drugs that have first undergone hepatic glucuronidation. (From Lehne et al: *Pharmacology of nursing care*, ed 8, St Louis, 2012, Elsevier.)

and metabolism are incomplete. Examples of a critically significant reduction in drug absorption are the bisphosphonate drugs alendronate (Fosamax), risedronate (Actonel), or ibandronate (Boniva) used in the treatment of osteoporosis. Absorption is negligible if these drugs are given with food and reduced by 60% if taken with coffee or orange juice. The manufacturer's instructions for alendronate or risedronate are to take the drug on an empty stomach with plain water at least 30 minutes before any other food, drink, or other medication. Ibandronate must be taken at least 60 minutes before any other food, drink, or medication.

The absorption of the iron from supplements can be decreased by 50% if taken with food. Iron is better absorbed when taken with 8 oz of water on an empty stomach, although orange juice, because of its vitamin C content, actually can increase absorption by 85% when taken concurrently. If iron must be taken with food to avoid GI distress, it should not be taken with bran, eggs, high-phytate foods, fiber supplements, tea, coffee, dairy products, or calcium supplements, because each of these can decrease iron absorption.

Various mechanisms may contribute to the reduction in the rate or extent of drug absorption in the presence of food or nutrients. The presence and type of meal or food ingested influence the rate of gastric emptying. Gastric emptying may be delayed by the consumption of high-fiber or high-fat meals. In general, a delay in drug absorption is not clinically significant as long as the extent of absorption is not affected. However, delayed absorption of antibiotics or analgesics may be clinically significant.

Chelation reactions occur between certain medications and divalent or trivalent cations, such as iron, calcium, magnesium, zinc, or aluminum, where the absorption of drugs may be reduced. Chelation reactions are seen most commonly with tetracycline and fluoroquinolone antibiotics.

The Parkinson disease drug entacapone (Comtan) chelates with iron; therefore the iron must be taken 1 hour before or 2 hours after taking the drug. The fluoroquinolone antibiotics and tetracycline form insoluble complexes with calcium in dairy products or calcium-fortified foods and beverages, or supplements, or aluminum in antacids, thus preventing or reducing the absorption of drugs and nutrients (Pronsky and Crowe, 2012). The optimal approach to avoid this interaction is to stop non-critical supplements for the duration of the antibiotic prescription. If this is not possible, particularly with magnesium, or with long-term antibiotic use, the drug should be administered at least 2 hours before or 6 hours after the mineral.

Gastrointestinal pH is another important factor in the absorption of drugs. Any situations resulting in changes in gastric acid pH, such as achlorhydria or hypochlorhydria, may reduce drug absorption. An example of such an interaction is the failure of antifungal medication, ketoconazole (Nizoral), to clear a *Candida* infection in patients with HIV or in persons taking potent acid-reducing agents for gastroesophageal reflux disease (GERD). Ketoconazole achieves optimal absorption in an acid medium. Because of the high prevalence of achlorhydria in patients infected with HIV, dissolution of ketoconazole tablets in the stomach is reduced, leading to impaired drug absorption. This is also a concern with hypochlorhydria in persons receiving chronic acid suppression therapy, such as antacids, histamine-2 (H₂) receptor antagonists (e.g., famotidine [Pepcid]), or proton-pump inhibitors (e.g., omeprazole [Prilosec]). Ingestion of ketoconazole with an acidic liquid such as cola, cranberry juice, orange juice, or a dilute

hydrochloric acid (HCl) solution may improve bioavailability in these patients (Pronsky and Crowe, 2012).

The presence of food in the stomach enhances the absorption of some medications, such as the antibiotic cefuroxime axetil (Ceftin) or the antiretroviral drug saquinavir (Invirase). These drugs are prescribed to be taken after a meal to reduce the dose that must be taken to reach an effective level. The bioavailability of cefuroxime axetil is substantially greater when taken with food, compared with taking it in the fasting state.

MEDICATION AND ENTERAL NUTRITION INTERACTIONS

Continuous enteral feeding is an effective method of providing nutrients to patients who are unable to swallow or eat adequately. However, use of the feeding tube to administer medication can be problematic. When liquid medications are mixed with enteral formulas, incompatibilities may occur. Types of **physical incompatibility** include granulation, gel formation, and separation of the enteral product. This leads to clogged feeding tubes and interruption of delivery of nutrition to the patient. Examples of drugs that can cause granulation and gel formation are ciprofloxacin suspension (Cipro), chlorpromazine (Thorazine) concentrate, ferrous sulfate elixir, guaifenesin (Robitussin expectorant), and metoclopramide (Reglan) syrup (Wohlt et al, 2009).

Most compatibility studies of medication and enteral products have looked at the effect of the drug on the integrity of the enteral product, which in turn changes the bioavailability. This area requires much more research because feeding tube placement is now a common practice. Bioavailability problems are common with phenytoin (Dilantin) suspension and tube feeding. Because blood levels of phenytoin are performed routinely to monitor the drug, much information exists about the reduction of phenytoin bioavailability when given with enteral feedings. Stopping the tube feeding before and after the phenytoin dose generally is suggested; a 1-2-hour feeding-free interval before and after the dose of phenytoin is administered can be recommended safely and can vary based on hospital system policies.

Information may not be readily available concerning a drug and enteral product interactions, even though the manufacturer may have unpublished information about the drug's interaction with enteral products. Checking with the manufacturer's medical information department may yield more information.

Drug Distribution

Albumin is the most important drug-binding protein in the blood. Low serum albumin levels are often the result of acute and chronic inflammatory conditions, and the low albumin leads to fewer binding sites for highly protein-bound drugs. Fewer binding sites mean that a larger free fraction of drug is present in the serum. Only the free fraction (unbound fraction) of a drug is able to leave the vasculature and exert a pharmacologic effect at the target organ. Patients with albumin levels below 3 g/dl are at increased risk for adverse effects. Usual adult doses of highly protein-bound drugs in such persons may produce more pronounced pharmacologic effects than the same dose in persons with normal serum albumin levels. A lower dose of such drugs often is recommended for patients with low albumin levels. In addition, the risk for displacement of one drug from albumin-binding sites by another drug is greater when albumin levels are less than 3 g/dl.

The anticoagulant warfarin, which is 99.9% serum protein bound, and the anticonvulsant phenytoin, which is greater than 90% protein bound, are used commonly in older patients. Low albumin levels tend to be more common in older patients and in critically ill patients. In the case of warfarin, higher levels of free drug lead to risk of excessive anticoagulation and bleeding. Phenytoin toxicity can result from too high or low serum levels of free phenytoin, resulting in seizures.

Drug Metabolism

Enzyme systems in the intestinal tract and the liver, although not the only sites of drug metabolism, account for a large portion of the drug metabolizing activity in the body. Food can inhibit and enhance the metabolism of medication by altering the activity of these enzyme systems. A diet high in protein and low in carbohydrates can increase the hepatic metabolism of the asthma management drug theophylline (Theo-24), which leads to toxicity because theophylline has a narrow therapeutic window.

Conversely, components found in grapefruit (juice, segments, extract) and related citrus fruits (Seville oranges, tangelos, minneolas, pummelos, and certain exotic oranges) called *furanocoumarins* inhibit the cytochrome P-450 3A4 enzyme system responsible for the oxidative metabolism of many orally administered drugs (Pronsky and Crowe, 2012). The intestinal metabolism of drugs such as calcium channel blockers that are dihydropyridine derivatives (felodipine [Plendil]) and some 3-hydroxy-3-methylglutaryl (HMG)-coenzyme A (CoA) reductase inhibitors such as simvastatin (Zocor) are affected (Sica, 2006). This interaction appears to be clinically significant for drugs with low oral bioavailability, which are substantially metabolized and inactivated in the intestinal tract by the cytochrome P-450 3A4 enzyme in the intestinal wall. When grapefruit or grapefruit juice is ingested, the metabolizing enzyme is inhibited irreversibly, which reduces the normal metabolism of the drug. This reduction in metabolism allows more of the drug to reach the systemic circulation; the increase in blood levels of unmetabolized drug results in a greater pharmacologic effect and possible toxicity. Unfortunately, the effects of grapefruit on intestinal cytochrome P-450 3A4 last up to 72 hours. Therefore separating the ingestion of the grapefruit and the daily dose of drug does not appear to alleviate this interaction.

Competition between food and drugs such as propranolol (Inderal) and metoprolol (Lopressor) for metabolizing enzymes in the liver may alter the first-pass metabolism of these medications. The term **first-pass** refers to the hepatic inactivation of oral medications when they are given initially. Drugs absorbed from the intestinal tract by the portal circulation first are transported to the liver before they reach the systemic circulation. Because many drugs are metabolized during this first pass through the liver, only a small percentage of the original dose is actually available to the systemic circulation and the target organ. In some cases, however, this percentage can be increased by concurrent ingestion of food with the drug. When food and drug compete for the same metabolizing enzymes in the liver, more of the drug is likely to reach the systemic circulation, which can lead to a toxic effect if the dose titration occurs in a fasting state.

Drug Excretion

Food and nutrients can alter the reabsorption of drugs from the renal tubule. Reabsorption of the bipolar medication lithium (Lithobid) is associated closely with the reabsorption of sodium. Patients who are concurrently hyponatremic and taking lithium

are at risk for toxicity, as the body reabsorbs lithium instead of excreting it due to the similar molecular structure of sodium and lithium. Likewise, when excess sodium is ingested, the kidneys eliminate more sodium in the urine and more lithium. This produces lower lithium levels and possible therapeutic failure.

Drugs that are weak acids or bases are resorbed from the renal tubule into the systemic circulation only in the nonionic state, meaning that they are not carrying a charge. An acidic drug is largely in the nonionic state in urine with an acidic pH, whereas a basic drug is largely in a nonionic state in urine with an alkaline pH. A change in urinary pH by food may change the amount of drug existing in the nonionic state, thus increasing or decreasing the amount of drug available for tubular reabsorption. Foods such as milk, fruits (including citrus fruits), and vegetables are urinary alkalinizers (see the Clinical Insight box: Urinary pH—How Does Diet Affect It? in Chapter 35). This change can affect the ionic state of a basic drug such as the antiarrhythmic agent quinidine. In alkaline urine, quinidine is predominantly in the nonionic state and available for reabsorption from the urine into the systemic circulation, which may lead to higher blood levels. The excretion of memantine (Namenda), a drug used to treat neurodegenerative disorders, also is decreased by alkaline pH, thus raising the drug blood levels. Elevated drug levels may increase the risk of toxicity. This interaction is most likely to be clinically significant when the diet is composed exclusively of a single food or food group. Patients should be cautioned against initiating major diet changes without consulting their physician, dietitian nutritionist, or pharmacist.

Licorice, or glycyrrhizic acid, is an extract of glycyrrhiza root used in “natural” licorice candy. Approximately 100 g of licorice (the amount in two or more twists of natural licorice) can increase cortisol concentration, resulting in pseudohyperaldosteronism, which can lead to hypernatremia, water retention, increased blood pressure, and greater excretion of potassium, which can lead to hypokalemia and electrocardiographic changes. The action of diuretics and antihypertensive drugs may be antagonized. The resultant hypokalemia may alter the action of some drugs (Pronsky et al, 2015).

EFFECTS OF DRUGS ON FOOD AND NUTRITION

Many of the interactions discussed in this section are the opposite of those discussed previously in the Effects of Food on Drug Therapy. For instance, the chelation of a mineral with a medication not only decreases the absorption and therefore the action of the drug but also decreases the absorption and availability of the nutrient.

Nutrient Absorption

Medication can decrease or prevent nutrient absorption. Chelation reactions between medications and minerals (metal ions) reduce the amount of mineral available for absorption. An example is tetracycline and ciprofloxacin, which chelate calcium found in supplements or in dairy products such as milk or yogurt. This is also true for other divalent or trivalent cations such as iron, magnesium, and zinc found in individual mineral supplements or multivitamin-mineral supplements. Standard advice is to take the minerals at least 2 to 6 hours apart from the drug.

Drugs can reduce nutrient absorption by influencing the transit time of food and nutrients in the gut. Cathartic agents and laxatives reduce transit time and may cause diarrhea, leading to losses of calcium and potassium. Diarrhea may be induced by drugs containing sorbitol, such as syrup or solution

forms of furosemide (Lasix), valproic acid (Depakene), carbamazepine (Tegretol), trimethoprim/sulfamethoxazole (Bactrim). Drugs that increase peristalsis such as the gastric mucosa protectant misoprostol (Cytotec) or the hyperosmotic, lactulose (Enulose) can also lead to this unpleasant side effect.

Drugs can also prevent nutrient absorption by changing the GI environment. H₂-receptor antagonists, such as famotidine (Pepcid) or ranitidine (Zantac), and proton pump inhibitors (PPIs), such as omeprazole (Prilosec) or esomeprazole (Nexium), are antisecretory drugs used to treat ulcer disease and GERD. They inhibit gastric acid secretion and raise gastric pH. These effects may impair absorption of vitamin B₁₂ by reducing cleavage from its dietary sources. Cimetidine (Tagamet) is a H₂-receptor antagonist that also reduces intrinsic factor secretion, which can be problematic for vitamin B₁₂ absorption, resulting in vitamin B₁₂ deficiency with long-term use. The effect on calcium absorption of proton pump inhibitors may raise the risk of osteoporosis in at risk individuals, and the effect appears to be stronger with PPIs than with H₂-receptor antagonists. (Corley et al, 2010 and Kwok et al, 2011). Aside from these well-known concerns, a number of recent studies have also shown correlations between PPI therapy, Small Intestine Bacterial Overgrowth (SIBO), and IBS (Chey and Spiegel, 2010). Further studies of this type are needed to determine the long-term effects of chronic disruption in the gastric environment and its impact on gut health.

Drugs with the greatest effect on nutrient absorption are those that damage the intestinal mucosa. Damage to the structure of the villi and microvilli can inhibit the brush-border enzymes and intestinal transport systems involved in nutrient absorption. The result is varying degrees of specific malabsorption, which can alter the ability of the GI tract to absorb minerals, specifically iron and calcium. Damage to the gut mucosa commonly results from chemotherapeutic agents, nonsteroidal antiinflammatory drugs (NSAIDs), and long-term antibiotic therapy. NSAIDs may adversely affect the colon by causing a nonspecific colitis or by exacerbating a preexisting colonic disease (Tonolini, 2013). Patients with NSAID-induced colitis present with bloody diarrhea, weight loss, and iron deficiency anemia; the pathogenesis of this colitis is still controversial.

Drugs that affect intestinal transport mechanisms include (1) colchicine (Colcrys), an antiinflammatory agent used to treat gout; (2) sulfasalazine (Azulfidine), used to treat ulcerative colitis; (3) trimethoprim (antibiotic in sulfamethoxazole-trimethoprim [Bactrim]) and (4) antiprotozoal agent pyrimethamine (Daraprim). The colchicine impairs absorption of vitamin B₁₂, while the others are competitive inhibitors of folate transport mechanisms.

Nutrient Metabolism

Drugs may increase the metabolism of a nutrient, potentiating excretion and resulting in higher nutrient requirements. Drugs may cause vitamin antagonism by blocking conversion of a vitamin to the active form. Anticonvulsants phenobarbital and phenytoin induce hepatic enzymes and increase the metabolism of vitamins D, K, and folic acid. Supplementation of these vitamins often is prescribed with phenobarbital and phenytoin. Carbamazepine (Tegretol) has been reported to affect the metabolism of biotin, vitamin D, and folic acid, leading to possible depletion. Regular measurement of vitamin D levels and supplementation are recommended with carbamazepine.

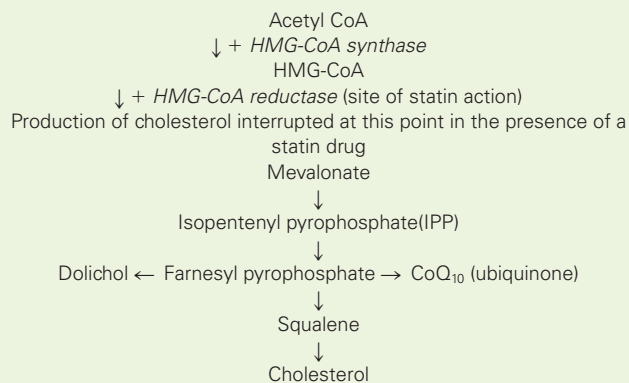

The anti-tuberculosis drug, isoniazid, blocks the conversion of pyridoxine (vitamin B₆) to its active form, pyridoxal

5-phosphate. Patients with low pyridoxine intake who are taking isoniazid may develop pyridoxine deficiency and peripheral neuropathy. Pyridoxal 5-phosphate supplementation (25 to 50 mg/day) generally is recommended with the prescription of isoniazid. Some other drugs that function as pyridoxine antagonists are hydralazine (Apresoline), penicillamine, levodopa (Dopar), and cycloserine (Seromycin).

Methotrexate (Rheumatrex) is a folic acid antagonist used in the treatment of ectopic pregnancies, cancer, and rheumatoid arthritis. Without folic acid, DNA synthesis is inhibited and cell replication stops, resulting in cell death. Pyrimethamine is used to treat HIV, malaria, and toxoplasmosis and is also a folic acid antagonist. Both methotrexate and pyrimethamine bind to and inhibit the enzyme dihydrofolate reductase, preventing conversion of folate to its active form, which can lead to megaloblastic anemia from folate deficiency (see Chapter 32). Leucovorin (folinic acid, the reduced form of folic acid) is used with folic acid antagonists to prevent anemia and GI damage, most commonly with high-dose methotrexate. Leucovorin does not require reduction by dihydrofolate reductase; thus, unlike folic acid, it is not affected by folic acid antagonists. Therefore leucovorin may “rescue” normal cells from methotrexate damage by competing for the same transport mechanisms into the cells. Administration of daily folic acid supplements or folinic acid can lower toxicity without affecting efficacy of the drug. Patients receiving methotrexate should be assessed for their folic acid status (see Chapter 7).

Statin drugs (HMG-CoA reductase inhibitors) such as atorvastatin (Lipitor) affect the formation of coenzyme Q₁₀ (CoQ₁₀; ubiquinone); See Box 8-3 on the mechanism of this effect. When HMG-CoA reductase is inhibited by statins, the production of cholesterol is decreased; a reasonable conclusion is that the production of CoQ₁₀ is also decreased. Studies have shown that circulatory, platelet, and lymphocyte levels of CoQ₁₀ are diminished. While initial small studies suggested that the muscle pain and weakness side effect of statins could be relieved by CoQ₁₀ supplementation, newer meta-analyses fail to show the same results, and conclude that more large-scale studies are needed (Banach et al, 2015). Overall, it is still considered prudent to advise CoQ₁₀ supplementation with 100 mg CoQ₁₀ daily for the purposes of repletion in patients taking HMG-CoA reductase inhibitors (Littarru and Langsojen, 2007).

BOX 8-3 Steps in the Hepatic Production of Cholesterol

CoA, Coenzyme A; CoQ₁₀, coenzyme Q₁₀; HMG, 3-hydroxy-3-methylglutaryl.

Nutrient Excretion

Some drugs either increase or decrease the urinary excretion of nutrients. Drugs can increase the excretion of a nutrient by interfering with nutrient reabsorption by the kidneys. For instance, loop diuretics including furosemide (Lasix) and bumetanide (Bumex) can increase the excretion of potassium while also increasing the excretion of magnesium, sodium, chloride, and calcium. Potassium supplements routinely are prescribed with loop diuretics, as hypokalemia can lead to serious cardiovascular toxicities. In addition, clinicians have to consider supplementation of magnesium and calcium, specifically with long-term or high doses of diuretics, or poor dietary intake. Electrolyte levels should be monitored for alterations.

Prolonged use of high-dose diuretics, particularly by older patients on low-sodium diets, can cause sodium depletion. Hyponatremia may be overlooked in older patients because the mental confusion that is symptomatic of sodium depletion may be misdiagnosed as organic brain syndrome or dementia. Thiazide diuretics such as hydrochlorothiazide (HCTZ) increase the excretion of potassium and magnesium, but reduce the excretion of calcium by enhancing renal reabsorption of calcium, although this is much less significant than with the loop diuretics.

Potassium-sparing diuretics such as spironolactone (Aldactone) or triamterene (Dyrenium) increase excretion of sodium, chloride, and calcium. Blood levels of potassium can rise to dangerous levels if patients also take potassium supplements or suffer from renal insufficiency. Antihypertensive angiotensin-converting enzyme (ACE) inhibitors such as enalapril (Vasotec) decrease potassium excretion, leading to increased serum potassium levels. The combination of a potassium-sparing diuretic and an ACE inhibitor increases the danger of hyperkalemia.

Corticosteroids such as prednisone decrease sodium excretion, resulting in sodium and water retention. Conversely, enhanced excretion of potassium and calcium is caused by these drugs; so a low-sodium, high-potassium diet is recommended.

Calcium and vitamin D supplements generally are recommended with long-term corticosteroid use to prevent osteoporosis. With corticosteroid use this risk is important because not only is calcium lost in the urine, but corticosteroids may also impair intestinal calcium absorption.

Phenothiazine-class antipsychotic drugs such as chlorpromazine (Thorazine) increase excretion of riboflavin and can lead to riboflavin deficiency in those with poor dietary intake. A complication associated with the use of anti-neoplastic drug, cisplatin, is the development of acute hypomagnesemia resulting from nephrotoxicity; hypocalcemia, hypokalemia, and hypophosphatemia are also common. Hypomagnesemia can result from cisplatin use even with high-dose magnesium replacement therapy. Magnesium level monitoring and repletion are essential for cardiovascular stability. Hypomagnesemia can persist for months or even years after the final course of cisplatin (See Appendix 23). Magnesium repletion is determined based on nutritional and cardiovascular status. If the patient is experiencing cardiovascular compromise then intravenous repletion is necessary, while patients with stable cardiac status may be repleted via oral methods.

MODIFICATION OF DRUG ACTION BY FOOD AND NUTRIENTS

Food or nutrients can alter the intended pharmacologic action of a medication by enhancing the medication effects or by opposing them. The classic example of an enhanced drug effect is the interaction between monoamine oxidase inhibitors (MAOIs) drugs such as phenelzine (Nardil) or tranylcypromine (Parnate) and **vasopressor agents**, such as dopamine, tyramine, (Figure 8-6). Other classes of medications including decongestants and antidepressants may also have similar properties. These biologically active amines are normally present in many foods (Box 8-4), but they rarely constitute a hazard because they are deaminated rapidly by monoamine oxidase (MAO) and diamine oxidase (DAO). Inhibition of MAO by medication prevents the

FIGURE 8-6 Mechanism of action of monoamine oxidase inhibitors. **A**, Under drug-free conditions, much of the norepinephrine or serotonin that undergoes reuptake into nerve terminals becomes inactivated by MAO. Inactivation helps maintain an appropriate concentration of transmitter within the terminal. **B**, MAO inhibitors prevent inactivation of norepinephrine and serotonin, thereby increasing the amount of transmitter available for release. Release of supranormal amounts of transmitter intensifies transmission. (From Lehne et al: *Pharmacology of nursing care*, ed 8, St Louis, 2012, Elsevier.)

BOX 8-4 Pressor Agents in Foods and Beverages (Tyramine, Dopamine, Histamine and Phenylethylamine)

Avoid with MAOI medications: phenelzine (Nardil), tranylcypromine (Par-nate), isocarboxazid (Marplan), selegiline (Eldepryl) in doses >10 mg/day, and the antibiotic linezolid (Zyvox)

Foods That Must Be Avoided

Aged cheeses (e.g., cheddar, blue, Gorgonzola, Stilton)
 Aged meats (e.g., dry sausage such as salami, mortadella, Chinese dried duck)
 Soy sauce
 Fermented soya beans, soya bean paste, teriyaki sauce
 Tofu/fermented bean curd, tempeh
 Miso
 Fava (broad) beans or pods, snow pea pods (contain dopamine)
 Sauerkraut, kim chee
 Tap beer, Korean beer
 Concentrated yeast extracts (Marmite, Vegemite)
 Banana peel
 Meats, fish, or poultry stored longer than 3-4 days in the refrigerator

Foods That May Be Used with Caution

Red or white wine 2-4 oz per day
 Coffee, cola*
 Pizza (homemade or gourmet pizzas may have higher content)
 Bottled beer, two 12-oz bottles, maximum

Alcohol-free beer, two 12-oz bottles, maximum
 Liquors or distilled spirits (two 1½-oz servings per day)

Foods Not Limited (Based on Current Analyses)

Unfermented cheeses (cream, cottage, ricotta, mozzarella, processed American if refrigerated less than 2-3 weeks)
 Smoked white fish, salmon, carp, or anchovies
 Pickled herring
 Fresh meat poultry or fish
 Canned figs, raisins
 Fresh pineapple
 Beetroot, cucumber
 Sweet corn, mushrooms
 Salad dressings, tomato sauce
 Worcestershire sauce
 Baked raised/yeast products, English cookies
 Boiled egg, yogurt, junket, ice cream
 Avocado, figs, banana, raspberries
 Brewer's yeast (vitamin supplements)
 Curry powder
 Peanuts, chocolate
 Packaged or processed meats (e.g., hot dogs, bologna, liverwurst), although they should be stored in refrigerator immediately and eaten as soon as possible; histamine content is highest in improperly stored or spoiled fish, tuna

MAOI, Monoamine oxidase inhibitor.

From Pronsky ZM et al: *Food medication-interactions*, ed 18, Birchrunville, Penn, 2015, Food-Medication Interactions.

*Contains caffeine, a weak pressor agent; in quantities >500 mg/day may exacerbate reactions

breakdown of tyramine and other vasopressor agents. Tyramine is a vasoconstrictor that raises blood pressure. Significant ingestion of high-tyramine foods such as aged cheeses and cured meats while being treated with an MAOI antidepressant can cause a hypertensive crisis and may lead to increased heart rate, flushing, headache, stroke, and even death. This reaction may be avoided with use of a transdermal administration method that bypasses the GI tract and omits contact with the indicated foods.

Caffeine in foods or beverages (see Appendix 33) increases the adverse effects of stimulant drugs such as amphetamines, methylphenidate (Ritalin), or theophylline, resulting in nervousness, tremor, and insomnia. Conversely, the central nervous system (CNS) stimulatory properties of caffeine can oppose or counteract the antianxiety effect of benzodiazepines such as lorazepam (Ativan).

Warfarin is an oral anticoagulant that reduces the hepatic production of four vitamin K–dependent clotting factors, II, VII, IX, and X, by inhibiting the conversion of vitamin K to a usable form. Because this is a competitive interaction, the ingestion of vitamin K in the usable form opposes the action of warfarin and allows the production of more clotting factors. To achieve an optimal level of anticoagulation, a balance must be maintained between the dose of the drug and the ingestion of vitamin K. Counseling of a person taking oral anticoagulation therapy should include nutrition therapy to maintain a *consistent* dietary vitamin K intake rather than prohibiting all high-vitamin K foods, such as dark green leafy vegetables (Pronsky and Crowe, 2012). CoQ₁₀, St. John's wort, green tea, and avocado also may counteract the effect of warfarin. Ingestion of other substances may enhance the anticoagulant effect of warfarin, including: onions, garlic, ginger, quinine, papaya, mango, or vitamin E supplements in doses greater than 400 IU. Certain herbal products, such as dong quai, which contain coumarin-like substances, or ginseng, which is a platelet inhibitor, also enhance the effect of the

warfarin. Enhancement of the anticoagulation effects of warfarin may lead to serious bleeding events.

Alcohol

Ethanol combined with certain medications can produce additive toxicities. Ethanol combined with CNS-depressant medications such as a benzodiazepine (e.g., diazepam) or a barbiturate (e.g., phenobarbital) may produce excessive drowsiness, incoordination, and other signs of CNS depression, including death.

In the GI tract ethanol acts as a stomach mucosal irritant. Combining ethanol with other mucosal irritants such as aspirin or other NSAIDs (ibuprofen [Advil or Motrin]) may increase the risk of GI ulceration and bleeding. Because of the hepatotoxic potential of ethanol, it should not be combined with other hepatotoxic medications such as acetaminophen (Tylenol), amiodarone (Cordarone), or methotrexate.

Ethanol can inhibit gluconeogenesis, particularly when consumed in a fasting state. Inhibition of gluconeogenesis prolongs a hypoglycemic episode caused by insulin or an oral hypoglycemic agent such as glyburide (Diabeta).

The combination of disulfiram (Antabuse) and ethanol produces a potentially life-threatening reaction characterized by flushing, rapid heartbeat, palpitations, and elevation of blood pressure. Disulfiram inhibits aldehyde dehydrogenase, an enzyme necessary for the normal catabolism of ethanol by the liver. As a result of this enzyme inhibition, high levels of acetaldehyde accumulate in the blood. Symptoms such as flushing, headache, and nausea appear within 15 minutes of alcohol ingestion. Because these symptoms are unpleasant, the drug is sometimes used as an aid to prevent alcoholics from returning to drinking. However, because these symptoms also may be life threatening, candidates for this drug must be chosen carefully. Other medications, when ingested concurrently with ethanol, may produce disulfiram-like reactions, including: the antibiotic metronidazole

(Flagyl), the oral hypoglycemic agent chlorpropamide (Diabinese), and the antineoplastic agent procarbazine (Matulane).

Ethanol also can affect the physical characteristics of a medication. The FDA required a change in the labeling of the extended-release capsules of morphine sulfate (Avinza) which now includes a black box warning that patients must not consume alcoholic beverages or take morphine sulfate with medications containing alcohol. **Black box warnings** are given to medications (and are required on their labels or package inserts to be “boxed”) with increased risks of adverse events and mortality. In the presence of alcohol, morphine can dissolve rapidly, delivering a potentially fatal dose, instead of the timed release mechanism of the medication.

EFFECTS OF DRUGS ON NUTRITION STATUS

The desired effects of medications often are accompanied by effects that are considered undesirable, or **side effects**. Side effects are often an extension of the desired effect. An example is the bacterial overgrowth that can occur from the use of an antibiotic that then results in pseudomembranous colitis (*Clostridium Difficile* or “*C.Diff.*”). Suppression of natural oral bacteria may lead to oral yeast overgrowth, or candidiasis (see Chapters 27 and 28).

Taste and Smell

Many drugs affect the ability to taste or smell foods (Box 8-5). Drugs can cause an alteration in taste sensation (dysgeusia), reduced acuity of taste sensation (hypogeusia), or an unpleasant aftertaste, any of which may affect food intake. The mechanisms by which drugs alter the chemical senses are not well understood. They may alter the turnover of taste cells, interfere with transduction mechanisms inside taste cells; or alter neurotransmitters that process chemosensory information. Common drugs that cause dysgeusia include the antihypertensive drug captopril (Capoten), the antineoplastic cisplatin, and the anticonvulsant phenytoin. When exploring taste changes related to medication use it is important to consider changes in zinc absorption related to the medication, as underlying zinc deficiency may affect the sense of taste.

BOX 8-5 Selected Examples of Drugs that Cause Altered Taste, or Dysgeusia

Antineoplastic Drugs	amiodarone (Pacerone)
carboplatin (Paraplatin)	gemfibrozil (Lopid)
cisplatin (Platinol-AQ)	
dactinomycin (Actinomycin-D)	Central Nervous System Drugs
fluorouracil (5-FU)	clomipramine (Anafranil)
interferon α -2a (Roferon-A)	eszopiclone (Lunesta)
interferon α -2b (Intron-A)	levodopa (Dopar)
methotrexate (Rheumatrex)	phenytoin (Dilantin)
oxaliplatin (Eloxatin)	phentermine (Adipex-P)
	sumatriptan (Imitrex)
Antiinfective Drugs	
cefuroxime (Ceftin)	Miscellaneous
clarithromycin (Biaxin)	disulfiram (Antabuse)
clotrimazole (Mycexel)	docusate (Colace)
metronidazole (Flagyl)	
Cardiovascular/ Antihyperlipidemic Drugs	
captopril (Capoten)	

From Pronsky ZM et al: Food-medication interactions, ed 18, Birchrunville, Penn, 2015, Food-Medication Interactions.

Box edits reviewed by Doris Dudley Wales, BA, BS, RPh.

Captopril may cause a metallic or salty taste and the loss of taste perception. The antibiotic clarithromycin (Biaxin) enters the saliva and has a bitter taste that stays in the mouth as long as the drug is present in the body. An unpleasant or metallic taste has been reported by up to 34% of patients taking the sleep aid eszopiclone (Lunesta).

Antineoplastic drugs, chemotherapy for cancer, affect cells that reproduce rapidly, including the mucous membranes. Inflammation of the mucous membranes, or mucositis, occurs and is manifest as stomatitis (mouth inflammation), glossitis (tongue inflammation), or cheilitis (lip inflammation and cracking). Mucositis can be extremely painful to the point that patients are not able to eat or even drink (see Chapter 36). Aldesleukin, also called interleukin-2 (Proleukin), paclitaxel (Taxol), and carboplatin are examples of antineoplastic agents that commonly cause severe mucositis.

Anticholinergic drugs compete with the neurotransmitter acetylcholine for its receptor sites, thereby inhibiting transmission of parasympathetic nerve impulses. This results in decreased secretions, including salivary secretions, causing dry mouth (xerostomia). Tricyclic antidepressants such as amitriptyline (Elavil), antihistamines such as diphenhydramine (Benadryl), and antispasmodic bladder control agents such as oxybutynin (Ditropan) are particularly problematic. Dry mouth immediately causes loss of taste sensation. Long-term dry mouth can cause dental caries and loss of teeth, gum disease, stomatitis, and glossitis, as well as nutritional imbalance and undesired weight loss (see Chapter 25).

Gastrointestinal Effects

GI irritation and ulceration are serious problems with many drugs. The osteoporosis medication, alendronate, is contraindicated in patients who are unable to sit upright for at least 30 minutes after taking it because of the danger of esophagitis. NSAIDs such as ibuprofen or aspirin can cause stomach irritation, dyspepsia, gastritis, ulceration, and sudden serious gastric bleeding, sometimes leading to fatalities. Fluoxetine (Prozac) and other selective serotonin reuptake inhibitors (SSRIs) also can cause serious gastric irritation, leading to hemorrhage, especially when aspirin or NSAIDs also are used (Box 8-6).

Antineoplastic drugs often cause severe nausea and vomiting. Severe, prolonged nausea and vomiting, lasting as long as a week and requiring hospitalization, have been reported with cisplatin and other chemotherapeutic medications. Dehydration and electrolyte imbalances are of immediate concern with nausea and vomiting. Weight loss and malnutrition are common long-term effects of these drugs, although it is often difficult to distinguish these effects from the complications of the disease itself (see Chapter 36). Serotonin antagonists such as ondansetron (Zofran) help to reduce these GI side effects, which decrease activity of the chemoreceptor trigger zone in the brain, thus reducing nausea and vomiting.

Drugs can cause changes in bowel function that can lead to constipation or diarrhea. Narcotic agents such as codeine and morphine cause a nonproductive increase in smooth muscle tone of the intestinal muscle wall, thereby decreasing peristalsis and causing constipation. Methylnaltrexone (Relistor) is a laxative, administered subcutaneously, and specifically indicated for severe opioid-induced constipation.

Drugs with anticholinergic effects can also cause GI distress by decreasing intestinal secretions, slowing peristalsis, and causing constipation. The atypical antipsychotics, tricyclic antidepressants, and antihistamines can cause constipation and

BOX 8-6 Selected Examples of Drugs that Cause Gastrointestinal Bleeding and Ulceration

Antiinfective Drugs

amphotericin B (Fungizone)
ganciclovir (Cytovene)

Antineoplastic Drugs

erlotinib (Tarceva)
fluorouracil (5-FU)
leuprolide (Lupron)
imatinib (Gleevec)
mitoxantrone (Novantrone)
methotrexate (Rheumatrex)
vinblastine (Velban)

Bisphosphonates

alendronate (Fosamax)
ibandronate (Boniva)
risedronate (Actonel)

Immunosuppressants

prednisone (Deltasone)
myophenolate (CellCept)

Central Nervous System Drugs

bromocriptine (Parlodel)
donepezil (Aricept)
fluoxetine (Prozac)
levodopa (Dopar)
paroxetine (Paxil)
sertraline (Zoloft)
trazodone (Desyrel)

NSAIDs, Analgesic, Antiarthritic Drugs

aspirin/salicylate (Bayer)

possibly impaction. Patients on any of these drugs should be monitored closely and kept adequately hydrated.

Some drugs are used to inhibit intestinal enzymes, such as the diabetic drugs acarbose (Precose) and miglitol (Glyset), which are α -glucosidase inhibitors. These medications lead to a delayed and reduced rise in postprandial blood glucose levels and plasma insulin responses. The major adverse effect is GI intolerance, specifically diarrhea, flatulence, and cramping secondary to the osmotic effect and bacterial fermentation of undigested carbohydrates in the distal bowel.

The use of antibiotics and particularly broad-spectrum antibiotics, when taken for long periods of time, destroy all sensitive bacteria of the gut flora and often lead to diarrhea (Box 8-7). Opportunistic intestinal flora that are not sensitive to the antibiotic continue to grow because they are no longer inhibited by the bacteria that have been destroyed. An example of this situation is the overgrowth of *Clostridium difficile*, causing pseudomembranous colitis, which is associated with very strong-smelling yellow diarrhea and can lead to death or serious morbidity (see Chapter 28). Administration of a probiotic containing healthy bacteria for the gastrointestinal tract, such as lactobacillus and bifidus, should be considered with antibiotic therapy. Recent meta-analyses have shown that using probiotics concurrently with antibiotics can reduce the risk of antibiotic associated diarrhea and *C.Diff* infections (Pattani et al, 2013) (see Chapter 28).

Appetite Changes

Drugs can suppress appetite (Box 8-8), leading to undesired weight changes, nutritional imbalances, and impaired growth in children. In the past the stimulant drug dextroamphetamine (Dexedrine) was used as an appetite suppressant.

In general, most CNS stimulants, including the amphetamine mixture (Adderall) and methylphenidate (Ritalin), suppress appetite or cause anorexia. These drugs are used extensively to

treat ADHD and may cause weight loss and inhibit growth (see Chapter 44).

Side effects of CNS stimulant drugs such as these include: hypertension, chest pain, and lowering of the seizure threshold. Use is contraindicated in hypertensive patients or those who have seizures or cardiac disease.

CNS side effects can interfere with the ability or desire to eat. Drugs that cause drowsiness, dizziness, ataxia, confusion, headache, weakness, tremor, or peripheral neuropathy can lead to nutritional compromise, particularly in older or chronically ill patients. Recognition of these problems as a drug side effect rather than a consequence of disease or aging is often overlooked, particularly in the elderly, who may instead be misdiagnosed with dementia (see Chapter 41).

Many medications stimulate appetite and cause weight gain (Box 8-9). Antipsychotic drugs such as clozapine and olanzapine (Zyprexa), tricyclic antidepressant drugs such as amitriptyline, and the anticonvulsant divalproex (Depakote) often lead to weight gain. Patients complain of a ravenous appetite and the inability to “feel full.” Weight gains of 40 to 60 lb in a few months are not uncommon. Corticosteroid use is also associated with dose-dependent weight gain in many patients. Sodium and water retention, as well as appetite stimulation, cause weight increases with corticosteroids. Medical nutrition therapy (MNT) is essential, as is routine exercise while taking these medications (see Chapter 21).

Appetite stimulation is desirable for patients suffering from wasting (cachexia) resulting from disease states such as cancer, HIV, or the acquired immunodeficiency (AIDS) virus. Drugs indicated as appetite stimulants include the hormone megestrol acetate (Megace), antidepressant mirtazapine (Remeron), human growth hormone somatropin (Serostim), the anabolic steroid oxandrolone (Oxandrin), and the marijuana derivative dronabinol (Marinol).

With the successful advent of highly active antiretroviral therapy (HAART) for HIV infections, lipodystrophy is a common side effect from the therapy. Redistribution of body fat, fat wasting, glucose intolerance, hypertension, and hyperlipidemia are common side effects from antiviral medications. Antidiabetic

drugs such as metformin (Glucophage) and rosiglitazone (Avandia) are used to normalize glucose and insulin levels in patients receiving HAART. Antihyperlipidemic drugs such as atorvastatin (Lipitor), pravastatin (Pravachol), and fenofibrate (Tricor) are used to control elevated triglycerides and cholesterol and may assist in the treatment of HAART associated adverse drug reactions (see Chapter 37).

Organ System Toxicity

Drugs can cause specific organ system toxicity. MNT may be indicated as part of the treatment of these toxicities. Although all toxicities are of concern, hepatotoxicity and nephrotoxicity are addressed here as the liver and kidneys are common elimination pathways for most medications.

Examples of drugs that cause hepatotoxicity (liver damage) including hepatitis, jaundice, hepatomegaly, or even liver failure include amiodarone, amitriptyline, antihyperlipidemic drugs, divalproex, carbamazepine (Tegretol), and methotrexate. Monitoring of hepatic function through routine blood work for liver enzyme levels generally is prescribed with use of these drugs (see Appendix 22 and Chapter 7). Toxicity related to liver failure can increase the amount of free drug and lead to toxicity from the medication as well.

Nephrotoxicity (kidney damage) may change the excretion of specific nutrients or cause acute or chronic renal insufficiency, which may not resolve with cessation of drug use. Examples of drugs that cause nephrotoxicity are antiinfectives amphotericin B (intravenous desoxycholate form [Fungizone]) and cidofovir (Vistide), antineoplastics cisplatin, gentamicin (Garamycin), ifosfamide (Ifex), methotrexate, and pentamidine. Hydration before drug infusion via intravenous administration can prevent renal toxicity. For example, with cidofovir, 1 L of intravenous normal saline (0.9% sodium chloride [NaCl]) is infused 1 to 2 hours before infusion of the drug. If tolerated, up to an additional liter may be infused after the drug infusion. Oral probenecid also is prescribed with cidofovir to reduce nephrotoxicity; this allows a dose reduction via increased contact with the gastrointestinal mucosa.

Glucose Levels

Many drugs affect glucose metabolism, causing hypoglycemia or hyperglycemia and in some cases diabetes (Box 8-10). The mechanisms of these effects vary. Drugs may stimulate glucose production or impair glucose uptake. They may inhibit insulin secretion, decrease insulin sensitivity, or increase insulin clearance.

Glucose levels may be altered related to medication use such as hypokalemia induced by thiazide diuretics or weight gain induced by antipsychotic medications (Izzedine et al, 2005). Corticosteroids, particularly prednisone, prednisolone, and hydrocortisone, may increase blood glucose because of increased gluconeogenesis, but they also cause insulin resistance and therefore inhibit glucose uptake. Second-generation antipsychotics, particularly clozapine or olanzapine, have been reported to cause hyperglycemia. Recently the FDA added a labeling requirement on all second-generation antipsychotics to warn of the possibility of developing hyperglycemia and diabetes.

EXCIPIENTS AND FOOD-DRUG INTERACTIONS

An **excipient** is added to drug formulations for its action as a buffer, binder, filler, diluent, disintegrant, glidant, flavoring,

BOX 8-11 Examples of Potential Interactive Drug Excipients

Albumin (egg or human): May cause allergic reaction. Human albumin is a blood product.

Alcohol (ethanol): CNS depressant used as a solvent. All alcohol and alcohol-containing products and drugs must be avoided with medications such as disulfiram (Antabuse) or limited with other drugs to prevent additive CNS or hepatic toxicity. Most elixirs contain 4% to 20% alcohol. Some solution, syrup, liquid, or parenteral forms contain alcohol.

Aspartame: A nonnutritive sweetener composed of the amino acids aspartic acid and phenylalanine. Patients with PKU lack the enzyme phenylalanine hydroxylase. If patients with PKU ingest aspartame in significant quantities, accumulation of phenylalanine causes toxicity to brain tissue.

Benzyl alcohol: A bacteriostatic agent used in parenteral solutions that can cause allergic reactions in some people. It has been associated with a fatal "Gasping Syndrome" in premature infants.

Caffeine: A member of the methylxanthine family of drugs which are CNS and heart muscle stimulants, cerebral vasoconstrictors and diuretics. Coffee, green and black teas, guarana, mate and cola nut are sources of caffeine and may affect medication action.

Lactose: Lactose is used as a filler. The natural sugar in milk, lactose is hydrolyzed in the small intestine by the enzyme lactase to glucose and galactose. Lactose intolerance (caused by lactase deficiency) results in gastrointestinal distress when lactose is ingested. Lactose in medications may cause this reaction.

Licorice (glycyrrhizic acid): Natural extract of glycyrrhiza root used in "natural" black licorice candy. Two or more twists per day (about 100 gm) of natural (usually imported), can increase cortisol concentration resulting in pseudohyperaldosteronism and increased sodium reabsorption, water retention, and K excretion and increased blood pressure. It antagonizes the action of diuretics and antihypertensives. The resultant hypokalemia may alter the action of some drugs.

Maltodextrin: In the US it is considered to be gluten-free since it can only be manufactured from corn.

Mannitol: The alcohol form of the sugar mannose, used as a filler. Mannitol is absorbed more slowly, yielding half as many calories per gram as glucose. Because of slow absorption, mannitol can cause soft stools and diarrhea.

Oxalate: A salt or ester of oxalic acid. Oxalate-containing foods must be avoided with some minerals due to formation of nonabsorbable complexes or oxalate kidney stones.

Phytate (phytic acid): Phosphorus-containing compound found in the outer husks of cereal grains. Amount of phosphate increases with maturity of the seed or grain. Phytate containing foods need to be avoided with some minerals (Ca, Fe, Mg, Zn) due to formation of nonabsorbable complexes.

Saccharin: Nonnutritive sweetener. Extensive human research has found no evidence of carcinogenicity.

Sorbitol: The alcohol form of sucrose. Absorbed more slowly than sucrose, sorbitol inhibits the rise in blood glucose. Because of slow absorption, sorbitol can cause soft stools or diarrhea.

Starch: Starch from wheat, corn, or potato is added to medication as a filler, binder, or diluent. Celiac disease patients have a permanent intolerance to gluten, a protein in wheat, barley, rye, and a contaminant of oat. In celiac disease, gluten causes damage to the lining of the small intestine.

Sulfites: Sulfiting agents are used as antioxidants. Sulfites may cause severe hypersensitivity reactions in some people, particularly asthmatics. They include sulfur dioxide, sodium sulfite, and sodium and potassium metabisulfite. The FDA requires the listing of sulfites when present in foods or drugs.

Tartrazine: Tartrazine is a yellow dye No. 5 color additive, which causes severe allergic reactions in some people (1 in 10,000). The FDA requires the listing of tartrazine on labels when present in foods or drugs.

Tyramine and other pressor agents (dopamine, phenethylamine, histamine): Tyramine is the decarboxylated product of the amino acid tyrosine. It is a vasoconstrictor which, in combination with some drugs such as monoamine oxidase inhibitors (MAOI), may cause a hypertensive crisis evidenced by dangerous increases in blood pressure, increased heart rate, flushing, headache, stroke and death. It is highest in aged, fermented or spoiled foods. See Chapter 26.

Vegetable oil: Soy, sesame, cottonseed, corn, or peanut oil is used in some drugs as solvent or vehicle. Hydrogenated vegetable oil is a tablet or capsule lubricant. May cause allergic reactions in sensitive people.

Modified from Pronsky ZM et al: *Food-medication interactions*, ed 18, Birchrunville, Penn, 2015, Food-Medication Interactions. CNS, Central nervous system; FDA, Food and Drug Administration; PKU, phenylketonuria.

dye, preservative, suspending agent, or coating. Excipients are also called *inactive ingredients* (Box 8-11). Hundreds of excipients are approved by the FDA for use in pharmaceuticals. Several common excipients have potential for interactions in persons with an allergy or enzyme deficiency. Often just one

brand of a drug or one formulation or strength of a particular brand may contain the excipient of concern. For example, tartrazine, listed as yellow dye no. 5, is used in a brand of clindamycin (Cleocin) capsules in the 75- and 150-mg strengths but not in the 300-mg strength. Certain formulations of the same

medication in different dosage strengths may have different excipients, including lactose, peanuts, and lecithin. Micronized progesterone (Prometrium) capsules contain peanut oil and lecithin, whereas other progesterone forms do not. Micronized progesterone labeling includes a warning that anyone allergic to peanuts should not use the drug.

Lactose is used commonly as a filler in many pills and capsules. The amount of lactose may be significant enough to cause GI problems for lactase-deficient patients, particularly those on multiple drugs throughout the day (see Chapter 28). Product information on prescription drugs and labeling on OTC drugs contain information on excipients, usually called “inactive ingredients,” including lactose.

Patients with celiac disease have gluten sensitivity and must practice lifelong abstinence from wheat, barley, rye, and oats (which may be contaminated with gluten; see Chapter 28). They are concerned particularly with the composition and source of excipients such as wheat starch or flour, which may contain gluten. Only a few pharmaceutical companies guarantee their products to be gluten free. Excipients such as dextrin and sodium starch glycolate usually are made from corn and potato, respectively, but can be made from wheat or barley. For example, the excipient dextrimaltose, a mixture of maltose and dextrin, is produced by the enzymatic action of barley malt on corn flour (Pronsky and Crowe, 2012). The source of each drug ingredient, if not specified, should be checked with the manufacturer.

Finally, some drug brands may contain enough excipient to be nutritionally significant (see Table 8-1), magnesium in quinapril (Accupril), calcium in calcium polycarbophil (Fibercon), and soybean oil lipid emulsion in propofol (Diprivan). Propofol is used commonly for sedation of patients in the intensive care unit. Its formulation includes 10% emulsion, which contributes 1.1 kcal/mL. When infused at doses up to 9 mg/kg/hr in a patient weighing 70 kg, for instance, it may contribute an additional 1663 kcal/day from the emulsion and enteral and/or parenteral goals must be adjusted accordingly. For a patient receiving total parenteral nutrition, limiting the use of long-chain fatty acids and using medium-chain

triglyceride (MCT) oil may also be recommended while taking propofol and triglyceride levels must be monitored closely. Specific brands or formulations of a specific brand provide significant amounts of sodium and therefore may be contraindicated for patients who need to limit sodium.

MEDICAL NUTRITION THERAPY

Medical nutrition therapy (MNT) can be divided into prospective and retrospective care.

Prospective Medical Nutrition Therapy

Prospective MNT occurs when the patient first starts a drug. A diet history must be obtained, including information about the use of OTC (nonprescription) drugs, alcohol, vitamin and mineral supplements, and herbal or phytonutrient supplements. The patient should be evaluated for genetic characteristics, weight and appetite changes, altered taste, and GI problems (see Chapter 4).

Prospective drug MNT provides basic information about the drug: the name, purpose, and duration of prescription of the drug including when and how to take the drug. This information includes whether to take the drug with or without food. Specific foods and beverages to avoid while taking the drug, and potential interactions between drug and vitamin or mineral supplements must be emphasized. For instance, the patient taking tetracycline or ciprofloxacin should be warned not to combine the drug with milk, yogurt, or supplements containing divalent cations, calcium, iron, magnesium, zinc, or vitamin-minerals containing any of these cations.

Potential significant side effects must be delineated, and possible dietary suggestions to relieve the side effects should be described. For instance, information about a high-fiber diet with adequate fluids should be part of MNT about an anticholinergic drug such as oxybutynin, which often causes constipation. Conversely, diarrhea can be controlled by the use of psyllium (Metamucil) or probiotics, such as *Lactobacillus acidophilus*, particularly for antibiotic-associated diarrhea, even in children. However, probiotics are contraindicated for some individuals such as those with pancreatitis and should be

TABLE 8-1 Examples of Drugs That Contain Nutritionally Significant Ingredients

Trade Name	Generic Name	Ingredient	Nutritional Significance
Accupril	Quinapril	Magnesium carbonate Magnesium stearate	Provides 50-200 mg magnesium daily
Accutane	Isotretinoin	Drug is related to vitamin A; contains soybean oil	Avoid vitamin A or β -carotene May cause allergic reaction
Atrovent (inhaler)	Ipratropium bromide	Soya lecithin	May cause allergic reaction
Fibercon/ Fiber-Lax	Calcium polycarbophil	Calcium polycarbophil	100 mg Ca/tablet; up to 6 tablets/day = 600 mg calcium total
Marinol	Dronabinol	Sesame oil	May cause allergic reaction
Phazyme	Simethicone	Soybean oil in capsule	May cause allergic reaction
Prometrium	Micronized progesterone	Peanut oil	May cause allergic reaction
Diprivan	Propofol	10% soybean oil emulsion Egg yolk phospholipids	Oil is significant caloric source, providing 1.1 kcals/mL of drug May cause allergic reaction
Videx	Didanosine	Sodium buffer in powder	≥ 2760 mg Na/adult daily dose
Zantac	Ranitidine	Sodium in <i>prescription</i> granules and tablets; Zantac 75 (nonprescription) is sodium free	350-730 mg Na/adult daily dose

Data from Pronsky ZM & Crowe JP: *Food-medication interactions*, ed 16, Birchrunville, Penn, 2010, Food-Medication Interactions.

prescribed and monitored by the physician. A commonly prescribed probiotic contains the yeast *Saccharomyces boulardii*. It should not be used in any patient with a central line for intravenous therapy, including those on dialysis.

Patients should be warned about potential nutritional problems, particularly when dietary intake is inadequate, such as hypokalemia with a potassium-depleting diuretic. Dietary changes that may alter drug action should be included, such as the effect of an increase in foods high in vitamin K on warfarin action. Special diet information, such as an anti-inflammatory, limited-sugar diet that includes healthy fats with atorvastatin (Lipitor) or other antihyperlipidemic drugs, is essential information. Written information should list medication ingredients such as nonnutrient excipients in the medication. Examples include lactose, starch, tartrazine, aspartame, and alcohol. Patients with lactose intolerance, celiac disease, allergies, phenylketonuria, or alcoholism need to avoid or limit one or more of these ingredients.

Prospective MNT also should cover potential concerns with OTC drugs and herbal and natural products. The pharmacokinetic and pharmacodynamic interactions explained in this chapter occur with all medications, whether obtained by prescription, OTC, or as natural or herbal products.

Retrospective MNT evaluates symptoms to determine whether medical problems or nutritional deficiencies may be

the result of food-drug interactions. To determine whether a patient's symptoms are the result of a food-drug interaction, a complete medical and nutrition history is essential, including prescription and nonprescription drugs, vitamin-mineral supplements, and herbal or phytonutrient products (see Chapter 4). The date of beginning to take the drugs versus the date of symptom onset is significant information. It is important to identify the use of nutrition supplements or significant dietary changes such as fad diets during the course of drug prescription. Finally, the reported incidence of side effects (by percentage compared with a placebo) must be investigated. For example, vomiting occurs in 1.5% of those taking omeprazole (Prilosec) compared with 4.7% of those taking a placebo. Therefore in a patient treated with omeprazole, it would be appropriate to consider other causes for vomiting. A rare drug effect is less likely to be the reason for a negative symptom than an effect that is common.

In summary, although food provides energy for sustenance and physiologic benefits for good health, and drugs prevent or treat many diseases, together the synergistic effects can be very positive. The medical nutrition therapist must assess, intervene, and evaluate the mixtures with care. As always, working in collaboration with each patient's medical team, including physicians and pharmacists, ensures provision of the highest quality care.

CLINICAL SCENARIO

Charles is a 29-year-old man who began to suffer seizures after a head trauma injury from a motorcycle accident at the age of 18. For the first 2 years after the accident, he was prescribed various anticonvulsant regimens. The combination of phenytoin (Dilantin), 300 mg daily, and phenobarbital, 120 mg daily, has proven to be the most effective therapy to control his seizures. Charles has been stabilized on this regimen for the last 11 years.

Charles is a senior computer programmer for a large corporation. He is 6 feet 2 inches tall and weighs 187 lb. He admits to having an aversion for exercise and athletics. In his free time, he enjoys reading, playing computer games, and watching television. During the past year, Charles has broken his left femur and tibia on two separate occasions. He broke his femur when he missed the bottom step on the stairway in his office building. Several months later he broke his tibia when he tripped over a broken branch in his yard. Charles recently complained to his orthopedic surgeon about hip and pelvic pain of several weeks' duration. An orthopedic examination with x-ray examination, bone scan, and DXA scan revealed that Charles is suffering from osteomalacia. A review of Charles

typical diet reveals a nutritionally marginal diet that commonly includes fast foods and frozen dinners. His diet is generally deficient in fresh fruits, vegetables, and dairy products.

Nutrition Diagnostic Statement

Food-medication interaction related to inadequate calcium and vitamin D intake while taking anticonvulsant medications as evidenced by osteomalacia.

Nutrition Care Questions

1. Is osteomalacia common in young men?
2. How does Charles' lifestyle contribute to the development of osteomalacia?
3. What vitamin or mineral deficiency may have contributed to the current state of Charles' bones?
4. Describe the food-drug interaction that has contributed to Charles' osteomalacia.
5. What medical nutritional therapy would you recommend for Charles?

Food Safety and Inspection Service (FSIS)	pandemic	tertiary prevention
foodborne illness	policy development	U.S. Department of Health and Human Services (USDHHS)
food security	primary prevention	What We Eat in America
genetically modified organisms (GMOs)	public health assurance	

Community nutrition is a constantly evolving and growing area of practice with the broad focus of serving the general population. Although this practice area encompasses the goals of public health, in the United States the current model has been shaped and expanded by prevention and wellness initiatives that evolved in the 1960s. Because the thrust of community nutrition is to be proactive and responsive to the needs of the community, current emphasis areas include access to a nutritionally adequate and safe food supply along with disaster and **pandemic** control, food and water safety, and controlling environmental risk factors related to obesity and other health risks. Food safety has entered the public health picture in new ways. Although traditional safety concerns continue to exist, potential safety issues such as genetic modification of the food supply is a new and growing concern and must be recognized as a part of community nutrition. (See *Focus On: GMO or Genetically Engineered (GE) Foods* in Chapter 26.)

Historically public health was defined as “the science and art of preventing disease, prolonging life, and promoting health and efficiency through organized community effort”. The public health approach, also known as a *population-based* or *epidemiologic* approach, differs from the clinical or patient care model generally seen in hospitals and other clinical settings. In the public health model the client is the community, a geopolitical entity. The focus of the traditional public health approach is **primary prevention** with health promotion, as opposed to **secondary prevention** with the goal of risk reduction, or **tertiary prevention** with rehabilitation efforts. Changes in the health care system, technology, and attitudes of the nutrition consumer have influenced the expanding responsibilities of community

nutrition providers. Growing involvement in and access to technology, especially social media, has framed new opportunities and challenges in public health and community nutrition.

In 1988 the Institute of Medicine published a landmark report that promoted the concept that the scope of community nutrition is a work in progress. This report defined a mission and delineated roles and responsibilities that remain the basis for community nutrition practice. The scope of community-based nutrition encompasses efforts to prevent disease and promote positive health and nutritional status for individuals and groups in settings where they live and work. The focus is on well-being and quality of life. “Well-being” goes beyond the usual constraints of physical and mental health and includes other factors that affect the quality of life within the community. Community members need a safe environment and access to housing, food, income, employment, and education. The mission of community nutrition is to promote standards and conditions in which people can be healthy.

SOCIAL DETERMINANTS OF HEALTH

The **social determinants of health** are the conditions in which people are born, grow, live, work, and age. These circumstances are shaped by the distribution of money, power, and other resources at global, national, and local levels. A summary report of conditions throughout the world, including the United States, by the World Health Organization (WHO) describes how stress, social exclusion, working conditions, unemployment, social support, addiction, quality of the food, and transport affect

opportunities (WHO, 2011). The report describes how people with fewer economic resources suffer from more acute and chronic disease and ultimately have shorter lives than their wealthier counterparts. This disparity has drawn attention to the remarkable sensitivity of health to the social environment, including psychological and social influences, and how these factors affect physical health and longevity. The report proposes that public policy can shape a social environment, making it more conducive to better health for all. Although it is a challenging task, if policy makers and advocates focus on policy and action for health needs to address the social determinants of health, the stage can be set for attacking the causes of ill health before they lead to problems (WHO, 2011; Wilkinson and Marmot, 2011).

Programming and services can be for any segment of the population. The program or service should reflect the diversity of the designated community, such as the politics, geography, culture, ethnicity, ages, genders, socioeconomic issues, and overall health status. Along with primary prevention, community nutrition provides links to programs and services with goals of disease risk reduction and rehabilitation.

In the traditional model, funding sources for public health efforts were monies allocated from official sources (government) at the local, state, or federal level. Currently nutrition programs and services are funded alone or from partnership between a broad range of sources, including public (government), private, and voluntary health sectors. As public source funding has declined, the need for private funding has become more crucial. The potential size and diversity of a designated “community” makes collaboration and partnerships critical, because a single agency may be unable to fund or deliver the full range of services. In addition, it is likely that the funding will be for services or product (in-kind) rather than cash. Creative funding and management skills are crucial for a community nutrition practitioner.

NUTRITION PRACTICE IN THE COMMUNITY

Nutrition professionals recognize that successful delivery of food and nutrition services involves actively engaging people in

their own community. The pool of nutrition professionals delivering medical nutrition therapy (MNT) and nutrition education in community-based or public health settings continues to expand. An example of community growth is the presence of registered dietitians (RD), registered dietitian nutritionists (RDN), and other health professionals in for-profit or retail settings such as supermarkets, big-box stores, or pharmacies as well as in gyms and fitness-oriented clubs.

The objectives of *Healthy People 2020* offer a framework of measurable public health outcomes that can be used to assess the overall health of a community. Although the settings may vary, there are three core functions in community nutrition practice: (1) community needs assessment, (2) policy development, and (3) public health assurance. These areas are also the components of community nutrition practice, especially community needs assessment as it relates to nutrition. The findings of these needs assessments shape policy development and protect the nutritional health of the public.

Although there is shared responsibility for completion of the core functions of public health, official state health agencies have primary responsibility for this task. Under this model, state public health agencies, community organizations, and leaders have responsibility for assessing the capacity of their state to perform the essential functions and to attain or monitor the goals and objectives of *Healthy People 2020*.

A Framework for Public Health Action: Friedan's Pyramid

Local health agencies are charged with protecting the health of their population groups by ensuring that effective service delivery systems are in place. In 2010 Dr. Thomas Frieden, MD, at the Centers for Disease Control published an article that described a new way of thinking about community-based health services (Frieden, 2010). In his article “A Framework for Public Health Action: The Health Impact Pyramid,” Frieden describes a five-tier pyramid derived from evidence-based research (Figure 9-1). The Pyramid describes the potential impact of various types of public health interventions and provides a framework to

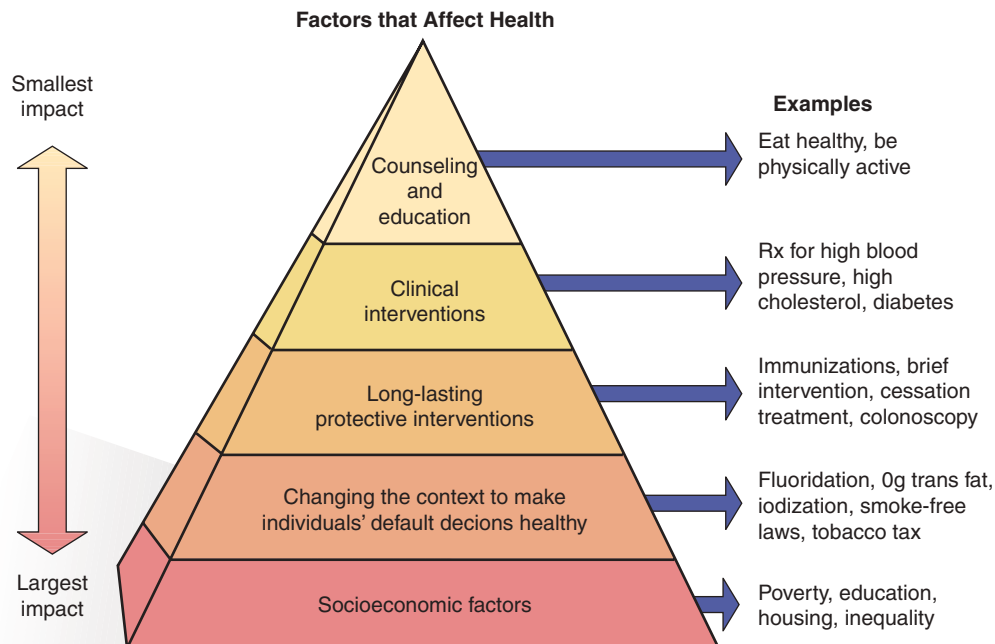

FIGURE 9-1 The Health Impact Pyramid.

<http://internaimedicinebook.com>

improve health. Each layer describes the spheres that influence the involvement of the community in health services including nutrition. The foundation of this Pyramid (graph X) depicts the largest and broadest involvement of partners and communities, which Frieden describes as more powerful in influencing positive health outcome than the more traditional model of one-to-one intervention (depicted at the top of the figure).

Friedan's Pyramid illustrates, in ascending order, the interventions that could change the context to make an individual's default decisions healthy (Frieden, 2010). In addition, the Pyramid includes clinical interventions that require limited contact but confer long-term protection, ongoing direct clinical care, health education, and counseling. Frieden's point is that interventions focusing on lower levels of the Pyramid tend to be more effective because they reach broader segments of society and require less individual effort. Implementing interventions at each of the levels can achieve the maximum possible sustained public health.

Government's Role in Public Health

The federal government can support the development and dissemination of public health knowledge and provide funding. Box 9-1 provides a list of government agencies related to food and nutrition. Typical settings for community nutrition include public health agencies (state and local), including the **Special Supplemental Nutrition Program for Women, Infants, and**

Children (WIC). WIC is a federal program that allocates funds to states and territories for specific foods, health care referrals, and nutrition education for low-income, nutritionally at-risk pregnant, breastfeeding, and non-breastfeeding postpartum women; infants; and children up to age 5 years. This program is a specific, nutrition-based food package that has evolved over the years to provide for the individual needs of the client and has adapted to changes in society. It is an illustration of a nutrition-based program tailored to current needs.

The expansion of community-based practice beyond the scope of traditional public health has opened new employment and outreach opportunities for nutrition professionals. Nutrition professionals often serve as consultants or may establish community-based practices. Nutrition services are often available in programs for senior adults, in community health centers, in early intervention programs, within health maintenance organizations, at food banks and shelters, in schools (including Head Start), and in physicians' offices or clinics.

Effective practice in the community requires a nutrition professional who understands the effect of economic, social, and political issues on health. Many community-based efforts are funded or guided by legislation resulting in regulations and policies. Community practice requires an understanding of the legislative process and an ability to translate policies into action. In addition, the community-based professional needs a working knowledge of funding sources and resources at the federal, state, regional, and local level in the official, nonprofit, and private sectors.

NEEDS ASSESSMENT FOR COMMUNITY-BASED NUTRITION SERVICES

Nutrition services should be organized to meet the needs of a "community." Once that community has been defined, a **community needs assessment** is developed to shape the planning, implementation, and evaluation of nutrition services. Evidence-based, assessment tools are available to aid in this process. One such tool is the Centers for Disease Control and Prevention's (CDC) *The Guide to Community Preventive Services*. This provides evidence-based recommendations for interventions and policies that can improve health and prevent disease in communities. It contains information on various topics related to health risk factors, such as nutrition, obesity, physical activity, tobacco use, and diabetes. Information on policies, programs or services, funding, research, and education are included in this guide (CDC, 2014).

Other sources are organizations and centers such as ChangeLabSolutions, the American Public Health Association, and the Rudd Policy Center at Yale University. Resources are available to communities for use in health and **nutrition policy** (course of action adopted by government or business) that include technical assistance to support communities in the process of developing policies and conducting assessments. Such tools and assistance can result in meaningful strategies and programming.

Community Needs Assessment

A *community needs assessment* is a current snapshot of a defined community with a goal of identifying the health risks or areas of greatest concern to the community's well-being. To be effective, the needs assessment must be a dynamic document responsive to changes in the community. A plan is only as good as the research used to shape the decisions, so a mechanism for ongoing review and revision should be built into the planning.

A needs assessment is based on objective data, including demographic information and health statistics. Information

should represent the community's diversity and be segmented by such factors as age, gender, socioeconomic status, disability, and ethnicity. Examples of information to be gathered include current morbidity and mortality statistics, number of low-birth-weight infants, deaths attributed to chronic diseases with a link to nutrition, and health-risk indicators such as incidence of smoking or obesity. *Healthy People 2020* outlines the leading health indicators that can be used to create target objectives. Ongoing evaluation of progress on these indicators builds on objectives and adds new direction. Subjective information such as input from community members, leaders, and health and nutrition professionals can be useful in supporting the objective data or in emphasizing questions or concerns. The process mirrors what the business world knows as *market research*.

Another step should be cataloging accessible community resources and services. As an example, consider how environmental, policy, and societal changes have contributed to the rapid rise in obesity over the past few decades. Resources to consider are affordable access to walkable neighborhoods, recreation facilities, and health-promoting foods (CDC, 2014).

In nutrition planning the goal is to determine who and what resources are available to community members when they need food or nutrition-related products or services. For example, what services are available for medical nutrition therapy (MNT), nutrition and food education, homecare, child care, or home-maker skills training? Are there safe areas for exercise or recreation? Is there access to transportation? Is there compliance with disability legislation? Are mechanisms in place for emergencies that may affect access to adequate and safe food and water?

At first glance some of the data gathered in this process may not appear to relate directly to nutrition, but an experienced community nutritionist or a community-based advisory group with public health professionals can help connect this information to nutrition- and diet-related issues. Often the nutritional problems identified in a review of nutrition indicators are associated with dietary inadequacies, excesses, or imbalances that can be triggers for disease risk (Box 9-2). Careful attention should be paid to the special needs of adults and children with disabilities or other lifestyle-limiting conditions. Once evaluated, the information is used to propose needed services, including MNT as discussed in other chapters, as part of the strategy for improving the overall health of the community.

Sources for Assessment Information

Community practitioners must know how to locate relevant resources and evaluate the information for validity and reliability. Knowing the background and intent of any data source and

BOX 9-2 Possible Nutrition Trigger Areas in a Community Needs Assessment

- Presence of risk factors for cardiovascular disease; diabetes and stroke
 - Elevated blood cholesterol and lipid levels
 - Inactivity
 - Smoking
 - Elevated blood glucose levels
 - High body mass index (BMI)
 - Elevated blood pressure
- Presence of risk factors for osteoporosis
- Evidence of eating disorders
- High incidence of teenage pregnancy
- Evidence of hunger and food insecurity

BOX 9-3 Community Nutrition Assessment Sources

NHANES, National Health and Nutrition Examination Survey
 NFNS, National Food and Nutrition Survey
 CSFII, Continuing Survey of Food Intake of Individuals

identifying the limitations and the dates when the information was collected are critical points to consider when selecting and using such sources. Census information is a starting point for beginning a needs assessment. Morbidity and mortality and other health data collected by state and local public health agencies, the CDC, and the National Center for Health Statistics (NCHS) are useful. Federal agencies and their state program administration counterparts are data sources; these agencies include the **U.S. Department of Health and Human Services (USDHHS)**, U.S. Department of Agriculture (USDA), and the Administration on Aging. Local providers such as community hospitals, WIC, child care agencies, health centers, and universities with a public health or nutrition department are additional sources of information. Nonprofit organizations such as the March of Dimes, the American Heart Association (AHA), the American Diabetes Association, and the American Cancer Society (ACS) also maintain population statistics. Health insurers are a source for information related to health care consumers and geographic area. Food banks and related agencies also may be able to provide insights into food access and security (Box 9-3).

NATIONAL NUTRITION SURVEYS

Nutrition and health surveys at the federal and state level provide information on the dietary status of a population, the nutritional adequacy of the food supply, the economics of food consumption, and the effects of food assistance and regulatory programs. Public guidelines for food selection usually are based on survey data. The data are also used in policy setting; program development; and funding at the national, state, and local levels. Until the late 1960s, the USDA was the primary source of food and nutrient consumption data. Although much of the data collection is still at the federal level, other agencies and states are now generating information that provides comprehensive information on the health and nutrition of the public.

National Health and Nutrition Examination Survey

The **National Health and Nutrition Examination Survey (NHANES)** provides a framework for describing the health status of the nation. Sampling the noninstitutionalized population, the initial study began in the early 1960s, with subsequent studies on a periodic basis from 1971 to 1994. NHANES has been collected on a continuous basis since 1999. The process includes interviewing approximately 6000 individuals each year in their homes and following approximately 5000 individuals with a complete health examination. Since its inception, each successive NHANES has included changes or additions that make the survey more responsive as a measurement of the health status of the population. NHANES I to III included medical history, physical measurements, biochemical evaluation, physical signs and symptoms, and diet information using food frequency questionnaires and a 24-hour recall. Design changes added special population studies to increase information on underrepresented groups. NHANES III (1988 to 1994) included a large proportion of persons age 65 years and older.

This information enhanced understanding of the growing and changing population of senior adults. Currently, reports are released in 2-year cycles. Sampling methodology is planned to oversample high-risk groups not previously covered adequately (low income, those older than the age of 60, blacks, and Hispanic Americans). Information on NHANES is available in a pdf document at http://www.cdc.gov/nchs/data/nhanes/survey_content_99_14.pdf. This report catalogs NHANES findings from its inception until 2014 (CDC, 2014).

The most current additions to NHANES include a sampling of the population from 3 to 15 years of age. The 2012 NHANES National Youth Fitness Survey (NNYFS) was a 1-year survey that set up the next phase of NHANES. The design of this part of NHANES was described in a report released November of 2013 (http://www.cdc.gov/nchs/data/nyfs/NNYFS_Plan_Ops.pdf).

Continuing Survey of Food Intake of Individuals: Diet and Health Knowledge Survey

The Continuing Survey of Food Intake of Individuals (CSFII) was a nationwide dietary survey instituted in 1985 by the USDA. In 1990 CSFII became part of the USDA National Nutrition Monitoring System. Information from previous surveys is available from the 1980s and 1990s. The Diet and Health Knowledge Survey (DHKS), a telephone follow-up to CSFII, began in 1989. The DHKS was designed as a personal interview questionnaire that allowed individual attitudes and knowledge about healthy eating to be linked with reported food choices and nutrient intakes. Early studies focused on dietary history and a 24-hour recall of dietary intake from adult men and women ages 19 to 50. The 1989 and 1994 surveys questioned men, women, and children of all ages and included a 24-hour recall (personal interview) and a 2-day food diary. Household data for these studies were determined by calculating the nutrient content of foods reported to be used in the home during the survey. These results were compared with nutrition recommendations for persons matching in age and gender. The information derived from the CSFII and DHKS is still useful for decision makers and researchers in monitoring the nutritional adequacy of American diets, measuring the effect of food fortification on nutrient intakes, tracking trends, and developing dietary guidance and related programs. In 2002 both surveys merged with NHANES to become the **National Food and Nutrition Survey (NFNS)**, or **What We Eat in America**.

National Food and Nutrition Survey: What We Eat in America

The integrated survey What We Eat in America is collected as part of NHANES. Food-intake data are linked to health status from other NHANES components, allowing for exploration of relationships between dietary indicators and health status. The USDHHS is responsible for sample design and data, whereas the USDA is responsible for the survey's collection and maintenance of the dietary data. Data are released at 2-year intervals and are accessible from the NHANES website (USDA, Agricultural Research Service, 2014).

National Nutrition Monitoring and Related Research Act

In 1990 Congress passed Public Law 101-445, the **National Nutrition Monitoring and Related Research (NNMRR) Act**. The purpose of this law is to provide organization, consistency, and unification to the survey methods that monitor the food habits and nutrition of the U.S. population and to coordinate the efforts of the 22 federal agencies that implement or review

nutrition services or surveys. Data obtained through NNMRR are used to direct research activities, develop programs and services, and make policy decisions regarding nutrition programs such as food labeling, food and nutrition assistance, food safety, and nutrition education. Reports of the various activities are issued approximately every 5 years and provide information on trends, knowledge, attitudes and behavior, food composition, and food supply determinants. They are available from the National Agricultural Library database.

National Nutrient Databank

The **National Nutrient Databank (NND)**, maintained by the USDA, is the United States' primary resource of information from private industry, academic institutions, and government laboratories on the nutrient content of foods. Historically the information was published as the series *Agriculture Handbook 8*. Currently, the databases are available to the public on tapes and on the Internet. The bank is updated frequently and includes supplemental sources, international databases, and links to other sites. This databank is a standard and updated source of nutrient information for commercial references and data systems. When using sources other than the USDA site, clinicians should check the sources and the dates of the updates for evidence that these sources are reliable and current.

The Centers for Disease Control and Prevention

The CDC is a component of the USDHHS. It monitors the nation's health, detects and investigates health problems, and conducts research to enhance prevention. The CDC is also a source of information on health for international travel. Housed at CDC is the NCHS, the lead agency for NHANES, morbidity and mortality, BMI, and other health-related measures. Public health threats, such as the H1N1 virus, also are monitored by CDC.

NATIONAL NUTRITION GUIDELINES AND GOALS

Policy development describes the process by which society makes decisions about problems, chooses goals, and prepares the means to reach them. Such policies may include health priorities and dietary guidance.

Early dietary guidance had a specific disease approach. The 1982 National Cancer Institute (NCI) landmark report, *Diet, Nutrition and Cancer*, evolved into *Dietary Guidelines for Cancer Prevention*. These were updated and broadened in 2004, combining recommendations on energy balance, nutrition, and physical activity. The ACS and the American Institute for Cancer Research (AICR) are excellent resources along with materials from the NCI. Another federal agency, the National Heart, Lung, and Blood Institute, provided three sets of landmark guidelines for identifying and treating lipid disorders between 1987 and 2010.

The most recent AHA guidelines continue to focus on reducing risks for hypertension and coronary artery disease with reduction of obesity, incorporation safe and regular exercise, control of individuals' sodium intake and cholesterol levels, and moderation of the type of dietary fat eaten. Additionally they focus on increasing the intake of fruits and vegetables, legumes and nuts. (See Chapter 33). In 2014 the issue of smoking was again updated.

Building on another consumer-friendly, single health guideline (5-a-Day for Better Health), the NCI, the NIH, and the Produce for Better Health Foundation put the focus on fruits and vegetables. This guidance was built around the message that fruits and vegetables are naturally low in fat and good sources of fiber, several vitamins and minerals, and phytonutrients. In keeping with

evidence-based messages, five to nine servings of fruits and vegetables a day are recommended to promote good health under the name of “Fruits and Veggies: More Matters”. The *More Matters* banner continues as the branding for health guidelines and is an ongoing message for My Plate and the Dietary Guidelines for Americans. ([Produce for Better Health, 2015](#)).

The release of My Plate after the update on The Dietary Guidelines for Americans in 2010 made this a source of a strong and ongoing public health message with materials focusing across the life cycle, professional and consumer updates, and a robust social media presence (<http://fnic.nal.usda.gov/dietary-guidance/fruits-veggies-more-matters-resources/fruits-veggies-more-matters>). See Chapter 11.

Dietary Guidelines for Americans

Senator George McGovern and the Senate Select Committee on Nutrition and Human Needs presented the first *Dietary Goals* for the United States in 1977. In 1980 the goals were modified and issued jointly by the USDHHS and the USDA as the *Dietary Guidelines for Americans (DGA)*. The original guidelines were a response to an increasing national concern for the rise in overweight, obesity, and chronic diseases such as diabetes, coronary artery disease, hypertension, and certain cancers. The approach continues to be one of health promotion and disease prevention, with special attention paid to specific population groups (see Chapter 11).

The release of the DGA led the way for a synchronized message to the community. The common theme has been a focus on a diet lower in sodium and saturated fat, with emphasis on foods that are sources of fiber, complex carbohydrates, and lean or plant-based proteins. The message is based on food choices for optimal health using appropriate portion sizes and calorie choices related to a person’s physiologic needs. Exercise, activity, and food safety guidance are standard parts of this dietary guidance. The current DGA are evidence-based rather than just “good advice.” The expert committee report provides scientific documentation that is used widely in health practice. The DGA have become a central theme in community nutrition assessment, program planning, and evaluation; they are incorporated into programs such as School Lunch and Congregate Meals. Updated every 5 years, the DGA recently have undergone revision in 2010 and are currently undergoing revision (see Chapter 11). The 2010 DGA set the path for our current food guide, My Plate, and set the stage for programs such as More Matters to evolve. The 2015 DGA are scheduled to be released at the time of this updated chapter. Emphasis continues to be on the 2010 DGA with emerging evidence on plant-based choices, total fat, types of fat, saturated fat, added sugars and sodium ([Dietary Guidelines 2015](#)).

Food Guides

In 1916 the USDA initiated the idea of food grouping in the pamphlet *Food for Young Children*. Food grouping systems have changed in shape (wheels, boxes, pyramids, and plates) and numbers of groupings (four, five, and seven groups), but the intent remains consistent: to present an easy guide for healthful eating. In 2005 an Internet-based tool called [MyPyramid.gov: Steps to a Healthier You](#) was released. In 2011 [MyPyramid.gov](#) was replaced with My Plate ([chooseMyPlate.gov](#)) along with a version for children called [chooseMyPlate.gov/kids](#). These food guidance systems focus on health promotion and disease prevention and are updated whenever DGA guidance

changes. This program has become a leading public education resource with My Tracker (a way to set and evaluate one’s own diet), downloadable tip sheets, and a list of well-done social media efforts that brings application to the food guide (see Chapter 11).

Healthy People and the Surgeon General’s Report on Nutrition and Health

The 1979 report of the Surgeon General, *Promoting Health/Preventing Disease: Objectives for the Nation*, outlined the prevention agenda for the nation with a series of health objectives to be accomplished by 1990. In 1988 *The Surgeon General’s Report on Nutrition and Health* further stimulated health promotion and disease prevention by highlighting information on dietary practices and health status. Along with specific health recommendations, documentation of the scientific basis was provided. Because the focus included implications for the individual as well as for future public health policy decisions, this report remains a useful reference and tool. *Healthy People 2000: National Health Promotion and Disease Prevention Objectives* and *Healthy People 2010* were the next generations of these landmark public health efforts. Both reports outlined the progress made on previous objectives and set new objectives for the next decade.

During the evaluation phase for setting the 2010 objectives, it was determined that the United States made progress in reducing the number of deaths from cardiovascular disease, stroke, and certain cancers. Dietary evaluation indicated a slight decrease in total dietary fat intake. However, during the previous decade there has been an increase in the number of persons who are overweight or obese, a risk factor for cardiovascular disease, stroke, and other leading chronic diseases and causes of death.

Objectives for *Healthy People 2020* have specific goals that address nutrition and weight, heart disease and stroke, diabetes, oral health, cancer, and health for seniors. These goals are important for consumers and health care providers. The website for *Healthy People 2020* offers an opportunity to monitor the progress on past objectives as well as on the shaping of future health initiatives (<https://www.healthypeople.gov/>).

National School Lunch Program

The National School Lunch Program (NSLP) is a federal assistance program that provides free or reduced-cost meals for low-income students in public schools and in nonprofit private residential institutions. It is administered at a state level through the education agencies that generally employ dietitians. In 1998 the program was expanded to include after-school snacks in schools with after-hours care. Currently the guidelines for calories, percent of calories from fat, percent of saturated fat, and the amount of protein and key vitamins and minerals must meet the DGA, but there is ongoing evaluation and interpretation. Efforts have been made to meet My Plate guidelines for whole grains, more fruits and vegetables, and skim or 1% milk. In addition, the issues of education of recipients to accept these foods and use of local foods and community gardens are evolving processes that are happening in communities.

A requirement for wellness policies in schools that participate in the NSLP is in place ([Edelstein et al, 2010](#)). However, the School Nutrition Dietary Assessment Study, a nationally representative study fielded during school year 2004 to 2005 to evaluate nutritional quality of children’s diets, identified that

80% of children had excessive intakes of saturated fat and 92% had excessive intakes of sodium (Clark and Fox, 2009). An increase in whole grains, fresh fruits, and a greater variety of vegetables is needed (Condon et al, 2009). The state of Texas made changes to their school lunches by restricting portion sizes of high-fat and high-sugar snacks and sweetened beverages, fat content of foods, and high-fat vegetables such as French fries; this led to a desired reduction in energy density (Mendoza et al, 2010). Other states and local programs have followed suit, partially because of new guidelines issued by the USDA.

On December 14, 2010, the Hunger-Free Kids Act was signed into law. It expanded the after-school meal program, created a process for a universal meal program that allows schools with a high percentage of low-income children to receive meals at no charge, allowed states to increase WIC coverage from 6 months to 1 year, mandated WIC use electronic benefits by 2020, and improved the nutritional quality of foods served in school-based and preschool settings by developing new nutrition standards.

The Recommended Dietary Allowances and Dietary Reference Intakes

The recommended dietary allowances (RDAs) were developed in 1943 by the Food and Nutrition Board of the National Research Council of the National Academy of Sciences. The first tables were developed at a time when the U.S. population was recovering from a major economic depression and World War II; nutrient deficiencies were a concern. The intent was to develop intake guidelines that would promote optimal health and lower the risk of nutrient deficiencies. As the food supply and the nutrition needs of the population changed, the intent of the RDAs was adapted to prevention of nutrition-related disease. Until 1989 the RDAs were revised approximately every 10 years.

The RDAs always have reflected gender, age, and life-phase differences: there have been additions of nutrients and revisions of the age groups. However, recent revisions are a major departure from the single list some professionals still view as the RDAs. Beginning in 1998 an umbrella of nutrient guidelines known as the *dietary reference intakes (DRIs)* was introduced. Included in the DRIs are RDAs, as well as new designations, including guidance on safe upper limits (ULs) of certain nutrients. As a group the DRIs are evaluated and revised at intervals, making these tools reflective of current research and population base needs (see Chapter 11).

FOOD ASSISTANCE AND NUTRITION PROGRAMS

Public health assurance addresses the implementation of legislative mandates, maintenance of statutory responsibilities, support of crucial services, regulation of services and products provided in the public and private sector, and maintenance of accountability. This includes providing for food security, which translates into having access to an adequate amount of healthful and safe foods.

In the area of **food security**, or access by individuals to a readily available supply of nutritionally adequate and safe foods programs have continued to evolve. The **Supplemental Nutrition Assistance Program (SNAP)**, formerly known as food stamps, along with food pantries, home-delivered meals, child nutrition programs, supermarkets, and other food sources have been highlighted to focus on the issues of quality, access, and

use. For example, research on neighborhood food access indicates that low availability of healthy food in area stores is associated with low-quality diets of area residents (Rose et al, 2010). See Table 9-1 for a list of food and nutrition assistance programs. *Clinical Insight: The History of the Supplemental Nutrition Assistance Program (SNAP)* provides additional information on this program.

There is an ongoing movement to encourage goals emphasized in My Plate, to add more vegetables and fruits and increase minimally processed foods, and to increase education for SNAP recipients as well as other food and nutrition assistance programs. The presence of food deserts is a concept that has become a focus of research and community planning. **Food deserts** are described by the Agricultural Marketing Service of USDA as urban neighborhoods and rural areas with limited access to fresh, healthy, affordable food (<http://apps.ams.usda.gov/fooddeserts/foodDeserts.aspx>). The Economic Research Service (ERS) of the USDA estimated in 2013 that 23.5 million people live in food deserts and more than half of those are low income. Although the definition of a food desert is controversial, the USDA defines it as a neighborhood where the nearest supermarket or grocery store is located 1 to 3 miles away for urban residents and 10 miles from home for those in rural settings.

FOODBORNE ILLNESS

CDC estimates that each year one in six Americans (or 48 million people) get sick, 128,000 are hospitalized, and 3000 die of foodborne diseases. The majority of **foodborne illness** outbreaks reported to the CDC result from bacteria, followed by viral outbreaks, chemical causes, and parasitic causes. Segments of the population are particularly susceptible to foodborne illnesses; vulnerable individuals are more likely to become ill and experience complications. Some of the nutritional complications associated with foodborne illness include reduced appetite and reduced nutrient absorption from the gut.

The 2000 edition of the DGA was the first to include food safety, important for linking the safety of the food and water supply with health promotion and disease prevention. This acknowledges the potential for foodborne illness to cause acute illness and long-term chronic complications. Since 2000 all revisions of the DGA have made food safety a priority. Persons at increased risk for foodborne illnesses include young children; pregnant women; older adults; persons who are immunocompromised because of human immunodeficiency virus or acquired immunodeficiency syndrome, steroid use, chemotherapy, diabetes mellitus, or cancer; alcoholics; persons with liver disease, decreased stomach acidity, autoimmune disorders, or malnutrition; persons who take antibiotics; and persons living in institutionalized settings. Costs associated with foodborne illness include those related to investigation of foodborne outbreaks and treatment of victims, employer costs related to lost productivity, and food industry losses related to lower sales and lower stock prices (American Dietetic Association, 2009). Table 9-2 describes common foodborne illnesses and their signs and symptoms, timing of onset, duration, causes, and prevention.

All food groups have ingredients associated with food safety concerns. There are concerns about microbial contamination of fruits and vegetables, especially those imported from other countries. An increased incidence of foodborne illness occurs with new methods of food production or distribution and with

Text continued on page 150

TABLE 9-1 U.S. Food Assistance and Nutrition Programs

Program Name	Goal/Purpose	Services Provided	Target Audience	Eligibility	Funding	Level of Prevention*
After-School Snack Program	Provides reimbursement for snacks served to students after school	Provides cash reimbursement to schools for snacks served to students after the school day. Snacks must contain two of four components: fluid milk, meat/meat alternate, vegetable or fruit or full-strength juice, whole-grain or enriched bread.	Children younger than 18 whose school sponsor a structured, supervised after-school enrichment program and provide lunch through the NSLP	School programs located within the boundaries of eligible low-income areas may be reimbursed for snacks served at no charge to students.	USDA	Primary, secondary
Child and Adult Care Food Program	Provides nutritious meals and snacks to infants, young children, and adults receiving day care services, as well as infants and children living in emergency shelters	Provides commodities or cash to help centers serve nutritious meals that meet federal guidelines	Infants, children, and adults receiving day care at childcare centers, family day care homes, and homeless shelters		USDA FNS	Primary, secondary
Commodity Supplemental Food Program	Provides no-cost monthly supplemental food packages composed of commodity foods to populations perceived to be at nutritional risk	Provides food packages; nutrition education services are available often through extension service programs; program referrals provided	Generally children ages 5-6, postpartum non-breastfeeding mothers from 6-12 months' postpartum, seniors	Between 130% and 185% of the poverty guideline	USDA FNS	Primary, secondary
Disaster Feeding Program	Makes commodities available for distribution to disaster relief agencies	Commodities are provided to disaster victims through congregate dining settings and direct distribution to households.	Those experiencing a natural disaster	Those experiencing a natural disaster	USDA FNS	Primary
TEFAP	Commodities are made available to local emergency food providers for preparing meals for the needy or for distribution of food packages.	Surplus commodity foods are provided for distribution.	Low-income households	Low-income households at 150% of the federal poverty income guideline	USDA FNS	Primary
EFSP	Funds are used to purchase food and shelter to supplement and extend local services.	EFSP provides funding for the purchase of food products, operation costs associated with mass feeding and shelter, limited rent or mortgage assistance, providing assistance for first month's rent, limited off-site emergency lodging, and limited utility assistance.	Those in need of emergency services	Primary	FEMA	Primary
Head Start	Provides agencies and schools with support and guidance for half- and full-day child development programs for low-income children	Programs receive reimbursement for nutritious meals and snacks and USDA-donated commodities, support for curriculum, social services, and health screenings.	Low-income children ages 3-5; parents are encouraged to volunteer and be involved	Same as NSLP	USDA (food) USDHHS (health)	Primary Secondary
National School Breakfast Program	Provides nutritionally balanced, low-cost or free breakfasts to children enrolled in participating schools	Participating schools receiving cash subsidies and USDA-donated commodities in return for offering breakfasts that meet same criteria as school lunch and offering free and reduced-price meals to eligible children	Children preschool age through grade 12 in schools; children and teens 20 years of age in residential childcare and juvenile correctional institutions	Same as NSLP	USDA FNS	Primary, secondary

NSLP	Provides nutritionally balanced, low-cost or free lunches to children enrolled in participating schools	Participating schools receive cash subsidies and USDA-donated commodities in return for offering lunches that meet dietary guidelines and 1/3 of RDA for protein, iron, calcium, vitamins A and C, and calories and for offering free and reduced-price meals to eligible children	Children preschool age through grade 12 in schools; children and teenagers 20 years of age and younger in residential childcare and juvenile correctional institutions	185% of federal poverty income guideline for reduced-price lunches; 130% for free lunches	USDA FNS	Primary, secondary
Nutrition Program for the Elderly/Area Agencies on Aging	Provides commodity and cash assistance to programs providing meal services to older adults	Provides nutritious meals for older adults through congregate dining or home-delivered meals	Older adults	No income standard applied	USDHHS administers through state and local agencies; USDA cash and commodity assistance	Primary
Seniors' Farmers Market Nutrition Program	Provides fresh, nutritious, unprepared, locally grown fruits, vegetables, and herbs from farmers' markets, roadside stands, and community-supported agriculture programs to low-income seniors	Coupons for use at authorized farmers' markets, roadside stands, and community-supported agriculture programs (Foods that are not eligible for purchase with coupons by seniors are dried fruits or vegetables, potted plants and herbs, wild rice, nuts, honey, maple syrup, cider, and molasses.)	Low-income adults older than age 60	Low-income seniors with household incomes not exceeding 195% of the federal poverty income guideline	USDA FNS	Primary
SNAP	Provides benefits to low-income people that they can use to buy food to improve their diets	Provides assistance such as food stamps	Any age	For households in the 48 contiguous states and the District of Columbia. To get SNAP benefits, households must meet certain tests, including resource and income tests.	USDA FNS	Primary Secondary
Special Milk Program	Provides milk to children in participating schools who do not have access to other meal programs	Provides cash reimbursement for milk with vitamins A and D at RDA levels served at low or no cost to children; milk programs must be run on nonprofit basis	Same target audience as school lunch and school breakfast programs	Eligible children do <i>not</i> have access to other supplemental foods programs.	USDA FNS	Primary, secondary
Summer Food Service Program	Provides healthy meals (per federal guidelines) and snacks to eligible children when school is out, using agriculture commodity foods	Reimburses for up to two or three meals and snacks served daily free to eligible children when school is not in session; cash based on income level of local geographic area or of enrolled children	Infants and children 18 years of age and younger served at variety of feeding sites		USDA FNS	Primary, secondary
WIC	Provides supplemental foods to improve health status of participants	Nutrition education, free nutritious foods (protein, iron, calcium, vitamins A and C), referrals, breastfeeding promotion	Pregnant, breastfeeding and postpartum women up to 1 year Infants, children up to 5 yrs.	185% of federal poverty income guideline nutritional risk	USDA FNS, home state support	Primary, secondary, tertiary
WIC FMNP	Provides fresh, unprepared, locally grown fruits and vegetables to WIC recipients, and to expand the awareness, use of and sales at farmers' markets	FMNP food coupons for use at participating farmers' markets stands; nutrition education through arrangements with state agency	Same as WIC recipients	Same as WIC recipients	USDA FNS	Primary

EFSP, Emergency Food and Shelter Program; FEMA, Federal Emergency Management Agency; FMNP, Farmers Market Nutrition Program; FNS, Food and Nutrition Service; NSLP, National School Lunch Program; RDA, recommended daily allowance; SNAP, Special Nutrition Assistance Program; USDA, U.S. Department of Agriculture; USDHHS, U.S. Department of Health and Human Services; WIC, Special Supplemental Nutrition Program for Women, Infants, and Children.

*Level of prevention rationale: Programs that provide food only are regarded as primary; programs that provide food, nutrients at a mandated level of recommended dietary allowances, or an educational component are regarded as secondary; and programs that used health screening measures on enrollment were regarded as tertiary.

CLINICAL INSIGHT

The History of the Supplemental Nutrition Assistance Program (SNAP)**Erik R. Stegman, MA, JD**

In the years after World War II, hunger and extreme malnutrition was a serious and pervasive problem in the United States. By the mid-1960s, one fifth of American households had poor diets. Among low-income households, this rate nearly doubled to 36% ([United States Department of Agriculture \[USDA\], Agricultural Research Service \[ARS\], 1969](#)). According to studies at the time, these rates of hunger, especially in low-income areas of the South, had a serious effect on the public at the time because of malnutrition and vitamin deficiency ([Wheeler, 1967](#)). Many Americans learned how serious the problem was in their living rooms when CBS News aired a landmark documentary, *Hunger in America*, in 1968 ([Dole Institute of Politics, 2011](#)). The documentary featured malnourished children with distended bellies and stories from everyday people about how hunger affected their lives—something that other Americans couldn't believe was happening in their backyard.

A public outcry resulted in the federal government's modern nutrition assistance system that began in the early 1960s as the Food Stamp program. Originally created as a small program during World War II to help bridge the gap between plentiful farm surpluses and urban hunger, it was discontinued in the 1950s because of the prosperous economy. President John F. Kennedy reintroduced it through an executive order in 1961 as a

broader pilot program. As part of President Lyndon B. Johnson's War on Poverty initiative, Congress finally made it permanent. It has since been reauthorized and strengthened several times and is today known as the Supplemental Nutrition Assistance Program (SNAP) (USDA, Food and Nutrition Service [FNS], 2010). Another important supplemental food program is for Women, Infants and Children (WIC) and was developed in the 1970s to provide specialized nutrition assistance and support to low-income pregnant women, infants, and children up to age 5 (USDA, Economic Research Service [ERS], 2009).

In 2013 SNAP helped more than 47 million Americans afford a nutritionally adequate diet in a typical month. It also kept about 4.9 million people out of poverty in 2012, including 1.3 million children ([Center on Budget and Policy Priorities, 2015](#)). A recent study has shown that after these expansions in the 1960s and 1970s, disadvantaged children with access to nutrition assistance in early childhood and who had mothers that received assistance during pregnancy, had improved health and education outcomes, better growth curves, and fewer diagnoses of heart disease and obesity ([Hoynes et al, 2012](#)). Today, state agencies administering SNAP have the option of providing nutrition education to SNAP participants through federal grants and matching fund programs ([USDA, 2015](#)).

TABLE 9-2 Common Foodborne Illnesses

Illness	Signs and Symptoms	Onset and Duration	Causes and Prevention	Comments
<i>Bacillus cereus</i>	Watery diarrhea, abdominal cramping, vomiting	6-15 hours after consumption of contaminated food; duration 24 hours in most instances	Meats, milk, vegetables, and fish have been associated with the diarrheal type; vomiting-type outbreaks have generally been associated with rice products; potato, pasta, and cheese products; food mixtures such as sauces, puddings, soups, casseroles, pastries, and salads may also be a source.	<i>B. cereus</i> is a gram-positive, aerobic spore former.
<i>Campylobacter jejuni</i>	Diarrhea (often bloody), fever, and abdominal cramping	2-5 days after exposure; duration 2-10 days	Drinking raw milk or eating raw or undercooked meat, shellfish, or poultry; to prevent exposure, avoid raw milk and cook all meats and poultry thoroughly; it is safest to drink only pasteurized milk; the bacteria also may be found in tofu or raw vegetables. Hand-washing is important for prevention; wash hands with soap before handling raw foods of animal origin, after handling raw foods of animal origin, and before touching anything else; prevent cross-contamination in the kitchen; proper refrigeration and sanitation are also essential.	Top source of foodborne illness; some people develop antibodies to it, but others do not. In persons with compromised immune systems, it may spread to the bloodstream and cause sepsis; may lead to arthritis or to GBS; 40% of GBS in the United States is caused by campylobacteriosis and affects the nerves of the body, beginning several weeks after the diarrheal illness; can lead to paralysis that lasts several weeks and usually requires intensive care.
<i>Clostridium botulinum</i>	Muscle paralysis caused by the bacterial toxin: double or blurred vision, drooping eyelids, slurred speech, difficulty swallowing, dry mouth, and muscle weakness; infants with botulism appear lethargic, feed poorly, are constipated, and have a weak cry and poor muscle tone	In foodborne botulism symptoms generally begin 18-36 hours after eating contaminated food; can occur as early as 6 hours or as late as 10 days; duration days or months	Home-canned foods with low acid content such as asparagus, green beans, beets, and corn; outbreaks have occurred from more unusual sources such as chopped garlic in oil, hot peppers, tomatoes, improperly handled baked potatoes wrapped in aluminum foil, and home-canned or fermented fish. Persons who home-can should follow strict hygienic procedures to reduce contamination of foods; oils infused with garlic or herbs should be refrigerated; potatoes that have been baked while wrapped in aluminum foil should be kept hot until served or refrigerated; because high temperatures destroy the botulism toxin, persons who eat home-canned foods should boil the food for 10 minutes before eating.	If untreated, these symptoms may progress to cause paralysis of the arms, legs, trunk, and respiratory muscles; long-term ventilator support may be needed. Throw out bulging, leaking, or dented cans and jars that are leaking; safe home-canning instructions can be obtained from county extension services or from the U.S. Department of Agriculture; honey can contain spores of <i>C. botulinum</i> and has been a source of infection for infants; children younger than 12 months old should not be fed honey.

TABLE 9-2 Common Foodborne Illnesses—cont'd

Illness	Signs and Symptoms	Onset and Duration	Causes and Prevention	Comments
<i>Clostridium perfringens</i>	Nausea with vomiting, diarrhea, and signs of acute gastroenteritis lasting 1 day	Within 6-24 hours from the ingestion	Ingestion of canned meats or contaminated dried mixes, gravy, stews, refried beans, meat products, and unwashed vegetables. Cook foods thoroughly; leftovers must be reheated properly or discarded.	
<i>Cryptosporidium parvum</i>	Watery stools, diarrhea, nausea, vomiting, slight fever, and stomach cramps	2-10 days after being infected	Contaminated food from poor handling Hand washing is important.	Protozoa causes diarrhea among immune-compromised patients.
Enterotoxigenic <i>Escherichia coli</i> (ETEC)	Watery diarrhea, abdominal cramps, low-grade fever, nausea and malaise	With high infective dose, diarrhea can be induced within 24 hours	Contamination of water with human sewage may lead to contamination of foods; infected food handlers may also contaminate foods; dairy products such as semisoft cheeses may cause problems, but this is rare.	More common with travel to other countries; in infants or debilitated elderly persons, electrolyte replacement therapy may be necessary.
<i>Escherichia coli</i> O157:H7 Enterohemorrhagic <i>E. coli</i> (EHEC)	Hemorrhagic colitis (painful, bloody diarrhea)	Onset is slow, usually approximately 3-8 days after ingestion Duration 5-10 days	Undercooked ground beef and meats, from unprocessed apple cider, or from unwashed fruits and vegetables; sometimes water sources; alfalfa sprouts, unpasteurized fruit juices, dry-cured salami, lettuce, spinach, game meat, and cheese curds Cook meats thoroughly, use only pasteurized milk, and wash all produce well.	Antibiotics are not used because they spread the toxin further; the condition may progress to hemolytic anemia, thrombocytopenia, and acute renal failure, requiring dialysis and transfusions; HUS can be fatal, especially in young children; there are several outbreaks each year, particularly from catering operations, church events, and family picnics; <i>E. coli</i> O157:H7 can survive in refrigerated acid foods for weeks
<i>Listeria monocytogenes</i> (LM)	Mild fever, headache, vomiting, and severe illness in pregnancy; sepsis in the immunocompromised patient; meningoencephalitis in infants; and febrile gastroenteritis in adults	Onset 2-30 days Duration variable	Processed, ready-to-eat products such as undercooked hot dogs, deli or lunchmeats, and unpasteurized dairy products; post pasteurization contamination of soft cheeses such as feta or Brie, milk, and commercial coleslaw; cross-contamination between food surfaces has also been a problem. Use pasteurized milk and cheeses; wash produce before use; reheat foods to proper temperatures; wash hands with hot, soapy water after handling these ready-to-eat foods; discard foods by their expiration dates.	May be fatal Caution must be used by pregnant women, who may pass the infection on to their unborn child.
<i>Norovirus</i>	Gastroenteritis with nausea, vomiting, and/or diarrhea accompanied by abdominal cramps; headache, fever/chills, and muscle aches also may be present.	24-48 hours after ingestion of the virus, but can appear as early as 12 hours after exposure	Foods can be contaminated either by direct contact with contaminated hands or work surfaces that are contaminated with stool or vomit or by tiny droplets from nearby vomit that can travel through air to land on food; although the virus cannot multiply outside of human bodies, once on food or in water, it can cause illness; most cases occur on cruise ships.	Symptoms are usually brief and last only 1 or 2 days; however, during that brief period, people can feel very ill and vomit, often violently and without warning, many times a day; drink liquids to prevent dehydration.
<i>Salmonella</i>	Diarrhea, fever, and abdominal cramps	12-72 hours after infection Duration usually 4-7 days	Ingestion of raw or undercooked meat, poultry, fish, eggs, unpasteurized dairy products; unwashed fruits and raw vegetables (melons and sprouts) Prevent by thorough cooking, proper sanitation, and hygiene.	There are many different kinds of <i>Salmonella</i> bacteria; <i>S. typhimurium</i> and <i>S. enteritidis</i> are the most common in the United States. Most people recover without treatment, but some have diarrhea that is so severe that the patient needs to be hospitalized; this patient must be treated promptly with antibiotics; the elderly, infants, and those with impaired immune systems are more likely to have a severe illness.
Shigellosis	Bloody diarrhea, fever, and stomach cramps	24-48 hours after exposure Duration 4-7 days	Milk and dairy products; cold mixed salads such as egg, tuna, chicken, potato, and meat salads Proper cooking, reheating, and maintenance of holding temperatures should aid in prevention; careful hand washing is essential.	This is caused by a group of bacteria called <i>Shigella</i> ; it may be severe in young children and the elderly; severe infection with high fever may be associated with seizures in children younger than 2 years old.

Continued

TABLE 9-2 Common Foodborne Illnesses—cont'd

Illness	Signs and Symptoms	Onset and Duration	Causes and Prevention	Comments
<i>Staphylococcus aureus</i>	Nausea, vomiting, retching, abdominal cramping, and prostration	Within 1-6 hours; rarely fatal Duration 1-2 days	Meat, pork, eggs, poultry, tuna salad, prepared salads, gravy, stuffing, cream-filled pastries Cooking does not destroy the toxin; proper handling and hygiene are crucial for prevention.	Refrigerate foods promptly during preparation and after meal service.
<i>Streptococcus pyogenes</i>	Sore and red throat, pain on swallowing; tonsillitis, high fever, headache, nausea, vomiting, malaise, rhinorrhea; occasionally a rash occurs	Onset 1-3 days	Milk, ice cream, eggs, steamed lobster, ground ham, potato salad, egg salad, custard, rice pudding, and shrimp salad; in almost all cases, the foodstuffs were allowed to stand at room temperature for several hours between preparation and consumption.	Entrance into the food is the result of poor hygiene, ill food handlers, or the use of unpasteurized milk. Complications are rare; treated with antibiotics.
<i>Vibrio vulnificus</i>	Vomiting, diarrhea, or both; illness is mild	Gastroenteritis occurs about 16 hours after eating contaminated food. Duration about 48 hours	Seafood, especially raw clams and oysters, that has been contaminated with human pathogens; although oysters can only be harvested legally from waters free from fecal contamination, even these can be contaminated with <i>V. vulnificus</i> because the bacterium is naturally present.	This is a bacterium in the same family as those that cause cholera; it yields a Norovirus; it may be fatal in immunocompromised individuals.
<i>Yersinia enterocolitica</i>	Common symptoms in children are fever, abdominal pain, and diarrhea, which is often bloody; in older children and adults, right-sided abdominal pain and fever may be predominant symptom and may be confused with appendicitis.	1-2 days after exposure Duration 1-3 weeks or longer	Contaminated food, especially raw or undercooked pork products; postpasteurization contamination of chocolate milk, reconstituted dry milk, pasteurized milk, and tofu are also high-risk foods; cold storage does not kill the bacteria. Cook meats thoroughly; use only pasteurized milk; proper hand washing is also important.	Infectious disease caused by the bacterium <i>Yersinia</i> ; in the United States most human illness is caused by <i>Y. enterocolitica</i> ; it most often occurs in young children. In a small proportion of cases, complications such as skin rash, joint pains, or spread of bacteria to the bloodstream can occur.

Adapted with permission from Escott-Stump S: *Nutrition and diagnosis-related care*, ed 7, Baltimore, 2011, Lippincott Williams & Wilkins. Other sources: <http://www.cdc.gov/health/diseases/>; accessed December 26, 2013.

GBS, Guillian-Barré Syndrome; HUS, hemolytic uremic syndrome.

increased reliance on commercial food sources (AND, 2014). Improperly cooked meats can harbor organisms that trigger a foodborne illness. Even properly cooked meats have the potential to cause foodborne illness if the food handler allows raw meat juices to contaminate other foods during preparation. Sources of a foodborne illness outbreak vary, depending on such factors as the type of organism involved, the point of contamination, and the duration and temperature of food during holding.

Targeted food safety public education campaigns are important. However, the model for food safety has expanded beyond the individual consumer and now includes the government, the food industry, food growers, and the general public. Several government agencies provide information through websites with links to the CDC, the USDA Food Safety and Inspection Service (FSIS), the Environmental Protection Agency (EPA), the National Institute of Allergy and Infectious Diseases (NIAID), and the Food and Drug Administration (FDA). A leading industry program, ServSafe, provides food safety and training certification and was developed and administered by the National Restaurant Association. Because the U.S. food supply comes from a global market, food safety concerns are worldwide. The 2009 Country of Origin Labeling (COOL) legislation requires that retailers provide customers with the source of foods such as meats, fish, shellfish, fresh and frozen fruits and vegetables, and certain nuts and herbs (USDA, 2013). The USDA Agricultural Marketing Service has responsibility

for COOL implementation. Future practice must include awareness of global food safety issues (see *Focus On: Global Food Safety*).

Hazard Analysis Critical Control Points

An integral strategy to reduce foodborne illness is risk assessment and management. **Risk assessment** entails hazard identification, characterization, and exposure. **Risk management** covers risk evaluation, option assessment and implementation,

FOCUS ON

Global Food Safety

The United States imports produce, meat, and seafood from other countries to meet the consumer demands for foods that are not readily available in the country. Global importation creates potential danger to the public. Our current food supply is becoming much harder to trace to a single source. Because of this, safety concerns must be addressed globally, as well as in the United States. Leadership from food growers, producers, distributors, and those involved in food preparation is essential to ensure a safe food supply. Protecting the food supply chain requires several safety management systems such as hazard analysis, critical control points, good manufacturing practice, and good hygiene practice (Aruoma, 2006). Food safety also includes attention to issues such as the use of toxins and pesticides in countries where standards and enforcement may be variable, as well as the importance of clean water. Finally, the effect of global warming on food production is an increasing concern.

and monitoring and review of progress. One formal program, organized in 1996, is the **Hazard Analysis Critical Control Points (HACCP)**, a systematic approach to the identification, evaluation, and control of food safety hazards. HACCP involves identifying any biologic, chemical, or physical agent that is likely to cause illness or injury in the absence of its control. It also involves identifying points at which control can be applied, thus preventing or eliminating the food safety hazard or reducing it to an acceptable level. Restaurants and health care facilities are obligated to use HACCP procedures in their food handling practices.

Those who serve populations at the greatest risk for food-borne illness have a special need to be involved in the network of food safety education and to communicate this information to their clients (Figure 9-2). Adoption of the HACCP regulations, food quality assurance programs, handling of fresh produce guidelines, technologic advances designed to reduce contamination, increased food supply regulations, and a greater emphasis on food safety education have contributed to a substantial decline in foodborne illness.

FOOD AND WATER SAFETY

Although individual educational efforts are effective in raising awareness of food safety issues, food and water safety must be examined on a national, systems-based level (AND, 2014). Several federal health initiatives include objectives relating to food and water safety, pesticide and allergen exposure, food-handling practices, reducing disease incidence associated with water, and reducing food- and water-related exposure to environmental pollutants. Related agencies can be found in Table 9-3.

Contamination

Controls and precautions in the area of limiting potential contaminants in the water supply are of continuing importance. Water contamination with arsenic, lead, copper, pesticides and herbicides, mercury, dioxin, polychlorinated biphenyls (PCBs), chlorine, and *Escherichia coli* continues to be highlighted by the media. It was estimated that many public water systems, built using early twentieth-century technology, will need to invest more than \$138 billion during the next 20 years to ensure

continued safe drinking water (AND, 2014). The effect on the potential safety of foods that have contact with these contaminants is an ongoing issue being monitored by advocacy and professional groups and governmental agencies.

Of interest to many is the issue of the potential hazards of ingestion of seafood that has been in contact with methyl mercury present naturally in the environment and released into the air from industrial pollution. Mercury has accumulated in

bodies of water (i.e., streams, rivers, lakes, and oceans) and in the flesh of seafood in these waters (USDA and EPA, 2013). The body of knowledge on issues such as this is being updated constantly, and current recommendations are to restrict the consumption of certain fish such as shark, mackerel, tilefish, tuna, and swordfish by pregnant women (FDA 2013 and Centers for Food Safety and Applied Nutrition 2013). (See Chapter 15 for further discussion.) Other contaminants in fish, such as PCBs, and dioxin are also of concern (California Office of Environmental Health Hazard Assessment [OEHHA], 2014).

Precautions are in place at the federal, state, and local levels that must be addressed by dietetics professionals whose roles include advocacy, communication, and education. Members of the public and local health officials must understand the risks and the importance of carrying out measures for food and water safety and protection. The EPA and the Center for Food Safety and Applied Nutrition (CFSAN) provide ongoing monitoring and guidance. In addition, food and water safety and foodborne illness issues are monitored by state and local health departments.

Organic Foods and Pesticide Use

The use of pesticides and contaminants from the water supply affect produce quality. The debate continues about whether organic foods are worth the extra cost. However, the beneficial effects of organic farming also must be considered (see *Focus On: Is It Really Organic, and Is It Healthier?*).

Genetic Modification/Genetic Engineering

An emerging safety issue is that of **genetically modified organisms** (GMOs). A GMO is a plant or animal in which the genetic material has been altered in a way that does not occur naturally. The process of making GMOs is called *genetic engineering*. More than 20 countries have banned the use of GMO crops, but it remains controversial in the United States. Currently labeling of GMO/GE foods is voluntary, but there has been considerable public outcry to require it be labeled. FDA is studying the issue (see *Focus On: GMO or Genetically Engineered (GE) Foods* in Chapter 26).

Bioterrorism and Food-Water Safety

Bioterrorism is the deliberate use of microorganisms or toxins from living organisms to induce death or disease. Threats to the nation's food and water supplies have made food **biosecurity**, or precautions to minimize risk, an issue when addressing preparedness planning. The CDC has identified seven foodborne pathogens as having the potential to be used by bioterrorists to attack the food supply: tularemia, brucellosis, *Clostridium botulinum* toxin, epsilon toxin of *Clostridium perfringens*, *Salmonella*, *Escherichia coli*, and *Shigella*. These pathogens, along with potential water contaminants, such as mycobacteria, *Legionella*, *Giardia*, viruses, arsenic, lead, copper, methyl butyl ether, uranium, and radon, are the targets of federal systems put in place to monitor the safety of the food and water supply. Current surveillance systems are designed to detect foodborne illness outbreaks resulting from food spoilage, poor food handling practices, or other unintentional sources, but they were not designed to identify an intentional attack.

Consequences of a compromised food and water supply are physical, psychologic, political, and economic. Compromise could occur with food being the primary agent such as a vector to deliver a biologic or chemical weapon or with food being a secondary target, leaving an inadequate food supply to feed a region or the nation. Intentional use of a foodborne pathogen

FOCUS ON

Is It Really Organic, and Is It Healthier?

Christine McCullum-Gomez, PhD, RD

There are a variety of reasons why organic foods can be considered to facilitate the creation of a healthful, sustainable food system (Scialabba, 2013; McCullum-Gómez and Scott, 2009). First, some organic fruits, vegetables, and juices may contain more antioxidants and polyphenols compared with their conventionally grown counterparts (Baranski et al, 2014), although there is an ongoing debate regarding the potential nutritional advantages of consuming organic versus conventional fruits and vegetables and other plant products (Baranski et al, 2014; Smith-Spangler et al, 2012). Second, organically raised meat may reduce the development of human antibiotic resistance and lessen air and water pollution (American Medical Association, 2009). Researchers have found a lower prevalence of antibiotic-resistant *Salmonella* spp. (Sapkota et al, 2014) and antibiotic-resistant Enterococci (Sapkota et al, 2011) on U.S. conventional poultry farms that transitioned to organic practices. Third, a published meta-analysis (Palupi et al, 2012) found that organic dairy products contained significantly higher protein, total omega-3 fatty acids, and conjugated linoleic acid than those of conventional types. Another study reported that individual omega-3 fatty acid concentrations and the concentration of conjugated linoleic acid were higher in organic milk (Benbrook et al, 2013). In an ongoing cohort study, consumption of organic dairy products was associated with a lower risk of eczema during the first 2 years of life. These authors hypothesize that “a high intake of omega-3 fatty acids and/or conjugated linoleic acids from organic dairy products by the child is protective against eczema (independent of atopy) and that . . . the mother’s intake of these fatty acids during pregnancy and lactation contributes to this protection” (Kummeling et al, 2008).

Fortunately, the presence of organic foods is increasing in the marketplace. Organic sales account for more than 4% of total U.S. food sales, although organic products account for a much larger share in some food product categories. Certified organic acreage and livestock have been expanding in the United States, particularly for fruits, vegetables, dairy, and poultry (Greene, 2014). These foods are produced following practices described in the USDA National Organic Program (NOP), a marketing program with a certification process throughout the production and

manufacturing chain, which describes the practices that are required for labeling a product “organic” (USDA, 2011). Organic foods that are certified through the USDA NOP also must meet the same state and federal food safety requirements as nonorganic foods (Riddle and Markhart, 2010).

In organic farming, raw animal manure must be composted (§205.203), “unless it is: i) applied to land used for a crop not intended for human consumption; ii) incorporated into the soil not less than 120 days prior to the harvest of a product whose edible portion has direct contact with the soil surface or soil particles; or iii) incorporated into the soil not less than 90 days prior to the harvest of a product whose edible portion does not have direct contact with the soil surface or soil particles” (Electronic Code of Federal Regulations, 2014).

Organic agriculture offers numerous opportunities to reduce exposure to agricultural pesticides through the community food and water supply, which may be detrimental to human health, particularly for high-risk groups, including pregnant women, infants, young children, and farmers (American College of Obstetricians and Gynecologists Committee, 2013; Costa et al, 2014). Studies with children reveal that there are dramatic reductions in organophosphate (OP) pesticide exposure with the consumption of organic food (Lu et al, 2008). Research with adults found that the consumption of an organic diet for 1 week significantly reduced OP pesticide exposure. These authors recommend consumption of organic food as a precautionary approach to reducing pesticide exposure (Oates et al, 2014).

Organically grown foods also can cultivate a more sustainable food system by reducing energy requirements for production, reducing soil erosion, rehabilitating poor soils, and sequestering carbon in soil, which may reduce carbon levels in the atmosphere (Gattinger et al, 2012; Scialabba, 2013). In addition, biodiversity is enhanced in organic agricultural systems (Tuck et al, 2014), which makes these farms more resilient to unpredictable weather patterns and pest outbreaks, as is predicted with climate change. Public investment in organic agriculture facilitates wider access to organic food for consumers, helps farmers capture high-value markets, and conserves natural resources, including soil and water.

as the primary agent may be mistaken as a routine outbreak of foodborne illness. Distinguishing normal illness fluctuation from an intentional attack depends on having in place a system for preparedness planning, rapid communication, and central analysis.

Experience with the series of hurricanes in 2005 emphasizes the need to provide access to a safe food and water supply after emergencies and disasters. Access to food and water may be limited, which results in social disruption and self-imposed quarantine. These situations require a response different from the traditional approach to disaster relief, during which it is assumed that hungry people will seek assistance and have confidence in the safety of the food that is offered (FDA, 2014). In the event of a disaster, dietetics professionals can play a key role by being aware of their environment, knowing available community and state food and nutrition resources, and participating in coordination and delivery of relief to victims of the disaster.

DISASTER PLANNING

Dietetics and health professionals working in food service are expected to plan for the distribution of safe food and water in any emergency situation. This may include choosing food preparation and distribution sites, establishing temporary kitchens, preparing foods with limited resources, and keeping

prepared food safe to eat through HACCP procedures. The Academy of Nutrition and Dietetics (AND) published two papers: *Emergency Preparedness: Infant Feeding During Disasters* and *Special Needs and Vulnerable Groups* (<http://www.eatright.org/search.aspx?search=disaster%20planning>).

Planning, surveillance, detection, response, and recovery are the key components of public health disaster preparedness. The key agencies are the USDA, the **Department of Homeland Security (DHS)**, the **Federal Emergency Management Agency (FEMA)**, the CDC, and the FDA. In conjunction with DHS, USDA operates Protection of the Food Supply and Agricultural Production (PFSAP). PFSAP handles issues related to food production, processing, storage, and distribution. It addresses threats against the agricultural sector and border surveillance. PFSAP conducts food safety activities concerning meat, poultry, and egg inspection and provides laboratory support, research, and education on outbreaks of foodborne illness.

Ready.gov (www.ready.gov) is an education tool informing the public on how to prepare for a national emergency, including possible terrorist attacks. In addition, the USDA **Food Safety and Inspection Service (FSIS)** operates the Food Threat Preparedness Network (PrepNet) and the Food Biosecurity Action Team (F-Bat). PrepNet ensures effective coordination of food security efforts, focusing on preventive activities to protect the food supply. F-Bat assesses potential vulnerabilities along the farm-to-table continuum, provides guidelines to industry

on food security and increased plant security, strengthens FSIS's coordination and cooperation with law enforcement agencies, and enhances security features of FSIS laboratories (Bruemmer, 2003).

CDC has three operations relating to food security and disaster planning: PulseNet, FoodNet, and the Centers for Public Health Preparedness. PulseNet is a national network of public health laboratories that performs deoxyribonucleic acid fingerprinting on foodborne bacteria, assists in detecting foodborne illness outbreaks and tracing them back to their source, and provides linkages among sporadic cases. FoodNet is the Foodborne Diseases Active Surveillance Network, which functions as the principle foodborne disease component of the CDC's Emerging Infections Program, providing active laboratory-based surveillance. The Centers for Public Health Preparedness fund academic centers linking schools of public health with state, local, and regional bioterrorism preparedness and public health infrastructure needs.

CFSAN in the FDA is concerned with regulatory issues such as seafood HACCP, safety of food and color additives, safety of foods developed through biotechnology, food labeling, dietary supplements, food industry compliance, and regulatory programs to address health risks associated with foodborne chemical and biologic contaminants. CFSAN also runs cooperative programs with state and local governments.

The FEMA, under the DHS, provides emergency support functions after a disaster or emergency. FEMA identifies food and water needs, arranges delivery, and provides assistance with temporary housing and other emergency services. Agencies that assist FEMA include the USDA, the Department of Defense, the USDHHS, the EPA, and the General Services Administration. Major players include nonprofit volunteer agencies such as the American Red Cross, the Salvation Army, and community-based agencies and organizations. Disaster management is evolving as it is tested by manufactured and natural disasters.

HEALTHY FOOD AND WATER SYSTEMS AND SUSTAINABILITY

This chapter began with a note that community nutrition is a constantly evolving and growing area of practice with the broad focus of serving the population at large with a thrust to be proactive and responsive to the needs of the community. Today's community and the community needs differ, but regardless of environmental, social, and geographic variations, a goal of all nutrition and dietetics professionals is to promote and sustain access to a safe, affordable, and health-promoting food sources.

In 2014 The Academy of Nutrition and Dietetics issued Standards of Professional Performance that addressed building and supporting sustainable, resilient, and healthy food and water systems (AND, 2014). These standards are meant to provide guidance to every RDN beyond the usual safety standards. This paper identifies sustainability as the ability to maintain the system for the long term. Resilience means a system can withstand interruptions that occur. From a community nutrition aspect, a practical example of resilience is that standards are in place for access to health-supporting and safe food and water even after a flood, natural disaster, or funding interruption. The sustainability is rooted in how the system is built, guided, and nourished. Public and private programs and resources are critical components and must meet the tests of resiliency to be sustainable to meet funding requirements.

The safety, adequacy, and quality of the food and water supply along with energy sources are components that build sustainability and resiliency. The nutrition and dietetics professional can be a major player but must have the expertise and competency as well as the initiative to build as well as promote standards and conditions in which people can reach the goal of being healthy. Additional resources are available at <http://www.andjrnl.org/content/sop#2012> <http://www.hendpg.org/page/professional-development>.

SUMMARY: A WORK IN PROGRESS

This chapter is indeed a work in progress, a snapshot of the evolving world of community nutrition. Changes are inherent in food, health, food access and safety, and our global environment. The Dietetics Professional is an important player but needs to be current and engaged. Box 9-7 notes some useful websites, many with access to regular updates on problems, issues and solutions.

Nutrition Diagnosis and Intervention

The type of nutrition care provided for an individual varies depending on the findings of the assessment process. The environment, surgery or trauma, food allergies, inadequate access to safe or sufficient food, stage of growth and development, harmful beliefs, lack of knowledge, and socioeconomic issues can all affect whether the individual has an adequate diet. In the healthy individual, omission of a specific food group or intake of high-energy, nutrient-poor foods does not lead to failed nutritional status overnight. It is the prolonged imbalanced intake that leads to chronic disease. Dramatic and acute insufficiency combined with acute disease also leads to undesirable nutritional consequences. Indeed, inadequacy of the types or amounts of macro- or micronutrients, fluid, or even physical activity may cause a decline in health status or immunity and dysfunction and disease.

The establishment of nutrition diagnoses helps to define and promote effective care according to specific nutrition problems. Such problems may be found in an individual, a group (such as persons who have diabetes or celiac disease), or even a community (such as sites where local produce is grown in mineral-depleted soil.)

Step two of the nutrition care process involves an analysis of the factors affecting adequacy of the current nutritional intake and overall nutritional status. In most cases, institutions use standards of care or national practice guidelines that describe recommended actions in the nutrition care process. These standards serve as the basis for assessing the quality of care provided.

Step three of the nutrition care process requires planning and goal-setting, followed by the selection of interventions that deal with the cause of the problem. For example, nutrition education is an appropriate intervention for the person who has little knowledge of how to manage his or her gluten-free diet. And, this requires a counseling approach, keeping the person's level of readiness to change in mind. It may be helpful to refer the individual to available cookbooks, health services, and support groups. Manipulation of dietary components, provision of enteral or parenteral nutrition, or in-depth nutrition counseling may also be needed. Coordination of care between hospital and home and community is important for life long management of nutrition and chronic disease.

The final step of the nutrition care process is specific to the individual patient or client, and is related to the signs and symptoms identified in the assessment. A separate chapter is not written here because this fourth step (monitoring and evaluation) would be developed according to the nutrition diagnoses, assessment factors, and outcomes for the individual being served.

Nutrition care is an organized group of activities allowing identification of nutritional needs and provision of care to meet these needs. Nutrition care can occur in a variety of settings and populations, involving members of the multidisciplinary team, as appropriate. For example, nutrition care occurs in schools with children and in collaboration with a school nurse and the education staff as well as in public health departments with low socioeconomic populations and in collaboration with public health officials. Conversely, nutrition care also occurs in clinical settings (e.g., skilled nursing facilities, dialysis clinics, and hospital settings) in populations who are acutely or chronically ill and in collaboration with the medical team (e.g., nurses, physicians, pharmacists, physical therapists). Comprehensive care may involve different health care providers (e.g., the physician, registered dietitian nutritionist [RDN], nurse, pharmacist, physical or occupational therapist, social worker, speech therapist, and case manager) who are integral in achieving desired outcomes, regardless of the care setting. The patient or client and family are core members of the team and must be included in all major decisions throughout the care process.

A collaborative approach helps to ensure that care is coordinated and that team members and the patient are aware of all goals and priorities. Team conferences, formal or informal, are useful in all settings: a clinic, a hospital, the home, the community,

a long-term care facility, or any other site where nutrition problems may be identified. Coordinating the activities of health care professionals also requires documentation of the process and regular discussions to offer complete nutritional care. Standardization of the care process (the Nutrition Care Process, NCP) improves consistency and quality of care as well as enables collection and assessment of nutrition related outcome measures.

THE NUTRITION CARE PROCESS

The **Nutrition Care Process (NCP)** is a standardized process for the provision of nutrition care established by the Academy of Nutrition and Dietetics (AND, known as the Academy, formerly the American Dietetic Association [ADA]). Per the Academy the NCP is a process for identifying, planning for, and meeting nutritional needs. The nutritional needs referred to in this definition may be of an individual, specific group, or population. Furthermore, the NCP gives the profession a framework for critical thinking and decision making, which may assist in defining the roles and responsibilities of registered dietitian nutritionists (RDN) and registered nutrition and dietetic technicians (NDTR) in all practice settings (AND, 2014).

The patient or client is the central focus of the NCP (Figure 10-1). The NCP includes four steps that are the responsibility of the RD: (1) nutrition assessment, (2) **nutrition diagnosis**, (3) nutrition intervention, and (4) monitoring and evaluation (AND, 2010a). Nutrition screening and outcomes management are also vital to safe, high-quality nutrition care; however, they are not included as

Sections of this chapter were written by Sylvia Escott-Stump, MA, RDN, LDN for previous editions of this text.

THE NUTRITION CARE PROCESS MODEL

FIGURE 10-1 The nutrition care process. (Copyright 2011 American Dietetic Association. Reprinted with permission.)

separate steps in the NCP because they are not specific to dietetics practice.

Each step of the NCP has corresponding terminology that allows for standardized documentation. This terminology is called the nutrition care process terminology (previously the international dietetics and nutrition terminology [IDNT]). It was previously available as a book published by the Academy but is now available only in a web-based format (<http://ncpt.webauthor.com/>) for a nominal cost. Using standardized terminology within the documentation process is critical. Systematic and accurate collection of outcomes data allows caregivers a process to determine whether interventions are effective in improving or resolving the nutrition diagnosis. For example, if an RDN were working in a public health department and implemented a program for reducing obesity in an inner city population, he or she would have to be able to collect standardized parameters pre-(assessment) and post (monitoring) intervention and compare

them for change (evaluation) to determine whether the intervention was effective. Without standardized language and corresponding definitions, different terms are used for the same condition and thus reduce the ability to show effectiveness of interventions.

Nutrition Screening

Nutrition screening helps to identify patients or clients who are at nutrition risk and thus should be referred to the RDN for assessment of nutritional status. Nutrition screening can be done in all settings: hospitals, long-term care facilities, schools, food banks, clinics, and hospital settings. When available, population-specific, validated tools should be used for screening (see Chapter 4). Regulatory agencies, including The Joint Commission (TJC), include nutrition screening in their standards. Most health care facilities have developed a multidisciplinary admission screening process that is completed by nursing staff during admission to the facility. Nutrition screening can be incorporated into this

admission assessment. Facilities that use an **electronic health record (EHR)** should build an automatic referral to the RDN when screening criteria are met. The nutrition risk screen should be quick, easy to administer, and cost effective. **Table 10-1** lists information that is included frequently in a nutrition screen.

When the Academy's Evidence Analysis Library (EAL) team conducted a systematic review of acute care screening tools, they determined that the Malnutrition Screening Tool (MST), the Mini-Nutrition Assessment-short form (MNA), and the Nutrition Risk Screen-2002 (NRS) had acceptable reliability and validity in various hospital settings (**AND, 2010b**). See Chapter 4 for a description of these screening tools. When used in a hospital setting, rescreening should occur at regular intervals during the admission. Policies for nutrition rescreening should take into account the average length of time a patient will stay at the facility.

Nutrition Assessment

Nutrition assessment is needed when the screening tool identifies the patient or client to be at nutritional risk (see Chapters 4 through Chapter 7 for detailed discussion of nutrition assessment). The radial in **Figure 10-2** presents a summary of all the aspects of the patient and his or her lifestyle that go into a complete assessment as designated in the center with ADIME and Personalized Nutrition Care. Nutrition assessment parameters have specific corresponding terms, which should be used during documentation. These terms are classified into five domains (food/nutrition related history, anthropometrics, biochemical, nutrition-focused physical examination findings, and client history) and can be found online (<http://ncpt.webauthor.com/pubs/idnt-en/category-1>). See Chapter 7 and Appendices 21 and 22.

Nutrition Diagnosis

RDNs evaluate all of the information from the nutrition assessment to determine a nutrition diagnosis. Accurate diagnosis of nutrition problems is guided by critical evaluation of each component of the assessment combined with critical judgment and decision-making skills. The purpose of identifying the presence of a nutrition diagnosis is “to identify and describe a specific nutrition problem that can be improved or resolved through nutrition treatment/nutrition intervention by a food and nutrition professional” (**AND, 2014a**). Patients with nutrition diagnoses may be at higher risk for nutrition-related complications,

such as increased morbidity, increased length of hospital stay, and infection with or without complications. Nutrition-related complications can lead to a significant increase in costs associated with hospitalization, lending support to the early diagnosis of nutrition problems followed by prompt intervention (**AND, 2009**).

The process of aggregating assessment data and using critical thinking to determine appropriate nutrition diagnoses can also allow for identification of the “cause” of the problem. For example, while assessing a patient with significant recent weight loss, the RDN may discover that the person is food insecure because of a lack of money or food assistance. Although the RDN can diagnose “unintended weight loss” and begin providing a high calorie diet to the patient within a hospital stay, this treatment will not resolve the root cause of the diagnosis (lack of food in the home). Conversely, by provision of nutrition education to the patient while in the hospital *and* enrolling the patient into a food assistance program such as Meals on Wheels after he gets home, the RDN may prevent the diagnosis from reoccurring. Identification of the cause (or **etiology**) is not always possible; however, when it is, it allows for greater understanding of the conditions in which the diagnosis came about and increased individualization of the intervention.

Many facilities use standardized formats to facilitate communication of nutrition diagnoses. It has been recommended that the nutrition diagnosis be documented using the **problem, etiology, signs and symptoms (PES)** format in a simple, clear statement. However, methods used for documenting nutrition care in the medical record are determined at the facility level. RDNs in private practice should also develop a systematic method for documenting care provided.

Nutrition Intervention

Nutrition interventions are the actions taken to treat nutrition problems. Nutrition intervention involves two steps: planning and implementation. Whenever possible, the nutrition intervention should target the etiology identified during the assessment step of NCP. Thus, if the nutrition diagnosis is *Excessive Carbohydrate* and the etiology is *lack of knowledge about high carbohydrate foods*, then the appropriate intervention would be *education on which foods are high in carbohydrate*.

As previously stated, intervention directed at the etiology is not always possible. When the RDN cannot treat the etiology of the nutrition diagnosis directly, the treatment should focus on ameliorating the signs and symptoms of the diagnosis. For example, a frequent etiology of malnutrition in hospitalized adult patients is inflammation. The RDN may not be able to intervene directly in the inflammatory process; however, inflammation can increase the patient's nutritional needs. Therefore, although the RDN may not be able to reduce the inflammation, the RDN can increase the amount of nutrients provided to the patient through high-calorie foods, nutritional supplements, or other nutrition support therapies.

During the planning phase of the nutrition intervention, the RDN, patient or client, and others as needed, collaborate to identify goals and objectives that will signify success of the intervention. Whether in an inpatient or outpatient clinical setting, a significant component of the plan is the patient prescription. A patient's prescription is a detailed description of the nutrient needs of that particular person. Typically, this should include estimated needs for calories, protein, and fluid but also may include nutrients pertinent to the patient's condition such as carbohydrate needs for patients with diabetes, calcium needs for patients with renal disease, or sodium needs for patients with hypertension.

TABLE 10-1 Nutrition Risk Screening

Responsible Party	Action	Documentation
Admitting health care professional	Assess weight status— Has the patient lost weight without trying before admission?	Check yes or no on admission screen.
Admitting health care professional	Assess GI symptoms— Has the patient had GI symptoms preventing usual intake over the past 2 weeks?	Check yes or no on admission screen.
Admitting health care professional	Determine need to consult RD.	If either screening criterion is “yes,” consult RD for nutrition assessment.

GI, Gastrointestinal; RD, registered dietitian.

FIGURE 10-2 The radial. (From Ford D et al: American Dietetic Association: Standards of Practice and Standards of Professional Performance for Registered Dietitians (Competent, Proficient, and Expert) in Integrative and Functional Medicine, *J Acad Nutr Diet* 111:902, 2011. Copyright Kathie Madonna Swift, MS, RD, LDN; Diana Noland, MPH, RD; and Elizabeth Redmond, PhD, MMSc, RD, LD. http://www.andjrn.org/cms/attachment/2002774838/2010029064/gr5_lrg.jpg)

Patient-centered goals and objectives are set, and then implementation begins. Interventions may include food and nutrition therapies, nutrition education, counseling, or coordination of care such as providing referral for financial or food resources. Because the care process is continuous, the initial plan may change as the condition of the patient changes, as new needs are identified, or if the interventions prove to be unsuccessful.

Interventions should be specific; they are the “what, where, when, and how” of the care plan. For example, in a patient with “inadequate oral food or beverage intake,” an objective may be to increase portion sizes at two meals per day. This could be implemented through provision of portions that are initially 5% larger with a gradual increase to 25% larger portion sizes. Plans should be communicated to the health care team and the patient to ensure understanding of the plan and its rationale. Thorough communication by the RDN increases the likelihood of adherence to the plan. **Box 10-1** presents the NCP applied to a sample patient, JW.

Four categories of interventions are within the Nutrition Care Process Terminology (eNCP): (1) food and nutrient delivery, (2) nutrition education, (3) nutrition counseling, and

(4) coordination of nutrition care by a nutrition professional. Interventions can occur in all settings. For example, a woman with little knowledge of heart-healthy foods may need a group class on cooking or an educational session on lowering saturated fat in her diet (nutrition education). An RDN working for the Women Infant and Children (WIC) clinic may counsel a pregnant woman on initiating breastfeeding as an intervention (nutrition counseling). A clinical RDN may write orders for initiation and progression of enteral feeding for a child with cystic fibrosis (delivery of nutrients). Finally, the RDN may communicate to the social worker the nutrition needs for a patient post discharge to ensure that the patient continues to improve (coordination of care). All of these are types of interventions that RDNs may recommend and implement.

Monitoring and Evaluation of Nutrition Care

The fourth step in the NCP involves monitoring and evaluation of the effect of nutrition interventions. This clarifies the effect that the RDN has in the specific setting, whether health care, education, consulting, food services, or research. During

this step, the RDN first determines indicators that should be monitored. These indicators should match the signs and symptoms identified during the assessment process. For example, if excessive sodium intake was identified during the assessment, then an evaluation of sodium intake is needed at a designated time for follow-up.

In the clinical setting the goal of nutrition care is to meet the nutritional needs of the patient or client; thus interventions must be monitored and progress toward goals must be evaluated frequently. This ensures that unmet objectives are addressed and care is evaluated and modified in a timely manner. Evaluation of the monitored indicators provides objective data to demonstrate effectiveness of nutrition interventions, regardless of the setting or focus. If objectives are written in measurable terms, evaluation is relatively easy because a change in the indicator is compared with the status of the indicator before implementation of the nutrition intervention.

An example in clinical practice is the sample case in [Box 10-1](#). Here, monitoring and evaluation include weekly reviews of

nutritional intake, including an estimation of energy intake. If intake was less than the goal of 1800 kcal, the evaluation may be: “JW was not able to increase his calorie intake to 1800 kcal because of his inability to cook and prepare meals for himself.” This also points to a missed nutrition diagnosis: JW does not have access to tools and supplies needed to cook for himself. A revision in the care plan at this point may include the following: “JW will be provided a referral to local agencies (Meals on Wheels) that can provide meals at home.” The new diagnosis and intervention then are implemented with continued monitoring and evaluation to determine whether the new objective can be met.

When evaluation reveals that objectives are not being met or that new needs have arisen, the process begins again with reassessment, identification of new nutrition diagnoses, and formulation of a new NCP. For example, in JW’s case, during his hospitalization, high-calorie snacks were provided. However, monitoring reveals that JW’s usual eating pattern does not include snacks, and thus he was not consuming them when in the

BOX 10-1 Applying the Nutrition Care Process for Patient JW

JW is a 70-year-old male who was admitted to the hospital for mitral valve replacement surgery. JW lives alone in his own home. JW is a widower and states that he hasn’t been able to prepare meals for the past 6 months. The nutrition risk screen reveals that he has lost weight without trying and has been eating poorly for several weeks before admission, leading to referral to the RD for nutrition assessment (Step 1 of the nutrition care process).

Assessment: Chart review, patient interview, and nutrition-focused physical examination reveal the following:

Laboratory Data and Medications

Glucose and electrolytes: WNL

Albumin: 3.8 g/dl

Cholesterol/triglycerides: WNL

Medications: Inderal, Lipitor, and and levothyroxine

Anthropometric Data

Height: 70”

Weight: 130 lb (15 lb weight loss over 3 months)

Nutrition Interview Findings

Caloric intake: 1200 kcal/day (less than energy requirements as stated in the recommended dietary allowances)

Meals: irregular throughout the day; drinks 4-6 cups of coffee throughout the day

Medical History

History of hypertension, thyroid dysfunction, asthma, prostate surgery

Psychosocial Data

- New widower; indicates depression and loneliness without his wife
- Has some social support from neighbors and community center but doesn’t like to ask for help

Nutrition Diagnosis: JW has been consuming fewer calories than he requires and has little interest in eating. There is support available in the community but JW doesn’t like to “impose” on others.

RDN diagnoses nutrition problems and establishes objectives for his care.

Nutrition Diagnostic (PES) Statements:

- Unintended weight loss related to poor oral food and beverage intake as evidenced by 15-lb loss in 3 months.

- Inadequate oral intake related to lack of interest in eating as evidenced by reported intake less than 75% of estimated requirements
- Limited access to food related to inability to prepare meals as evidenced by patient report.

Identification of the nutrition diagnoses allows the RDN to focus the nutrition intervention on treatment of the cause of the problem (in this case the missing meals). Goal setting is the first step, and short-term and long-term plans are established. In the education process the client and the RDN must jointly establish achievable goals. Objectives should be expressed in behavioral terms and stated in terms of what the patient will do or achieve when the objectives are met. Objectives should reflect the educational level and the economic and social resources available to the patient and the family.

Short-Term Objectives

During the hospitalization, JW will maintain his current weight; after discharge he will begin to slowly gain weight up to a target weight of 145 lb.

Interventions:

While in the hospital, JW will include nutrient-dense foods in his diet, especially if his appetite is limited.

Long-Term Objectives

JW will modify his diet to include adequate calories and protein through the use of nutrient-dense foods to prevent further weight loss and eventually promote weight gain.

After discharge, JW will attend a local senior center for lunch on a daily basis to help improve his socialization and caloric intake.

Interventions:

Provide diet to meet JW’s needs during hospitalization

Monitor weight

Refer to social services following discharge

Monitoring and Evaluation: Choosing the means for monitoring if the interventions, and nutritional care activities have met the objectives or goals is important. Evaluation of the monitoring criteria will provide the RDN with information on outcomes, and this should occur over time. Finally, documentation is important for each step of the process to ensure communication between all parties.

For JW, weekly weight measurements and nutrient intake analyses are required while he is in the hospital and biweekly weight measurements are taken at the senior center or clinic when he is back at home. If nutrition status is not improving, which in this case would be evidenced by JW’s weight records, and the goals are not being met, it is important to reassess JW and perhaps develop new goals and definitely create plans for new interventions.

PES, Problem, etiology, and signs and symptoms; RDN, registered dietitian nutritionist; WNL, within normal limits.

hospital. The evaluation showed these snacks to be an ineffective intervention. JW agrees to a new intervention: the addition of one more food to his meals. Further monitoring and evaluation will be needed to ascertain if this new intervention improves his intake.

Evidence-Based Guidelines

In health care, providers must use the best available evidence in caring for patients. The Center for Evidence Based Medicine defines evidence-based practice as “the conscientious, explicit and judicious use of current best evidence in making decisions about the care of individual patients.” Best evidence includes properly designed and executed prospective, randomized controlled trials (PRCT), systematic reviews of the literature, and meta-analysis to support decisions made in practice (CEBM, 2014; Sackett et al, 1996). **Evidence-based guidelines (EBGs)** are developed by first conducting a systematic review and then using the conclusion of the systematic review to develop practice-based guidelines. A work group of subject matter experts and specially trained analysts work together to evaluate the research and to develop recommendations for patient care. These guidelines give providers a summary of the best available evidence by which to conduct their practice.

Appropriate use of EBGs may lead to improved quality of care. RDNs must be able to evaluate the EBG and determine whether a given guideline is appropriate in a given situation for a given patient. Many health care professional organizations and practice specialties have developed EBGs, leading to a “glut of guidelines.” The National Guideline Clearinghouse, sponsored by the Agency for Healthcare Research and Quality (AHRQ), contains thousands of guidelines for a variety of health conditions (AHRQ, 2014). Because of potential significant differences in quality and applicability, RDNs must be able to evaluate these guidelines.

In the 1990s, the Academy began developing nutrition practice guidelines and evaluating how guideline use affected clinical outcomes; diabetes management was among the first clinical situations examined. These **evidence-based nutrition practice guidelines (EBNPG)** are disease- and condition-specific recommendations with corresponding toolkits. The EBNPG include major recommendations, background information, and a reference list. To assist the RDN in implementing the EBNPG into their routine care, the guidelines are organized by the NCP steps as appropriate, and NCPT is used throughout the guidelines and within the toolkits.

Medical nutrition therapy (MNT) evidence-based guides are available to assist dietetic practitioners in providing nutrition care, especially for patients with diabetes and early stages of chronic kidney disease (CKD). MNT provided by a Medicare Part B licensed provider can be reimbursed when the EBNPG are used and all procedural forms are documented properly and coded (White et al, 2008). Benefits of nutrition therapy can be communicated to physicians, insurance companies, administrators, or other health care providers using evidence provided from these guidelines.

To define professional practice by the RDN, the Academy published a Scope of Dietetics Practice Framework, a Code of Ethics, and the **Standards of Professional Performance (SOPPs)** (AND Quality Management Committee, 2013). Specialized standards for knowledge, skills, and competencies required to provide care at the generalist, specialist, and advanced practice

level for a variety of populations are now complete for many areas of practice.

The Academy’s Evidence Analysis Library (EAL) is a good starting point to answer questions that arise during provision of nutrition care. Use of the EAL may protect the practitioner and the public from the consequences of ineffective care. These guidelines are extremely valuable for staff orientation, competence verification, and training of RDNs.

Accreditation and Surveys

Accreditation by **The Joint Commission (TJC)** and other accrediting agencies involves review of the systems and processes used to deliver health care along with evaluation of actual care processes. TJC survey teams evaluate health care institutions to determine the level of compliance with established minimum standards. For example, TJC requires that nutrition screening be completed within 24 hours of admission to acute care but does not mandate a method to accomplish screening. However, policies must be applied consistently and must reflect commitment to provision of high-quality, timely nutrition services to all patients.

The “Care of the Patient” section of the *TJC Accreditation Manual for Hospitals* contains standards that apply specifically to medication use, rehabilitation, anesthesia, operative and other invasive procedures, and special treatments, as well as nutrition care standards. The focus of the nutrition care standards is provision of appropriate nutrition care in a timely and effective manner using an interdisciplinary approach. Appropriate care requires screening of patients for nutrition needs, assessing and reassessing patient needs, developing a nutrition care plan, ordering and communicating the diet order, preparing and distributing the diet order, monitoring the process, and continually reassessing and improving the nutrition care plan. A facility can define who, when, where, and how the process is accomplished; but TJC specifies that a qualified dietitian must be involved in establishing this process. A plan for the delivery of nutrition care may be as simple as providing a regular diet for a patient who is not at nutritional risk or as complex as managing enteral feedings in a ventilator-dependent patient, which involves the collaboration of multiple disciplines.

RDNs are involved actively in the survey process. Standards set by TJC play a large role in influencing the standards of care delivered to patients in all health care disciplines. For more information, see the TJC website at www.jointcommission.org.

Dietitians also are involved with surveys from other regulatory bodies, such as a state or local health department, a department of social services, or licensing organizations. Introduction of diagnostic-related groups (DRG) in the mid-1980s led to decreasing acute care length of stay (LOS). However, some patients who no longer need acute hospital care but are not ready to care for themselves at home are admitted to “subacute” care units that are regulated by Center for Medicare-Medicaid Services (CMS). Subacute units also undergo an annual review by CMS. (See Chapter 20 for more information.)

Sentinel events are unanticipated events that involve death, serious physical or psychologic injury, or the risk thereof (TJC, 2014). When there is a sentinel event, the outcomes must be documented in the medical record and there must be clinical and administrative follow-up to document steps taken to prevent recurrence of the event. Regardless of the source of the survey, clinicians must follow all regulations and guidelines at all times and not just when a survey is due.

DOCUMENTATION IN THE NUTRITION CARE RECORD

MNT and other nutrition care provided must be documented in the health or medical record. The medical record is a legal document; if interventions are not recorded, it is assumed that they have not occurred. Documentation affords the following advantages:

- It ensures that nutrition care will be relevant, thorough, and effective by providing a record that identifies the problems and sets criteria for evaluating the care.
- It allows the entire health care team to understand the rationale for nutrition care, the means by which it will be provided, and the role each team member must play to reinforce the plan and ensure its success.

The medical record serves as a tool for communication among members of the health care team. Most health care facilities are using or in the process of implementing EHRs to document patient care, store and manage laboratory and test results, communicate with other entities, and maintain information related to an individual’s health. During the transition to EHRs, those using paper documentation maintain paper charts that typically include sections for physician orders, medical history and physical examinations, laboratory test results, consults, and progress notes. Although the format of the medical record varies depending on facility policies and procedures, in most settings all professionals document care in the medical record. The RDN must ensure that all aspects of nutrition care are summarized succinctly in the medical record.

Medical Record Charting

Problem-oriented medical records (POMR) are used in many facilities. The POMR is organized according to the patient’s primary problems. Entries into the medical record can

be done in many styles. One of the most common forms is the **subjective, objective, assessment, plan (SOAP) note format** (Table 10-2).

The **assessment, diagnosis, interventions, monitoring, evaluation (ADIME) format** reflects the steps of the NCP (Box 10-2; Table 10-3). See Table 10-4 for examples of nutrition diagnostic (PES) statements. However, each patient and situation is different, and the NCP should be individualized appropriately.

Documentation must be accurate, clear, and concise and must be able to convey important information to the physician and other health care team members. All entries made by the RDN should address the issues of nutrition status and needs. Those using EHRs must use great caution when using “copy and paste” functions to document care.

Electronic Health Records and Nutrition Informatics

Beginning in the 1990s costs for computer memory decreased, hardware became more portable, and computer science advanced to make computers and technology a permanent fixture in health care. Additional impetus to change standard practice came with publication of several Institute of Medicine (IOM) reports that brought to light a high rate of preventable medical errors along with the recommendation to use technology as a tool to improve health care quality and safety. (See: <http://www.iom.edu/Reports/1999/To-Err-is-Human-Building-A-Safer-Health-System.aspx>.)

Clinical information systems used in health care are known by different names; although some use **electronic medical record (EMR)**, EHR, and **personal health record (PHR)** interchangeably, there are important differences. An EHR describes information systems that contain all the health information for an individual over time regardless of

TABLE 10-2 Evaluation of a Note in SOAP Format

	Outstanding 2 Points	Above Expectations 1 Point	Below Expectations 0 Points	Score
DATE & TIME		Present	Not present	
S (SUBJECTIVE)	Pertinent components documented	Accurately summarizes most of the pertinent information	One or more pertinent elements missing	
Tolerance of current diet

DBW, Desired body weight; Dx, diagnosis; EER, estimated energy requirements; F/U, follow up; ht, height; hx, history; PO, by mouth; PRN, as necessary; pt, patient; Rx, prescription; SOAP, subjective, objective, assessment, plan; TF, tube feeding; TPN, total parenteral nutrition; UBW, usual body weight; wt, weight.

BOX 10-2 Chart Note Using ADIME

Nutrition Assessment

- Pt is 66-year-old woman admitted with heart failure: Ht: 62 cm; Wt: 56 kg; IBW: 52-58 kg
- Laboratory values within normal limits
- Estimated energy requirement: 1570-1680 calories (28-30 cal/kg)
- Estimated protein requirement: 56-73 g protein (1-1.3 g/kg)
- Current diet order is “no added salt” with pt consuming 95% of meals recorded
- Consult for education received

Nutrition Diagnosis

- Food- and nutrition-related knowledge deficit related to no previous education on low sodium diet as evidenced by client report.

Nutrition Intervention

- Education: Provided pt with written and verbal instruction on a no added salt diet (3 gm) diet.
- Goals: Develop 1-day menu using dietary restrictions.

Monitoring and Evaluation

- Follow up with pt regarding questions about diet indicated no further questions; good comprehension.
 - Evaluation: anticipate no problems following diet at home. Provided contact information for outpatient clinic.
- J Wilson, MS, RDN 1/2/15 15 AM

TABLE 10-4 Sample PES Statements Based on Medical Diagnosis*

Medical Diagnosis	Nutrition Diagnosis** (Problem)	Etiology (E)	Signs/Symptoms (S)
Obesity	Obesity	Energy intake >> estimated requirements and physical inactivity	Current weight 175% desired body weight
	Excessive energy intake	Intake greater than estimated requirements	Diet history; intake approximately 150% estimated requirements
Unintentional weight loss	Lack of physical activity	Lack of time to exercise	Patient report
	Unintended weight loss	Nausea after chemotherapy	Loss of 10% usual body weight in past month
	Inadequate oral intake	Inability to consume more than 25% of most meals	Intake approximately 25% of most meals
Newly diagnosed type 2 diabetes	Food/nutrition-related knowledge deficit	No previous instruction on nutrition management of type 2 diabetes	Patient report
Major trauma	Inadequate oral food/beverage intake	Intubation after surgery	NPO × 48 hours.
GI surgery with complications	Inadequate energy intake	Parents report skipping most meals	Intake <25% estimated requirements at least 7 days before admission
Anorexia nervosa	Excessive fluid intake	Patient reports excessive thirst	Estimated fluid intake 150% of physician-ordered restriction
Congestive heart failure	Inability to self-manage daily activities	Patient reports being “thirsty all the time”	Three admissions for fluid overload in past 2 months
Dysphagia	Inadequate oral food/beverage intake	Swallowing difficulty	Inability to consume most foods served
	Swallowing difficulty	Cerebrovascular accident	Requires thickened liquids and does better with thickened liquids
Referral for social services	Limited access to food	Financial constraints	Patient/SWS reports disqualified from SNAP program

*These are only examples. Each patient is different; each nutrition problem diagnosed by the RDN has an etiology and signs/symptoms that are unique to that patient.

**Each patient can have more than one nutrition diagnosis.

the care setting. An EMR is a clinical information system used by a health care organization to document patient care during one episode of care or admission. EHRs and EMRs are maintained by health care providers or organizations. In contrast, the PHR is a system used by individuals to maintain health information. A PHR can be web or paper based or integrated into a facility's EMR. Information in the PHR is controlled by the person, not the provider or healthcare organization.

EHRs include all of the information typically found in a paper-based documentation system along with tools such as clinical decision support (CDS), electronic medication records, computerized provider order entry (CPOE), and alert systems that support clinicians in making decisions regarding patient care. Current government regulations include requirements to implement and “meaningfully use” EHRs to enter, store, retrieve, and manage information related to patient care. Dietitians must have at least a basic understanding of technology and health information management to ensure a smooth transition from paper to EHR and to use effectively the powerful tools provided by a well-designed EHR. Such transitions include development of nutrition screens for patient admission, documentation, information sharing, decision support tools, and order entry protocols. Customization capabilities vary depending on vendor contracts and facility requirements. Because it can take several years to implement an EHR, RDNs managing nutrition services must be involved in EHR system decisions from the very beginning.

In paper and electronic formats, medical records and the information contained are vital conduits for communicating patient care to others, providing information for quality evaluation and improvement and as a legal document. RDN documentation includes information related to NCPs. Documentation must follow the facility policy and be brief and concise while accurately describing actions taken to those authorized to view the record. Figure 10-3 shows how a computerized medical record may look when using the ADIME method.

Current efforts are focused on ensuring that health information stored in clinical information systems can be exchanged safely and securely between providers and facilities. Systems that are able to share information seamlessly are said to be “interoperable.” Although this concept seems simple on the surface, problems with interoperability will be very difficult and expensive to overcome. RDNs in private practice and ambulatory care must ensure that systems they are using have the capability to share health information.

The transition from paper medical records to EHRs is facilitated by thorough planning, training, and support. Many health care professionals do not have sufficient experience with health care technology to understand the practice improvement that can be realized with proper implementation and use of technology. Others may resist any change in the workplace that interrupts their current workflow. These clinicians are not resisting change because they are afraid of technology; instead, resistance is based on real or imagined fears that technology will impede their workflow or hinder patient care. Change is never easy but

proper attention to all of the implications of change can lessen its impact (Schifalacqua, 2009).

INFLUENCES ON NUTRITION AND HEALTH CARE

The health care environment has undergone considerable change related to the provision of care and reimbursement in the last decade. Governmental influences, cost containment issues, changing demographics, and the changing role of the patient as a “consumer” have influenced the health care arena. The United States currently spends more on health care than any other nation, yet health care outcomes lag far behind those seen in other developed nations. Exponential increases in health care costs in the United States have been a major impetus for drives to reform how health care is provided and paid for in the United States (Ross, 2009).

Affordable Health Care for America: Reconciliation Bill

The intent of the **Affordable Care Act (ACA)**, passed by the U.S. Senate in 2009, is to ensure that Americans have access to quality, affordable health care. Other aims are to protect Americans from predatory insurance industry practices, offer the uninsured and small businesses the opportunity to obtain affordable health care plans, cover 32 million uninsured Americans, and reduce the deficit by \$143 billion over the next decade.

Final regulations require group health plans and health insurance issuers to provide coverage of dependent children

younger than age 26 (see *Clinical Insight: The ACA: How Does Nutrition Fit?*).

Confidentiality and the Health Insurance Portability and Accountability Act

Privacy and security of personal information are a concern in all health care settings. In 1996 Congress passed the **Health Insurance Portability and Accountability Act (HIPAA)** (Centers for Medicare and Medicaid Services, 2013). The initial intent of HIPAA was to ensure that health insurance eligibility is maintained when people change or lose jobs. The Administrative Simplification provisions of HIPAA require development of national standards that maintain privacy of electronically transmitted **protected health information (PHI)**. In 2013 the HIPAA Omnibus Rule expanded patient rights to their own health information, strengthened rules surrounding privacy and confidentiality of PHI, and increased penalties for unauthorized sharing or loss of PHI (U.S. Department of Health and Human Services, 2015).

HIPAA requires that health care facilities and providers (covered entities) take steps to safeguard PHI. Although HIPAA does not prevent sharing of patient data required for care, patients must be notified if their medical information is to be shared outside of the care process, or if protected information (e.g., address, e-mail, income) is to be shared. Violations of HIPAA rules have resulted in large fines, loss of jobs, and criminal prosecution. In an effort to avoid the

serious repercussions of HIPAA violations, health care institutions have implemented mandatory annual education on HIPAA for each employee.

Payment Systems

One of the largest influences on health care delivery in the last decade has been changes in health care payment methods. There are several common methods of reimbursement: private insurance, cost-based reimbursement, negotiated bids, and DRGs. Under the DRG system, a facility receives payment for a patient's admission based on the principal diagnosis, secondary diagnosis (comorbid conditions), surgical procedure (if appropriate), and the age and gender of the patient. Approximately 500 DRGs cover the entire spectrum of medical diagnoses and surgical treatments. **Preferred-provider organizations (PPOs)** and **managed-care organizations (MCOs)** also are changing health care. MCOs finance and deliver care through a contracted network of providers in exchange for a monthly premium, changing reimbursement from a fee-for-service system to one in which fiscal risk is borne by health care organizations and physicians.

The Patient Protection and Affordable Care Act (PPACA) was signed into law by President Obama on March 23, 2010. PPACA is the most significant change to the U.S. health care system since the 1965 passage of legislation that created Medicare and Medicaid. The goal of PPACA or the Affordable Care Act (ACA) is to ensure that affordable health insurance is available to all Americans. ACA uses several methods to improve access to health insurance including an individual mandate, subsidies, state insurance exchanges, and assurance of coverage for preexisting conditions (U.S. Government Publishing Office, 2010) (see *Clinical Insight: The ACA: How Does Nutrition Fit?*)

Quality Management

To contain health care costs while providing efficient and effective care that is consistently of high quality, practice guidelines, or **standards of care**, are used. These sets of recommendations serve as a guide for defining appropriate care for a patient with a specific diagnosis or medical problem. They help to ensure consistency and quality for providers and clients in a health care system and, as such, are specific to an institution or health care organization. **Critical pathways**, or care maps, identify essential elements that should occur in the patient's care and define a timeframe in which each activity should occur to maximize patient outcomes. They often use an algorithm or flowchart to indicate the necessary steps required to achieve the desired outcomes. **Disease management** is designed to prevent a specific disease progression or exacerbation and to reduce the frequency and severity of symptoms and complications. Education and other strategies maximize compliance with disease treatment. Educating a patient with type 1 diabetes regarding control of blood glucose levels would be an example of a disease management strategy aimed at decreasing the complications (nephropathy, neuropathy, and retinopathy) and the frequency with which the client needs to access the care provider. Decreasing the number of emergency room visits related to hypoglycemic episodes is a sample goal.

Patient-Centered Care and Case Management

The **case management** process strives to promote the achievement of patient care goals in a cost-effective, efficient manner. It is an essential component in delivering care that provides a positive experience for the patient, ensures achievement of clinical outcomes, and uses resources wisely. Case management

CLINICAL INSIGHT

The ACA: How Does Nutrition Fit?

Patricia Davidson DCN, MS, RD, CDE

To get paid for their services of nutritional counseling under the new Affordable Care Act (ACA), registered dietitian nutritionists (RDNs) must gain an understanding of the language and steps involved in reimbursement as well as how to become a provider. According to Medicare standards, an MNT provider must have completed the educational and clinical experience required of an RDN (AND, 2014; ADA, 2011). Next, he or she has to obtain the 10-digit **National Provider Identifier (NPI)**, required for billing and credentialing (a term used by insurance companies, the payers, for enrolling service providers). Credentialing is a binding contract of services, conditions, and diseases for which nutritional counseling will be paid, codes to use, and the fee schedule. The diagnosis code (ICD-10) and Common Procedure Terminology (CPT) are required for billing purposes. The ICD-10 describes the person's medical condition, obtained from the physician, and the CPT documents the procedure performed by the RDN. Since 2002, MNT has been designated as 97802 (initial visit) and 97803 (follow-up) procedural codes that are applicable for nutritional counseling for the ACA.

By researching insurance companies, RDNs can find out if MNT is covered, if RDNs are accepted into network, the covered diagnosis and procedure codes, the limits to MNT, and the fee schedules. The fee schedule is the payment per billing unit (blocks of 15 minutes, or per visit). Plans differ, even if they are offered by the same insurance company.

From changes stimulated by the passage of the ACA, it is evident that the chronic care model is replacing the acute care model. A **chronic care model (CCM)** is a multidisciplinary and multifaceted approach for chronic disease management and prevention, whose premise is the development of self-management skills while enhancing the patients' relationships to their care and the team providing that care (Coleman et al, 2009). With this CCM comes development of the Patient-Centered Medical Home (PCMH), Accountable Care Organizations (ACOs) and Comprehensive Primary Care Initiative Projects (CPCI), which combine PCMH and ACOs. A PCMH's focus is on the patient-provider relationship incorporating the team approach (Boyce, 2012).

After the passage of the ACA, ACOs were formed to provide a team approach for coordinating the care provided by doctors, hospitals, and other allied health providers for Medicare patients. Seven states and regions participate in the CPCI, but it is expected to grow, requiring the dietitian-nutritionist to think beyond the traditional MNT model of fee for service, to comprehensive care and new areas of practice, such as primary care settings rather than hospitals (AND, 2013). A survey conducted in 2009 demonstrated that RDNs have a poor awareness of and participation in the PCMH, which adds to the urgency for RDNs to become educated about the ACA and their activity in its implementation (AND, 2013).

involves assessing, evaluating, planning, implementing, coordinating, and monitoring care, especially in patients with chronic disease or those who are at high risk. In some areas, dietitians have added skill sets that enable them to serve as case managers. Patient-centered care has become a movement in the United States that puts more decision making in the hands of the consumer. It places more emphasis on outcomes, sometimes at the expense of physician autonomy (Bardes, 2012). In long-term care the goal is focused on ensuring dignity as well as choice (see Chapter 20).

Utilization management is a system that strives for cost efficiency by eliminating or reducing unnecessary tests, procedures, and services. Here, a manager usually is assigned to a group of patients and is responsible for ensuring adherence to pre-established criteria.

The **patient-centered medical home (PCMH)** is a new development that focuses on the relationship between the patient and his or her personal physician. The personal physician takes responsibility for coordinating health care for the patient and coordinates and communicates with other providers as needed. Other providers such as nurses, dietitian nutritionists, health educators, and allied health professionals may be called on by the patient or personal physician for preventive and treatment services. When specialty care is needed, the personal physician becomes responsible for ensuring that care is seamless and that transitions between care sites go smoothly. The RDN should be considered part of the medical home treatment plan.

Regardless of model, the facility must manage patient care prudently. Nutrition screening can be important in identifying patients who are at nutrition risk. Early identification of these factors allows for timely intervention and helps prevent the comorbidities often seen with malnutrition, which may cause the length of stay and costs to increase. The **Centers for Medicare and Medicaid Services (CMS)** has identified conditions such as heart failure, heart attack, and pneumonia, to name a few, for which no additional reimbursement will be received if a patient is readmitted to acute care within 30 days of a prior admission. Although many view this rule as punitive, it does provide an opportunity for RDNs to demonstrate how nutrition services, including patient education, can save money through decreased readmissions.

Other recent developments include “never events.” Never events are those occurrences that should never happen in a facility that provides high-quality, safe, **person-focused care**. CMS will not reimburse facilities for additional costs of care related to “never events.” RDNs must pay attention to new or worsening pressure ulcers and central line infections as potential “never events.”

Staffing

Staffing also affects the success of nutrition care. Clinical RDNs may be centralized (all are part of a core nutrition department) or decentralized (individual dietitians are part of a unit or service that provides care to patients), depending on the model adopted by a specific institution. Certain departments such as food service, accounting, and human resources remain centralized in most models because some of the functions for which these departments are responsible are not related directly to patient care. Dietitians should be involved in the planning for any redesign of patient care (see *Focus On: Nutrition Standardized Language and Coding Practices*).

FOCUS ON

Nutrition Standardized Language and Coding Practices

The history of the International Classification of Diseases (ICD) can be traced to the mid-1600s and the London Bills of Mortality. It was not until the late 1800s that ICD codes were introduced in health care. The ICD coding system has been revised and updated several times and is used by most countries. Because ICD initially was developed as a system to track causes of death, its use for coding medical diagnoses has been criticized. The United States has been using ICD-9-CM (version 9, clinical modifications) for several years, whereas most other developed nations have been using ICD-10. It currently is mandated that the United States move to ICD-10 in October 2015, but there is ongoing discussion about the difficulties associated with the move.

Medical records departments review medical records and assign codes to the medical diagnoses based on specific findings documented by health care providers as well as complicating factors (“comorbidities”) to determine reimbursement rates. Commonly, pulmonary, gastrointestinal, endocrine, mental disorders, and cancer can lead to malnutrition as a comorbid factor. Thus coordinated nutrition care and coding for malnutrition are important elements in patient services.

A study by White et al (2008) found that self-employed RDNs are more likely to be reimbursed by private or commercial payers, and RDNs working in clinic settings are more likely to be reimbursed by Medicare. RDNs must know and be accountable for the business and clinical side of their nutrition practices (White et al, 2008).

In private practice, use of correct codes and following payers’ claims processing policies and procedures are essential. For example, an NPI is a 10-digit number that is required on claims. To apply for an NPI, registered dietitians can complete the online application at the NPPES website at <https://nppes.cms.hhs.gov/NPPES/Welcomedo>.

ADA, American Dietetic Association; ICD, International Classification of Disease; NPI, National Provider Identifier; NPPES, National Plan and Provider Enumeration System; RD, registered dietitian.

NUTRITION INTERVENTIONS

The RDN is responsible for provision of food and nutrition services that are reliable and highly individualized. RDNs are responsible for using evidence-based practice that is not compromised by market forces.

The evaluation of general and modified diets requires in-depth knowledge of the nutrients contained in different foods. In particular, it is essential to be aware of the nutrient-dense foods that contribute to dietary adequacy and how foods can be fortified to increase their nutrition value (see *Focus On: Food First* in Chapter 20.) Balance and judgment are needed. Sometimes a vitamin-mineral supplement is necessary to meet the patient’s needs when the intake is limited.

Interventions: Food and Nutrient Delivery

The **nutrition prescription**, written by the RDN, designates the type, amount, and frequency of nutrition based on the individual’s disease process and disease management goals. The prescription may specify a caloric level or other restriction to be implemented. It also may limit or increase various components of the diet, such as carbohydrate, protein, fat, alcohol, fiber, water, specific vitamins or minerals, bioactive substances such as phytonutrients, or probiotics. RDNs write the nutrition prescription after the diagnosis of nutrition problems.

A diet order differs from a nutrition prescription. In most states, only a licensed independent health care provider can enter diet orders into a patient’s medical record. Typically, physicians,

physician assistants, and advanced practice nurses are considered to be licensed independent providers. In some facilities, RDNs have been granted order-writing privileges, usually under the supervision of a licensed independent provider. The ability to enter orders does not absolve the RDN of the need to communicate and coordinate care with the provider who is ultimately responsible for all aspects of patient care.

Therapeutic or modified diets are based on a general, adequate diet that has been altered to provide for individual requirements, such as digestive and absorptive capacity, alleviation or arrest of a disease process, and psychosocial factors. In general, the therapeutic diet should vary as little as possible from the individual's normal diet. Personal eating patterns and food preferences should be recognized, along with socioeconomic conditions, religious practices, and any environmental factors that influence food intake, such as where the meals are eaten and who prepares them (see "Cultural Aspects of Dietary Planning" in Chapter 11).

A nutritious and adequate diet can be planned in many ways. One foundation of such a diet is the MyPlate Food Guidance System (see Figure 11-1). This is a basic plan; additional foods or more of the foods listed are included to provide additional energy and increase the intake of required nutrients for the individual. The Dietary Guidelines for Americans also are used in meal planning and to promote wellness. The dietary reference intakes (DRIs) and specific nutrient recommended dietary allowances are formulated for healthy persons, but they also are used as a basis for evaluating the adequacy of therapeutic diets. Nutrient requirements specific to a particular person's genetic makeup, disease state, or disorder always must be kept in mind during diet planning.

Modifications of the Normal Diet

Normal nutrition is the foundation on which therapeutic diet modifications are based. Regardless of the type of diet prescribed, the purpose of the diet is to supply needed nutrients to the body in a form that it can handle. Adjustment of the diet may take any of the following forms:

- Change in consistency of foods (liquid diet, pureed diet, low-fiber diet, high-fiber diet)
- Increase or decrease in energy value of diet (weight-reduction diet, high-calorie diet)
- Increase or decrease in the type of food or nutrient consumed (sodium-restricted diet, lactose-restricted diet, fiber-enhanced diet, high-potassium diet)
- Elimination of specific foods (allergy diet, gluten-free diet)
- Adjustment in the level, ratio, or balance of protein, fat, and carbohydrate (diet for diabetes, ketogenic diet, renal diet, cholesterol-lowering diet)
- Rearrangement of the number and frequency of meals (diet for diabetes, postgastrectomy diet)
- Change in route of delivery of nutrients (enteral or parenteral nutrition)

Diet Modifications in Hospitalized Patients

Food is an important part of nutrition care. Attempts must be made to honor patient preferences during illness and recovery from surgery. This means that the patient must be involved in the decision to follow a therapeutic diet. Imagination and ingenuity in menu planning are essential when planning meals acceptable to a varied patient population. Attention to color, texture, composition, and temperature of the foods, coupled with a sound knowledge of therapeutic diets, are required for

menu planning. However, to the patient, good taste and attractive presentation are most important. When possible, patient choices of food are most likely to be consumed. The ability to make food selections gives the patient an option in an otherwise limiting environment.

Hospitals and long-term care facilities are required to adopt a diet manual that serves as the reference for the diets served in the facility. The Academy has an online manual that can be purchased for several users per facility. All hospitals or health care institutions have basic, routine diets designed for uniformity and convenience of service. These standard diets are based on the foundation of an adequate diet pattern with nutrient levels as derived from the DRIs. Types of standard diets vary but generally can be classified as general or regular or modified in consistency. The diets should be realistic and meet the nutritional requirements of the patients. The most important consideration of the type of diet offered is providing foods that the patient is willing and able to eat and that accommodate any required dietary modifications. Shortened lengths of stay in many health care settings result in the need to optimize intake of calories and protein, and this often translates into a liberal approach to therapeutic diets. This is especially true when the therapeutic restrictions may compromise intake and subsequent recovery from surgery, stress, or illness.

Regular or General Diet

"Regular" or "general" diets are used routinely and serve as a foundation for more diversified therapeutic diets. In some institutions a diet that has no restrictions is referred to as the *regular* or *house* diet. It is used when the patient's medical condition does not warrant any limitations. This is a basic, adequate, general diet of approximately 1600 to 2200 kcal; it usually contains 60 to 80 g of protein, 80 to 100 g of fat, and 180 to 300 g of carbohydrate. Although there are no particular food restrictions, some facilities have instituted regular diets that are low in saturated fat, sugar, and salt to follow the dietary recommendations for the general population. In other facilities the diet focuses on providing foods the patient is willing and able to eat, with less focus on restriction of nutrients. Many institutions have a selective menu that allows the patient certain choices; the adequacy of the diet varies based on the patient's selections. More recent developments in health-care food service include use of "room service" similar to the hotel room service model; patients have complete freedom to choose what and when they will eat.

Consistency Modifications

Modifications in consistency may be needed for patients who have limited chewing or swallowing ability. Chopping, mashing, pureeing, or grinding food modifies its texture. See Chapter 40 and Appendix 28 for more information on consistency modifications and patients with neurologic changes that require these diets.

Clear liquid diets include some electrolytes and small amounts of energy from tea, broth, carbonated beverages, clear fruit juices, and gelatin. Milk and liquids prepared with milk are omitted, as are fruit juices that contain pulp. Fluids and electrolytes often are replaced intravenously until the diet can be advanced to a more nutritionally adequate one.

Little scientific evidence supports the use of clear liquid diets as transition diets after surgery (Jeffery et al, 1996). The average clear liquid diet contains only 500 to 600 kcal, 5 to 10 g of protein, minimum fat, 120 to 130 g of carbohydrate, and small amounts of sodium and potassium. It is inadequate in calories, fiber, and all other essential nutrients and should be used only

for short periods. In addition, full liquid diets also are not recommended for a prolonged time. If needed, oral supplements may be used to provide more protein and calories and could be offered as liquids with which to take medications if appropriate.

Food Intake

Food served does not necessarily represent the actual intake of the patient. Prevention of malnutrition in the health care setting requires observation and monitoring of the adequacy of patient intake. This nutrient intake analysis (NIA) is described in Chapter 4. If food intake is inadequate, measures should be taken to provide foods or supplements that may be better accepted or tolerated. Regardless of the type of diet prescribed, the food served and the amount actually eaten must be considered to obtain an accurate determination of the patient's energy and nutrient intake. Nourishments and calorie-containing beverages consumed between meals also are considered in the overall intake. The RDN must maintain communication with nursing and food service personnel to determine adequacy of intake.

Acceptance and Psychologic Factors

Meals and between-meal nourishments are often highlights of the day and are anticipated with pleasure by the patient. Mealtime should be as positive an experience as possible. Whatever setting the patient is eating in should be comfortable for the patient. Food intake is encouraged in a pleasant room with the patient in a comfortable eating position in bed or sitting in a chair located away from unpleasant sights or odors. Eating with others often promotes better intake.

Arrangement of the tray should reflect consideration of the patient's needs. Dishes and utensils should be in a convenient location. Independence should be encouraged in those who require assistance in eating. The caregiver can accomplish this by asking patients to specify the sequence of foods to be eaten and having them participate in eating, if only by holding their bread. Even visually impaired persons can eat unassisted if they are told where to find foods on the tray. Patients who require eating assistance should be fed when the foods are still at an optimal temperature. The assisted eating process requires about 20 minutes as a general rule.

Poor acceptance of foods and meals may be caused by unfamiliar foods, a change in eating schedule, improper food temperatures, the patient's medical condition, or the effects of medical therapy. Food acceptance is improved when personal selection of menus is encouraged.

Patients should be given the opportunity to share concerns regarding meals, which may improve acceptance and intake. The attitude of the caregiver is important for encouraging acceptance of a therapeutic diet. The nurse who understands that the diet contributes to the restoration of the patient's health communicates this conviction by actions, facial expressions, and conversation. Patients who understand that the diet is important to the success of their recovery usually accept it more willingly. When the patient must adhere to a therapeutic dietary program indefinitely, a counseling approach helps him or her achieve nutritional goals (see Chapter 14). Because they have frequent contact with patients, nurses play an important role in a patient's acceptance of nutrition care. Ensuring that the nursing staff is aware of the patient's nutrition care plan can greatly improve the probability of success.

Interventions: Nutrition Education and Counseling

Nutrition education is an important part of the MNT provided to many patients. The goal of nutrition education is to help the patient acquire the knowledge and skills needed to make changes, including modifying behavior to facilitate sustained change. Nutrition education and dietary changes can result in many benefits, including control of the disease or symptoms, improved health status, enhanced quality of life, and decreased health care costs.

As the average length of hospital stays has decreased, the role of the inpatient dietitian in educating inpatients has changed to providing brief education or "survival skills." This education includes the types of foods to limit, timing of meals, and portion sizes. Many patients now transfer to a rehabilitation facility to complete their recovery because of the lower cost of care. RDNs are able to follow them for longer periods of time and are able to continue the diet counseling started in the hospital. Follow-up outpatient counseling should be encouraged at discharge. See Chapter 13 for managing nutrition support and Chapter 14 for counseling.

Intervention: Coordination of Care

Nutrition care is part of **discharge planning**. Education, counseling, and mobilization of resources to provide home care and nutrition support are included in discharge procedures. Completing a discharge nutritional summary for the next caregiver is imperative for optimal care. Appropriate discharge documentation includes a summary of nutrition therapies and outcomes; pertinent information such as weights, laboratory values, and dietary intake; potential drug-nutrient interactions; expected progress or prognosis; and recommendations for follow-up services. Types of therapy attempted and failed can be very useful information. The amount and type of instruction given, the patient's comprehension, and the expected degree of adherence to the prescribed diet are included. An effective discharge plan increases the likelihood of a positive outcome for the patient.

Regardless of the setting to which the patient is discharged, effective coordination of care begins on day 1 of a hospital or nursing home stay and continues throughout the institutionalization. The patient should be included in every step of the planning process whenever possible to ensure that decisions made by the health care team reflect the desires of the patient.

When needed, the RDN refers the patient or client to other caregivers, agencies, or programs for follow-up care or services. For example, use of the home-delivered meal program of the Older Americans Act Nutrition Program traditionally has served frail, homebound, older adults, yet studies show that older adults who have been discharged recently from the hospital may be at high nutritional risk but not referred to this service (Sahyoun et al, 2010; see Chapter 20). Thus the RD plays an essential role in making the referral and coordinating the necessary follow-up.

NUTRITION FOR THE TERMINALLY ILL OR HOSPICE PATIENT

Maintenance of comfort and quality of life are most typically the goals of nutrition care for the terminally ill patient. Dietary restrictions are rarely appropriate. Nutrition care should be mindful of strategies that facilitate symptom and pain control. Recognition of the various phases of dying—denial, anger, bargaining, depression, and acceptance—will help the health

care practitioner understand the patient's response to food and nutrition support.

The decision as to when life support should be terminated often involves the issue of whether to continue enteral or parenteral nutrition. With **advance directives**, the patient can advise family and health care team members of his or her individual preferences with regard to end-of-life issues. Food and hydration issues may be discussed, such as whether tube feeding should be initiated or discontinued, and under what circumstances. Nutrition support should be continued as long as the patient is competent to make this choice (or as specified in the patient's advance directives).

In advanced dementia, the inability to eat orally can lead to weight loss (see Chapter 20). One clear goal-oriented alternative to tube feeding may be the order for "comfort feeding only" to ensure an individualized eating plan (Palecek et al, 2010). **Palliative care** encourages the alleviation of physical symptoms, anxiety, and fear while attempting to maintain the patient's ability to function independently.

Hospice home care programs allow terminally ill patients to stay at home and delay or avoid hospital admission. Quality of life is the critical component. Indeed, individuals have the right to request or refuse nutrition and hydration as medical treatment. RDN intervention may benefit the patient and family as they adjust to issues related to the approaching death. Families who may be accustomed to a modified diet should be reassured if they are uncomfortable about easing dietary restrictions. Ongoing communication and explanations to the family are important and helpful. RDNs should work collaboratively to make recommendations on providing, withdrawing, or withholding nutrition and hydration in individual cases and serve as active members of institutional ethics committees. The RDN, as a member of the health care team, has a responsibility to promote use of advanced directives of the individual patient and to identify their nutritional and hydration needs.

CLINICAL CASE STUDY

Mr. B, a 47-year-old man, 6 ft 2 in tall and weighing 200 lb, is admitted to the hospital with chest pain. Three days after admission, at patient care rounds, it is discovered that Mr. B has gained 30 pounds over the last 2 years. Review of the medical record reveals the following laboratory data: LDL: 240 (desirable 130), HDL 30 (desirable >50), triglyceride 350 (desirable <200). Blood pressure is 120/85. Current medications: multivitamin/mineral daily. Cardiac catheterization is scheduled for tomorrow. Diet history reveals frequent consumption of high fat foods.

Nutrition Diagnostic Statements

Altered nutrition-related laboratory values related to undesirable food choices as evidenced by elevated LDL and low HDL.

Excessive fat and energy intake related to consumption of high fat foods at all meals as evidenced by patient report.

Nutrition Care Questions

1. What other information do you need to develop a nutrition care plan?
2. Was nutrition screening completed in a timely manner? Discuss the implications of timing of screening versus implementing care.
3. Develop a chart note, using ADIME format, based on this information and the interview you conduct with the patient.
4. What nutrition care goals would you develop for this patient during his hospital stay?
5. What goals would you develop for this patient after discharge? Discuss how the type of health care insurance coverage the patient has might influence this plan.

HDL, High-density lipoprotein; LDL, low-density lipoprotein.

An appropriate diet is adequate and balanced and considers the individual's characteristics, such as age and stage of development, taste preferences, and food habits. It also reflects the availability of food, storage and preparation facilities, socioeconomic conditions, cultural practices and family traditions, and cooking skills. An adequate and balanced diet meets all the nutritional needs of an individual for maintenance, repair, living processes, growth, and development. It includes energy and all nutrients in proper amounts and in proportion to each other. The presence or absence of one essential nutrient may affect the availability, absorption, metabolism, or dietary need for others. The recognition of nutrient interrelationships provides further support for the principle of maintaining food variety to provide the most complete diet.

Dietitians translate food, nutrition, and health information into food choices and diet patterns for groups and individuals. With increasing knowledge of the relationship of diet to incidence of chronic disease among Americans, the importance of an appropriate diet cannot be overemphasized. In this era of vastly expanding scientific knowledge, food intake messages for health promotion and disease prevention change frequently.

DETERMINING NUTRIENT NEEDS

According to the Food and Nutrition Board (FNB) of the Institute of Medicine (IOM), choosing a variety of foods should provide adequate amounts of nutrients. A varied diet also may ensure that a person is consuming sufficient amounts

of **functional food** constituents that, although not defined as nutrients, have biologic effects and may influence health and susceptibility to disease. Examples include foods containing dietary fiber and carotenoids, as well as lesser known **phytochemicals** (components of plants that have protective or disease-preventive properties) such as isothiocyanates in Brussels sprouts or other cruciferous vegetables and lycopene in tomato products (see Chapter 19).

WORLDWIDE GUIDELINES

Numerous standards serve as guides for planning and evaluating diets and food supplies for individuals and population groups. The Food and Agriculture Organization (FAO) and the World Health Organization (WHO) of the United Nations have established international standards in many areas of food quality and safety, as well as dietary and nutrient recommendations. In the United States the FNB has led the development of nutrient recommendations since the 1940s. Since the mid-1990s, nutrient recommendations developed by the FNB have been used by the United States and Canada.

The U.S. Departments of Agriculture (USDA) and Health and Human Services (DHHS) have a shared responsibility for issuing dietary recommendations, collecting and analyzing food composition data, and formulating regulations for nutrition information on food products. Health Canada is the agency responsible for Canadian dietary recommendations. In Australia, the guidelines are available through the National Health and Medical Research Council of the Department of Health. In 1996 the WHO and FAO published guidelines for the development and use of food-based dietary guidelines ([FAO/WHO, 1996](#)). On the African continent, dietary guidelines have been developed in Namibia, Nigeria, and South

Portions of this chapter were written by Deborah H. Murray, David H. Holben and Janice L. Raymond.

Africa. In South America, several countries such as Argentina, Brazil, Chile, Uruguay, and Venezuela released dietary guidelines in the late 1990s or early 2000s. The same is true for Asian countries, including Bangladesh, India, Indonesia, Malaysia, Nepal, Philippines, Singapore, and Thailand.

Several countries have developed food-based dietary guidelines that are illustrated using images including a pyramid, a house, a staircase, or a palm tree. In the United States the **MyPlate Food Guidance System**, shown in [Figure 11-1](#), replaced the previous MyPyramid diagram. For comparison, see *Eating Well with Canada's Food Guide* as shown in *Clinical Insight: Nutrition Recommendations for Canadians* and [Figure 11-2](#). Mexico's *El Plato del Bien Comer*, with its five plate sections including one for legumes, is shown in [Figure 11-3](#). The Australian Guide for Healthy Eating uses a pie-shaped image with the five food groups represented proportionally in terms of recommended intakes ([Figure 11-4](#)). In Japan, the Ministry of Health, Labour and Welfare and the Ministry of Agriculture, Forestry and Fisheries jointly develop and update their Dietary Guidelines, and in 2005 created the "Japanese Food Guide Spinning Top" to encourage a well-balanced diet ([Figure 11-5](#)). The Chinese Nutrition Society released its latest update to its dietary Pagoda in 2008 ([Figure 11-6](#)). Several other countries use images to illustrate their food-based dietary guidelines, including the Netherlands ([Figure 11-7](#)), France ([Figure 11-8](#)), Greece ([Figure 11-9](#)),

Balancing Calories

- Enjoy your food, but eat less.
- Avoid oversized portions.

Foods to Increase

- Make half your plate fruits and vegetables.
- Make at least half your grains whole grains.
- Switch to fat-free or low-fat (1%) milk.

Foods to Reduce

- Compare sodium in foods like soup, bread, and frozen meals – and choose the foods with lower numbers.
- Drink water instead of sugary drinks.

FIGURE 11-1 MyPlate showing the five essential food groups. (Courtesy from the United States Department of Agriculture. Accessed October 2014 from <http://www.choosemyplate.gov/>)

Hungary ([Figure 11-10](#)), Ireland ([Figure 11-11](#)), Saudi Arabia ([Figure 11-12](#)), Slovenia ([Figure 11-13](#)), South Korea ([Figure 11-14](#)), and the United Kingdom ([Figure 11-15](#)). The latest dietary guidelines from Brazil include mention of the environment in which one eats, the time spent consuming a meal, and the importance of developing cooking skills (*Guia alimentar para a população Brasileira, 2014*). The Brazilian guidelines also offer advice on choosing fresh or freshly made foods at the grocery store and at restaurants, and suggest that the consumer look objectively at food product advertisements.

Dietary Reference Intakes

American standards for nutrient requirements have been the **recommended dietary allowances (RDAs)** established by the FNB of the IOM. They were first published in 1941 and most recently revised in 2010. Each revision incorporates the most recent research findings. In 1993 the FNB developed a framework for the development of nutrient recommendations, called **dietary reference intakes (DRIs)**. Nutrition and health professionals always should use updated food composition databases and tables and inquire whether data used in computerized nutrient analysis programs have been revised to include the most up-to-date information. An interactive DRI calculator is available at <http://fnic.nal.usda.gov/interactiveDRI/>. This can be used to determine an individual's daily nutrient recommendations based on the DRI, including energy, macronutrients, vitamins, and minerals, as well as calculating BMI.

DRI Components

The DRI model expands the previous RDA and RNI (Canada's Recommended Nutrient Intakes), which focused only on levels of nutrients for healthy populations to prevent deficiency diseases. To respond to scientific advances in diet and health throughout the life cycle, the DRI model now includes four reference points: **adequate intake (AI)**, estimated average requirement (EAR), recommended dietary allowance (RDA), and tolerable upper intake level (UL), as well as Acceptable Macronutrient Distribution Ranges (AMDR).

The **adequate intake (AI)** is an average daily intake level that is based on observed or experimentally determined approximations of nutrient intake by a group (or groups) of healthy people when sufficient scientific evidence is not available to calculate an RDA. Some key nutrients are expressed as an AI, including potassium (see Chapter 6). The **estimated average requirement (EAR)** is the average daily requirement of a nutrient for healthy individuals based on gender and stage of life. It is the amount of a nutrient with which approximately one half of individuals would have their needs met and one half would not. The EAR should be used for assessing the nutrient adequacy of populations, but not for individuals.

The **recommended dietary allowance (RDA)** presents the amount of a nutrient needed to meet the requirements of almost all (97% to 98%) of the healthy population of individuals for whom it was developed. An RDA for a nutrient should serve as a goal for intake for individuals, not as a benchmark for adequacy of diets of populations. Finally the **tolerable upper intake level (UL)** was established for many nutrients to reduce the risk of adverse or toxic effects from consumption of nutrients in concentrated forms—either alone or combined with others (not in

Recommended Number of Food Guide Servings per Day

Age in Years	Children			Teens		Adults			
	2-3	4-8	9-13	14-18		19-50		51+	
	Sex			Females	Males	Females	Males	Females	Males
Vegetables and Fruit	4	5	6	7	8	7-8	8-10	7	7
Grain Products	3	4	6	6	7	6-7	8	6	7
Milk and Alternatives	2	2	3-4	3-4	3-4	2	2	3	3
Meat and Alternatives	1	1	1-2	2	3	2	3	2	3

The chart above shows how many Food Guide Servings you need from each of the four food groups every day.

Having the amount and type of food recommended and following the tips in *Canada's Food Guide* will help:

- Meet your needs for vitamins, minerals and other nutrients.
- Reduce your risk of obesity, type 2 diabetes, heart disease, certain types of cancer and osteoporosis.
- Contribute to your overall health and vitality.

What is One Food Guide Serving?
Look at the examples below.

<p>Fresh, frozen or canned vegetables 125 mL (½ cup)</p>	<p>Leafy vegetables Cooked: 125 mL (½ cup) Raw: 250 mL (1 cup)</p>	<p>Fresh, frozen or canned fruits 1 fruit or 125 mL (½ cup)</p>	<p>100% Juice 125 mL (½ cup)</p>		
<p>Bread 1 slice (35 g)</p>	<p>Bagel ½ bagel (45 g)</p>	<p>Flat breads ½ pita or ½ tortilla (35 g)</p>	<p>Cooked rice, bulgur or quinoa 125 mL (½ cup)</p>	<p>Cereal Cold: 30 g Hot: 175 mL (¾ cup)</p>	<p>Cooked pasta or couscous 125 mL (½ cup)</p>
<p>Milk or powdered milk (reconstituted) 250 mL (1 cup)</p>	<p>Canned milk (evaporated) 125 mL (½ cup)</p>	<p>Fortified soy beverage 250 mL (1 cup)</p>	<p>Yogurt 175 g (¾ cup)</p>	<p>Kefir 175 g (¾ cup)</p>	<p>Cheese 50 g (1½ oz.)</p>
<p>Cooked fish, shellfish, poultry, lean meat 75 g (2½ oz.)/125 mL (½ cup)</p>	<p>Cooked legumes 175 mL (¾ cup)</p>	<p>Tofu 150 g or 175 mL (¾ cup)</p>	<p>Eggs 2 eggs</p>	<p>Peanut or nut butters 30 mL (2 Tbsp)</p>	<p>Shelled nuts and seeds 60 mL (¾ cup)</p>

Oils and Fats

- Include a small amount – 30 to 45 mL (2 to 3 Tbsp) – of unsaturated fat each day. This includes oil used for cooking, salad dressings, margarine and mayonnaise.
- Use vegetable oils such as canola, olive and soybean.
- Choose soft margarines that are low in saturated and trans fats.
- Limit butter, hard margarine, lard and shortening.

FIGURE 11-2 Eating Well with Canada's Food Guide. (Courtesy from Health Canada. Data from Health Canada: Eating well with Canada's food guide, Her Majesty the Queen in Right of Canada, represented by the Minister of Health Canada, 2011. Accessed October 2014 from <http://www.hc-sc.gc.ca/fn-an/food-guide-aliment/index-eng.php>.)

Continued

Make each Food Guide Serving count... wherever you are – at home, at school, at work or when eating out!

- ▶ **Eat at least one dark green and one orange vegetable each day.**
 - Go for dark green vegetables such as broccoli, romaine lettuce and spinach.
 - Go for orange vegetables such as carrots, sweet potatoes and winter squash.
- ▶ **Choose vegetables and fruit prepared with little or no added fat, sugar or salt.**
 - Enjoy vegetables steamed, baked or stir-fried instead of deep-fried.
- ▶ **Have vegetables and fruit more often than juice.**

- ▶ **Make at least half of your grain products whole grain each day.**
 - Eat a variety of whole grains such as barley, brown rice, oats, quinoa and wild rice.
 - Enjoy whole grain breads, oatmeal or whole wheat pasta.
- ▶ **Choose grain products that are lower in fat, sugar or salt.**
 - Compare the Nutrition Facts table on labels to make wise choices.
 - Enjoy the true taste of grain products. When adding sauces or spreads, use small amounts.

- ▶ **Drink skim, 1%, or 2% milk each day.**
 - Have 500 mL (2 cups) of milk every day for adequate vitamin D.
 - Drink fortified soy beverages if you do not drink milk.
- ▶ **Select lower fat milk alternatives.**
 - Compare the Nutrition Facts table on yogurts or cheeses to make wise choices.

- ▶ **Have meat alternatives such as beans, lentils and tofu often.**
- ▶ **Eat at least two Food Guide Servings of fish each week.***
 - Choose fish such as charr, herring, mackerel, salmon, sardines and trout.
- ▶ **Select lean meat and alternatives prepared with little or no added fat or salt.**
 - Trim the visible fat from meats. Remove the skin on poultry.
 - Use cooking methods such as roasting, baking or poaching that require little or no added fat.
 - If you eat luncheon meats, sausages or prepackaged meats, choose those lower in salt (sodium) and fat.

Enjoy a variety of foods from the four food groups.

Satisfy your thirst with water!
 Drink water regularly. It's a calorie-free way to quench your thirst. Drink more water in hot weather or when you are very active.

* Health Canada provides advice for limiting exposure to mercury from certain types of fish. Refer to www.healthcanada.gc.ca for the latest information.

Advice for different ages and stages...

Children

Following *Canada's Food Guide* helps children grow and thrive.

Young children have small appetites and need calories for growth and development.

- Serve small nutritious meals and snacks each day.
- Do not restrict nutritious foods because of their fat content. Offer a variety of foods from the four food groups.
- Most of all... be a good role model.

Women of childbearing age

All women who could become pregnant and those who are pregnant or breastfeeding need a multivitamin containing **folate** every day. Pregnant women need to ensure that their multivitamin also contains **iron**. A health care professional can help you find the multivitamin that's right for you.

Pregnant and breastfeeding women need more calories. Include an extra 2 to 3 Food Guide Servings each day.

Here are two examples:

- Have fruit and yogurt for a snack, or
- Have an extra slice of toast at breakfast and an extra glass of milk at supper.

Men and women over 50

The need for **vitamin D** increases after the age of 50.

In addition to following *Canada's Food Guide*, everyone over the age of 50 should take a daily vitamin D supplement of 10 µg (400 IU).

Eat well and be active today and every day!

The benefits of eating well and being active include:

- Better overall health.
- Lower risk of disease.
- A healthy body weight.
- Feeling and looking better.
- More energy.
- Stronger muscles and bones.

Be active

To be active every day is a step towards better health and a healthy body weight.

Canada's Physical Activity Guide recommends building 30 to 60 minutes of moderate physical activity into daily life for adults and at least 90 minutes a day for children and youth. You don't have to do it all at once. Add it up in periods of at least 10 minutes at a time for adults and five minutes at a time for children and youth.

Start slowly and build up.

Eat well

Another important step towards better health and a healthy body weight is to follow *Canada's Food Guide* by:

- Eating the recommended amount and type of food each day.
- Limiting foods and beverages high in calories, fat, sugar or salt (sodium) such as cakes and pastries, chocolate and candies, cookies and granola bars, doughnuts and muffins, ice cream and frozen desserts, french fries, potato chips, nachos and other salty snacks, alcohol, fruit flavoured drinks, soft drinks, sports and energy drinks, and sweetened hot or cold drinks.

Take a step today...

- ✓ Have breakfast every day. It may help control your hunger later in the day.
- ✓ Walk wherever you can – get off the bus early, use the stairs.
- ✓ Benefit from eating vegetables and fruit at all meals and as snacks.
- ✓ Spend less time being inactive such as watching TV or playing computer games.
- ✓ Request nutrition information about menu items when eating out to help you make healthier choices.
- ✓ Enjoy eating with family and friends!
- ✓ Take time to eat and savour every bite!

How do I count Food Guide Servings in a meal?

Here is an example:

Vegetable and beef stir-fry with rice, a glass of milk and an apple for dessert	
250 mL (1 cup) mixed broccoli, carrot and sweet red pepper	= 2 Vegetables and Fruit Food Guide Servings
75 g (2 1/2 oz.) lean beef	= 1 Meat and Alternatives Food Guide Serving
250 mL (1 cup) brown rice	= 2 Grain Products Food Guide Servings
5 mL (1 tsp) canola oil	= part of your Oils and Fats intake for the day
250 mL (1 cup) 1% milk	= 1 Milk and Alternatives Food Guide Serving
1 apple	= 1 Vegetables and Fruit Food Guide Serving

Read the label

- Compare the Nutrition Facts table on food labels to choose products that contain less fat, saturated fat, trans fat, sugar and sodium.
- Keep in mind that the calories and nutrients listed are for the amount of food found at the top of the Nutrition Facts table.

Limit trans fat

When a Nutrition Facts table is not available, ask for nutrition information to choose foods lower in trans and saturated fats.

Nutrition Facts	
Per 0 mL (0 g)	
Amount	% Daily Value
Calories 0	
Fat 0 g	0 %
Saturated 0 g	0 %
Trans 0 g	
Cholesterol 0 mg	
Sodium 0 mg	0 %
Carbohydrate 0 g	0 %
Fibre 0 g	0 %
Sugars 0 g	
Protein 0 g	
Vitamin A 0 %	Vitamin C 0 %
Calcium 0 %	Iron 0 %

FIGURE 11-3 El Plato del Bien Comer (The Plate of Good Eating). (Courtesy of Mexico Ministry of Health. Accessed January 2014 from http://www.promocion.salud.gob.mx/dgps/descargas1/programas/6_1_plato_bien_comer.pdf.)

food)—or from enrichment and fortification. A UL is the highest level of daily nutrient intake that is unlikely to have any adverse health effects on almost all individuals in the general population. The DRIs for the macronutrients, vitamins, and minerals, including the ULs, are presented on the inside front and back covers and opening page of this text. The AMDRs are ranges of intakes of macronutrients associated with reduced risk of chronic disease. The AMDRs for fat, carbohydrate, and protein are based on energy intake by age group. See [Table 11-1](#) and the DRI tables on the inside front and back covers of this text.

Target Population

Each of the nutrient recommendation categories in the DRI system is used for specific purposes among individuals or populations. As noted previously, the EAR is used for evaluating the nutrient intake of populations. The AI and RDA can be used for individuals. Nutrient intakes between the RDA and the UL may further define intakes that may promote health or prevent disease in the individual.

Age and Gender Groups

Because nutrient needs are highly individualized depending on age, gender, and the reproductive status of females, the DRI framework has 10 age groupings, including age group categories for children, adolescents, men and women 51 to 70 years of age, and those older than 70 years of age. It separates three age group categories each for pregnancy and lactation—14 to 18 years, 19 to 30 years, and 31 to 50 years of age.

Reference Men and Women

The requirement for many nutrients is based on body weight, according to reference heights and weights that are specific to gender and stage of life. Reference height and weight

FIGURE 11-4 Australian Guide to Healthy Eating (Courtesy from the Australian Government, National Health and Medical Research Council, Department of Health and Ageing. Accessed June 2015 from <http://eatforhealth.gov.au/guidelines>.)

information used in determining the DRIs was obtained from the Centers for Disease Control and Prevention (CDC)/National Center for Health Statistics (NCHS) growth charts. Although this does not necessarily imply that these weight-for-height values are ideal, at least they make it possible to define recommended allowances appropriate for the greatest number of people.

NUTRITIONAL STATUS OF AMERICANS

Food and Nutrient Intake Data

Information about the diet and nutritional status of Americans and the relationship between diet and health is collected primarily by the CDC via its NCHS and National Health and Nutrition Examination Survey (NHANES).

Unfortunately, gaps still exist between actual consumption and government recommendations in certain population subgroups. Nutrition-related health measurements indicate that overweight and obesity are increasing from lack of physical activity. Data from the combined NHANES and NHANES National Youth Fitness Survey showed that only about 25% of youth ages 12 to 15 engage in moderate to vigorous physical

activity for more than 60 minutes daily. In males, this number decreased as weight increased (NHANES, 2012). Hypertension remains a major public health problem in middle-age and older adults and in non-Hispanic blacks in whom it increases the risk of stroke and coronary heart disease (see Chapter 33). Osteoporosis develops more often among non-Hispanic whites than non-Hispanic blacks (see Chapter 24). Concern about preventable conditions, along with an increased emphasis on sustainability, has led to many hospitals taking on the challenge for healthier food intake (see *Focus On: The “Healthy Food in Health Care” Pledge*).

TABLE 11-1 Acceptable Macronutrient Distribution Ranges

NUTRIENT	AMDR (PERCENTAGE OF DAILY ENERGY INTAKE)			AMDR SAMPLE DIET ADULT, 2000-KCAL/DAY DIET	
	1-3 Years	4-18 Years	>19 Years	%Reference*	g/Day
Protein [†]	5-20	10-30	10-35	10	50
Carbohydrate	45-65	45-65	45-65	60	300
Fat	30-40	25-35	20-35	30	67
α-Linolenic acid (*omega-3) [‡]	0.6-1.2	0.6-1.2	0.6-1.2	0.8	1.8
Linoleic acid (omega-6)	5-10	5-10	5-10	7	16
Added sugars [§]	≤25% of total calories			500	125

Modified from Food and Nutrition Board, Institute of Medicine: *Dietary reference intakes for energy, carbohydrate, fiber, fat, fatty acids, cholesterol, protein, and amino acids*, Washington, DC, 2002/2005: National Academies Press.

AMDR, Acceptable macronutrient distribution range; DHA, docosahexaenoic acid; DRI, dietary reference intakes; EPA, eicosapentaenoic acid.

[†]Suggested maximum.

[‡]Higher number in protein AMDR is set to complement AMDRs for carbohydrate and fat, not because it is a recommended upper limit in the range of calories from protein.

[§]Up to 10% of the AMDR for α-linolenic acid can be consumed as EPA, DHA, or both (0.06%-0.12% of calories).

[§]Reference percentages chosen based on average DRI for protein for adult men and women, then calculated back to percentage of calories. Carbohydrate and fat percentages chosen based on difference from protein and balanced with other federal dietary recommendations.

FOCUS ON

The “Healthy Food in Health Care” Pledge

Health care facilities across the nation have recognized that their systems of purchasing, producing, and distributing food may be misaligned with the U.S. dietary guidelines and have joined a movement to change their practices. One organization promoting this plan is called “Health Care Without Harm.” In 2009, The American Medical Association (AMA) approved a new policy resolution in support of practices and policies within health care systems that promote and model a healthy and ecologically sustainable food system. The resolution also calls on the AMA to work with health care and public health organizations to educate the health care community and the public about the importance of healthy and ecologically sustainable food systems. Hospitals are using the online pledge form to commit to these eight steps:

1. Increase offerings of nutritionally dense foods, including fruits and vegetables.
2. Communicate to Group Purchasing Organizations an interest in identifying the source and production practices of procured foods.

3. Develop a program to source from producers that uphold the dignity of family, farmers, workers, and their communities and support sustainable systems.
4. Work with farmers, organizations, and suppliers to increase the availability of locally produced food.
5. Educate patients and the community about nutritious, socially just, and ecologically sustainable food practices and procedures.
6. Minimize or beneficially reuse food waste and support the use of food packaging that is ecologically protective.
7. Encourage vendors and food management companies to supply food that is produced in systems that support farm and farm worker health and welfare and use ecologically protective and restorative agriculture.
8. Report annually on implementation.

Modified from *Health Care without Harm* (website): <https://noharm-uscanada.org/civicism/petition/sign?sid=2>. Accessed October 2014.

CLINICAL INSIGHT

Nutrition Recommendations for Canadians

The revision to Canada’s Food Guide to Healthy Eating, released in 2007, developed age- and gender-specific food intake patterns. These suggested patterns include 4 to 7 servings of vegetables and fruits, 3 to 7 servings of grain products, 2 to 3 servings of milk or milk alternatives, and 1 to 3 servings of meat or meat alternatives. Canada’s Eating Well with Canada’s Food Guide contains four main food groupings presented in a rainbow shape.

Tips include the following:

- Eat at least one dark green and one orange vegetable each day.
- Make at least half of your grain products whole grain each day.
- Compare the Nutrition Facts table on food labels to choose products that contain less fat, saturated fat, trans fat, sugar, and sodium.

- Drink skim, 1% or 2% milk, or fortified soy beverages each day.
- Include a small amount — 30-45 ml (2-3 Tbsp) — of unsaturated fat each day.
- Eat at least two Food Guide Servings of fish each week.

It is recommended that adults accumulate at least 2½ hours of moderate to vigorous physical activity each week and that children and youth accumulate at least 60 minutes per day. The Canadian Food Guide recognizes the cultural, spiritual, and physical importance of traditional Aboriginal foods as well as the role of nontraditional foods in contemporary diets, with a First Nations, Inuit, and Métis guide available. The guide is available in 12 languages.

Data from Health Canada: *Eating Well with Canada’s Food Guide, Her Majesty the Queen in Right of Canada, represented by the Minister of Health Canada, 2011* (website): from <http://www.hc-sc.gc.ca/fn-an/food-guide-aliment/index-eng.php>. Eating Well with Canada’s Food Guide – First Nations, Inuit, and Métis accessed October 2014 from <http://hc-sc.gc.ca/fn-an/pubs/fnim-pnim/index-eng.php>. Accessed October 2014.

Finally, in spite of available choices, many Americans experience **food insecurity**, meaning that they lack access to adequate and safe food for an active, healthy life. Table 11-2 provides a list of food components and public health concerns related to those components.

Healthy Eating Index

The Center for Nutrition Policy and Promotion of the USDA releases the **Healthy Eating Index (HEI)** to measure how well people’s diets conform to recommended healthy eating patterns. The index provides a picture of foods people are

TABLE 11-2 Food Components and Public Health Concerns

Food Component	Relevance to Public Health
Energy	The high prevalence of overweight indicates that an energy imbalance exists among Americans because of physical inactivity and underreporting of energy intake or food consumption in national surveys.
Total fat, saturated fat, and cholesterol	Intakes of fat, saturated fatty acids, and cholesterol among all age groups older than 2 years of age are above recommended levels. Cholesterol intakes are generally within the recommended range of 300 mg/dl or less.
Alcohol	Intake of alcohol is a public health concern because it displaces food sources of nutrients and has potential health consequences.
Iron and calcium	Low intakes of iron and calcium continue to be a public health concern, particularly among infants and females of childbearing age. Prevalence of iron deficiency anemia is higher among these groups than among other age and sex groups. Low calcium intake is a particular concern among adolescent girls and adult women in most racial and ethnic groups.
Sodium*	Sodium intake exceeds government recommendations of 2300 mg/day in most age and sex groups. Strategies to lower intake can be found at the Institute of Medicine website at http://www.iom.edu/Reports/2010/Strategies-to-Reduce-Sodium-Intake-in-the-United-States.aspx .
Other nutrients at potential risk	Some population or age groups may consume insufficient amounts of total carbohydrate and carbohydrate constituents such as dietary fiber; protein; vitamin A; carotenoids; antioxidant vitamins C and E; folate, vitamins B ₆ and B ₁₂ ; magnesium, potassium, zinc, copper, selenium, phosphorus, and fluoride. Studies also suggest that vitamin D deficiency is very common.
Imbalanced Nutrients	Intakes of polyunsaturated and monounsaturated fatty acids, trans-fatty acids, and fat substitutes are often excessive.

*Recommended intake of 1500 mg or less in at-risk populations defined as African Americans, people with hypertension, diabetes, or chronic kidney disease, and anyone 51 years or older (Dietary Guidelines for Americans, 2010).

eating, the amount of variety in their diets, and compliance with specific recommendations in the [Dietary Guidelines for Americans](#) (DGA). The HEI is designed to assess and monitor the dietary status of Americans by evaluating 12 components, each representing different aspects of a healthy diet. The HEI was last updated after the release of the 2010 DGA. The dietary components used in HEI-2010 include nine related to adequacy: whole fruit, total fruit, whole grains, dairy, total protein foods, seafood and plant proteins, greens and beans, total vegetables, fatty acids, and three for which moderation is recommended: refined grains, sodium, and empty calories ([Guenther et al, 2013](#)). The reports from HEI-2010 noted the suboptimal quality of the American diet, for adults as well as children and adolescents, revealing an inadequate intake of beans and dark green vegetables, and the need to substitute whole grains for refined grains more frequently. Americans also need to decrease sodium intake and reduce consumption of empty calories from added sugars and solid fats.

NATIONAL GUIDELINES FOR DIET PLANNING

Eating can be one of life's greatest pleasures. People eat for enjoyment and to obtain energy and nutrients. Although many genetic, environmental, behavioral, and cultural factors affect health, diet is equally important for promoting health and preventing disease. Over the past several decades, attention has been focused increasingly on the relationship of nutrition to chronic diseases and conditions. Although this interest derives somewhat from the increasing percentage of older adults in the population as well as their longevity, it also is prompted by the desire to prevent premature deaths from diseases such as coronary heart disease, diabetes mellitus, and cancer. Approximately two thirds of deaths in the United States are caused by chronic disease.

Current Dietary Guidance

In 1969 President Nixon convened the White House Conference on Nutrition and Health ([White House conference on food, nutrition and health, 1969](#)). Increased attention was being given to prevention of hunger and disease. The development of dietary guidelines in the United States is discussed in Chapter 9. Guidelines directed toward prevention of a

particular disease, such as those from the National Cancer Institute; the American Diabetes Association; the American Heart Association; and the National Heart, Lung, and Blood Institute's cholesterol education guidelines, contain recommendations unique to particular conditions. The Academy of Nutrition and Dietetics supports a total diet approach, in which the overall pattern of food eaten, consumed in moderation with appropriate portion sizes and combined with regular physical activity, is key ([Academy of Nutrition and Dietetics, 2013](#)). Various guidelines that can be used by health counselors throughout the developed world are summarized in [Box 11-1](#).

Implementing the Guidelines

The task of planning nutritious meals centers on including the essential nutrients in sufficient amounts as outlined in the most recent DRIs, in addition to appropriate amounts of energy, protein, carbohydrate (including fiber and sugars), fat (especially saturated and trans fats), cholesterol, and sodium. Suggestions are included to help people meet the specifics of the recommendations. When specific numeric recommendations differ, they are presented as ranges.

BOX 11-1 Universal Prescription for Health and Nutritional Fitness

- Adjust energy intake and exercise level to achieve and maintain appropriate body weight.
- Eat a wide variety of foods to ensure nutrient adequacy.
- Increase total carbohydrate intake, especially complex carbohydrates.
- Eat less total fat and less saturated fat.
- Eat more fiber-rich foods, including whole grains, fruits, and vegetables.
- Limit or omit high-sodium foods.
- Reduce intake of concentrated sugars.
- Drink alcohol in moderation or not at all.
- Meet the recommendations for calcium, especially important for adolescents and women.
- Meet the recommendation for iron, especially for children, adolescents, and women of childbearing age.
- Limit protein to no more than twice the recommended dietary allowance.
- If using a daily multivitamin, choose dietary supplements that do not exceed the recommended dietary allowance.
- Drink fluoridated water.

BOX 11-2 The 2015 Dietary Guidelines for Americans

1. Follow a healthy eating pattern across the lifespan.
2. Focus on variety, nutrient density, and amount.
3. Limit calories from added sugars and saturated fats and reduce sodium intake.
4. Shift to healthier food and beverage choices.
5. Support healthy eating patterns for all.

Accessed January 2016 from <http://www.health.gov/dietaryguidelines/2015/guidelines/>.

To help people select an eating pattern that achieves specific health promotion or disease prevention objectives, nutritionists should assist individuals in making food choices (e.g., to reduce saturated fat, to increase fiber). Although numerous federal agencies are involved in the issuance of dietary guidance, the USDA and DHHS lead the effort. The DGA first were published in 1980 and are revised every 5 years; the 2015 guidelines are included (Box 11-2). The DGA are designed to help nutrition and health professionals assist the public (> age 2) in consuming a healthy diet. The information in the DGA is used by the Federal government to create educational materials for consumers and helps guide development of Federal health policies and programs. initiatives (U.S. Department of Health and Human Services, 2015).

FOOD AND NUTRIENT LABELING

To help consumers make choices between similar types of food products that can be incorporated into a healthy diet, the FDA established a voluntary system of providing selected nutrient information on food labels. The regulatory framework for nutrition information on food labels was revised and updated by the USDA (which regulates meat, poultry products and eggs) and the FDA (which regulates all other foods) with enactment of the Nutrition Labeling and Education Act (NLEA) in 1990. The labels became mandatory in 1994. In 2014 changes to the layout of information on the food label were proposed, to help consumers make better informed decisions, placing greater emphasis on calorie content and serving size, as well as replacing nutrients abundant in the food supply (e.g., vitamin A) with those that are underconsumed by certain population groups (e.g., potassium). The new labels also include a separate line for added sugars, because many health experts recommend decreasing intake of sugars in favor of more nutrient-dense foods, as well as to help decrease overall caloric intake (Figure 11-15).

Mandatory Nutrition Labeling

As a result of the NLEA, nutrition labels must appear on most foods, except products that provide few nutrients (such as coffee and spices), restaurant foods, and ready-to-eat foods prepared on site, such as supermarket bakery and deli items. Providing nutrition information on many raw foods is voluntary. However, the FDA and USDA have called for a voluntary point-of-purchase program in which nutrition information is available in most supermarkets. Nutrition information is provided through brochures or point-of-purchase posters for the 20 most popular fruits, vegetables, and fresh fish and the 45 major cuts of fresh meat and poultry. In addition, many food processors in the United States and elsewhere are using front-of-package labeling that employs a score, symbols, or color coding to reflect a product's overall nutrient content. Examples of front-of-package

labeling include Smart Choices, NuVal, Guiding Stars, or the "traffic light" color-coding system used in the United Kingdom.

Nutrition information for foods purchased in restaurants is widely available at the point of purchase or from websites. New FDA regulations require restaurant chains, retail food establishments, and vending machines with 20 or more locations to disclose calorie information on their menus or menu board (or on a sign or sticker on or adjacent to the vending machine). Additional nutrient information that must be made available upon request include total calories, calories from fat, total fat, saturated fat, trans fat, cholesterol, sodium, total carbohydrates, fiber, sugars, and protein.

The new regulations also cover ready-to-eat unpackaged foods in delicatessens or supermarkets that meet requirements above. If a food makes the claim of being organic, it also must meet certain criteria and labeling requirements.

Standardized Serving Sizes on Food Labels

Serving sizes of products are set by the United States government based on reference amounts commonly consumed by Americans. For example, a serving of milk is 8 oz, and a serving of salad dressing is 2 tbsp. Standardized serving sizes make it easier for consumers to compare the nutrient contents of similar products (Figure 11-16).

Nutrition Facts Label

The **nutrition facts label** on a food product provides information on its per-serving calories and calories from fat. The label must list the amount (in grams) of total fat, saturated fat, trans fat, cholesterol, sodium, total carbohydrate, dietary fiber, sugar, and protein. For most of these nutrients the label also shows the

Nutrition Facts

Serving Size: About (20g)
Servings Per Container: 16

	Amount Per Serving	%Daily Value*
Total Calories	60	
Calories From Fat	15	
Total Fat	2 g	3%
Saturated Fat	1 g	4%
Trans Fat	0 g	
Cholesterol	0 mg	0%
Sodium	45 mg	2%
Total Carbohydrates	15 g	5%
Dietary Fiber	4 g	17%
Sugars	4 g	
Sugar Alcohols (Polyols)	3 g	
Protein	2 g	
Vitamin A		0%
Vitamin C		0%
Calcium		2%
Iron		2%

*Percent Daily Values are based on a 2,000 calorie diet.

Ingredients: Wheat flour, unsweetened chocolate, erythritol, inulin, oat flour, cocoa power, evaporated cane juice, whey protein concentrate, corn starch (low glycemic), natural flavors, salt, baking soda, wheat gluten, guar gum

FIGURE 11-16 Standard food label showing serving size.

percentage of the **daily value (DV)** supplied by a serving, showing how a product fits into an overall diet by comparing its nutrient content with recommended intakes of those nutrients (Table 11-3). DVs are not recommended intakes for individuals; they are simply reference points to provide some perspective on daily nutrient needs and are based on a 2000-kcal diet. For example, individuals who consume diets supplying more or fewer calories can still use the DVs as a rough guide to ensure that they are getting adequate amounts of vitamin C, for example, but not too much saturated fat.

The DVs are listed for nutrients for which RDAs already exist (in which case they are known as **reference daily intakes [RDIs]**) (Table 11-4) and for which no RDAs exist (in which case they are known as **daily reference values [DRVs]**) [Table 11-5]. However, food labels use only the term *daily value*. RDIs provide a large margin of safety; in general, the RDI for a nutrient is greater than the RDA for a specific age group. As new DRIs are developed in various categories, labeling laws are updated. Box 11-3 provides tips for reading and understanding food labels.

Nutrient Content Claims

Nutrient content terms such as *reduced sodium*, *fat free*, *low-calorie*, and *healthy* must meet government definitions that apply to all foods (Box 11-4). For example, *lean* refers to a serving of meat, poultry, seafood, or game meat with less than 10 g of fat, less than 4 g of saturated fat, and less than 95 mg of

TABLE 11-3 Daily Value (Based on 2000 kcal Diet)

Nutrient	Amount
Total Fat	65 grams (g)
Saturated Fat	20 g
Cholesterol	300 milligrams (mg)
Sodium	2,400 mg
Potassium	3,500 mg

TABLE 11-5 Daily Reference Values

Food Component	DRV	Calculation
Fat	65 g	30% of kcal
Saturated fat	20 g	10% of kcal
Cholesterol	300 mg	Same regardless of kcal
Carbohydrates (total)	300 g	60% of calories
Fiber	25 g	11.5 g per 1000 kcal
Protein	50 g	10% of kcal
Sodium	2400 mg	Same regardless of kcal
Potassium	3500 mg	Same regardless of kcal

DRV, Daily reference value.

NOTE: The DRVs were established for adults and children over 4 years old. The values for energy yielding nutrients below are based on 2000 calories per day.

BOX 11-3 Tips for Reading and Understanding Food Labels

Interpret the Percent Daily Value.

- Nutrients with %DV of 5 or less are considered low or poor sources
- Nutrients with %DV of 10-19 or less are considered moderate or "good sources."
- Nutrients with %DV of 20 or more are considered high or "rich sources."

Prioritize nutrient needs and compare %DV levels accordingly. For example, if a consumer wishes to lower osteoporosis risk versus limiting sodium, a packaged food containing 25%DV calcium and 15%DV sodium may be considered a sensible food selection.

Note the calories per serving and the servings per container. Consider how the energy value of a specific food fits into the total energy intake "equation." Be conscious of the portion size that is consumed and "do the math" as to how many servings per container that portion would be.

Be aware of specific nutrient content claims. As shown in Box 11-4, there are many nutrient content claims, but only specific ones may relate to personal health priorities. For example, if there is a positive family history for heart disease, the "low fat" nutrient claim of 3 grams or less per serving may serve as a useful guide during food selection.

Review the ingredient list. Ingredients are listed in order of prominence. Pay particular attention to the top five items listed. Ingredients that contain sugar often end in *-ose*. The term *hydrogenated* signals that trans fats may be present. Sodium-containing additives also may be present in multiple forms.

BOX 11-4 Nutrient Content Claims

Free: *Free* means that a product contains no amount of, or only trivial or “physiologically inconsequential” amounts of, one or more of these components: fat, saturated fat, cholesterol, sodium, sugar, or calories. For example, *calorie-free* means the product contains fewer than 5 calories per serving, and *sugar-free* and *fat-free* both mean the product contains less than 0.5 g per serving. Synonyms for *free* include *without*, *no*, and *zero*. A synonym for fat-free milk is *skim*.

Low: *Low* can be used on foods that can be eaten frequently without exceeding dietary guidelines for one or more of these components: fat, saturated fat, cholesterol, sodium, and calories. Synonyms for low include *little*, *few*, *low source of*, and *contains a small amount of*.

- **Low fat:** 3 g or less per serving
- **Low saturated fat:** 1 g or less per serving
- **Low sodium:** 140 mg or less per serving
- **Very low sodium:** 35 mg or less per serving
- **Low cholesterol:** 20 mg or less and 2 g or less of saturated fat per serving
- **Low calorie:** 40 calories or less per serving

Lean and extra lean: *Lean* and *extra lean* can be used to describe the fat content of meat, poultry, seafood, and game meats.

- **Lean:** less than 10 g fat, 4.5 g or less saturated fat, and less than 95 mg cholesterol per serving and per 100 g
- **Extra lean:** less than 5 g fat, less than 2 g saturated fat, and less than 95 mg cholesterol per serving and per 100 g

Reduced: *Reduced* means that a nutritionally altered product contains at least 25% less of a nutrient or of calories than the regular, or reference,

product. However, a *reduced* claim cannot be made on a product if its reference food already meets the requirement for a “low” claim.

Less: *Less* means that a food, whether altered or not, contains 25% less of a nutrient or of calories than the reference food. For example, pretzels that have 25% less fat than potato chips could carry a *less* claim. *Fewer* is an acceptable synonym.

Light: *Light* can mean two things:

- First, that a nutritionally altered product contains one-third fewer calories or half the fat of the reference food. If the food derives 50% or more of its calories from fat, the reduction must be 50% of the fat.
- Second that the sodium content of a low-calorie, low-fat food has been reduced by 50%. In addition, *light in sodium* may be used on food in which the sodium content has been reduced by at least 50%.
- The term *light* still can be used to describe such properties as texture and color, as long as the label explains the intent (e.g., *light brown sugar* and *light and fluffy*).

High: *High* can be used if the food contains 20% or more of the daily value for a particular nutrient in a serving.

Good source: *Good source* means that one serving of a food contains 10% to 19% of the daily value for a particular nutrient.

More: *More* means that a serving of food, whether altered or not, contains a nutrient that is at least 10% of the daily value more than the reference food. The 10% of daily value also applies to *fortified*, *enriched*, *added*, *extra*, and *plus* claims, but in these cases the food must be altered.

Data adapted from Food and Drug Administration. Accessed October 2014 from <http://www.fda.gov/food/guidanceregulation/guidancedocumentsregulatoryinformation/labelingnutrition/ucm064911.htm> and <http://www.fda.gov/Food/GuidanceRegulation/GuidanceDocumentsRegulatoryInformation/LabelingNutrition/ucm064916.htm>.

cholesterol per serving or per 100 g. Extra lean meat or poultry contains less than 5 g of fat, less than 2 g of saturated fat, and the same cholesterol content as lean, per serving, or per 100 g of product.

Health Claims

A **health claim** is allowed only on appropriate food products that meet specified standards. The government requires that health claims be worded in ways that are not misleading (e.g., the claim cannot imply that the food product itself helps prevent disease). Health claims cannot appear on foods that supply

more than 20% of the DV for fat, saturated fat, cholesterol, and sodium. The following is an example of a health claim for dietary fiber and cancer: “Low-fat diets rich in fiber-containing grain products, fruits, and vegetables may reduce the risk of some types of cancer, a disease associated with many factors.” **Box 11-5** lists health claims that manufacturers can use to describe food-disease relationships. In 2013 the FDA added a regulation that defines “gluten-free,” to clarify its voluntary use in food labeling and to help consumers with celiac disease to avoid foods containing gluten (see Chapters 26 and 28).

BOX 11-5 Health Claims for Diet-Disease Relationships

Calcium and Osteoporosis

- “Adequate calcium throughout life, as part of a well-balanced diet, may reduce the risk of osteoporosis.”

Calcium, Vitamin D, and Osteoporosis

- “Adequate calcium and vitamin D, as part of a well-balanced diet, along with physical activity, may reduce the risk of osteoporosis.”

Sodium and Hypertension

- “Diets low in sodium may reduce the risk of high blood pressure, a disease associated with many factors.”

Dietary Fat and Cancer

- “Development of cancer depends on many factors. A diet low in total fat may reduce the risk of some cancers.”

Dietary Saturated Fat and Cholesterol and Risk of Coronary Heart Disease

- “While many factors affect heart disease, diets low in saturated fat and cholesterol may reduce the risk of this disease.”

Fiber-Containing Grain Products, Fruits, and Vegetables and Cancer

- “Low-fat diets rich in fiber-containing grain products, fruits, and vegetables may reduce the risk of some types of cancer, a disease associated with many factors.”

Fruits, Vegetables and Grain Products That Contain Fiber, Particularly Soluble Fiber, and Risk of Coronary Heart Disease

- “Diets low in saturated fat and cholesterol and rich in fruits, vegetables, and grain products that contain some types of dietary fiber, particularly soluble fiber, may reduce the risk of heart disease, a disease associated with many factors.”

Fruits and Vegetables and Cancer

- “Low-fat diets rich in fruits and vegetables [*foods that are low in fat and may contain dietary fiber, vitamin A, or vitamin C*] may reduce the risk of some types of cancer, a disease associated with many factors. Broccoli is high in vitamin A and C, and it is a good source of dietary fiber.”

BOX 11-5 Health Claims for Diet-Disease Relationships—cont'd**Folate and Neural Tube Defects**

- “Healthful diets with adequate folate may reduce a woman’s risk of having a child with a brain or spinal cord defect.”

Dietary Noncariogenic Carbohydrate Sweeteners and Dental Caries

- Full claim: “Frequent between-meal consumption of foods high in sugars and starches promotes tooth decay. The sugar alcohols in [name of food] do not promote tooth decay”; Shortened claim on small packages only: “Does not promote tooth decay.”

Soluble Fiber from Certain Foods and Risk of Coronary Heart Disease

- “Soluble fiber from foods such as [name of soluble fiber source, and, if desired, name of food product], as part of a diet low in saturated fat and cholesterol, may reduce the risk of heart disease. A serving of [name of food product] supplies ___ grams of the [necessary daily dietary intake for the benefit] soluble fiber from [name of soluble fiber source] necessary per day to have this effect.”

Soy Protein and Risk of Coronary Heart Disease

- “25 grams of soy protein a day, as part of a diet low in saturated fat and cholesterol, may reduce the risk of heart disease. A serving of [name of food] supplies ___ grams of soy protein.”
- “Diets low in saturated fat and cholesterol that include 25 grams of soy protein a day may reduce the risk of heart disease. One serving of [name of food] provides ___ grams of soy protein.”

Plant Sterol/Stanol Esters and Risk of Coronary Heart Disease

“Foods containing at least 0.65 gram per of vegetable oil sterol esters, eaten twice a day with meals for a daily total intake of at least 1.3 grams, as part of a diet low in saturated fat and cholesterol, may

reduce the risk of heart disease. A serving of [name of food] supplies ___ grams of vegetable oil sterol esters.”

“Diets low in saturated fat and cholesterol that include two servings of foods that provide a daily total of at least 3.4 grams of plant stanol esters in two meals may reduce the risk of heart disease. A serving of [name of food] supplies ___ grams of plant stanol esters.”

**FDA Modernization Act Health Claims
Whole Grain Foods and Risk of Heart Disease and Certain Cancers**

- “Diets rich in whole grain foods and other plant foods and low in total fat, saturated fat, and cholesterol may reduce the risk of heart disease and some cancers.”

Potassium and the Risk of High Blood Pressure and Stroke

- “Diets containing foods that are a good source of potassium and that are low in sodium may reduce the risk of high blood pressure and stroke.”

Fluoridated Water and Reduced Risk of Dental Caries

- “Drinking fluoridated water may reduce the risk of [dental caries or tooth decay].”

Saturated Fat, Cholesterol, and Trans Fat, and Reduced Risk of Heart Disease

- “Diets low in saturated fat and cholesterol, and as low as possible in trans fat, may reduce the risk of heart disease.”

Substitution of Saturated Fat in the Diet with Unsaturated Fatty Acids and Reduced Risk of Heart Disease

- “Replacing saturated fat with similar amounts of unsaturated fats may reduce the risk of heart disease. To achieve this benefit, total daily calories should not increase.”

DIETARY PATTERNS AND COUNSELING TIPS**Vegetarian Diet Patterns**

Vegetarian diets are popular. Those who choose them may be motivated by philosophic, religious, or ecologic concerns, or by a desire to have a healthier lifestyle. Considerable evidence attests to the health benefits of a vegetarian diet. For example, studies of Seventh-Day Adventists indicate that the diet helps lower rates of metabolic syndrome (Rizzo et al, 2011).

Of the millions of Americans who call themselves **vegetarians**, many eliminate “red” meats but eat fish, poultry, and dairy products. A **lactovegetarian** does not eat meat, fish, poultry, or eggs but does consume milk, cheese, and other dairy products. A **lactoovovegetarian** also consumes eggs. A **vegan** does not eat any food of animal origin. The vegan diet is the only vegetarian diet that has any real risk of providing inadequate nutrition, but this risk can be avoided by careful planning (American Dietetic Association, 2009). A type of **semivegetarian** is known as a **flexitarian**. Flexitarians generally adhere to a vegetarian diet for the purpose of good health and do not follow a specific ideology. They view an occasional meat meal as acceptable. A public health awareness campaign called Meatless Monday advocates that Americans have a vegetarian meal at least one day per week to help reduce the incidence of preventable chronic health conditions such as diabetes, obesity, and cardiovascular disease.

Vegetarian diets tend to be lower in iron than omnivorous diets, although the nonheme iron in fruits, vegetables, and

unrefined cereals usually is accompanied either in the food or in the meal by large amounts of ascorbic acid that aids in iron assimilation. Vegetarians do not have a greater risk of iron deficiency than those who are not vegetarians (American Dietetic Association, 2009). Vegetarians who consume no dairy products may have low calcium intakes, and vitamin D intakes may be inadequate among those in northern latitudes where there is less exposure to sunshine. The calcium in some vegetables is made unavailable for absorption by the presence of oxalates. Although phytates in unrefined cereals also can make calcium unavailable, this is not a problem for Western vegetarians, whose diets tend to be based more on fruits and vegetables than on the unrefined cereals of Middle Eastern cultures.

Long-term vegans may develop megaloblastic anemia because of a deficiency of vitamin B₁₂, found only in foods of animal origin. The high levels of folate in vegan diets may mask the neurologic damage of a vitamin B₁₂ deficiency. Vegans should have a reliable source of vitamin B₁₂ such as fortified breakfast cereals, soy beverages, or a supplement. Although most vegetarians meet or exceed the requirements for protein, their diets tend to be lower in protein than those of omnivores. Lower protein intake usually results in lower saturated fat intake because many high-protein animal products are also rich in saturated fat (American Dietetic Association, 2009).

Well-planned vegetarian diets are safe for infants, children, and adolescents and can meet all of their nutritional requirements for growth. They are also adequate for pregnant and

lactating females. The key is that the diets be well planned. Vegetarians should pay special attention to ensure that they get adequate calcium, iron, zinc, and vitamins B₁₂ and D. Calculated combinations of complementary protein sources is not necessary, especially if protein sources are reasonably varied. Useful information on vegetarian meal planning is available at <http://www.eatright.org/Public/list.aspx?TaxID=6442452074&page=1> through the Academy of Nutrition and Dietetics.

CULTURAL ASPECTS OF DIETARY PLANNING

To plan diets for individuals or groups that are appropriate from a health and nutrition perspective, registered dietitian nutritionists and health providers must use resources that are targeted to the specific client or group. Numerous population subgroups in the United States and throughout the world have specific cultural, ethnic, or religious beliefs and practices to consider. These groups have their own set of dietary practices, which are important when considering dietary planning (*Diabetes Care and Education Dietetic Practice Group, 2010*). The IOM report entitled *Unequal Treatment* recommended that all health care professionals receive training in cross-cultural communication to help reduce ethnic and racial disparities in health care. Cultural competence training improves the skills and attitudes of the clinician and can facilitate a dialogue that encourages the client to share more information during a session (*Betancourt and Green, 2010*).

Attitudes, rituals, and practices surrounding food are part of every culture in the world, and there are so many cultures that it defies enumeration. Many world cultures have influenced American cultures as a result of immigration and intermarriage. This makes planning a menu that embraces cultural diversity and is sensitive to the needs of a specific group of people a major challenge. It is tempting to simplify the role of culture by attempting to categorize dietary patterns by race, ethnicity, or religion. However, this type of generalizing can lead to inappropriate labeling and misunderstanding.

To illustrate this point, consider the case of Native Americans. There are more than 550 different federally recognized tribes

in 35 states. The food and customs of the tribes in the Southwest are different from those of the Northwest. With traditional foods among Native Americans, the situation is complicated further by the fact that many tribes were removed from their traditional lands in the nineteenth century by the government. Another example of the complexity of diet and culture in the United States is that of African Americans. “Soul food” is commonly identified with African Americans from the South. Traditional food choices, likely borne out of hard times, limited choices, and creativity, may include greens such as collards, mustard, kale, prepared with pork; beans, field peas, yams, fried meats, grits, and cornbread. However, this by no means represents the diet of all African Americans. Similarly, the diet of Mexican Americans does not necessarily equal that of immigrants from Central America.

When faced with planning a diet to meet the needs of an unfamiliar culture, it is important to avoid forming opinions that are based on inaccurate information or stereotyping (see Chapter 14). Some cultural food guides have even been developed for specific populations to help manage disease conditions.

Religion and Food

Dietary practices have been a component of religious practice for all of recorded history. Some religions forbid the eating of certain foods and beverages; others restrict foods and drinks during holy days. Specific dietary rituals may be assigned to members with designated authority or with special spiritual power (e.g., a *shohet*, certified to slaughter animals in accordance with Jewish law). Sometimes dietary rituals or restrictions are observed based on gender. Dietary and food preparation practices (e.g., halal and kosher meat preparation) can be associated with rituals of faith.

Fasting is practiced by many religions. It has been identified as a mechanism that allows one to improve one’s body, to earn approval or to understand and appreciate the sufferings of others. Attention to specific eating behaviors such as overeating, use of alcoholic or stimulant-containing beverages, and vegetarianism also are considered by some religions. Before planning menus for members of any religious group, clinicians must gain an understanding of the traditions or dietary practices (*Table 11-6*). In all

TABLE 11-6 Some Religious Dietary Practices

	Buddhist	Hindu	Jewish (Orthodox)	Muslim	Christian Roman Catholic	Christian Eastern Orthodox	Christian Mormon	Christian Seventh Day Adventist
Beef	A	X						A
Pork	A	A	X	X				X
Meats, all	A	A	R	R	R	R		A
Eggs/dairy	O	O	R			R		O
Fish	A	R	R			R		A
Shellfish	A	R	X			O		X
Alcohol		A		X			X	X
Coffee/tea				A			X	X
Meat/dairy at same meal			X					
Leavened foods			R					
Ritual slaughter of meats			+	+				
Moderation	+			+				+
Fasting*	+	+	+	+	+	+	+	+

Modified from Kittler PG et al: *Food and culture*, ed 6, Belmont, Calif, 2011, Wadsworth/Cengage Learning; Escott-Stump S: *Nutrition and diagnosis-related care*, ed 7, Baltimore, Md, 2011, Lippincott Williams & Wilkins.

+, Practiced; A, avoided by the most devout; O, permitted, but may be avoided at some observances; R, some restrictions regarding types of foods or when a food may be eaten; X, prohibited or strongly discouraged.

*Fasting varies from partial (abstention from certain foods or meals) to complete (no food or drink).

cases, discussing the personal dietary preferences of an individual is imperative (Kittler et al, 2011).

Health Literacy

A critical yet often overlooked aspect of communication with individuals or groups about an optimal diet is the audience's level of health literacy. The average American reads at an eighth grade level and 20% read at or below a fifth grade level. A systematic review of nutrition and health literacy found that several gaps exist, including lack of training in health literacy and unfamiliarity with readability assessments and other health literacy screening tools (Carbone and Zoellner, 2012). Several readability tests exist that use criteria such as sentence length and number of multisyllabic words to produce a score and then either translate that score to a U.S. grade level, or compare it to a desired value. For example, the Flesch Reading Ease algorithm uses the average number of words in a sentence and average number of syllables per word, producing a score that ideally should be 60 or higher. Nutrition professionals should be familiar with these indices, especially if they write for the media or contribute to or manage a website.

FOCUS ON

What Is a Locavore?

There is a growing movement in the United States fueled by books like *Animal, Vegetable, Miracle: A Year of Food Life* (Kingsolver, 2007) and *The Omnivore's Dilemma* (Pollan, 2008) to build a more locally based, self-reliant food economy. The movement is one in which sustainable food production, processing, distribution, and consumption are integrated to enhance the economic, environmental, and social health of a particular area. A *locavore*, a term whose creation is attributed to Jessica Prentice in conjunction with World Environment Day in 2005 (Oxford University Press blog, 2007), is one who eats food grown or produced locally or within a certain limited radius. The locavore movement encourages consumers to buy from farmers' markets or even to produce their own food. They argue that locally produced food is fresher and more nutritious and uses less fossil fuel to grow and transport. Another component of this movement is the condemnation of the factory farming method of grain feeding animals, known as concentrated animal feeding operations. There is a growing demand for meat that is grass or range fed and not transported long distances.

The locavore movement is not without its critics, however. In his essay, "Green Eggs and Ham? The Myth of Sustainable Meat and the Danger of the Local," Vasile Stănescu challenges the "food miles" concept that long-distance distribution of food creates greater greenhouse gas emissions, noting that the production phase actually produces significantly more emissions than the distribution phase (Stănescu, 2010). As an example, he cites a study showing that fewer emissions were produced when consumers in the United Kingdom bought certain food items from New Zealand compared with the same items produced in Britain (Saunders et al, 2006). Some authors have suggested that a shift from a meat-based to a plant-based diet would have the greatest impact on greenhouse gas emissions (Weber and Matthews, 2008). In any case, concern about the environment among nutrition professionals, particularly as it relates to food production and distribution, has moved from the fringe to the mainstream.

FOCUS ON

Nutrition Transition

Sudha Raj PhD, RDN, FAND

The term *nutrition transition*, coined in the early 1990s, describes alterations in diet, body composition, and physical activity patterns in people in developing countries undergoing rapid urbanization, and demographic, socioeconomic and acculturative changes (Popkin, 2001; Shetty, 2013). The shifts in traditional ways, value systems and behaviors experienced in emerging economies such as India, China, the Middle East, North Africa, and Latin America are associated with notable increases in nutrition related chronic diseases, while infectious and nutrition related deficiency diseases persist. Consequently, these populations face a double burden of disease—the struggles of undernutrition coexist with the maladies of overnutrition within the same individual, family, or community (Schmidhuber and Shetty, 2005).

Rapid advancements in medicine, food production, and agricultural technologies, along with the liberalization of markets leading to changes in food distribution and retail, have proven to be a double-edged sword in these countries. On the one hand, enormous economic developments and health benefits have accrued; on the other, a myriad of challenges marked by nutritional imbalances and chronic disease trajectories have risen (WHO/FAO, 2013). Inequalities in income and access to quality food and health care exist. Inactive lifestyles and increased toxic burden exposure and processed food consumption at the expense of indigenous foods are important nutrition transition determinants. In addition, there is increased vulnerability of individuals because of epigenetic fetal programming changes (Barker, 2006).

Several holistic, sustainable nutrition intervention approaches using a food-based and community involvement focus are currently underway to address nutrition transition worldwide (Sunguya et al, 2014; Vorster et al, 2011). These initiatives are directed at achieving optimal and balanced nutrition for all using evidence-based interventions and timely policies (Garmendia et al, 2013).

CLINICAL CASE STUDY

Jacob is a 45-year-old Jewish male who emigrated from Israel to the United States 3 years ago. He follows a strict kosher diet. In addition, he does not drink milk but does consume other dairy products. He has a body mass index of 32 and a family history of heart disease. He has come to you for advice on increasing his calcium intake.

Nutrition Diagnostic Statement

Knowledge deficit related to calcium as evidenced by request for nutrient and dietary information

Nutrition Care Questions

1. What type of dietary guidance would you offer Jacob?
2. What type of dietary plan following strict kosher protocols would meet his daily dietary needs and promote weight loss?
3. What suggestions would you offer him about dietary choices for a healthy heart?
4. Which special steps should Jacob take to meet calcium requirements without using supplements?
5. How can food labeling information be used to help Jacob meet his weight loss and nutrient goals and incorporate his religious dietary concerns?

Food and Nutrient Delivery: Complementary and Integrative Medicine and Dietary Supplementation

Kelly Morrow, MS, RDN

KEY TERMS

Adverse events (AEs)	Dietary supplement	Integrative medicine
Acupuncture	Dietary Supplement Health and Education Act (DSHEA)	Megadose
Alternative medicine	Dietary Supplement Label Database	Meridians
Ayurveda	Drug Nutrient Interaction (DNI)	Moxibustion
Bioactive compound	East Asian Medicine	Naturopathy
Botanical medicine	Excipients	New Dietary Ingredient (NDI)
Chi (Qi)	Functional medicine	Pharmacognosy
Chiropractic	Generally Recognized As Safe (GRAS)	Phytochemical
Codex Alimentarius Commission (Codex)	Health claim	Phytotherapy
Commission E Monographs	Holistic medicine	Structure-function claim
Complementary medicine	Homeopathy	Subluxation
Complementary and alternative medicine (CAM)		Third party certification
		Vis Medicatrix Naturae

COMPLEMENTARY AND INTEGRATIVE MEDICINE

Some people may be confused by the multiple names used to describe natural medicine approaches. **Holistic medicine**, from the Greek word *holos* means “whole.” Holistic therapies are based on the theory that health is a vital dynamic state and is more than just the absence of disease. **Vis medicatrix naturae**, the healing force of nature, is the underlying precept of holistic medicine. The philosophy states that when a person lives according to the laws of nature, the body has the ability to self-heal. **Alternative medicine** refers to holistic therapies used *in place* of conventional medicine. **Integrative medicine** and **complementary medicine** refer to holistic therapies used *in addition* to conventional medicine (National Center for Complementary and Integrative Health [NCCIH], 2015). (see Tables 12-1 and 12-2).

Functional medicine is another iteration of holistic medicine that has gained esteem in recent years. It shifts the disease-centered focus of traditional medical practice to a more patient-centered approach (IFM, 2015). The goal is to evaluate the whole person rather than individual symptoms and to consider care

in relation to prevention and treatment of chronic disease. Functional medicine practitioners acknowledge a web-like interconnectedness of internal physiologic factors within the body and use nutrition therapy, dietary supplements, and physical manipulations as the foundation of medical care. They assess for core imbalances, including dietary intake, hormones and neurotransmitters, markers of oxidative stress, detoxification, immune function, and psychological and spiritual health.

The Academy of Nutrition and Dietetics (AND) practice group, Dietitians in Integrative and Functional Medicine (DIFM), has developed a nutrition-oriented functional medicine radial for dietetics practitioners to assess clients using Integrative and Functional Medical Nutrition Therapy (IFMNT) (Ford et al, 2011). A functional nutrition assessment can overlap with the nutrition care process (NCP) and includes expanded categories in the clinical, biochemical, and physical domains. (See Chapter 10 and Fig 10-1).

USE OF COMPLEMENTARY AND INTEGRATIVE THERAPIES

According to the National Center for Complementary and Integrative Health (NCCIH), almost 40% of adults and 12% of children in the United States use health care approaches that are outside of the mainstream. Worldwide, the prevalence is 12% of

Portions of this chapter were written by Cynthia A. Thomson, PhD, RD, for the previous edition of this text.

TABLE 12-1 Common Holistic Therapies According to the National Center for Complementary and Integrative Health (NCCIH)

Complementary and Integrative Medical systems	Naturopathy , Traditional Chinese Medicine (also known as East Asian Medicine), Ayurveda , and Homeopathy
Mind /Body therapies	Meditation, prayer, art or music therapy, and cognitive behavior therapy
Biologically based therapies	Herbs, whole-foods diets, and nutrient supplementation
Manipulative therapies	Massage, chiropractic medicine, osteopathy, and yoga
Energy therapies	Qi gong, magnetic therapy, or reiki

National Center for Complementary and Integrative Health (NCCIH). Complementary, Alternative or Integrative Health: What's In a Name? <http://nccam.nih.gov/health/whatiscam>. Accessed June 19, 2015.

TABLE 12-2 Description of Commonly Used Complementary and Integrative Therapies

	Description
Naturopathy (naturopathic medicine)	<p>Is a primary care medicine that uses the healing power of nature, <i>Vis Medicatrix Naturae</i>, to restore and maintain optimum health. Guiding principles include the following:</p> <p><i>Primum Non Nocere</i>—First do no harm</p> <p><i>Tolle Causam</i>—Treat the root cause of illness</p> <p><i>Docere</i>—Doctor as teacher</p> <p>Therapeutic methods and substances are used that work in harmony with a person's self-healing process, including diet and nutrient therapy, botanical medicine, psychotherapy, physical and manipulative therapy, minor surgery, prescription medicines, naturopathic obstetrics (natural childbirth), homeopathy, and acupuncture.</p> <p>Licensed in the United States to practice in 17 states and 2 territories.</p> <p>Training includes pathology, microbiology, histology, and physical and clinical diagnosis; pharmacognosy (clinical training in botanical medicine), hydrotherapy, physiotherapy, therapeutic nutrition, and homeopathy.</p>
Chiropractic	<p>Embraces many of the same principles as naturopathy, particularly the belief that the body has the ability to heal itself and that the practitioner's role is to assist the body in doing so. Like naturopathy, chiropractic focuses on wellness and prevention and favors noninvasive treatments.</p> <p>Chiropractors do not prescribe drugs or perform surgery.</p> <p>Focus on locating and removing interferences to the body's natural ability to maintain health, called subluxations (specifically musculoskeletal problems that lead to interference with the proper function of the nervous and musculoskeletal systems)</p> <p>Therapeutic approach is the manual manipulation of the body, such as spinal adjustment and massage and lifestyle recommendations, including physical exercises and stretching.</p> <p>Two fundamental precepts: (1) the structure and condition of the body influence how well the body functions, and (2) the mind-body relationship is important in maintaining health and in promoting healing</p> <p>Licensed and regulated in all 50 states and in some 30 countries.</p> <p>Must complete a 4-year program from a federally accredited college of chiropractic and, like other licensed practitioners, successfully pass an examination administered by a national certifying body</p>
Homeopathy	<p>The root words of <i>homeopathy</i> are derived from the Greek <i>homios</i>, meaning <i>like</i> and <i>pathos</i>, meaning <i>suffering</i>. Homeopathy is a medical theory and practice advanced to counter the conventional medical practices of 200 years ago. It endeavors to help the body heal itself by treating like with like, commonly known as the "law of similars." The law of similars is based on the theory that, if a large amount of a substance causes symptoms in a healthy person, a smaller amount of the same substance can be used to treat an ill person</p> <p>Samuel Hahnemann, an eighteenth-century German physician, is credited with founding homeopathy.</p> <p>The amounts of the remedies used in homeopathic medicines are extremely diluted. According to homeopathic principles, remedies are potentized and become more powerful through a shaking process called succussion.</p> <p>Homeopathic tinctures are made from a variety of source materials including botanicals, minerals, and animal tissues. Dosages are based on the following dilutions. A remedy becomes stronger the more it is diluted.</p> <p>X: 1 drop tincture in 10 drops water</p> <p>C: 1 drop tincture in 100 drops water</p> <p>M: 1 drop tincture in 1000 drops water</p> <p>The minimum-dose principle means that many homeopathic remedies are so dilute that no actual molecules of the healing substance can be detected by chemical tests.</p> <p>The goal of homeopathy is to select a remedy that will bring about a sense of well-being on all levels—physical, mental, and emotional—and that will alleviate physical symptoms and restore the patient to a state of wellness and creative energy.</p> <p>Although this form of medicine has a long history of use, clinical evidence on the efficacy of homeopathy is highly contradictory.</p>
East Asian Medicine	<p>Based on the concept that energy, also termed chi (Qi) or life-force energy, is central to the functioning of the body. Chi is the intangible force that animates life and enlivens all activity. Wellness is a function of the balanced and harmonious flow of chi, whereas illness or disease results from disturbances in its flow. Wellness also requires preserving equilibrium between the contrasting states of yin and yang (the dual nature of all things). The underlying principle is preventive in nature, and the body is viewed as a reflection of the natural world.</p> <p>Four substances—blood, jing (essence, substance of all life), shen (spirit), and fluids (body fluids other than blood)—constitute the fundamentals.</p> <p>The nutritional modality has several components: food as a means of obtaining nutrition, food as a tonic or medicine, and the abstention from food (fasting). Foods are classified according to taste (sour, bitter, sweet, spicy, and salty) and property (cool, cold, warm, hot, and plain) to regulate yin, yang, chi, and blood.</p> <p>The meridians are channels that carry chi and blood throughout the body. These are not channels per se, but rather they are invisible vertical networks that act as energy circuits, unifying all parts of the body and connecting the inner and the outer body; organs are not viewed as anatomic concepts but as energetic fields.</p>

TABLE 12-2 Description of Commonly Used Complementary and Integrative Therapies—cont'd

	Description
Acupuncture	Acupuncture is the use of thin needles, inserted into points on the meridians, to stimulate the body's chi, or vital energy. Moxibustion , the application of heat using moxa, dried leaves from mugwort, along meridian acupuncture points for the purpose of affecting chi and blood so as to balance substances and organs, is related to acupuncture. This therapy is used to treat disharmony in the body, which leads to disease. Disharmony, or loss of balance, is caused by a weakening of the yin force in the body, which preserves and nurtures life, or a weakening of the yang force, which generates and activates life. The concept of yin and yang expresses the dual nature of all things, the opposing but complementary forces that are interdependent on each other and must exist in equilibrium. Acupuncturists are licensed to practice in 44 states and the District of Columbia.
Ayurveda	Is a 5,000-year-old system of natural healing that originated in India <i>Ayur</i> means life and <i>Veda</i> means science of knowledge. Assessment and treatment is based on three fundamental forces that govern the internal and external environments and determine an individual's constitution and overall health: Vata (wind): energetic, creative, and adaptable. If out of balance can be anxious, dry, thin, and have poor concentration Pitta (fire): intense, driven, and strong. If out of balance can be compulsive, irritable, inflamed, and have poor digestion Kapha (earth): nurturing, methodical, and stable. When out of balance can be sluggish, phlegmatic, and gain weight easily. Mental and physical health are achieved when these forces are in balance. Therapeutic modalities include diet, herbal, and lifestyle recommendations, massage and aromatherapy.
Massage therapy/body work	The philosophy behind massage therapy and body work is that there is a healing that occurs through the action of touching. Massage therapy became a profession in the United States in the 1940s and has grown in use over the last several decades. The key principles of body work are the importance of increasing blood circulation, moving lymphatic tissue to remove waste and release toxins, calming of the spirit, enhancing physiologic functions of body systems, and improving musculoskeletal function. This therapy also has been widely used to reduce stress and increase energy.

the adult population in Canada, 26% in the United Kingdom, 56% in Malaysia, and 76% in Japan (Harris et al, 2012). Preferences in medical care are influenced by economic and sociocultural factors. In poor countries where access to modern medicine is limited, there is a heavy reliance on herbalists and traditional healers. In affluent countries, the decision to use natural therapies usually aligns with personal beliefs and preferences and is used commonly in addition to western medicine (Harris et al, 2012).

The use of integrative therapies has been evaluated three times in the National Health Interview Survey (NHIS)—in 2002, 2007, and most recently in 2012. In U.S. adults, the most popular integrative modalities include the use of nonvitamin, nonmineral supplements such as herbs, phytochemicals, fiber, and glucosamine (17.9%), chiropractic or osteopathic manipulation (8.5%), yoga (8.4%), massage (6.8%), meditation (4.1%), and massage (6.8%). The report also highlighted regional differences in the United States: the Pacific, Mountain, and West North Central regions have the

highest use and the Middle and South Atlantic regions have the lowest use (Peregoy et al, 2014).

Figure 12-1 highlights the most common forms of integrative medicine used by adults in the United States.

A significant number of Americans use some form of integrative therapy more frequently than the services of a primary care physician. Use has been shown to be greatest among women, people ages 30 to 69, people with higher education, those residing in the western United States, and people who were hospitalized in the previous 12 months (Barnes et al, 2008). Factors associated with greater use among children include having college-educated parents, concurrent prescription medication use, reported anxiety or stress, as well as sinusitis, dermatologic, or musculoskeletal conditions (Birdee et al, 2010). By race or ethnicity, Native Americans (50.3%) and Hawaiians and Pacific Islanders (43.2%) report the highest use, followed by non-Hispanic whites (43.1%) (Barnes et al, 2008).

FIGURE 12-1 Percentage of adults who used complementary health approaches in the past 12 months, by type of approach: United States, 2012. (Retrieved from <http://www.cdc.gov/nchs/data/databriefs/db146.pdf>.)

Integrative therapies are often considered when conventional medicine is not perceived as effective by the patient (as often found in insomnia, pain, and anxiety), when integrative approaches are shown to be effective (**chiropractic** medicine for back pain, **acupuncture** for pain relief, select dietary supplementation for conditions such as macular degeneration, depression, and diarrhea), and when integrative approaches are supported by significant historical evidence of efficacy. The NHIS survey also suggested that integrative medicine use increased when conventional treatments were too costly.

As a result of the increased interest in these therapies, the Office of Alternative Medicine of the National Institutes of Health (NIH) was created in 1992 to evaluate their effectiveness. This office became the twenty-seventh institute or center within the NIH in 1998, when it was renamed the National Center for Complementary and Alternative Medicine (NCCAM). In 2015, the name was changed again to the National Center for Complementary and Integrative Health (NCCIH) because the use of holistic medicine in the US is so common, it no longer warrants the term “alternative.” **Complementary and alternative medicine** (CAM) had been the most common term used to describe the use of holistic medicine, although this term may be falling out of favor. The NCCIH explores complementary and integrative healing practices scientifically using research, training, outreach, and integration (**National Center for Complementary and Integrative Health [NCCIH], 2015**). In recent years, there has been an expansion of training opportunities and medical reimbursement for integrative therapies in the conventional medical system. Increasingly, nursing and medical curricula include integrative training.

In 2011 the Bravewell Collaborative, a philanthropic organization that works to improve health care, published results from a national survey on the use of integrative medicine among 29 major integrative medical centers and programs across the United States. Top conditions for which the centers reported the most success in treatment included chronic pain, gastrointestinal disorders, depression, anxiety, and stress. The most common interventions included nutrition, dietary supplements, yoga, meditation, acupuncture, massage, and pharmaceuticals (**Horrigan et al, 2012**).

DIETARY SUPPLEMENTATION

More than half of all Americans are taking some form of dietary supplement, and many of them may not be well informed (ADA, 2009; **Gahche et al, 2014**). Historically, dietetics professionals focused their assessment, care plan, and counseling on diet or food-related recommendations. The demand for information about dietary supplements from dietetics professionals is high. In fact, the 2009 Position Paper of the Academy of Nutrition (formerly the American Dietetic Association) on nutrient supplementation calls on registered dietitian nutritionists (RDN) to be the “first source” of information on nutrient supplementation by keeping up to date on issues associated with regulation, safety, and efficacy of dietary supplements (American Dietetic Association [ADA], 2009).

Defining Dietary Supplements

According to the Food and Drug Administration (FDA), a dietary supplement is a substance that is taken orally and is

intended to add nutritional value to the diet. Dietary supplements can come in many forms, including tablets, capsules, powders, and liquid. A complete description can be found in **Box 12-1**.

Herbal Medicine

Herbal medicine has been used since the beginning of time and has a written history of more than 5000 years. In many parts of the world it is the primary source of medicine (AHG, 2015). Herbs and plants provide a large array of **phytochemicals** and **bioactive compounds** (plant based chemicals and compounds) that have biologic activity within the human body. Although some of the phytochemicals have been identified and characterized, many of them have unknown actions and may interact with pharmaceutical drugs (**Gurley, 2012**). When herbs are used in combination with each other or in concentrated forms, the likelihood for a drug nutrient interaction (DNI) or side effect increases.

Botanical Medicines are made up of a variety of plant parts including leaves, flowers, stems, bark, rhizomes, and roots. They are produced in a variety of forms and are used orally and topically, including teas, infusions, decoctions, extracts, and pills as shown in **Box 12-2**. Topical application of botanicals or nutrients such as salves and aroma therapy are not classified as **dietary supplements** under the current regulatory definition because they are not ingested. The **Commission E Monographs** on phytomedicines were developed in Germany by an expert commission of scientists and health care professionals as references for practice of **phytotherapy**, the science of using plant-based medicines to prevent or treat illness. Other useful herbal references are listed at the end of the chapter.

Trends in Dietary Supplement Use

According to the National Health and Nutrition Examination Survey (NHANES) 1999-2010, about 50% of U.S. adults and 30% of children regularly take dietary supplements (**CDC, 2012; Gahche, 2014**). The most common reasons to supplement are to improve or maintain health, supplement the diet, support bone health (in women), lower cholesterol, and improve immunity (**Bailey et al, 2013**).

BOX 12-1 FDA Definition of a Dietary Supplement

Intended to be a supplement to the diet
 Intended to be taken by mouth; this excludes other routes of administration, such as intranasal, transdermal, and suppository
 Contains one or more dietary ingredients, including the following:
 Macronutrients (protein, carbohydrates, fats)
 Vitamins and minerals
 Herbs and botanicals
 “Other” dietary substances that are either grandfathered in or are approved as:
 New Dietary Ingredients (NDIs), such as
 Phytochemicals
 Bee pollen
 Probiotics
 Glandulars
 Some hormones, including melatonin and DHEA
 Does not contain any unapproved ingredients, such as:
 Thyroid hormone, cortisol, estrogen, progesterone, or testosterone
 Pathogenic bacteria
 Human tissue

BOX 12-2 Botanical Formulations

Type	Form
Bulk Herbs	
	Sold loose to be used as teas, in cooking, and to prepare capsules; rapidly lose potency; should be stored in opaque containers, away from heat and light
Beverages	
Teas	Beverage weak in concentration; steep fresh or dried herbs in a cup of hot water for a few minutes, strain, and drink
Infusions	More concentrated than teas; steep fresh or dried herbs for approximately 15 min to allow more of the active ingredients to be extracted than for teas. A cold infusion is made by steeping an herb over time in a cold liquid.
Decoctions	Most concentrated of the beverages, made by simmering the root, rhizome, bark or berries for 30-60 min to extract the active ingredients
Extracts	
	Herbs are extracted with an organic solvent to dissolve the active components; forms a concentrated form of the active ingredients. <i>Standardized extracts</i> concentrate a specific constituent(s) of an herb. Removal of the solvent creates a <i>solid extract</i> .
Tinctures	Extract in which the solvent is alcohol, glycerine, honey or occasionally vinegar. Ratios are listed herb:quantity of solvent. A 1:1 tincture is equal parts herb and solvent.
Glycerites	Extract in which the solvent is glycerol or a mixture of glycerol and water; more appropriate for children than a tincture
Salve	An infusion of herbs in oil and beeswax that is used topically. This preparation is not considered to be a dietary supplement under DSHEA.
Pill Forms	
	Pills should be taken with at least 4-8 oz of water to avoid leaving residue in the esophagus.
Capsules	Herbal material is enclosed in a hard shell made from animal-derived gelatin or plant-derived cellulose (vegetarian caps).
Tablets	Herbal material is mixed with filler material to form the hard tablet; may be uncoated or coated with starches and polymers
Lozenges	Also called <i>troches</i> ; method of preparation allows the active components to be readily released in the mouth when chewed or sucked
Soft gels	Soft capsule used to encase liquid extracts such as fatty acids or vitamin E
Essential oils	Fragrant, volatile plant oils; used for aromatherapy, bathing; concentrated form and not to be used internally unless specifically directed (such as enteric-coated peppermint oil)

The industry has grown steadily for the past 30 years. Industry sales were more than \$32 billion in 2012 and sales are expected to continue to increase (National Institutes of Health/ Office of Dietary Supplements, [NIH/ODS], 2015). The most common supplements taken are multivitamin-minerals (MVM), calcium, vitamin C, herbals, fish oil, probiotics, vitamin D, glucosamine, and products for weight management and athletic enhancement (Bailey et al, 2013). Sales of herbal dietary supplements rose 7.9% in 2013. The most popular were turmeric (*Curcuma longa*), wheat and barley grass (*Triticum aestivum* and *Hordeum vulgare*), aloe (Aloe vera) and spirulina (*Arthrospira* spp.) (Lindstrom et al, 2013).

Use of dietary supplements has been shown to increase with advancing age, higher education and socioeconomic status, white race, and female gender. Reports find that use of dietary

supplements is highest among those who: are in the best state of health, have a body mass index less than 25 kg/m², are nonsmokers, are physically active, report good health, adhere to a healthy diet, and use food labels in making food choices (NIH, 2015).

Multivitamin Efficacy

Many people take an MVM to increase nutrient levels in the diet. Dietary surveillance data from the National Center for Health Statistics (NCHS) and NHANES reveal that most adults and children in the United States are not meeting dietary guidelines and are under-consuming dark greens, orange vegetables, legumes, and whole grains (Krebs-Smith et al, 2010). Total nutrient intakes for vitamin D, vitamin E, calcium, vitamin A, vitamin C, and magnesium have been found to be significantly below the estimated average requirement (EAR), and less than 3% of the population is meeting the adequate intake (AI) for potassium (Fulgoni et al, 2011).

Use of multivitamins and minerals has been shown to improve micronutrient status among adults and children (Bailey et al, 2012; Murphy et al, 2007; NIH, 2006). Unfortunately, increased nutrient intake has not translated into reduced risk of chronic disease in people without overt nutrient deficiencies. Research reviews by the National Institutes of Health State of Science Panel and the U.S. Preventive Services Task Force have evaluated observational and randomized controlled trials (RCTs) of more than 400,000 people using single or paired vitamins or MVM and have not found evidence that they reduce chronic disease or prevent early death (Fortman et al, 2013; Neuhouser et al, 2009; NIH, 2006). Two trials, the Supplementation in Vitamins and Mineral Antioxidants Study (SU.VI.MAX) and the Physicians Health Study II (PHS-II), found a small reduction in cancer incidence for men only after 12½ years (SU.VI.MAX) and 8 years (PHS-II) of supplementation (Fortman et al, 2013). Trials looking at cardiovascular disease, cognitive decline, and all-cause mortality have not shown statistically significant incidence of either harm or benefit (Fortman et al, 2013). Chronic diseases are complex and usually have multifactorial causes. Studying the effect of an MVM on nutrient intake and overall health is a difficult undertaking. Almost all Americans are taking in supplemental forms of nutrients via fortified foods, which complicates efforts to quantify the impact of taking a MVM supplement. In observational trials, people take a variety of MVMs with differing compositions and potencies. People who self-select to take a MVM are usually healthier and have better diets, suggesting that MVMs are probably not helpful for most well nourished people. A few long-term RCTs evaluated the merits of MVMs, and the results have been population or gender specific and not generalizable to the entire U.S. population (Fortman et al, 2013). MVMs may have efficacy based on assessment of individual needs but are not useful for all people.

Antioxidant Supplements

Oxidative stress is implicated in a variety of disease states, and many Americans take antioxidant supplements. A recent Cochrane review of 78 RCTs with 296,707 participants found that all-cause mortality was increased slightly with regular antioxidant use. The effect was strongest with beta carotene in smokers, and high-dose vitamin E and vitamin A. Vitamin C and selenium were not found to increase mortality but also did not improve longevity (Bjelakovic et al, 2012). Antioxidant supplements may be beneficial, however, for prevention of age-related macular degeneration (AMD). In the Age Related Eye Disease Study (AREDS), high-dose vitamin C (500 mg),

TABLE 12-3 Populations Potentially at Risk for Nutrient Deficiencies

At-Risk Population or Life Cycle Stage	Nutrients of Concern that Could Potentially be Corrected by Supplementation
Those living in poverty (especially children)	Iron, calcium, magnesium, folate, vitamins A, B ₆ , C, D, and E
Women taking oral contraceptives	Zinc, folic acid, B ₆ , and B ₁₂
Adolescent women	Iron and calcium
Pregnant women	Iron and folic acid
Elders	B ₁₂ and vitamin D, multiple micronutrients
Vegans	B ₁₂
Those following a calorie-restricted, allergy-restricted diet	Multiple nutrients
People with dark pigmented skin	Vitamin D
People with malabsorption (IBD, gastric bypass)	Multiple nutrients
Those with genetic predisposition to nutrient deficiencies (i.e., MTHFR or vitamin D receptor mutations)	Folate, B ₁₂ , vitamin D
Smokers	Vitamin C
Alcoholics	Folate and thiamin

Reference: Position of the American Dietetic Association: Nutrient supplementation, *J Acad Nutr Diet* 109:2073-2085, 2009.

vitamin E (400 IU), beta carotene (15 mg), and zinc (80 mg) had a significant reduction in the risk of developing AMD after taking the antioxidant supplements for 6.3 years. The effects were still present after a 10-year follow-up (Chew et al, 2013). For the majority of people, it is probably best to get antioxidants and phytonutrients by eating a variety of plant-based foods, including fruits, vegetables, herbs, spices, nuts, seeds, legumes, and whole grains.

Potentially At-Risk Populations

Although dietary supplement use is most common among people who are least likely to have a nutrient deficiency, the Academy of Nutrition and Dietetics has identified several populations and life cycle stages that potentially could benefit from dietary supplements (ADA, 2009). Table 12-3 outlines potentially at risk populations. Clinicians should be aware of these at-risk subgroups and complete a nutrition assessment to determine the need for supplementation on an individual basis if nutrition status cannot be improved by dietary changes alone.

DIETARY SUPPLEMENT REGULATION

Dietary supplements (DS) are regulated by two government agencies, The Food and Drug Administration (FDA), which oversees safety concerns, and the Federal Trade Commission (FTC), which oversees advertising, label, and health claims. Before 1994, dietary supplements existed in limbo under the general, but unspecified, regulation of the FDA. The **Dietary Supplement Health and Education Act of 1994 (DSHEA)** defined DS under the category of food and explicitly removed them from consideration as drugs or dietary additives. This was seen as a victory to the dietary supplement industry and consumers; they had become accustomed to

open access in ability to manufacture and purchase dietary supplements.

Dietary Supplement regulation set forth by DSHEA includes the following (Dickinson, 2011; FDA/DSHEA, 2014):

- **Generally recognized as safe (GRAS)** status to all supplements produced before October 15, 1994. This allows manufacturers to continue to sell all of the products that were on the market at the time DSHEA was passed. Any company that introduces a new dietary supplement must send notification and safety information to the FDA 75 days before selling the supplement.
- A supplement facts panel that defines how ingredients must be listed on the label. See Figure 12-2 for an example of a dietary supplement label.
- Structure function claims vs. health claims: Supplement companies are no longer allowed to list disease states or make specific health claims on a DS label. A **structure function claim** allows for a description that includes a structure or function of the body or a stage of life. “Supports strong bones” is an allowable structure function claim; “Prevents osteoporosis” is not. The label must also include the disclaimer, “This statement has not been evaluated by the Food and Drug Administration. This product is not intended to diagnose, treat, cure or prevent any disease.” Opponents of DSHEA feel that structure function claims are too similar to drug claims and encourage DS to be used like drugs. By contrast, a **health claim** can mention a disease state as long as it has met the significant scientific agreement standard of the FDA and can exist on foods and dietary supplements. For example, “soluble fiber from foods such as oat bran, as part of a diet low in saturated fat and cholesterol, may reduce the risk of heart disease.” The FDA has approved only a limited number of health claims (Food and Drug Administration [FDA], 2003).

Supplement Facts	
Serving Size 1 Capsule	
Amount Per Capsule	% Daily Value
Calories 20	
Calories from Fat 20	
Total Fat 2 g	3%*
Saturated Fat 0.5 g	3%*
Polyunsaturated Fat 1 g	†
Monounsaturated Fat 0.5 g	†
Vitamin A 4250 IU	85%
Vitamin D 425 IU	106%
Omega-3 fatty acids 0.5 g	†
* Percent Daily Values are based on a 2,000 calorie diet. † Daily Value not established.	

Ingredients: Cod liver oil, gelatin, water, and glycerin.

FIGURE 12-2 A dietary supplement facts label per Food and Drug Administration regulation as defined under the Dietary Supplement Health Education Act. (From <http://www.fda.gov/ucm/groups/fdagov-public/documents/image/ucm070717.gif> Accessed June 19, 2015.)

- Disseminating product literature: DS manufacturers and retailers are no longer able to display product information or technical data sheets next to products because they can mislead consumers and make DS appear to be drugs.
- Because a wide variety of DS are available, including some hormones and megadose vitamins, it is up to consumers to be educated about the DS they choose to consume. The National Institutes of Health founded the Office of Dietary Supplements (ODS) in 1994 to fund research and disseminate credible information on DS to consumers. On this government website, consumers can find basic consumer information, technical data sheets about dietary supplements and herbs, and FDA warnings.
- Good manufacturing procedures (GMPs) were adopted in 2007 and went into full enforcement in 2010. According to the GMPs, manufacturers of DS must meet minimum standards for production and are subject to random audits. The GMPs regulate the design and construction of manufacturing plants, maintenance and cleaning procedures, manufacturing procedures, quality control procedures, testing of materials, handling of consumer complaints, and maintaining records ([Food and Drug Administration \[FDA\], 2010](#)).

Under DSHEA, DS are regulated only for safety and not for efficacy. Manufacturers are beholden to follow the regulatory laws governing dietary supplements; however, they do not have to send any premarket notification to the FDA except for structure function claims and safety documentation for **new dietary ingredients (NDIs)** that were not used before 1994. The FDA randomly inspects more than 300 DS manufacturers per year. According to the Director of Dietary Supplement Programs at the FDA, almost two-thirds of the companies audited in 2012 were found to not be in compliance with the federal GMPs, and warning letters were sent to one-third of those companies inspected ([Trine, 2012](#)). The most common noncompliance issues were failure to test products for identity, potency and purity, and contamination with non-approved dietary ingredients or pharmaceutical drugs. The FDA is increasing its auditing program every year. With repeated audits, many of the noncompliant companies will be forced to comply or shut down, which will help ensure increased safety in the industry. For now, health care providers should recommend dietary supplements only from reputable companies.

Ensuring Dietary Supplement Safety

Under DSHEA, the FDA bears the burden of proving a supplement is unsafe. This can be a challenging task once a product is released onto the market. To date, only two dietary supplements have been banned by the FDA over safety issues, *Ephedra sinica* in 2004, and dimethylamylamine (DMAA) in 2013. Both have been linked to cardiovascular toxicity and death. The most common supplements with health and safety concerns are those used for weight loss, performance enhancement (ergogenic aids), and sexual dysfunction ([Food and Drug Administration \[FDA\], 2010](#)). These supplements have the highest risk of contamination and adulteration with unapproved dietary ingredients and pharmaceutical drugs, especially when purchased from obscure retailers and the Internet. Internet sales of DS is the fastest-growing retail market and is also the hardest to regulate. Consumers can find banned supplements easily on the Internet.

In December 2006 the Dietary Supplement and Nonprescription Drug Consumer Protection Act was signed into law, requiring mandatory reporting by manufacturers and retailers

of known serious **adverse events (AEs)** related to dietary supplement and over-the-counter (OTC) medications ([Frankos, 2010](#)). Serious adverse events include a life-threatening event, incapacitation, hospitalization, a birth defect, or death. These must be reported to the FDA MedWatch website and can be filed by an individual, health care provider, or industry representative. In addition, supplement manufacturers are required by law to have contact information on supplement bottles. Adverse event reports are forwarded to the Center for Food Safety and Applied Nutrition, where they are further evaluated by qualified reviewers ([Frankos, 2010](#)). Health care providers and consumers are not mandatory reporters under the law but are strongly encouraged to report adverse events.

Between 2008 and 2011 the FDA and poison control centers received almost 13,000 adverse event reports related to DS. Of those 71% were considered serious adverse events. During that same time, the FDA logged 2.7 million adverse drug events, of which 63% were considered serious ([Government Accountability Office, 2013](#)). It is estimated that many adverse events from taking supplements are not being reported or are not being reported correctly. Common barriers from consumers include downplaying the significance, not knowing where or how to report, and embarrassment ([Food and Drug Administration \[FDA\], 2012](#)). After 9 years of tracking (2004-2013), the CDC released a report indicating that an estimated 23,000 emergency department visits per year could be attributed to dietary supplements. Among young adults aged 20-34, the most common supplements causing adverse events were for weight loss and energy (ergogenic aids) and the most common symptoms were tachycardia, chest pain and palpitations. For adults 65 and older, adverse events were mostly attributed to choking on micronutrient pills. 20% of dietary supplement related emergency visits were for unsupervised children who ingested dietary supplements ([Geller A, et al, 2015](#)). Health care providers who wish to stay abreast of alerts from the FDA can subscribe to the MedWatch email list on the FDA website. The Office of Dietary Supplements website is another resource for information about current warnings and recalls as well as consumer tips for buying and taking dietary supplements safely.

Botanical supplements are increasing in popularity, and some have the likelihood for producing adverse events, especially when taken in combination products and in concentrated form. Most of the common herbs used in the United States do not pose a great risk for a **drug nutrient interaction (DNI)**. Of the herbs most commonly used, St. John's wort is the most problematic and has been shown to reduce efficacy of many drugs, including antiretrovirals for HIV, antirejection medications for organ transplants, oral contraceptives, cardiac medications, chemotherapy, and cholesterol medications. Two other herbs have been shown to have a high risk for DNI, including goldenseal (*Hydrastis canadensis*) and black pepper (*Piper nigrum*), although black pepper is only a problem in supplemental form and not in amounts commonly found in food ([Gurley et al, 2012](#)).

In recent years the Office of Dietary Supplements has worked collaboratively with several organizations and experts to develop a **Dietary Supplement Label Database** of dietary supplements used in the United States. Because the database provides specific information on the nutrient, herbal, or other constituents contained in a supplement, it allows clinicians to assess more accurately the appropriate use of select supplements by their patients. (See [Figure 12-3](#)). The database includes dietary supplement label information for more than

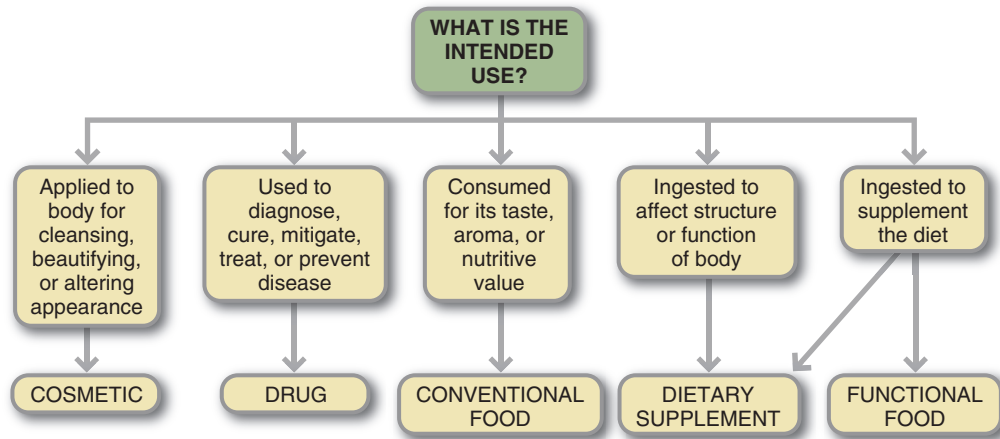

FIGURE 12-3 Use of dietary supplementation in clinical practice requires use of a credible resource for evaluation and application. (From Thomson CA, Newton T: Dietary supplements: evaluation and application in clinical practice, *Topics Clin Nutr* 20(1):32, 2005. Reprinted with permission.)

17,000 supplements, including the structure and function claims. The Office of Dietary Supplements (www.ods.od.nih.gov) offers Supplement Fact Sheets containing information about dietary supplements that is linked to PubMed, allowing clinicians access to peer-reviewed information on use in human trials, adverse events associated with use, and information regarding the mechanism of action. The subscription databases, Natural Standard (www.naturalstandard.com) and the Natural Medicines Comprehensive Database (www.naturaldatabase.com), offer similar information.

Third Party Certification

The FDA and FTC have primary jurisdiction for ensuring dietary supplements are safe and do not have misleading advertising. With 85,000 products on the market, this is a daunting task. Because supplement manufacturers are audited randomly, it is not easy for consumers to know whether a company is truly following good manufacturing procedures (GMPs). Several private companies offer **third party certification** in the supplement industry. Consumer Lab is a well-known subscription-based company that randomly pulls supplements from store shelves to test them for potency, identity, and purity. Subscribers to the Consumer Lab website are able to access reports that reference specific brands (Consumer Labs, 2015). The U.S. Pharmacopeia (USP) (USP, 2015) the National Sanitation Foundation (NSF) (NSF, 2015) and the Therapeutic Goods Association (TGA) (TGA, 2015) each certify supplement companies for compliance with federal GMPs. Once verified, companies can display a stamp on their supplement labels that signifies the products have been third party certified. In addition, NSF offers a “Certified for Sport” certification for supplements that are used by competitive athletes to ensure they are not contaminated with illegal substances (NSF, 2015).

The **Codex Alimentarius Commission (Codex)** is an agency with international significance. It was created in 1963 by two U.N. organizations, the Food and Agriculture Organization and the World Health Organization, to protect the health of consumers and to ensure fair practices in international food trade. Codex participants work on the development of food standards, codes of practice, and guidelines for products such as

dietary supplements. Codex standards and guidelines are developed by committees from 180 member countries, where they voluntarily review and provide comments on standards at several stages in the development process (Crane, 2010).

Quality Issues in Dietary Supplements

Not all dietary supplements are high quality. As discussed previously, many manufacturers are not in full compliance with DSHEA, which means many substandard and contaminated products are on the market. Many of the mainstream brands in health food stores and major retail outlets are likely safe. Products bought off the Internet and from obscure retailers may be adulterated and/or may not meet label claim. What determines quality in a supplement must go beyond the safety issues to address the quantity, formulations, and quality of all ingredients used.

Quantity of Ingredients

Many MVMs contain **megadoses** of nutrients, which greatly exceed the RDA and may or may not be appropriate for each individual consumer. Some individuals may benefit from high doses of certain nutrients because of genetic variations in enzyme function or other pharmacologic effects of megadoses. Examples include increased need for folic acid with an MTHFR gene variant or reduction in triglycerides with megadoses of niacin (Ames et al, 2002; Boden et al, 2014).

It is important to assess for upper limits, especially when patients are taking multiple sources of nutrients. Most water-soluble vitamins do not have overt toxicity at high doses with the exception of niacin (flushing, prickly heat, and liver irritation in some people) and pyridoxine (reversible neuropathy). Fat-soluble vitamins can become toxic more quickly, such as vitamin A (hepatotoxicity and teratogenicity) and vitamin D (nephrolithiasis, calcification of soft tissue). Often vitamin A is listed in its provitamin form, beta carotene, which does not pose the same health risks at high doses.

Minerals can become toxic more easily than vitamins, so they often are not formulated using megadoses. In some cases, people may take a megadose of a mineral for a limited time, such as zinc for the common cold. To ensure patient safety, it is important to coordinate care with a physician when a patient is

taking a megadose of a mineral. Although it is not a megadose, the FDA limits potassium content in dietary supplements to 99 mg because of the prevalence of chronic kidney disease.

Formulations

Dietary supplements come in many formulations, including capsules, tablets, gels, chewables, liquids, and powders. The form a consumer selects has to do with convenience, preference, and affordability. Supplement powders can be added easily to foods and beverages, but most have added sugars to increase palatability. Chewable and liquid supplements often are missing multiple nutrients to increase taste appeal, so it is important to assess the label to ensure it meets the patient's needs.

Tablets tend to be more compressed than capsules and require fewer number of pills to achieve the optimal dosage. Capsules tend to be easier to swallow but less concentrated than tablets. Gelatin capsules may not be suitable for vegetarians. Some companies make vegetarian capsules out of vegetable cellulose to accommodate vegetarian consumers. Other nutrient forms that may not be suitable for vegetarian clients include cholecalciferol (often from fish oil or lambswool) and vitamin A/retinol (also usually from fish oil). Vegetarian formulations usually contain ergocalciferol and beta carotene as alternatives.

Excipients

Excipients are extra ingredients added to dietary supplements to increase bulk, mask “off flavors,” add color, and improve compressibility and flow through machinery. To assess whether a dietary supplement is right for an individual, it is important to consider the quality of the excipients used. Some contain allergens and potentially unfavorable ingredients such as hydrogenated oils and artificial colors. When choosing a dietary supplement, it is important to read the label for quantity and quality of active ingredients and excipients.

Vitamins

Most vitamins in dietary supplements are similar across brands with the exception of B₆ (pyridoxine), B₁₂ (cyanocobalamin), folate (folic acid), and vitamin E. Some formulations contain active, methylated, or phosphorylated forms of these nutrients such as in active B₆: pyridoxyl 5'-phosphate, active B₁₂: methylcobalamin, and active folate: methyltetrahydrofolate. Individuals with genetic polymorphisms, nervous system disorders, increased oxidative stress, or impaired digestion may benefit from the increased bioavailability of these nutrients; however, research is limited on their widespread need and efficacy. In addition, the active forms tend to be more expensive (Head et al, 2006; Hendren, 2013).

Vitamin E can be made synthetically or extracted naturally from soybean oil, sunflower oil, or other vegetable oils. Natural vitamin E (d-alpha tocopherol) is more expensive but has a greater bioavailability than synthetic vitamin E (dl-alpha tocopherol) (Azzi et al, 2000). High-quality vitamin E products usually contain mixed tocopherols in addition to the d-alpha tocopherol, which is thought to mimic more closely what one would get from eating a food source of vitamin E. Some tocopherols, especially gamma tocopherol, has been studied for its cardioprotective effects (Liu et al, 2003).

Minerals

Chelated minerals bound to an amino acid or a Krebs cycle intermediary are considered the most easily absorbed form of a mineral supplement and most similar to how a mineral would exist

in food. Examples of chelates include citrate, bisglycinate, succinate, aspartate, and picolinate. Quality differences exist between companies that produce chelated minerals. A mineral must be bonded covalently to its ligand to be considered a bioavailable “true chelate” (Albion, 2014). Chelated minerals are best for elders and people with low stomach acid and compromised digestion and can be taken on an empty stomach. Ionic mineral preparations such as carbonates and oxides should be taken with food, especially protein, to increase absorption (Straub, 2007).

ASSESSMENT OF DIETARY SUPPLEMENT USE IN PATIENTS

Health care professionals should be aware that patients typically do not report their use of botanicals or other dietary supplements. Therefore practitioners must inquire specifically about the use of supplements by their patients. To facilitate disclosure, health care providers should approach patients in an open-minded, nonjudgmental manner. Key questions to ask are summarized in Box 12-3. Ideally, patients should be encouraged to bring all of their dietary supplements and medications into the clinic to be evaluated. In this way the health care provider can review doses (including those above the upper limit [UL]), forms, frequency of use, rationale for use, side effects, and the patient-perceived efficacy of each supplement (American Dietetic Association [ADA], 2009; National Institutes of Health/Office of Dietary Supplements [NIH/ODS], 2015). This should be done on a regular basis. It is particularly important that dietary supplement use be reviewed before surgery because some dietary supplements and botanicals alter the rate of blood coagulation. Box 12-4 provides specific recommendations regarding the discontinuation of dietary supplements before surgery to avoid complications associated with prolonged bleeding time. In addition, patients on blood-thinning medications may have to be monitored for a potential interaction with these supplements (American College of Surgeons, 2014).

For assessing patients for dietary supplement use using the nutrition care process, potential diagnosis and intervention codes are shown in Box 12-5.

Recommendation and Sale of Dietary Supplements

Many health care professionals are uncomfortable recommending dietary supplements. Clinical guidelines for recommending and selling dietary supplements have been published previously by the Academy of Nutrition (Thompson et al, 2002). Dietitians and nutritionists who recommend dietary supplements must take the initiative to develop their knowledge, skills, and resources to provide accurate and safe recommendations. The Academy has developed *The Academy Scope of Practice Decision Tool: A Self-Assessment Guide* for dietetics providers; it is available through the Academy website. It can be used to assess competence and scope of practice as defined by training, place of employment, and state of residence (Academy of Nutrition and Dietetics [AND], 2015). It is advisable to use this tool before beginning any new practice, including recommending or selling dietary supplements.

When recommending dietary supplements to clients, clinicians should use an evidence- or science-based approach and document thoroughly in the patient's medical chart. Documentation should include the supplement name, dosage, form, duration of use, and a short description of supporting evidence. Each provider is responsible to cross-check for contraindications and potential drug nutrient interactions (DNIs) and document any risks in the patients' medical chart. See Box 12-6 for guidelines

BOX 12-3 Evaluating Dietary Supplement Use: The Patient–Health Care Provider Information Exchange

Ask

- What dietary supplements are you taking (type: vitamin, mineral, botanical, amino acid, fiber)?
- Why are you taking these dietary supplements? Include review of patient's medical diagnosis and symptoms for reasons why he or she may be taking supplements (e.g., osteoarthritis, heart disease, high blood pressure, PMS, loss of memory, fatigue).
- How long have you been taking these dietary supplements?
- What dose or how much are you taking? For each, include supplement form and manufacturer.
- With what frequency are you taking each supplement?
- Where were the supplements purchased (e.g., health food store, Internet, health care provider)?
- Who recommended the supplement (e.g., media, physician, nurse, dietitian, alternative medicine practitioner, friend, family)?

Evaluate

- Dietary intake (including intake of fortified foods and beverages, and nutritional and sports bars)
- Health status and health history—include lifestyle habits (e.g., smoking, alcohol, exercise)
- Biochemical profile, laboratory data
- Prescribed and OTC medications
- Clinical response to supplements
- Adverse events, symptoms

Educate

- Scientific evidence of benefit and effectiveness
- Potential interaction with foods, nutrients, and medications or other dietary supplements
- Appropriate dose, brand, and chemical form; duration of supplementation; appropriate follow-up
- Quality of products, manufacturers, good manufacturing practices (USP, Consumer Labs)
- Mechanism of action of the primary active ingredient
- Appropriate storage of the dietary supplement
- Administration instructions: With or without food? Potential food-supplement interactions?
- Awareness and reporting of any side effects or adverse events, symptoms
- Recommend necessary dietary changes to support needs. Food should come first.

Document

- List specific supplements and brand names of each supplement being taken.
- Record batch number from bottle in case of an adverse event.
- Record patient perception and expected level of compliance.
- Monitor efficacy and safety, including health outcomes and adverse effects.
- Record medication-supplement or supplement-supplement interactions.
- Plan for follow-up.

BOX 12-4 Dietary Supplements that Affect Blood Clotting and Should be Discontinued 10 To 14 Days Before Surgery or Certain Medical Tests

Ajoene, birch bark, cayenne, Chinese black tree fungus, cumin, evening primrose oil, feverfew, garlic, ginger, *Ginkgo biloba*, ginseng, grapeseed extract, milk thistle, omega-3 fatty acids, onion extract, St. John's wort, turmeric, vitamins C and E

Reference: American College of Surgeons. College of Education: *Medication and Surgery Before Your Operation* (website): <http://www.facs.org/patienteducation/medications.html>. Accessed January 31, 2014.

for choosing dietary supplements and botanical products and [Box 12-7](#) for information about usage, dosage, and safety of some of the most commonly used dietary supplements.

Resources for Clinicians

As awareness of dietary supplement use expands within the health care community, the number of evidence-based resources available to clinicians also is growing considerably. Clinicians should have access to online and print resources that are updated at regular intervals. Resources that provide reference to the original research are preferable. A list of evidence-based resources can be found at the end of the chapter. In addition, accessing available medical literature is advised, given that there are a growing number of studies being published in peer-reviewed literature.

Text continued on page 12-17

BOX 12-5 International Dietetics and Nutrition Terminology (IDNT) that Applies to the Documentation of Dietary Supplement use Among Patients

Assessment Terminology: Food and Nutrient Intake, Medication and Complementary and Alternative Medicine Use and Knowledge, Beliefs and Attitudes

Diagnosis Terminology: Inadequate bioactive substance intake (NI-4.1), Excessive bioactive substance intake (NI-4.2), Increased nutrient needs (NI-5.1), Decreased nutrient needs (NI-5.4), Imbalance of nutrients (NI-5.5), Less than optimal intake of types of fats (NI-5.6.3), Less than optimal intake of types of proteins or amino acids (NI-5.7.3), Inadequate fiber intake (NI-5.8.6), Inadequate vitamin intake (specify) (NI-5.9.1), Excessive vitamin intake (specify) (NI-5.9.2), Inadequate mineral intake (specify) (NI-5.10.1), Excessive mineral intake (specify) (NI-5.10.2), Predicted suboptimal nutrient intake (specify) (NI-5.11.1), Predicted excessive nutrient intake (specify) (NI-5.11.2), Impaired nutrient utilization (NC-2.1), Altered nutrition related laboratory values (specify) (NC-2.2), Food medication interaction (NC-2.3), Predicted food-medication interaction (NC-2.4), Food and nutrition related knowledge deficit (NB-1.1), Unsupported beliefs and attitudes about food or nutrition related topics (NB-1.2), Limited adherence to nutrition related recommendations (NB-1.6)

Intervention Terminology: Vitamin and mineral supplements (specify) (ND-3.2), Bioactive substance management (specify) (ND-3.3), Nutrition related medication management: Nutrition related complementary/alternative medicine (ND-6.3), Nutrition education (specify) (E-1), Nutrition counseling (specify) (C-1), Collaboration and referral of nutrition Care (RC-1)

BOX 12-6 Guidelines For Choosing Dietary Supplements and Botanical Products

- Ensure the supplement is appropriate for the individual patient based on state of health, dietary deficiency, and scientific evidence.
- Consider multiple sources of dietary supplements including fortified foods, bars, cereals, and beverages to ensure patients are not exceeding safe intake limits.
- Check for potential drug nutrient interactions and be aware of side effects and contraindications. For example, fish oil can reduce blood clotting in high doses and antioxidant supplements can inhibit the effects of some chemotherapy drugs.
- Investigate the quality of the manufacturer to ensure a quality product. Look for companies that have third party certification (NSF, USP), or well-known companies with a longstanding reputation for quality. Check Consumer Labs or the FDA warning letters website for documented problems (www.fda.gov/ICEC/EnforcementActions/WarningLetters).
- Use the dietary supplement label to obtain important information, including the following:
 - Product identity (including scientific or botanical names), form, and dosage
 - Allergy information in case the patient has a dietary restriction. Excipients (inactive ingredients) are often the source of allergens or unwanted ingredients.
 - A lot number, which is helpful if problems arise because it allows the product to be tracked through each stage of the manufacturing process
 - An expiration date
- After determining that a manufacturer and its product meet these standards, compare prices among products of similar quality. Prices can vary widely.

National Institutes of Health, Office of Dietary Supplements. *Dietary Supplements: What You Need to Know*. http://ods.od.nih.gov/HealthInformation/DS_WhatYouNeedToKnow.aspx. BOX 12-7 Popular Dietary Supplements and Their Efficacy

Supplement	Benefits	Dosage	Potential Contraindications	Quality Considerations
Vitamins				
Vitamin B ₆	Effective for hereditary sideroblastic anemia, pyridoxine-dependent seizures; Likely effective for hyperhomocysteinemia, age related macular degeneration, hypertension, calcium oxalate kidney stones, pregnancy induced nausea and vomiting	Most supplemental doses are 5 mg-50 mg/day. 25 mg q 8 hours for pregnancy induced nausea and vomiting. Doses up to 200 mg/day have been used for carpal tunnel, but close monitoring is recommended.	Doses up to 200 mg/day appear to be tolerated by most people, although high doses can cause hypotension and reversible neuropathy.	Available as pyridoxine and pyridoxyl 5'-phosphate (active form). People with genetic polymorphisms, nervous system disorders, increased oxidative stress, or impaired digestion may benefit from the active form.
Vitamin B ₁₂	Effective for pernicious anemia and B ₁₂ deficiency. Likely effective for hyperhomocysteinemia, Possibly effective for age related macular degeneration	Doses in supplements are often in megadoses due to lack of toxicity. Can be taken orally and injected. Common dosage range is 2.4- 1000 mcg/day.	Most risk is associated with intravenous forms, not oral forms. People with pernicious anemia will not benefit from oral dosing.	Available as cyanocobalamin or methylcobalamin (active form). Active form may be beneficial for those with genetic polymorphisms, nervous system disorders, increased oxidative stress, or impaired digestion.
Vitamin C	Effective for scurvy; Likely effective for iron absorption enhancement; Possibly effective for age related macular degeneration, cancer prevention, common cold prevention and treatment, complex regional pain syndrome, hypertension, osteoarthritis, sunburn	Doses vary widely but usually range from 100 mg-2000 mg/day; Divided doses for larger amounts.	Safe at lower doses and in amounts found in foods. Higher doses can cause diarrhea and gastrointestinal cramping. Greater than 500 mg is contraindicated for those who have a history of calcium oxalate kidney stones.	Mineral ascorbates (buffered vitamin C) may be better tolerated than ascorbic acid.
Vitamin D	Effective for familial hypophosphatemia, hypoparathyroidism, osteomalacia, psoriasis, renal osteodystrophy and rickets. Likely effective for corticosteroid induced osteoporosis, fall prevention in older adults, osteoporosis. Possibly effective for prevention of cancer, dental caries, multiple sclerosis, respiratory tract infections, Rheumatoid arthritis and obesity.	Dose is usually based on individual serum levels and can vary from person to person. Optimal serum level is considered to be 30-50 nmol/L. In research, doses range from 400 IU to 50,000 IU/day. The UL is 4,000 IU (100 mcg)/day.	Exceeding the UL and elevated serum concentrations are associated with calcification of soft tissues (damage to the heart, blood vessels, and kidney), and increased risk for kidney stones. Risk may be increased in postmenopausal women who also take supplemental calcium. Best to coordinate care with primary care provider and monitor blood levels.	Cholecalciferol (D ₃) is the most common supplement and is usually sourced from fish or sheep (lanolin). Ergocalciferol (D ₂) is suitable for vegetarians and vegans.

Continued

BOX 12-7 Popular Dietary Supplements and Their Efficacy—cont'd

Supplement	Benefits	Dosage	Potential Contraindications	Quality Considerations
Vitamins				
Vitamin E	Effective for vitamin E deficiency. Possibly effective for slowing cognitive decline in Alzheimer's disease, improving response to erythropoietin in hemodialysis, reducing cisplatin induced neurotoxicity and pain in rheumatoid arthritis, prevention of dementia, dysmenorrhea, PMS, Parkinson's disease and radiation induced fibrosis and increasing muscle strength in the elderly.	Most supplements are between 50 and 2000 IU. Most common dose is 200-400 IU/day. Higher doses used therapeutically.	Doses above 400 IU/day may increase risk for bleeding, prostate cancer, and have prooxidant effects.	D-alpha tocopherol is the natural form of vitamin E and dl- alpha tocopherol is the synthetic form. Natural forms with mixed tocopherols, specifically gamma tocopherol, may have cardioprotective effects.
Folic acid	Effective for folate deficiency. Likely effective for hyperhomocysteinemia, methotrexate toxicity, and neural tube defects. Possibly effective for age related macular degeneration, depression, hypertension	RDA level is recommended in most people, although those with MTHFR variant or chronic conditions may need higher levels (200 mcg-5 mg/day has been used). Coordinate care with physician for megadose amounts.	Caution with folate supplementation in those at risk for colon cancer.	Supplemental sources have greater bioavailability than folate in food. People with a MTHFR variant may have increased need for folate. Activated form, methylenetetrahydrofolate is also used.
Minerals				
Calcium	Effective for dyspepsia, hyperkalemia, and renal failure (as a phosphate binder). Likely effective for osteoporosis and premenstrual syndrome. Possibly effective for reducing risk of colorectal cancer, hypercholesterolemia, hypertension and prevention of weight gain.	500-1000 mg/day is a typical dose. Do not exceed the UL.	High doses can increase risk for kidney stones, cardiovascular disease, and constipation. Caution in patients with hyperparathyroidism.	Chelated forms such as citrate and malate are better absorbed than carbonate unless taken with a meal. Coadministration with vitamin K may be helpful to reduce risk of hypercalcemia except in those taking blood-thinning medications
Chromium	Effective for chromium deficiency. Possibly effective for reducing blood sugar in diabetes, decreasing LDL cholesterol and triglycerides.	Studies have used 150-1000 mcg/day. Adequate intakes have thought to be 25-35 mcg/day for adults. No UL has been established.	Trivalent chromium is found in appropriate dietary supplements. Poor quality brands may contain hexavalent chromium, which is toxic and linked to cancer. Caution in those with diabetes, renal impairment. Higher doses may cause dermatitis and/or gastrointestinal irritation.	Chromium picolinate is the most common form and is thought to be well absorbed.
Iron	Effective for anemia. Possibly effective for ACE Inhibitor induced cough, cognitive function, heart failure	RDA is recommended unless blood work indicates increased need. Needs increase in pregnancy. Vegetarians may need higher levels because of decreased bioavailability from plant foods. 4-6 mg/kg /day or 60-120 mg/day for those with anemia.	Do not exceed the UL except with coordination of care with a physician. Excessive iron intake can cause nausea, constipation, and black stools and may increase the risk of heart disease.	Chelated iron (citrate, bisglycinate) may be better tolerated and cause less gastrointestinal side effects.
Magnesium	Effective for constipation, dyspepsia, pre-eclampsia and eclampsia. IV forms are effective for cardiac arrhythmia and asthma. Magnesium is often used in fibromyalgia and migraine headache, but the results are mixed.	Typical dose is 100-500 mg/day. Exceeding the UL from supplements (350 mg/day) is not recommended because of potential for diarrhea.	The most common side effects with high doses are diarrhea, bloating, and reduction in blood pressure. Serious side effects are a risk with IV magnesium, including hypotension, nausea, and ataxia.	Similar to calcium, chelated forms such as citrate, bisglycinate, and amino acid chelate may be better absorbed and tolerated than oxide form.
Selenium	Possibly effective for autoimmune thyroiditis and dyslipidemia. Often used as an antioxidant supplement to support glutathione production.	DRI is between 55-70 mcg/day although most supplemental doses are in the 100-200 mcg range. Exceeding the UL of 400 mcg/day is not recommended.	Gastrointestinal symptoms, nausea and vomiting, are most common with high doses. Acute toxicity may impair liver, kidney, and cardiac function.	Brazil nuts are an excellent source of selenium. Selenium and vitamin E have a synergistic effect and are best taken together.

BOX 12-7 Popular Dietary Supplements and Their Efficacy—cont'd

Supplement	Benefits	Dosage	Potential Contraindications	Quality Considerations
Minerals				
Zinc	Likely effective for diarrhea and Wilson's disease. Possibly effective for acne, age related macular degeneration, anemia, anorexia nervosa, attention deficit hyperactivity disorder, burns, common cold, dandruff, depression, diabetic foot ulcers, diaper rash, halitosis, gingivitis, herpes simplex virus, muscle cramps, radiation mucositis, osteoporosis, peptic ulcers, pressure ulcers, sickle cell disease, vitamin A deficiency, warts	Doses vary depending on condition. 15-45 mg/day range is common. Much higher doses sometimes given for wound healing short term. Coordination of care recommended.	Mostly nontoxic below the UL of 40 mg/day in adults. High Zn intake can deplete copper and can cause nausea, dermatitis, and copper deficient anemia.	Take Zn supplements with copper to prevent depletion of copper.
Other Supplements				
Alpha lipoic acid	Possibly effective for atherosclerosis, cardiovascular disease, hypertension, and pneumonia. Often used to treat neuropathy with success.	Doses used in research are 600, 1200, and 1800 mg/day for up to 2 years. 5% topical preparation for skin aging	Doses over 600 mg/day can cause nausea, vomiting and vertigo and may interfere with some chemotherapy. In patients with cardiovascular disease, high doses can cause angina, blood pressure changes, and arrhythmia. Can reduce blood glucose in diabetes. Caution with hypoglycemia	Bioactive form is R-ALA. Some quality issues exist with production, so ensure a quality brand. Helps to regenerate vitamin C, E, and glutathione
Arginine	Possibly effective for angina, erectile dysfunction, hypertension, necrotizing enterocolitis (NEC), peripheral artery disease, post surgery recovery and pre-eclampsia.	Therapeutic dose range is thought to be from 400-6,000 mg/day. There is no tolerable upper limit and higher doses (up to 30 g/day) have been used. Coordination of care recommended	High doses may increase bleeding in those on warfarin, may lower blood sugar and blood pressure. Caution in those with history of myocardial infarction or cancer	No special production or quality control issues with arginine. L-arginine is the active form.
Beta-glucan	Likely effective for hyperlipidemia. Possibly effective for allergic rhinitis (hayfever), cancer survival, and postoperative infection.	3 g beta-glucan/day (from oats) per the FDA as a cholesterol lowering food. In supplements, 2-16 g/day is common dosing for hyperlipidemia.	Generally well tolerated with few side effects. May cause mild gastrointestinal symptoms in some. Can lower blood pressure and blood sugar	Found widely in plant-based foods, especially oats and mushrooms.
Coenzyme Q10 (Ubiquinone)	Possibly effective for age related macular degeneration, congestive heart failure, diabetic neuropathy, HIV/AIDS, Hypertension, Ischemic reperfusion injury, migraine headache, and Parkinson's disease.	Doses vary from 30 mg -600 mg/day.	Very few side effects reported other than mild nausea, headache, and skin itching. May decrease blood pressure Caution with people on blood-thinning medications	Oil-based preparations may be better absorbed.
Creatine	Possibly effective for athletic performance enhancement (muscle mass and muscle strength).	Usually taken as a loading dose (0.3 g/kg/day) followed by a maintenance dose (0.03 g/kg/day). Doses up to 30 g have been taken safely short term.	Considered safe for healthy people Increased fluid needs when taking creatine Caution with kidney disease especially if taking NSAIDs Increased symptoms of anxiety and depression have been noted.	Usually sold as creatine monohydrate
DHEA <i>Dehydroepiandrosterone</i>	Possibly effective for aging skin and depression. Mixed results in studies on use in adrenal insufficiency, chronic fatigue syndrome, fibromyalgia, HIV/AIDS, osteoporosis, physical performance, sexual dysfunction, weight loss. Most doctors treat with DHEA based on individual lab values.	Dose should be recommended by a physician and based on laboratory results. Doses range from 5- 450 mg/day.	May increase estrogen and testosterone and risk for cancer May increase acne, facial hair growth, and cause other hormonal side effects Avoid with hormone blockers such as tamoxifen. Multiple contraindications	7 Keto DHEA is a metabolite of DHEA that is not converted into estrogen or testosterone and is thought to be a safer alternative to DHEA.

Continued

BOX 12-7 Popular Dietary Supplements and Their Efficacy—cont'd

Supplement	Benefits	Dosage	Potential Contraindications	Quality Considerations
Other Supplements				
Fish oil	Effective for hypertriglyceridemia. Likely effective for cardiovascular disease. Possibly effective for age related macular degeneration, asthma, atherosclerosis, attention deficit hyperactivity disorder, cachexia, heart failure, hypertension, psoriasis, Raynaud's syndrome, Rheumatoid arthritis, stroke. Conflicting evidence for depression, inflammatory bowel disease, autism	1-4 g/day of EPA and DHA combined Up to 3 g/day is considered GRAS	More than 3 g/day EPA/DHA may increase risk for bleeding, bruising, and elevation in blood sugar Caution with people on blood-thinning medications and those with diabetes	Molecular distilled fish oil is considered the best quality. For vegetarians, flaxseed oil may also be beneficial. Use cold pressed oil in dark bottles or refrigerate.
Glucosamine	Likely effective for osteoarthritis; Conflicting or insufficient evidence to rate effectiveness for interstitial cystitis and temporomandibular (TMJ) disorders	Typical dose for joint conditions is 1500 mg/day taken in 2-3 divided doses Lower doses of 400-1000 mg/day have been used for other conditions.	Considered to be a safe supplement for most people Most is sourced from shellfish, so may be an allergen in some High doses can disrupt blood sugar metabolism in those with diabetes. Caution in those with renal dysfunction or in those taking warfarin	Most research has been done on glucosamine sulfate form, although glucosamine hydrochloride has also been used with success. Glucosamine is often sold in combination with chondroitin for added benefit.
Glutamine	Possibly effective for use in burn patients, bone marrow transplants, burns, critical illness (trauma), AIDS wasting, oral mucositis and improve nitrogen balance in surgery. Conflicting evidence for use in diarrhea, inflammatory bowel disease and short bowel syndrome.	5-30 g/day orally is a typical dose. Doses in IV or TPN in the critically ill may be higher.	Considered safe Many drugs deplete body stores of glutamine.	Take separately from food (especially protein) for maximal absorption.
Melatonin	Likely effective for delayed sleep phase syndrome, and sleep disorders; Possibly effective for insomnia, benzodiazepine withdrawal, jet lag, improved tumor regression in chemotherapy	500 mcg – 5 mg/day have been used in research. 3 - 5 mg/day is the most common dose.	Generally regarded as safe for use up to 3 months and is even tolerated in neonates. Most common side effects are headache, nausea, and drowsiness. May lower blood pressure and disrupt hormone balance	Usually taken 30 minutes before bed
N-Acetyl Cysteine	Effective for acetaminophen toxicity and tracheostomy care. Can be used as a mucolytic. Possibly effective for angina, bronchitis, bipolar disorder, COPD, hyperlipidemia, hyperhomocysteinemia, prevention of cardiovascular events in end stage renal disease. Often used to support glutathione production	400-600 mg/day for respiratory infections Most common dose is between 600-1200 mg/day for a variety of conditions Much higher dose for acetaminophen poisoning	Well tolerated at usual doses with little evidence of toxicity Very high doses are associated with nausea, vomiting, diarrhea, skin flushing, tachycardia, dizziness, headache, and zinc malabsorption. May increase bleeding time in those on anticoagulants	No special considerations except to use a quality product
Probiotics (lactobacillus acidophilus and bifidobacteria)	Likely effective for rotaviral diarrhea. Possibly effective for anti-biotic associated diarrhea, atopic dermatitis (eczema), clostridium difficile diarrhea, chemotherapy induced diarrhea, constipation, Helicobacter pylori inflammation, infantile colic, irritable bowel syndrome, pouchitis, respiratory tract infections, travelers diarrhea, ulcerative colitis	Dosage varies and is measured in colony forming units (CFU's). Range is 1-450 billion CFU depending on the disease condition and therapeutic goal.	May be contraindicated in the immune suppressed, those with central line placement, and in those on hemodialysis due to risk of sepsis May cause diarrhea in high doses	Refrigeration is important to preserve quality in most products.

BOX 12-7 Popular Dietary Supplements and Their Efficacy—cont'd

Supplement	Benefits	Dosage	Potential Contraindications	Quality Considerations
Herbs				
Chamomile <i>Matricaria recutita</i> (Gernam Chamomile)	Possibly effective for anxiety, colic, diarrhea, dyspepsia, and oral mucositis.	250-500 mg/day in capsules or 1-4 cups/day as tea	Generally recognized as safe. Caution in those with allergy to ragweed or asteraceae family	Ensure correct plant is used. German chamomile is the most common.
Cinnamon <i>Cinnamomum cassia</i>	Conflicting evidence for diabetes and for use topically as a mosquito repellent	Typical dose is 1-6 g/day in capsules or 1 teaspoon/day in food. 5% cream used topically as a mosquito repellent.	Generally safe Caution in people with diabetes or blood sugar dysregulation or in those with impaired liver function May enhance blood-thinning effects of warfarin	Cassia cinnamon is thought to be more biologically active than Ceylon cinnamon.
Cranberry <i>Vaccinium macrocarpon</i>	Possibly effective for urinary tract infection, (prevention and treatment). Preliminary evidence for reducing urinary odor and improve symptoms in benign prostatic hyperplasia (BPH).	As juice: 1 ounce cranberry concentrate or 10 ounces cranberry cocktail (sweetened). As capsules: 300-500 mg twice/day	Generally safe. Caution with sugar in juice for diabetics, may increase calcium oxalate kidney stones	Blueberries have similar constituents and may be similarly beneficial.
Echinacea <i>angustifolia</i> , <i>pallida</i> and <i>purpurea</i>	Possibly effective for the common cold and for vaginal candidiasis. Insufficient evidence for influenza and otitis media	Can be taken as a capsule, tablet, tea or tincture. Doses vary and are dependent on the variety used and preparation.	Caution in people with allergy to Asteraceae family (daisy, sunflower), and those on immunosuppressive medications	Sometimes standardized to contain a specific amount of echinacoside or cichoric acid
Garlic <i>Allium sativum</i>	Possibly effective for atherosclerosis, colorectal cancer, gastric ulcer, hypertension, reduced number of tick bites, and topical treatment of ringworm and athlete's foot. Conflicting evidence for hyperlipidemia, common cold	2-5 g fresh garlic, 0.4-1.2 g dried powder, 2-5 mg oil, or 300-1000 mg extract to deliver 2-5 mg allicin (active constituent) per day. One clove fresh garlic has also been used	Generally well tolerated. Higher doses may cause gastric irritation, body odor and decreased blood pressure. Caution with those who are taking blood thinners.	Comes in many forms in supplements. Those that preserve allicin content may be more effective. Aged extracts have shown benefits as well because of the multitude of sulfur compounds present.
<i>Ginkgo biloba</i>	Possibly effective for cognitive function, dementia, generalized anxiety disorder, and schizophrenia, premenstrual syndrome, peripheral vascular disease, vertigo, glaucoma, and diabetic retinopathy.	80-240 mg standardized extract and 3-6 mg of a 40 mg/mL liquid extract in 2-3 divided doses per day has been used. 30-40 mg in a tea bag has also been used.	Generally considered safe except in high-risk patients. Ginkgo can reduce blood pressure, decrease blood sugar, and cause mild gastrointestinal discomfort in some. Some reports of dizziness and sedation	Ginkgo leaf preparations are the most commonly used. Often standardized to 24% ginkgoflavone glycosides and 6% terpenes
Green tea <i>Camellia sinensis</i>	Likely effective for hypercholesterolemia and mental alertness. Possibly effective for coronary artery disease, hypotension, osteoporosis. Conflicting evidence for cancer prevention, cardiovascular disease, obesity.	Epigallocatechin (EGCG) epicatechin gallate, and epicatechin levels vary when taken as tea. 3 cups daily is a common dosage. Standardized extracts (60-97% polyphenols) of 200-500 mg/day are common for a variety of conditions. 10% topical cream for skin aging and acne.	Well tolerated in most people. Most side effects come from the caffeine content (nervousness, anxiety, sleeplessness, and increased blood pressure). Use with caution in patients with psychiatric or cardiovascular conditions.	Decaffeinated versions are available to eliminate caffeine side effects.
Kava Kava <i>Piper methysticum</i>	Possibly effective for anxiety; Insufficient evidence for benzodiazepine withdrawal, insomnia and menopausal anxiety.	60-400 mg standardized extract per day	Typical therapeutic doses are tolerated by most. Significant evidence of liver injury in the literature. Caution in people with liver disease. Chronic use can cause dry, scaly skin and photosensitivity.	Often standardized to contain 30% to 70% kavalactones. May be best to start at lower doses and titrate up
Milk thistle <i>Silybum marianum</i>	Although it is commonly used to reduce inflammation and fibrosis in liver disease, there is conflicting and insufficient evidence for alcohol related liver disease, amanita mushroom poisoning, cirrhosis, and hepatitis induced liver damage.	160-1200 mg/day based on condition treated. Take as divided doses.	Low toxicity risk. Can cause a mild laxative effect if taken in large amounts. Rare risk of allergic reaction. May lower blood sugar. May mildly inhibit CYP 3A4, 2C19 and 2D6 cytochrome enzymes	Often standardized to contain 70% to 80% silymarin. Tea preparation is not recommended because of poor water solubility. Whole, ground milk thistle seeds can be added to food.

Continued

BOX 12-7 Popular Dietary Supplements and Their Efficacy—cont'd

Supplement	Benefits	Dosage	Potential Contraindications	Quality Considerations
Herbs				
Red Yeast Rice (RYR) <i>Monascus purpureus</i>	Likely effective for hyperlipidemia. Possibly effective for cardiovascular disease and HIV/AIDS related dyslipidemia. Preliminary evidence for use in non alcoholic fatty liver disease (NAFLD).	The most common dose is between 600- 2400 mg/day. It is estimated that average intake of naturally occurring RYR in Asia is 14-55 g/day.	Limited data on adverse events. Side effects appear to be similar to those with low-dose statin medications (headache, gastrointestinal discomfort, and muscle pain). May increase serum liver enzyme levels.	Contains naturally occurring lovastatin (Monacolin K). Dosing is difficult because of natural variations in products. It is illegal in the United States to standardize Monocolin K levels in supplements.
Saw palmetto <i>Serenoa repens</i>	Conflicting evidence for use in benign prostatic hyperplasia (BPH). Insufficient evidence for use in androgenic alopecia, neurogenic bladder and prostate cancer.	1-2 g of ground, dried berries, 2-4 ml tincture (1:4) three times per day or 160 mg four times per day	Well tolerated in most people. Studies show low risk for allergy or herb drug interactions. Some reports of mild gastrointestinal side effects. May have estrogenic effects.	Berries have the active constituents (sterols and fatty acids). Tea preparations may be ineffective due to lipophilic nature.
St Johns Wort <i>Hypericum perforatum</i>	Likely effective for mild to moderate depression. Possibly effective for menopausal symptoms, somatization disorder. Conflicting or insufficient evidence for anxiety, obsessive compulsive disorder, premenstrual syndrome, seasonal affective disorder. Can be used topically for wound healing.	Typical dose is 300-450 mg three times per day	Has the most drug nutrient interactions of any common herb. Inhibit CYP 3A4, 2C19 and 2C9 cytochrome enzymes and the P-glycoprotein (P-gp) transporter. Reduces the effectiveness of immunosuppressive, antiretroviral, cardiovascular, and oral contraceptive medications among others. Can cause photosensitivity	Typically standardized at 0.3% hypericin
Turmeric <i>Curcuma longa</i>	Possibly effective for osteoarthritis. Insufficient or conflicting evidence for Alzheimer's disease, colorectal cancer, Crohn's disease, irritable bowel syndrome, rheumatoid arthritis, ulcerative colitis.	500 mg-2 g curcumin per day depending on disease condition Higher doses taken in divided doses	Safe in amounts eaten in food Higher doses can lower blood pressure and blood sugar and increase risk of bleeding. Caution in those with liver and gall bladder diseases and in those taking blood-thinning medications	May be best absorbed when taken with food, especially a meal that contains fat Curcumin supplements bound to phosphatidyl choline may be better absorbed.

Popular Dietary Supplements and Their Efficacy According to the Natural Medicines Database <https://naturalmedicines.therapeuticresearch.com>. Accessed June 19, 2015.

CLINICAL CASE STUDY

Ellen is a 60-year-old female who was referred from her primary care provider for evaluation of her dietary supplements. Medical history includes hypertension, hypercholesterolemia, osteopenia, mild depression, and memory problems. Two years ago, she had angioplasty (PTCA) with a stent placement in her coronary artery. Ellen is a retired school teacher, married, and has two grown children. Her neighbor works in a supplement store and recommended some herbs and supplements to address Ellen's health concerns.

At the initial consult Ellen reports she is taking the following supplements: calcium carbonate 1200 mg/d, garlic (*Allium sativum*) 500 mg/d, *Ginkgo biloba* 240 mg/d, and St. John's wort (*Hypericum perforatum*) 900 mg/d. Her prescription medications include warfarin, simvastatin, sertraline, and atenolol.

Height: 64" Weight 165 lbs BMI: 28.4

Blood pressure readings: 134/92, 140/95 "This is higher than it usually is" Ellen reports.

Recent labs:

Total cholesterol: 284 mg/dl

HDL: 36 mg/dl

LDL: 140 mg/dl

Prothrombin times (INR) has been inconsistent lately.

Typical dietary intake includes the following:

Breakfast: Total cereal with milk and calcium fortified orange juice for breakfast

Lunch: Frozen entrée—beef and broccoli with rice and a diet coke

Snack: Strawberry yogurt and pretzels, coffee with milk

Dinner: Meatloaf, mashed potatoes with gravy and carrots. Glass of red wine.

Dessert: Chocolate ice cream, coffee with milk

Questions to consider:

1. Using the Office of Dietary Supplements Fact sheets (ODS website), identify what each dietary supplement Ellen is taking is used for and if it has good evidence to support use.
2. List any potential drug nutrient interactions (DNI) Ellen may have with her current concomitant use of medications and dietary supplements.
3. Looking at Ellen's labs, is there any evidence she may be having a drug nutrient interaction (DNI)?
4. Does Ellen need to be taking a calcium supplement? Are there any potential risks with taking 1200 mg/day with a positive history of cardiovascular disease (CVD)?
5. Write a PES statement for your top concern based on your assessment.

Food and Nutrient Delivery: Nutrition Support¹

*Carol S. Ireton-Jones, PhD, RDN, LD, CNSC, FAND, FASPEN,
Mary Krystofiak Russell MS, RDN, LDN, FAND*

KEY TERMS

advance directives	gastric residual volume (GRV)	percutaneous endoscopic gastrostomy (PEG)
bolus enteral feeding	hang time	percutaneous endoscopic jejunostomy (PEJ)
catheter	hemodynamic stability	peripheral parenteral nutrition (PPN)
central parenteral nutrition (CPN)	home enteral nutrition (HEN)	peripherally inserted central catheter (PICC or PIC)
closed enteral system	home parenteral nutrition (HPN)	polymeric enteral formula
computerized provider order entry (CPOE)	intermittent enteral feeding	rebound hypoglycemia
durable medical equipment (DME) provider	multiple lumen tube	refeeding syndrome
enteral nutrition (EN)	nasoduodenal tube (NDT)	sentinel event
essential fatty acid deficiency (EFAD)	nasogastric tube (NGT)	total nutrient admixture (3-in-1)
extended dwell catheter	nasojejunal tube (NJT)	transitional feeding
French size	open enteral system	
gastrointestinal decompression	osmolality	
gastrojejunostomy	osmolarity	
	parenteral nutrition (PN)	

Nutrition support is the delivery of formulated enteral or parenteral nutrients for the purpose of maintaining or restoring nutritional status. **Enteral nutrition (EN)** refers to nutrition provided through the gastrointestinal tract (GIT) via a **catheter** or a tube or stoma that delivers nutrients distal to the oral cavity. **Parenteral nutrition (PN)** is the provision of nutrients intravenously.

RATIONALE AND CRITERIA FOR APPROPRIATE NUTRITION SUPPORT

When patients cannot or will not eat enough to support their nutritional needs for more than a few days, nutrition support should be considered as part of the integrated care plan. Using the GIT (EN) vs. using PN alone helps preserve the intestinal mucosal barrier function and integrity. In critically ill patients, feeding the GIT has been shown to attenuate the catabolic response and preserve immunologic function (McClave et al, 2009). Research shows less septic morbidity, fewer infectious complications, and significant cost savings in critically ill adult patients who received EN vs. PN. There is limited evidence that EN vs. PN affects hospital length of stay (LOS), but an impact on mortality has not been demonstrated (Academy of Nutrition and Dietetics [AND], Evidence Analysis Library [EAL],

2012). A recent study found no significant difference in 30-day mortality in critically ill adults who received nutrition support by the parenteral or the enteral route (Harvey et al, 2014).

A variety of diseases and conditions may result in the need for nutrition support (Table 13-1). PN should be used in patients who are or will become malnourished and who do not have sufficient gastrointestinal function to be able to restore or maintain optimal nutritional status (McClave et al, 2009). EN should be considered when an individual has a functional GIT and is unable or unwilling to consume sufficient nutrients to meet his or her estimated needs. Figure 13-1 presents an algorithm for selecting appropriate routes for EN and PN. Although these guidelines provide ideas, the choice of the most optimal method of nutrition support can be challenging. For example, the small bowel feeding access for EN may not be available in every health care setting. In such a case, PN may be the only realistic option for provision of nutrition support. PN may be used temporarily until adequate gastrointestinal function to support EN or oral intake returns, or PN may be used to supplement EN or oral intake to meet needs effectively for energy, protein, and other key nutrients. “Transitional Feeding,” described later in the chapter, refers to the provision of nutrition support via two or more methods, until nutrition adequacy is reached via oral intake alone.

Although specific nutrition support regimens may be standardized for specific disease states or courses of therapy, each patient presents a unique challenge. Nutrition support frequently

¹Sections of this chapter were written by Janice L. Raymond, MS, RDN, CSG for the previous edition of this text.

TABLE 13-1 Conditions That May Require Nutrition Support

Recommended Route of Feeding	Condition	Typical Disorders	
Enteral nutrition	Inability to eat	Neurologic disorders (dysphagia)	
		Facial trauma	
		Oral or esophageal trauma	
		Congenital anomalies	
		Respiratory failure (on a ventilator)	
		Traumatic brain injury	
		Comatose state	
		GI surgery (e.g., esophagectomy)	
		Inability to eat enough	Hypermetabolic states such as with burns
			Cancer
Heart failure			
Congenital heart disease			
Impaired intake after orofacial surgery or injury			
Anorexia nervosa			
Failure to thrive			
Cystic fibrosis			
Impaired digestion, absorption, metabolism	Severe gastroparesis		
	Inborn errors of metabolism		
	Crohn's disease		
	Short bowel syndrome with minimum resection		
	Pancreatitis		
	Parenteral nutrition	Gastrointestinal incompetency	Short bowel syndrome—major resection
			Severe acute pancreatitis with intolerance to enteral feeding
			Severe inflammatory bowel disease
			Small bowel ischemia
			Intestinal atresia
Severe liver failure			
Persistent postoperative ileus			
Intractable vomiting/diarrhea refractory to medical management			
Distal high-output fistulas			
Severe GI bleeding			
Critical illness with poor enteral tolerance or accessibility	Critical illness with poor enteral tolerance or accessibility	Multi-organ system failure	
		Major trauma or burns	
		Bone marrow transplantation	
		Acute respiratory failure with ventilator dependency and gastrointestinal malfunction	
		Severe wasting in renal failure with dialysis	
		Small bowel transplantation, immediate after surgery	

McClave SA et al: Guidelines for the provision and assessment of nutrition support therapy in the adult critically ill patient, *J Parenter Enteral Nutr* 33:277, 2009. GI, Gastrointestinal.

must be adapted to address unanticipated developments or complications. An optimal treatment plan requires interdisciplinary collaboration that is aligned closely with the comprehensive plan of patient care. In rare cases, nutrition support may be warranted but physically impossible to implement. In other situations, nutrition support may be possible but not warranted

because it presents an unacceptable risk or is not indicated because of the prognosis or the patient's right to self-determination.

In all cases, it is important to prevent errors in ordering, delivery, and monitoring of nutrition support to prevent undesirable risks or outcomes (**sentinel events**) such as an unexpected death, serious physical injury with loss of limb or function, or psychologic injury (Joint Commission, 2014). A **computerized provider order entry (CPOE)** system allows prescribers to enter an order directly into a computer, often aided by decision-support technology to help facilitate accuracy and clinical effectiveness (Bankhead et al, 2009).

ENTERAL NUTRITION

By definition, *enteral* implies using the GIT, usually via a feeding tube with the tip in the stomach or small bowel. The location of nutrient administration and type of enteral access device are selected after the patient is determined to be a candidate for EN. (The process for determining whether an individual is a candidate for EN is described later.) Enteral access selection depends on the (1) anticipated length of time enteral feeding will be required, (2) degree of risk for aspiration or tube displacement, (3) patient's clinical status, (4) adequacy of digestion and absorption, (5) patient's anatomy (e.g., after previous surgical resection or in extreme obesity), and (6) whether future surgical intervention is planned.

Feeding tubes may be referred to by their **French size**, which is a measure of the outer tube diameter. One French unit is 0.33 mm. A French size of 5 to 12 typically is considered "small bore," and a French size of more than 14 is considered "large bore."

ENTERAL NUTRITION ACCESS

Short-Term Enteral Nutrition Support

Nasogastric Access

Nasogastric tubes (NGTs) are used most commonly to access the GIT, for gastric decompression, medication delivery, and/or feeding. They are appropriate only for those patients who require short-term (no more than 3 to 4 weeks) EN. Typically, the tube is inserted at the bedside by a nurse or physician (or a registered dietitian with appropriate clinical privileges) and passed through the nose into the stomach (Figure 13-2). Polyurethane or silicone tubes of various diameters, lengths, and design features may be used, depending on formula characteristics and feeding requirements. These tubes are soft, flexible, and often well tolerated by patients. Tube placement is verified by aspirating gastric contents in combination with auscultation of air insufflation into the stomach or by radiographic confirmation of the tube tip location. Techniques for placing a tube are described by Metheny and Meert (2004).

NGT feedings are provided by bolus administration or by intermittent or continuous infusions (see Administration later in this chapter). Patients with normal gastrointestinal function are often fed via this route, which takes advantage of normal digestive, hormonal, and bactericidal processes in the stomach. Rarely, complications occur (Box 13-1).

Gastric Versus Small-Bowel Access

Placement of a feeding tube into the stomach is more straightforward and far less time consuming than placing a tube into the small bowel, so gastric feedings generally are initiated

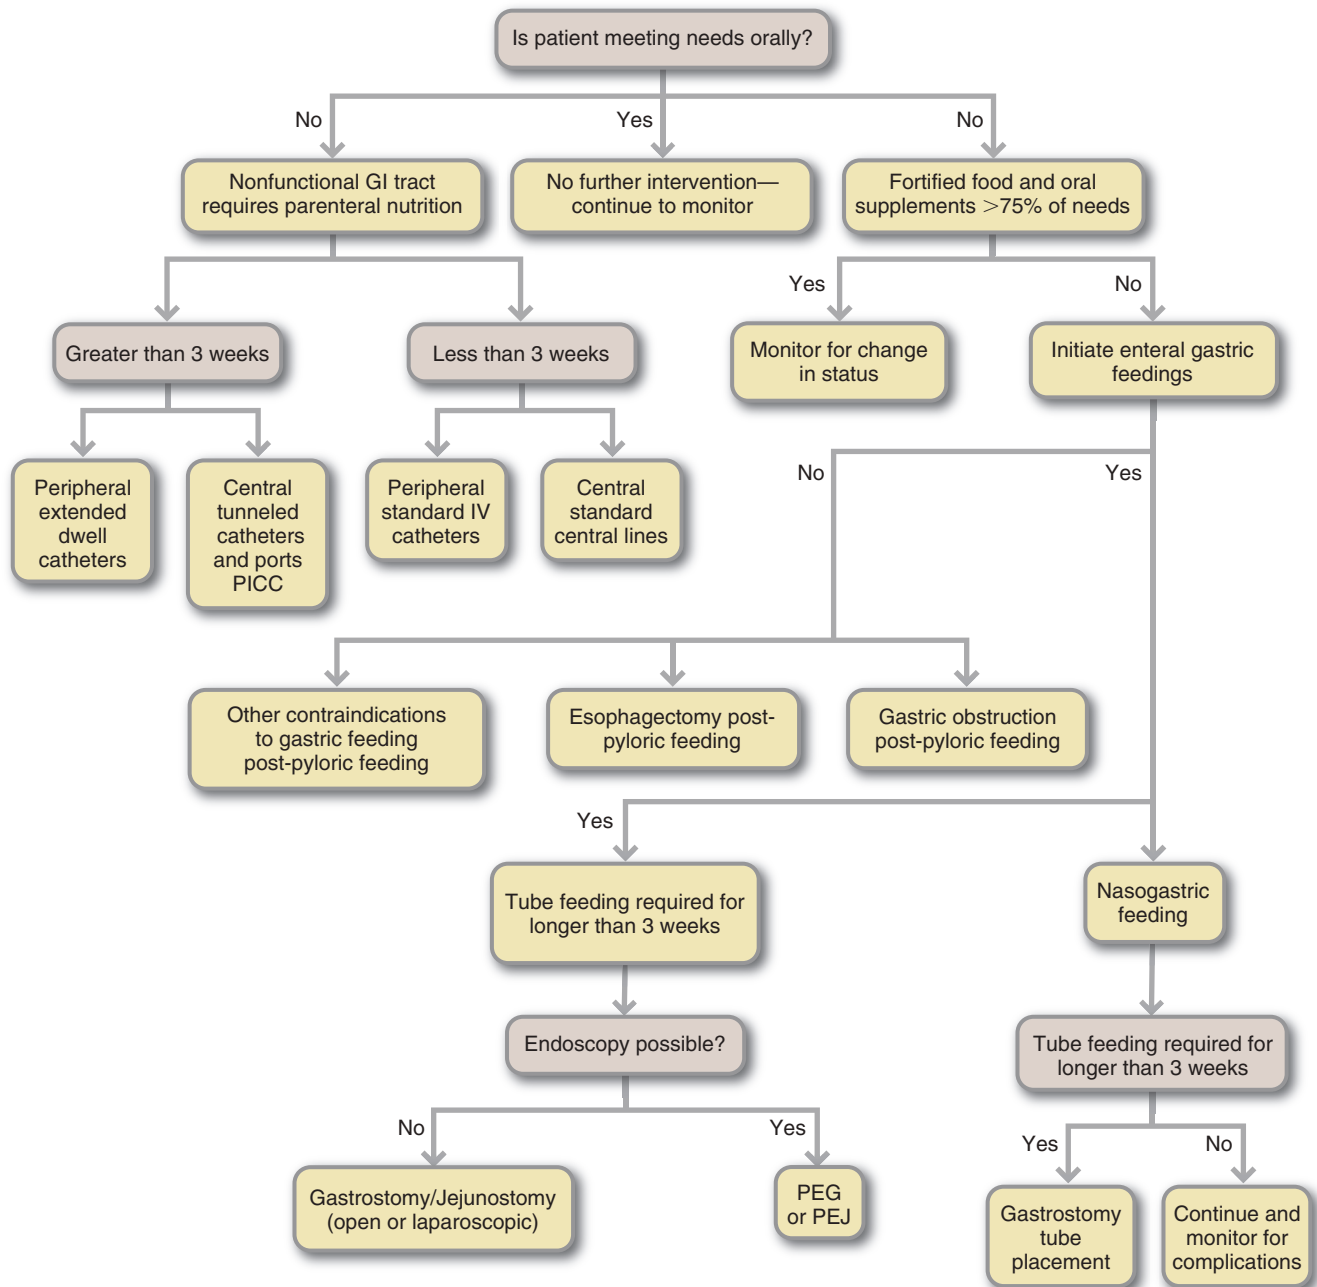

FIGURE 13-1 Algorithm for route selection for nutrition support.

more quickly. However, ease of access is only one consideration. Critically ill patients, including those who have undergone surgery, or suffered a head injury or major intra-abdominal trauma, may not tolerate gastric feeding (see Chapter 38).

Signs and symptoms of intolerance to gastric feeding include, but are not limited to, the following:

- Abdominal distention and discomfort
- Vomiting
- Persistent diarrhea

Some clinicians believe that intragastric feeding increases the risk of aspiration pneumonia; the data on this subject are not totally clear (Bankhead et al, 2009; McClave et al, 2009).

Nasoduodenal or Nasojejunal Access

Patients who do not tolerate gastric feedings and require relatively short-term enteral nutrition support will benefit from placement of a **nasoduodenal tube (NDT)** or a **nasojejunal tube (NJT)**, described by the point at which the tube tip terminates. These tubes may be placed with endoscopic or fluoroscopic guidance (Figure 13-3, A); using a computer guidance system (Figure 13-3, B); or intraoperatively as part of a surgical procedure.

In some cases, a feeding tube may be placed intragastrically with the goal of migration into the duodenum by peristalsis; this process is unlikely to result in desired location of the feeding tube tip and inevitably delays initiation of appropriate EN. Spontaneous migration never achieves jejunal tip placement.

FIGURE 13-2 Diagram of enteral tube placement.

BOX 13-1 Potential Complications of Nasoenteric Tubes

- Esophageal strictures
- Gastroesophageal reflux resulting in aspiration pneumonia
- Tracheoesophageal fistula
- Incorrect position of the tube leading to pulmonary injury
- Mucosal damage at the insertion site
- Nasal irritation and erosion
- Pharyngeal or vocal cord paralysis
- Rhinorrhea, sinusitis, otitis media
- Ruptured gastroesophageal varices in hepatic disease
- Ulcerations or perforations of the upper gastrointestinal tract and airway

Adapted from McClave SA et al: Guidelines for the provision and assessment of nutrition support therapy in the adult critically ill patient, *J Parenter Enteral Nutr* 33:277, 2009; Cresci G: Enteral access. In Charney P, Malone A: *Pocket guide to enteral nutrition*, ed 2, Chicago, 2013, AND, p 62.

Long-Term Enteral Access

Gastrostomy or Jejunostomy

When EN is required for more than 3 to 4 weeks, a surgically or endoscopically placed gastrostomy or jejunostomy feeding tube should be considered for overall patient comfort (Figure 13-4) and to minimize nasal and upper GIT irritation (see Box 13-1). Such a tube may be placed during a required surgical or endoscopic procedure to maximize efficiency and cost effectiveness.

Percutaneous endoscopic gastrostomy (PEG) or **percutaneous endoscopic jejunostomy (PEJ)** is a nonsurgical technique for placing a tube directly into the stomach through the abdominal wall, using an endoscope and local anesthesia. The

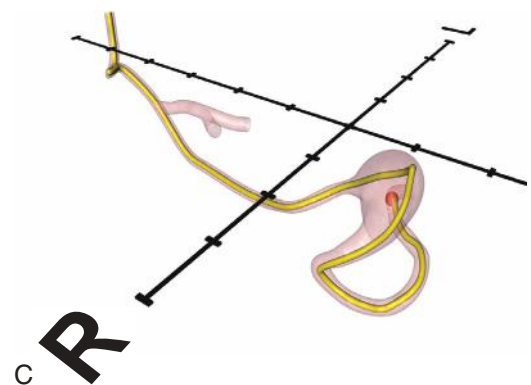

CORTRAK[®]
Enteral Access System

B

C

FIGURE 13-3 Computerized Cortrak tube feeding placement system. **A**, CORTRAK System; **B**, CORTRAK anterior view compared with abdominal radiograph; **C**, 3-Dimensional graphic representation of a CORTRAK feeding tube in post pyloric position. (Used with permission from CORPAK MedSystems.)

tube is guided from the mouth into the stomach or the jejunum and brought out through the abdominal wall. The short procedure time and limited anesthesia requirements have contributed to making it a very common method of feeding tube placement.

FIGURE 13-4 A man with a gastrostomy tube out hiking. (From Oley Foundation, Albany, NY: www.oley.org. Accessed December 2014.)

Tubes placed by PEG (note the PEG is the procedure, not the tube, although clinicians commonly refer to “PEGs” as the tube) are generally large bore (or French size), facilitating administration of medications and reducing the incidence of clogging. These tubes may be connected to a short piece of tubing used to infuse a bolus feeding or connect to a bag of prepared formula. Some tubes placed by PEG are flush to the skin, or “low profile.” These tubes, also known as “buttons,” are a good choice for children and adults with dementia who may be likely to pull out a tube that protrudes from the skin. Active individuals, and those who prefer a sleeker profile under clothing, also may opt for this type of tube. [Figure 13-5](#) shows a component from a skin level balloon G-tube kit, designed to improve patient comfort and increase the length of time the G-tube may remain in place. To prevent the accidental parenteral infusion of enteral formula, a universal connector that is incompatible with IV equipment has been developed. [Figure 13-5](#) shows a silicone G-tube with a purple connector, which is incompatible with a Luer lock syringe or an IV connection. This innovation, recently made the industry standard, is designed to reduce the risk of accidental connection or infusion. During the placement procedure, if the color of the device changes, the operator will immediately see that the tube is malpositioned and must be removed immediately.

A tube placed by PEG may be converted to a [gastrojejunostomy](#) using fluoroscopy or endoscopy by threading a small-bore tube through the larger tube into the jejunum.

Other Minimally Invasive Techniques

High-resolution video cameras have made percutaneous radiologic and laparoscopic gastrostomy and jejunostomy enteral access an option for patients in whom endoscopic procedures are contraindicated. Using fluoroscopy, a radiologic technique, tubes can be guided visually into the stomach or

FIGURE 13-5 Baxter Clinimix Compounding System. (Image provided by Baxter Healthcare Corporation. CLINIMIX is a trademark of Baxter International Inc.)

the jejunum and then brought out through the abdominal wall to provide the access route for enteral feedings. Laparoscopic or fluoroscopic techniques offer alternative options for enteral access.

Gastrojejunal dual tubes, used for early postoperative feeding, are available for endoscopic or surgical placement. These tubes are designed for patients in whom prolonged [gastrointestinal decompression](#) (removal of the contents of the stomach through a nasogastric tube) is anticipated. The [multiple lumen tube](#) has one lumen for decompression and one to feed into the small bowel.

Formula Content and Selection

More than 75 enteral formulas, marketed for a wide variety of clinical conditions and indications, are currently available ([Charney and Malone, 2013](#)):

- Enteral formulas are classified as (1) standard, (2) chemically defined (elemental); or (3) specialized (marketed for specific clinical conditions or diseases). A significant variety of formulas are available in each of these categories. Health care organizations, including hospitals and long-term care organizations, typically develop a formulary of products to be used within the facility. Selection of an enteral formula for a specific patient should involve consideration of the patient’s:
 - Nutrient needs
 - GIT function
 - Clinical status

In the past, [osmolality](#) was considered key to EN tolerance, and belief was widespread that EN formulas should be the same osmolality as body fluids (290 mOsm/kg). However, studies in the mid-1980s showed that patients tolerate feedings across a wide range of osmolality, and clinical experience of many clinicians has reinforced those study results. Cost of the formula and its availability after discharge from the hospital or other facility

can be of significant concern to facility administrators, clinicians, patients, and families.

Formulas often are classified based on protein or overall macronutrient composition. Most patients with a variety of clinical conditions tolerate standard (**polymeric**) **enteral formulas** intended to meet the nutritional requirements of healthy individuals, and by extension patients with a variety of medical conditions. The formulas contain intact macronutrients, 1 to 2 kcal/ml, are lactose free, and may be used as oral supplements as well as for enteral feeding. The higher nutrient density (1.5 to 2 kcal/ml) formulas are useful when fluid restriction is required (cardiopulmonary, renal, and/or hepatic dysfunction), and for patients with intolerance to typical feeding volume. Products intended to supplement oral diets may be used for EN in some cases; these products are flavored and may contain simple sugars to enhance palatability. See Appendix 24.

The manufacture and labeling of enteral formulas are regulated by the Food and Drug Administration (FDA), which classifies enteral formulas as medical foods (a subclassification of foods for special dietary use). As such, these products are exempt from specific nutrition labeling requirements in the Code of Federal Regulations. The products must be labeled as “intended to be used under medical supervision” (FDA, 2014).

Manufacturers are not obligated to register enteral products with the FDA or obtain FDA approval before placing them on the market. Many enteral nutrition formulas lack rigorous scientific evidence to support their specific composition, and their marketing materials are not subject to the rigorous standards used for prescription drugs. Evaluation of the efficacy of enteral nutrition products and the statements made in marketing materials and by company representatives requires the attention of qualified RDNs. Claims of pharmacologic effects must be evaluated using clinical evidence before a decision is made to use a specific product (Box 13-2).

Blenderized (Homemade) Tube Feedings

Tube feedings made from common ingredients such as eggs, sugar, and wine have been used since the 1500s, and blenderized tube feedings (BTF) were used in the United States throughout the first half of the twentieth century (Vassilyadi, 2013). Clinicians often are concerned about nutritional adequacy, food safety, and the additional burden preparation of BTF places on the caregivers (Malone, 2005). Advantages of BTF may include cost effectiveness (because commercial formulas may not be covered by insurance), health benefits from using whole foods, and ability to tailor the formula exactly to patient needs. The social bond between the caregiver who prepares the feeding (possibly from foods served to the rest of the family) and the patient also is cited as a strong driver for BTF use.

BTF are contraindicated for patients who are immunocompromised, for infusion through tubes smaller than 10 French, for continuous feeding (unless the formula hangs for ≤ 2 hours), if fluid restriction of less than 900 ml/day is required, in cases of multiple food allergies, and if a jejunostomy tube (JT) is used (Novak, 2009). Some state regulations prohibit use of BTF in long-term care facilities (see *New Directions: Pureed by Gastrostomy Tube – the PBGT Diet*).

BOX 13-2 Factors to Consider when Choosing an Enteral Formula

- Ability of the formula to meet the patient’s nutrient requirements
- Caloric and protein density of the formula (i.e., kcal/ml, g protein/ml, ml fluid/L)
- Gastrointestinal function
- Sodium, potassium, magnesium, and phosphorus content of the formula, especially for patients with cardiopulmonary, renal, or hepatic failure
- Form and amount of protein, fat, carbohydrate, and fiber in the formula relative to the patient’s digestive and absorptive capacity
- Cost effectiveness of formula
- Patient compliance
- Cost-to-benefit ratio

NEW DIRECTIONS

Pureed by Gastrostomy Tube – the PBGT Diet

by **Therese O’Flaherty MS, RD, CSP, LD**

The Pureed by Gastrostomy (G) Tube (PBG T) Diet is a specialized, nutritionally balanced blended food feeding given by G-tube. It was originally designed to decrease or eliminate symptoms of retching and gagging which can be a complication of a Nissen Fundoplication surgery. In addition to improving tolerance of bolus feeds for individuals who are volume sensitive, the PBGT diet is also used by families seeking an alternative to commercial formulas.

The goals of the PBGT diet are to:

- Decrease frequency of GT feedings and transition from drip feedings
- Meet all nutritional and fluid requirements
- Improve weight gain, growth, and overall nutritional status
- Encourage increased opportunities for oral intake
- Improve and sustain quality of life for individuals and their families

The PBGT diet is different from the usual blended tube feeding in that it is calculated and formulated by a registered dietitian nutritionist (RDN) to provide an individual with complete nutrition through small, calorie-dense gastrostomy tube boluses, thereby eliminating the need and cost for a feeding pump. In addition to the easier preparation of the PBGT, special attention is also given to the variety of foods, nutrient content, cost, and ease of the 5-10 minute bolus administration (Pentiuk, et al 2011).

The use of Stage 2 infant foods promotes consistency in the viscosity of the diet, provides availability and affordability, and eliminates the need for an expensive blender. They can be premeasured, and individually sealed in containers that can be easily used in formula rooms within hospitals if allowed by hospital policy. Families can be educated on the easy preparation method and proper storage, along with additional fluid and vitamin and mineral supplementation guidelines (O’Flaherty, et al 2011; O’Flaherty, 2015).

Protein

The amount of protein in available commercial enteral formulas varies from 6% to 25% of total kilocalories. The protein typically is derived from casein, whey, or soy protein isolate. Standard formulas provide intact protein, whereas elemental formulas contain di- and tripeptides and amino acids, which are absorbed more easily. Specialized formulas (for hepatic or renal failure or in cases of multiple, severe allergies) may include crystalline amino acids.

Specific amino acids may be added to some enteral formulas. Branched chain amino acids are used in formulas for patients with severe hepatic disease, and arginine has been added to formulas marketed for critically ill patients. (See Chapter 38 for further discussion.)

Carbohydrate

Carbohydrate content in enteral formulas varies from 30% to 85% of kilocalories. Corn syrup solids typically are used in standard formulas. Sucrose is added to flavored formulas that are meant for oral consumption. Hydrolyzed formulas contain carbohydrate from cornstarch or maltodextrin.

Carbohydrate or fiber that cannot be processed by human digestive enzymes is added frequently to enteral formulas. Fibers are classified as water soluble (pectins and gums) or water insoluble (cellulose or hemicellulose). The effectiveness of different fibers added to enteral formulas in treating GIT symptoms of critically ill patients is controversial. The Adult Critical Illness guidelines, in the Evidence Analysis Library of the Academy of Nutrition and Dietetics (AND, EAL, 2012) suggests that the RDN “consider using soluble fiber to prevent and/or manage diarrhea.”

Fructooligosaccharides (FOS), which are prebiotics, have been added to enteral formulas, often in combination with a source of dietary fiber, for more than 15 years. FOS have been shown to stimulate the production of beneficial bifidobacteria, and when combined with dietary fiber may produce beneficial changes in colonic pH, fecal microbiota, and short-chain fatty acid concentrations. Animal models provide evidence that FOS may help to achieve colonization resistance against *Clostridium difficile*. Use of FOS in individuals with irritable bowel syndrome (IBS) may worsen symptoms transiently; some studies have suggested that these adverse symptoms may abate with consistent FOS use (Charney and Malone, 2013).

All commercially available enteral formulas are lactose free, because lactase insufficiency is common in acutely ill patients.

Lipid

Lipid content of enteral formulas varies from 1.5% to 55% of the total kilocalories. In standard formulas, lipid as corn, sunflower, safflower, or canola oil provides between 15% and 30% of the total kilocalories. Elemental formulas contain minimal amounts of fat, typically in the form of medium-chain triglycerides (MCTs) rather than long-chain (LCTs) triglycerides.

Most of the fat in standard enteral formulas is in the form of LCTs and MCTs. Some formulas contain “structured lipids,” which are a mix of LCTs and MCTs and contain properties of both. Most of the LCTs found in structured lipids are omega-3 fatty acids (such as eicosapentaenoic acid and docosahexanoic acid); these omega-3 fatty acids may have anti-inflammatory effects (see Chapter 3). Structured lipids are absorbed more readily and better tolerated than LCT/MCT combinations (Malone, 2005).

MCTs do not require bile salts or pancreatic lipase for digestion and are absorbed directly into the portal circulation. The percentage of fat as MCT in enteral formulas varies from 0 to 85%. Approximately 2% to 4% of daily energy intake from linoleic and linolenic acid is necessary to prevent **essential fatty acid deficiency (EFAD)**. MCTs do not provide linoleic or linolenic acids; the clinician must ensure that patients who receive high MCT enteral formulas receive linoleic and linolenic acids from other sources.

Vitamins, Minerals, and Electrolytes

Most, but not all, available formulas provide the dietary reference intakes (DRIs) for vitamins and minerals in a volume that

may be administered to most patients. Because the DRIs are intended for healthy populations, not specifically for individuals (whether healthy or acutely or chronically ill), it is difficult to know for certain whether the vitamin and mineral provision from these formulas is adequate. Formulas intended for patients with renal or hepatic failure are intentionally low in vitamins A, D, and E, sodium, and potassium. Conversely, disease-specific formulas often are supplemented with antioxidant vitamins and minerals and marketed to suggest that these additions improve immune function or accelerate wound healing. Definitive studies demonstrating these effects are not available.

Electrolyte content of enteral formulas is typically modest compared with the oral diet. Patients who experience large electrolyte losses (e.g., because of diarrhea, fistula, emesis) likely will require electrolyte supplementation.

Fluid

Adult fluid needs often are estimated at 1 ml of water per kilocalorie consumed, or 30 to 35 ml/kg of usual body weight. Patients fed exclusively by EN may receive insufficient fluid (water) to meet their needs, especially when concentrated formulas are used. Insufficient fluid intake along with a high-fiber product may lead to a number of undesirable consequences, including inadequate urine output, constipation, and formation of a fiber bezoar (a hard ball of hair or vegetable fiber that may develop within the stomach of humans). All sources of fluid, including feeding tube flushes, medications, and intravenous fluids, should be considered when assessing a patient’s fluid intake relative to his or her needs.

Standard (1 kcal/ml) formulas contain approximately 85% water by volume; concentrated (2 kcal/ml) formulas contain only approximately 70% water by volume. Additional water (as flushes and for additional hydration) may be necessary.

Administration

EN may be administered as a bolus, intermittent, or continuous feeding. Selection of the optimal method should be based on the patient’s clinical status, living situation, and quality-of-life considerations. One method may serve as a transition to another method as the patient’s status changes.

In a **closed enteral system** the container or bag is prefilled with sterile liquid formula by the manufacturer and is “ready to feed” after connecting to the patient’s feeding access. In an **open enteral system**, the contents of formula cans or packages are poured into a separate, empty container or bag and then connected to the feeding access.

Hang time is the length of time an enteral formula hanging at room temperature is considered safe for delivery to the patient. Most facilities allow a 4-hour hang time for a product in an open system and 24 to 48 hours for products in closed system (depending on the manufacturer’s directions).

Bolus

Syringe **bolus enteral feedings** may be optimal for patients with adequate gastric emptying who are clinically stable (see Figure 13-4). Administered over 5 to 20 minutes, these feedings are more convenient and less expensive than pump or gravity bolus feedings and should be encouraged when tolerated. A 60-ml syringe may be used to infuse the formula. If bloating or abdominal discomfort develops, the patient should

wait 10 to 15 minutes before infusing the remainder of formula allocated for that feeding. Patients with normal gastric function generally tolerate 500 ml or more of formula per feeding; therefore, three or four bolus feedings per day typically provide their daily nutritional requirements. However some people, especially the elderly, may not be able to tolerate such large boluses and need a regimen of smaller, more frequent feedings. Formula at room temperature may be better tolerated than cold formula; however, food safety must be the primary consideration. Follow label directions for storing partially used cans of formula.

Intermittent and Cyclic

Quality-of-life issues are often the reason for the initiation of **intermittent enteral feedings**, and cyclical regimens allow mobile patients to enjoy an improved quality of life by offering time “off the pump” and more autonomy than do continuous infusions. They are initiated to allow time for treatments, therapies, and activities. Intermittent feedings can be given by pump or gravity drip. Gravity feeding is accomplished by pouring formula into a feeding bag that is equipped with a roller clamp. The clamp is adjusted to the desired drips per minute. A typical daily feeding schedule is four to six feedings, each administered over 20 to 60 minutes. Formula administration is initiated at 100 to 150 ml per feeding and increased incrementally as tolerated. Patients who most often succeed with this regimen are motivated, organized, alert, and mobile. Cyclic feeding also allows for a period of time away from the tube feeding. This feeding regimen is a good choice for patients who are receiving physical therapy or participate in other activities that make being tethered to a feeding apparatus inconvenient. A typical daily feeding schedule is 90 to 125 ml per hour of formula administered over 18 to 20 hours. This type of feeding often is used in transition to oral feedings and often is done at night to avoid feeding during meal times.

Continuous

Continuous infusion of EN requires a pump. This method is appropriate for patients who do not tolerate the volume of infusion used with the bolus, cyclical or intermittent methods. Patients with compromised gastrointestinal function because of disease, surgery, cancer therapy, or other physiologic impediments are candidates for continuous feedings. Patients with a feeding tube tip in the small intestine should be fed only by continuous or cyclic infusion. (Use of bolus or gravity feeding in these patients is strongly discouraged, although anecdotal verbal reports of use of both have been shared by some providers.) The feeding rate goal, in milliliters per hour, is set by dividing the total daily volume by the number of hours per day of administration. Full strength feeding is started at one quarter to one half of the hourly goal rate and advanced every 8 to 12 hours to the final volume. Dilution of formulas is not necessary and can lead to underfeeding. High osmolality formulas may require more time to achieve tolerance and should be advanced conservatively.

One possible drawback to continuous feedings is when the patient requires medication be given on an empty stomach. For example, when administering phenytoin (Dilantin) it is recommended that tube feedings be stopped before and after

administration. The times vary by situation and medication (see Chapter 8).

Enteral pumps available today are small and easy to handle. Many pumps run for up to 8 hours on battery power, with a “plug-in” option, allowing flexibility and mobility for the patient. Pump sets typically include bags and tubing compatible with proper pump operation. Feeding bags should be labeled in accordance with the A.S.P.E.N. Enteral Nutrition Practice Guidelines and should include information on the name of the formula and its concentration, the date and time the bag was filled, and the initials of the health care provider who hung the feeding.

Monitoring and Evaluation

Monitoring for Complications

Box 13-3 provides a comprehensive list of complications associated with EN. Many complications can be prevented or managed with careful patient monitoring.

Aspiration, a common concern for patients receiving EN, is also a controversial topic. Many experts believe that aspiration

BOX 13-3 Complications of Enteral Nutrition

Access

- Leakage from ostomy/stoma site
- Pressure necrosis/ulceration/stenosis
- Tissue erosion
- Tube displacement/migration
- Tube obstruction/occlusion

Administration

- Microbial contamination
- Enteral misconnections or misplacement of tube, causing infection, aspiration pneumonia, peritonitis, pulmonary or venous infusion
- Regurgitation
- Inadequate delivery for one or more reasons

Gastrointestinal

- Constipation
- Delayed gastric emptying/elevated gastric residual volume
- Diarrhea
 - Osmotic diarrhea, especially if sorbitol is present in liquid drug preparations
 - Secretory
- Distention/bloating/cramping
- Formula choice/rate of administration
- Intolerance of nutrient components
- Maldigestion/malabsorption
- Nausea/vomiting

Metabolic

- Drug-nutrient interactions
- Glucose intolerance/hyperglycemia/hypoglycemia
- Dehydration/overhydration
- Hypernatremia/hyponatremia
- Hyperkalemia/hypokalemia
- Hyperphosphatemia/hypophosphatemia
- Micronutrient deficiencies (notably thiamin)
- Refeeding syndrome

Data from Russell M: Complications of enteral feedings. In Charney P, Malone A, editors: *Pocket guide to enteral nutrition*, ed 2, Chicago, 2013, AND, p 170.

of throat contents and saliva is as much as or more important than aspiration of formula. To minimize the risk of aspiration, patients should be positioned with their heads and shoulders above their chests during and immediately after feeding (Bankhead et al, 2009; McClave et al, 2009).

Significant disagreement exists about the value of **gastric residual volumes (GRV)** as an indicator of EN tolerance. GRV procedures are not standardized and checking GRV does not protect patients from aspiration. GRV does not have to be checked regularly in patients who are stable on a feeding regimen and those who have a long history on tube feedings. In critically ill tube-fed patients the best methods for reducing the risk of aspiration include elevation of the head of the bed, continuous subglottic suctioning, and oral decontamination (Bankhead et al, 2009; McClave et al, 2009).

In the presence of gastroparesis, doses of a promotility drug may increase gastrointestinal transit, improve EN delivery, and improve feeding tolerance (McClave et al, 2009).

Diarrhea is a common EN complication, often related to the antibiotic therapy, colonic bacterial overgrowth, and gastrointestinal motility disorders associated with acute and critical illness. Hyperosmolar medications such as magnesium-containing antacids, sorbitol-containing elixirs, and electrolyte supplements also contribute to diarrhea. Adjustment of medications or administration methods may reduce or eliminate the diarrhea. FOS, pectin, guar gum, bulking agents, and antidiarrheal medications also can be beneficial. (Care must be taken to avoid clogging the feeding tube when using bulking agents or pectin.) A predigested formula may be useful but is rarely the best “first line” option, because the formula is often not the cause of the diarrhea.

Constipation is a concern with EN, particularly among bed-bound patients who receive long-term feedings. Fiber-containing formulas or stool-bulking medication may be helpful; daily provision of adequate fluid is important. Narcotic pain relievers slow GIT activity; iron supplements can cause constipation. Diarrhea may coexist with constipation, usually when there is also a fecal impaction because the liquid stool can get past the impaction.

Monitoring for Tolerance and Nutrient Intake Goals

Monitoring the patient’s *actual* (not prescribed) intake and tolerance is necessary to ensure that all nutrition goals are achieved and maintained. Monitoring of metabolic and gastrointestinal tolerance, hydration status, weight, and lean body mass is extremely important (Box 13-4). The development and use of practice guidelines, institutional protocols, and standardized ordering procedures are helpful to ensure optimal, safe monitoring of EN (McClave et al, 2009).

During routine patient care, time commonly is lost from the prescribed feeding schedule as a result of issues such as NPO status for medical procedures, clogged tubes, dislodged or misplaced tubes, and perceived or actual gastrointestinal intolerance. The result of “held” feedings is always inadequate nutrition with the risk of new or worsening malnutrition. Adjustment in the tube feeding regimen must be made. For example, if tube feedings are being turned off for 2 hours every afternoon for physical therapy, the feeding rate on the feeding should be increased and the feeding time decreased to accommodate the therapy schedule.

BOX 13-4 Monitoring the Patient Receiving Enteral Nutrition

Abdominal distention and discomfort
Confirm proper tube placement and maintain head of bed >30 degrees (daily)
Change feeding delivery container and tubing (daily)
Fluid intake and output (daily)
Gastric residual volume if appropriate
Signs and symptoms of edema or dehydration (daily)
Stool frequency, volume, and consistency (daily)
Weight (at least three times/wk)
Nutritional intake adequacy (daily)
Clinical status/physical examination (daily)
Serum electrolytes, blood urea nitrogen, creatinine, (daily till stable, then 2 to 3 times/wk)
Serum glucose, calcium, magnesium, phosphorus (daily till stable, then weekly)

Data from McClave SA et al: Guidelines for the provision and assessment of nutrition support therapy in the adult critically ill patient, *J Parenter Enteral Nutr* 33:277, 2009.

Shelton M: Monitoring and evaluation of enteral feedings. In Charney P, Malone A: *Pocket guide to enteral nutrition*, ed 2, Chicago, 2013, AND, p 153.

PARENTERAL NUTRITION

PN provides nutrients directly into the bloodstream intravenously. PN is indicated when the patient or individual is unable or unwilling to take adequate nutrients orally or enterally. PN may be used as an adjunct to oral or EN to meet nutrient needs. Alternatively, PN may be the sole source of nutrition during recovery from illness or injury or may be a life-sustaining therapy for patients who have lost the function of their intestine for nutrient absorption. As any type of nutrition support other than oral is invasive, it is important to evaluate ethical issues if the patient is terminal or has a short life expectancy (Barrocas et al, 2010).

Getting Started with Parenteral Nutrition

After the patient has been deemed to require nutrition support via the parenteral route, the clinician must choose between central and peripheral access. *Central access* refers to catheter tip placement in a large, high-blood-flow vein such as the superior vena cava; this is **central parenteral nutrition (CPN)**. **Peripheral parenteral nutrition (PPN)** refers to catheter tip placement in a small vein, typically in the hand or forearm.

The osmolarity of the PN solution dictates the location of the catheter; central catheter placement allows for the higher caloric PN formulation and therefore greater osmolarity (Table 13-2). The use of PPN is limited: it is short-term therapy and therefore has a minimum effect on nutritional status because the type and amount of fluids that can be provided peripherally are limited and most often do not fully meet nutrition requirements. Volume-sensitive patients such as those with cardiopulmonary, renal, or hepatic failure are not good candidates for PPN. PPN may be appropriate when used as a supplemental feeding or in transition to enteral or oral feeding, or as a temporary method to begin feeding when central access has not been initiated. Calculation of the osmolarity of a parenteral solution is important to ensure venous tolerance. **Osmolarity**, or mOsm/ml, is used to

TABLE 13-2 Osmolarity of Nutrients in PN Solutions

Nutrient	Osmolarity (mOsm/ml)	Sample Calculations
Dextrose 5%	0.25	500 ml = 125 mOsm
Dextrose 10%	0.505	500 ml = 252 mOsm
Dextrose 50%	2.52	500 ml = 1260 mOsm
Dextrose 70%	3.53	500 ml = 1765 mOsm
Amino acids 8.5%	0.81	1000 ml = 810 mOsm
Amino acids 10%	0.998	1000 ml = 998 mOsm
Lipids 10%	0.6	500 ml = 300 mOsm
Lipids 20%	0.7	500 ml = 350 mOsm
Electrolytes	Varies by additive	
Multitrace elements	0.36	5 ml = 1.8 mOsm
Multivitamin concentrate	4.11	10 ml = 41 mOsm

Data from RxKinetics: *Calculating Osmolarity of an IV Admixture* (website): http://www.rxkinetics.com/iv_osmolarity.html. Accessed December 2014.

calculate IV fluids rather than osmolality, which is used for body fluids.

Access

Peripheral Access

Peripheral parenteral nutrition (PPN) solutions of up to 800 to 900 mOsm/kg of solvent can be infused through a routine peripheral intravenous angiocatheter placed in a vein in good condition (Gura, 2009). Most often, PPN solutions are provided through catheters called *midline* or *midclavicular catheters*, depending on their position. They are not central catheters. **Extended dwell catheters**, which can remain at the original site for 3 to 6 weeks, require a vein large enough to advance the catheter 5 to 7 inches into the vein. These catheters make PPN a more feasible option in patients with veins large enough to tolerate the catheter for more than 2 to 3 days.

Short-Term Central Access

Catheters used for CPN ideally consist of a single lumen. If central access is needed for other reasons, such as hemodynamic monitoring, drawing blood samples, or giving medications, multiple-lumen catheters are available. To reduce the risk of infection, the catheter lumen used to infuse CPN should be reserved for that purpose only. Catheters are inserted most commonly into the subclavian vein and advanced until the catheter tip is in the superior vena cava, using strict aseptic technique. Alternatively, an internal or external jugular vein catheter can be used with the same catheter tip placement. However, the motion of the neck makes this site much more difficult for maintaining the sterility of a dressing. Radiologic verification of the tip site is necessary before infusion of nutrients can begin. Strict infection control protocols should be used for catheter placement and maintenance. **Figure 13-6** shows alternative venous access sites for CPN; femoral placement is also possible.

A **peripherally inserted central catheter (PICC)** may be used for short- or moderate-term infusion in the hospital or in the home. This catheter is inserted into a vein in the antecubital area of the arm and threaded into the subclavian vein with the catheter tip placed in the superior vena cava. Trained nonphysicians can insert a PICC, whereas placement of a tunneled catheter is a surgical procedure. All catheters must have

FIGURE 13-6 Venous sites from which the superior vena cava may be assessed.

radiologic confirmation of the placement of the catheter tip before initiating any infusion.

Long-Term Central Access

A commonly used long-term catheter is a “tunneled” catheter. This single- or multiple-lumen catheter is placed in the cephalic, subclavian, or internal jugular vein and fed into the superior vena cava. A subcutaneous tunnel is created so that the catheter exits the skin several inches from its venous entry site. This allows the patient to care for the catheter more easily as is necessary for long-term infusion. Another type of long-term catheter is a surgically implanted port under the skin where the catheter normally would exit at the end of the subcutaneous tunnel. A special needle must access the entrance port. Ports can be single or double; an individual port is equivalent to a lumen. Both tunneled catheters and PICCs can be used for extended therapy in the hospital or for home infusion therapy. Care of long-term catheters requires specialized handling and extensive patient education.

Parenteral Solutions

Protein

Commercially available standard PN solutions contain all essential amino acids and only some of the nonessential amino acids. Nonessential nitrogen is provided principally by the amino acids alanine and glycine, usually without aspartate, glutamate, cysteine, and taurine. Specialized solutions with adjusted amino acid content that contain taurine are available for infants, for whom taurine is thought to be conditionally essential.

The concentration of amino acids in PN solutions ranges from 3% to 20% by volume. Thus a 10% solution of amino acids supplies 100 g of protein per liter (1000 ml). The percentage of a solution usually is expressed at its final concentration after dilution with other nutrient solutions. The caloric content of amino acid solutions is approximately 4 kcal/g of protein provided. Protein needs are calculated based on the nutrition assessment data related to disease, injury, or clinical/nutrition status and range between 15% to 20% of total energy intake (Mueller et al, 2011).

Carbohydrates are supplied as dextrose monohydrate in concentrations ranging from 5% to 70% by volume. The dextrose

monohydrate yields 3.4 calories per gram. As with amino acids, a 10% solution yields 100 g of carbohydrates per liter of solution. The use of carbohydrates (100 g daily for a 70-kg person) ensures that protein is not catabolized for energy during conditions of normal metabolism.

Maximum rates of carbohydrate administration should not exceed 5 to 6 mg/kg/min in critically ill patients. When PN solutions provide 15% to 20% of total calories as protein, 20% to 30% of total calories as lipid, and the balance from carbohydrate (dextrose), infusion of dextrose should not exceed this amount. Excessive administration can lead to hyperglycemia, hepatic abnormalities, or increased ventilatory drive (see Chapter 34).

Lipids

Lipid emulsions provide calories and essential fatty acids in PN to avoid essential fatty acid deficiency. Lipid emulsions, currently on the market in the United States, available in 10%, 20%, and 30% concentrations, are composed of aqueous suspensions of soybean oil with egg yolk phospholipid as the emulsifier. Lipid emulsions containing egg phospholipids should not be used when a patient has an egg allergy. No safflower oil emulsions have been available in the United States in recent years. Intralipid (Fresenius Kabi, FDA approved 1975, marketed by Baxter Healthcare), Nutrilipid (BBraun, FDA approved but not marketed in the United States), and Liposyn III (Hospira, FDA approved but not marketed in the United States) are soybean oil emulsions.

Approximately 10% of calories per day from soybean based fat emulsions provide the 2% to 4% of calories from linoleic acid required to prevent EFAD. Administration should not exceed 2 g of lipid emulsion per kilogram of body weight per day, although recommendations of 1 to 1.5 g/kg are more common. Triglyceride levels should be monitored. When they exceed 400, the lipid infusion should be discontinued.

A 10% lipid emulsion contains 1.1 kcal/ml, whereas a 20% emulsion contains 2 kcal/ml. Providing 20% to 30% of total calories as lipid emulsion should result in a daily dosage of approximately 1 g of fat per kilogram of body weight. For critically ill patients who receive sedation in a lipid emulsion, these calories should be included in the nutrient intake calculations to avoid overfeeding or underfeeding (Drover et al, 2010). Diprivan (propofol) is an example of a sedation/anesthesia agent administered as an injectable infusion in a lipid emulsion providing approximately 1.1 kcal/ml infused. In the hospital, lipid is infused during 24 hours when mixed with the dextrose and amino acids. Alternatively, lipids can be provided separately by infusion via an infusion pump. Providing 20% to 30% of total calories as lipid emulsion should result in a daily dosage of approximately 1 g of fat per kilogram of body weight. In the hospital, lipid is infused during 24 hours when mixed with the dextrose and amino acids. Alternatively, lipids can be provided separately by infusion via an infusion pump. For adult patients receiving PN at home or home parenteral nutrition (HPN), the PN most often is infused during 10 to 12 hours per day with the lipid as part of the PN solution. It may be infused as a daily component of the home parenteral nutrition (HPN) or a few times per week.

Alternative forms of lipids are available that contain varying levels of omega-6 polyunsaturated fatty acids as indicated earlier but also contain omega-3 fatty acids and monounsaturated fat. Lipid sources other than soybean or safflower oil including coconut, olive, and fish oil are used (Waitzberg et al, 2006). ClinOleic/Clinolipid (Baxter Healthcare, FDA approved but not

marketed in the United States) is a new lipid emulsion that contains 80% olive oil and 20% soybean oil as well as egg phosphatides for emulsion. It provides essential fatty acids and contains 2 kcal/ml and should be dosed similarly at 1 to 1.5 g/kg to prevent any risk of EFAD. A lipid emulsion containing soybean oil, medium-chain triglycerides, olive oil, and fish oil (SMOFlipid, Fresenius Kabi—not FDA approved) is available outside the United States and has been shown to be safe and efficacious in healthy subjects and patients as compared with a standard soybean oil emulsion. The results of the clinical studies indicate that SMOFlipid is safe and well tolerated. Because of the multiple lipid types in the emulsion, the plasma fatty acid pattern demonstrated a rise in EPA- and DHA-derived lipid mediators and maintenance of an adequate vitamin E status.

Omegaven (Fresenius Kabi, not FDA approved, available in the United States for compassionate use only) is a fish oil–based lipid emulsion. Proposed benefits of fish oil lipid emulsion, as well as those that contain medium-chain triglycerides, include decreased inflammatory effects and less immunosuppression (Manzanares et al, 2014). Careful attention to the caloric load as well as the adequacy of essential fatty acids is important when these lipids are used. In a study of surgical patients who received one of four different intravenous lipid emulsions: medium-chain triglycerides/long-chain triglycerides (soybean oil; MCT/LCT), olive/soybean oil (oleic), long-chain triglycerides (soybean oil; LCT), or structured lipids, all were well tolerated and safe (Puiggros, 2009). The authors did note the serum fatty acid levels were similar to the pattern of fatty acids in the administered lipid emulsion. In addition, those who received the olive oil–based lipid emulsion had favorable changes in serum lipid levels. All lipid emulsions should be administered through a 1.2 micron filter set.

Electrolytes, Vitamins, Trace Elements

General guidelines for daily requirements for electrolytes are given in Table 13-3, for vitamins in Table 13-4, and for trace elements in Table 13-5. Parenteral solutions also represent a significant portion of total daily fluid and electrolyte intake. Once a solution is prescribed and initiated, adjustments for proper fluid and electrolyte balance may be necessary, depending on the stability of the patient. The choice of the salt form of electrolytes (e.g., chloride, acetate) affects acid-base balance.

Parenterally administered multivitamin and mineral preparations are designed to meet most patient's needs. These levels may be inadequate in some situations when additional

TABLE 13-3 Daily Electrolyte Requirements During Total Parenteral Nutrition—Adults

Electrolyte	Standard Intake/Day
Calcium	10-15 mEq
Magnesium	8-20 mEq
Phosphate	20-40 mmol
Sodium	1-2 mEq/kg + replacement
Potassium	1-2 mEq/kg
Acetate	As needed to maintain acid-base balance
Chloride	As needed to maintain acid-base balance

TABLE 13-5 Daily Trace Element Supplementation for Adult Parenteral Formulations

Trace Element	Intake
Chromium	10-15 mcg
Copper	0.3-0.5 mg
Manganese	60-100 mcg
Zinc	2.5-5.0 mg
Selenium	20-60 mcg

individual supplementation is required (Vanek et al, 2012). Patients receiving PN as their sole source of nutrition should receive added multivitamins and trace elements daily and be monitored closely, especially those who are critically ill (Sriram and Lonchyna, 2009). Monitoring of manganese and chromium status is recommended for patients receiving PN for longer than 6 months (Buchman et al, 2009).

Iron is not normally part of parenteral infusions because it is not compatible with lipids and may enhance certain bacterial growth. In addition, care must be taken to ensure that a patient can tolerate the separate iron infusion. When patients receive iron on an outpatient basis, the first dose should be done in a controlled setting (such as an outpatient infusion suite) to observe for any reactions that the patient may experience.

One of the challenges in PN in the last 5 years has been the occurrence of drug shortages that have affected micro- and macronutrients, including intravenous lipid emulsion, multivitamins, multitrace elements, and electrolytes including phosphorous. Patients in the hospital, at home, and in long-term care receiving not only parenteral nutrition but also other intravenous and injectable therapies have been affected. This problem is expected to be ongoing, and therefore clinicians should be aware of alternative products as well as methods to allocate safely products in short supply.

Fluid

Fluid needs for PN or EN are calculated similarly. Maximum volumes of CPN rarely exceed 3 L, with typical prescriptions of 1.5 to 3 L daily. In critically ill patients, volumes of prescribed CPN should be coordinated closely with their overall care plan.

The administration of other medical therapies requiring fluid administration, such as intravenous medications and blood products, necessitates careful monitoring. Patients with cardiopulmonary, renal, and hepatic failure are especially sensitive to fluid administration. For HPN, higher volumes may be best provided in separate infusions. For example, if additional fluid is required as a result of high output by the patient, then a liter bag of intravenous fluid containing minimal electrolytes may be infused during a short time during the day if the PN is infused overnight. See Appendix XX on calculating PN prescriptions.

Compounding Methods

PN prescriptions historically have required preparation or compounding by competent pharmacy personnel under laminar airflow hoods using aseptic techniques. Hospitals may have their own compounding pharmacy or may purchase PN solutions that have been compounded outside the hospital in a central location and then returned to the hospital for distribution to individual patients. A third method of providing PN solutions is to use multichamber bag technology, whereby solutions are manufactured in a quality-controlled environment using good manufacturing processes. PN solutions of two chamber bags contain amino acids (with or without electrolytes) and dextrose and are available in multiple formulas with varying amounts of dextrose and amino acids, making them suitable for CPN or PPN infusion. Some multichamber bag formulas may contain lipids in a third chamber; however, these are not currently available in the United States but are available in Europe and Canada. They contain conservative amounts of electrolytes or may be electrolyte free. These products have a shelf life of 2 years and do not have to be refrigerated unless the product covering has been opened to reveal the infusion bag. They do not contain vitamins or trace elements that may be added to the solutions; therefore the clinician must add vitamins/minerals to the patients' treatment plan to avoid any deficiencies. Institutions frequently use standardized solutions, which are compounded in batches, thus saving labor and lowering costs; however, flexibility for individualized compounding should be available when warranted (Ayers et al, 2014).

Prescriptions for PN are compounded in two general ways. One method combines all components except the fat emulsion,

which is infused separately. The second method combines the lipid emulsion with the dextrose and amino acid solution and is referred to as a **total nutrient admixture** or **3-in-1** solution. The PN Safe Practices Guidelines provide clinicians with information on many techniques and procedures that enhance safety and prevent mistakes in the preparation of PN (Boullata et al, 2014).

A number of medications, including antibiotics, vasopressors, narcotics, diuretics, and many other commonly administered drugs, can be compounded with PN solutions. In practice this occurs infrequently because it requires specialized knowledge of physical compatibility or incompatibility of the solution contents. The most common drug additives are insulin for persistent hyperglycemia and histamine-2 antagonists to avoid gastroduodenal stress ulceration. One other consideration is that the PN usually is ordered 24 hours before its administration, and patient status may have changed.

Administration

The methods used to administer PN are addressed after the goal infusion rate has been established. For critically ill and hospitalized patients, a 24-hour infusion rate is used. However, for patients transitioning to a long term or lifetime of receiving PN, infusion rate should be decreased to 10- to 12-hour cycle per day to complete activities of daily living and improve quality of life. Nevertheless, general considerations as listed in **Box 13-5** can be applied to almost any protocol.

Continuous Infusion

Parenteral solutions usually are initiated below the goal infusion rate via a volumetric pump and then increased incrementally over a 2- or 3-day period to attain the goal infusion rate. Some clinicians start PN based on the amount of dextrose, with initial prescriptions containing 100 to 200 g daily and advancing over a 2- or 3-day period to a final goal. With high dextrose concentrations, abrupt cessation of CPN should be avoided, particularly if the patient's glucose tolerance is abnormal. If CPN is to be stopped, it is prudent to taper the rate of infusion in an unstable patient to prevent **rebound hypoglycemia**, low blood sugar levels resulting from abrupt cessation. For most stable patients this is not necessary.

Cyclic Infusion

Individuals who require PN at home benefit from a cyclic infusion; this entails infusion of PN for 8- to 12-hour periods, usually at night. This allows the person to have a free period of 12 to 16 hours each day, which may improve quality of life. The goal cycle for infusion time is established incrementally when a higher rate of infusion or a more concentrated solution is required. Cycled infusions should not be attempted if glucose intolerance or fluid tolerance is a problem. The pumps used for home infusion of PN are small and convenient, allowing mobility during daytime infusions. Administration time may be decreased because of patient ambulation and bathing, tests or other treatments, intravenous administration of medications, or other therapies.

Monitoring and Evaluation

As with enteral feeding, routine monitoring of PN is necessary more frequently for the patient receiving PN in the hospital. For

BOX 13-5 Nutrition Care Process for Enteral and Parenteral Nutrition

Assessment

1. Clinical status, including medications
2. Fluid requirement
3. Route of administration
4. Energy (kcal) requirement
5. Protein requirement
6. Carbohydrate/lipid considerations
7. Micronutrient considerations
8. Formula selection or PN solution considerations
 - A. Concentration (osmolality)
 - B. Protein content
 - C. Carbohydrate/lipid content
 - D. Micronutrient content
 - E. Special formula considerations
9. Calculations
 - A. Energy: use kcal/ml formula
 - B. Protein: use g/1000 ml
 - C. Fat and micronutrient considerations: units/1000 ml
 - D. Fluid considerations: extra water, IV fluids (including medications)

Nutrition Diagnosis

1. Identify the problems affecting oral nutritional intake.
2. Identify problems related to access or administration of tube feedings.
3. Write PES statements. These may include inadequate or excess infusion of enteral or parenteral nutrition, or other nutrition diagnoses.

Intervention

1. Each problem should have an intervention and a way to evaluate it.
2. Recommend what method and how to begin feedings.
3. Recommend how to advance feedings.
4. Determine how fluids will be given in adequate amounts.
5. Calculate final feeding prescription.

Monitoring and Evaluation

1. Describe clinical signs and symptoms to monitor for feeding tolerance.
2. List laboratory values and other measurements to be monitored.
3. Determine how feeding outcomes will be evaluated.

IV, Intravenous; PES, problem, etiology, and signs and symptoms; PN, parenteral nutrition.

patients receiving HPN, initial monitoring is done on a weekly basis or less frequently as the patient becomes more stable on PN. Monitoring is done not only to evaluate response to therapy but also to ensure compliance with the treatment plan.

COMPLICATIONS

Infection

The primary complication associated with PN is infection (**Box 13-6**). Therefore strict adherence to protocols and monitoring for signs of infection such as chills, fever, tachycardia, sudden hyperglycemia, or elevated white blood cell count are necessary. Monitoring of metabolic tolerance is also critical. Electrolytes, acid-base balance, glucose tolerance, renal function, and cardiopulmonary and **hemodynamic stability** (maintenance of adequate blood pressure) can be affected by PN and should be monitored

BOX 13-6 Parenteral Nutrition Complications

Mechanical Complications

Air embolism
Arteriovenous fistula
Brachial plexus injury
Catheter fragment embolism
Catheter misplacement
Cardiac perforation
Central vein thrombophlebitis
Endocarditis
Hemothorax
Hydromediastinum
Hydrothorax
Pneumothorax or tension pneumothorax
Subcutaneous emphysema
Subclavian artery injury
Subclavian hematoma
Thoracic duct injury

Infection and Sepsis

Catheter entrance site
Catheter seeding from bloodborne or distant infection
Contamination during insertion
Long-term catheter placement
Solution contamination

Metabolic Complications

Dehydration from osmotic diuresis
Electrolyte imbalance
Essential fatty acid deficiency
Hyperosmolar, nonketotic, hyperglycemic coma
Hyperammonemia
Hypercalcemia
Hyperchloremic metabolic acidosis
Hyperlipidemia
Hyperphosphatemia
Hypocalcemia
Hypomagnesemia
Hypophosphatemia
Rebound hypoglycemia on sudden cessation of PN in patient with unstable glucose levels
Uremia
Trace mineral deficiencies

Gastrointestinal Complications

Cholestasis
Gastrointestinal villous atrophy
Hepatic abnormalities

carefully. Table 13-6 lists parameters that should be monitored routinely.

The CPN catheter site is a potential source for introduction of microorganisms into a major vein. Protocols to prevent infection vary and should follow Centers for Disease Control Prevention guidelines (Naomi et al, 2011). Catheter care and prevention of catheter-related bloodstream infections are of utmost importance in the hospital and alternate settings. These infections not only are costly but also may be life-threatening. Catheter care is dictated by the site of the catheter and the setting in which the patient receives care.

TABLE 13-6 Inpatient Parenteral Nutrition Monitoring (Critical/Acute Care)

VARIABLE TO BE MONITORED	SUGGESTED FREQUENCY	
	Initial Period*	Later Period*
Weight	Daily	Weekly
Serum electrolytes	Daily	1-2/wk
Blood urea nitrogen	3-wk	Weekly

I&O	Daily	Daily

McClave SA et al: Guidelines for the provision and assessment of nutrition support therapy in the adult critically ill patient, *J Parenter Enteral Nutr* 33:277, 2009.

I&O, Intake and output; WBC, white blood cell.

*Initial period is that period in which a full glucose intake is being achieved. Later period implies that the patient had achieved a steady metabolic state. In the presence of metabolic instability, the more intensive monitoring outlined under initial period should be followed.

I&O refers to all fluid going into the patient: oral, intravenous, medication; and all fluid coming out: urine, surgical drains, exudates.

REFEEDING SYNDROME

Patients who require enteral or PN therapies may have been eating poorly before initiating therapy because of the disease process and may be moderately to severely malnourished. Aggressive administration of nutrition, particularly via the intravenous route, can precipitate **refeeding syndrome** with severe, potentially lethal electrolyte fluctuations involving metabolic, hemodynamic, and neuromuscular problems. Refeeding syndrome occurs when energy substrates, particularly carbohydrate, are introduced into the plasma of anabolic patients (Parrish, 2009).

Proliferation of new tissue requires increased amounts of glucose, potassium, phosphorus, magnesium, and other nutrients essential for tissue growth. If intracellular electrolytes are not supplied in sufficient quantity to keep up with tissue growth, low serum levels of potassium, phosphorus, and magnesium develop. Low levels of these electrolytes are the hallmark of refeeding syndrome, especially hypokalemia. Carbohydrate metabolism by cells also causes a shift of electrolytes to the intracellular space as glucose moves into cells for oxidation. Rapid infusion of carbohydrate stimulates insulin release, which reduces salt and water excretion and increases the chance of cardiac and pulmonary complications from fluid overload.

Patients starting on PN who have received minimal nutrition for a significant period should be monitored closely for electrolyte fluctuation and fluid overload. A review of baseline laboratory values, including glucose, magnesium, potassium, and phosphorus should be completed and any abnormalities corrected before initiating nutrition support, particularly PN. Conservative amounts of carbohydrate and adequate amounts

of intracellular electrolytes should be provided. The initial PN formulation usually should contain 25% to 50% of goal dextrose concentration and be increased slowly to avoid the consequences of hypophosphatemia, hypokalemia, and hypomagnesemia. PN compatibilities must be assessed when very low levels of dextrose are provided with higher levels of amino acids and electrolytes. The syndrome also occurs in enterally fed patients, but less often because of the effects of the digestive process.

In managing the nutrition care process, refeeding syndrome is an undesirable outcome that requires monitoring and evaluation. Most often, the nutrition diagnosis may be “excessive carbohydrate intake” or “excessive infusion from enteral or parenteral nutrition” in the undernourished patient. Thus, in the early phase of refeeding, nutrient prescriptions should be moderate in carbohydrate and supplemented with phosphorus, potassium, and magnesium.

TRANSITIONAL FEEDING

All nutrition support care plans strive to use the GIT when possible, either with EN or by a total or partial return to oral intake. Therefore patient care plans frequently involve **transitional feeding**, moving from one type of feeding to another, with several feeding methods used simultaneously while continuously administering estimated nutrient requirements. This requires careful monitoring of patient tolerance and quantification of intake from parenteral, enteral, and oral routes. Most experts advise that initial oral diets be low in simple carbohydrates and fat, as well as lactose free. These provisions make digestion easier and minimize the possibility of osmotic diarrhea. Attention to individual tolerance and food preferences also helps maximize intake. During the transition stage from HPN to HEN or an oral diet, careful attention should be paid to assuring multivitamin and mineral adequacy. This may require laboratory assessment of micronutrients if a deficiency is suspected.

Parenteral to Enteral Feeding

To begin the transition from PN to EN, introduce a minimal amount of enteral feeding at a low rate of 30 to 40 ml/hr to establish gastrointestinal tolerance. When there is severe gastrointestinal compromise, predigested formula to initiate enteral feedings may be better tolerated. Once formula has been given during a period of hours, the parenteral rate can be decreased to keep the nutrient levels at the same prescribed amount. As the enteral rate is increased by 25 to 30 ml/hr increments every 8 to 24 hours, the parenteral prescription is reduced accordingly. Once the patient is tolerating about 75% of nutrient needs by the enteral route, the PN solution can be discontinued. This process ideally takes 2 to 3 days; however, it may become more complicated, depending on the degree of gastrointestinal function. At times the weaning process may not be practical, and PN can be stopped sooner, depending on overall treatment decisions and likelihood for tolerance of enteral feeding.

Parenteral to Oral Feeding

The transition from parenteral to oral feeding ideally is accomplished by monitoring oral intake and concomitantly decreasing the PN to maintain a stable nutrient intake. Approximately 75% of nutrient needs should be met consistently by oral intake

before the PN is discontinued. The process is less predictable than the transition to enteral feeding. Variations include the patient's appetite, motivation, and general well-being. It is important to continue monitoring the patient for adequate oral intake once PN has been stopped and to initiate alternate nutrition support if necessary. Generally patients are transitioned from clear liquids to a diet that is low in fiber and fat and is lactose free. It takes several days for the GIT to regain function; during that time, the diet should be composed of easily digested foods.

Special nutrient needs may be employed, especially when transitioning a patient with gastrointestinal disorders such as short bowel syndrome. Specialized nutrients, optimized drug therapy, and nutrition counseling should be comprehensive to improve outcome. Some PN patients may not be able to discontinue PN fully but may be able to use PN less than 7 days per week, necessitating careful attention to nutrient intake. A skilled registered dietitian nutritionist (RDN) can coordinate diet and PN needs for this type of patient.

Enteral to Oral Feeding

A stepwise decrease also is used to transition from EN to oral feeding. It is effective to move from continuous feeding to a 12- and then an 8-hour formula administration cycle during the night; this reestablishes hunger and satiety cues for oral intake during daytime. In practice, oral diets often are attempted after inadvertent or deliberate removal of a nasogastric tube. This type of interrupted transition should be monitored closely for adequate oral intake. Patients receiving EN who desire to eat and for whom it is not contraindicated can be encouraged to do so. A transition from liquids to easy-to-digest foods may be necessary during a period of days. Patients who cannot meet their needs by the oral route can be maintained by a combination of EN and oral intake.

Oral Supplements

The most common types of oral supplements are commercial formulas meant primarily to augment the intake of solid foods. They often provide approximately 250 kcal/8 oz or 240-ml portion and approximately 8 to 14 g of intact protein. Some products have 360 or 500 or as much as 575 kcal in a can. There are different types of products for different disease states.

Fat sources are often long-chain triglycerides, although some supplements contain MCTs. More concentrated and thus more nutrient-dense formulas are also available. A variety of flavors, consistencies, and modifications of nutrients are appropriate for various disease states. Some oral supplements provide a nutritionally complete diet if taken in sufficient volume.

The form of carbohydrate is a key factor to patient acceptance and tolerance. Supplements with appreciable amounts of simple carbohydrate taste sweeter and have higher osmolalities, which may contribute to gastrointestinal intolerance. Individual taste preferences vary widely, and normal taste is altered by certain drug therapies, especially chemotherapy. Concentrated formulas or large volumes can contribute to taste fatigue and early satiety. Thus oral nutrient intake and the intake of prescribed supplements should be monitored.

Oral supplements that contain hydrolyzed protein and free amino acids such as those developed for patients with renal,

liver, and malabsorptive diseases tend to be mildly to markedly unpalatable, and acceptance by the patient depends on motivation. Formulas for renal and liver disease in particular may lack sufficient vitamins and minerals and are not nutritionally complete and therefore useful only to the specific population.

Although commercially available modular supplements are used most commonly for convenience, modules of protein, carbohydrate, or fat or commonly available food items can produce highly palatable additions to a diet. As examples, liquid or powdered milk, yogurt, tofu, or protein powders can be used to enrich cereals, casseroles, soups, or milk shakes. Thickening agents are now used to add variety, texture, and aesthetics to pureed foods, which are used when swallowing ability is limited (see Chapter 40). Imagination and individual tailoring can increase oral intake, avoiding the necessity for more complex forms of nutrition support.

NUTRITION SUPPORT IN LONG-TERM AND HOME CARE

Long-Term Care

Long-term care (LTC) generally refers to a skilled nursing facility but includes subacute care for the purpose of rehabilitation that often can take several weeks or even months. Health care provided in this environment focuses on quality of life, self-determination, and management of acute and chronic disease. Indications for EN and PN are generally the same for older patients as for younger adults and varies according to the age, gender, disease state, and most importantly, the care goals of the individual. PN and EN often are provided to these facilities by offsite pharmacies that specialize in LTC. These providers may employ dietitians and specially trained nurses to assist the facilities with education and training on PEN.

Oral supplements have gained widespread use in this LTC over the last two decades, again for convenience. However, they appear to have detrimental effects, and real food always should be attempted first. See Chapter 19 for a discussion of the Dining Standards for Long Term Care that have been endorsed by 12 professional organizations. A major goal in the Dining Standards is the elimination of canned nutrition supplements.

Advance directives are legal documents that residents use to state their preferences about aspects of care, including those regarding the use of nutrition support. These directives may be written in any setting, including acute or home care but are especially useful in LTC to guide interventions on behalf of long-term care residents when they are no longer able to make decisions (Barrocas et al, 2010).

Differentiation between the effects of advanced age versus malnutrition is an assessment challenge for dietitians working in long-term care (see Chapter 20). This is an area of active research, as is the influence that nutrition support has on the quality of life among long-term care residents. Studies generally show that use of nutrition support in older adults is beneficial, especially when used in conjunction with physical activity. Patients who are actively pursuing physical therapy are good candidates for nutrition support. However, when there is a terminal illness or condition, starting nutrition support may have no advantage and may prolong suffering in some cases. Dietitians can be strong patient advocates in end-of-life decisions and should be involved in writing and implementing the policies in their institutions.

BOX 13-7 Considerations When Deciding on Home Nutrition Support

- Sanitation of the home environment to preserve the patient's health and reduce risk of infection
- Potential for improvement in quality of life and nutritional status
- The financial and time commitment needed by patient or family; potential loss of income outside the home in some cases
- Ability to understand the techniques for administration of the product and safe use of all equipment and supplies
- Any physical limitations that prevent the implementation of HEN or HPN therapy
- Capacity for patient or caregiver to contact medical services when needed

HEN, Home enteral nutrition; *HPN*, home parenteral nutrition.

Home Care

Home enteral nutrition (HEN) or **home parenteral nutrition (HPN)** support usually entails the provision of nutrients or formulas, supplies, equipment, and professional clinical services. Resources and technology for safe and effective management of long-term enteral or parenteral therapy are widely available for the home care setting. Although home nutrition support has been available for more than 30 years, few outcome data have been generated. Because mandatory reporting requirements do not exist in the United States for patients receiving home nutrition support, the exact number of patients receiving this support is unknown.

The elements needed to implement home nutrition successfully include identification of appropriate candidates and a feasible home environment with responsive caregivers, a choice of a suitable nutrition support regimen, training of the patient and family, and a plan for medical and nutritional follow-up by the physician as well as by the home infusion provider (Box 13-7). These objectives are best achieved through coordinated efforts of an interdisciplinary team (see *Clinical Insight: Home Tube Feeding—Key Considerations*).

Patients receiving HEN may receive supplies only, or formula and supplies with or without clinical oversight by the provider. Many enteral patients receive services from a **durable medical equipment (DME) provider** that may or may not provide clinical services. A home infusion provider provides intravenous therapies, including home PN, intravenous antibiotics, and other therapies. Home nursing agencies may be associated with a DME company or a home infusion agency to provide nursing services to home EN or PN patients. Often the patient's reimbursement source for home therapy plays a major role in determining the type of home infusion provider. In fact, reimbursement is a key component of a patient's ability to receive home therapy of any kind and should be evaluated early in the care plan so that appropriate decisions can be made before discharge or initiating a therapy.

Companies that provide home infusion services for EN or PN may be private or affiliated with acute care facilities. Criteria for selecting a home care company to provide nutrition support should be based on the company's ability to provide ongoing monitoring, patient education, and coordination of care. When a patient is receiving home EN or PN, it is important to determine whether the provider has an RDN on staff or access to the services of a RDN. The RDN is uniquely qualified not only to provide oversight and monitoring for the patient while receiving EN or PN but also to provide the appropriate nutrition

CLINICAL INSIGHT**Home Tube Feeding—Key Considerations****What Is the Best Kind of Tube?**

In general, nasal tubes should be avoided because they are more difficult to manage, clog easily, are easily dislodged, and over time can cause tissue irritation and even erosion. PEG tubes are now the most common and preferred method for home tube feedings. They can be either low profile (flat to the abdomen), button-type tubes, or they can have a short piece of tubing attached through the abdomen and into the stomach. The button tubes require some manual dexterity to access and can be difficult to use for patients who are very obese. **Percutaneous endoscopic jejunostomy (PEJ)** tubes are best for patients who require postpyloric feedings as a result of intolerance of gastric feeding, but PEJ feedings require a pump, which severely limits mobility of the patient.

What Is the Best Method of Administration?

Bolus feeding is the easiest administration method and generally should be tried first. It should be started slowly at half of an 8-oz can four to six times a day. If bolus feeding is not tolerated, gravity feeding is a second option. It does require a bag and pole but can be accomplished fairly quickly and requires less manual dexterity than bolus feeding.

Pump feeding is sometimes necessary when a patient requires small amounts of formula delivered slowly. Although it is well tolerated, it has major implications for a patient at home because even the simplest pump is often viewed as “high tech.” Its use greatly limits mobility, and, like any piece of equipment, it can break and interrupt feeding schedules.

What Is the Best Way to Educate the Patient and Caregiver?

- Directions should be written in common measurements such as cups, tablespoons, and cans rather than milliliters.
- The enteral nutrition regimen should be as simple as possible; use whole cans of formula rather than partial cans.
- Additives to the feedings should be minimized to avoid confusion and clogging of the feedings tubes.
- Provide clear directions for gradually increasing to the goal feeding rate.
- Provide clear directions for water flushing of the tube and for additional water requirements to prevent dehydration.
- Discuss common problems that may come up and provide guidance for resolving them.
- Make sure that the patient or caregiver can demonstrate understanding of the feeding process by either explaining it or by doing it.

counseling and food suggestions when the patient transitions between therapies (Fuhrman et al, 2009).

Ethical Issues

Whether to provide or withhold nutrition support is often a central issue in “end-of-life” decision making. For patients who are terminally ill or in a persistent vegetative state, nutrition support can extend life to the point that issues of quality of life and the patient’s right to self-determination come into play. Often surrogate decision makers are involved in treatment decisions. The nutrition support clinician has a responsibility to know whether documentation, such as a living will regarding the patient’s wishes for nutrition support, is in the medical record and whether counseling and support resources for legal and ethical aspects of patient care are available to the patient and his or her significant others (Barrocas et al, 2010).

CLINICAL CASE STUDY

A 24-year-old has newly diagnosed type 1 diabetes mellitus and Crohn’s disease. She recently had surgery for removal of one third of her ileum. She is 75% of her usual weight, which is 125 lb; she is 65 inches tall. She requires specialized nutrition support for several months until her body adapts to the shortened bowel.

Nutrition Diagnostic Statements

- Involuntary weight loss related to poor intake, surgery, and pain during flare-up of Crohn’s disease as evidenced by 25% weight loss.
- Inadequate oral food and beverage intake related to recent ileal resection as evidenced by 75% of usual weight and need for artificial nutrition.

Nutrition Care Questions

1. What immediate nutrition support method would be recommended?
2. What long-term nutrition support plan is likely to be designed?
3. What specialty products, if any, may be beneficial?
4. What parameters would you monitor to determine tolerance and response to the nutrition plan?

Education and Counseling: Behavioral Change

Karen Chapman-Novakofski, PhD, RDN, LDN

KEY TERMS

alignment	health belief model (HBM)	reframing
ambivalence	health literacy	self-efficacy
behavior change	maleficence	self-management
behavior modification	motivational interviewing (MI)	self-monitoring
cognitive behavioral therapy (CBT)	negotiation	social cognitive theory (SCT)
cultural competency	normalization	social-ecological model
discrepancy	peer educator	stages of change
double-sided reflection	PRECEDE-PROCEED model	theory of planned behavior (TPB)
empathy	reflective listening	transtheoretical model (TTM)

Key factors in changing nutrition behavior are the person's awareness that a change is needed and the motivation to change. Nutrition education and nutrition counseling provide information and motivation, but they do differ. *Nutrition education* can be individualized or delivered in a group setting; it is usually more preventive than therapeutic, and there is a transmission of knowledge. *Counseling* is used most often during medical nutrition therapy, one-on-one. In the one-on-one setting, the nutritionist sets up a transient support system to prepare the client to handle social and personal demands more effectively while identifying favorable conditions for change. The goal of nutrition education and nutrition counseling is to help individuals make meaningful changes in their dietary behaviors.

BEHAVIOR CHANGE

Although there are differences between education and counseling as intervention techniques, the distinctions are not as important as the desired outcome, behavior change. **Behavior change** requires a focus on the broad range of activities and approaches that affect the individual choosing food and beverages in his or her community and home environment. **Behavior modification** implies the use of techniques to alter a person's behavior or reactions to environmental cues through positive and negative reinforcement, and extinction of maladaptive behaviors. In the context of nutrition, education and counseling can assist the individual in achieving short-term or long-term health goals.

Factors Affecting the Ability to Change

Multiple factors affect a person's ability or desire to change, the educator's ability to teach new information, and the counselor's

ability to stimulate and support small changes. Financial constraints, unstable living environments, inadequate family or social support, insufficient transportation, and low literacy are some of the socioeconomic factors that may be barriers for obtaining and maintaining a healthy diet. With a population that is culturally diverse, it is imperative to appreciate the differences in beliefs or understanding that may lead to the inability to change.

Physical and emotional factors also make it hard to change, especially for seniors. Older adults need education and counseling programs that address low vision, poor hearing, limited mobility, decreased dexterity, and memory problems or cognitive impairments (Kamp et al, 2010). Expectations of the food preparer, time restraints, routines, preferences, and roles within the family also may hinder changes in food intake (Brown and Wenrich, 2012). For children, barriers include taste, ease of eating, and competing foods that may be available that are less healthy (Nicklas et al, 2013). Across all ages are issues of how culture affects what foods are eaten and how and perceptions about education, counseling, health, and health care (see Chapters 9 and 11).

MODELS FOR BEHAVIOR CHANGE

Changing behavior is the ultimate goal for nutrition counseling and education. Providing a pamphlet or a list of foods can reinforce information, but it usually does nothing to change eating behavior. Because so many different factors influence what someone eats, nutritionists have been learning from behavioral scientists to identify and intervene based on mediators of people's eating behavior. Health professionals can support individuals in deciding what and when to change by using a variety of health behavior

TABLE 14-1 Overview of Behavior Theories Used in Nutrition Education and Counseling

Health Belief Model (HBM)	Perceived susceptibility: An individual's belief regarding the chance that he or she may get a condition or disease Perceived severity: An individual's belief of how serious a condition and its consequences are Perceived benefits: An individual's belief in the positive effects of the advised action in reducing the risk or the seriousness of a condition Perceived barriers: An individual's belief about the tangible and psychologic costs of the advised action Self-efficacy: An individual's belief that he or she is capable of performing the desired action Cues to action: Strategies to activate one's readiness to change a behavior
Social Cognitive Theory (SCT)	Personal factors: Outcome expectations, self-efficacy, reinforcements, impediments, goals and intentions, relapse prevention Behavioral factors: Knowledge and skills, self-regulation and control, and goal setting Environmental factors: Include imposed, selected, and created environments
Theory of Planned Behavior (TPB)	Subjective norms: The people who may influence the patient Attitudes: What the patient thinks about the behavior Perceived control: How much control the patient has to change things that affect the behavior Behavioral intention: Whether the patient plans to perform the behavior
Transtheoretical Model (TM), or Stages of Change Model	Precontemplation: The individual has not thought about making a change. Contemplation: The individual has thought about making a change but has done no more than think about it. Preparation: The individual has taken some steps to begin to make the desired change. Action: The individual has made the change and continues it for less than 6 months. Maintenance: The individual has continued the behavior for longer than 6 months. Termination: The individual no longer thinks about the change; it has become a habit.

theories. Some of the most common theories for behavior change are listed in [Table 14-1](#), with examples described in the following paragraphs.

Health Belief Model

The **health belief model (HBM)** focuses on a disease or condition, and factors that may influence behavior related to that disease ([Rosenstock, 1974](#)). The HBM has been used most with behaviors related to diabetes and osteoporosis, focusing on barriers to and benefits of changing behaviors ([James et al, 2012](#); [Plawecki and Chapman-Novakofski, 2013](#)).

Social Cognitive Theory

Social cognitive theory (SCT) represents the reciprocal interaction among personal, behavioral, and environmental factors ([Bandura, 1977, 1986](#)). This theory is extensive and includes many variables; some of the most important to counseling include self-efficacy, goal setting, and relapse prevention ([Poddar et al, 2012](#)).

Theory of Planned Behavior

The **theory of planned behavior (TPB)** and the reasoned action approach are based on the concept that intentions predict behavior ([Ajzen, 1991](#); [Fishbein and Ajzen, 2010](#)). Intentions are predicted by attitudes, subjective norms (important others), and perceived control. This theory is most successful when a discrete behavior is targeted (e.g., vegetable intake) but has also been used for healthy diet consumption ([Sheats et al, 2013](#)).

Transtheoretical Model of Change

The **transtheoretical model (TTM)**, or **stages of change** model, has been used for many years to alter addictive behaviors and often is described as “tailored education.” TTM describes behavior change as a process in which individuals progress through a series of six distinct stages of change, as shown in [Figure 14-1](#) ([Prochaska and Norcross, 2001](#)). The value of the TTM is in determining the individual's current stage, then using change processes matched to that stage ([Mochari-Greenberger et al, 2010](#)).

FIGURE 14-1 A model of the stages of change. In changing, a person progresses up these steps to maintenance. If relapse occurs, he or she gets back on the steps at some point and works up them again.

MODELS FOR COUNSELING STRATEGIES

Cognitive behavior therapy (CBT) focuses on identifying and changing erroneous perceptions of the self, environment, and behavioral consequences. CBT often identifies behavior and thoughts that have a negative impact on desired behavioral goals and apply strategies to change those. CBT counselors can help clients explore troubling themes, strengthen their coping skills, and focus on their well-being ([Beck, 2011](#)).

CBT often is used for obesity interventions and eating disorders as well as a range of psychological and psychiatric disorders (Cooper et al, 2010; Murphy et al, 2010).

Motivational interviewing (MI) has been used in a variety of conditions to encourage clients to identify discrepancies between how they would like to behave and how they are behaving and then motivate them to change. The following are principles used in MI to enhance behavior change (Johnston and Stevens, 2013).

Expressing Empathy

The nutrition counselor should demonstrate **empathy** for what a client feels, rather than giving advice. As clients review situations in their lives and the lack of time for dietary changes, the nutrition counselor will hear **ambivalence**. On the one hand, clients want to make changes; on the other hand, they want to pretend that change is not important.

Developing Discrepancy

An awareness of consequences is important. Identifying the advantages and disadvantages of modifying a behavior, or developing **discrepancy**, is a crucial process in making changes.

Client: I want to follow the new eating pattern, but I just can't afford it.

Nutrition counselor: Let's look at your diet record and discuss some healthy, low-cost changes.

Rolling with Resistance (Legitimation, Affirmation)

Rolling with resistance involves inviting new perspectives without imposing them. The client is a valuable resource in finding solutions to problems. Perceptions can be shifted, and the nutrition counselor's role is to help with this process. For example, a client who is wary of describing why she is not ready to change may become much more open to change if she sees openness to her resistive behaviors. When it becomes okay to discuss resistance, the rationale for its original existence may seem less important.

Client: I just feel that my level of enthusiasm for following the diet is low. It all seems like too much effort.

Nutrition counselor: I appreciate your concerns. At this point in following a new diet, many people feel the same way. Tell me more about your concerns and feelings.

Supporting Self-Efficacy

Belief in one's own capability to change is an important motivator. The client is responsible for choosing and carrying out personal change. However, the nutrition counselor can support **self-efficacy** by having the client try behaviors or activities while the counselor is there.

Client: I just don't know what to buy once I get to the grocery store. I end up with hamburger and potato chips.

Nutrition counselor: Let's think of one day's meals right now. Then we can make a grocery list from that.

MODELS FOR EDUCATIONAL PROGRAM DEVELOPMENT

The **PRECEDE-PROCEED model** is a participatory health program planning model that has been used in a variety of health topics communities to optimize positive outcomes. PRECEDE consists of four planning phases represented in its acronym for

FIGURE 14-2 The intrapersonal, interpersonal, institutional, community, and policy levels of the social-ecological model.

predisposing, reinforcing, enabling, constructs in education/ecological diagnosis and evaluation. This reflects the needs assessment and participatory planning of the educational program. PROCEED's acronym stands for **Policy, Regulatory, and Organizational Constructs in Educational and Environmental Development** and provides a framework for program implementation and evaluation (Green et al, 1980). This model has been applied to a number of nutrition education programs (Kattelman et al, 2014; Walsh et al, 2014).

The **social-ecological model** (Sallis and Owen, 2015) (Figure 14-2) can be applied to health promotion and disease prevention programs by addressing interventions at each stage of the model: intrapersonal, interpersonal, institutional, community, and policy levels (Fitzgerald et al, 2013).

SKILLS AND ATTRIBUTES OF THE NUTRITION EDUCATOR OR COUNSELOR

Cultural Competency

The medical community was one of the first to promote **cultural competency** and, although there is no agreement on its exact definition, it is fair to say it involves cultural sensitivity or awareness. Learning about different cultures is important; however, memorizing attributes commonly thought to reflect a certain culture can lead to stereotyping. A preferred approach is to develop skills in eliciting the learner's perceptions, skills, and literacy as an individual (Stein, 2009).

Gregg et al (2006) define the following five tenets as the basis for cultural competency:

- Understanding the role of culture. Learning the skills to elicit patients' individual beliefs and interpretations and to negotiate conflicting beliefs is important to good patient care, regardless of the social, ethnic, or racial backgrounds of the patient.
- Learning about culture and becoming "culturally competent" is not a panacea for health disparities.

- *Culture, race, and ethnicity* are distinct concepts. Just learning about the culture will not eliminate racism.
- Culture is mutable and multiple; any understanding of a particular cultural context is always incompletely true, always somewhat out of date, and partial.
- Context is critical. Because culture is so complex, so shape-shifting, and so ultimately inseparable from its social and economic context, it is impossible to consider it as an isolated or static phenomenon.

Multicultural awareness is the first step toward establishing rapport and becoming a competent nutrition educator or counselor. It is important to evaluate one's own beliefs and attitudes and become comfortable with differences among racial, ethnic, or religious beliefs, culture, and food practices (see *Clinical Insight: The Counselor Looks Within*). Heightening awareness of personal biases and increasing sensitivity allow the counselor to be more effective in understanding what the client may need to move forward.

Educating or counseling with cultural competency should acknowledge surface and deep structure. Surface structure includes such things as language and foods (see Chapter 11). Deep structure includes psychological or social beliefs and the context of the intervention.

Language is the primary surface structure issue that is addressed. Although knowing several languages can be an asset, many counselors rely on translators. Unofficial translators, such as family or friends, are not usually a good choice because of a lack of understanding of nutrition and health. Using professional translators is also not without limitations in that the educator must understand the client and the interpreter. The educator should maintain contact with the client and explain the role of the interpreter (Mossavar-Rahmani, 2007). When working with clients who have limited ability to speak and understand English, always use common terms, avoiding slang and words with multiple meanings. Always speak directly to the client, even when using a translator, and watch the client for nonverbal responses during the translation.

Effective communication in education or counseling should encompass not only language but also deeper structure issues, such as the role of the individual within a group, and how or why certain foods are prepared (Broyles et al, 2011). Spatial relationships vary among cultures and among individuals. Movements such as gestures, facial expressions, and postures are often the cause of confusion and misinterpretations in intercultural communication. Rules regarding eye contact are usually complex and vary according to issues such as gender, distance apart, and social status (see *Clinical Insight: Body Language and Communication Skills*).

CLINICAL INSIGHT

The Counselor Looks Within

Before entering a counseling relationship and after reflecting on the session, the nutritionist should look inward and consider any factors that affect his or her own thinking and how they may affect the client. The nutritionist should reflect on ethical issues, such as the autonomy of the client, and beneficence versus **maleficence** (harm). An example may be when a female client decides not to set goals for her blood glucose levels and not to learn the amounts of carbohydrates in foods (autonomy). These choices serve as barriers to the benefit the counselor would make in teaching these **self-management** tools (beneficence) and the need for nonmaleficence (do no harm). Whenever clients decide a behavior change is not right for them, the counselor's role is not to force the issue but to encourage its future consideration.

CLINICAL INSIGHT

Body Language and Communication Skills

Active listening forms the basis for effective nutrition counseling. There are two aspects to effective listening: nonverbal and verbal. Nonverbal listening skills consist of varied eye contact, attentive body language, a respectful but close space, adequate silence, and encouragers. Eye contact is direct yet varied. Lack of eye contact implies that the counselor is too busy to spend time with the client. When the counselor leans forward slightly and has a relaxed posture and avoids fidgeting and gesturing, the client will be more at ease. Silence can give the client time to think and provide time for the counselor to contemplate what the client has said. Nodding one's head in agreement can be a positive encourager, leading to more conversation. Moving forward slightly toward the client is an encourager that allows for more positive interaction.

When developing interventions that are culturally competent, the clinician can use the PRECEDE-PROCEED model to provide the framework to guide appreciation for the target audience's surface and deep structure culture (DePue et al, 2010).

Asking Questions

Qualities of good counselors and educators include empathy, positive regard, and genuineness, as well as knowledge of nutritional sciences. For counseling, there also should be periods of information gathering. For information gathering, open-ended questions are most effective when they elicit more discussion. Questions that do not often lead to effective discussion include data questions (e.g., "What did you eat ...?") and knowledge questions that often elicit a defensive response (e.g., "Can you tell me about low-fat diets?").

Open-ended questions allow the client to express a wider range of ideas, whereas closed questions can help in targeting concepts and eliminating tangential discussions. For the person who is not ready to change, targeted discussions around difficult topics can help focus the session. The nutritionist asks questions that must be answered by explaining and discussing, not by one-word answers. This is particularly important for someone who is not ready to change, because it opens the discussion to problem areas that keep the client from being ready. The following statements and questions are examples that create an atmosphere for discussion:

- "We are here to talk about your dietary change experiences to this point. Could you start at the beginning and tell me how it has been for you?"
- "What are some things you would like to discuss about your dietary changes so far? What do you like about them? What don't you like about them?"

Framing the optimal discussion question is not easy and requires the counselor to be self-reflective on which questions were successful. Teaching counseling skills has included simulated patient-counselor scenarios with a standardized patient. A tool for evaluating has been developed called the Feedback on Counseling Using Simulation (FOCUS) instrument (Henry and Smith, 2010). Verbal and nonverbal communication is important; for the latter, maintaining an appropriate facial expression and using affirmative gestures seem to be important (Collins et al, 2010).

Building Rapport

It may be difficult to build rapport with some clients. Someone who appears hostile, unusually quiet, or dismissive may

have more success with either a different nutritionist or someone with whom he or she has background in common. In those cases, working with a peer educator may be most effective. The **peer educator** ideally should share similarities with the target population in terms of age or ethnicity and have primary experience in the nutrition topic (e.g., has breastfed her infant). Peer educators are usually community health workers or paraprofessionals. The Expanded Food and Nutrition Education Program (EFNEP) has demonstrated the effectiveness and cost efficiency of peer educators (Dollahite et al, 2008). In prenatal or WIC clinics, breastfeeding peer counselors are often highly effective in helping new mothers with their questions and concerns (Pérez-Escamilla et al, 2008).

Reflective Listening

Nutrition counselors listen and try to tag the feelings that surface as a client is describing difficulties with an eating pattern. Listening is not simply hearing the words spoken by the client and paraphrasing them. Figure 14-3 shows a nutrition counselor listening reflectively to her client.

Reflective listening involves a guess at what the person feels and is phrased as a statement, not a question. By stating a feeling, the nutrition counselor communicates understanding. The following are three examples of listening reflectively:

Client: I really do try, but I am retired and my husband always wants to eat out. How can I stay on the right path when that happens?

Nutrition counselor: You feel frustrated because you want to follow the diet, but at the same time you want to be spontaneous with your husband. Is this correct?

Client: I feel like I let you down every time I come in to see you. We always discuss plans and I never follow them. I almost hate to come in.

Nutrition counselor: You are feeling like giving up. You haven't been able to modify your diet, and it is difficult for you to come into our visits when you haven't met the goals we set. Is this how you are feeling? (reflective listening) Can you think of a specific time when you feel that you had an opportunity to achieve your plan, but didn't?

Client: Some days I just give up. It is on those days that I do very badly in following my diet.

FIGURE 14-3 This nutrition counselor is using reflective listening techniques with her client.

Nutrition counselor: You just lose the desire to try to eat well on some days and that is very depressing for you. Do I have that right?(rephrasing) Are those days when something in particular has happened?

Affirming

Counselors often understand the idea of supporting a client who is very depressed about their eating style, but does not put those thoughts into words. When the counselor affirms someone, there is alignment and normalization. During **alignment**, the counselor tells the client that he or she understands these difficult times. **Normalization** means telling the client that he or she is perfectly within reason and that it is normal to have such reactions and feelings. The following statements indicate affirmation:

- “I know that it is hard for you to tell me this. But thank you.”
- “You have had amazing competing priorities. I feel that you have done extremely well, given your circumstances.”
- “Many people I talk with express the same problems. I can understand why you are having difficulty.”

Summarizing

The nutrition counselor periodically summarizes the content of what the client has said by covering all the key points. Simple and straightforward statements are most effective, even if they involve negative feelings. If conflicting ideas arise, the counselor can use the strategy exemplified by the statement, “On the one hand you want to change, but love those old eating patterns.” This helps the client recognize the dichotomy in thinking that often prevents behavior change.

ASSESSMENT RESULTS: CHOOSING FOCUS AREAS

Health and Nutrition Literacy

Low **health literacy**, or the ability to understand health information well enough to make informed decisions, is common among older adults, minorities, and those who are medically underserved or have a low socioeconomic status (Health Resources and Services Administration, 2010). This problem can lead to poor management of chronic health conditions, as well as low adherence to recommendations. Useful resources available from the Agency on Healthcare Research and Quality are *Rapid Estimate of Adult Health Literacy in Medicine* (REALM) and *Short Assessment of Health Literacy for Spanish Adults* (SAHLSA-50) (Agency on Healthcare Research and Quality, 2014). Nutrition-targeted evaluation measures include the Newest Vital Sign, which focuses on a nutrition facts label (Rowlands et al, 2013) and the Nutrition Literacy Assessment Instrument, which evaluates several components, including understanding of nutrition and health, macronutrients, household food measurement, food labels and numeracy, and food groups (Gibbs and Chapman-Novakofski, 2013). Relying on the client's educational attainment provides some guidance, but asking the client to repeat explanations in his or her own words also can help the nutrition educator evaluate the client's level of understanding.

Assessing Readiness to Change

One purpose of assessment is to identify the client's stage of change and to provide appropriate help in facilitating change. The assessment should be completed in the first visit if possible.

If conversation extends beyond the designated time for the session, the assessment steps should be completed at the next session. The nutritional assessment requires gathering the appropriate anthropometric, biochemical, clinical, dietary, and economic data relating to the client's condition (see Chapters 4 and 7). The nutritional diagnosis then focuses on any problems related to food or nutrient intake (see Chapter 10).

Determining present eating habits provides ideas on how to change in the future. It is important to review the client's eating behavior, to identify areas needing change, and to help the client select goals that will have the most effect on health conditions. For instance, if the nutrition diagnosis includes excessive fat intake (nutrient intake NI-51.2), inappropriate intake of food fats (NI-51.3), excessive energy intake (NI-1.5), inadequate potassium intake (NI-55.1), food- and nutrition-related knowledge deficit (nutrition behavior NB-1.1), and impaired ability to prepare foods or meals (NB-2.4), the counselor may have to focus on the last diagnosis before the others. If all other diagnoses are present except impaired ability to prepare foods or meals (NB-2.4), the nutritionist may want to have a discussion about whether excessive fat intake, inappropriate intake of types of food fats, or excessive energy intake are more appealing or possible for the client to focus on first.

Once the nutrition diagnosis is selected for intervention, it is important to assess readiness for change. Using a ruler that allows the client to select his or her level of intention to change is one method of allowing client participation in the discussion. The counselor asks the client, "On a scale of 1 to 12, how ready are you right now to make any new changes to eat less fat? (1 = not ready to change; 12 = very ready to change)." The nutritionist may use this method with each nutrition diagnosis to help the client decide where to focus first.

Three possibilities for readiness exist: (1) not ready to change; (2) unsure about change; (3) ready to change. These three concepts of readiness have condensed the six distinct stages of change described in this chapter to assist the counselor in determining the level of client readiness. There are many concepts to remember, and readiness to change may fluctuate during the course of the discussion. The counselor must be ready to move back and forth between the phase-specific strategies. If the client seems confused, detached, or resistant during the discussion, the counselor should return and ask about readiness to change. If readiness has lessened, tailoring the intervention is necessary. Not every counseling session has to end with the client's agreement to change; even the decision to think about change can be a useful conclusion.

COUNSELING APPROACHES AFTER THE ASSESSMENT

Not-Ready-to-Change Counseling Sessions

In approaching the "not-ready-to-change" stage of intervention, there are three goals: (1) facilitate the client's ability to consider change, (2) identify and reduce the client's resistance and barriers to change, and (3) identify behavioral steps toward change that are tailored to each client's needs. At this stage identifying barriers from the HBM in Table 14-1, the influence of subjective norms and attitudes (TPB), or personal and environmental factors (SCT) that may have negative influences on the intention to change can be helpful. To achieve these goals, several communication skills are important to master: asking open-ended questions, listening reflectively, affirming the

patient's statements, summarizing the patient's statements, and eliciting self-motivational statements.

The four communication strategies (asking open-ended questions, listening reflectively, affirming, and summarizing) are important when eliciting self-motivational statements. The goal here is for the client to realize that a problem exists, that concern results, and that positive steps in the future can be taken to correct the problem. The goal is to use these realizations to set the stage for later efforts at dietary change. Examples of questions to use in eliciting self-motivational feeling statements follow.

Problem Recognition

- "What things make you think that eating out is a problem?"
- "In what ways has following your diet been a problem?"

Concern

- "How do you feel when you can't follow your diet?"
- "In what ways does not being able to follow your diet concern you?"
- "What do you think will happen if you don't make a change?"

Intention to Change

- "The fact that you're here indicates that at least a part of you thinks it's time to do something. What are the reasons you see for making a change?"
- "If you were 100% successful and things worked out exactly as you would like, what would be different?"
- "What things make you think that you should keep on eating the way you have been?" And in the opposite direction, "What makes you think it is time for a change?"

Optimism

- "What encourages you that you can change if you want to?"
- "What do you think would work for you if you decided to change?"

Clients in this "not-ready-to-change" category have already told the counselor they are not doing well at making changes. Usually if a tentative approach is used by asking permission to discuss the problem, the client will not refuse. One asks permission by saying, "Would you be willing to continue our discussion and talk about the possibility of change?" At this point, it is helpful to discuss thoughts and feelings about the current status of dietary change by asking open-ended questions:

- "Tell me why you picked _____ on the ruler." (Refer to previous discussion on the use of a ruler.)
- "What would have to happen for you to move from a _____ to a _____ (referring to a number on the ruler)? How could I help get you there?"
- "If you did start to think about changing, what would be your main concern?"

To show real understanding about what the client is saying, it is beneficial to summarize the statements about his or her progress, difficulties, possible reasons for change, and what has to be different to move forward. This paraphrasing allows the client to rethink his or her reasoning about readiness to change. The mental processing provides new ideas that can promote actual change.

Ending the Session

Counselors often expect a decision and at least a goal-setting session when working with a client. However, it is important in

NEW DIRECTIONS

Counseling and Educating Online

More counselors and educators are turning to online connections with their clients and target audiences. Although all the basics of counseling and education remain the same, there are additional issues to consider when online. If clients are recording food intake and physical activity through mobile technology, the frequency of monitoring and providing feedback must be considered. Although many best practices in nutrition education include the use of mobile technology, development and maintenance of the website or app in a constantly changing technological world must be addressed. Short message service (SMS) usually does not require a data plan for mobile phones, but clinicians should check with clients about their mobile plans so as not to increase monthly charges. Other online ways to reach clients include social media platforms, blogs, and recipe apps and websites. However, Health Insurance Portability and Accountability Act (HIPAA) regulations and confidentiality should be considered.

this stage to realize that traditional goal setting will result in feelings of failure on the part of the client and the nutritionist. If the client is not ready to change, respectful acknowledgment of this decision is important. The counselor may say, “I can understand why making a change right now would be very hard for you. The fact that you are able to indicate this as a problem is very important, and I respect your decision. Our lives do change, and, if you feel differently later on, I will always be available to talk with you. I know that, when the time is right for you to make a change, you will find a way to do it.” When the session ends, the counselor lets the client know that the issues will be revisited after he or she has time to think. Expression of hope and confidence in the client’s ability to make changes in the future, when the time is right, is beneficial. Arrangements for follow-up contact can be made at this time.

With a client who is not ready to change, it is easy to become defensive and authoritarian. At this point, it is important to avoid pushing, persuading, confronting, coaxing, or telling the client what to do. It is reassuring to a nutritionist to know that change at this level often occurs outside the office. The client is not expected to be ready to do something during the visit (see *New Directions: Counseling and Educating Online*).

UNSURE-ABOUT-CHANGE COUNSELING SESSIONS

The only goal in the “unsure-about-change” session is to build readiness to change. This is the point at which changes in eating behavior can escalate. This “unsure” stage is a transition from not being ready to deal with a problem eating behavior to preparing to continue the change. It involves summarizing the client’s perceptions of the barriers to a healthy eating style and how they can be eliminated or circumvented to achieve change. Heightened self-efficacy may provide confidence that goals can be achieved. A restatement of the client’s self-motivational statements assists in setting the stage for success. The client’s ambivalence is discussed, listing the positive and negative aspects of change. The nutritionist can restate any statements that the client has made about intentions or plans to change or to do better in the future.

One crucial aspect of this stage is the process of discussing thoughts and feelings about current status. Use of open-ended questions encourages the client to discuss dietary change progress

and difficulties. Change is promoted through discussions focused on possible reasons for change. The counselor might ask the question, “What would need to be different to move forward?”

This stage is characterized by feelings of **ambivalence**. The counselor should encourage the client to explore ambivalence to change by thinking about the “pros” and “cons.” Some questions to ask are:

- “What are some of the things you like about your current eating habits?”
- “What are some of the good things about making a change?”
- “What are some of the bad things about making a change?”

By trying to look into the future, the nutrition counselor can help a client see new and often positive scenarios. As a change facilitator, the counselor helps to tip the balance away from being ambivalent about change toward considering change by guiding the client to talk about what life may be like after a change, anticipating the difficulties as well as the advantages. An example of an opening to generate discussion with the client might be: “I can see why you’re unsure about making changes in your eating habits. Imagine that you decided to change. What would that be like? What would you want to do?” The counselor then summarizes the client’s statements about the “pros” and “cons” of making a change and includes any statements about wanting, intending, or planning to change.

The next step is to negotiate a change. The **negotiation** process has three parts. The first is setting goals. Set broad goals at first and hold more specific nutritional goals until later. “How would you like things to be different from the way they are?” and “What would you like to change?”

The second step in negotiation is to consider options. The counselor asks about alternative strategies and options and then asks the client to choose from among them. This is effective because, if the first strategy does not work, the client has other choices. The third step is to arrive at a plan, one that has been devised by the client. The counselor touches on the key points and the problems, and then asks the client to write down the plan.

To end the session the counselor asks about the next step, allowing the client to describe what may occur next in the process of change. The following questions provide some ideas for questions that may promote discussion:

- “Where do you think you will go from here?”
- “What do you plan to do between now and the next visit?”

RESISTANCE BEHAVIORS AND STRATEGIES TO MODIFY THEM

Resistance to change is the most consistent emotion or state when dealing with clients who have difficulty with dietary change. Examples of resistance behaviors on the part of the client include contesting the accuracy, expertise, or integrity of the nutrition counselor; or directly challenging the accuracy of the information provided (e.g., the accuracy of the nutrition content). The nutrition counselor may even be confronted with a hostile client. Resistance also may surface as interrupting, when the client breaks in during a conversation in a defensive manner. In this case the client may speak while the nutrition counselor is still talking without waiting for an appropriate pause or silence. In another, more obvious manner, the client

may break in with words intended to cut off the nutrition counselor's discussion.

When clients express an unwillingness to recognize problems, cooperate, accept responsibility, or take advice, they may be denying a problem. Some clients blame other people for their problems (e.g., a wife may blame her husband for her inability to follow a diet). Other clients may disagree with the nutrition counselor when a suggestion is offered, but they frequently provide no constructive alternative. The familiar "Yes, but . . ." explains what is wrong with the suggestion but offers no alternative solution.

Clients try to excuse their behavior. A client may say, "I want to do better, but my life is in turmoil since my husband died 3 years ago." An excuse that was once acceptable is reused even when it is no longer a factor in the client's life.

Some clients make pessimistic statements about themselves or others. This is done to dismiss an inability to follow an eating pattern by excusing poor compliance as just a given resulting from past behaviors. Examples are, "My husband will never help me" or "I have never been good at sticking with a goal. I'm sure I won't do well with one now."

In some cases, clients are reluctant to accept options that may have worked for others in the past. They express reservations about information or advice given. "I just don't think that will work for me." Some clients express a lack of willingness to change or an intention not to change. They make it very clear that they want to stop the dietary regimen.

Often clients provide evidence that they are not following the nutrition counselor's advice. Such clues include using a response that does not answer the question, providing no response to a question, or changing the direction of the conversation.

These types of behavior can occur within a counseling session as clients move from one stage to another. They are not necessarily stage-specific, although most are connected with either the "not ready" or "unsure-about-change" stages. A variety of strategies are available to assist the nutrition counselor in dealing with these difficult counseling situations. These strategies include reflecting, double-sided reflection, shifting focus, agreeing with a twist, emphasizing personal choice, and reframing. Each of these options is described in the following paragraphs.

Reflecting

In reflecting, the counselor identifies the client's emotion or feeling and repeats it. This allows the client to stop and reflect on what was said. An example of this type of counseling is, "You seem to be very frustrated by what your husband says about your food choices."

Double-Sided Reflection

In **double-sided reflection**, the counselor uses ideas that the client has expressed previously to show the discrepancy between the client's current words and the previous ones. For example:

Client: I am doing the best I can. (Previously this client stated that she sometimes just gives up and doesn't care about following the diet.)

Nutrition counselor: On the one hand you say you are doing your best, but on the other hand I recall that you said you just felt like giving up and didn't care about following the

diet. Do you remember that? How was that point in time different than now?

Shifting Focus

Clients may hold onto an idea that they think is getting in the way of their progress. The counselor may question the feasibility of continuing to focus on this barrier to change when other barriers may be more appropriate targets. For example:

Client: I will never be able to follow a low-saturated fat diet as long as my grandchildren come to my house and want snacks.

Nutrition counselor: Are you sure that this is really the problem?

Is part of the problem that you like those same snacks?

Client: Oh, you are right. I love them.

Nutrition counselor: Could you compromise? Could you ask your grandchildren which of this long list of low-saturated fat snacks they like and then buy them?

Agreeing with a Twist

This strategy involves offering agreement, then moving the discussion in a different direction. The counselor agrees with a piece of what the client says but then offers another perspective on his or her problems. This allows the opportunity to agree with the statement and the feeling but then to redirect the conversation onto a key topic.

For example:

Client: I really like eating out, but I always eat too much, and my blood sugars go sky high.

Nutrition counselor: Most people do like eating out. Now that you are retired it is easier to eat out than to cook. I can understand that. What can we do to make you feel great about eating out so that you can still follow your eating plan and keep your blood glucose values in the normal range?

Reframing

With **reframing**, the counselor changes the client's interpretation of the basic data by offering a new perspective. The counselor repeats the basic observation that the client has provided and then offers a new hypothesis for interpreting the data. For example:

Client: I gave up trying to meet my dietary goals because I was having some difficulties when my husband died, and I have decided now that I just cannot meet those strict goals.

Nutrition counselor: I remember how devastated you were when he died and how just cooking meals was an effort. Do you think that this happened as a kind of immediate response to his death and that you might have just decided that all of the goals were too strict at that time? (Pause)

Client: Well, you are probably right.

Nutrition counselor: Could we look at where you are now and try to find things that will work for you now to help you in following the goals we have set?

These strategies help by offering tools to ensure that nutrition counseling is not ended without appropriate attempts to turn difficult counseling situations in a more positive direction.

Ending the Session

Counselors always should emphasize that any future action belongs to the client, that the advice can be taken or disregarded. This emphasis on personal choice (autonomy) helps

clients avoid feeling trapped or confined by the discussion. Belief in the ability to change through his or her own decisions is an essential and worthy goal. A sense of self-efficacy reflects the belief about being capable of influencing events and choices in life. These beliefs determine how individuals think, feel, and behave. If people doubt their capabilities, they will have weak commitments to their goals. Success breeds success, and failure breeds a sense of failure. Having resilience, positive role models, and effective coaching can make a significant difference.

READY-TO-CHANGE COUNSELING SESSIONS

Setting goals

The major goal in the “ready-to-change” session is to collaborate with the client to set goals that include a plan of action. The nutrition counselor provides the client with the tools to use in meeting nutrition goals. This is the stage of change that most often is assumed when a counseling session begins. To erroneously assume this stage means that inappropriate counseling strategies set the stage for failure. Misaligned assumptions often result in lack of adherence on the part of the client and discouragement on the part of the nutritionist. Therefore, it is important to discuss the client’s thoughts and feelings about where he or she stands relative to the current change status. Use of open-ended questions helps the client confirm and justify the decision to make a change and in which area. The following questions may elicit information about feelings toward change:

- “Tell me why you picked _____ on the ruler.”
- “Why did you pick (nutrition diagnosis 1) instead of (other nutrition diagnoses)?”

In this stage, goal setting is extremely important. Here the counselor helps the client set a realistic and achievable short-term goal: “Let’s do things gradually. What is a reasonable first step? What may be your first goal?”

Action Plan

After goal setting, an action plan is set to assist the client in mapping out the specifics of goal achievement. Identifying a network to support dietary change is important. What can others do to help?

Early identification of barriers to adherence is also important. If barriers are identified, plans can be formed to help eliminate these roadblocks.

Many clients fail to notice when their plan is working. Clients can be asked to summarize their plans and identify markers of success. The counselor then documents the plan for discussion at future sessions and ensures that the clients also have their plans in writing. The session should close with an encouraging statement and reflection about how the client identified this plan personally. Indicate that each person is the expert about his or her own behavior. Compliment the client on carrying out the plan. Some ways to express these ideas to clients are the following:

- “You are working very hard at this, and it’s clear that you’re the expert about what is best for you. You can do this!”
- “Keep in mind that change is gradual and takes time. If this plan doesn’t work, there will be other plans to try.”

FIGURE 14-4 This client is connecting with her nutrition counselor using Skype to discuss how she is doing with her eating behavior changes.

The key point for this stage is to avoid telling the client what to do. Clinicians often want to provide advice. However, it is critical that the client express ideas of what will work best: “There are a number of things you could do, but what do you think will work best for you?” The next contact may be in person, online, or by phone.

Following up with clients by phone or online has become a popular counseling method for many nutritionists (Figure 14-4). When behavior and counseling theories are combined with phone counseling, the results have been effective in managing weight, type 2 diabetes, and hypertension (Eakin et al, 2009; Kim et al, 2010). Online weight reduction programs also have been successful, especially when the websites are interactive and communication with counselors is available (Krukowski et al, 2009).

EVALUATION OF EFFECTIVENESS

Counseling

Clinicians and educators must evaluate their services. Just completing the counseling process with clients does not mean that outcomes will match the goals. A review of literature related to behavior change theories and strategies used in nutrition counseling reported the following (Spahn et al, 2010):

1. Strong evidence supports the use of CBT in facilitating modification of targeted dietary habits, weight, and cardiovascular and diabetes risk factors.
2. MI is a highly effective counseling strategy, particularly when combined with CBT.
3. Few studies have assessed the application of the TTM or SCT on nutrition-related behavior change.
4. **Self-monitoring**, meal replacements, and structured meal plans are effective; financial reward strategies are not.
5. Goal setting, problem solving, and social support are effective strategies.
6. Research is needed in more diverse populations to determine the most effective counseling techniques and strategies.

Educational Programs

The LOGIC model often is used to evaluate a program's effectiveness. The most simple version includes inputs (resources or investments into a program), outputs (activities, services and events), and outcomes (behavior change of individuals, group or communities), although some include multiple levels within these three broad categories. The LOGIC model has guided evaluation of national nutrition programs as well as educational programs at the individual level, such as a video program to improve dietary habits of children (Beasley et al, 2012).

SUMMARY

For nutrition education and counseling efforts to be effective, skills must be developed by the educator or counselor, the characteristics of the target audience or client must be assessed, a behavioral theory should be incorporated, and evaluation of the process and outcomes should be completed.

CLINICAL CASE STUDY

Mrs. Lee is originally from mainland China. She has been living in your area for several years and has numerous health problems, including high blood pressure and glaucoma. You have been asked to counsel her about making changes in her diet. Because her vision is poor, she will not be able to use printed materials that you have in your office that have been translated into Chinese.

Nutrition Diagnostic Statement

Impaired ability to prepare food and meals related to inability to see as evidenced by client report and history of glaucoma

Nutrition Care Questions

1. What steps should you take to make her comfortable with this session?
2. Should you invite family members to attend the counseling session? Why or why not?
3. What tools may be useful to help Mrs. Lee understand portions or types of food that she should select?
4. Would a supermarket tour be useful? Why or why not?
5. What other types of information will be needed to help Mrs. Lee?

Nutrition in the Life Cycle

The importance of nutrition throughout the life cycle cannot be refuted. However, the significance of nutrition during specific times of growth, development, and aging is becoming increasingly appreciated.

Health professionals have recognized for quite some time the effects of proper nutrition during pregnancy on the health of the infant and mother, even after her childbearing years. However looking at “nutrition in the womb” encompasses not only maternal health history and nutrition but also paternal nutrition and the health of sperm before conception. “Fetal origin” has far more lifelong effects on the new life than originally thought.

Establishing good dietary habits during childhood lessens the possibility of inappropriate eating behavior later in life. Although the influence of proper nutrition on morbidity and mortality usually remains unacknowledged until adulthood, dietary practices aimed at preventing the degenerative diseases that develop later in life should be instituted in childhood.

During early adulthood many changes begin that lead to the development of chronic disease, the so called diseases of aging, years later. Many of these changes can be accelerated or slowed over the years, depending on the genetic makeup of the individual, quality of the nutritional intake, the health of the gut, and the function of the immune system.

With the rapid growth of the population of older adults has evolved a need to expand the limited nutrition data currently available for these individuals. Although it is known that energy needs decrease with aging, little is known about whether requirements for specific nutrients increase or decrease. Identifying the unique nutritional differences among the various stages of aging is becoming even more important.

Nutrition for Reproductive Health and Lactation

Jean T. Cox, MS, RD, LN and Virginia H. Carney, MPH, RDN, LDN, IBCLC, RLC, FILCA, FAND

KEY TERMS

amylophagia	gestational diabetes mellitus (GDM)	Montgomery glands
assisted reproductive technology (ART)	gestational hypertension	mother-led weaning
baby-led weaning	gravidia	nausea and vomiting in pregnancy (NVP)
colostrum	HELLP syndrome	neural tube defects (NTDs)
conception	hindmilk	oxytocin
congenital anomalies	hyperemesis gravidarum (HG)	pagophagia
developmental origins of health and disease (DOHaD)	intrauterine fetal demise (IUFD)	perinatal mortality
fetal alcohol syndrome (FAS)	intrauterine growth restriction (IUGR)	pica
fetal origins of disease	lactogenesis I	postpartum depression (PPD)
foremilk	lactogenesis II	preeclampsia
galactagogue	let-down	prolactin
geophagia	macrosomia	ptyalism gravidarum
	mature milk	transitional milk

Optimal nutrition during pregnancy, which includes adequate amounts of all of the required vitamins, minerals, and energy-providing macronutrients, actually begins preconceptually. Because developing fetuses depend solely on the transfer of substrates from their host, there is simply no other means to acquire nutrition in utero. The cliché that the “fetus is the perfect parasite” implies fetuses take all they require at the expense of the host. However, at some point nutritional deficiency can result in premature labor, relieving the host of an ongoing nutritional debt. After birth, quality nutrition during lactation continues the process of providing nutritional building blocks for normal cerebral development, and growth of all body organs in the neonate.

This time period—growing a new human being—sets the stage for the health of future generations. The quality and quantity of nourishment to the developing zygote, then fetus, then neonate, then adult emerge as one explanation for diseases that manifest in adulthood. This concept is known as **fetal origins of disease** or **developmental origins of health and disease** (DOHaD) (Guéant et al, 2013; Monk et al, 2013).

PRECONCEPTION AND FERTILITY

Reproductive Readiness and Fertility

The focus on preconceptual nutrition and health is important for women and men. Infertility affects 10% to 12% of U.S.

couples of reproductive age, and extremes in body mass index (BMI) in either partner may be one cause. Women with a BMI less than 20 have an increased risk of anovulation. Men and women have increased rates of subfertility when overweight or obese; weight loss and increased physical activity may be helpful (Simon, 2014). **Box 15-1** lists additional risk factors for birth defects.

Dietary changes have been shown to decrease ovulatory disorders and improve fertility. Vitamin D deficiency in men and women can be associated with infertility (Pludowski et al, 2013). For women, vitamin D deficiency may be associated with insulin resistance and metabolic syndrome in polycystic ovary syndrome (PCOS); for men it is associated with lower testosterone levels and lower sperm quality. However, in both cases, neither causality nor ability to treat has yet been demonstrated. Calcium has been shown to be important in males for spermatogenesis, sperm motility, hyperactivation, and acrosome (area of the sperm that contains digestive enzymes to break down the outer layers of the ovum) reactions. Healthier sperm counts are associated with optimal dietary zinc, folic acid, and antioxidants, as well as avoidance of tobacco and alcohol (Gaur et al, 2010). Recommendations for improved male fertility include eating a higher fiber, lower glycemic index (including high-fat dairy products and monounsaturated fats, but reducing trans fats) and lower animal protein diet, in addition to obtaining iron from plant sources, consuming a multivitamin daily, and being moderately physically active (Simon, 2014). Oxidative stress is associated with impaired spermatogenesis. However, the evidence for a supplementation

Sections of this chapter were written by Miriam Erick, MS, RDN, CDE, LDN for previous editions of this text.

BOX 15-1 Potential Risk Factors for Development of Birth Defects

Assisted reproductive technologies (ART)
 Genetic alterations
 Gene-environmental interactions, such as maternal smoking
 Hypoxia during pregnancy
 Infection during pregnancy (bacterial, parasitic, viral)
 In utero exposure to toxins or heavy metals (lawn chemicals, formaldehyde, endocrine disruptors, agricultural products, pesticides, carbon monoxide, radiation, mercury, lead)
 Maternal medical conditions (diabetes, hypothyroidism, phenylketonuria)
 Maternal medication or substance exposure (including but not restricted to isotretinoin, phenytoin, carbamazepine, triamterene, trimethoprim, warfarin, and radioactive iodine), illicit recreational substances, alcohol
 Nutrient deficits during early pregnancy (iodine, vitamin B₁₂, vitamin D, vitamin A, vitamin K, copper, zinc, folic acid, choline)
 Obesity
 Older mother or father

benefit appears weak and inconsistent. The optimal types and dosages of the specific antioxidants are not yet known, and individuals also may exhibit variable responses (Mora-Esteves and Shin, 2013). On the other hand, supplementation is not likely to be harmful, assuming it is at levels of the RDA or less. Whether supplements are as effective as a diet rich in antioxidants is unknown.

Preconceptional guidance is based on findings that many women enter pregnancy with suboptimal nutritional status, including obesity, and with low intakes of long-chain polyunsaturated fatty acids (LCPUFA), protein, zinc, iron, and choline (Monk et al, 2013). Although current public health recommendations primarily promote folic acid supplementation, many other nutrients are also important in the preconceptional period. Optimal intakes are associated with lower risk of growth restricted babies (low birth weight [LBW] or small-for-gestational age [SGA]) or preterm births (Ramakrishnan et al, 2012; see Table 15-1). Thus a preconceptional multivitamin-multimineral supplement may confer more benefit than single supplements for a pregnant woman, or **gravida**.

FOCUS ON

Omega-3 Fatty Acids in Pregnancy and Lactation

Our ancestors likely consumed a diet with equal amounts of omega-3 and omega-6 fatty acids. American diets currently are estimated to contain much higher levels of omega-6 than omega-3 fatty acids. This dramatic change in the ratio is thought to affect overall disease prevalence, as well as pregnancy outcome. However, there is no evidence that the absolute amounts of essential fatty acids provided by any culture are inadequate for the placenta, fetus, or infant growth (Lauritzen and Carlson, 2011).

Fatty acids are found in all cell membranes; the fetal brain contains equal amounts of omega-6 (arachidonic acid) and omega-3 (docosahexaenoic acid [DHA]). Arachidonic acid intake is seldom limited. The omega-3s, primarily eicosapentaenoic acid (EPA) and DHA, are important for fetal neurodevelopment, vasodilation, reduced inflammation, and thrombosis inhibition. Although EPA is thought to be beneficial, the separate effects have not yet been tested because purified EPA supplements are only recently available.

DHA is important for the growth and development of the fetal central nervous system and the retina. It is speculated that DHA may be helpful

TABLE 15-1 Examples of Nutrients Likely Important in the Periconceptual Period: Preconception Through Organogenesis

System or Function	Nutrients
Brain and nervous system	Iron, zinc, iodine, LCPUFA, vitamins A, B ₆ , B ₁₂ , folic acid, copper, protein, selenium
Placental function and structure	Iron, LCPUFA, vitamins E, C, B ₁₂ , zinc, selenium, copper, omega-3 PUFA, folate
Inflammation and immune function	Vitamins A, D, zinc, fatty acids
Oxidative stress	Vitamins C, E, B ₆ , B ₁₂ , folic acid
Embryogenesis	Vitamins A, B ₆ , B ₁₂ , folic acid, zinc

Adapted from Cetin I et al: Role of micronutrients in the periconceptual period, *Hum Reprod Update* 16:80, 2010; Monk C et al: Research review: maternal prenatal distress and poor nutrition—mutually influencing risk factors affecting infant neurocognitive development, *J Child Psychol Psychiatry* 54:115, 2013; Ramakrishnan U et al: Effect of women's nutrition before and during early pregnancy on maternal and infant outcomes: a systematic review, *Paediatr Perinat Epidemiol* 26:285, 2012.
 LCPUFA, Long chain polyunsaturated fatty acids; PUFA, polyunsaturated fatty acids.

Preconception educational programs for both parents are promoted, but evidence of benefit is inconsistent. However, it appears that nutrition interventions are more effective in promoting change than those targeting smoking and alcohol cessation (Temel et al, 2013).

Toxins

Screening women for alcohol, tobacco (including e-cigarettes), and recreational drug use is critical and also may be important for occupational toxin exposure. In vitro studies, using first trimester placental villous cells from terminated pregnancies transplanted to a nutrient medium, demonstrate poor placental growth and function, including lower taurine transport to the fetus, when the fetus is exposed to high amounts of alcohol in early pregnancy (Lui et al, 2014). Women may be at risk for entering pregnancy with toxic levels of mercury, and the types of fish eaten should be discussed. (see **Focus On: Omega-3 Fatty Acids in Pregnancy and Lactation**). The effect of maternal caffeine intake on infertility often is debated. No increased risk of miscarriage has been seen with caffeine consumption less than 200 mg/day, but data are conflicting for higher intakes (ACOG, 2010; see Appendix 39).

regarding birth weight and gestational length, as well as maternal depression, but the results of supplementation trials have been mixed (Carlson et al, 2013). There may be a slight benefit with supplementation on infant visual and neural development, as well as infant immune function and lowered risk of food allergy (Larqué et al, 2012).

There is selective and preferential transfer of DHA across the placenta (Lauritzen and Carlson, 2011). Fetal DHA accretion is highest in the last half of pregnancy, reaching 30 to 45 mg/day in the last trimester (Koletzko et al, 2007), primarily to the brain and adipose tissue, and in the first few months of life. DHA must be mobilized from maternal stores or the prenatal diet must include adequate amounts of preformed DHA. Transfer rates are highly variable and are lower among women with obesity, preeclampsia, hypertension, and diabetes (type 1, type 2, and GDM) (Lauritzen and Carlson, 2011). Women who smoke and have growth restricted fetuses also have lower transfer rates. It is thought that short interconceptional periods may cause a mother to enter a subsequent pregnancy depleted.

An average daily intake of 200 mg DHA during pregnancy and lactation currently is recommended (Koletzko et al, 2007), but studies are underway testing the benefit of larger amounts (Carlson et al, 2013). Current intakes are often far lower. Intakes of up to 1 g/day of DHA or 2.7 g/day of total omega-3 PUFAs appear safe (Koletzko et al, 2007). The main food source of DHA is fatty, cold-water fish, and a couple of meals per week of low-mercury fish during pregnancy appear to provide adequate amounts of DHA. Those fish that are low in methylmercury but high in DHA include salmon, sardines, trout, herring, anchovies, and mackerel (not King mackerel). Caviar and brains (do not use where prion contamination is of concern) are also particularly high in DHA. Others also may be used, depending on local availability and acceptability of safe sources.

Vegetable sources of omega-3 fats (alpha-linolenic acid [ALA]) include flaxseeds and nuts, especially walnuts, but the conversion rate to DHA is usually very low. Other options to increase the DHA content in the diet of pregnant and lactating women include the consumption of DHA fortified eggs, but other fortified foods contain very little DHA. Foods labeled as fortified with omega-3s likely contain ALA.

Any pregnant woman allergic to fish should seek an algal source of supplemental DHA. However, this contains only DHA. It is currently unknown if EPA or other components (e.g., other fatty acids, vitamin D, iodine, and selenium) are also important (Oken et al, 2013). Fish oil supplements contain EPA and DHA, although better long-term outcomes are seen with fish consumption than with supplements. In general, fish contain more DHA than EPA (although there is variability between species)

and fish oil supplements contain more EPA than DHA. (Kris-Etherton et al, 2009). Caution is advised, though, with the fish liver oils (such as cod liver oil) because of high preformed vitamin A levels.

The breastfed infant obtains DHA through maternal milk when the mother eats sufficient quantities of foods containing DHA. If the exclusively breastfeeding mother is not consuming fish or DHA supplements, a DHA supplement can be given to the infant. Most infant formulas are fortified with DHA.

There is no DRI for either EPA or DHA in the United States and the intake levels that provide benefit still have to be determined. The benefit of maternal supplementation has not been proven as of yet and there are potential epigenetic effects that must also be considered. Maternal fish consumption is associated with better child neurodevelopment, at least in observational studies subject to confounding. Perhaps supplementation is merited only for those women with very low intakes of LCPUFAs and/or for the premature infants who had insufficient time to accumulate enough.

Promoting a variety of safe seafood choices is preferable. Women have consumed less fish since the mercury advisories were issued (Oken et al, 2013); they should be reassured that fish can be eaten safely as a good protein source as long as care is taken in choosing and preparing the fish (see Box 15-9). If at least some of the high DHA sources are chosen, pregnancy outcomes, as well as infant neurodevelopment and visual acuity, may improve. In addition, if women eat these fish during pregnancy, they are also likely to continue eating them postpartum, improving the child's DHA accretion that continues after birth.

Exposure of men and women to environmental chemicals, including pesticides, heavy metals, and organic solvents, is associated with an increased time to pregnancy. However, most studies are plagued with important confounders (age, smoking, alcohol use, parity, use of contraceptives, underlying disease) and causality cannot be determined; it is also unknown whether men and women have different susceptibility to the effects of environmental toxins. The strongest evidence of adverse effect

is with pesticide and lead exposure. Pesticide exposure affects semen quality and increases risk of sterility (ACOG, 2013d; see Table 15-2).

A father's regular preconceptional smoking is associated with DNA damage to the sperm. Smoking also increases the risk that his child will have acute lymphoblastic leukemia, but the absolute risk is still very small, raising it from 27 per million births to 34 per million births (Van der Zee et al, 2013). Habitual alcohol

TABLE 15-2 Examples of Reproductive Health Effects of Prenatal Exposure to Environmental Contaminants

Chemicals	Exposure Sources and Pathways	Reproductive or Developmental Health Effects
Pesticides	Pesticides are applied in large quantities in agricultural, community, and household settings. In 2001, more than 1.2 billion pounds of active ingredients were used in the United States. Pesticides can be ingested, inhaled, and absorbed by the skin. The pathways of pesticide exposure include food, water, air, dust, and soil.	Impaired cognitive development Impaired neurodevelopment Impaired fetal growth Increased susceptibility to testicular cancer Childhood cancer
Solvents	Examples include benzene, toluene, xylene, styrene, 1-bromopropane, 2-bromopropane, perchloroethylene, and trichloroethylene. Solvents include some of the highest production volume chemicals in the United States. They are used in plastics, resins, nylon, synthetic fibers, rubber, lubricants, dyes, detergents, drugs, pesticides, glues, paints, paint thinners, fingernail polish, lacquers, detergents, printing and leather tanning processes, insulation, fiberglass, food containers, carpet backing, and cleaning products. Solvents are a component of cigarette smoke. Exposure is primarily through breathing contaminated air.	Fetal loss Miscarriage
Toluene	Exposure occurs from breathing contaminated air at the workplace, in automobile exhaust, some consumer products, paints, paint thinners, fingernail polish, lacquers, and adhesives.	Decreased fetal and birth weight Congenital malformations
Phthalates	Phthalates are synthetically derived. They are used in a variety of consumer goods, such as medical devices, cleaning and building materials, personal care products, cosmetics, pharmaceuticals, food processing, and toys. Exposure occurs through ingestion, inhalation, and dermal absorption.	Reduced masculine play in boys Reduced anogenital distance Shortened gestational age Impaired neurodevelopment in girls
Lead	Occupational exposure occurs in battery manufacturing and recycling, smelting, car repair, welding, soldering, firearm cleaning and shooting, and stained glass ornament and jewelry production. Nonoccupational exposure occurs in older homes where lead-based paints were used, water pipes, imported ceramics and pottery, herbal remedies, traditional cosmetics, hair dyes, contaminated soil, toys, and costume jewelry.	Alterations in genomic methylation Intellectual impairment Increased likelihood of allergies

Continued

TABLE 15-2 Examples of Reproductive Health Effects of Prenatal Exposure to Environmental Contaminants—cont'd

Chemicals	Exposure Sources and Pathways	Reproductive or Developmental Health Effects
Mercury	Mercury from coal-fired power plants is the largest man-made source of mercury pollution in the United States. Primary human exposure is by consumption of contaminated seafood.	Reduced cognitive performance Impaired neurodevelopment
Polychlorinated biphenyls	Polychlorinated biphenyls were used as industrial insulators and lubricants. They were banned in the 1970s but are persistent in the aquatic and terrestrial food chains, resulting in exposure by ingestion.	Development of attention deficit and hyperactivity disorder-associated behavior Increased body mass index Reduced IQ
Air pollutants	Common air pollutants include carbon monoxide, lead, ground-level ozone, particulate matter, nitrogen dioxide, and sulfur dioxide. Air pollution arises from a variety of sources, including motor vehicles, industrial production, energy (coal) production, wood burning, and small local sources, such as dry cleaners.	Low birth weight Birth defects
Cigarette smoke	Cigarette smoke exposure includes active smoking, passive smoking, or both.	Miscarriage Intrauterine growth restriction, low birth weight, and preterm delivery Decreased semen quality Altered thyroid function
Perchlorate	Perchlorate is used to produce rocket fuel, fireworks, flares, and explosives and also can be present in bleach and some fertilizers. Sources of exposure are contaminated drinking water, food, and other nonwater beverages. Infants also may be exposed through breast milk.	Reduced birth weight
Perfluorochemicals	Perfluorochemicals are widely used man-made organofluorine compounds with many diverse industrial and consumer product applications. Examples are perfluorooctane sulfonate and perfluorooctanate, which are used in cookware products with nonstick surfaces and in packaging to provide grease, oil, and water resistance to plates, food containers, bags, and wraps that come into contact with food. They persist in the environment. Occupational exposure and general population exposure occurs by inhalation, ingestion, and dermal contact.	Reduced birth weight
Polybrominated diphenyl ethers	These include flame retardant materials that persist and bioaccumulate in the environment. They are found in furniture, textiles, carpeting, electronics, and plastics that are mixed into but not bound to foam or plastic.	Impaired neurodevelopment Premature delivery, low birth weight, and stillbirth
Bisphenol A	Bisphenol A is a chemical intermediate for polycarbonate plastic and resins. It is found in food, consumer products, and packaging. Exposure occurs through inhalation, ingestion, and dermal absorption	Recurrent miscarriage Aggression and hyperactivity in female children
Formaldehyde	Formaldehyde is used in the production of wood adhesives, abrasive materials, and other industrial products and in clinical laboratories and embalming. It is found in some germicides, fungicides, insecticides, and personal care products. Routes of exposure are oral, dermal, and inhaled.	Spontaneous abortion Low birth weight
Antineoplastic drugs	This class of chemotherapy drugs presents an occupational exposure for nurses and other health care professionals.	Spontaneous abortion Low birth weight
Anesthetic gases	Anesthetic gases are administered by inhalation in health care settings and veterinary care. Occupational exposure is a risk for nurses, physicians, dentists, veterinarians and, other health care professionals who work in settings where anesthetic gases are used.	Congenital anomalies Spontaneous abortion
Ethylene oxide	Ethylene oxide is used to sterilize heat-sensitive medical items, surgical instruments, and other objects that come into contact with biologic tissues. Occupational exposure is a risk in some health care settings, particularly sterilization units. Exposure is through inhalation.	Spontaneous abortion and pregnancy loss Preterm and postterm birth

Reprinted, WITH PERMISSION, from American College of Obstetricians and Gynecologists: Exposure to toxic environmental agents, companion document. Accessed 12/23/13 at <http://www.acog.org/~media/Committee%20Opinions/Committee%20on%20Health%20Care%20for%20Underserved%20Women/ExposuretoToxic.pdf>, 2013d.

consumption may be associated with reduced semen quality and changes in testosterone and sex hormone-binding globulin levels. Although higher intakes are of more concern, even five drinks per week have been associated with a reduced sperm count and concentration, as well as a reduction in the percentage of spermatozoa with normal morphology (Jensen, 2014).

Obesity and Endocrine Conditions

Preconceptional obesity raises risk for men and women. In men, elevated BMI is associated with lower success with in

vitro fertilization (IVF). Maternal prepregnant obesity is correlated with lower rates of conception, higher rates of congenital anomalies, and lower live birth rates (Merhi et al, 2013). Obesity affects ovulation, oocyte development, embryo development, endometrial development, implantation, and pregnancy loss. Those with known diabetes and hypothyroidism, as well as hypertension, should be in good control before conception. Although weight loss improves fertility for women, it has less effect on fertility in men (see *Focus On: Special Case of Obesity*).

FOCUS ON

Special Case of Obesity

The rates of obesity have increased dramatically in industrialized and, to a lesser extent, in developing countries (see Chapter 21).

Among women with obesity, rates of conception are lower and **congenital anomalies** (neural tube defects [NTDs], cardiovascular anomalies, oral clefts, anorectal atresia, hydrocephaly, limb reductions) occur more frequently and are detected less often prenatally than in the general population. Rates of NTDs increase with the degree of obesity; for severely obese women, rates are more than triple that for women with normal weight. Supplementation with folic acid is not as protective for these women, but the benefit of supplementing with more than 400 mcg folic acid/day has not been studied (Tenenbaum-Gavish and Hod, 2013).

During pregnancy, women with obesity have an exaggerated response to the normal physiologic changes. Genetic, hormonal, and biochemical environments are altered, influencing fetal growth and organ development. Women who enter pregnancy with a BMI greater than 30 have a higher risk of spontaneous abortion (SAB, i.e., miscarriage), **intrauterine fetal demise (IUFD)** or stillbirth, and increased risk of gestational diabetes, hypertension, or preeclampsia (ACOG, 2013a; Tenenbaum-Gavish and Hod, 2013), with the risk of many complications increasing linearly (Nelson et al, 2010). Normal fetal growth patterns are disrupted. Risk is increased for macrosomia, birth injury (shoulder dystocia, brachial plexus injury, fetal hypoxia), and childhood obesity, but there are also significant rates of growth restricted babies and preterm deliveries. These women are more likely to have intrapartum, operative, and postoperative complications, and their infants are more likely to require admission to the NICU. Women with obesity are also less likely to initiate and sustain breastfeeding.

Although excessive gestational weight gain is common among overweight or obese women and this weight gain is associated with similar

increased risks, the prepregnant BMI is the more important factor. Weight loss before pregnancy is recommended (Tenenbaum-Gavish and Hod, 2013), and women who have undergone bariatric surgery are less likely to develop gestational diabetes, hypertension, preeclampsia, or to have a macrosomic infant.

How maternal obesity mediates poor maternal and fetal outcomes is not clear (Tenenbaum-Gavish and Hod, 2013). There are likely genetic and fetal-maternal interactions. It was thought that exposure to hyperglycemia was the main predictor, but it is now recognized that other factors are also important, including hypertriglyceridemia, insulin and insulin resistance, androgens, leptin, and increased blood pressure. Obesity, with low levels of adiponectin, is associated with increased fetal growth. The normal two-fold to threefold increases in serum cholesterol and free fatty acid levels during pregnancy are exaggerated in obese women. Triglycerides do not pass through the placenta easily, but there is increased placental transfer of metabolites and an increase in fetal fat deposits with obesity. Altered placental development or function, leading to increased amino acid transfer, contributes to a fetal hyperinsulinemic state. In addition, obesity is associated with tissue-specific changes in mitochondrial function and elevated oxidative stress. High lipid levels also may cause epigenetic changes in lipid sensing and metabolism genes. Obesity may also alter the regulation of appetite, satiety, and adipocyte maturation of the fetus.

These babies born to obese mothers also have permanently altered body weight-regulating mechanisms and there are changes in the hypothalamus, pancreatic islet cells, and adipose tissue (Tenenbaum-Gavish and Hod, 2013). They are more likely to have obesity, hypertension, and diabetes as adults. They also have increased rates of neurodevelopmental disorders and autism spectrum disorders if exposed to diabetes, hypertension, and obesity in utero.

Polycystic ovary syndrome (PCOS) affects up to 10% of women of reproductive age (Usadi and Legro, 2012). These ovarian cysts alter the testosterone-estrogen balance, resulting in insulin resistance and infertility. Recent recommendations suggest that 5% to 10% weight loss is preferred to the use of metformin for ovulation induction in patients with PCOS (Usadi and Legro, 2012; see Chapter 31).

A healthy diet and exercise program helps parents prepare for an optimal pregnancy outcome, with the goal of achieving normal weight before conception. However, although preconceptional intervention is recommended, it is seldom achieved because half of pregnancies in the United States are unplanned. In addition, advances in **assisted reproductive technology (ART)** mean that “parents” may be egg or sperm donors or surrogate mothers. The preconceptional health of these “parents” is likely also important but the impact is unknown.

CONCEPTION

Conception involves a complex series of endocrine events in which a healthy sperm fertilizes a healthy ovum (egg) within 24 hours of ovulation. Conception does not guarantee successful pregnancy outcome, and it is estimated that 41% to 70% fail, depending on the timing and sensitivity of the pregnancy test (Kwak-Kim et al, 2010).

The Carnegie Stages are a system used to describe predictable embryonic changes and developmental milestones. As noted in Table 15-3, as well as in Table 15-1 and Box 15-1, optimal conditions, including the absence of hostile factors and optimal status of many nutrients, are thought to be critical preconceptionally and during organogenesis.

PREGNANCY

Physiologic Changes of Pregnancy

Blood Volume and Composition

Blood volume expands by nearly 50% by the end of pregnancy, with wide variability among women. This increased blood volume results in decreased levels of hemoglobin, serum albumin, other serum proteins, and water-soluble vitamins, primarily after the end of the first trimester. In contrast, serum concentrations of fat-soluble vitamins and other lipid fractions such as triglycerides, cholesterol, and free fatty acids increase to ensure sufficient transport to the fetus. A compilation of laboratory values by trimester is available, and selected values are listed in Table 15-4. However, wide individual variability makes determination of an inadequate intake or a deficient nutrient state difficult. Normal hematocrit and hemoglobin values change by trimester and cutpoints increase with altitude and smoking status, as shown in Table 15-5 (CDC, 1998).

Cardiovascular and Pulmonary Function

Increased cardiac output accompanies pregnancy, and cardiac size increases by 12%. Blood pressure, primarily diastolic, decreases during the first two trimesters because of peripheral vasodilation but may return to prepregnancy values in the third trimester. Mild lower extremity edema is a normal condition of pregnancy resulting from the pressure of the expanding uterus on the inferior vena cava.

Maternal oxygen requirements increase and the threshold for carbon dioxide lowers, making the pregnant woman feel dyspneic. Adding to this feeling of dyspnea is the growing uterus pushing the diaphragm upward. Compensation results from more efficient pulmonary gas exchange and larger chest diameter.

TABLE 15-3 The Carnegie Stages of Human Gestation Through 16 Weeks Postovulation

Carnegie Stage (time postovulation)	Structure Size	Highlighted Developmental Events with Selected Potential Nutrient Implications
Stage 1 Fertilization (1 day)	0.1-0.15 millimeters (mm); smaller than the size of a pencil point	Fertilization begins when the sperm penetrates the oocyte. This requires the sperm, which can survive up to 48 hours, to travel 10 hours up the female reproductive track. Then the sperm must successfully penetrate the zona pellucida, a tough membrane surrounding the egg, a process that takes approximately 20 minutes. Once the fertilization is successful, the structure now becomes a zygote. This is the end of the fertilization process. Optimal amounts of folate are needed for cell division and formation of DNA.
Stage 2 First Cell Division (1.5-3 days)	0.1-0.2 mm	Zygote begins to divide. Division begins to occur approximately every 20 hours. When cell division generates a mass of approximately 16 cells, the zygote now becomes a morula, a mulberry shaped structure. The newly created morula leaves the fallopian tube and enters the uterine cavity 3-4 days after fertilization.
Stage 3 Early Blastocyst (4 days)	0.1-0.2 mm	The morula enters the uterus and cell division continues. A cavity (hole), known as a blastocele, forms in the middle of the morula. Cells are flattening and compacting inside this cavity. The zona pellucida remains the same size as it was after fertilization, with the cavity in the center. The entire structure is now called a blastocyst. Two cell types are forming: embryoblasts, on the inside of the blastocele, and trophoblasts, on the outside portion of the blastocele.
Stage 4 Implantation Begins (5-6 days)	0.1-0.2 mm	Pressure from the blastocele expanding in the middle of the blastocyst against the rigid wall of the zona pellucida creates a "hatching" of the blastocyst from this zona pellucida. Separation of the embryoblasts and trophoblasts is complete. The outer layer of trophoblast cells secretes an enzyme that erodes the epithelial lining of the uterus so the blastocyst can implant. Trophoblast cells also secrete hCG, which stimulates the corpus luteum (the yellow glandular mass in the ovary formed by an ovarian follicle that has matured and discharged its ovum) to continue progesterone production, important in maintaining the blood-rich uterine lining. Progesterone is also later produced by the placenta. Five days is the latest that an IVF embryo would be transferred.
Stage 5 Implantation Complete (7-12 days)	0.1-0.2 mm	Consider vitamin D. Trophoblast cells continue to destroy cells of the uterine lining, creating blood pools and stimulating new capillaries to grow. This begins the growth of the placenta. The blastocyst inner cell mass differentiates into the epiblast (top layer of cells, becoming the embryo and the amniotic cavity) and the hypoblast (lower layer of cells, becoming the yolk sac). Ectopic pregnancies are those that do not implant in the uterus at this time, eventually becoming a life-threatening problem.
Stage 6 Primitive Streak (13 days)	0.2 mm	Placental formation: Chorionic villi "fingers" form, anchoring the embryo to the uterus. Blood vessels begin appearing. Stalk formation: The embryo is attached to the developing placenta by a stalk, which later becomes part of the umbilical cord. Gastrulation: A narrow line of cells, called the <i>primitive streak</i> , appears on the surface of the two-layered embryonic disc. Cells migrate in, with bilateral symmetry, from the outer edges of the disc to the primitive streak and begin to form 3 layers: the ectoderm (top layer of the embryonic disc that will later form skin, hair, lenses of the eye, lining of the internal and external ear, nose, sinuses, mouth, anus, tooth enamel, pituitary and mammary glands, and all parts of the nervous system), the mesoderm (middle cell layer that will later form muscles, bones, lymphatic tissue, spleen, blood cells, heart, lungs, reproductive, and excretory systems), and the endoderm (inner cell layer that will later form the lining of the lungs, the tongue, tonsils, urethra and associated glands, the bladder, and the digestive tract).
Stage 7 Neurulation (16 days)	0.4 mm	Consider vitamins A, E, C, copper, and DHA. Gastrulation continues, forming the three-layered embryonic disc. Neural crest cells originate at the top of the neural tube and migrate extensively throughout the embryo, differentiating into many cell types, including neurons, glial cells, pigmented cells of the epidermis, epinephrine-producing cells of the adrenal glands, and various skeletal and connective tissues of the head. Fetal alcohol syndrome results from disruption of the migration of neural crest cells.
Stage 8 (17-19 days)	1-1.5 mm	Consider vitamins A, E, folic acid, choline, zinc, selenium, DHA, and antioxidants. The embryonic area is now shaped like a pear, with the head region broader than the tail. The ectoderm has thickened to form the neural plate. The edges rise, forming the concave neural groove. This groove is the precursor of the embryo's nervous system, one of the first organs to develop. Blood cells are already developed and begin to form channels alongside the epithelial cells that are also forming. <i>Sonic hedgehog (Shh)</i> is one of three genes that are now secreted from the notochord (rod-shaped body composed of mesoderm cells). These genes encode for signaling molecules involved in patterning processes during embryogenesis, including the development of cerebral neurons, the separation of the single eye field into two bilateral fields, hair growth, and limb development. A repression of Shh by the notochord initiates pancreatic development. Consider vitamin B₁₂, omega-3 fatty acids, folate, and choline.

TABLE 15-3 The Carnegie Stages of Human Gestation Through 16 Weeks Postovulation—cont'd

Carnegie Stage (time postovulation)	Structure Size	Highlighted Developmental Events with Selected Potential Nutrient Implications
Stage 9 Appearance of Somites (19-21 days)	1.5-2.5 mm	Embryo looks like a peanut with a larger head end compared with the tail end. One to three pairs of somites (mesoderm tissue that looks like “bumps”) are now present, with every ridge, bump, and recess indicating cellular differentiation. The head fold rises on either side of the primitive streak. Endocardial (muscle) cells begin to fuse and form into the early embryo’s two heart tubes. Secondary blood vessels now appear in the chorion/placenta. Hematopoietic cells (forming blood cells) and endothelial cells (forming blood vessels) appear on the yolk sac simultaneously. Consider folic acid, copper, and iron.
Stage 10 (21-23 days)	1.5-3.0 mm	At this time, the embryo looks like an old fashioned key-hole with a big oval top, with an ear of corn in the bottom two thirds of the structure. Rapid cell growth elongates the embryo and expands the yolk sac. By the end of this stage, 4-12 somite pairs can exist. Cells that will become the eyes and ears appear. Neural folds begin to rise and fuse, “zippering” the neural tube closed. Failure of this closure results in a neural tube defect, including anencephaly and spina bifida, which varies in severity depending on location and extent of the area left open. The two endocardial tubes fuse into one. This heart tube takes on an S-shaped form and cardiac muscle contraction begins. Consider folate, B₆, B₁₂, choline, vitamin A, zinc, and methionine.
Stage 11 (23-25 days)	2.5-3.0 mm	Embryo has a modified S-curve shape with a bulb-like tail and a stalk connecting to the developing placenta. Somites increase to 20 pairs, at which point the forebrain is completely closed. The primitive tubal heart is beating and peristalsis begins. Consider Vitamin A.
Stage 12 (25-27 days)	3-5 mm	Embryo now has a C-shape. Brain and spinal cord are the largest tissue in the embryo. Face is becoming apparent, eyes and ears are beginning to form. Heart valves and septa may become apparent. Blood system is developing. Blood cells follow the surface of the yolk sac (where they originated), then move along the central nervous system to the chorionic villi, part of the maternal blood system. Liver cells are beginning to form, before the rest of the digestive system. Upper limb buds appear. Consider vitamin A, folic acid, choline, methionine, and zinc.
Stage 13 (26-30 days)	4-6 mm; size of the head of a pencil eraser	More than 30 somite pairs are now evident, precursors of multiple organ systems. First thin surface layer of skin appears to cover the embryo. Back muscles and ribs begin to form. The digestive epithelium layer begins to differentiate, eventually developing into the liver, lung, stomach, and pancreas.
Stage 14 (31-35 days)	5-7 mm	Brain and head are growing rapidly, sections of the brain and spinal cord wall are becoming differentiated. The eye is developing and the nasal plate can be detected. The adenohypophyseal pouch, later developing into the anterior pituitary, is defined. The esophagus is forming and lung sacs appear. Ureteric buds and the metanephros, later developing into the kidney, appear. Upper limbs elongate and innervation begins. Consider LCPUFA (especially DHA and AA), protein, zinc, iron, choline, copper, iodine, vitamin A, and folate.
Stage 15 (35-38 days)	7-9 mm	Brain is still larger than the trunk. Maxillary and mandibular arches are more prominent. The stomodeum, the depression in the ectoderm that will develop into the mouth and oral cavity, appears. Retinal pigment may appear in the optic cup. Symmetric and separate nasal pits appear as depressions in the nasal disc. Future cerebral hemispheres are distinct. Blood flowing through the atrioventricular canal is now divided into left and right streams. Handplate, forearm, arm, and shoulder may now be discerned in the upper limb bud. Lower limb bud begins to develop and innervation begins.
Stage 16 (37-42 days)	9-11 mm	Hindbrain, responsible for heart regulation, breathing, and muscle movements, begins to develop. Future lower jaw is now visible. Nasal pits rotate to face ventrally as head widens. Cardiac tube begins to develop. Mammary gland tissue begins to mature. Mesentery, the tissue that attaches the intestines to the rear abdominal wall and supplies them with blood, nerves, and lymphatics, is now defined. Hands begin to develop. Thigh, leg, and foot areas can now be distinguished. Consider vitamin A.
Stage 17 (42-44 days)	10-13 mm	Jaw and facial muscles are developing. The nasofrontal groove becomes distinct. An olfactory bulb (sense of smell) forms in the brain. Teeth buds (without a clear cell arrangement) begin to form. Heart separates into four distinct chambers. The diaphragm forms and the pituitary gland, trachea, larynx, and bronchi begin to form. Intestines begin to develop within the umbilical cord, later migrating to the abdomen when there is space. Primitive germ cells arrive at the genital area, responding to genetic instructions on whether they develop into female or male genitals. Digital rays are apparent on feet and hands. Consider vitamin K.

Continued

TABLE 15-3 The Carnegie Stages of Human Gestation Through 16 Weeks Postovulation—cont'd

Carnegie Stage (time postovulation)	Structure Size	Highlighted Developmental Events with Selected Potential Nutrient Implications
Stage 18 (44-48 days)	11-14 mm	Body appears more like a cube. Eyelids begin to develop, eyes are pigmented. Nipples appear on the chest. Kidneys begin to produce urine. Ossification of the skeleton begins. Consider calcium, phosphorus, magnesium, vitamins A, D, and K. See Box 15-2.
Stage 19 (48-51 days)	13-18 mm	Semicircular canals are forming in the inner ear, enabling a sense of balance and body position. Gonads are forming. Knee and ankle locations are now apparent, joints are more distinct. Toes are nearly completely notched and toenails begin to appear. Bone cartilage begins to form a more solid structure. Muscles develop and strengthen.
Stage 20 (51-53 days)	15-20 mm	Spontaneous movement begins. Nose is fully formed. Anal membrane is perforated. Testes or ovaries, as well as toes, are distinguishable.
Stage 21 (53-54 days)	17-22 mm	Eyes are well developed but have not yet migrated forward from the side of the head. External ears have not yet migrated up. Tongue is developing. Intestines begin to recede into the abdominal cavity. Failure to recede may result in either <i>gastrochisis</i> or <i>omphalocele</i> .
Stage 22 (54-56 days)	19-24 mm	Development of multiple organs continues. Upper lip now fully formed. The brain can signal muscle movement. Limbs begin to ossify (replacing cartilage with bone), starting in the upper limbs. Consider the bone nutrients. See Box 15-2.
Stage 23 Embryonic Period Ends (56-60 days)	23-26 mm	Head is erect and round. External ear is completely developed. Retina is fully pigmented. Eyelids begin to unite and are half closed. Taste buds begin to form. Bones of the palate begin to fuse. Primary teeth are at cap state (cells are now arranged and look like a cap). Upper and lower limbs are well formed; fingers and toes no longer webbed. Intestines continue to migrate from the umbilical cord into the body cavity. Layers of rather flattened cells (precursors to the surface layer of skin) replace the thin ectoderm. Consider vitamins A, D, and K, calcium, phosphorus, magnesium, protein, and omega-3 fatty acids.
(61-68 days, approximately 10 weeks)	31-42 mm	Basic brain structure is complete and the brain mass is rapidly growing. Sockets for all 20 teeth are formed in the gum line. Face has human appearance. Vocal cords form and the fetus can make sounds. Fetus develops reflexes. Digestive track muscles can function and practice contraction. Nutrient-extracting villi line the folded intestines. The liver begins to secrete bile (thick, brown-green liquid containing bile salts, bile pigments, cholesterol, and inorganic salts), which is stored in the gallbladder. The thyroid and pancreas are fully developed. The pancreas produces insulin. Genitalia are not yet fully formed. Fingernails begin growing. Skin is very sensitive. Consider folate, omega-3 fatty acids, vitamins D, A, choline, Bs, protein, zinc, iron, copper, and iodine.
(12 weeks)	Length: crown-rump length 61 mm (almost 2.5 inches) Weight: 8-14 g (0.3-0.5 oz)	Fetus begins to move around as muscle and nervous systems continue to develop. Heartbeat can be detected. Sucking muscles develop, salivary glands begin to function. Sweat glands and body hair begin to grow. Scalp hair pattern is discernible. Fetus inhales and exhales amniotic fluid, essential for the development of the air sacs in the lungs. Spleen is fully functional, removing old red blood cells and producing antibodies.
(Approximately 14 Weeks)	Length: 80-104 mm (3.2-4.1 inches) Weight: 25 g (almost 1 oz)	Bones continue to form, muscles strengthen. Eyes face more forward and ears are near their final position. Torso is growing rapidly, increasing its proportion to the head. Limbs are well developed. Toenails begin to grow. Heart pumps 25 quarts of blood/day (by the time of delivery it will be 300 quarts/d). Breathing, swallowing, and sucking are all becoming more developed. Consider vitamin A, protein, and the bone nutrients. See Box 15-2.
(16 weeks)	Length: 109-117 mm (4.3-4.6 inches) Weight: 80 g (approximately 2.8 oz)	The placenta is now the size of the fetus. The umbilical cord system grows and thickens, with the blood providing nourishment to the fetus through considerable force. 7.5 oz (250 ml) of amniotic fluid surround the conceptus. Eyes and ears are in correct positions. Fetus can blink, ears stand out from head. Fingerprints and toe prints develop. Circulation is completely functional. Meconium, the product of cell loss, digestive secretions, and swallowed amniotic fluid, begins to accumulate in the intestines. Nerves are being coated with myelin, a fatty substance that speeds nerve cell transmission and insulates them for uninterrupted impulses. Consider omega-3 fatty acids, iron, vitamin A, and cholesterol.

AA, Arachidonic acid; DNA, deoxyribonucleic acid; hCG, human chorionic gonadotropin; LCPUFA, long chain polyunsaturated fatty acids, DHA, docosahexaenoic acid.

TABLE 15-4 Selected Reference Ranges for Nutrient Levels in Nonpregnant and Pregnant Women, by Trimester

Component	Nonpregnant Adult	First Trimester	Second Trimester	Third Trimester
Albumin, g/dl	4.1-5.3	3.1-5.1	2.6-4.5	2.3-4.2
Protein, total, g/dl	6.7-8.6	6.2-7.6	5.7-6.9	5.6-6.7
Cholesterol, total, mg/dl	< 200	141-210	176-299	219-349
Triglycerides, mg/dl	< 150	40-159	75-382	131-453
Vitamin A (retinol), mcg/dl	20-100	32-47	35-44	29-42
Vitamin B ₁₂ , pg/ml	279-966	118-438	130-656	99-526
Vitamin C, mg/dl	0.4-1.0	Not reported	Not reported	0.9-1.3
Vitamin D, 25 hydroxy, ng/ml	14-80	18-27	10-22	10-18
Vitamin E, mcg/ml	5-18	7-13	10-16	13-23
Folate, red blood cell, ng/ml	150-450	137-589	94-828	109-663
Calcium, total, mg/dl	8.7-10.2	8.8-10.6	8.2-9.0	8.2-9.7
Copper, mcg/dl	70-140	112-199	165-221	130-240
Ferritin, ng/ml	10-150	6-130	2-230	0-116
Hemoglobin, g/dl	12-15.8	11.6-13.9	9.7-14.8	9.5-15.0
Hematocrit, %	35.4-44.4	31.0-41.0	30.0-39.0	28.0-40.0
Magnesium, mg/dl	1.5-2.3	1.6-2.2	1.5-2.2	1.1-2.2
Selenium, mcg/L	63-160	116-146	75-145	71-133
Zinc, mcg/dl	75-120	57-88	51-80	50-77

Gastrointestinal Function

During pregnancy the function of the gastrointestinal (GI) tract changes in several ways that affect nutritional status. Gums may bleed more easily because of increased blood flow. In the first trimester nausea and vomiting may occur, followed by a return of appetite that may be ravenous (see [Nausea and Vomiting, Hyperemesis Gravidarum, and Ptyalism](#)). Cravings for and aversions to foods are common (see [Cravings, Aversions, and Pica](#)). Increased progesterone concentration relaxes the uterine muscle to allow for fetal growth while also decreasing GI motility with

BOX 15-2 Bone Nutrients

Protein

Forms organic matrix, for collagen, production of hormones, growth factors

Minerals

Boron: Considered to have minor role in bone function

Calcium: Main bone-forming mineral; 99% in skeleton

Copper: Functions in lysyl oxidase, an enzyme essential for cross-linking of collagen fibrils

Fluoride: Can replace hydroxyl groups in hydroxyapatite to form less soluble fluoroapatite

Iron: Cofactor in enzyme involved in collagen bone matrix synthesis, cofactor in 25-hydroxycholecalciferol hydroxylase

Magnesium: 60% of this mineral is in bone; it has an indirect role in ATP metabolism

Manganese: For biosynthesis of mucopolysaccharides in bone matrix, cofactor for several enzymes in bone tissue

Phosphorus: Essential bone-forming mineral

Zinc: For osteoblastic activity, collagen synthesis, alkaline phosphatase activity

Fat-Soluble Vitamins

Vitamin A: Essential in bone remodeling process: osteoblasts and osteoclasts have receptors for retinoic acid

Vitamin D: Maintains calcium levels

Vitamin K: Cofactor for gamma carboxylation of glutamic acid residues, including osteocalcin, the noncollagenous protein of bone

Water-Soluble Vitamins

Folic acid: Coenzyme mediating variety of reactions critical to nucleic and amino acid metabolism critical to bone development

Riboflavin: Needed to convert vitamin B₆ and folate into active forms

Vitamin B₆: Essential cofactor for enzyme ornithine decarboxylase; osteoblast NADPH concentrations, essential for Vitamin K

Vitamin B₁₂: Osteoblast function; cofactor for osteoblast-related proteins (bone alkaline phosphatase and osteocalcin); iron metabolism

Vitamin C: Hydroxylation of lysine, proline; linking of collagen fibril; stimulates alkaline phosphatase for osteoblast formation

ATP, Adenosine triphosphate; NADPH, nicotinamide adenine dinucleotide phosphate.

Adapted from Palacios C: The role of nutrients in bone health, from A to Z, *Crit Rev Food Sci Nutr* 46:621, 2006.

increased reabsorption of water. This often results in constipation. In addition, a relaxed lower esophageal sphincter and pressure on the stomach from the growing uterus can cause regurgitation and gastric reflux (see [Heartburn](#)).

Gallbladder emptying becomes less efficient because of the effect of progesterone on muscle contractility. Constipation, dehydration, and a low-calorie diet are risk factors for gallstone development. During the second and third trimesters, the volume of the gallbladder doubles and its ability to empty efficiently is reduced. Bile composition also changes, becoming more sludge-like, increasing the intrinsic risk of gallstones.

Metabolic Responses

The metabolism of macronutrients changes during pregnancy. This response varies between normal weight women and obese women (see [Table 15-6](#)).

Renal Function

The glomerular filtration rate (GFR) increases by 50% during pregnancy, although the volume of urine excreted each day is not increased. Renal plasma flow increases because of the increased GFR with lower serum creatinine and blood urea nitrogen concentrations. Renal tubular reabsorption is less efficient than in the nonpregnant state, and glucosuria, because of increased GFR, may occur, along with increased excretion of water-soluble vitamins and amino acids. Small amounts of glucosuria increase the risk for urinary tract infections.

Placenta and Uterine Environment

The fetus is not provided nutrients and oxygen through the placenta until after blood flow is established through the umbilical cord, around 10 weeks' gestation. Before that, nourishment is

through the endometrium and uterine gland secretions, the contents of which are poorly understood ([Bloomfield, 2011](#)).

The placenta produces several hormones responsible for regulating fetal growth and the development of maternal support tissues. It is the conduit for exchange of nutrients, oxygen, and waste products. Placental insults compromise the ability to nourish the fetus, regardless of how well nourished the mother is. These insults can be the result of poor placentation from early pregnancy or small infarcts associated with preeclampsia or other hypertensive disorders.

A small placenta has a smaller surface area of placental villi, with a reduced functional capacity, often resulting in [intrauterine growth restriction \(IUGR\)](#). However, the placenta also has the ability to respond to a poor environment. For example, women affected by the World War II Dutch famine in their first trimesters had larger placentas, resulting in normal weight infants ([Belkacemi et al, 2010](#)). Although the efficiency of the placenta to support fetal growth varies, exhibiting morphologic and functional adaptations with varying environmental conditions, the fetus is also more than just a passive recipient of nutrients from the placenta ([Fowden et al, 2009](#)). Fetal and maternal endocrine changes signal nutrient availability and match the rate of fetal growth to the nutrient supply.

A less-than-optimal environment in utero can lead to a mismatch between available nutrients and the genetically determined fetal drive for growth. The goal is to support a healthy environment through a proper balance of nutrients and the avoidance of teratogens (see [Clinical Insight: High-Risk Pregnancies with Nutritional Components](#)).

CLINICAL INSIGHT

High-Risk Pregnancies with Nutritional Components

Approximately 10% of all pregnancies are considered "high risk," meaning there is a maternal preexisting complication or a situation that antedates pregnancy or presents in the current gestation that puts the mother or the fetus at risk for a poor outcome. Many of these may include nutritional concerns as well. Women who present with the following issues need increased medical surveillance and nutrition assessment to ensure the most favorable outcomes, controlled medical costs, and the fewest complications.

- Anemias: microcytic or macrocytic
- Cardiovascular issues: maternal cardiac structural defects, preexisting cardiovascular disease
- Endocrine issues: polycystic ovary syndrome, thyroid disease, gestational diabetes, type 1 or 2 diabetes
- Functional alterations: deafness, blindness, paralysis, paraplegia, quadriplegia
- Gastrointestinal issues: food allergies, celiac disease, Crohn's disease, ulcerative colitis, postbariatric surgery, gallstones
- Hyperemesis gravidarum
- Hypertension: preexisting, pregnancy-induced, preeclampsia
- Infections: HIV and AIDS, malaria, dental disease, intestinal parasites
- Maternal genetic diseases or mental retardation
- Medical problems: lupus, myasthenia gravis, cystic fibrosis, pancreatitis, phenylketonuria, cancer, sickle cell disease
- Multiple fetuses
- Obesity: BMI ≥ 30
- Pica
- Psychiatric: eating disorders, depression, bipolar disorders, Munchausen syndrome, suicidal ideation, substance abuse
- Respiratory issues: asthma, tuberculosis, adult respiratory distress disorder
- Surgeries: cancers, gallbladder, appendectomy, trauma
- Young age - teenagers

TABLE 15-6 Metabolic Changes During Pregnancy for Women of Normal Weight and Obese

Component	Normal Weight	Obese
Fat deposition with gestational weight gain	Gestational fat gain is primarily accumulated centrally, both subcutaneous and visceral fat. Visceral accumulation may increase as pregnancy progresses.	Locations are similar, amount may be less
Lipid metabolism	50% to 80% increase in basal fat oxidation and in response to glucose, marked hyperlipidemia	Hyperlipidemia is exaggerated
Amino acid metabolism	Protein synthesis increases in the second (15%) and third (25%) trimesters	Unknown, but limited evidence suggests anabolic response may be impaired
Glucose metabolism, insulin resistance	Improved fasting glucose levels, glucose tolerance and insulin sensitivity in early pregnancy, then insulin sensitivity decreases 50% to 70% by third trimester	Early fasting glucose improves less if at all, more insulin resistance, which increases serum levels of all macronutrients

Adapted from Nelson SM et al: Maternal metabolism and obesity: modifiable determinants of pregnancy outcome, *Human Reprod Update* 16:255, 2010.

AIDS, Acquired immune deficiency syndrome; HIV, human immunodeficiency virus.

All nutrients are thought to be important, although some are better studied than others. Table 15-1 lists some potential functions, however, in reality more complex interactions involving multiple functions, are likely. For example, multiple nutrients are involved in the creation of bone (see Box 15-2) and brain (see Table 15-7). When either macro- or micronutrients are lacking, the timing of the deficit is important in predicting the impact of that insult (Monk et al, 2013; Wu et al, 2012a).

Effects of Nutritional Status on Pregnancy Outcome

Fetal Growth and Development

In the early 1900s U.S. women with poor nutritional status had adverse pregnancy outcomes with hemorrhage at delivery, prolonged labor, and LBW infants, conditions still of concern today in many developing countries. During World War II, the effects of severe food deprivation on previously

well-nourished Dutch populations were explored. Higher rates of miscarriage (spontaneous abortion, “SAB”), stillbirths, neonatal deaths, and congenital malformations were noted in offspring born to women who conceived during the famine; surviving infants were smaller if exposed to famine late in gestation (Roseboom et al, 2011). Similar findings have been found in other countries as well. In addition, individuals may be at higher risk of undernutrition because of preexisting medical conditions or because of either physical or cultural limitations on food availability.

Even if a mother is not starving, the developing fetus may be unable to obtain optimal nutrients from a host who is compromised nutritionally, resulting in growth restriction. The causes of IUGR are many and include maternal, fetal, and placental factors (see Box 15-3). Infants born LBW (<2500 g) and especially very low birth weight (<1500 g) are at higher risk for **perinatal mortality** (infant death occurring

TABLE 15-7 Key Nutrients for Fetal and Neonatal Brain Development

Nutrient	Function in Brain Development	Negative Effect of Deficiency
Long-chain polyunsaturated fatty acids, primarily DHA and AA	Cell membrane formation, myelin, synaptosomes, intracellular communication, signal transduction	Neurodevelopment, visual development
Protein	Neuronal and glial structural proteins, synaptic structures and numbers, neurotransmitter peptide production, especially in cerebellum, hippocampus, and cerebral cortex	Overall central nervous system growth, neurodevelopment
Zinc	Cofactor in enzymes mediating protein and nucleic biochemistry, growth, gene expression, neurotransmitters, especially affecting cerebellum, limbic system, cerebral cortex, temporal lobe, frontal lobe	Attention, motor development delays, short-term memory, brain growth
Iron	Myelination, dendritogenesis, synaptogenesis, neurotransmission, especially in the hippocampus, striatum, frontal cortex	Global intelligence, general motor development, neurodevelopment, attention, memory, language, auditory recognition
Choline	Methylation, myelin, neurotransmitters, especially affecting hippocampus, septum, striatum, anterior neocortex, midposterior neocortex	Visual spatial and auditory memory in rodents (no information yet available for humans)
Copper	Iron transport, antioxidant activity, neurotransmitter synthesis, neuronal and glial energy metabolism, especially affecting cerebellum	Motor control, cognitive function
Iodine	Thyroid synthesis, neuronal synthesis, myelination	Cognitive function
Vitamin A	Structural development, antioxidant	Visual function
Folate	One-carbon metabolism	Neural tube development

Adapted from Monk C et al: Research review: maternal prenatal distress and poor nutrition—mutually influencing risk factors affecting infant neurocognitive development, *J Child Psychol Psychiatry* 54:115, 2013.

BOX 15-3 Potential Causes of Intrauterine Growth Restriction (IUGR)

Maternal Factors

Medical conditions: chronic hypertension, preeclampsia (early in gestation), diabetes, systemic lupus erythematosus, chronic kidney disease, inflammatory bowel disease, severe lung disease, cancer, hyperemesis gravidarum

Infections: syphilis, toxoplasmosis, cytomegalovirus, rubella, hepatitis B, herpes simplex virus 1 or 2, HIV-1, *Helicobacter pylori*, malaria

Malnutrition: low prepregnant weight, small maternal size, poor weight gain (especially in the last half of pregnancy), obesity (especially if combined with weight loss), nutrient deficiencies, including protein, vitamins A, Bs, C, folic acid, zinc, calcium, iron, recent history of pregnancy, high parity, multiple pregnancy, history of IUGR, active eating disorders

Social conditions: very young age; poverty; lack of food because of war, famine, natural disasters (earthquake, tsunami); physical or mental abuse; substance abuse (cigarettes, alcohol, heroin, cocaine); exposure

to teratogens; exposure to therapeutic medications (antimetabolites, warfarin, phenytoin)

Fetal Factors

Genetic: race, ethnicity, sex, genetic disorders

Parity: first baby often weighs less than subsequent siblings

Chromosomal anomalies: chromosomal deletions, trisomy 13, 18, 21

Congenital malformations: anencephaly, gastrointestinal atresia, Potter syndrome, pancreatic agenesis

Placental Factors

Placental insufficiency: reduced blood flow, impaired transfer of nutrients

Anatomic problems: multiple infarcts, aberrant cord insertions, umbilical vascular thrombosis and hemangiomas, premature placental separation, small placenta

Adapted from Alisi A et al: Intrauterine growth retardation and nonalcoholic fatty liver disease in children, *Int J Endocrinol* 2011:269853, 2011; Wu G et al: Biological mechanisms for nutritional regulation of maternal health and fetal development, *Paediatr Perinat Epidemiol* 26:4, 2012a.

between 28 weeks' gestation and 4 weeks postpartum). Babies who are born LBW may suffer from necrotizing enterocolitis, respiratory distress syndrome, intraventricular hemorrhage, cerebral palsy, or retinopathy of prematurity (see Chapter 42).

In addition to fetal growth restriction, any adverse maternal condition, including poor nutritional status, puts the fetus at risk for being delivered prematurely. Associated with prematurity is increased neonatal morbidity and mortality, especially if the baby is also growth restricted. Preterm rates are rising in developed countries and are higher in the United States than in Europe (Bloomfield, 2011). In the United States, rates are highest among non-Hispanic black women, and it is unclear if early fetal developmental programming is playing a role. Preterm rates are higher with ART, among both singletons and twins.

Oxidative stress, metabolic stress, and inflammation may be important in increasing risk of preterm delivery, and it appears that periconceptual malnutrition is more important than nutrition later in pregnancy. Although obesity does not predict optimal nutrition, it is somewhat protective for preterm delivery. However, prepregnant underweight, combined with low weight gain during pregnancy, has an additive effect on preterm and LBW risk. Even for those women of normal weight, low weight gain doubles the risk of preterm delivery; weight loss triples the risk (Bloomfield, 2011). Those women who are still growing or who have eating disorders may have competition for nutrients. Supplementation with macronutrients may be helpful, but there are no preconceptional studies. For many micronutrients, including omega-3 polyunsaturated fatty acids (PUFAs), folic acid, iron, vitamin C, vitamin D, calcium, magnesium, and zinc, it is unclear whether supplementation during pregnancy provides an acute beneficial effect or whether long-term stores are more important (Bloomfield, 2011).

Particular toxins may increase the risk of prematurity. One study found nearly double the risk of preterm delivery if women consumed more than four servings of diet soda per day (Bloomfield, 2011), although that finding has been disputed (La Vecchia, 2013). Licorice (*glycyrrhiza glabra* root) blocks the enzyme that inactivates cortisol, and the effect on preterm risk is dose-related. Similar results are seen when mother is exposed to psychological stress (see *Clinical Insight: Stress During Pregnancy*). The role of paternal nutrition in preterm risk is unexplored (Bloomfield, 2011).

The effect of poor maternal nutrition or exposure to toxins may follow the infant for decades. A very preterm, growth-restricted baby may suffer permanent brain damage. **Neural tube defects (NTDs)** may cause lifelong problems with mobility and bodily functions. Fetal alcohol syndrome (FAS) is a major cause of mental retardation and learning disorders. However, even those babies who are born with no apparent defects may suffer increased risk of chronic diseases because of a less-than-optimal prenatal environment. See Figure 15-1 for a summary of the effects of maternal malnutrition.

Epigenetic Effects

Compromises in structural or cognitive potential may not be evident when an infant is born but may manifest later in life. A child with IUGR, often resulting from maternal hypertension or severe malnutrition or anemia, may have permanent

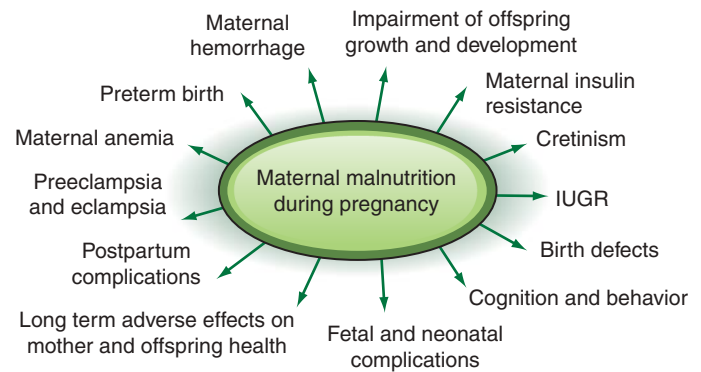

FIGURE 15-1 Major negative effects of maternal malnutrition (both under- and overnutrition) on mother and infant.

mild neurodevelopmental cognitive abnormalities. Babies born preterm or growth restricted are more likely to have a higher risk of obesity, type 2 diabetes, and cardiovascular disease (CVD) later in life. Those babies exposed to the Dutch famine early in gestation were at highest risk of CVD and had double the risk for schizophrenia, whereas those exposed midpregnancy were three times more likely to develop microalbuminuria and decreased creatinine clearance, as well as having an increased risk for obstructive airway disease (Roseboom et al, 2011).

Girls born preterm are more likely to deliver preterm with their own pregnancies and more likely to develop anorexia nervosa (Bloomfield, 2011). Immune function, learning ability, mental health, cancer, and aging are likely affected by LBW. Functional neural pathways controlling appetite and satiety likely develop in the third trimester, so preterm infants may experience disruptions in their development.

Those babies born large for gestational age (LGA) or exposed to hyperglycemia or maternal obesity are at increased risk of chronic diseases, likely through multiple mechanisms (see *Focus On: Special Case of Obesity*).

Birth weight may not be the only predictor for the propensity for adult disease. Exposure to high folate during pregnancy is associated with insulin resistance and obesity in later life if combined with low vitamin B₁₂ levels (DelCurto et al, 2013), and increased rates of cancer are associated with supraphysiologic intakes of methyl donors (Milagro et al, 2013; see Chapter 5). Maternal and paternal nutritional imbalances are likely to increase the risk of metabolic syndrome (DelCurto et al, 2013).

Exposure to endocrine-disrupting chemicals may modify gene expression and the effects, including increased risk of obesity, insulin resistance, and type 2 diabetes, may be nonlinear (i.e., low doses may be more harmful than high doses) (Barouki et al, 2012). In one study, mothers who ate an unbalanced high-protein diet (1 pound red meat/day, no carbohydrate) during late pregnancy produced offspring who experienced higher cortisol levels when exposed to stress as adults (Bloomfield, 2011).

This developmental plasticity can be helpful. However, when there is a mismatch between in utero programming and the later environment, the risk of chronic disease rises. Whether the fetus develops a thrifty phenotype or whether harm is caused by overcompensation later with catch-up growth is unknown. Altered organ structure, cell numbers, and metabolic functioning

appear important (Koletzko et al, 2012). See Chapter 5 for more information.

Exposure of the embryo or fetus to specific maternal nutrients, as well as environmental contaminants, can turn the imprinting genes that control growth and development on or off, but the amounts, timing, and effects are still being investigated. Paternal nutrient imbalance and gene-environment interactions are also likely important (Barouki et al, 2012; DelCurto et al, 2013). Although DOHaD originally focused on undernutrition, overnutrition also is being studied. Effects of macro- and micronutrients, as well as phytonutrients and hypoxia, are being examined, primarily through animal studies so far, and the ideal maternal and paternal diet for epigenetic effects has not yet been established (Vanhees et al, 2014).

New research also is focusing on the grandchildren of people affected by the Dutch famine (Roseboom et al, 2011) to document the long-term epigenetic effects. Preliminary results show that under- and overnutrition are important issues, but there are differences in response by sex, and the timing of the insult matters (Vanhees et al, 2014). The preconceptional nutritional role in altering the epigenome has yet had little attention, although animal research shows components of a preconceptional diet may resolve toxicant epigenetic changes (Owen et al, 2013). Maternal and paternal nutritional status, as well as that of previous generations, are likely important in affecting, and being affected by, genetic variations (see Chapter 5).

Nutrient Requirements During Pregnancy

Nutrition during pregnancy often is equated with weight gain because weight is most easily and consistently measured. However, the increased need for nutrients to support adequate fetal growth is greater than the limited additional energy needed, and maternal weight gain is not necessarily predictive of health outcomes, especially for heavier women. The U.S. DRIs are found on the inside front cover, and estimated requirements vary between countries (see Table 15-8).

Energy

Additional energy is required during pregnancy to support the metabolic demands of pregnancy and fetal growth. Metabolism increases by an average of 15% in the singleton pregnancy, but with wide variability, especially in the third trimester. The DRI for energy increases by only 340 kcal/day during the second trimester and by 452 kcal/day in the third trimester. If maternal weight gain is within the desirable limits, the range of acceptable energy intakes varies widely, given individual differences in energy output and basal metabolic rate. Modifying intakes to achieve recommended weight gain (see [Pregnancy Weight Gain Recommendations](#)) is more useful than calculating caloric requirements.

Exercise. Energy expended in voluntary physical activity is the largest variable in overall energy expenditure. Physical activity increases energy expenditure proportional to body weight. However, most pregnant women compensate for increased weight gain by slowing their work and movement pace; thus total daily energy expenditure may not be substantially greater than before pregnancy.

The American College of Obstetricians and Gynecologists (ACOG) recommends at least 30 minutes of moderate intensity exercise on most, if not all, days for pregnant women without contraindications. Short duration strenuous exercise appears un concerning, but the impact of long duration strenuous exercise

on the fetus is unknown (Szymanski and Satin, 2012). Excessive exercise, combined with inadequate energy intake, may lead to suboptimal maternal weight gain and poor fetal growth. Therefore a pregnant woman should always discuss exercise with her health practitioner. Although there is limited evidence that exercise helps modify gestational weight gain, there is also no evidence of harm.

Protein

Additional protein is required to support the synthesis of maternal and fetal tissues. This demand increases throughout gestation and is maximized during the third trimester. The protein RDA of 0.8 g/kg current body weight/day for pregnant women (46 g for someone with a prepregnant weight of 126 pounds) in the first half of pregnancy is the same as that for the nonpregnant women. Needs increase in the second half to 1.1 gm/kg/day, which would be 71 g/day only for that same reference woman who is also gaining weight appropriately. For many women, the protein requirement is higher. For each additional fetus, at least another 25 g/day of protein is recommended, but because protein is also used as an energy source, the total may be as much as 175 g/day for the normal-weight woman carrying a twin gestation who is consuming 3500 kcal/day (Goodnight and Newman, 2009). The World Health Organization (WHO) uses slightly different calculations in their 2007 report; 0.83 g/kg/day as a baseline protein requirement with additional recommended intakes of + 0.7 g/day (first trimester), + 9.6 g/day (second trimester), or + 31.2 g/day (third trimester) to support a total 13.8 kg weight gain, although some researchers recommend the older (1985) and more conservative guidelines (additional intakes of 1.2, 6.1, and 10.7 g/day respectively, averaged to an additional 6 g/day throughout pregnancy added to the prepregnant value) (Millward, 2012).

Protein deficiency during pregnancy has adverse consequences, including poor fetal growth. Protein also is involved in the synthesis of hormones and neurotransmitters. Limited intakes of protein and energy usually occur together, making it difficult to separate the effects of energy deficiency from those of protein deficiency. Although most women in the United States likely eat more than enough protein, there are some for whom particular attention must be paid, including those consuming a vegetarian diet, those who are still growing themselves, or those who are pregnant with multiples.

The optimal balance of protein to total calories has yet to be determined and recommendations, as well as intakes, vary across cultures (Blumfield and Collins, 2014). Caution is advised when considering very high protein supplements. Intakes at the high end of the acceptable macronutrient distribution ranges (AMDR) (i.e., 30% to 35% of calories from protein) have been associated with an increased risk of adverse outcomes in some studies (Millward, 2012). Current U.S. practice often targets protein intakes at 20% of total calories, possibly higher for multiples. WHO recommends 23% of calories from protein (Millward, 2012). Supplementation, if necessary, should be done with food rather than with protein supplements. For example, someone consuming 2240 kcal from 6 cups/day of 2% milk, 8 oz of meat, six servings of starch, three vegetable servings, two fruit servings, and six fat servings gets 23% of her calories from protein (128 g). If using skim milk, the total is 1970 kcal with 26% from protein.

Carbohydrates

The RDA for carbohydrates increases slightly, helping maintain appropriate blood glucose and prevent ketosis. Intakes may be greater in women consuming more calories, but careful carbohydrate choices are needed to include all the daily nutrients for pregnancy. Priority should be given to complex carbohydrates from whole grains, fruits, and vegetables rather than just simple sugars, including refined liquid sugars, whether natural (juices) or industrially produced (soda).

Fiber

Daily consumption of whole-grain breads and cereals, leafy green and yellow vegetables, and fresh and dried fruits should be encouraged to provide additional minerals, vitamins, and fiber. The DRI for fiber during pregnancy is 14 g/day/1000 kcal and, if met, will help a great deal in managing the constipation that often accompanies pregnancy.

Lipids

As with nonpregnant women, there is no DRI for total lipids during pregnancy. The amount of fat in the diet should depend on energy requirements for proper weight gain. However, recommendations for omega-6 PUFA (linoleic acid) and omega-3 PUFA (alpha-linolenic acid) increase slightly. Although not a DRI, the recommended intake of docosahexaenoic acid (DHA) is 200 mg/day and can be met by one to two portions of fish per week (Koletzko et al, 2007) (see *Focus On: Omega-3 Fatty Acids in Pregnancy and Lactation*).

Vitamins

All vitamins and minerals are needed for optimal pregnancy outcome. In some instances requirements may be met through diet; for others a supplement, started preconceptually, is often necessary. Many, but not all, vitamin and mineral recommendations increase with pregnancy, but the magnitude of the increase varies by nutrient (see the DRI tables on the inside cover).

Folic Acid. The RDA for dietary folate equivalents increases to support maternal erythropoiesis, DNA synthesis, and fetal and placental growth. Low folate levels are associated with miscarriages, LBW, and preterm birth. Early maternal folate deficiency is associated with an increased incidence of congenital malformations, including NTDs (including spina bifida and anencephaly), and possibly orofacial clefts and congenital heart defects (Guéant et al, 2013; Obeid et al, 2013). Approximately 3000 new cases of NTDs occur in the United States annually (CDC, 2014a).

Because more than half of all U.S. pregnancies are unplanned, and the neural tube closes by 28 days of gestation, before most women realize they are pregnant, the Centers for Disease Control and Prevention (CDC) recommends that all women of childbearing age in anticipation of pregnancy increase their intake of folic acid by 400 mcg/day, the synthetic version that is available in supplements and fortified foods, especially some breakfast cereals (CDC, 2014a). The U.S. Preventive Services Task Force (USPSTF) recommends 400 to 800 mcg/day of folic acid preconceptually. Women who have had a previous NTD-affected pregnancy should consume 400 mcg/day when not planning to conceive; those planning pregnancy should consider 4000 mcg/day (4 mg/day) from 1 month before to 3 months after conception (CDC, 2014a). These higher doses should be taken as a separate supplement

and not as part of a multiple vitamin supplement to avoid excess intakes of other nutrients in the multivitamin. Although this level is recommended by many medical providers, the lower dose may be equally beneficial. Supplementation recommendations vary by country (Talaulikar and Arulkumaran, 2011), and some evidence suggests that, although the 800 mcg dose achieves recommended blood levels in 4 weeks, the 400 mcg dose requires 8 to 12 weeks to reach these levels (Berti et al, 2011). Also available is synthetic 5-methyltetrahydrofolate, the primary circulating form of folate proposed to be better used, especially by those with polymorphisms (see Chapter 5), and without the detrimental rise in unmetabolized folic acid. However, its role in preventing NTDs or other birth defects is untested in clinical trials (Obeid et al, 2013).

Red blood cell folate levels exceeding 906 nmol/L (400 ng/ml) have been associated with the fewest NTDs (Obeid et al, 2013). Natural folate is less bioavailable and has not been shown to raise blood levels as well as the synthetic folic acid or to lower the risk of NTDs. Although theoretically natural folate could be effective, 6 to 12 cups of raw spinach (more than 2 cups cooked) daily is the bioequivalent level of natural folate that is found in one bowl of fortified breakfast cereal.

Women who are obese or who smoke, consume alcohol moderately or heavily, or use recreational drugs are at risk for marginal folate status, as are those with malabsorption syndromes or genetic differences related to methylation and the metabolic use of dietary folate, including the estimated 11% of the U.S. population with the MTHFR 677 C to T variation (Caudill, 2010). European prevalence is estimated to be 10% to 22% (Obeid et al, 2013). Although increased folate intake is helpful, added riboflavin also may be beneficial (see Chapters 5 and 7). Women using antiseizure medications must be monitored closely when starting folic acid because it can reduce their seizure control (see Chapter 8).

Enriched grain products in the United States are fortified with folic acid and are estimated to provide an average 200 mcg/day, with resulting higher blood folate levels and reduced (19% to 54%) NTD rates (Caudill, 2010). Because NTD rates remain higher among the Hispanic population in the United States, targeted fortification of corn masa flour has been proposed. However, grain fortification also exposes the entire population to extra folic acid, which is potentially undesirable; in some countries, folic acid fortification is not practiced.

Possible adverse effects include masking of vitamin B₁₂ deficiency, tumor promotion, epigenetic hypermethylation, interference with antifolate treatments, and an increase in miscarriages and multiple births. Widespread problems have not been seen. However, high intakes of folic acid also have potential epigenetic effects, but data are fragmentary and sometimes conflicting. Caution is advised with the use of pharmacologic doses (Milagro et al, 2013). For example, although some studies have seen no negative effects on DNA methylation at doses up to 4000 mcg/day (Crider et al, 2011), other studies have found that in the context of low vitamin B₁₂ status, supplementing pregnant women with just 500 mcg/day was associated with an increased risk of offspring adiposity and insulin resistance at age 6 (Yajnik et al, 2008).

On the other hand, adequate folic acid in the second trimester may decrease inflammation, and folate status is associated inversely with the severity of bacterial vaginosis, a documented risk factor for preterm delivery (Dunlop et al, 2011). Murine studies have found that the negative effect of maternal exposure

to bisphenol A is effectively neutralized by maternal supplementation with folic acid, betaine, and choline (Guéant et al, 2013). Supplementation with methyl donors, such as folic acid, also may reduce the harmful effects of fumonisin (a mycotoxin produced by *Fusarium* molds that grow on agricultural commodities, especially corn, that has been associated with increased risk of NTDs) contamination and of a father's exposure to dioxins (Guéant et al, 2013).

An estimated 50% to 70% (not 100%) of NTDs could be prevented with the periconceptual use of 400 mcg folic acid/day (CDC, 2014a). Optimal levels of other methyl donors (B₂, B₆, B₁₂, and choline) may also lower the risk of NTDs and improve birth weight.

Vitamin B₆. Pyridoxine functions as a cofactor for many decarboxylase and transaminase enzymes, especially those involved in amino acid metabolism. Although this vitamin catalyzes a number of reactions involving neurotransmitter production, it is not known whether this function is involved in the relief of nausea and vomiting. Because meat, fish, and poultry are good dietary sources, deficiency is not common, and routine prenatal vitamins contain sufficient amounts (Hovdenak and Haram, 2012). Regarding nausea and vomiting, standard doses of 25 mg three times per day have questionable efficacy but do not appear to be dangerous.

Vitamin B₁₂. Cobalamin is required for enzyme reactions and for generation of methionine and tetrahydrofolate; it is important in growth and development, including immune function (Wu et al, 2012a). Vitamin B₁₂ is naturally found exclusively in foods of animal origin, so vegetarians, especially vegans, are at risk for dietary vitamin B₁₂ deficiency and should consume fortified foods or supplements. Also at risk are those people with malabsorption, including those with Crohn's disease involving the terminal ileum, women who have had gastric bypass surgery, and those using proton pump inhibitor medications (see Chapter 8) (People taking metformin also may be at risk). Deficiencies in folate and vitamin B₁₂ have been related to depression in adults. Inadequate amounts of folate and B₁₂ may affect negatively infant cognitive and motor development as well as increase risk of NTDs and inadequate fetal growth.

Choline. Choline is needed for structural integrity of cell membranes, cell signaling, and nerve impulse transmission and is a major source of methyl groups. Choline and folate are metabolically interrelated; both support fetal brain development and lower risk of NTDs and orofacial clefts (Zeisel, 2013). Choline also appears to be important in placental functioning and may affect maternal and fetal responses to stress.

The DRI for choline increases slightly during pregnancy. Genetic variations and concurrent intakes of folate and methionine may affect requirements, and de novo synthesis may not meet fetal and maternal needs (Zeisel, 2013). Choline-rich foods include milk, meat, and eggs (see Table 15-9), and women not eating these foods may need supplementation. Many popular prenatal supplements do not contain choline and those that do contain very little. Large supplemental doses may cause gastrointestinal discomfort, but a small study using 750 mg during pregnancy did not identify adverse effects (Zeisel, 2013).

Vitamin C. The DRI for vitamin C increases during pregnancy and may be even higher for those who smoke, abuse alcohol or drugs, or regularly take aspirin. Daily consumption of good food sources should be encouraged. Low plasma levels are associated with preterm labor (Dror and Allen, 2012), possibly

TABLE 15-9 Choline Content of Selected Foods

Food	Serving Size	Choline (mg)
Eggs		
Egg, whole	1 large	146.9
Egg, white	1 large	0.4
Egg, yolk	1 large	139.4
Fish		
Fish, Atlantic cod	3 oz	71.1
Fish, pink salmon	3 oz	96.4
Shrimp	3 oz	115.1
Oysters, Eastern	3 oz	110.5
Meats		
Beef chuck	3 oz	93.7
Beef liver	3 oz	362.1
Beef kidneys	3 oz	436.2
Beef brains	3 oz	417.3
Beef heart	3 oz	194.5
Pork loin	3 oz	65.7
Chicken, dark meat	3 oz	84.2
Chicken, light meat	3 oz	72.5
Chicken liver	3 oz	277.8
Turkey, dark meat	3 oz	76.8
Turkey, light meat	3 oz	59.3
Milk		
Milk, whole	1 cup	34.9
Milk, skim	1 cup	39.2
Cheese, cheddar	1.5 oz	7.0
Others		
Soybeans, mature, roasted	1 oz	35.2
Peanuts, dry roasted	1 oz	15.7
Mushrooms, shiitake, cooked	½ cup	26.7
Mushrooms, white, cooked	½ cup	15.9
Broccoli, cooked	½ cup	31.3
Bread, white	1 slice	4.1
Bread, whole wheat	1 slice	8.7

because of its antioxidant function or its role in collagen synthesis. However supplemental vitamin C is not recommended for the prevention of premature rupture of membranes (PROM). Supplementation with vitamin C (1000 mg) along with vitamin E (400 IU) also is not recommended for prevention of preeclampsia (ACOG, 2013e) and actually may increase risk of gestational hypertension and PROM (Dror and Allen, 2012). Vitamin C is actively transported across the placenta, so there is also potential for excessive levels in the fetus (Dror and Allen, 2012).

Vitamin A. Vitamin A is critical during periods of rapid growth, important in cellular differentiation, ocular development, immune function, and lung development and maturity, as well as gene expression (Wu et al, 2012a). Low vitamin A levels are associated with IUGR and increased risk of maternal and neonatal mortality. Malformations are seen in animals exposed to deficiencies, but confirmation of human malformations has not been established. However, among women positive for human immunodeficiency virus (HIV), improved vitamin A status is associated with improved birth weight possibly by improving immunity (Hovdenak and Haram, 2012).

Excess preformed vitamin A is teratogenic. Supplementation is usually not necessary and is often limited to 5000 IU/day, although doses up to 10,000 IU/day are not associated with increased risk of malformations (Hovdenak and Haram, 2012). The acne medication isotretinoin is a vitamin A analog, and exposed infants are at extremely high risk for fetal anomalies and miscarriages. Women should stop its use for at least 1 month before conception. Beta-carotene is not associated with birth defects. Although no cases have been seen, theoretically someone eating liver could consume as much preformed vitamin A as has been associated with fetal anomalies, so large amounts of liver, liver pâté, and liverwurst or braunschweiger are not recommended in the first trimester.

Vitamin D. According to the IOM, vitamin D requirements do not increase during pregnancy; intakes of 600 IU/day (15 mcg/day) are sufficient when considering bone health. The few dietary sources of vitamin D are salmon and other fatty fish, as well as some fortified breakfast cereals and mushrooms exposed to UV light. Not all dairy products are fortified, but liquid milk (if sold interstate) is a good source, usually containing 100 IU/8 oz (see Appendix Table 51 and *Clinical Insight: Vitamin D: How Much Sun is Needed?*).

CLINICAL INSIGHT

Vitamin D: How Much Sun Is Needed?

Skin exposure is the best source of vitamin D, but the amount of sun exposure that is necessary is difficult to predict. For example, a Caucasian with light skin at 42° N (latitude for Boston or Chicago) can satisfy her vitamin D requirements by exposing arms and legs to sunlight (at noon on a clear day) for 5 to 15 minutes 2 to 3 times/week in the summertime. On the other hand, people living north of 35° N (or south of 35° S) can produce almost no vitamin D in the winter months. A person's age, BMI, and skin pigmentation, the use of sunscreen, clothing style, the time of day, season of the year, latitude, altitude, and weather conditions all matter (Holick, 2014). See Appendix 51 for apps for estimating sun exposure requirements and vitamin D in foods.

Vitamin D deficiency is recognized increasingly in dark-skinned and veiled women living in latitudes where sun exposure is low. Women who are at risk of entering pregnancy with low vitamin D levels also include those with BMI more than 30, those with fat malabsorption, and those with high use of sunblock, along with poor dietary intake. Screening for vitamin D status is advised for those women (ACOG, 2011).

Severe vitamin D deficiency is associated with congenital rickets and newborn fractures and also may manifest as seizures (ACOG, 2011), although it is unknown if calcium insufficiency also plays a role (Brannon and Picciano, 2011). There is concern that low maternal vitamin D status may negatively affect fetal bone accrual. However, small studies have shown that although maternal supplementation can increase cord blood levels, there is no effect on fetal calcium, phosphorus, parathyroid hormone (PTH), or skeletal parameters (Kovacs, 2012). A recent study found no association between maternal vitamin D status and her offspring's bone mineral content at ages 9 to 10 years (Lawlor et al, 2013).

Vitamin D metabolism changes in pregnancy, with the conversion of 25(OH)D to 1,25(OH)₂D drastically increased (Pludowski et al, 2013). 1,25(OH)₂D levels are three times non-pregnant levels by 12 weeks and keep rising throughout the pregnancy, depending on 25(OH)D availability. These levels are

not associated with hypercalciuria or hypercalcemia and appear to be driven by the pregnancy itself rather than by increasing vitamin D-binding protein levels. Mechanisms are still unknown but likely include an uncoupling of renal 1-alpha-hydroxylase from feedback control and upregulating it twofold to fivefold for reasons other than calcium homeostasis (Kovacs, 2012). It is assumed that high 1,25(OH)₂D values increase delivery of vitamin D to tissues and may modulate innate and adaptive immunity. Vitamin D may be important in regulating gene expression and in promoting successful implantation (Wu et al, 2012a). It also may have a role in preventing preeclampsia, preterm delivery, gestational diabetes, bacterial vaginosis, and the need for cesarean delivery. In addition, it may be involved in the development of the infant's immune function and development of allergy, and other developmental programming (Brannon and Picciano, 2011), including risk of type 1 diabetes (Kovacs, 2012). However, associations are inconclusive, often contradictory, confounded, and lack causality. Although supplementation raises maternal vitamin D levels, it has not been positively associated with improved obstetric outcomes (Kovacs, 2012).

Optimal serum levels of 25(OH)D during pregnancy are not yet known but must be at least 20 ng/ml (50 nmol/L) for bone health (ACOG, 2011). Other experts suggest at least 32 ng/ml (80 nmol/L) for pregnancy, but increased risk of growth restriction at levels exceeding 70 nmol/L and child eczema at levels exceeding 75 nmol/L also have been reported (Brannon and Picciano, 2011). Research is active and ongoing. Vitamin D supplementation may be needed to reach desired serum concentrations, although there is insufficient evidence to recommend routine supplementation. A dosage of 1000 to 2000 IU/day of vitamin D appears safe (ACOG, 2011). Although some researchers have found no hypercalciuria with 4000 IU/day (the UL), caution is advised; only spot checks of urine were done, not 24-hour urine collections, and there was no long-term follow-up on kidney stone formation rates (Kovacs, 2012). Very high supplementation (≥ 1000 mcg = 40,000 IU/day) has been associated with hypercalcemia, and although vitamin D does not appear to be teratogenic, some animal data suggest the need for concern (Roth, 2011). The potency of vitamin D supplements is variable; many contain less than the labeled amounts (LeBlanc et al, 2013).

Vitamin E. Vitamin E requirements do not increase. Although deficiency is speculated to cause miscarriage, preterm birth, preeclampsia, and IUGR, vitamin E deficiency specifically has not yet been reported in human pregnancy. Vitamin E is an important lipophilic antioxidant, but supplementation of vitamin E (along with vitamin C) is not an effective strategy for preventing preeclampsia nor does it reduce risk of fetal or neonatal loss, SGA, or preterm delivery. Supplementation actually may be proinflammatory, preventing the switch from Th1 cytokines (proinflammatory) to Th2 cytokines (antiinflammatory) that is normal during pregnancy (Hovdenak and Haram, 2012; see Appendix 49 for food sources of vitamin E).

Vitamin K. Although vitamin K requirements do not increase during pregnancy, usual diets often do not provide sufficient vitamin K as most food sources (e.g., dark leafy green vegetables) are not consumed in recommended amounts. Vitamin K has an important role in bone health as well as in coagulation homeostasis, so adequate amounts during pregnancy are vital (see Chapter 24). Vitamin K deficiency has been reported in women who have had hyperemesis gravidarum,

Crohn's disease, or gastric bypass. See Appendix 50 for sources of vitamin K.

Minerals

Calcium. Hormonal factors strongly influence calcium metabolism in pregnancy. Human placental lactogen modestly increases the rate of maternal bone turnover, and although estrogen inhibits bone resorption, accretion and resorption increase. Maternal absorption of calcium across the gut doubles during pregnancy (Olausson et al, 2012). PTH often drops in North American and European women consuming adequate calcium. In areas with lower calcium diets that are also rich in phytates, PTH levels stay the same or increase; more research is necessary on the limitations of maternal response when intakes are marginal or low (Olausson et al, 2012). These changes maintain maternal serum calcium levels and promote calcium retention to meet progressively increasing fetal skeletal demands for mineralization. Fetal hypercalcemia and subsequent endocrine adjustments ultimately stimulate the mineralization process.

The net effects of pregnancy and lactation on the maternal skeleton are not yet clear. Bone mineral is mobilized during pregnancy and replenished starting in later lactation. The degree of bone changes varies considerably by site and also between individuals; it appears that genetics, endocrine responses, and nutritional factors are important. No prospective studies have examined whether there is increased risk of osteoporosis later in life attributed to pregnancy or lactation; retrospective studies are inconsistent. Higher intakes are associated with improved calcium balance when intakes are low, but some evidence suggests that supplementation may temporarily disrupt the process of adaptation to habitually low intakes (Olausson et al, 2012).

Approximately 30 g of calcium is accumulated during pregnancy, primarily in the fetal skeleton (25 g), but there is wide variation. The remainder is stored in the maternal skeleton, held in reserve for the calcium demands of lactation. Most fetal accretion occurs during the last half of pregnancy, increasing from 50 mg/day at 20 weeks to 330 mg/day at 35 weeks (Olausson et al, 2012). There is conflicting evidence regarding whether maternal calcium intake affects a child's long-term accretion.

In addition to its role in bone formation, low calcium intake is associated with increased risk of IUGR and preeclampsia (Hovdenak and Haram, 2012). Calcium also is involved in many other processes, including blood clotting, intracellular proteolysis, nitric oxide synthesis, and has a role in regulating uterine contractions (Wu et al, 2012a).

The requirement for calcium during pregnancy does not increase. However, many women enter pregnancy with low intakes and often need encouragement to increase consumption of calcium-rich foods. Dairy products are the most common sources of dietary calcium.

Milk, including extra dry milk powder, can be incorporated into foods. One-third cup of dried skim milk is equivalent to 1 cup of fluid milk. Small amounts can be added to liquid milk; much more can be added to foods with stronger flavors. Although most of the dry milk sold in the United States is nonfat, powdered whole milk is also available in the ethnic food sections of grocery stores. Yogurt is often well accepted, and using plain nonfat yogurt with fruit and minimal added sugar can maximize nutrients without providing as many extra calories. Greek yogurt, although higher in protein, may contain less calcium than regular yogurt. Although cheese can be used, often the higher calories from fat become a limiting factor. Lactose intolerance can be managed (see Chapter 28).

Soy milks are fortified with calcium, but this often precipitates to the bottom of the container. It is difficult to reincorporate the sludge, with the milk containing only 31% of the labeled amount without shaking, 59% with shaking (Heaney and Rafferty, 2006). The fortificant should be calcium carbonate for best absorption. Other drinks, including enriched rice, coconut, and nut milks, are often low in protein, and caution is advised. Regarding vegetable sources of calcium, the concern is one of quantity and bioavailability (see Table 15-10 and Appendix 51).

Care should be taken when considering the use of calcium supplements. Overconsumption of calcium through food is not common; however, elevated serum calcium levels also can result from excess antacid ingestion if the UL is exceeded (see Heartburn).

Copper. Diets of pregnant women are often marginal in copper, and requirements rise slightly in pregnancy. In addition to primary deficiency from genetic mutation (Menkes disease),

TABLE 15-10 Comparison of Absorbable Calcium with 1 cup Milk

Food	Calcium Content	Fractional Absorption	Estimated Absorbed Calcium	Amount Needed to Equal 1 c Milk
Milk	300 mg/c	32.1%	96.3 mg	1.0 cup
Beans, pinto	44.7 mg/0.5 c*	26.7	11.9	4.05 cups, cooked*
Beans, red	40.5 mg/0.5 c	24.4	9.9	4.85 cups
Beans, white	113 mg/0.5 c	21.8	24.7	1.95 cups
Bok choy	79 mg/0.5 c	53.8	42.5	1.15 cups
Broccoli	35 mg/0.5 c	61.3	21.5	2.25 cups
Cheddar cheese	303 mg/1.5 oz	32.1	97.2	1.5 oz
Chinese mustard greens	212 mg/0.5 c	40.2	85.3	0.55 cup
Chinese spinach	347 mg/0.5 c	8.36	29.0	1.65 cups
Kale	61 mg/0.5 c	49.3	30.1	1.6 cups
Spinach	115 mg/0.5 c	5.1	5.9	8.15 cups
Sweet potatoes	44 mg/0.5 c	22.2	9.8	4.9 cups
Tofu with calcium	258 mg/0.5 c	31.0	80.0	0.6 cup
Yogurt	300 mg/c	32.1	96.3	1.0 cup

* All vegetables are cooked portions.

secondary deficiency from increased zinc or iron intake, certain drugs, and gastric bypass surgery is also of concern. Copper deficiency alters embryo development; induced copper deficiency has been shown to be teratogenic. There is decreased activity of cuproenzymes, increased oxidative stress, altered iron metabolism, abnormal protein crosslinking, decreased angiogenesis, and altered cell signaling (Uriu-Adams et al, 2010). Copper interacts with iron, affecting neurocognitive and neurobehavioral development. Although not commonly included in prenatal supplements, it is recommended that copper be supplemented when zinc and iron are given during pregnancy (Uriu-Adams et al, 2010).

Fluoride. The role of fluoride in prenatal development is controversial, and fluoride requirements do not increase during pregnancy. Development of primary dentition begins at 10 to 12 weeks' gestation. From the sixth to the ninth month, the first four permanent molars and eight of the permanent incisors are forming. Thus 32 teeth are developing during gestation. Controversy involves the extent to which fluoride is transported across the placenta and its value in utero in the development of caries-resistant permanent teeth (see Chapter 25). Most bottled water does not contain fluoride.

Iodine. Iodine is part of the thyroxine molecule, with a critical role in the metabolism of macronutrients, as well as in fetal neuronal myelination and gene expression (Wu et al, 2012a). Because the thyroid hormone synthesis increases 50% during pregnancy, iodine requirements also increase (Stagnaro-Green and Pearce, 2012). Severe iodine deficiency is associated with increased risk of miscarriage, congenital anomalies, fetal goiter, and stillbirth, as well as prematurity, poor fetal growth, and decreased IQ. Infant cretinism, although rare in the United States, is a significant public health problem; iodine deficiency is the most common cause of preventable mental retardation in the world (Leung et al, 2013).

Worldwide, many people are at risk for iodine deficiency caused by low intake of seafood or by consuming produce grown in iodine-deficient soils, especially if eating locally and consuming goitrogens or exposed to perchlorate contamination. An estimated 70% of the world population has access to iodized salt (Pearce et al, 2013). Salt iodization is voluntary in the United States and Canada; iodized salt rarely is used in processed foods, the primary source of dietary sodium, and must be labeled if used. Kosher salt and sea salt do not naturally contain iodine. Women should be encouraged to use iodized salt when cooking at home and to limit the intake of processed foods made with uniodized salt.

Median urinary iodine values in the United States have declined, mainly because of the reduction of iodine in dairy and bread products, such that 35% of U.S. women of childbearing age now have urinary iodine values suggesting mild iodine deficiency or insufficiency (Leung et al, 2013). Similar reductions have been seen in women in other developed countries as well (Pearce et al, 2013).

Although the effects of severe iodine deficiency on fetal brain development are well established, the effects of milder deficits are not as clear. Results of supplementation studies are mixed regarding thyroid function and the neurodevelopment of children, but children of women with mild to moderate deficiency demonstrate better neurocognitive scores if mothers were supplemented starting very early in pregnancy, that is, by 4 to 6 weeks' gestation (Leung et al, 2013). Current research is studying the effect of iodine supplementation on obstetric outcomes and long-term child development (Stagnaro-Green and Pearce, 2013).

Because of the concern that a subset of the population may be at risk for mild deficiency, the American Thyroid Association now recommends that women receive 150 mcg/day during pregnancy and lactation as potassium iodide, given the variability of iodine content in kelp and seaweed (Leung et al, 2013; Stagnaro-Green and Pearce, 2012). However, only half the prenatal supplements in the United States contain iodine, and the content is highly variable.

High iodine levels are also of concern, potentially causing the same symptoms as low levels. There is concern about the safety of iodine supplementation in areas of iodine sufficiency, but the problems appear to be temporary (Pearce et al, 2013). However, congenital hypothyroidism resulting from high prenatal intake of seaweeds has been documented (Nishiyama et al, 2004). The iodine content is variable, but kombu and kelp often contain extremely high levels, and ingesting even very small amounts may be problematic (Teas et al, 2004). Very high breastmilk iodine levels also have been seen among Korean women ingesting the customary brown seaweed soup postpartum (Rhee et al, 2011), and it is not recommended for those whose babies are preterm.

As a reminder, postpartum thyroiditis affects an estimated 5.4% of all women (Stagnaro-Green and Pearce, 2012). Thyroiditis can manifest as either hyper- or hypothyroidism, and both can affect breastmilk production (see Chapter 32).

Iron. The RDA for iron nearly doubles in pregnancy. An estimated 42% of pregnant women worldwide have iron deficiency anemia, with wide regional variability. Although prevalence is highest in developing countries, an estimated 33% of low-income pregnant women in the United States are anemic in the third trimester (Murray-Kolb, 2011).

Inadequate iron consumption may lead to poor hemoglobin production, followed by compromised delivery of oxygen to the uterus, placenta, and developing fetus. Iron deficiency anemia (IDA) is associated with IUGR, preterm delivery, increased fetal and neonatal mortality, and if severe (hemoglobin <9 g/dl), with complications during delivery (Lee and Okam, 2011). IDA also is associated with increased fetal cortisol production and oxidative damage to fetal erythrocytes (Hovdenak and Haram, 2012). Early iron deficiency affects fetal brain development and the regulation of brain function in multiple ways (see Table 15-7). Neonatal iron deficiency can result if the mother is extremely iron deficient, but maternal hypertension and therefore restricted blood flow, as well as maternal smoking and prematurity, also increase the risk. Infants of mothers with diabetes are also more likely to develop iron deficiency because of increased fetal demands. These changes result in long-term neurobehavioral impairments affecting temperament, interactions with others, learning, and memory and also may result in genomic changes (Georgieff, 2011).

Maternal effects of IDA include fatigue, dyspnea, light-headedness, and poor exercise tolerance. Prenatal weight gain is likely to be low. Mother is at risk of increased blood loss with uterine atony during delivery, thus increasing her risk of needing a blood transfusion. Wound healing and immune function are impaired. She is more likely to suffer from postpartum depression, poor maternal/infant interaction, and impaired lactation. There is some evidence that negative alterations in cognition, emotions, quality of life, and behavior may occur before overt IDA is reached, but the degree of iron deficiency associated with negative consequences remains unknown (Murray-Kolb, 2011). Treatment during pregnancy improves maternal iron status

postpartum and also is associated with improved infant development (Murray-Kolb, 2011).

Plasma volume increases 50% from baseline, and normal erythrocyte volume increases by 20% to 30% in pregnancy (Lee and Okam, 2011). This marked increase in the maternal blood supply during pregnancy, as well as fetal needs, greatly increases the demand for iron. The estimated total requirement for pregnancy is 1190 mg, but with the cessation of menses, the average net deficit is 580 mg (Lee and Okam, 2011). Added to her normal requirements, a pregnant woman often needs to absorb 17 mg/day; normal absorption is often 1 to 2 mg/day from a normal diet, and 3 to 5 mg/day if the diet contains high-iron foods (Lee and Okam, 2011). Most accretion occurs after the twentieth week of gestation, when maternal and fetal demands are greatest. Those at highest risk of IDA are women with inadequate iron stores, including those with short interconceptual periods, poor habitual intakes, those with impaired absorption, including those with a history of bariatric surgery or chronic use of antacids, those who have experienced red cell destruction from malaria or excessive blood loss from heavy menstrual flow or prior hookworm infections.

A first trimester serum ferritin level may be assessed and if less than 20 mcg/L, supplementation may be necessary (Lee and Okam, 2011). However, checking red blood cell indices on the complete blood count (CBC) (see Chapter 7) is often adequate. Hemoglobin and hematocrit values decrease in the second trimester (see Table 15-5); not decreasing is a sign of poor blood volume expansion, associated with increasing risk of a growth-restricted infant, preterm delivery, and stillbirth (Luke, 2015). Serum values should increase again in the third trimester for best outcomes, but often this rise is not seen and intervention is merited. If anemia does not improve with iron therapy (i.e., an increase of 1 g hemoglobin or 3% in hematocrit by 4 weeks [CDC, 1998]), it is advised to check vitamins B₆, B₁₂, and folate status, although many other nutrients, including protein, cobalt, magnesium, selenium, zinc, copper, vitamins A and C, lipids, and carbohydrate, also may play a role (Lee and Okam, 2011; Mechanick et al, 2013; Wu et al, 2012a).

Because many women do not enter pregnancy with sufficient iron stores to cover the physiologic needs of pregnancy, iron supplementation (usually as a ferrous salt) often is prescribed, but the amount of elemental iron contained varies by the preparation (ODS iron 2014). The iron in the supplement already is reduced (i.e., ferrous rather than ferric), so taking the supplement with water is effective and consuming it with juice is not necessary. As with all nonheme sources, supplements should not be taken with coffee, tea, or milk to optimize absorption; iron supplements should be taken separately from the prenatal vitamins. Absorption is best if taken on an empty stomach, but tolerance is often worse. Multiple supplements should be taken separately from each other to maximize absorption, but diminishing absorption is seen with increasing dosage, so tolerance of side effects should be balanced against need. Enteric-coated and delayed-release preparations produce fewer side effects, but because they are not well absorbed they are not recommended. Parenteral iron is also available. Although it will promote a faster response, it also is associated with more potential complications. However, newer, safer preparations are now available (Lee and Okam, 2011).

Iron supplementation is controversial. CDC and WHO recommend early iron supplementation to lower the risk of LBW. The U.S. Preventive Services Task Force (USPSTF) recently reported that, while supplementation may improve maternal iron status, the evidence supporting routine supplementation to improve

either maternal or infant clinical outcomes is inconclusive (Cantor et al, 2015). ACOG recommends screening everyone and supplementing those with documented IDA. However, for those at risk of chronic iron overload, including those with hemochromatosis and beta-thalassemia, iron supplementation may not be recommended. Iron supplements may cause oxidative damage and may exacerbate inflammation; overtreatment of IDA is now thought to be associated with preterm delivery, IUGR, and GDM (Hovdenak and Haram, 2012; see Chapter 3 for other examples of oxidative damage). Intermittent supplementation (one to two times per week) may be effective (Kaiser and Campbell, 2014). In addition, iron supplements are extremely dangerous for small children. Doses as little as 36 mg elemental iron/kg body weight have been lethal (ODS, 2014), so mothers must be reminded to keep supplements out of the reach of children.

Because of the concerns with iron supplementation, including compliance, safety, and effectiveness, emphasizing dietary sources of iron is necessary. The best sources of iron are red meats (see Box 15-4) because of their heme content, and many

BOX 15-4 Comparison of Selected Iron Sources

Serving sizes for meats are all 3 oz. Ranges depend on the type of animal or the cut of meat.

Excellent Sources of Iron

Spleen	6.26-33.46 mg
Bear	9.12 mg
Liver	4.34-25.95 mg limit in first trimester
Braunschweiger/liverwurst	5.44-9.53 mg limit in first trimester
Octopus	8.11 mg
Oysters	5.70-7.83 mg
Mussels	5.71 mg
Blood sausage	5.44 mg
Kidneys	4.5-10.54 mg
Heart	3.67-7.68 mg

Good Sources of Iron

Horse	4.28 mg
Antelope	3.57 mg
Deer/Venison	2.85-4.26 mg
Goat	3.17 mg
Elk	2.84-3.47 mg
Gizzards	2.71-3.13 mg
Bison	2.45-4.13 mg
Sardines	1.95-2.48 mg
Beef	1.44-3.20 mg
Tongue	1.78-4.24 mg
Clams	2.39 mg
Lamb	1.52-2.38 mg
Shrimp	1.81 mg

Fair Sources of Iron

Breakfast cereals that say "iron fortified"	9-18 mg/ serving
Chitterlings (intestines)	1.25 mg
Stomach	0.56-1.05 mg
Pork	0.54-1.57 mg
Leg and thigh of chicken or turkey	0.44-1.35 mg
Tuna	0.55-1.39 mg
Breast of chicken or turkey	0.37-0.97 mg

Adapted from United States Department of Agriculture (USDA), Nutrient Data Labs: *USDA food composition tables, release 27* (website): <http://ndb.nal.usda.gov/ndb/search/list>, 2015. Accessed June 2015.

organ meats may contain even higher levels of iron. It is important to limit the amount of liver and liver products (pâté, liverwurst, braunschweiger) in the first trimester because of their high vitamin A contents.

Vegetable sources, containing only nonheme iron, are less well absorbed, and volume may become the limiting factor, especially late in pregnancy. Absorption can be enhanced by eating them with ascorbic acid or a little meat.

Women who follow vegetarian diets should pay particular attention to iron and try to prevent having their hematocrit drop so far that it cannot recover sufficiently. Followers of Jehovah's Witness also must pay close attention to their iron levels. Because they choose not to receive blood transfusions, these women should receive nutrition counseling on high-iron foods early in pregnancy, with reinforcement as the pregnancy continues.

Magnesium. Magnesium functions as an enzyme cofactor and activator. The full-term fetus accumulates 1 g of magnesium during gestation, and maternal deficiency may interfere with fetal growth and development, including possible teratogenesis (Hovdenak and Haram, 2012). Recommendations for magnesium increase slightly during pregnancy. Magnesium sulfate is sometimes used to treat women with preeclampsia. Maternal magnesium deficiency has been speculated to play a part in increased risk for SIDS, but prospective supplementation trials have not been done. Optimal magnesium levels may be beneficial in helping prevent leg cramps (see *Edema and Leg Cramps*). However, too few data are available to give supplementation recommendations (Hovdenak and Haram, 2012). See Appendix 50 for good dietary sources.

Phosphorus. Phosphorus is found in a variety of foods, and deficiency is rare if one is able to eat normally. Requirements do not rise with pregnancy. However, low phosphorus levels, indicative of "refeeding syndrome," have been found in women experiencing severe vomiting or other situations resulting in starvation. Hypophosphatemia can be life threatening because phosphorus is important in energy metabolism as a component of adenosine triphosphate (ATP) and must be replenished promptly.

Selenium. Selenium functions as an antioxidant and is important for reproduction. Low selenium status is associated with recurrent miscarriages, preeclampsia, and IUGR. The DRI increases slightly during pregnancy, but there are no evidence-based recommendations for supplementation (Hovdenak and Haram, 2012). Excess selenium intake is also of concern, especially if women eat locally from areas where soil selenium contents are high. There are no known areas in the United States or Canada with recognized cases of selenosis.

Sodium. The hormonal milieu of pregnancy affects sodium metabolism. Increased maternal blood volume leads to increased glomerular filtration of sodium; compensatory mechanisms maintain fluid and electrolyte balance.

Rigorous sodium restriction stresses the renin-angiotensin-aldosterone system. Although moderation in the use of salt and other sodium-rich foods is appropriate for the general population, aggressive restriction is usually unwarranted in pregnancy, and the use of diuretics in pregnant women with edema is not recommended. Normal intakes are often much higher than the DRI, which does not increase during pregnancy. ACOG recommends that sodium intake should not be restricted below 2300 mg/day (ACOG, 2013e). Use of iodized salt should be encouraged, but processed food consumption, the source of more than 75% of

dietary sodium in the United States, should be limited because of the noniodized salt content.

Zinc. Zinc is critical for growth and development, and requirements rise during pregnancy. A zinc-deficient diet does not result in effective mobilization of zinc stored in the maternal skeletal muscle and bone; therefore a compromised zinc status develops rapidly. Zinc is part of 100 enzymes related to the metabolism of macronutrients (Hovdenak and Haram, 2012). It provides a structural function in many tissues, including some proteins involved in gene expression. Deficiency is highly teratogenic, leading to congenital malformations, including anencephaly and possibly oral clefts. Even a mild zinc deficiency may lead to impaired fetal growth and brain development, as well as impaired immune function. Women with untreated low zinc levels associated with acrodermatitis enteropathica have increased risk of miscarriage, fetal growth restriction, hypertension, preeclampsia, preterm delivery, and intrapartum hemorrhage.

Zinc is widely available and good sources include red meat, seafood, whole grains, and some fortified breakfast cereals (see Appendix 53). Extra supplementation exceeding that found in prenatal vitamins usually is not required but may be necessary for women with gastrointestinal disorders that affect absorption. Overt deficiency is rare in the United States, but rates are higher where the main staple foods are high in phytates (i.e., the unrefined cereals), and women following a vegetarian diet may experience low zinc bioavailability. High levels of iron supplementation may inhibit zinc absorption if both are taken without food (Kaiser and Campbell, 2014).

Pregnancy Weight Gain Recommendations

General Weight Gain Recommendations

With a singleton gestation, less than half of the total weight gain of a normal-weight pregnant woman resides in the fetus, placenta, and amniotic fluid. The remainder is in maternal reproductive tissues (breast tissues and uterus), interstitial fluid, blood volume, and maternal adipose tissue. Increased subcutaneous fat in the abdomen, back, and upper thigh serves as an energy reserve for pregnancy and lactation. The normal distribution of weight is illustrated in Figure 15-2.

Recommended weight gains to support a healthy pregnancy vary by prepregnant BMI and are summarized in Table 15-11. Designed for women living in healthy environments, the Institute of Medicine (IOM) balanced the risk of adverse birth outcomes with the mother's risk of postpartum weight retention. Insufficient gain, especially if also associated with prepregnant

FIGURE 15-2 Distribution of weight gain during pregnancy.

TABLE 15-11 U.S. Institute of Medicine (IOM) Prenatal Weight Gain Goals

Prepregnant Weight Category	Total Singleton Weight Gain	Rates of Gain in 2 nd and 3 rd Trimesters for Singletons* Mean/week (Range)	Total Twins Weight Gain (Provisional guidelines)
Underweight BMI < 18.5	28-40 lb [12.5-18 kg]	1 lb (1-1.3) [0.51 kg (0.44-0.58)]	Insufficient information available for guideline
Normal weight BMI 18.5-24.9	25-35 lb [11.5-16 kg]	1 lb (0.8-1) [0.42 kg (0.35-0.50)]	37-54 lb [17-25 kg]
Overweight BMI 25.0-29.9	15-25 lb [7-11.5 kg]	0.6 lb (0.5-0.7) [0.28 kg (0.23-0.33)]	31-50 lb [14-23 kg]
Obese BMI ≥ 30.0	11-20 lb [5-9 kg]	0.5 lb (0.4-0.6) [0.22 kg (0.17-0.27)]	25-42 lb [11-19 kg]

* Calculations assume a first trimester gain for singleton pregnancy of 1-3 kg (2.2-6.6 lb) for women who are underweight, normal weight, or overweight and 0.5–2 kg (1.1-4.4 lb) for those who are in the obese category.

Adapted from Rasmussen KM et al: Recommendations for weight gain during pregnancy in the context of the obesity epidemic, *Obstet Gynecol* 116:1191, 2010; Rasmussen KM, Yaktine AL: *Weight gain during pregnancy: reexamining the guidelines*, Washington, DC, 2009, IOM, NRC.

underweight, is associated with increased risk of SGA babies and spontaneous preterm deliveries. Excessive gain often results in LGA babies, with increased risk during delivery. Excessive gain is also the strongest predictor of later maternal obesity. Outcomes are best when women gain within the recommended ranges. However, less than one third of pregnant women do so, and most (especially those who are overweight or obese) gain too much, although a significant proportion of underweight women gain too little (Siega-Riz and Gray, 2013).

Height and, ideally, prepregnant weight should be measured, not asked, to determine prepregnant BMI. Women need guidance on target weight gains. One third try to keep the same weight or even lose weight during pregnancy (Rasmussen and Yaktine, 2009). Weight gain should be monitored as a way to evaluate progress and to intervene when necessary. The pattern of weight gain is also important; higher rates of weight gain in the second trimester are associated with higher birth weight, especially among women whose prepregnant BMI is less than 26 (Rasmussen and Yaktine, 2009). Maternal weight gain plotted on the appropriate grid is an effective teaching tool. See Figure 15-3 for weight gain grids for singleton pregnancies.

Weight loss during pregnancy should be discouraged. There are no intervention studies documenting benefit (Furber et al, 2013). As adipose tissue is mobilized, semivolatile organic compounds may be released (see *Clinical Insight: What's in That Fat When You Lose It* in Chapter 21). Because of the accelerated starvation characteristic of pregnancy, women are more likely to develop ketonemia and ketonuria after a 12- to 18-hour fast, with ketone levels higher than in nonpregnant women. Although the fetus has a limited ability to metabolize ketones, these compounds may adversely affect fetal brain development (Rasmussen and Yaktine, 2009). In addition, mobilized protein stores, increased free fatty acids, urinary nitrogen excretion, and lower plasma glucose, insulin, and gluconeogenic amino acids have been seen, resulting in increased risk of IUGR and preterm birth (Furber et al, 2013; Rasmussen et al, 2010).

The IOM guidelines are based on observational, not interventional, data. Thus many countries do not advocate either a particular weight gain or even routine weighing after determining the prepregnant BMI status. Although there are many small intervention studies, large trials are not yet available. It also must be noted that it is unclear whether maternal weight gain itself is a critical variable or whether it is a marker for

nutritional status. Even so, tracking weight gain is useful and when variation from normal patterns is noted, more questions should be asked.

Obesity Weight Gain Recommendations

Pregravid obesity is described as class I (BMI 30 to 34.9), class II (BMI 35 to 39.9), and class III (BMI at least 40). The IOM's weight gain recommendation of 11 to 20 pounds does not distinguish between these classes (Rasmussen and Yaktine, 2009). Optimal gestational weight gains for these groups are not yet known and research continues, with some evidence that lower gains, or even loss, can be managed successfully as individuals may balance intakes well enough to avoid ketonemia (Rasmussen et al, 2010). Overweight, and therefore overnutrition, is not the same as good quality nutrition and, in fact, obesity is associated with lower serum levels of carotenoids; vitamins C, D, B₆, K; folate; iron; and selenium (Saltzman and Karl, 2013). Individual guidance and clinical judgment, including optimizing nutrient intakes and encouraging exercise, is necessary, and fetal growth must be monitored (ACOG, 2013a). Although weight gain targets may be too high for some women, some evidence suggests that the risk of preterm delivery, IUGR, and perinatal mortality all increase if the weight gain is too restrictive; long-term effects also must be considered.

Postbariatric Surgery. The prevalence of obesity has resulted in an increase in bariatric surgeries. Although prepregnancy weight loss may improve fertility, it has the potential to provide a suboptimal uterine environment for the developing fetus. Pregnancy should be delayed for at least 12 to 18 months (Mechanick et al, 2013; Usadi and Legro, 2012), and adequate nutrient supplementation is essential. Which nutrients are most likely to be deficient will be determined by the type of surgery and the nutritional status since that surgery (see Chapter 21). ACOG recommends evaluating iron, calcium, vitamins B₁₂, D, and folate, and supplementing if necessary (ACOG, 2013a). Other deficiencies, although potentially severe, are more sporadic (Saltzman and Karl, 2013). If anemia does not respond to treatment, vitamin B₁₂, folate, protein, copper, selenium, and zinc should be assessed (Mechanick et al, 2013).

An optimum nutrient prescription and caloric requirement for pregnant women after bariatric surgery has not been determined and must be individualized. These women may have more difficulty eating enough if they have had a restrictive procedure and the gastric band may have to be adjusted. Those with bypass procedures may have malabsorptive problems.

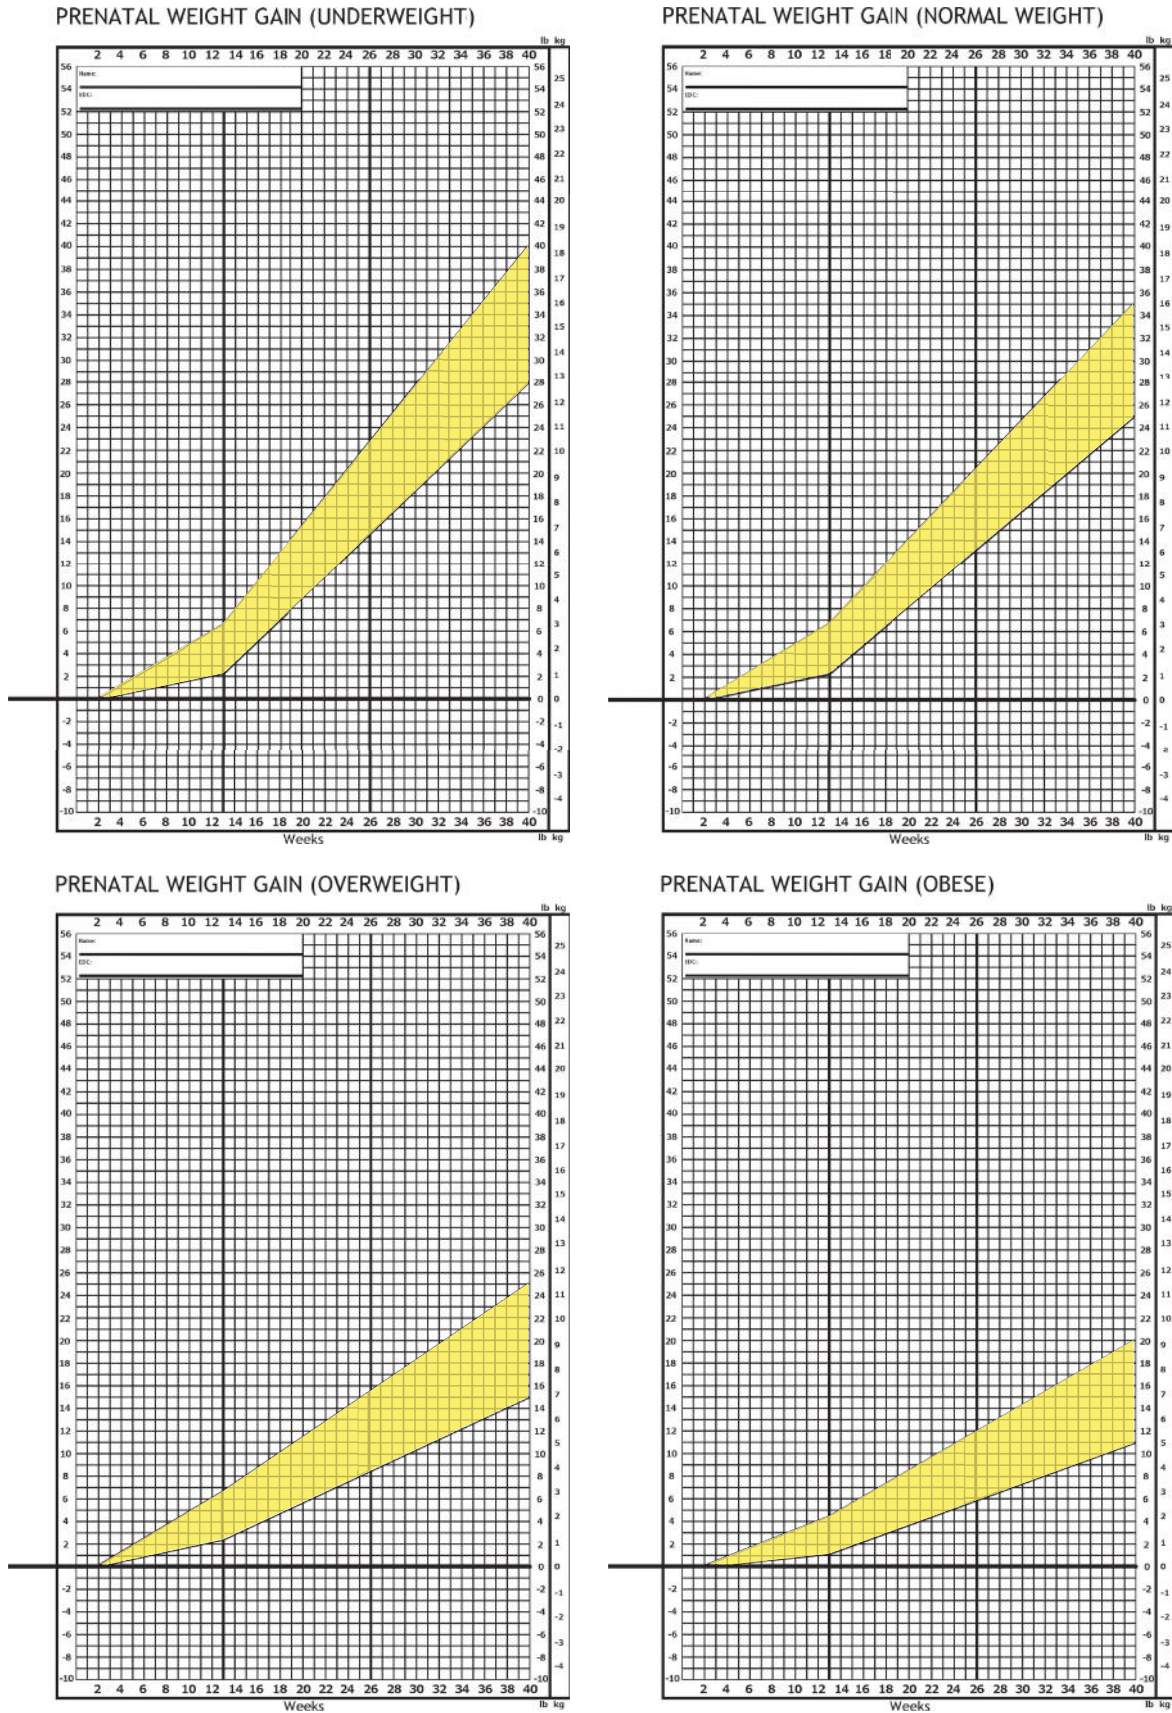

FIGURE 15-3 Desirable weight gain during singleton pregnancy for a woman whose prepregnant weight (BMI) category is a) underweight, b) normal weight, c) overweight, or d) obese. (Adapted from Rasmussen KM et al (2010): Recommendations for weight gain during pregnancy in the context of the obesity epidemic. *Obstetrics & Gynecology* 116:1191.)

Those experiencing dumping syndrome may require glucose monitoring rather than trying to use the glucola to diagnose gestational diabetes. In addition, women with a history of bariatric surgery may be less willing to gain enough weight after having invested so much in losing it, so guidance with reassurance and support may be necessary (see Chapter 21).

Women who have had bariatric surgery often have successful pregnancy outcomes, with lower rates of gestational diabetes, hypertension, preeclampsia, and macrosomia than seen among obese women who have not undergone bariatric surgery (ACOG, 2013a). However, they also may have higher risk of fetal growth restriction, shorter gestational length, and possibly increased rates of perinatal mortality (Johansson et al, 2015). If women have had Roux-en-Y or biliopancreatic diversion surgery, with or without the duodenal switch, they also have higher risk of fetal malformations (Pelizzo et al, 2014).

Multiple Births

The incidence of multiple births in the United States is rising because of the increased use of fertility drugs and ART, age at conception, and obesity rates among pregnant women. Multifetal gestations cause significant maternal physiologic adaptations beyond the usual pregnancy changes, including increased plasma volume, metabolic rate, and increased insulin resistance (Goodnight and Newman, 2009).

These infants have a greater risk of preterm delivery with accompanying IUGR or LBW than do singletons. Adequate maternal weight gain, especially early in pregnancy, has been shown to be particularly important; a rule of thumb is to target a 24-pound gain by 24 weeks for twins (Goodnight and Newman, 2009). The IOM guidelines for twins are provisional but are now delineated by prepregnant BMI (see Table 15-11).

The optimal nutrient requirements for twins and higher-order multiples are not yet known but are certainly higher than for singleton pregnancies. One nutritional plan for twins is summarized in Table 15-12 but may have to include iodine and choline as well; newer evidence cautions against high doses of vitamins C and E (see Hypertension and nutrient sections) (ACOG, 2013e; Hovdenak and Haram, 2012). Because of a greater need for nutritional density in the diet, it is recommended that only 40% of calories come from carbohydrate, with 20% from protein, and 40% from fat (Goodnight and Newman, 2009).

For those pregnant with triplets or other higher-order multiples, there is limited information available, but best practice advice does exist (Luke and Eberlein, 2011; Luke, 2015). Mean gestational weight gain for triplets is 45 to 51 pounds (20.5 to 23 kg) at 32 to 34 weeks; for quadruplets, it is 46 to 68 pounds (20.8 to 31 kg) at 31 to 32 weeks (Rasmussen and Yaktine, 2009).

Adolescent Pregnancy

Public health initiatives have helped reduce the incidence of teen pregnancies overall, but it continues as a major problem in the United States among some minority groups (CDC, 2014b). Risk factors for poor outcome in pregnant adolescents are listed in Box 15-5.

Increased rates of LBW and preterm delivery are especially common among those who are very young and underweight, for whom there may be competition for nutrients between the mother and the fetus (see Chapter 18). Poor outcomes are also common in obese teens who become pregnant. Many teens enter pregnancy with suboptimal nutritional status, especially

TABLE 15-12 Nutrient Recommendations for Women Pregnant with Twins

Nutrient	Twins	Comments
Calories	Underweight: 4000 kcal Normal: 3000-3500 kcal Overweight: 3250 kcal Obese: 2700-3000 kcal	Estimated needs are 40-45 kcal/kg. Monitor weight gain and modify calories to meet target weight goals.
Protein	Underweight: 200 g Normal: 175 g Overweight: 163 g Obese: 150 g	Target 20% of calories from protein. Choose concentrated sources as space becomes limiting.
Carbohydrate	Underweight: 400 g Normal: 350 g Overweight: 325 g Obese: 300 g	Encourage low glycemic choices.
Fat	Underweight: 178 g Normal: 156 g Overweight: 144 g Obese: 133 g	Encourage healthy fats.
Vitamin D	1000 IU/day	Assessment of maternal levels should be considered in first and early third trimesters to allow alterations in the supplemental dose, especially important if the mother is on bed rest.
Vitamin C	500-1000 mg/day	This is half of the UL of 1800-2000 mg/day. See more recent cautions.
Vitamin E	400 mg/day	This is half of the UL of 800-1000 mg/day. See more recent cautions.
Zinc	15 mg/day (T1); 30mg/day (T2-3)	Diet alone may not be enough. Supplementation may be required.
Iron	30 mg/day as part of 1 multivitamin/day (T1), 2 multivitamins/day (T2 and T3)	Twin gestation requirement is likely double that of singletons. Higher intakes may be needed for treatment of anemia.
Folic acid	1000 mcg/day	
Calcium	1500 mg/day (T1); 2500 mg (T2-3)	UL: 2500 mg/day, consider limiting if there is a history of kidney stones.
Magnesium	400 mg/day (T1); 800 mg/day (T2-3)	
DHA + EPA	300-500 mg/day	

Adapted from Goodnight W, Newman R: Optimal nutrition for improved twin pregnancy outcome, *Obstet Gynecol* 114:1121, 2009.

DHA, Docosahexaenoic acid; EPA, eicosapentaenoic acid; T, trimester; UL, tolerable upper limit.

for iron, calcium, and folic acid. In one study, women in the United States who gave birth as teens were more likely to be overweight or obese as adults (Chang et al, 2013).

Improved dietary practices can be one of the most important factors for the pregnant teen. In counseling young mothers, the nutrition professional must be aware of the teen's psychosocial and literacy levels, her economic status and level of independence, as well as her cultural environment, all of which may influence her food choices.

BOX 15-5 Risk Factors for Poor Pregnancy Outcome in Teenagers

- Young maternal age
- Pregnancy less than 2 years after onset of menarche
- Poor nutrition and low prepregnancy weight
- Preexisting anemia
- Inappropriate weight gain (too low and too high)
- Obesity
- Sexually transmitted disease or infection
- Substance abuse: smoking, drinking, and drugs
- Poverty
- Lack of social support
- Low educational level
- Rapid repeat pregnancies
- Lack of access to age-appropriate prenatal care
- Late entry into the health system
- Unmarried status
- Unstable housing, shelter living, homelessness

Complications and Nutritional Implications

Many of the following complications follow from the normal hormonal changes during the pregnancy. These changes cause the gastrointestinal transit time to slow so that more nutrients are available to the fetus. However, that causes more nausea and vomiting, constipation, and heartburn. Although normal, these complications can be uncomfortable and potentially dangerous but can be managed.

Constipation and Hemorrhoids

Pregnant women become constipated if they fail to consume adequate water and fiber. Women who are treated with ondansetron for nausea and vomiting often experience severe constipation. Compression of the pelvic floor by the fetus, as well as straining during stooling (Valsalva), increases the risk for hemorrhoids. Increased consumption of fluids and fiber-rich foods (see Appendix 41), including dried fruits (especially prunes), usually controls these problems. Some women also may require a bulking type of stool softener.

Cravings, Aversions, and Pica

Most women change their diets during their pregnancies as a result of medical advice, cultural beliefs, or changes in food preference and appetite. Food avoidances may not reflect a mother's conscious choice but may include smell aversity caused by enhanced perception of aromas, a heightened gag response, getting ill while eating or smelling a particular food, or altered gastric comfort.

Cravings and Aversions. Cravings and aversions are powerful urges toward or away from foods, including foods about which women experience no unusual attitudes when not pregnant. In the United States, the most commonly craved foods are sweets and dairy products, or foods that can be eaten quickly. The most common aversions reported are to alcohol, coffee, other caffeinated drinks, and meats. However, cravings and aversions are not limited to any particular food or food groups, and they vary widely across cultures.

Pica. Consumption of nonfood substances (**pica**) during pregnancy most often involves **geophagia** (consumption of dirt or clay), **amylophagia** (laundry starch or corn starch), or **pagophagia** (ice). Other substances include paper, burnt matches, stones or gravel, charcoal, bleach, cigarette ashes, baking soda, soap, tires, and coffee grounds. Although some of the common

substances are of little concern, others are dangerous to the mother. The local poison control center can give guidance on which require immediate intervention.

Pica is common in pregnancy, and the incidence of pica in the United States is estimated to be 14% to 44%, with wide variability (**Scolari Childress and Myles, 2013**). Pica is not limited to any one geographic area, race, culture, or social status, but there are cultural components related to the substances chosen and the acceptability of disclosure. Preferred substances often are imported from home countries, including dirt or clay and blocks of magnesium carbonate.

The cause of pica is poorly understood. One theory suggests that pica relieves nausea and vomiting, although pica often appears later in pregnancy when nausea and vomiting are not so prevalent. One hypothesis is that it is due to a deficiency of an essential nutrient, most often iron, but zinc, calcium, and potassium also have been mentioned (**Cardwell, 2013**). Although it is hypothesized that the craving causes one to eat the nonfood substance that contains the missing nutrients, that is seldom the case. Pica also can be a craving for smell or texture as well as taste. Taste perceptions often change, but whether that is associated with lower zinc levels is not known.

Malnutrition can be a consequence of pica when nonfood substances displace essential nutrients in the diet. Starch in excessive amounts contributes to obesity and can negatively affect glucose control. Large intakes of baking soda can raise blood pressure and extreme doses (1 box/day) have caused rhabdomyolysis and cardiomyopathy (**Scolari Childress and Myles, 2013**). Excessive intakes of baking powder can mimic preeclampsia. Substances may contain toxic compounds or heavy metals, including lead, parasites, or other pathogens. The absorption of iron or other minerals may be disrupted. Excessive geophagia can result in intestinal obstruction or perforation (**Young, 2011**).

Recommending stopping a pica often fails, either because of the physiologic drive or the cultural perception that not complying with the craving will cause harm to the fetus. Rather than insisting on cessation, resulting only in less willingness to admit the pica, a more productive approach is to offer a better alternative. Allowing the mother to continue to smell the wet dirt, but trading its consumption for a burned tortilla, toast, or jicama often is successful. Pica often is associated with iron deficiency anemia, but whether the pica is a result, a cause, or a marker of other concurrent deficiencies is unknown. However, treatment with very high iron foods often decreases the cravings.

Diabetes Mellitus

Gestational diabetes mellitus (GDM), carbohydrate intolerance with onset or recognition during pregnancy, encompasses two distinct groups; those who have unrecognized preexisting diabetes and those for whom the pregnancy precipitates the carbohydrate intolerance (**ACOG, 2013c**).

Women with risk factors for type 2 diabetes (including but not limited to a history of GDM, known impaired glucose metabolism, and BMI ≥ 30) should be screened early in pregnancy using standard diagnostic criteria (**ACOG, 2013c; ADA, 2014**; see Chapter 30). According to the American Diabetes Association (ADA), those women identified with diabetes in the first trimester should be given a diagnosis of overt diabetes rather than GDM (**ADA, 2014**).

Women identified by early screening, as well as those with known preexisting diabetes (either type 1 or 2), should be

referred to a Certified Diabetes Educator (CDE) and/or a diabetes management team. Fetuses of mothers with poorly controlled diabetes at conception are at risk for multiple congenital anomalies.

As pregnancy progresses and insulin resistance increases, GDM resulting from the pregnancy may appear. GDM rates in the United States are 5% to 6% of the prenatal population (NIH, 2013), but the prevalence can be much greater in high-risk groups, including women with a high BMI, advanced maternal age, and personal and family history (first-degree relative with diabetes). Rates are higher among African American, Asian, Hispanic, Native American, and Pacific Islander women compared with non-Hispanic white women (ACOG, 2013c).

A diagnosis of GDM is associated with increased risk of gestational hypertension and of preeclampsia, as well as increased risk of type 2 diabetes and cardiovascular disease later in life. Fetal implications include hyperinsulinemia, **macrosomia** (often defined as a baby weighing more than 4000 g), and, therefore, increased risk of delivery complications, including shoulder dystocia and cesarean delivery. The neonate is more likely to require admission to NICU and to experience respiratory distress syndrome and metabolic complications, including hyperbilirubinemia and hypoglycemia. Infant iron levels may be lower because of overgrowth and therefore increased demand (Monk et al, 2013); other nutrients also may be low. Fetal programming, with increased longterm risk of obesity and type 2 diabetes, is also of concern.

Although some practitioners believe that GDM may represent the early stages of type 2 diabetes, others feel that women should not be labeled at all with a GDM diagnosis. However, treatment for GDM is merited, because it lowers the risk by 40% for gestational hypertensive disorders, reduces the risk of macrosomia, and therefore reduces the risk of shoulder dystocia from 3.5% to 1.5% (NIH, 2013).

The diagnostic criteria for GDM are controversial. Historically, the United States and other countries have used a two-step process, whereas the World Health Organization (WHO) has advocated a one-step approach. Cutoffs and testing protocols vary. Table 15-13 summarizes current practice. Recently

the International Association of the Diabetes and Pregnancy Study Groups (IADPSG) advocated for a universal one-step approach developed from the Hyperglycemia and Adverse Pregnancy Outcomes (HAPO) trials. The HAPO study was the first to correlate glucose values with pregnancy outcomes; all other protocols were designed to identify women at risk of developing type 2 diabetes later in life. Because only one elevated value is diagnostic, using the more liberal IADPSG criteria results in a twofold to threefold increase in the number of people defined as having GDM, arriving at a national prevalence of 15% to 20% (NIH, 2013).

Because of the increased cost to the medical system and the patient, increased patient stress with likely increased interventions, combined with concern that treatment may not be as beneficial for those at the lower glucose levels, a National Institutes of Health (NIH) consensus committee concluded there is currently insufficient evidence to recommend changing to the IADPSG approach (NIH, 2013).

The ADA and ACOG recommend screening all pregnant women for GDM (unless already identified with diabetes) at 24 to 28 weeks (ACOG, 2013c; ADA, 2014). Only those with an abnormal result on the 1-hour screen receive the 3-hour diagnostic test. ACOG recommends that the choice of a screening cutpoint and the choice of diagnostic tests (using the Carpenter and Coustan criteria if testing serum or plasma, or the National Diabetes Data Group criteria if testing plasma), be guided by local community GDM prevalence rates (ACOG, 2013c).

As with preexisting diabetes, those women with GDM should be followed carefully during pregnancy and managed by a diabetes team that includes a CDE. See Chapter 30 for diet and exercise recommendations, including target glucose values. Medications may be necessary to manage blood sugars; insulin and some oral hypoglycemic agents (e.g., metformin and glyburide) can be used. Long-term use of metformin is associated with decreased vitamin B₁₂ levels, but its use only in late pregnancy has not been shown to be problematic for maintenance of normal B₁₂ levels (Gatford et al, 2013).

Women with GDM should be screened for persistent diabetes at 6 to 12 weeks postpartum, and at least every 3 years for

TABLE 15-13 Screening and Diagnosis of Gestational Diabetes Mellitus (GDM) at 24-28 Weeks' Gestation: Blood Glucose Thresholds and Testing Protocols

Approach	Fasting mg/dl	1-hour mg/dl	2-hour mg/dl	3-hour mg/dl	Source
Two Step: universal screening; only those \geq cutoff need diagnostic test					
Screening: (nonfasting) 50 g glucose load		130, 135, or 140			
Diagnosis: (fasting)					
100 g load, 2 values \geq	95	180	155	140	Carpenter and Coustan
100 g load, 2 values \geq	105	190	165	145	National Diabetes Data Group
75 g load, 1 value \geq	95	191	160		Canadian Diabetes Association
One Step: universal testing					
Diagnosis: (fasting)					
75 g load, 1 value \geq	92-125 *	180	153-199 *		World Health Organization (WHO)**
75 g load, 1 value \geq	92	180	153		International Association of the Diabetes and Pregnancy Study Groups

* Values above these cutpoints are considered diagnostic of diabetes mellitus in pregnancy rather than GDM, as is a random plasma value of \geq 200 mg/dl with diabetes symptoms.

** Considered diagnostic of GDM when found any time during the pregnancy.

Adapted from National Institutes of Health consensus development conference statement: diagnosing gestational diabetes mellitus, March 4-6, 2013, *Obstet Gynecol* 122:358, 2013; World Health Organization: *Diagnostic Criteria and Classification of Hyperglycaemia First Detected in Pregnancy* (website): http://apps.who.int/iris/bitstream/10665/85975/1/WHO_NMH_MND_13.2_eng.pdf?ua=1. Accessed July 2015.

diabetes or prediabetes, using nonpregnancy diagnostic criteria (ADA, 2014; see Chapter 30).

Eating Disorders

The rates of eating disorders during pregnancy are 1% for anorexia nervosa and slightly more for bulimia, with the prevalence likely underestimated (Cardwell, 2013). Anorexia and bulimia are associated with increased risk of miscarriage, birth defects, hyperemesis, IUGR, and micronutrient deficiencies, as well as postpartum depression and impaired infant bonding. For those with binge eating, excessive weight gain, macrosomia, and increased cesarean rates are seen. Those that purge may have caries or fractured teeth severe enough that they cannot chew meat.

The effect of pregnancy on the individual with an eating disorder varies, but 70% may show improvement, especially with purging behaviors (Harris, 2010). However, symptoms often are exacerbated after delivery; pregnancy will not cure the eating disorder. In fact, in some cases the newborn is seen as “too fat,” to the point of restricting food, administering suppositories or enemas, or inducing vomiting. A team approach to treating the mom is helpful in those cases.

For the woman with an eating disorder, pregnancy may be particularly frightening because of the loss of control and disturbed body image. Anorexia can be diagnosed during pregnancy. Substance abuse, as well as the use of laxatives or diet pills, may be coping mechanisms; insulin has been used as a purging mechanism. Women may fear being weighed and may need reassurance that the nausea and vomiting of pregnancy is not necessarily a resurgence of purging. Fatigue, irritability, and depression may be due to starvation. These pregnant women should be treated with particular care, including focusing on healthy eating for optimal fetal growth and development (see Chapter 22).

Edema and Leg Cramps

Mild physiologic edema is usually present in the third trimester and should not be confused with the pathologic, generalized edema associated with preeclampsia. Normal edema in the lower extremities is caused by the pressure of the enlarging uterus on the vena cava, obstructing the return of blood flow to the heart. When a woman reclines on her side, the mechanical effect is removed, and extravascular fluid is mobilized and eventually eliminated by increased urine output. No dietary intervention is required, assuming her protein intake is adequate. If, however, her urine is dark and/or she has swelling in her hands, increased fluid intake is recommended.

Increased fluid intake also is recommended for leg cramps. Women should be advised to stretch with their toes pointing back toward their bodies rather than away from them. The literature is conflicting about the benefit of magnesium supplementation for treatment of pregnancy-related leg cramps (Garrison et al, 2012). Caution is advised against large intakes of supplements.

Heartburn

Gastric esophageal reflux is common during the latter part of pregnancy and often occurs at night. The pressure of the enlarged uterus on the intestines and stomach, along with the relaxation of the esophageal sphincter, may result in regurgitation of stomach contents into the esophagus. Relief measures may include eating smaller meals, limiting caffeine, carbonated beverages, tomatoes, citrus, fat, and spicy foods, and staying upright for at least 3 hours after a meal, but

interventions have not been evaluated for effectiveness (Kaiser and Campbell, 2014). Using more pillows at night also may help (see Chapter 27).

Although heartburn medicines can be used, they are not benign and use should be limited. Taking excessive calcium carbonate can lead to life-threatening milk-alkali syndrome (hypercalcemia, renal sufficiency, and metabolic alkalosis). The UL of 2500 mg of elemental calcium (food plus supplements) should be observed. If a couple of calcium carbonate tablets (two regular strength Tums contain 400 mg calcium; two ultra-strength tablets provide 800 mg) do not resolve the heartburn, switching to those containing magnesium may be beneficial. Proton pump inhibitors may reduce the bioavailability of many nutrients, including vitamins C, B₁₂, and nonheme iron (see Chapter 8). The use of antacids also potentially can increase the risk of food allergies by impeding gastric protein digestion, but whether that translates into a higher risk of food allergy or asthma for the child is unclear.

Hypertension

Hypertension observed during pregnancy may be preexisting or observed for the first time. Elevated blood pressure that is first diagnosed in pregnancy may be relatively benign. However, a rise in blood pressure, accompanied by other changes listed in this chapter, can be a sign that preeclampsia is developing, a progressive, systemic problem with high morbidity and mortality for mother and fetus. Although delivery resolves the problem for most, some women develop hypertension after delivery.

Chronic hypertension predates pregnancy and is associated with fetal growth restriction. Avoidance of severe hypertension is a goal, but the optimal blood pressure during pregnancy for someone with preexisting hypertension is unclear (see Chapter 33). Appropriate weight gain, a modified DASH diet (see Appendix 33), and regular aerobic exercise for those without complications are recommended. Although excessive sodium should be reduced, intake should not be less than 2300 mg/day (ACOG, 2013e). Calcium supplementation for those with low calcium intakes may be helpful. Some antihypertensive medications can be used during pregnancy but may have to be modified during breastfeeding.

Gestational hypertension is defined as elevated blood pressure that appears after 20 weeks, but without proteinuria or other findings. Some women (at least 25%) go on to develop preeclampsia; others have no risk except the elevated blood pressure (ACOG, 2013e). They are treated the same as those with chronic hypertension and monitored for worsening of symptoms. Gestational hypertension may predict increased risk for future hypertension. Optimal periconceptual nutrition, including focus on folate, sodium, calcium, potassium, iron, copper, and zinc intakes, is important (Tande et al, 2013).

Some women who develop hypertension during pregnancy develop preeclampsia. Risk factors include women who are primiparous, have a personal or family history of preeclampsia, chronic hypertension, obesity, type 1 or 2 diabetes, chronic renal disease, history of thrombophilia, systemic lupus erythematosus, multifetal pregnancy, IVF, and maternal age of more than 40 years (ACOG, 2013e). Paternal factors also likely play a role; risk increases with advanced paternal age, paternal obesity, and family history of early-onset CVD. Risk of preeclampsia is less likely in subsequent pregnancies with the same partner than when the mother is pregnant with a new partner. Paternal genes

also may be important; increased risk for preeclampsia is seen if the man has fathered a preeclamptic pregnancy or if he was born of a preeclamptic pregnancy (Dekker et al, 2011). Maternal smoking reduces the risk by 35% (ACOG, 2013e), but if preeclampsia occurs, the severity increases (Trogstad et al, 2011).

Preeclampsia involves dysfunction of multiple organ systems. It is dynamic, progressive, and once evident, is not reversible and delivery is needed because it is potentially fatal for mother and baby. Growth restriction is common and babies are often also premature in an effort to avoid the mother progressing to eclampsia (new onset grand mal seizures) or **HELLP syndrome** (hemolysis, elevated liver enzymes, and low platelets), which have high rates of maternal morbidity and mortality. Those women with superimposed preeclampsia onto chronic hypertension (13% to 40% of women) have much worse consequences (ACOG, 2013e). Women with preeclampsia that develops near term have double the risk of CVD later in life; the risk of CVD is nearly 10-fold for those who must be delivered at less than 34 weeks because of preeclampsia (Roberts and Bell, 2013).

Preeclampsia has been defined by elevated blood pressure and proteinuria, but newer guidelines now recommend not waiting for the proteinuria to appear. Box 15-6 summarizes diagnostic criteria designed to facilitate earlier diagnosis and therefore earlier treatment.

The causes of preeclampsia are under intense investigation. It appears to be a two-stage process, with a poorly perfused placenta (from failed remodeling of the maternal spiral arteries) being the root cause (ACOG, 2013e). Reduced perfusion and increased velocity of blood perfusing the intervillous spaces alters placental function and leads to maternal disease through oxidative and endoplasmic reticulum stress and inflammation,

as well as modified endothelial function and angiogenesis. The second-stage, called *maternal syndrome*, is a cascade of events; what links the hypoxic placenta and the maternal syndrome is unclear and possibly involves oxidative stress (Roberts and Bell, 2013). The hypertension and proteinuria are only a small part of the syndrome; reduced perfusion of any organ in the body can lead to hemorrhage and necrosis. Not all women with inadequate placental perfusion develop preeclampsia; a woman's underlying disease (e.g., diabetes, hypertension), lifestyle (e.g., obesity, activity, sleep), genetics, and environmental conditions (e.g., air pollution) may affect the maternal response (Roberts and Bell, 2013). The inflammatory response is accentuated in preeclampsia. Predictive tests are being studied but are not ready for clinical use (ACOG, 2013e). It is now thought that preeclampsia is actually a syndrome of many diseases with subsets of pathophysiology and varied contributions of maternal and placental factors (Roberts and Bell, 2013; Trogstad et al, 2011).

Prevention of preeclampsia has not yet been effective, although daily low-dose aspirin may be beneficial (ACOG, 2013e). Vitamin C and E supplements do not prevent occurrence of preeclampsia or adverse outcomes and may be associated with increased risk of gestational hypertension and LBW (ACOG, 2013e; Hovdenak and Haram, 2012). Calcium supplementation may help reduce symptom severity if a mother's baseline calcium intake has been less than 600 mg/day (ACOG, 2013e). There is insufficient evidence to provide guidance on fish oil, garlic, or vitamin D supplementation. Protein and calorie restriction for obese women does not reduce the risk of either gestational hypertension or preeclampsia and may increase the risk of IUGR. Neither bed rest nor salt restriction appear to reduce risk, but the trials may have been too small. Diuretics are not recommended. Moderate exercise (30 minutes/day) is recommended as during normal pregnancy, but it is unclear whether it can help reverse the endothelial dysfunction and prevent adverse pregnancy outcomes. Obesity, leptin, insulin, and free fatty acids appear to affect various stages of preeclampsia. Endothelial cell disorder from placental ischemia and hypoxia appear important. An imbalance of angiogenic factors, immune factors, inflammation, endothelin (a protein that constricts blood vessels), nitric oxide, oxidative and endoplasmic reticulum stress, the stress response gene hemeoxygenase and its catalytic product carbon monoxide, and the effect of statins are being studied.

For those women with a history of preeclampsia, weight loss, increased physical activity, and optimization of blood glucose levels and nutrient intakes preconceptionally are recommended. During pregnancy, helping women maintain a normal rate of weight gain, with optimal calcium intake and fruits and vegetables (antioxidants), may be beneficial. Encourage notifying the medical provider immediately if there is a sudden onset of face or hand swelling, persistent headaches, seeing spots or changes in eyesight, pain in the upper right quadrant or stomach, nausea and vomiting in the second half of pregnancy, rapid weight gain, or difficulty breathing.

Although delivery resolves the preeclampsia for most, a subset of women have a worsening of preeclampsia after delivery; others may first develop preeclampsia postpartum, including HELLP. Pain medications may have to be modified. Blood pressure may be labile for months but usually normalizes by 1 year postpartum. Postpartum hypertension may predict future chronic hypertension (ACOG, 2013e).

BOX 15-6 Preeclampsia Diagnostic Criteria

Elevated blood pressure Confirmed ≥ 160 or ≥ 110 for anyone (confirmed over a few minutes) or ≥ 140 or ≥ 90 after 20 weeks (confirmed over 4 hours) if previously normal	AND
Proteinuria ≥ 300 mg/24-hour urine collection, an extrapolated amount from a timed collection, protein/creatinine ratio ≥ 0.3 , or dipstick reading of 1+ if no other quantitative methods are available	
	OR
Elevated blood pressure Confirmed ≥ 160 or ≥ 110 for anyone (confirmed over a few minutes) or ≥ 140 or ≥ 90 after 20 weeks (confirmed over 4 hours) if previously normal	AND
New onset of any of the following: Thrombocytopenia: platelets $< 100,000$ /microliter Renal insufficiency: serum creatinine > 1.1 mg/dl or doubling of serum creatinine concentration in absence of other renal disease Impaired liver function: elevated liver transaminases to twice normal blood concentrations Pulmonary edema Cerebral or visual symptoms	

Adapted from American College of Obstetricians and Gynecologists (ACOG): *Hypertension in Pregnancy* (website): http://www.acog.org/Resources_And_Publications/Task_Force_and_Work_Group_Reports/Hypertension_in_Pregnancy, 2013e. Accessed December 2013.

Nausea and Vomiting, Hyperemesis Gravidarum, and Pylalism

Morning sickness, **nausea and vomiting in pregnancy (NVP)**, affects 50% to 90% of all pregnant women during the first trimester and usually resolves by 20 weeks' gestation (Clark et al, 2012). The cause of NVP is unclear but likely includes a genetic predisposition, combined with changes in human chorionic gonadotropin (hCG), estrogen, and progesterone levels. It may be mediated through the vestibuloocular reflex pathway (Fejzo et al, 2012). Those pregnant with a female fetus, multiple fetuses, or a molar pregnancy (sperm fertilizes an empty egg, resulting in no embryo but a placenta that develops into an abnormal mass of cells) are more likely to suffer with either NVP or hyperemesis gravidarum, as are those with hyperthyroid disorders, gastrointestinal disorders, preexisting diabetes, or a psychiatric illness. Maternal age more than 30 years and smoking are protective, but paternal smoking increases risk (Fejzo et al, 2012). NVP is associated with more favorable pregnancy outcomes, including fewer birth defects, reduced risk of miscarriage, preterm delivery or stillbirth, and greater birth weight.

Treatment for NVP involves managing the symptoms. Motion, loud noises, bright lights, and adverse climate conditions may trigger the nausea. Fortunately, most women with NVP are functional, able to work, do not lose weight, and are helped by simple dietary measures. Although many dietary and lifestyle recommendations have not been evaluated in the literature (Kaiser and Campbell, 2014), ginger (1 g/day divided in four doses) reduces the severity of symptoms of NVP better than vitamin B₆ but not the number of vomiting episodes (Medscape, 2014). However women on anticoagulation therapy, those with duodenal ulcers, or those at risk for intestinal obstruction should avoid ginger use. Other therapies suggested include eating crackers or potato chips, sucking on special lollipops, drinking red raspberry leaf tea, or wearing elastic or electronic wrist bands. Noise reduction, acupuncture, and hypnosis also can be helpful. Stopping the prenatal vitamins may help, but women should continue the supplemental folic acid if possible. Various anti-nausea medications are also available, with different modes of action.

Small, frequent snacks of carbohydrate foods reduce nausea for some, whereas protein foods may help others (Erick, 2014). Some women do not tolerate odors; some are bothered by hot foods and may prefer foods that are cold or at least at room temperature. Smelling lemons may help block noxious odors. Avoiding hunger by eating more frequently often helps, as does separating dry foods from liquids. Avoiding highly spiced foods or bitter foods is helpful for some; for others taste sensitivity decreases and strong flavors are craved. Women should avoid odors or situations that trigger symptoms and should eat whatever reduces the nausea sensation. Unfortunately, there is no cure-all. However, reminding the mother that this is a good sign for the pregnancy (i.e., the body is responding as it should), and that it *will* end, often reassures her and lowers the worry and stress, thus helping with the nausea.

When early pregnancy is characterized by excessive vomiting and weight loss (often >5% prepregnant weight), fluid and electrolyte imbalances can occur. Here, "morning sickness" becomes **hyperemesis gravidarum (HG)**, and prevalence is 0.3% to 3% of pregnancies (Clark et al, 2012). Risk factors are the same as those with NVP; recurrence risk is high, but not 100% (Fejzo et al, 2012).

Complications of HG vary but include poor fetal growth, preterm delivery, and increased risk of fetal loss with gestational malnutrition. Chondrodysplasia punctata resulting

from maternal vitamin K deficiency has been documented (Erick, 2014), as have permanent neurobehavioral and neuroendocrine abnormalities in exposed fetuses.

Maternal complications may include splenic avulsion (spleen is torn from its normal location, resulting in an emergency situation due to excessive bleeding), esophageal rupture, diaphragmatic tears, Valsalva retinopathy, acute renal failure, rhabdomyolysis, and delirium, as well as maternal posttraumatic stress syndrome and high risk of pregnancy termination when management of HG fails (Erick, 2014; Fejzo et al, 2012). Difficulty producing breastmilk and bonding also may have to be addressed.

Hospitalization for nutrition support and hydration usually is indicated for HG. Management goals include appropriate weight gain for pregnancy, correction of fluid and electrolyte deficits, avoidance of ketosis, control of HG symptoms, and achievement of nitrogen, vitamin, and mineral balance.

Because pregnancy is a condition of accelerated starvation, refeeding syndrome is seen often. Phosphorus, magnesium, and potassium must be evaluated daily because low levels may result in cardiac irregularities and respiratory failure (see Chapter 13). Another potentially serious complication is Wernicke's encephalopathy, with at least 63 cases being reported worldwide (Di Gangi et al, 2012). Caused by maternal vitamin deficiencies, including thiamin depletion, there is no consensus on early diagnosis, treatment, or prevention (see Chapter 29). The classic triad of nystagmus and ophthalmoplegia, mental status changes, and ataxia has been found in only 16% of known cases; women in 60% of cases displayed ocular symptoms, 83% had cerebellar changes, and 52% had memory impairment (Di Gangi et al, 2012). Symptoms are often vague and nonspecific, including headaches, fatigue, abdominal discomfort, irritability, and inability to concentrate. Wernicke's encephalopathy is associated with a 37% fetal loss rate and can progress to Korsakoff syndrome, with chronic maternal memory impairment (Clark et al, 2012). Thiamin blood levels are not useful for diagnosis; thiamin is given intravenously, and a presumptive diagnosis is made if the patient responds (Di Gangi et al, 2012). Correcting deficiencies of niacin and magnesium also may be helpful.

In HG, enteral nutrition has variable effectiveness. Women with severe emesis and retching have often dislodged tubes and are sometimes reluctant for replacement. During hospitalization, frequent nursing checks on tube placement add to sleep deprivation issues, which have not been fully appreciated (Erick, 2014). Parenteral nutrition is used if the GI tract is not accessible or if enteral nutrition is not tolerated.

Women historically have been reassured that even with HG the fetus is protected, using adequate birth weight as evidence. However, given the results of the Dutch famine studies, it is known that birth weight does not necessarily predict long-term health and that there are consequences of early malnutrition, even if later resolved (Erick, 2014; Roseboom et al, 2011). HG merits aggressive attention and treatment.

Some women develop **ptyalism gravidarum**, or excess saliva. Salivary output can be substantial, up to 500 to 1000 ml/day, and can be a source of lost electrolytes (Cardwell, 2013). It may interfere with swallowing, the sense of taste, sleep, and speech but does not appear dangerous for the fetus. Antihistamines may be helpful.

Oral Health

Good oral health is important throughout one's lifetime, including during pregnancy (see Chapter 25). Pregnant women

can receive dental care while pregnant, with some qualifications; the National Maternal and Child Oral Health Resource Center provides guidance. Although periodontal infection is associated with preterm birth and LBW, treatment does not appear to lower that risk. However, optimal maternal oral hygiene may lower the amount of *Streptococcus mutans* transmitted to the infant through sharing spoons or licking pacifiers, thus lowering or delaying the risk of childhood caries. During pregnancy, increased inflammatory response to dental plaque causes gingivae to swell and bleed more easily. Rinsing with salt water (1 tsp salt in 1 cup warm water) can help soothe the irritation. Erosion of enamel may occur with increased exposure to gastric acid from vomiting or gastric reflux. Rinsing with a baking soda solution (1 tsp baking soda in 1 cup water) may help neutralize the acid (ACOG, 2013b).

Preexisting Medical Conditions

Many women begin pregnancy with preexisting conditions that can complicate the pregnancy and modify nutrient requirements and appropriate food sources, as well as the supplementation that is necessary. As an example, celiac disease adversely affects fertility for men and women, and the absorption of nutrients often is impaired (Freeman, 2010). Women with celiac disease have increased risk of miscarriages and premature deliveries. Some prenatal supplements may contain gluten or wheat binders and should be avoided (see Chapter 28). Women with inflammatory bowel disease may have low serum vitamin B₁₂ levels if there is damage to the intestines. Women with HIV

infection may have higher energy needs and the interaction of nutrients with medications may have to be considered. Immigrant women may suffer with active malaria, which invades the placenta, or gastrointestinal parasites, which can decrease nutrient intakes and increase nutrient losses. Women with preexisting depression are at risk for poor pregnancy outcome and postpartum depression, putting the mother and her newborn at risk if she is unable to function optimally.

Women also may develop conditions resulting from the pregnancy that need particular attention, including HG, gallstones, or intrahepatic cholestasis of pregnancy. She also may be involved in a motor vehicle accident or other trauma that requires special care or even time in an ICU. In all cases, the needs of the mother and the fetus must remain paramount. Although guidance is available for some conditions, strong evidence-based recommendations are lacking.

Food Safety During Pregnancy

Although a pregnant woman is no more likely to be exposed to pathogens than a nonpregnant woman, she and her fetus may be at higher risk of suffering negative consequences from foodborne illnesses. In addition, because metabolically active tissues may be more susceptible to the action of toxins, along with the potential long-term effects of fetal exposure to suboptimal conditions, a pregnant woman often has questions regarding the safety of common foods and nonnutritive substances. Those food safety issues of most concern vary between populations. Box 15-7 summarizes general food safety guidelines.

BOX 15-7 General Food Safety Guidelines

Clean

- Wash hands thoroughly with soap and water, especially before and after handling food, and after using the bathroom, changing diapers, or handling pets. Do not touch mucous membranes after handling meats.
- Wash cutting boards, dishes, utensils, and countertops with hot water and soap. Washing utensils, including cutting boards, in the dishwasher is preferable.
- Rinse raw fruits and vegetables thoroughly under running water, even if the skin will not be eaten.
- Do not wash or rinse meat and poultry.

Separate to Avoid Cross Contamination

- Separate raw meat, poultry, and seafood from ready-to-eat foods when shopping, preparing, and storing foods.
- Use one cutting board for raw meat, poultry, and seafood and another one for fresh fruits and vegetables.
- Place cooked food on a clean plate. The unwashed plate that held raw meat, poultry, or seafood, may be contaminated.

Cook to Proper Temperature

- Cook foods thoroughly. Use a food thermometer to check the temperature. (Color is not a reliable indicator of meat doneness.) Examples include the following:
 - Beef, pork, veal, lamb large cuts (steaks, roasts, and chops): 145° F + 3-minute rest
 - Fish: 145° F
 - Beef, pork, veal, lamb ground meats: 160° F
 - Egg dishes: 160° F
 - Turkey, chicken, duck (whole animal, pieces, ground): 165° F

- Cook eggs until firm.
- Reheat leftovers to at least 165° F and sauces, gravies, and soups should be boiled.

Chill to Avoid the Danger Zone

- Refrigerator should register at 40° F or below and the freezer at 0° F. Check the temperature periodically with an appliance thermometer.
- Limit the time foods are in the danger zone, the range of temperatures at which bacteria can grow quickly, usually between 40° F and 140° F.
- Defrost (and marinate) foods in the refrigerator, not on the kitchen counter.
- Refrigerate or freeze perishables (foods that can spoil or become contaminated by bacteria if left unrefrigerated) promptly.
- Use ready-to-eat, perishable foods (dairy, meat, poultry, seafood, produce) as soon as possible.
- 2-hour rule: discard perishable foods left out at room temperature for more than 2 hours. If it is a hot day (more than 90° F), shorten the time to 1 hour.

Avoid High-Risk Foods

- Avoid unpasteurized milks, including goat milk, and foods made of unpasteurized milks. Even if soft cheeses are pasteurized, hard cheeses are safer.
- Avoid raw or undercooked meats, poultry, eggs, fish, or seafood.
- Avoid unpasteurized fruit or vegetable juices. Unpasteurized juice must be boiled (full rolling boil) for at least 1 minute.
- Avoid raw or undercooked sprouts, including alfalfa, clover, mung bean, and radish. Cooked sprouts are lower risk.
- Do not open bulging cans.
- Boil home-canned foods for 20 minutes.
- Pay attention to food recalls. This is not the time to gamble.

Adapted from Cox JT, Phelan ST: Food safety in pregnancy, part 1: putting risks into perspective, *Contemporary Ob/Gyn* 54:44, 2009a; United States Department of Health and Human Services (USDHHS): *Checklist Of Foods To Avoid During Pregnancy* (website): http://www.foodsafety.gov/poisoning/risk/pregnant/chklist_pregnancy.html, 2014. Accessed January 2014.

However, caution is advised to not overestimate the risk of food contamination in pregnancy or the amount of control that an individual has in lowering that risk. It is critical to avoid the impression that a healthy baby is guaranteed if parents do everything right and that the mother is to blame if anything goes wrong. In addition, it is becoming increasingly apparent that maternal psychological stress is also harmful to the pregnancy (see *Clinical Insight: Stress During Pregnancy*).

CLINICAL INSIGHT

Stress During Pregnancy

Prenatal psychological stress is associated with shorter gestations and lower birth weights. Stress also appears to interact with poor nutrition to negatively affect fetal neurocognitive development, especially the hippocampus and memory functioning, using the same mechanisms as infectious stress (Monk et al, 2013).

All nutrients are important for neuronal and glial cell growth and development. Stress alters the metabolism of many nutrients (protein, glucose, zinc, iron, choline, folate), but not others (LCPUFA, copper, iodine, vitamin A), and some nutrients (LCPUFA, protein, zinc, iron, choline) have a role in the stress response (Monk et al, 2013).

Distress can induce insulin resistance and proinflammatory cytokines, diverting amino acids to gluconeogenesis and energy production rather than protein production (Monk et al, 2013). Stress also raises the risk of hypertension, increasing uterine artery resistance and lowering nutrient delivery to the fetus (Monk et al, 2013). Risk of autism and schizophrenia may increase, but the timing of the insult may affect the response (Marques et al, 2013).

Maternal and fetal immune systems communicate bidirectionally, and the fetal immune system (innate and adaptive) can be disrupted with maternal stress, as well as by exposure to toxins and malnutrition. This disruption may be sufficient to affect a child's response to vaccines but there is no consensus on the timeframe of vulnerability or on the mechanisms (Marques et al, 2013).

When studying infant neurocognitive development, psychological stress and nutritional status must be studied together to examine their synergistic effects and optimal intervention strategies (Monk et al, 2013).

Often issues of psychological stress arise in the course of discussing food intake and weight gain. They would include, but are not limited to, catastrophic life events, verbal or physical abuse, unemployment, and food insecurity, as well as anxiety about the pregnancy itself. A referral to a mental health professional for evaluation and treatment is warranted (Kaiser and Campbell, 2014).

Alcohol

Abundant evidence from animal studies and human experience associates maternal alcohol consumption with teratogenicity. Features of **fetal alcohol syndrome (FAS)** include a specific pattern of abnormalities (see *Figure 15-4*). Alcohol has been shown to alter gene expression; changes involve proteins associated with central nervous system development, organ morphogenesis, immunologic responses, endocrine function, and skeletal, cardiovascular, and cartilage development.

Use of alcohol during pregnancy has been associated with an increased rate of miscarriage, placenta abruption, LBW, and cognitive compromise. Although there is individual variability, problems appear to be more severe with successive pregnancies, especially with bingeing, intoxication, and in older mothers. Drinking at least one drink per day is associated with a five-fold

FIGURE 15-4 Child presents with all three facial features that are diagnostic for fetal alcohol syndrome. (Copyright 2016, Susan Astley PhD, University of Washington.)

increased risk of LBW and two-fold risk of preterm delivery (Cox and Phelan, 2009b). The cognitive and behavioral deficits seen with moderate intake can affect later school performance. For lower intakes of alcohol there is less consistency in the negative findings, but the evidence is too weak to say that any level of alcohol intake is safe.

ACOG, the American Academy of Pediatrics (AAP), and the March of Dimes, recommend that alcohol not be used during pregnancy, because no safe threshold has been identified. Reduced-alcohol wines and beers do contain small amounts of alcohol and also are contraindicated. Despite the multiple warnings of fetal injury caused by alcohol, some women continue to drink in pregnancy and they should be offered assistance. However, for those women who are fearful of the alcohol they consumed early in pregnancy, possibly before realizing they were pregnant, reassurance is advised.

Allergens

Restriction of the maternal diet during pregnancy and lactation is not advised as a strategy to lower the risk of infant food allergies (Joneja, 2012). The mother should avoid her own allergens during pregnancy and lactation but should eat a variety of other foods, including the father's allergenic foods, so that the fetus and neonate can adapt. Regarding peanuts, studies have shown the child has a slightly increased risk of developing peanut sensitization if a mother eats peanuts more than twice a week, but avoidance by the mother appears to be associated with even higher risk (Fleischer et al, 2013). The mother is encouraged to breastfeed exclusively; foods should be added carefully, but delaying introduction of solid foods past 6 months provides no benefit. Use of probiotics by the mother or child may be beneficial, but type, timing, and dose are unknown (see Chapter 26).

Artificial Sweeteners

Research on the safety of artificial sweeteners is limited, but the FDA has deemed the following safe for use in moderation, including during pregnancy and lactation: saccharin, acesulfame-K, sucralose, aspartame, neotame, advantame,

steviol glycosides from stevia leaves, and extracts from monk fruit.

Food additives, including artificial sweeteners, are tested for short- and long-term toxicity; reproductive effects, including teratogenicity; and any adverse effects on an animal's reproductive organs or systems, any birth defects, and genetic toxicity (Rulis and Levitt, 2009). From that data, a safety factor is applied, usually 1/100th of the dose in which any problems have been seen. The resulting value is the Acceptable Daily Intake (ADI), defined as the estimated amount of a food additive that someone can safely consume on average every day over a lifetime without any appreciable health risk. Except for advantame, stevia, and monk fruit, all too new for ADIs to have been determined, current intakes of the other sweeteners listed here are well below these ADI levels (Kroger et al, 2006; Shankar et al, 2013; see Chapter 30).

Saccharin (Sweet'N Low, Sweet Twin, Sugar Twin, Necta Sweet) crosses the placenta (Cohen-Addad et al, 1986) and may accumulate in the fetus and in breastmilk, but adverse effects on the fetus and infant have not been seen. It has been delisted as a human carcinogen (Kroger et al, 2006; Shankar et al, 2013).

Acesulfame-K (Sunett, Sweet One) consumption by pregnant women is classified as safe, even without long-term studies during human pregnancy. It often is used in conjunction with other artificial sweeteners. It is said to not be metabolized in humans (Kroger et al, 2006), but in mice it can appear in the amniotic fluid and breastmilk after an oral infusion (Zhang et al, 2011).

Sucralose (Splenda, Nevella), a carbohydrate derived from sucrose, appears to pass through the GI track relatively unchanged, is not bioreactive, and does not bioaccumulate (Shankar et al, 2013) and therefore is assumed to have little effect on pregnancy and lactation. It has not been found to be teratogenic in animal studies.

Aspartame (Equal, NutraSweet, Natra Taste) is metabolized to phenylalanine, aspartic acid, and methanol in the GI track. Studies have shown no significant effect on fertility, conception rates, embryo toxicity, fetotoxicity, or teratogenesis at the levels tested in animals (London, 1988). Its use during pregnancy and lactation has not been found to increase risk of brain tumors in children (Shankar et al, 2013). The aspartic acid does not cross the placenta in monkeys, and the methanol content is less than that of many fruit juices (Kroger et al, 2006; London, 1988). Although it is not absolutely contraindicated for women with phenylketonuria (PKU) or for women breastfeeding an infant with PKU, it must be counted as a phenylalanine source. High circulating concentrations of phenylalanine are known to damage the fetal brain (see Chapter 43). Neotame is also a source of phenylalanine and aspartic acid but, because it is much sweeter, the amounts consumed are negligible and do not have to be counted (Kroger et al, 2006). The newly approved advantame is also a source of phenylalanine but at such low concentrations that it also does not need to be counted (FDA, 2014). There are no human reproductive studies on advantame, but it is sweeter than neotame, so very small amounts would likely be consumed.

Both stevia and monk fruit are plant-derived sweeteners considered GRAS in their purified forms. Stevia (Pure Via, Truvia, SweetLeaf), has not been found to affect fetal development, at least with short-term use. *Stevia rebaudiana* traditionally has

been used by the indigenous populations of Paraguay for fertility control (Ulbricht et al, 2010). Animal studies have suggested that steviol glycosides may have adverse effects on the male reproductive system, but there are no confirming studies in humans (Kroger et al, 2006; Ulbricht et al, 2010). Caution is advised when used by pregnant or lactating women, or for use longer than 2 years, because of insufficient evidence of safety (Ulbricht et al, 2010). There is little information on the excretion of Rebaudioside A (the refined preparation of the active ingredient, now considered GRAS) and the other plant components, including steviol glycosides, into breastmilk, so caution is advised when nursing a newborn or a preterm infant. For the extracts of *Siraitia grosvenorii*, known as Swingle fruit, Luo Han Guo, or monk fruit, there is no information available for pregnancy or lactation.

Artificial sweeteners often are found in foods with low nutrient content. Intakes may have to be limited so as not to displace the more valuable, nutrient dense foods. Although average intakes are well below the ADI, an assessment of the diet is warranted to identify those women who may be ingesting multiple sources of artificial sweeteners. If intakes are high, alternatives should be offered.

Bisphenol-A, Phthalates, and Other Environmental Toxins

Bisphenol-A (BPA), an endocrine disruptor, is associated with recurrent miscarriages and may affect thyroid function in humans, especially in the fetus. Its function at the cellular level is still being investigated but there is evidence in mice that it acts similar to diethylstilbestrol (DES) (ACOG, 2013d). Phthalates are associated with shortened gestational length and developmental disruptions. BPA and phthalates, along with 20 other chemicals, are associated with increased risk of weight gain, insulin resistance, and type 2 diabetes later in life after developmental exposure (Barouki et al, 2012). See Table 15-2 for more examples.

There are calls to limit the use of BPA, phthalates, and other environmental toxins. Although recommendations can be made to avoid specific plastics and canned foods (BPA is used as a lining material), most people also have high exposure through air, dust, and personal care products (Sathyanarayana et al, 2013), and changing behavior does not necessarily reduce risk. In addition, having a plastic labeled "BPA free" does not ensure safety. Most plastics under stress (exposure to boiling water, ultraviolet rays in sunlight, or microwaving) release estrogenic chemicals that may be of more concern than those plastics containing BPA (Yang et al, 2011).

Although it is known that exposure to environmental toxins can have long-term effects, it is unknown whether the effects vary by gender or life stage. It is also unknown how the placenta mediates exposure to toxins (ACOG, 2013d; Bloomfield, 2011). The effects may be nonlinear; low doses can be more harmful than high doses (Barouki et al, 2012). There are also potential effects on gene expression. ACOG is calling for better research on the reproductive effects of environmental toxins and societal change regarding exposure to these toxins (ACOG, 2013d).

Much of the effect of these chemicals may be during organogenesis, so reducing preconceptional exposure is likely to be most productive. Raising concerns with a mother later in pregnancy without actually being able to change outcomes would not be helpful.

Caffeine and Energy Drinks

Caffeine crosses the placenta and increases maternal catecholamines, but it appears that intakes of less than 200 mg/day are not associated with increased risk of miscarriages or preterm birth (ACOG, 2010). It does not decrease uterine blood flow or oxygenation. However, although there is no clear evidence of harm, the evidence also does not follow the expected dose-response curve, so the effect cannot be determined definitively. Caffeinated beverages are not considered to be of high nutritional quality, and moderation is encouraged. See Appendix 39 for caffeine food sources.

Energy drinks are not recommended during pregnancy. In addition to the high caffeine and sugar contents they contain, these drinks often have high levels of added nutrients and herbal products that have not been evaluated for safety during pregnancy (Procter and Campbell, 2014).

Lead

Contaminants in food are the exception rather than the rule in the United States, but they do occur. In high concentrations, they can pass across the placenta to the fetus (see Figure 15-5). Lead contamination is associated with increased risk of miscarriage, gestational hypertension, IUGR, preterm delivery, and impaired neurobehavioral development.

In addition to old paint chips, poorly glazed dishware (often imported) and leaded crystal decanters may contain high amounts of lead. Pregnant women should avoid using dolomite as a calcium supplement; the seashells or sea coral often contain heavy metals, including lead, the result of dumping industrial wastes in the oceans. Imported candies from many areas, including Mexico, India, China, and Hong Kong have also been found to contain lead (see <http://www.cdph.ca.gov/data/documents/fdblicic07.pdf>).

Listeria monocytogenes

Listeria monocytogenes affects 1600 Americans each year and, with a 21% case fatality rate, is the third leading cause of

death resulting from food poisoning (CDC, 2013). Pregnant women are 10 times more likely than other healthy adults to become infected with *Listeria* spp.; rates among U.S. Hispanic women are 24 times higher than the general population (CDC, 2013). It is a known cause of miscarriage (10% to 20%), preterm birth (50%), or stillbirth (11%) (Adams Waldorf and McAdams, 2013) and can cause neonatal meningitis, sepsis, and pneumonia. It may only cause flu-like symptoms in the mother and can mimic a urinary tract infection, but many women have no symptoms. Most cases of listeriosis are associated with sporadic contamination rather than epidemics (CDC, 2013). Fetal transmission is not inevitable, and outcomes are worse if infection occurs early in the pregnancy (Cox and Phelan, 2009a).

Listeria is a soilborne bacteria; infection results from eating contaminated foods of animal origin and raw produce. Because it can also be airborne, can tolerate high salt environments, and grows in moist environments at refrigeration temperatures, raw milk, smoked seafood, frankfurters, pâté, soft cheeses (especially if made with unpasteurized milk), and uncooked meats are likely sources. Because of improvements in processing, the risk of contamination in packaged cold cuts is now one fifth that of retail-sliced meats (Batz, 2011). Recommendations to reduce risk include using only pasteurized food products and heating precooked meat products to steaming (see Box 15-8).

Mercury and Polychlorinated Biphenyls (PCBs)

Methylmercury contamination is known to affect fetal neural development disproportionately. It crosses the placenta and blood-brain barrier and accumulates in the fetus; cord blood levels are 70% higher than maternal levels (Cox and Phelan, 2009b).

Traces of methylmercury are found in most fish, but concentrations are highest in those fish that are large and predatory. Although advisories are specific to local conditions, the U.S. EPA and FDA currently recommend that all women of

FIGURE 15-5 Transfer of substances across the placental membrane. Ig, Immunoglobulin.

BOX 15-8 Listeria Guidelines

Follow the general safety guidelines in Box 15-7, including the following:

- Avoid cross contamination with the fluid from hot dog packages.
- Keep raw meats separated from vegetables, cooked foods, and ready-to-eat foods.
- Wash vegetables thoroughly.
- Eat perishable and ready-to-eat foods (dairy, meat, poultry, seafood, produce) as soon as possible. Check for “use by” dates once/week and throw out food that has passed. Follow recommended storage times for foods.
- Wipe up spills immediately. Clean the refrigerator regularly with hot water and mild liquid detergent, rinse.

Choose lower risk foods.

- Avoid unpasteurized milk or any foods made from raw milks.
- Make sure soft cheeses (feta, Brie, Camembert, blue-veined, or Mexican style “queso blanco,” “queso fresco,” or Panela) are made with pasteurized milk.
- Do not eat hot dogs, luncheon meats, or deli meats unless reheated to steaming (165° F). Meats may be chilled afterward. As an alternative, cooked meats or canned meats (salmon, chicken, tuna) may be used for sandwiches.
- Do not eat refrigerated pâtés or meat spreads. Canned or shelf-stable versions may be eaten.
- Do not eat ham salad, chicken salad, or seafood salad made at the store. Instead, make them at home following general food safety guidelines.
- Do not eat refrigerated smoked seafood unless it is in a cooked dish (165° F). This includes smoked salmon, trout, whitefish, cod, tuna, and mackerel. They are often labeled “nova-style,” “lox,” “kippered,” “smoked,” or “jerky.” They are found in the refrigerated section or sold at the deli counter. Canned or shelf-stable versions may be eaten.

Adapted from Cox JT, Phelan ST: Food safety in pregnancy, part 1: putting risks into perspective, *Contemporary Ob/Gyn* 54:44, 2009a; United States Department of Health and Human Services (USDHHS): *Checklist of Foods to Avoid During Pregnancy* (website): http://www.foodsafety.gov/poisoning/risk/pregnant/chklist_pregnancy.html, 2014. Accessed January 2014.

childbearing age avoid the consumption of those fish that surpass 1 ppm methylmercury. The methylmercury accumulates in the lean tissue, so cooking methods do not affect the mercury content of the fish (see *Focus On: Childhood Methylmercury Exposure and Toxicity* in Chapter 17).

Not everyone has found long-term problems with methylmercury consumption (Van Wijngaarden et al, 2013). Research shows that selenium can form selenoproteins that may mitigate the harmful effects of mercury and other heavy metals. The selenium and mercury contents of fish and shellfish are now being characterized worldwide (Burger and Gochfeld, 2013). However, although some have promoted a selenium:mercury ratio as a better way to characterize risk, that may be premature. Selenium appears to protect against mercury toxicity only up to a limit, and excess selenium also can be highly toxic.

Fish also can be a source of polychlorinated biphenyls (PCBs), and prenatal exposure has been associated with child neurologic deficits (Cox and Phelan, 2009b). Although no longer produced, PCBs still remain in the water systems. Although PCBs can be absorbed through the skin and lungs, they primarily enter the body from ingestion of contaminated fatty fish. Farmed and wild ocean fish can contain PCBs, but fresh water fish from the Great Lakes are often of more concern.

PCBs readily pass through the placenta and breastmilk; pregnant and nursing women should avoid eating fish from water known to be highly contaminated with PCBs. For fish from other areas, they should be cooked to minimize the ingestion of the fat and the skin should not be eaten.

Regarding wild versus farmed salmon, there is controversy. Farmed Atlantic salmon is higher in contaminants (PCBs, dioxins, PBDEs, and some pesticides) than wild Pacific salmon, but it also contains higher levels of omega-3s than wild Pacific salmon. Although no data are specific to pregnancy, researchers conclude that the benefit (lives saved from coronary disease) from North and South American farmed sources outweighs the risk (lives lost to cancer) and is on par with the wild sources (Cox and Phelan, 2009b).

Local fresh waters and, therefore, fish also may be contaminated. Questions regarding methylmercury, PCBs, and other contaminants should be directed to state natural resource departments.

Most fish and seafood are low in methylmercury, and a few are particularly high in DHA (see *Focus On: Omega-3 Fatty Acids in Pregnancy and Lactation*). Fish may carry pathogens as well and all fish and seafood should be well cooked (see Box 15-9).

Other Foodborne Pathogens and Probiotics

Brucella spp., *Salmonella* spp., and *Campylobacter jejuni* are also of particular concern for pregnant women (Procter and Campbell, 2014). Prompt diagnosis of brucellosis and maternal antibiotic treatment can save the life of the fetus. Transmission of *Brucella* spp. through breastmilk also has been reported. Cases of fetal sepsis and multiorgan failure, leading to death, have been reported with nontyphoidal *Salmonella*. *Salmonella typhi*, the bacteria that cause typhoid fever, and *Campylobacter jejuni* can cross the placenta and infect the fetus, causing miscarriage, stillbirth, or preterm labor (Dean and Kendall, 2012; see Chapter 9).

For a discussion of the issues regarding the microbiome, see *Clinical Insight: The Microbiome During Pregnancy and Lactation*.

BOX 15-9 Fish Safety Guidelines

- Do not eat shark, tilefish (also called golden or white snapper), king mackerel, or swordfish.
- Albacore (“white”) tuna should be limited to 6 oz/week. Limit marlin, orange roughy, and large tuna, often used in sushi or as tuna steaks.
- Other cooked fish and seafood may be eaten, up to 12 oz/week. See *Focus On: Omega-3 Fatty Acids in Pregnancy and Lactation* for recommended choices.
- Avoid refrigerated seafood products unless cooked before eating (165° F).
- Avoid raw or undercooked fish and seafood, including sushi and shellfish. All fish and shellfish should be cooked to 145° F.
- Observe local advisories regarding mercury and other contaminants. (For access to your state’s or territory’s advisories, see: <http://fishadvisoryonline.epa.gov/General.aspx>. Accessed October 2015.)

Accessed January 2014.

CLINICAL INSIGHT**The Microbiome During Pregnancy and Lactation**

Probiotics are being investigated for potential benefit during pregnancy. Long-term effects include the influence on offspring immunity, including the potential prevention of atopic disorders. Probiotics also may play a role in early life programming, affecting the ability to metabolize macronutrients and maintain energy balance. In addition, effects on the pregnancy are also being investigated, including the lowered risk of preterm birth and preeclampsia, and improvement of glucose metabolism, lipid profiles, inflammation, and gestational weight gain (Lindsay et al, 2013). The abilities of the human microbiome to sequester toxic metals, degrade pesticides and carcinogens, and to lower blood pressure and serum cholesterol levels are also under investigation.

Although preliminary studies show probiotic use is associated with reduced rates of preeclampsia and GDM, these studies are few and small, with variable types and amounts of organisms being used (Lindsay et al, 2013). For most, interventions have been studied only in women with normal weights, although there are ongoing studies among overweight and obese women.

General guidelines cannot yet be made. It is now known that the fetus is not sterile and that microbes move from the maternal to the fetal environment from her GI tract as well as vaginally (Prince et al, 2014). Transfer of bacteria to amniotic fluid could cause inflammation and therefore preterm delivery. Particular concern is raised for those women with immune suppression or dysfunction, as well as those with abnormalities in the gastrointestinal mucosal barrier. However, so far probiotics appear safe when used by healthy people.

During lactation, the milk microbiome may contribute to short- and long-term infant health and also to mammary health. Mammary dysbiosis often leads to acute, subacute, or subclinical mastitis. This condition may be resistant to antibiotics and could lead to undesired early weaning. New research providing selected lactobacilli strains isolated from breast milk show potential in treating this painful condition so that the continuation of successful breastfeeding is not jeopardized (Fernandez et al, 2012).

Toxoplasma gondii

Toxoplasma gondii is a parasite that may cross the placenta, causing miscarriage, fetal death, chorioretinitis, and long-term neurologic and neurocognitive deficits for baby. Rates of congenital toxoplasmosis in the United States are unknown (it is not a reportable disease) but are estimated at 400 to 4000 cases/year (Cox and Phelan, 2009a). Although present in all countries, the prevalence varies considerably; highest rates of congenital toxoplasmosis are found in some countries in South America, the Middle East, and Africa (Torgerson and Mastroiacovo, 2013).

Symptoms are often mild, flu-like, and unrecognized, although people with immunosuppression can have chorioretinitis and encephalitis (Torgerson and Mastroiacovo, 2013). Clinical toxoplasmosis is rare in the United States, and 90% of pregnant women who are infected have no noticeable symptoms (Cox and Phelan, 2009a). However, even without maternal symptoms, the fetus can become infected. Overall transmission rates appear to be 20% to 50% but vary by trimester (Cox and Phelan, 2009a). Although transmission is lowest in the first trimester, the severity is also highest. The risk of passing the parasite to the fetus is reduced greatly if the mother has been previously exposed and is already seropositive. Although some countries (including France and Austria) routinely screen pregnant women, this is not standard practice in the United States.

Commonly women are encouraged to not handle used kitty litter when pregnant, because the cat is the definitive host for *Toxoplasma*. However, a cat passes the oocysts for only a few

BOX 15-10 Toxoplasma Guidelines

- Follow the general food safety guidelines from [Box 15-7](#).
- Freeze meats for several days before cooking.
- Wash hands after handling raw meats.
- Cook meats to at least 150° F + 3-minute rest (whole cuts), 160° F (ground meats, wild game), or 165° F (poultry). These temperatures may be higher than the USDA recommends for other pathogens. Do not sample meat until it is cooked. Meats that are smoked, cured in brine, or dried may still be infectious.
- Raw oysters, mussels, and clams should not be eaten.
- Keep children's sandboxes covered when not in use.
- Wear gloves when gardening or handling sand from a sandbox. Wash hands thoroughly afterward.
- Peel or thoroughly wash fruits and vegetables before eating.
- Avoid unpasteurized milk, including goat's milk.
- Do not drink water from the environment unless it is boiled.
- Keep your cats indoors. Do not feed them raw or undercooked meats or unpasteurized milks.
- Clean the litter box daily. If possible, have someone else change the litter box. If not, wear gloves and wash hands with soap and warm water afterward.
- Do not adopt a new cat while pregnant nor handle strays, especially kittens.
- Control rodents and other potential intermediate hosts.
- If butchering wild game or venison, bury the organs so that wild cats cannot eat them and spread the infection.

Adapted from Cox JT, Phelan ST: Food safety in pregnancy, part 1: putting risks into perspective, *Contemporary Ob/Gyn* 54:44, 2009a; Jones JL, Dubey JP: Foodborne toxoplasmosis, *Clin Infect Dis* 55:845, 2012.

weeks in its lifetime. In addition, these oocysts are infective only after being exposed to the environment for at least a day; if the litter box is changed daily, there is little danger, even if the cat were infected and passing the eggs. Cats should be kept indoors and not fed raw meat.

Because the oocysts can live in the environment for years, water, dust, and garden soil can also be contaminated. Fruits and vegetables must be washed and contaminated water should not be ingested. Gloves should be used when gardening.

Meats and milks also can be infected with tissue cysts, and it is estimated that up to half the cases of toxoplasmosis occur with handling or eating undercooked or raw infected meats, especially wild game and those meats labeled "free-range" or organic (Jones and Dubey, 2012). Oysters, clams, and mussels can be contaminated through water runoff. Unpasteurized goat milk is also a known source, as are homemade cured, dried, and smoked meats. The injected salt solution that often is used in pork and chicken will kill tissue cysts, as may freezing the meat for a few days. To kill the parasite, meats must be cooked well (see [Box 15-10](#)).

Guide for Eating During Pregnancy**Recommended Food Intake**

The increased nutrient requirements of pregnancy can often be met by following the Daily Food Guide (see [Table 15-14](#)). The USDA Daily Food Plan for Moms can be used interactively online. Although it can be a starting point, it is designed for those women with uncomplicated pregnancies. In addition, unless very nutrient-dense foods are chosen, it is likely to be deficient in iron, vitamin D, vitamin E, choline, potassium, and DHA (CNPP, 2013). [Box 15-11](#) provides a summary of nutritional care. Weight gain and fetal growth should be monitored and the plan modified as needed.

TABLE 15-14 Daily Food Guide: Recommended Servings for a Woman Pregnant with a Singleton or Lactating

Food Group	PREGNANT WOMAN (NORMAL WEIGHT, < 30 MINUTES EXERCISE/WEEK)			LACTATING WOMAN (NO FORMULA SUPPLEMENTATION)		Serving Sizes (1)
	First Trimester	Second Trimester	Third Trimester	Early Lactation (0-6 mos)	Later Lactation (6+ mos)	
Total daily calories	1800	2200	2400	2130	2200	
Meat and beans, oz	5	6	6.5	7	6	1 oz = 1 oz meat, poultry, or fish, 1 egg, 1/4 c beans, 1/2 oz nuts, 1/4 c tofu
Milk products, cups	3	3	3	3-4	3	1 c = 1 c milk or yogurt, 1.5 oz hard cheese, 2 c cottage cheese
Breads, grains, oz – half should be whole grains	6	7	8	8	9	1 oz = 1 slice bread, 1/2 c cooked starch, 1 c RTE cereal
Fruits and Vegetables (cups)	4	5	5	6	6	1 c = 1 c raw or cooked fruit or vegetable, 1/2 c dried fruit, 2 c leafy vegetables
<i>Vitamin C rich</i>	1	1	1	1	1

BOX 15-11 Summary of Nutritional Care During Pregnancy

1. Include a variety of foods, focusing on nutrient dense food choices
2. Energy intake to allow for appropriate weight gain
3. Protein intake to meet nutritional needs, approximately an additional 25 g/day; additional 25 g/day/fetus if pregnant with more than one fetus. This often requires 20% of energy intake from protein
4. DHA from fatty fish (low in methylmercury) twice a week
5. Mineral and vitamin intakes to meet the recommended daily allowances. Folic acid supplementation is often required; iron supplementation may be necessary
6. Sodium intake that is not excessive but not <2300 mg/day. Iodized salt is recommended
7. Sufficient fluid intake to produce dilute urine, usually at least 2 L/day
8. Alcohol omitted
9. Omission of toxins and nonnutritive substances from food, water, and environment as much as possible

Fluids

Drinking 8 to 10 glasses of quality fluid daily, mainly water, is encouraged. The DRI for fluid increases slightly during pregnancy, but a woman's body size as well as climatic conditions are important considerations. Adequate hydration improves the overall sense of well-being. Frequent urination is often a complaint from pregnant women; however, optimal hydration reduces risks

for urinary tract infections, kidney stones, and constipation and dehydration can cause uterine irritability. Women often have to be reminded to pay attention to their intake of liquids, using urine color after the first morning void as a guide.

Nutrient Supplementation During Pregnancy

Supplementation of a mother's diet during pregnancy may take the form of additional energy, protein, fatty acids, vitamins, or minerals that exceed her routine daily intake. The more compromised the nutritional status of the woman, the greater the benefit for pregnancy outcome with improved diet and nutrient supplementation. The goal is to consume the necessary nutrients as food, taking advantage of the likely beneficial synergistic effects and including phytonutrients or other bioactive compounds whose effects are not yet fully appreciated. However, judicious use of supplements is needed with undernourished women, teenage mothers, women with substance abuse, women with a short interval between pregnancies, women with a history of delivering a LBW infant, and those pregnant with multiple fetuses. Preconceptional supplementation is recommended for folic acid and may be warranted for other nutrients as well.

Pregnant women at nutritional risk are encouraged to enroll in the Special Supplemental Nutrition Program for Women, Infants, and Children (WIC), under the auspices of the U.S. Department of Agriculture (USDA). The WIC program serves

eligible pregnant women, breastfeeding (until 1 year postpartum) and nonbreastfeeding postpartum women (until 6 months postpartum), as well as infants and children (up to age 5; see Chapter 9). For women, “nutritional risk” criteria may include anemia, poor gestational weight gain, and inadequate diet, as well as a variety of preexisting medical conditions. WIC provides targeted supplemental foods, nutrition education and

breastfeeding support, as well as health care referrals. Outcome studies show improved birth weights and higher mean gestational ages in infants born to WIC participants.

Many pregnant women have limited knowledge regarding the nutrients in the supplements they have been advised to purchase. The composition of multivitamin-multimineral supplements varies, and formulations change frequently (see Table 15-15). It is

TABLE 15-15 Comparison of Selected Prenatal Supplements

THE TOTAL NUTRIENT CONTENT IS SUPPLIED BY THE NUMBER OF RECOMMENDED TABLETS OR GUMMIES NOTED FOR EACH OF THE SUPPLEMENTS LISTED							
Nutrient	1 Tablet/ Day	1 Tablet/ Day	1 Tablet/ Day	3 Tablets/Day	2 Gummies/Day	6 Tablets/Day	Child's Chewable: 1 Tablet/ Day

Nutrient	1 Tablet/ Day	1 Tablet/ Day	1 Tablet/ Day	3 Tablets/Day	2 Gummies/Day	6 Tablets/Day	Child's Chewable: 1 Tablet/ Day
Enzymes						"Digestive support" - protease, amylase, lipase, betaine	
Probiotics				<i>Lactobacillus casei</i> , <i>L. plantarum</i> , <i>L. salivarius</i> , <i>L. acidophilus</i> , <i>L. rhamnosus</i> , <i>Streptococcus thermophilus</i> , <i>Bifidobacterium bifidus</i> , <i>B. infantis</i> , <i>B. longum</i> , <i>B. breve</i> .		<i>Lactobacillus sporogenes</i> - 30 million	
Foods, herbs				Brown rice, oats, blueberries, prunes, blackberries, flame raisins, raspberries, dandelion leaf, rose hips, lavender, lemon balm, peppermint, cloves, broccoli, cauliflower, kale, daikon radish, cabbage, mustard		80 mg lemon bioflavonoids, 10 mg rutin, spirulina, alfalfa, chlorella, red raspberry, chamomile, ginger	

DHA, Docosahexaenoic acid; PUFAs, polyunsaturated fatty acids.

important to read the label on prenatal supplements—some are much more complete than others, and some include ingredients in addition to the vitamins and minerals. Women often need advice on local, suitable choices. Look for those that contain the USP, Consumer Labs, or NSF seals of approval for quality (not safety or effectiveness). A balanced prenatal supplement should contain 400 to 800 mcg of folic acid and also should contain iron unless contraindicated. Copper is recommended if the supplement also contains zinc or iron (Uriu-Adams et al, 2010). It should contain 150 mcg of iodine in the form of potassium iodide, not kelp or seaweed (Leung et al, 2013). Although some contain DHA, at least as much benefit can come from including high DHA fish regularly in the diet (see *Focus On: Omega-3 Fatty Acids in Pregnancy and Lactation*).

Those supplements containing levels much higher than the DRI are not recommended because of known teratogenic effects (e.g., preformed vitamin A), as well as potential epigenetic effects. Some contain many additional ingredients, including herbal preparations, many of which have not been evaluated for safety during pregnancy.

As a reminder, prenatal multivitamins-multiminerals may be more critical when a woman's nutritional status is at risk. For others, they may be used as insurance but should not be used as a substitute for eating well. Whether prenatal multivitamin-multimineral supplements are necessary for women living in affluent societies is debated, but their use is common. For women living in low- and middle-income conditions, prenatal supplementation has been associated with better birth outcomes (Hovdenak and Haram, 2012).

Nutrition Education

Nutrition intervention, including medical nutrition therapy (MNT), has been effective in improving the maternal diet, reducing the risk of anemia in late pregnancy, and improving gestational weight gain, thus lowering the risk of preterm birth,

improving infant head circumference size, and birth weight (Girard and Olude, 2012). For low-income recipients, results are enhanced if education is combined with balanced energy and protein supplementation and/or micronutrient supplements.

Regarding the effectiveness of MNT on curbing excessive maternal weight gain, results are mixed. Many types of interventions are effective for some groups but not others and studies are ongoing, but dietary interventions appear to be more effective than those focusing on physical activity (Thangaratinam et al, 2012). Women should be given appropriate guidance on the weight gain, as well as nutrient intakes, expected. Although energy needs increase slightly, the mother is not "eating for two." Helping a mother find acceptable concentrated sources of nutrients and minimizing the intake of high-calorie, low-nutrient foods is likely to reassure the woman who starts the pregnancy overweight or obese and/or is gaining excessively. Most likely to be effective are more intense and frequent interventions (Nelson et al, 2010) with personalized advice (Kaiser and Campbell, 2014); just giving printed materials is likely to not be beneficial.

MNT is known to be helpful during pregnancy. However, to be most effective, dietitians and nutritionists must consider all current issues. A pregnant woman may have poor weight gain but also low iron levels; foods that address both issues should be used. She may have low calcium intake but also have GDM, thus modifying how she is counseled. She may have cultural practices that could affect her nutritional status (e.g., veiling and vitamin D). She may have preexisting medical conditions that must be managed, including carrying parasitic infections common in her home country. She may develop issues during pregnancy (e.g., anemia, gallstones, or GDM) but also may find medical issues that are not directly related to the pregnancy (e.g., cancer or a Crohn's disease flare-up). She may experience trauma from a motor vehicle accident or physical abuse that

could require an ICU admission. All nutritional issues must be balanced, often with little research data to give firm guidance. One should give the best advice known but be open to changes as the evidence becomes available.

In addition, cultural aspects of counseling also must be kept in mind (see Chapter 14). A woman's perceived risk of abnormal weight gain may differ from the U.S. norm. Childrearing, including pregnancy and lactation, usually has strong cultural components, and it is advisable to understand the beliefs and customs of the population groups being served. Although each individual does not necessarily follow, or may not even be aware of, all the beliefs held in the culture, they may color a person's response to nutritional suggestions. For example, a woman coming from a culture that believes that cleft lip and palate are caused by seeing an eclipse may rely on the safety pin over her abdomen to protect her and may therefore be less concerned about taking her folic acid supplements. A Vietnamese woman who is fearful of drinking cold orange juice immediately postpartum because of the negative effect it will have on the skin years later may be willing to warm the juice, put sugar in it, or eat kiwis for vitamin C instead. A woman from Mexico who believes that you must comply with a craving or something will be missing from the baby, will be afraid to NOT eat the dirt she is craving. However, she may be willing to smell the wet dirt and eat a burned tortilla, thus complying with the craving but ingesting something that is not likely to be contaminated. She may believe that "vitamins make you hungry" and so will stop taking her prenatal supplements if she feels, or has been told, she is gaining too much weight.

Families often need to be reassured that low-fat and nonfat milks contain the same levels of protein, calcium, and vitamin D as the whole milk (i.e., they are not watered down milk and therefore dangerous for pregnancy). Immigrants from countries where tap water is not potable need to be reassured that it is treated in the United States and is safe to drink, and that bottled water is not only more expensive but also often does not contain fluoride. On the other hand, an immigrant may be fearful of the prenatal care in the United States, when she is not routinely screened for *Toxoplasma gondii*, as is the standard of care at home.

Cultural differences are not apparent just with immigrants. Women who are vegetarians may need nutritional guidance regarding protein, iron, calcium, and vitamin B₁₂, especially as volume of food becomes the limiting factor later in the pregnancy. Followers of Jehovah's Witness need advice on high-iron foods to lower their risk of needing a blood transfusion. Those who practice different dietary patterns during holidays, including fasting, may need guidance on how to minimize the impact of that change on the developing fetus. Someone working nights may need ideas on how to distribute her meals to optimize glucose control.

Pregnant women are adult learners and relevant, simple, concrete messages are most effective, especially if they are memorable and motivational (Girard and Olude, 2012). All people should be counseled with sensitivity, reinforcing those practices that are particularly helpful and modifying only those practices that may be harmful. One must investigate atypical dietary patterns and food sources to best fit the customs of the patient. Cultural differences should not be ignored or rejected outright. If there are some that must be modified now, it is best to explain why, how, and for how long. Otherwise, the guidance of grandmothers and cultural history will likely prevail.

Pregnancy is a time of great impact. Although historically the goal had just been a full-term, full-size newborn, now the

focus has expanded to include ensuring someone biologically predisposed to be healthy from birth to old age (ACOG, 2013d). It is often a time when a mother is very receptive to doing her best for her child. Eating more fruits and vegetables, lean meats, low-fat milks, and whole grains while minimizing excess fat, sugar, and salt intakes will likely improve maternal health and birth outcomes in the short term. Animal research is showing high maternal intakes of fats and sugars during pregnancy and lactation results in altered development of the central reward system in offspring, leading to excessive intakes of these foods postnatally (Mennella, 2014). In addition, human research has demonstrated that flavors familiar to the infant, from exposure through the amniotic fluid and breastmilk, are more likely to be accepted by that child when first offered, thus increasing the chance that he or she will consume it. Although this may be important nutritionally, exposure to a variety of flavors early in life when the developing brain has heightened sensitivity to environmental influences also appears to facilitate acceptance of novel foods later (Mennella, 2014). Eating better during pregnancy helps develop better food habits for the mother and the rest of her family that, hopefully, will carry on past the current pregnancy, improving the entire family's health. In addition, she is likely to be having positive epigenetic effects, improving the health of future generations.

POSTPARTUM PERIOD = PRECONCEPTUAL PERIOD

Reproductive health concerns do not end at delivery. For many women, the postpartum period can be considered a preconceptional period. Excess postpartum weight retention is associated with increased risk of GDM and hypertension during a subsequent pregnancy, even in normal- and underweight women who gain appropriately in that subsequent pregnancy (Bogaerts et al, 2013). Nutrition and exercise counseling should continue postpartum, with the goal of returning the mother to her prepregnant weight within 6 to 12 months and achieving normal BMI before attempting another pregnancy (ACOG, 2013a). Medical issues, including GDM, must be resolved or appropriately treated before a subsequent pregnancy.

Nutrient stores also have to be replenished, and short interpregnancy intervals (less than 12 to 18 months) are associated with increased risk of miscarriage, preterm delivery, IUGR or LBW, stillbirth, and early neonatal death (Wendt et al, 2012; Wu et al, 2012a). The nutritional demands of breastfeeding also must be considered, and for those in areas with limited resources, it may take at least 1 year to recover. Even in high-income countries, LBW risk increases if the interpregnancy interval is less than 6 months (Wendt et al, 2012), and a significant proportion of low-income women in the United States are still iron deficient 2 years after delivery (Bodnar et al, 2002). Other nutrients also may be depleted for an extended period, including folate, vitamin A, and DHA. An antioxidant-rich diet may lower oxidative stress and improve pregnancy outcomes. Inflammation is also thought to play a role in increased risk with short interconceptional periods (Wendt et al, 2012), and those women who have no nonpregnant, nonlactating time may be at particular risk.

Current theory is that preconceptional nutrition is as critical as nutrition during pregnancy and for many nutrients, likely more critical because of their role in placental formation and organogenesis (see [Preconception and Fertility](#)).

LACTATION

Exclusive breastfeeding is unequivocally the preferred method of infant feeding for the first 6 months of life. Many professional health organizations have endorsed this recommendation, including the Academy of Nutrition and Dietetics, the AAP, ACOG, the American Academy of Family Practitioners, Healthy People 2020, the WIC program, the U.S. Surgeon General, and the U.S. Breastfeeding Committee. These organizations recommend breastfeeding throughout the first year and beyond, as long as mutually desired by mother and child; the WHO encourages breastfeeding throughout the second year of life. Breastfeeding offers protection from gastrointestinal and other infections and serves as a critical source of energy and nutrients during illness, reducing mortality among malnourished children. The development of strong immune and digestive systems in breastfed babies is thought to be due to the development of beneficial bacteria in the baby's gut, providing a healthy gut microbial population.

Mothers should be encouraged to breastfeed for as long as possible, even if it is not the full year. Nutrition from breastmilk and the protection from illness it provides are unmatched by any other substitute. Women should be supported in their decision to breastfeed for any length of time, whether it is for just 2 weeks, 2 years, or longer. Breastmilk continues to provide nutrition and immunities throughout the time the mother is lactating. Many women face barriers that may prevent them from breastfeeding for as long as they would like, so support from the health care system along with family members and the community is necessary for mothers to reach their goals (see [Figure 15-6](#)).

There are many health benefits for mother and child, as shown in [Box 15-12](#). A recent study examined the racial and socioeconomic disparities in infant feeding, noting that higher rates of breastfeeding are seen in families in which the mother is older, married, with a higher education and income. Longterm health outcomes of breastfed infants and their non-breastfed siblings

FIGURE 15-6 A nursing mother and her infant enjoy the close physical and emotional contact that accompanies breastfeeding. (Courtesy Robert Raab.)

BOX 15-12 Benefits of Breastfeeding

For Infant

Decreases Incidence and Severity of Infectious Diseases

- Bacterial meningitis
- Bacteremia
- Diarrhea
- Infant botulism
- Necrotizing enterocolitis
- Otitis media
- Respiratory tract infection
- Septicemia
- Urinary tract infection

Decreases Rates of Other Diseases

- Asthma
- Celiac disease
- Crohn's disease
- Food allergies
- Hodgkin disease
- Hypercholesterolemia
- Leukemia
- Lymphoma
- Overweight and obesity
- Sudden infant death syndrome
- Types 1 and 2 diabetes

Other Benefits

- Promotes analgesia during painful procedures (heel stick for newborns)
- Promotes enhanced performance on cognitive development tests
- Promotes mother-child bonding
- Promotes ready acceptance of solid foods

For Mother

- Decreases menstrual blood loss
- Decreases postpartum bleeding
- Decreases risk of hormonal (breast and ovarian) cancers
- Promotes earlier return to prepregnancy weight
- Increases child spacing
- Promotes rapid uterine involution
- Decreases need for insulin in mothers with diabetes
- Decreases risk of postmenopausal hip fracture and osteoporosis

For Society

- Reduces health care costs
- Decreases costs to public programs (i.e., WIC)
- Prevents excess lost wages resulting from employee absenteeism for sick children
- Supports greener environment

were compared and researchers noted that many of these children had similar long-term positive outcomes as their breastfed siblings or children in a comparative group. The authors concluded that a supportive breastfeeding environment and not breastfeeding alone contributes to long-term positive health outcomes of children (Colen and Ramey, 2014). Studies also have shown that levels of C-reactive protein (CRP), a key biomarker of inflammation and a predictor of increased cardiovascular and metabolic disease risk in adulthood, are significantly lower among individuals who were breast fed. Decreased concentrations corresponded to the duration of earlier breastfeeding. Researchers conclude that the longer the duration of breastfeeding, the less inflammation and lower risk for heart and metabolic diseases later in life (McDade et al, 2014).

In 1991 the WHO and the United Nations Children's Fund adopted the Baby-Friendly Hospital Initiative, a global effort to increase the incidence and duration of breastfeeding. To become "baby-friendly," a hospital must demonstrate to an outside review board that it implements the "Ten Steps to Successful Breastfeeding," a guideline for mother-baby management in the hospital; see Box 15-13.

The *Surgeon General's Call to Action to Support Breastfeeding* 2011 report states that breastfeeding should be promoted to all women in the United States and supported by clinicians, employers, communities, researchers, and government leaders. All are encouraged to commit to enabling mothers to meet their personal goals for breastfeeding. However, too many mothers are still not able to reach these goals. Improvement of support systems is needed for mothers to overcome challenges and barriers so often in the way of successful breastfeeding. Excess health risks associated with not breastfeeding can be found in Box 15-14.

Contraindications

Contraindications to breastfeeding are rare, but a few conditions warrant at least a temporary interruption from either direct feeding from the breast or from feeding breastmilk. Breastfeeding is contraindicated for infants with classic galactosemia, and for mothers who have active untreated tuberculosis, are positive for human T-cell lymphotropic virus type 1 or 2, have brucellosis, use drugs of abuse (without medical supervision), have

BOX 15-13 Baby-Friendly Hospital Initiative: Ten Steps to Successful Breastfeeding

1. Have a written breastfeeding policy that is routinely communicated to all health care staff.
2. Train all health care staff in the skills necessary to implement this policy.
3. Inform all pregnant women about the benefits and management of breastfeeding.
4. Help the mother initiate breastfeeding within a half-hour of birth.
5. Show mothers how to breastfeed and how to maintain lactation, even if they are separated from their infants.
6. Give newborn infants no food or drink other than breast milk unless medically indicated.
7. Practice rooming-in; allow mothers and infants to remain together 24 hours a day.
8. Encourage breastfeeding on demand.
9. Give no artificial teats or pacifiers (also called dummies or soothers) to breastfeeding infants.
10. Foster the establishment of breastfeeding support groups and refer mothers to them on discharge from the hospital or clinic.

BOX 15-14 Excess Health Risks Associated with Not Breastfeeding

Outcome	Excess Risk* (%)	Comparison Groups
Among full-term infants		
Acute ear infections (otitis media)	100	EFF [‡] vs. EBF [§] for 3 or 6 mos
Eczema (atopic dermatitis)	47	EBF <3 mos vs. EBF ≥3 mos
Diarrhea and vomiting (gastrointestinal infection)	178	Never BF [¶] vs. ever BF
Hospitalization for lower respiratory tract diseases in the first year	257	Never BF vs. EBF ≥4 mos
Asthma, with family history	67	BF <3 mos vs. ≥3 mos
Asthma, no family history	35	BF <3 mos vs. ≥3 mos
Childhood obesity	32	Never BF vs. ever BF
Type 2 diabetes mellitus	64	Never BF vs. ever BF
Acute lymphocytic leukemia	23	Never BF vs. >6 mos
Acute myelogenous leukemia	18	Never BF vs. >6 mos
Sudden infant death syndrome	56	Never BF vs. ever BF
Among preterm infants		
Necrotizing enterocolitis	138	Never BF vs. ever BF
Among mothers		
Breast cancer	4	Never BF vs. ever BF (per year of breastfeeding)
Ovarian cancer	27	Never BF vs. ever BF

*The excess risk is approximated by using the odds ratios reported in the referenced studies.

HIV (in the United States), or who take certain medications (i.e., antimetabolites and chemotherapeutic agents).

A mother should not breastfeed with active herpes simplex lesions on her breast; however, expressed milk can be used without concern. If a mother develops varicella 5 days before through 2 days after delivery, she should be separated from her infant but can provide her expressed milk to the infant. Mothers acutely infected with H1N1 influenza should separate themselves from their infants while febrile, but again, can provide their expressed milk for feedings (AAP, 2012). The use of most radioactive isotopes requires temporary cessation of breastfeeding, ranging from 6 hours to up to 1 month (Hale, 2012). Women undergoing procedures using these types of medications should consult with their health care provider to determine the specific drug used so that adequate time is allowed for clearance, but no more time than is necessary so that breastfeeding can be resumed. Clearance time varies between drugs; expressing and discarding breastmilk can help preserve milk production if extended cessation is necessary.

CDC advises women in the United States who have HIV to refrain from breastfeeding to avoid postnatal transmission to their infants through their breastmilk. Because sanitary conditions for safe use of infant formula are available in the United States, experts believe the morbidity risk can be kept to a minimum. However, in developing countries where sanitary conditions are not as prevalent, and the rate of mortality in the infant from infectious diseases and malnutrition are high, the

health risks of not breastfeeding must be considered. In addition, in areas where HIV is prevalent, exclusively breastfeeding for the first 3 months has been shown to reduce the risk of infants acquiring HIV compared with infants who receive a mixed diet of human milk and other foods, including infant formula. Six months of exclusive breastfeeding while the mother receives antiretroviral therapy has been shown to significantly reduce the postnatal acquisition of HIV (AAP, 2012).

Nutritional Requirements of Lactation

Despite the fact that breastfeeding increases the need for energy and some nutrients, human milk is made from maternal nutrient stores, so well-nourished mothers need not worry that the quality of their breastmilk will suffer from an imperfect diet. Breastmilk remains perfect for the infant even in cases of hardship and famine. Only in rare cases when mothers experience long-term, severe nutritional deficiency is their breastmilk affected. An excuse to not choose breastfeeding based on the fact that a woman enjoys drinking coffee or tea, or an occasional alcoholic beverage, is unwarranted.

Unless a vitamin-mineral deficiency is identified, or the mother has a restricted diet, dietary supplements are not necessary. A diet including a variety of foods, adequate in calories, should provide the woman with all the nutrients she needs. Despite this fact, many clinicians recommend the continued use of a prenatal vitamin/mineral supplement for the duration of lactation (AAP, 2012).

Increased **prolactin** receptors in the breast and therefore higher maternal prolactin levels develop with early suckling stimulation and milk removal, a process enhanced with increased frequency of breastfeeding in the early neonatal period. The maternal response to her infant's hunger cues will stimulate her milk supply, averaging about 8 to 12 breastfeeds over 24 hours in the first 2 to 3 weeks. The belief that more milk is made with increased fluid consumption is misguided because the body will excrete excessive fluid to maintain electrolyte balance. This actually may result in a decrease of milk production. Concern for the mother's hydration and her ability to produce an adequate milk supply is only valid during extreme conditions such as severe drought or famine. Insufficient milk supply can be as much of a problem in well-nourished as well as poorly nourished women; cross-cultural studies show it to be unrelated to maternal nutrition status. Poor maternal nutrition may affect the quantity, but not quality, of mothers' milk (Lawrence and Lawrence, 2011). Although a mother's milk maintains its quality even when nutrient intake is suboptimal, the woman feels the effects of eating poorly, possibly affecting her immune system, and feeling tired with less energy. A nutritious dietary intake helps her cope with the everyday demands of caring for a new infant.

Milk composition varies according to the mother's diet. For example, the fatty acid composition of a mother's milk reflects her dietary intake. In addition, milk concentrations of selenium, iodine, and some of the B vitamins reflect the maternal diet. Breastmilk of *extremely malnourished* mothers has been shown to have lower levels of various nutrients, reflecting the foods she has available to eat. One must remember that milk composition varies widely in the concentration of macronutrients within and between individual mothers. Several factors, including length of pregnancy, mother's diet, stage of lactation, duration of a feeding, and the time of day the feeding takes place, can affect the composition of human milk. Protein levels tend to fall in the early postpartum period, whereas the fat component of the milk initially may decrease and eventually increase in concentration over time. During an individual feeding, fat content typically increases significantly and can result in a much higher caloric content in the milk toward the end of the feeding (Khan et al, 2013). Fat

content also may be higher when the interval between breastfeedings is closer together. When the infant "cluster feeds," the milk available in the breast is higher in fat content. When more time is allowed between feedings, the breasts fill with milk with higher water content. At the next feeding, the infant may not be able to consume all the milk available and ends up taking mainly low-fat milk.

Energy

Milk production is 80% efficient: production of 100 ml of milk (approximately 75 kcal) requires an 85-kcal expenditure (Lawrence and Lawrence, 2011). During the first 6 months of lactation, average milk production is 750 ml/day (about 24 oz), with a range of 550 to more than 1200 ml/day. Because production is a function of the frequency, duration, and intensity of infant suckling, infants who feed well are likely to stimulate the production of larger volumes of milk.

The DRI for energy during lactation is 330 kcal greater during the first 6 months of lactation and 400 kcal greater during the second 6 months of lactation over that for a nonpregnant woman. However, considering milk production usually drops to an average of 600 ml/day (approximately 20 oz/day) after other foods are introduced into the infant's diet, ingested calorie levels may have to be adjusted for the individual woman who wishes to avoid weight gain. A mother is able to draw approximately 100 to 150 kcal/day from pregnancy fat stores.

Healthy breastfeeding women can lose as much as 1 pound per week and still supply adequate milk to maintain their infants' growth. The combination of diet and exercise together, or diet alone can help women to lose weight after childbirth (Amorim Adegboye and Linne, 2013). In a study of 68 adolescent mothers and 64 adult mothers, postpartum weight loss in both groups was significantly greater in those who were exclusively breastfeeding (EBF) compared with those who did not EBF. Moreover, the infants of the mothers continued to grow according to the 2006 WHO growth standards despite their mothers' weight loss (Sámano et al, 2013). However, milk production has been shown to decrease in mothers whose intakes are suboptimal (less than 1500 to 1800 calories/day) (West and Marasco, 2009). Mothers are advised to wait until breastfeeding is well established (approximately 2 months) before consciously trying to lose weight so that an adequate milk supply can be established. Appropriate fluid intake (such as drinking for thirst) and adequate rest also are recommended. A slow weight loss of no more than about 5 pounds per month supports more permanent weight loss as well as allows for adequate energy and nutrition for new motherhood.

Protein

The DRI suggests an additional 25 g of protein a day for lactation, or 71 g of protein a day, based on an RDA of 1.1 gm/kg/day of a woman's body weight. Clinical judgment is necessary with protein recommendations because 71 g/day may be too low in an overweight woman and too high for the woman with a lower BMI. Women with surgical delivery and women who enter pregnancy with poor nutritional status may need additional protein. The average protein requirement for lactation is estimated from milk composition data and the mean daily volume of 750 mL, assuming 70% efficiency in the conversion of dietary protein to milk protein.

Breastmilk has a whey:casein ratio of 90:10 early in lactation, which changes to 80:20 as an average, and to 60:40 as the baby gets older. It is speculated that this ratio makes breastmilk more digestible. In contrast, the whey:casein ratio of cow's milk protein is 18:82. Cow's milk-based infant formula varies among

commercial manufacturers, ranging from 18:82 whey:casein, to 52:48 whey:casein, and even up to 100% whey (see Chapter 16).

Carbohydrates

The RDA for carbohydrate is designed to provide enough calories in the diet for adequate volumes of milk and to maintain an adequate energy level during lactation. This may have to be adjusted depending on activity of the mother and the amount of breastfeeding. The woman with poor gestational weight gain may require more carbohydrates.

The principal carbohydrate in human milk is lactose; however, there is no evidence that maternal intake of carbohydrates affects the level of lactose in her milk.

Lipids

Dietary fat choices by the mother can increase or decrease specific fatty acids in her milk, but not the total amount of fat in the milk. Severe restriction of energy intake results in mobilization of body fat, and the milk produced has a fatty acid composition resembling that of the mother's body fat.

There is no DRI for total lipids during lactation because it depends on the amount of energy required by the mother to maintain milk production. The recommended amounts of specific omega-6 and omega-3 LCPUFAs during lactation vary little from pregnancy; they are crucial for fetal and infant brain development. One to two servings of fish per week meet this need (herring, canned light tuna, salmon). Mothers should avoid eating predatory fish to prevent excessive levels of dietary mercury (pike, marlin, mackerel, and swordfish) (AAP, 2012). Intake of trans fats should be kept to a minimum by the nursing mother so that the potential for their appearance in her breastmilk is reduced. See *Focus On: Omega-3 Fatty Acids in Pregnancy and Lactation* for more information about including DHA in the maternal diet.

Human milk contains 10 to 20 mg/dl of cholesterol, resulting in an approximate consumption of 100 mg/day, which has been determined to be essential to the diet of the infant. The amount of cholesterol in milk does not reflect the mother's diet and decreases over time as lactation progresses.

Vitamins and Minerals

Vitamin D. The vitamin D content of milk is related to maternal vitamin D intake as well as environmental conditions. Numerous case reports document marginal or significant vitamin D deficiency in infants of lactating women who are veiled, dark skinned, with BMI of more than 30, who use sunscreens heavily, or who live in latitudes with decreased sun exposure. Women with lactose intolerance who do not drink vitamin D–fortified milk or take a vitamin supplement may be at higher risk for vitamin D deficiency. Hypocalcemic rickets, including cases of dilated cardiomyopathy, have been reported in the United States in breastfed, dark-skinned infants (Brown et al, 2009).

Because of reports of clinical rickets, the AAP recommends that all breastfed infants receive 400 IU (10 mcg) of vitamin D as a daily supplement starting at birth, allowing him or her to easily achieve vitamin D sufficiency. Canada recommends 800 IU/day for adults living north of 45° N latitude, but the mother may need much higher doses (100 mcg or 4000 IU/day) to achieve normal 25(OH)D concentrations and vitamin D adequacy in her exclusively breastfed infant. Because the antirachitic activity of human milk is low (5–80 IU/L), the lactating mother requires a significant amount of vitamin D daily from food or UV exposure. Maternal circulation allows transfer of the parent

compound, Vitamin D3 itself, and not circulating 25(OH)D, into human milk. Although maternal baseline circulating 25(OH)D level may be adequate, it cannot be assumed that the vitamin D activity of her milk is adequate for the infant. Because of the binding affinity to vitamin D binding protein, the circulating half-life of 25(OH)D is 3–4 weeks, while that of vitamin D3 is just 12–24 hours; the reduced affinity of vitamin D3 allows the unbound vitamin D3 to diffuse across cell membranes from blood into the milk. In order for levels for vitamin D to be sustained in both the maternal circulation as well as the milk supply, a daily dose of Vitamin D is required. Recent studies have shown that a daily maternal intake of 6400 IU of vitamin D is safe, and allows a mother to produce milk that will provide adequate amounts of vitamin D to her exclusively breastfed nursing, without additional supplementation directly to the infant (Hollis, 2015).

Calcium. Although breastfeeding mothers should be encouraged to meet their DRI for calcium from their diet, the calcium content of breastmilk is not related to maternal intake, and there is no convincing evidence that maternal change in bone mineral density is influenced by calcium intake across a broad range of intakes up to 1600 mg/day. A recent study evaluated calcium intakes of 33 Gambian lactating women during two different lactational time periods. The study found that even with suboptimal intakes, the bone mineral mobilization during lactation was recovered after lactation. They concluded that successive periods of long lactation are not associated with progressive skeletal depletion (Sawo et al, 2013).

Iodine. Adequate breastmilk iodine levels are particularly important for proper neurodevelopment in nursing infants, and required intakes are nearly double nonpregnant values. Iodine concentrations in breastmilk are considered to be adequate to meet infants' iodine nutritional needs in areas where food sources are adequate. However, mothers living in iodine-deficient areas, especially if also consuming goitrogens or exposed to perchlorate contamination, may produce milk with iodine concentrations insufficient to meet the needs of the infant. As mentioned earlier, hyper- and hypo-thyroidism can affect breastmilk production, and so mothers should choose food sources of iodine, such as iodized salt, dairy foods, seafood, and breads made with iodide. Recent recommendations from the American Academy of Pediatrics state that lactating women should ensure a daily intake of 290 mcg of iodide, which generally requires supplementation of 150 mcg/day.

Zinc. The requirements for zinc during lactation are greater than those during pregnancy. Breastmilk provides the only dietary source of zinc for exclusively breastfed infants, and it remains a potentially important source of zinc for children beyond infancy who continue to breastfeed. In the process of normal lactation, the zinc content of breastmilk drops dramatically during the first few months from 2 to 3 mg/day to 1 mg/day by the third month after birth. Zinc supplementation has not been found to affect concentrations in the breastmilk of women in developed countries but may increase the zinc content of the milk of women in developing countries with suboptimal zinc status (Sazawal et al, 2013).

Vitamin B₁₂ and the Vegan Mother. For lactating mothers who follow a strict vegan diet without any animal products, a vitamin B₁₂ supplement is recommended strongly. The milk of a vegan mother can be severely deficient in vitamin B₁₂, leading to a deficiency in her infant which, if not treated, can lead to growth failure and permanent damage to the nervous system. Nursing mothers who follow a strict vegetarian diet should have their infant's B₁₂ levels monitored.

Sodium. Sodium intake during lactation should be controlled with the inclusion of a diet composed of foods high in nutritional value, which are naturally lower in sodium. Although there is no specific recommendation or restriction for sodium in the diet of breastfeeding mothers, a relationship has been established between the sodium intake of mothers and breastfeeding success. A recent study examined whether maternal salt preference may facilitate breastfeeding. The investigators found that mothers with a preference for a low salt intake had higher rates of successful breastfeeding beyond day 7 compared with mothers with high salt preference. Mothers with high salt preference had the shortest exclusive breastfeeding duration up to postnatal day 25 (Verd et al, 2010). Future studies are warranted to determine exactly what effect maternal sodium intake has on the success of breastfeeding.

Fluids

A nursing mother may feel a need to drink simply because of increased fluid output when breastfeeding her infant. She should drink to thirst but not feel she must force fluids, which is not beneficial and may cause discomfort. The beverage of choice is water; however, water is the main component of many beverages and can be used as such in the body.

Caffeine. Caffeine is acceptable in moderate amounts (less than 300 mg daily, see Appendix 39) and does not present a problem for the healthy full-term infant. If the mother is nursing a preterm infant, however, the baby may be particularly sensitive to large intakes of caffeine. In this case the mother is advised to observe her infant closely for signs of overstimulation, such as being unusually fussy or not being able to settle easily. If so, the mother should adjust her caffeine intake accordingly. It may take a few days after reducing caffeine intake for mother to notice a difference in the baby's symptoms. There is no evidence that caffeine affects milk supply, although if a baby is overstimulated, he may not nurse well, which could lead to dysfunctional breastfeeding and eventually a lowered maternal milk supply.

Alcohol. No safe amount of alcohol has been established for the nursing mother, but recommendations include limiting intake to 0.5 g alcohol/kg maternal body weight (AAP, 2012). For a 60-kg mother, this equals approximately 2 oz liquor, 8 oz wine, or two beers per day. Peak alcohol levels occur in about ½ to 1 hour after drinking, although this varies among women depending on mother's body composition. There is no need for a mother to express and discard her milk after taking 1 to 2 drinks, thinking this will speed the elimination of alcohol from the milk, unless it is for her own comfort. As blood alcohol decreases, so does alcohol concentration in the milk. Mothers should be discriminatory about any alcohol intake when nursing a premature, young, or sick baby because this baby would be affected much more than the older, more mature baby. In addition, mothers should consider their ability to care for their children when under the influence of alcohol. If occasional alcohol intake occurs, moderation is advised at all times for breastfeeding mothers.

See Table 15-14 and Box 15-15 for summaries of nutritional care during lactation.

Physiology and Management of Lactation

Mammary gland growth during menarche and pregnancy prepares the woman for lactation. Hormonal changes in pregnancy markedly increase breast, areola, and nipple size as well as

BOX 15-15 Summary of Nutritional Care During Lactation

1. Include a variety of foods, focusing on nutrient dense food choices.
2. Energy intake to allow for maintaining health and well-being; calorie level no less than 1800 kcal/day. Intentional weight loss not advised before breastfeeding is well established (approximately 2 months).
3. Protein intake to meet nutritional needs, approximately an additional 25 g/day from base level pre-pregnancy. This often requires 20% of energy intake from protein.
4. DHA from fatty fish (low in methylmercury) twice a week.
5. Mineral and vitamin intakes to meet the recommended daily allowances (usually met from a variety of foods in the diet). Supplements as directed from health care provider.
6. Drink to thirst; have beverages readily available during nursing and when expressing breastmilk.
7. If desired, alcoholic beverages can be consumed on occasion, in moderation. Not recommended with preterm, very young, or sick infants.
8. Omission of toxins and nonnutritive substances from food, water, and environment as much as possible.

significantly increase ducts and alveoli and influence mammary growth. Late in pregnancy the lobules of the alveolar system are maximally developed, and small amounts of colostrum may be released for several weeks before term and for a few days after delivery. After birth there is a rapid drop in circulating levels of estrogen and progesterone accompanied by a rapid increase in prolactin secretion, setting the stage for a copious milk supply.

The usual stimulus for milk production and secretion is suckling. Subcutaneous nerves of the areola send a message via the spinal cord to the hypothalamus, which in turn transmits a message to the pituitary gland, where the anterior and posterior areas are stimulated. Prolactin from the anterior pituitary stimulates alveolar cell milk production, as shown in Figure 15-7. Women who have diabetes, who are obese, who are stressed during

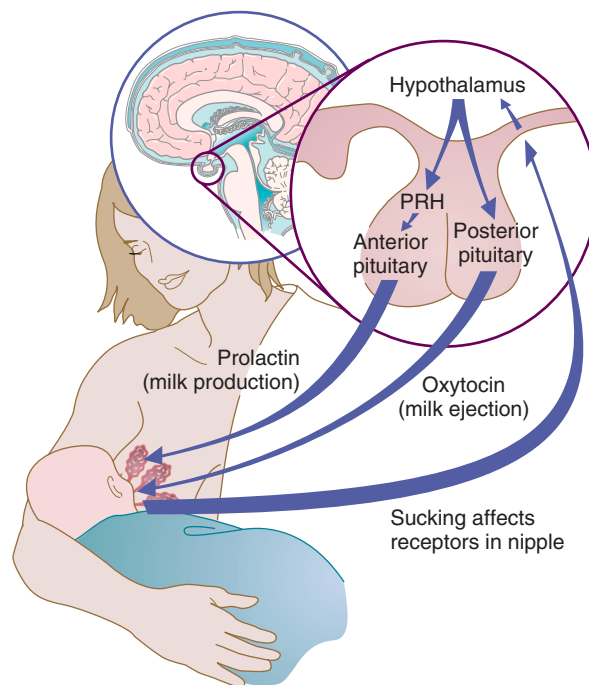

FIGURE 15-7 Physiology of milk production and the let-down reflex. PRH, Pituitary-releasing hormone.

delivery, or who have retained placental fragments in the uterus are at risk for delayed milk production (i.e. when signs of lactogenesis are absent 72 hours after birth).

Oxytocin from the posterior pituitary stimulates the myoepithelial cells of the mammary gland to contract, causing movement of milk through the ducts and lactiferous sinuses, a process referred to as **let-down**. “Let-down” is highly sensitive. Oxytocin may be released by visual, tactile, olfactory, and auditory stimuli; and even by thinking about the infant. Oxytocin secretion also can be inhibited by pain, emotional and physical stress, fatigue, and anxiety.

Prenatal Breastfeeding Education

The advantages of breastfeeding should be presented throughout the childbearing years. During pregnancy, counseling on the risks of formula feeding and the process of lactation should be provided to women so that they can make an informed decision about how they will feed their baby and so that they understand how to achieve successful breastfeeding. Prenatal breastfeeding education is recommended strongly for women and their partners. The emotional support provided by the mother’s partner contributes heavily to the success of the breastfeeding experience.

During this time the mother should identify a support person to call upon after breastfeeding begins. Because initiation and establishment of breastfeeding can seem intense and full of challenges for new mothers, it is wise for her to know whom to turn to when questions or concerns arise. A knowledgeable family member or health professional, a doula, or childbirth educator can provide the encouragement so often needed for a mother in the early postpartum period. Prenatal breastfeeding counseling with regular follow-up after delivery has shown to have a positive effect on early initiation and sustained exclusive breastfeeding, especially among primiparous mothers, with group counseling having even more beneficial impact than individual counseling (Rai et al, 2014). When more complicated problems are identified, an International Board Certified Lactation Consultant (IBCLC) can intervene, which may mean the difference between early weaning and a successful breastfeeding experience.

Stages of Milk and Variations in Composition

Human milk varies in nutritional composition throughout the maternal lactational period and seems to be more sensitive to maternal factors such as body composition, diet, and parity during later lactation than during the first few months (Lawrence and Lawrence, 2011). This fluid is constantly changing to meet the needs of the growing infant; nutrient composition changes throughout the duration of lactation, but also over the course of a day, and even during a feeding.

The delivery of the placenta after the birth of a baby triggers **lactogenesis I**, or the beginning of milk production. **Colostrum** is the thick, yellowish secretion that is the first feeding for the infant. It is higher in protein and lower in fat and carbohydrate, including lactose, than mature milk. It facilitates the passage of meconium (first stool of neonate), is high in antioxidants, and is lower in water-soluble vitamins than mature milk. Colostrum is also higher in fat-soluble vitamins, protein, sodium, potassium, chloride, zinc, and immunoglobulins than mature milk. Colostrum provides approximately 20 kcal/oz and is a rich source of antibodies. It is considered the baby’s first immunization.

Transitional milk begins to be produced approximately 2 to 5 days after delivery until around 10 to 14 days postpartum. During this stage of **lactogenesis II**, this white, creamy milk is produced in much greater quantities than colostrum, and breasts become larger and firmer. This is the time when mothers feel their milk “come in.” It is important for mothers to breastfeed often during this stage (8 to 12 times/day) to avoid engorgement and allow proper emptying of the breast by the infant. This also ensures adequate fluid and nutrition for the baby during this time. This period is an extremely important time to bring in a full milk supply, which can be established by the infant only with unrestricted access to breastfeeding.

Mature milk is the final stage of milk production and usually begins to appear near the end of the second week after childbirth. **Foremilk**, the first milk released during a breastfeed, is high in water content to meet the baby’s hydration needs. It is low in calories but high in water-soluble vitamins and protein. This milk is thinner, sometimes with a bluish color, and resembles skim milk when first released from the breast.

As the baby nurses during a breastfeed, the milk becomes creamier, indicating a higher fat content. This milk, high in fat-soluble vitamins and other nutrients, is called **hindmilk**. It provides satiety and the calories to ensure growth in the baby. It is important for the mother to allow the infant to empty the first breast at each feeding to obtain this hindmilk, before offering the other breast. This way, the baby is assured of obtaining the complete nutrition available from the mother’s milk. Hindmilk is released as the breast is emptied and signals to the baby that a feeding is over. This mechanism helps the infant to learn when to end a feeding and may contribute to the prevention of overeating and subsequently becoming overweight later in life. The longer the mother goes between feedings, the more foremilk will be stored in the breast; however, when feedings are closer together, the baby receives more hindmilk in each feeding. Babies need a balanced diet, with sufficient amounts of foremilk and hindmilk for proper growth and development.

As the mother progresses during the lactational stage of motherhood, her breasts return to her prepregnancy size and may appear somewhat softer and smaller than earlier. This does not indicate a lower milk supply, but only her body’s adjustment to established breastfeeding. A woman continues to produce nutritious mature milk, as well as enjoy the emotional and immunologic benefits, for as long as she breastfeeds. Exclusive breastfeeding is recommended for the first 6 months, followed by continued breastfeeding as complementary foods are introduced, with continuation of breastfeeding for 1 year or longer, as mutually desired by mother and child (AAP, 2012).

As mentioned previously, breastmilk is a dynamic fluid, changing throughout the lactational period of the mother. Breastmilk continues to provide an infant with needed amounts of essential nutrients well beyond the first year of life, especially protein, fat, and most vitamins. Breastfed infants tend to gain less weight and usually are leaner than are formula-fed infants in the second half of infancy, which does not seem to be the result of nutritional deficits, but rather infant self-regulation of energy intake. The nutrients most likely to be limiting in the diets of breastfed infants after 6 months of exclusive breastfeeding are minerals, such as iron, zinc, and calcium. These nutrients are readily available through an age-appropriate diet consisting of meats, whole grains, dairy foods, fruits, and vegetables.

During growth spurts, or times of rapid infant development—typically around 2 weeks, again at 4 to 6 weeks, and anytime

between 3 and 6 months—babies may increase their desire to nurse to meet caloric needs. If allowed to do so, this triggers an increase in the mother's prolactin level, and after a few days, she will begin to make more milk. If supplements are introduced at these times to satisfy the infant's hunger, the mother will not have the advantage of increased stimulation from the infant's suckling and will not be able to keep up her supply to meet the baby's nutritional needs. Many mothers do not understand this concept of "supply and demand" and unintentionally may sabotage their breastfeeding relationship.

Initiation of Breastfeeding

Breastfeeding is a learned skill for mother and her infant. The baby should be put to breast soon after birth (within the first 30 to 60 minutes) and remain in direct skin-to-skin contact until the first feed is accomplished (AAP, 2012). Within 48 to 96 hours after birth the breasts become fuller and firmer as the milk volumes increase.

Exclusively breastfed babies do not need additional water because 87% of breastmilk is water. However, cases of hypernatremic dehydration in babies caused by suboptimal breastfeeding do occur. Most cases are due to lack of support for mothers who feel intimidated and overwhelmed at delivery, lack breastfeeding education, and are unaware of the consequences of dehydration. Extreme heat or hot weather also may increase the need for more frequent breastfeeding to avoid dehydration. The consequence of hypernatremic dehydration can be permanent brain damage or death. Therefore it is vital that an experienced health care professional evaluate the breastfeeding within 3 to 5 days after birth; problems identified can be addressed and a plan of care can be implemented (AAP, 2012).

During the first days and weeks of breastfeeding, mothers should feed on demand or "on cue." Watching and listening to the infant guides a mother to know when to offer a feeding. When a mother responds to her infant's hunger cues, nursing "on demand," she provides the quantity the baby needs, as long as supplements are avoided, and pacifiers are not used to "mask" the baby's hunger. A newborn's stomach is very small and holds only about a teaspoon or two of fluid at a time, matching the small amount of colostrum available from the mother. The colostrum is very easily absorbed, and that is why the infant will give frequent cues to his mother that he is hungry again. As a newborn's stomach enlarges over the next few days and weeks, so does the mother's milk supply as long as no supplement has interfered with this process of supply and demand. Extra bottle feedings can stretch the infant's stomach so that the supply the mother has available can no longer satisfy the baby. This situation may cause a mother to feel that she does not have enough milk and has failed at breastfeeding, and possibly unnecessarily cause her to wean. It is common to breastfeed 8 to 12 times a day while the breastmilk is increasing and an adequate supply is being established. After breastfeeding has been fully established after the first few weeks, lactating women may begin to feel the strong tingling sensation in the breasts caused by oxytocin release, signaling the let-down reflex. (See earlier explanation.) This sensation automatically causes a sudden release of milk from the breasts. If this occurs when the mother is not available for her baby, firm pressure on the breasts stops milk from flowing.

As breastfeeding continues, mothers begin to settle into a pattern of feeding that is comfortable and relaxed. Although each mother-baby couplet is different, most babies become more efficient at the breast and are able to take in more milk at

a feeding time, as much as several ounces in just a few minutes. This allows the feedings to become less frequent and take less time. When breastfeeding is total nourishment for the baby, some feeds may be short just to satisfy a baby's thirst, and others may last 20 to 30 minutes if the baby is very hungry. This is no cause for worry, as long as the mother continues to respond to the infant's cues. Parents should be educated about this process so that they do not get discouraged or think that the intense feeding schedule that is common in the early weeks will last for the entire breastfeeding experience.

Practice, patience, and perseverance are necessary for successful breastfeeding, along with a strong support system for the mother, including family, friends, health care personnel, her workplace, and the community around her (see Box 15-13). With learned hand expression or the help of an effective breast pump, the mother is able to express and store her milk for later use when she is away from her infant. Pump rentals or purchase may be covered by insurance or available through the WIC program. See Box 15-16 for a summary of tips for success in breastfeeding.

Breastfeeding by Women with Diabetes. Women who have insulin-dependent diabetes may experience "lactation hypoglycemia" as they increase their breastfeeding sessions. Plasma glucose levels in the lactating diabetic mother are lower because of maternal stores being used for milk production. The daily maternal insulin requirement is usually lower in these women, and frequent glucose monitoring must be emphasized to ensure safety for the mother and baby. Because newborns of mothers with diabetes frequently are admitted to the NICU for closer observation, more support should be offered to these mothers to ensure breastfeeding success.

Breastfeeding Preterm and Sick Infants. Breastmilk for a preterm infant is not only beneficial but also absolutely necessary to ensure protection from infection and other illnesses (see

BOX 15-16 Tips for Breastfeeding Success

During your pregnancy:

- Enroll in the WIC program, if eligible.
- Attend a breastfeeding class.
- Read about breastfeeding.
- Get 1 to 2 good nursing bras.
- Find a supportive person that can help you.

In the hospital:

- Let doctors and nurses know that you plan to breastfeed.
- Do not use any bottles or pacifiers.
- Breastfeed during the first hour after birth.
- Keep baby in room with you 24 hours/day.
- Ask for lactation consultant (IBCLC) to help with correct latch.
- Breastfeed every 2 to 3 hours.
- Hold baby skin-to-skin to bond with baby and increase milk supply.
- If doctor orders supplementation, use expressed breastmilk.
- If you and your baby are separated because of illness, ask for a breast pump.

During the first 2 to 3 weeks at home:

- Don't give bottles or a pacifier.
- Breastfeed every 2 to 3 hours, at least 8 times a day.
- Make sure baby latches onto the breast correctly.
- Continue skin-to-skin care whenever possible.
- Watch for 6 to 8 wet and 2 to 3 messy diapers daily by end of first week.
- For questions or concerns, call the WIC Lactation Specialist or an IBCLC.
- See baby's doctor at 4 to 5 days of age for a weight check.
- If enrolled in WIC, see nutritionist to obtain nutritious foods for yourself!

Chapter 42). A mother may be overwhelmed when her baby is delivered before the due date or is admitted to the NICU for any reason. If the baby is not strong enough for effective breastfeeding, professional help should be used so that the mother can begin milk expression, and her milk can be available for the infant's nutrition.

A mother may find that she is totally dependent on the breast pump for several days, weeks, or even months. During this time, it is important for the mother (and father) to employ skin-to-skin care of their baby to allow appropriate stimulation of prolactin production in mother for her milk supply to be maintained. This connection with her newborn also assists in the bonding process, so important in the development of a healthy, loving relationship, which is challenged by the unfortunate situation in which the mother and her family find themselves. The mother will continue to need support and encouragement throughout the baby's hospitalization, and even more so when discharge gets closer. The total transfer of care to the parents can be an even bigger challenge, and they will need much guidance and follow-up to ensure breastfeeding is successful.

In the case of adoption, a devastating prognosis, or infant death, the mother can prepare herself for a gradual decrease in her milk supply to allow for her physical health. Any milk she has in storage can be donated to a human milk bank (see Focus On: *What Is a Human Milk Bank?* in Chapter 42). This will give her comfort in knowing that the milk she produced and saved for her own baby will not be wasted but be used for another infant who may need it. Again, much support and guidance from knowledgeable professionals is necessary during these trying times.

Breastfeeding Multiples. Breastfeeding twins, triplets, or more is certainly challenging, but possible. A mother who plans to breastfeed multiples will most likely need assistance, especially in the early days. If the babies are healthy and brought home soon after birth, she can begin breastfeeding them right away and establish her milk supply with the help of at least two babies instead of one. This means a greater milk supply will be

available if she responds to their hunger cues, just like with a singleton. She will be busier, no doubt, and feeding multiples during the first few weeks will be intense, to say the least. If the mother is determined to establish a good breastmilk supply early on and has the household help she needs, she can be successful. If, however, the infants are sick and must remain hospitalized for a while, she needs to use an effective breast pump to bring in her milk supply and should make her expressed breastmilk available for the babies' nutrition. A lactation consult with an IBCLC is strongly recommended in such cases.

See [Table 15-16](#) for a summary of common problems that breastfeeding mothers may encounter, with ways to prevent or remedy these situations.

Galactagogues

Low milk supply is a common concern among breastfeeding mothers. Whether real or perceived, mothers throughout the ages have turned to herbal remedies and medications to assist them in increasing their milk supply. Because milk supply is determined mainly by emptying the breasts regularly and effectively, this should be the first action taken to promote milk production. However, sometimes because of the effects of maternal or infant illness and hospitalization or separation because of work or school, a mother may find that despite her efforts, her milk supply is faltering. Galactagogues also have been used in cases of adoption or relactation (re-establishing a milk supply after weaning). **Galactagogues**, or milk production stimulants, can be classified as medications, herbals, or foods—each with its own results. Herbals must be used with caution as many contain chemical substances that may be dangerous to the infant. A lactation consultant or herbalist who is knowledgeable about their use in breastfeeding mothers should be consulted before using them. Standard recommended doses should not be exceeded ([Hale, 2012](#)).

[Table 15-17](#) provides a list of common galactagogues along with possible side effects and contraindications. Medications

TABLE 15-16 Management of Breastfeeding Difficulties

Problem	Approaches
Inverted nipples	Breast shells with appropriate backing can be used during the last trimester of pregnancy. Before feeding the infant, roll the nipple gently between the fingers until erect. May use breast pump for 1-2 minutes before latching baby to bring nipple out.
Breast engorgement	Soften breasts/nipple by expressing a small amount of milk or use reverse pressure softening technique; allow baby to nurse frequently and/or express with hand or pump after feeding to relieve engorgement. Use cool compresses to ease pain after breastfeeding. Raw cabbage leaves placed on breasts for a few minutes every few hours may help to reduce swelling. Approved oral antiinflammatory medication may be used for pain.
Poor latch	Ensure proper positioning at breast; encourage baby to take a "mouth-full" of breast into his mouth; use nipple shield as last resort (use only with professional guidance).
Baby's mouth not open wide enough	Before feeding, depress the infant's lower jaw with one finger as the nipple is guided into the mouth. Elicit wide-open mouth from baby tickling upper lip with nipple.
Sore nipples	Strive for proper latch (possible temporary use of nipple shields with professional guidance); for pain relief: approved nipple ointment, breast shells with appropriate backing if extremely sensitive, hydrogel pads, approved pain meds. Check for ankyloglossia, fungal infection, or improperly fitting pump flange.
Baby sucks poorly	Stimulate sucking motions by pressing upward under the baby's chin. Use breast massage to express milk in baby's mouth and stimulate suck/swallow. Rule out infant/maternal physical or medical issues.
Baby demonstrates rooting but does not grasp the nipple; eventually cries in frustration	Interrupt the feeding, comfort the infant; the mother should take time to relax before trying again. Place baby in a comfortable position facing the breast. Express a few drops of milk on the nipple to entice the baby to latch.
Baby falls asleep while nursing	Mother may be able to awaken the infant by holding baby upright using skin-to-skin (when possible), rubbing baby's back, talking to baby, or providing similar quiet stimuli; another effort at feeding can then be made. If the baby falls asleep again, the feeding should be postponed. Use breast massage to encourage milk to flow more rapidly and stimulate infant to suck/swallow.

TABLE 15-16 Management of Breastfeeding Difficulties—cont’d

Problem	Approaches
Plugged ducts	Firm fingertip massage in area of plug. Warm compresses before/during feedings on affected area. Frequent emptying of breast. Point baby’s tongue in direction of plugged duct. Lecithin supplement may help to prevent reoccurrence.
Mastitis	Signs of infection: breast is red and tender. Possible maternal fever, malaise. Maternal antibiotics may be indicated; call physician. Continue to breastfeed as comfort allows; frequent emptying of breasts with breastfeeding or expression. Breastmilk is safe for baby. Maternal rest recommended.
Thrush	Treatment must include mother and baby to prevent cross-infection/reinfection. Wash hands meticulously; sterilize items in contact with mother’s breasts or baby’s mouth or diaper area. Keep nipples dry. Approved nipple ointment for mother and oral medication (antifungal) for infant indicated—call physician. Breastmilk is safe for baby. Continue to treat at least 1 week after symptoms are gone to prevent return of infection. Some natural remedies may help: vinegar rinses on nipples and baby’s diaper area, garlic supplements, probiotics/acidophilus, Echinacea, grapefruit seed extract—consult physician or lactation consultant.
Raynaud’s Nipple vasospasms	Ensure proper latch to prevent worsening of symptoms. Keep nipples warm; lambswool bra pads may be helpful. May apply dry heat immediately after nursing. Use approved pain medication as needed; consider calcium channel blocker. Avoid caffeine, nicotine, and other vasoconstrictive drugs.
Perceived low milk supply	Offer breast frequently to allow infant to stimulate milk supply as desired; practice skin-to-skin care to stimulate prolactin production; express milk after/between feedings; avoid pacifiers and bottle supplementation unless advised by health care professional. Good nutrition, rest, and stress management is also advised. Watch for signs of adequate infant output (frequent wet diapers; appropriate bowel movements). Monitor baby’s weight for reassurance of adequate maternal milk supply/infant intake.
True low milk supply	Ensure infant is latched correctly for maximum comfort & effectiveness; offer both breasts at every feeding—switch sides a few times during a feeding session for extra stimulation; avoid pacifiers and bottles; increase breast emptying by nursing or expression (length and frequency)—8-12 times/day; use pump for a few minutes after a breastfeed; when pumping, continue for 5 minutes after milk stops flowing to elicit additional let down; include pumping session between 1 and 5 A.M. when milk production is highest; use high-quality electric double pump (consider renting hospital grade pump); massage breast while pumping; always use correct flange size; use skin-to-skin care at each nursing session; rest/adequate nutrition/hydration; manage stress. Consider galactagogues (natural herbs or medication)—only with medical supervision (see Table 15-17). Supplementation may be necessary (human milk preferred, possibly using supplementer at breast, cup, syringe, dropper).

Consult with physician and IBCLC (International Board Certified Lactation Consultant) for expert advice.

TABLE 15-17 Common Galactagogues

Class of Galactagogue	Specific Substance	Comments
Medications	Domperidone (<i>Motilium</i>)	Raises prolactin and proven useful as a galactagogue; few CNS effects such as depression. Recommended dosage: 10-20 mg orally 3-4 times daily.
	Metoclopramide (<i>Reglan/Maxeran/Maxolon</i>)	Raises prolactin and proven useful as a galactagogue; side effects may include diarrhea, sedation, gastric upset, nausea, extrapyramidal symptoms, severe depression. Recommended dosage: 10-15 mg orally 3 times daily.
Herbals	Fenugreek (<i>Trigonella foenum graecum</i>)	Strong reputation as an effective galactagogue, but undocumented. Side effects include maple syrup odor in urine and sweat (mother and baby); may cause diarrhea, hypoglycemia, dyspnea. Not to be taken during pregnancy. Recommended dosage: 2-3 capsules orally 3 times daily (no more than 6 grams per day).
	Milk Thistle (<i>Silybum marianum/Silymarin</i>)	Reputation as a galactagogue, but undocumented. Side effects include occasional mild GI side effects, increased clearance of metronidazole. Suggested dosage: 420 mg daily or 2-6 cups tea/day.
	Cooking herbs: anise, blackseed, caraway, coriander, dill, fennel Nonfood herbs: alfalfa, blessed thistle, nettle, goats rue, red clover, shatavari	Historical and cultural uses as galactagogues; effectiveness undocumented. Assumed to be safe with recommended dosages (varies with specific herbs), although strengths of herbal product ingredients may vary depending on particular plant used and how processed; caution is advised for use during pregnancy. Some companies make special blends for breastfeeding mothers.
Foods/beverages	Grains, nuts, seeds: oats (not instant), barley, brown rice, beans, sesame, almonds Fruits/Vegetables: dark green leafy vegetables, apricots, dates, figs, cooked green papaya Soups made from Torbangun or Mulunggay leaves	Historical and cultural uses as galactagogues; effectiveness undocumented. Recommended daily intake not documented.

Adapted from Marasco L: Inside track: increasing your milk supply with galactagogues, *J Hum Lact* 24:455, 2008; Hale TW: *Medications and mother’s milk*, ed 15, Amarillo, Tex, 2012, Hale Publishing; Academy of Breastfeeding Medicine Protocol Committee (ABM): ABM Clinical Protocol #9: Use of Galactagogues in initiating or augmenting the rate of maternal milk secretion, *Breastfeeding Med* 6:41, 2011.

used to increase a mother’s milk supply must be prescribed by the mother’s health care provider. Lactating women always should let the baby’s health care provider know if anything is taken to increase milk supply. Although traditional use of galactogogues suggests safety and possible efficacy, the mechanisms of action for most herbals have not been proven (ABM, 2011). Despite some traditional beliefs, beer and other alcoholic beverages do not increase milk supply and should not be used for this purpose.

Sustaining Maternal Milk Supply and Preservation of Successful Breastfeeding

Insufficient milk supply is rarely a problem for the well-fed, well-rested, and unstressed mother who stays in close contact with her baby. Sucking stimulates the flow of milk; thus feeding on demand should supply ample amounts of milk to the infant. Skin-to-skin care also can benefit the mother and baby by stimulating prolactin production in the mother while keeping the baby comforted and familiar with the mother. In the early days, indications of sufficient milk supply are that the baby continues to gain weight and length steadily, has at least six to eight wet diapers daily, and has frequent stools. Refer to Table 15-16 for tips on increasing milk supply.

Occasionally, however, breastfeeding complications can interfere with success. Figure 15-8 illustrates potential problems in the mother or the infant that should be investigated if the mother feels that her milk supply is dropping or the baby is showing signs of slow growth. The cause of the problem must be identified and corrected to preserve the breastfeeding relationship and maintain the infant’s growth and development. Professional assistance is available to identify and correct any complications that may interfere with successful breastfeeding. An IBCLC can be found at birth hospitals or centers, pediatric hospitals, maternal-child clinics, physicians’ offices, and private practices.

Sometimes the infant may show intolerance (i.e., fussiness, loose stools) to something the mother has ingested. The mother is advised to temporarily eliminate suspected irritants until a

later time when the baby is older and the gastrointestinal track more mature. Many times food sensitivity is outgrown after a few weeks or months. Any food may be the culprit, including cow’s milk protein (casein fraction), cruciferous vegetables, carbonated drinks, or even spicy foods. When suspicious foods are removed from the mother’s diet, it is important to assess the nutritional quality of her diet and supplement appropriately.

Concerns During Lactation

Transfer of Drugs and Toxins into Human Milk

Almost all drugs taken by the mother appear in her milk to some degree. The amount that usually transfers is small and only rarely does the amount transferred into the mother’s milk result in clinically relevant doses in the infant. Many factors influence how medications transfer into human milk: milk/plasma ratio, molecular weight of the drug, and the protein binding and lipid solubility of the drug. Once a drug has been ingested by the infant through the mother’s milk, it must travel through the baby’s gastrointestinal tract before absorption. There are many processes here that may disallow the drug actually to be metabolized in the infant’s system. Caution is recommended especially for mothers who are nursing premature or ill infants as they are at a higher risk of the effects of even small amounts of medications that may come through maternal milk (Hale, 2012).

Many mothers have discontinued breastfeeding because of their need for a medication, when in fact there was a good chance that the drug could have been taken without risk to the baby. It is likely that medications penetrate into colostrum more than in mature milk, although even during this time, the amounts the baby is exposed to are very low. When the medication increases in the mother’s plasma, it also increases in her milk. When the medication level falls in the mother’s plasma, equilibrium is sought in the mother’s milk, which drives the medication back into her plasma for elimination (Hale, 2012).

Centrally active drugs (anticonvulsants, antidepressants, anti-psychotics) frequently penetrate milk in elevated levels based

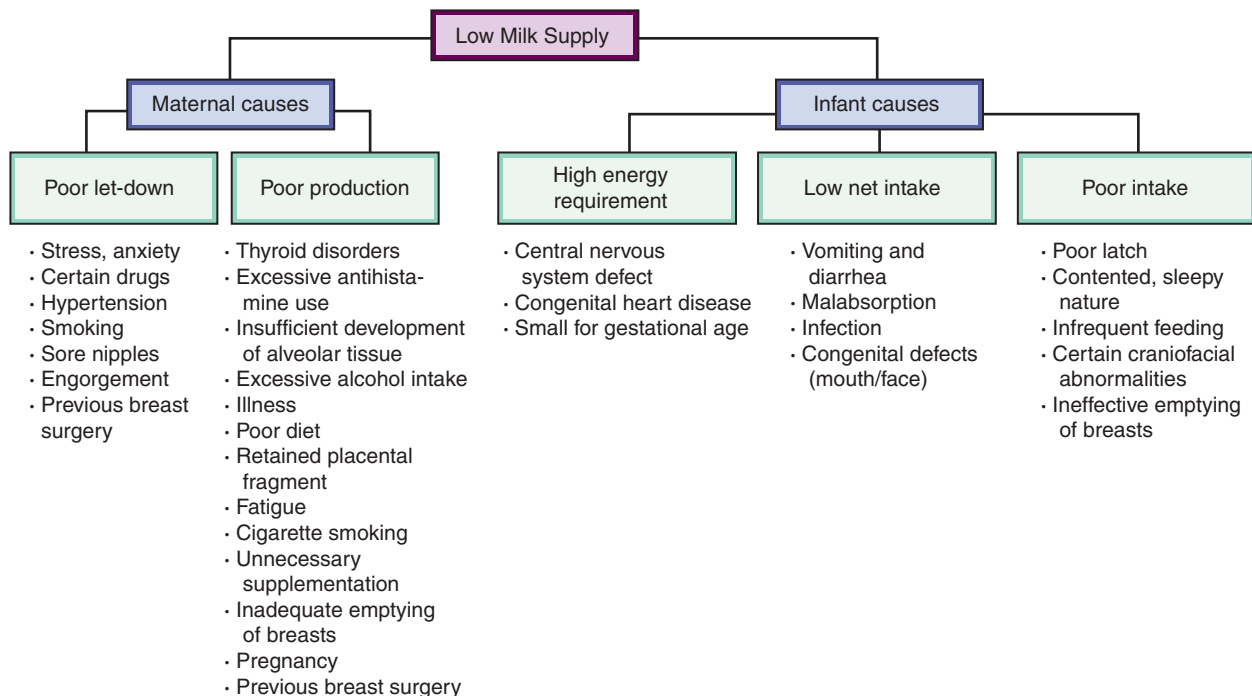

FIGURE 15-8 Diagnostic flow chart for inadequate maternal milk supply.

merely on their physiochemistry. When sedation, depression, or other CNS effects are experienced by the mother when taking the medication, it is likely to penetrate the milk and cause similar effects in the infant. These drugs must be used with caution, and the mother should always discuss risk-benefits of breastfeeding and her need for such medications with her health care provider.

Maternal Substance Abuse. According to the AAP, maternal substance abuse is not a categorical contraindication to breastfeeding. If a mother is well nourished and negative for HIV, even if narcotic-dependent, she should be encouraged to breastfeed as long as she is supervised in a methadone maintenance program (AAP, 2012; ABM and Jansson, 2009). Breastfeeding still provides the many immunologic, nutritional, and bonding advantages over artificial feeding. Very little methadone is transferred into breastmilk; however, studies are mixed reporting how breastfeeding should be managed in the mother-infant dyad to lessen the risk for neonatal abstinence syndrome (Dryden et al, 2009; Isemann et al, 2011). Growth parameters in the child should be monitored to ensure adequate development, but breastfeeding should continue to be encouraged as long as these measures are within the normal range. The long-term effect of methadone exposure beyond the neonatal period is relatively unknown. Studies have shown samples of blood and breastmilk up to 1 year show low concentrations of methadone, justifying the recommendation that mothers continue to breastfeed (Hudak et al, 2012). If a mother decides to discontinue breastfeeding, weaning slowly over 3 to 4 weeks helps to protect the infant from withdrawal symptoms.

The AAP and ACOG have provided information regarding the transfer of drugs and other chemicals into human milk (AAP, 2006). Websites that can provide more information include the AAP (www.aap.org), Lactmed (<http://toxnet.nlm.nih.gov/newtoxnet/lactmed.htm>), and the Infant Risk Center (www.infantrisk.com).

Environmental Toxins. There is concern about environmental toxins entering the milk of a lactating mother; however, at this time there are no established “safe” levels to aid in clinical interpretation. Despite any pollutants that may be found in human milk, the benefits of breastfeeding far outweigh the risks posed by any contaminants that may be found there. Nonetheless, mothers should take care not to allow any unnecessary exposure to pesticides and other harsh chemicals, as well as limit intake of animal fat, which can contain higher amounts of environmental contaminants. This helps safeguard against unwanted substances in human milk.

In the past, mothers were told not to lose too much weight too fast after pregnancy because it was thought that a rapid weight loss could possibly accelerate the release of toxins stored in a woman’s body fat. However, this has not been proven to be true. Nonetheless, slow, steady weight loss during the postpartum period is recommended to allow a healthy return to prepregnancy weight with greater likelihood of keeping the weight off.

Overweight or Obesity

Overweight or obese lactating women can restrict their energy intake (once the milk supply is well-established) by 500 kcal per day by decreasing consumption of foods high in fat and simple sugars, but they must increase their intake of foods high in calcium, vitamin D, vitamin A, vitamin C, and omega-3 fats to provide key nutrients for their milk supply. The lactational period can be used as a time to allow natural slow weight loss in these mothers by taking advantage of the caloric demands of breastfeeding. The nutritional status of lactating women who have previously

undergone gastric bypass surgery requires close attention, because suboptimal levels of iron, vitamin A, vitamin D, vitamin K, folate, and calcium have been reported (see Chapter 21).

Women with higher prepregnant BMI values also warrant extra lactation support to prevent early weaning and to reach their breastfeeding goals. Research has shown that although intentions of the obese woman to breastfeed may be strong, there can be many psychosocial determinants that may influence her commitment and ability to initiate or continue nursing her infant. Obese women also have shown to have delayed lactogenesis II, the sudden increase in volume a few days after delivery, which could be a risk factor in not establishing a milk supply. Although obese women experience lower rates of successful breastfeeding, the association between maternal obesity and breastfeeding outcomes has not been explained fully (Hauff et al, 2014).

Exercise and Breastfeeding

The breastfeeding mother should be encouraged to resume an exercise routine a few weeks after delivery and after lactation is well established. Aerobic exercise at 60% to 70% of maximum heart rate has no adverse effect on lactation; infants gain weight at the same rate, and the mother’s cardiovascular fitness improves. Exercise also improves plasma lipids and insulin response in lactating women (Lovelady, 2011).

Mothers may be reluctant to exercise because of concerns of how this affects their breastmilk and consequently the growth of their infants. Moderate aerobic exercise (45 minutes/day, 5 days/week) has not been shown to affect milk volume or its composition. Mothers who incorporate diet and exercise into their routines in an effort to lose weight during the postpartum period also have been studied and have shown no ill effects on the growth of their infants (Daley et al, 2012; Lovelady, 2011).

Breast Augmentation

Breast augmentation, a procedure in which an implant is inserted into the breast to enlarge it, is a common elective breast procedure. Periareolar and transareolar incisions can cause lactation insufficiency. These mothers should be encouraged to breastfeed, and their infants monitored for appropriate weight gain. Other means of augmentation, in which implants are placed between breast tissue and the chest wall, usually have no effect on the woman’s ability to produce a full milk supply.

Reduction Mammoplasty

Reduction mammoplasty often is recommended for women with extremely large breasts who suffer from back, shoulder, or neck pain or poor body image. In lactating women who have had this surgery there are wide variations in milk production, from a little to full production, depending on the amount of tissue removed and the type of surgical incision. These mothers also should be encouraged to breastfeed and be given anticipatory guidance and support; their infants should be monitored closely for appropriate weight gain.

Postpartum Depression

Postpartum depression (PPD) may be one of the most underdiagnosed obstetric complications in the United States. PPD leads to numerous negative consequences affecting the mother and child, including increased costs of medical care, inappropriate medical care, child abuse and neglect, discontinuation of breastfeeding, and family dysfunction. All this adversely affects early brain development in the infant (Earls, 2010), which could possibly lead to future problems.

Although effective treatment is available, fewer than half of mothers with this condition are recognized or seek help. PPD has been found to be lower in breastfeeding mothers (Xu et al, 2014). Because breastfeeding triggers the release of the hormone oxytocin, many women report feeling calm and relaxed while they are nursing. When breastfeeding is successful and things are going well, with maintenance of a good milk supply without complications, and baby is gaining appropriate weight, the breastfeeding relationship can ward off feelings of loneliness, emptiness, or failure—common feelings in PPD. A higher circulating oxytocin level sustains a sense of calm and allows a mother to cope with the everyday stresses of new motherhood. Conversely, when things are not going well, when complications of breastfeeding and new motherhood become overwhelming, many new mothers experience signs of the “blues,” which can escalate into full PPD. The “baby blues,” affecting 70% to 80% of all new mothers (APO, 2014), is short lived, does not impair functioning, and can be treated with reassurance and emotional support. PPD, however, is characterized by a major depressive episode within 1 month after delivery, and is experienced in 10% to 15% of women after giving birth. Symptoms are restlessness, anxiety, fatigue, and a sense of worthlessness. Some new mothers worry they will hurt themselves or their babies. Unlike the “baby blues,” PPD does not go away quickly. A mother with diagnosed PPD usually requires a more intensive approach to treatment (USDHHS, 2014).

Diet quality and overall nutritional status may affect the risk of postpartum depression (Procter and Campbell, 2014). Many dietary components are being investigated regarding their role in minimizing PPD, including omega-3 fatty acids, folate, vitamins B₂, B₆, B₁₂, D, calcium, iron, and selenium. However, there is little evidence of benefit from supplementation. Mawson and Wang recently proposed that high levels of vitamin A compounds may be in part responsible for maternal PPD, and that breastfeeding offers protection against PPD by maintaining endogenous retinoids below a threshold concentration. Women accumulate retinoids in the liver and the breast during pregnancy in preparation of providing vitamin A to their infants. Because prolonged lactation reduces maternal stores of retinoids, this also provides a natural means of reducing potentially toxic concentrations in the mother (Mawson and Wang, 2013).

When early signs of PPD are present, and a mother stops breastfeeding, even more severe depression can affect the mother. Oxytocin levels fall abruptly, and a mother's feelings of failure may become even more pronounced. It is critical for families to be aware and for health care providers to screen for early symptoms of PPD not only to prevent more serious symptoms of the disease but also to protect and preserve the breastfeeding relationship. Maternal-child health care providers must prepare mothers and families for expected breastfeeding challenges, advocate for a supportive environment in birthing hospitals, and promote breastfeeding as the cultural norm in the community so that the breastfeeding relationship is successfully established early in the postpartum period (Olson et al, 2014).

PPD can affect milk production, let-down, and the ability to maintain an adequate milk supply for the baby. The elevated levels of cortisol present in PPD may delay lactogenesis II. When the blues turns into a more serious form of PPD, the establishment of a healthy bond between mother and child may be affected, jeopardizing the breastfeeding relationship and potentially leading to early weaning (Wu et al, 2012b).

Medical treatment for PPD while breastfeeding includes medications such as Zoloft, Paxil, and Prozac. These should be taken immediately after a feeding to allow the maximum time for drug clearance from milk before the next feeding. Also, the mother can express and discard her milk collected when peak serum levels of the drug are present. Monoamine oxidase (MAO) inhibitors are contraindicated for treatment of PPD if the mother is breastfeeding (Hale, 2012; see Chapter 8).

Birth Control and Breastfeeding

Many women begin to think about birth control shortly after delivery and while they are breastfeeding a new baby. The mother must consider the effects of the birth control method on her nursing, as well as how it may affect her milk supply.

The Lactation Amenorrhea Method (LAM) does not involve any device or medication and is completely safe for breastfeeding mothers. LAM is an important modern contraceptive method that, when practiced correctly, has a 98% effectiveness rate 6 months postpartum (Fabric and Choi, 2013). It must be emphasized that the method is effective ONLY when three conditions are met: (1) the infant is less than 6 months old, (2) the mother is amenorrheic, and (3) the mother is fully breastfeeding (baby not receiving anything other than milk at the breast, meeting all sucking needs at the breast without a pacifier). Mothers must be very attentive to the inclusion of all these factors if they are dependent on this method to prevent pregnancy. As soon as one of these parameters is absent, the mother is advised that she should employ an additional form of birth control if pregnancy is still not desirable.

Birth control methods using a combination of progestin and estrogen come in several different forms: combination birth control pill, monthly injections, patch, and the vaginal ring. Although progestin and estrogen are approved by the AAP for use in breastfeeding mothers, it is possible that estrogen-containing contraceptives may affect a mother's milk supply and therefore a progestin-only medication (minipill) may be a better choice, at least until 6 months postpartum. A longer lasting form of progestin-only birth control is the Depo-Provera (“depo”) shot that lasts at least 12 weeks but may be effective even up to a year.

There are concerns that Latina women with a history of gestational diabetes taking the minipill or depo shot as a means of birth control may be at a higher risk of developing chronic diabetes (Kjos et al, 1998). This is especially the case when the depo shot is taken when other risk factors are present, including increased baseline diabetes risk, weight gain during use, and high baseline triglycerides or during breastfeeding (Xiang et al, 2006). Latina women with a history of GDM may need to consider another form of birth control other than progestin-only medications; combination oral contraceptives (COC) do not seem to increase the risk of type 2 diabetes, however, these are not recommended during lactation because of the negative effect on maternal milk supply.

A progestin-only IUD such as Mirena may have fewer side effects on a mother's milk supply. This product delivers hormones directly to the lining of the uterus, leading to only a slight increase in serum progesterone levels, less than with the minipill. The birth control implant (Norplant, Implanon) is another choice for women who wish to choose progestin-only means of birth control. The implant can last up to 5 years. Women are warned they may want to consider the pill form before using a longer-lasting form of birth control in case they are susceptible to a drop in milk supply even with progestin-only pills. This allows them to stop the pills and choose another

birth control method (i.e., LAM or barrier) so that they do not have to wait for the effects of the progestin to wear off. No effect on infant growth has been noted with these medications, but for those who may be concerned about the unknown, barrier methods of birth control, an IUD without hormones (Para-Gard), or LAM, ensure that no drug is secreted in breastmilk.

One other form of birth control pill, meant to be used as a last resort (breastfeeding or not), is the so-called “morning-after pill.” These are also available in a combination of estrogen and progestin (Preven, Ovral), or the progestin-only form (Plan B, Plan B One-Step). Mothers should consult with their health care providers or lactation consultants if a drop in milk supply is noticed. This may be just a short-lived, temporary condition, but close follow-up can ensure that this is the case. The AAP has approved this medication for use during breastfeeding, although it should be used only in rare circumstances.

Breastfeeding during Pregnancy

Mothers may discover they are pregnant while they are still nursing a young baby or child. If the pregnancy is normal and healthy, it is considered safe to continue to breastfeed throughout the pregnancy. A mother need not worry that her milk will be any less nutritious for her nursling. She may be concerned that the act of breastfeeding will interfere with her pregnancy, but that is not a valid concern unless she experiences a difficult pregnancy and is at risk for early labor. If she has been told to avoid intercourse by her physician, this also may indicate that she should stop breastfeeding since the release of oxytocin is involved in both. Earlier in pregnancy, the amount of oxytocin normally released during breastfeeding is not usually enough to cause the cervix to open.

Increased fatigue and nausea early in pregnancy may be challenging for the expectant mother; however, if breastfeeding continues, rest and a concerted effort to maintain good nutritional intake is a must. Sore nipples are also common early in pregnancy and may be the first sign to the mother that she is pregnant. She may need to employ methods of dealing with nipple tenderness (i.e., distraction, pain management techniques) to get through this period of time if breastfeeding is to continue. Because the quantity of the milk may decrease and the taste of the milk may change early during pregnancy, the nursling may reject breastfeeding altogether and self-wean. A mother may need to encourage her baby to continue to breastfeed if desired, especially if the baby is very young and still dependent on her milk for the majority of his or her nutritional intake.

Tandem Nursing

Tandem nursing is when the mother breastfeeds siblings who are not twins. As soon as the placenta is delivered, the mother will begin to produce colostrum once again. The mother should ensure that the new baby always has priority to this because it provides the protection the newborn needs. Sometimes mothers find that the nursing toddler is a help to her by preventing or relieving engorgement. In fact, with the stronger suck and intake of the toddler, the mother may begin to overproduce for the newborn. If she develops a strong let-down reflex releasing a large quantity of milk when the newborn first latches, it may cause coughing and choking. In this case the mother may want to express a small amount of milk before latching her newborn, or simply allow the toddler to nurse for a few minutes first.

Concerns of hygiene are unwarranted when a mother is nursing two siblings. The small bumps on the areola called

Montgomery glands produce a natural oil that cleans, lubricates, and protects the nipple during pregnancy and breastfeeding. This oil contains an enzyme that kills bacteria so that both children are protected. In addition, more immunities will be passed on through the breastmilk itself. If, however, the mother or one child develops thrush, she is advised to limit each child to one breast temporarily.

An older baby who has weaned prior to the birth of a new sibling may express interest in breastfeeding again. Handling this situation is a delicate one and calls for special attention to the older child, whether or not the mother decides to offer the breast again.

Weaning

Weaning begins at the first introduction of anything other than mother’s milk. As a breastmilk substitute or solid foods begin to be offered to the baby, the weaning process has begun. Although breastfed babies tend to accept a variety of solid foods well, because of the fact that they already have been introduced to different flavors of food through their mother’s milk, this does not mean that the infant is ready to stop breastfeeding. Breastmilk is recommended for the infant throughout at least the first year of life as stated previously, and even through the second year of life by some authorities (WHO, 2013). A mother may choose to allow **baby-led weaning**, which simply means she will offer breastfeeding for as long as the baby is interested. If a baby seems to be losing interest in breastfeeding while still very young (i.e., younger than 12 months), the mother can try various methods of encouraging him to continue to breastfeed, such as ensuring a good position at the breast, and cutting out any bottles or foods so that more nutrition will be offered through breastfeeding. An older baby may be distracted easily during nursing sessions; a quiet, darkened room may help to keep the baby focused on nursing, and get him back on track with breastfeeding regularly. Human milk remains a nutritious fluid for as long as it is produced by the mother; however, the breastfeeding relationship changes as the baby gets older. Babies may show a lack in desire to breastfeed at different ages, depending on many factors. As the child grows, breastfeeding becomes less of a nutritional need but more of a need for the psychological bond with their mother. Older infants may be happy to nurse three to four times a day, and toddlers may show interest only every now and then.

Some mothers may choose **mother-led weaning**, which is when the mother encourages the baby to stop breastfeeding. She may begin to offer other foods or beverages when the baby wants to nurse, or try to distract the baby in other ways. If this method is used, the mother should ensure that the baby’s emotional needs are met because this could be a trying time for mother and child. The decision is up to the mother, and her decision should be supported, although if at all possible, she should be encouraged to provide her milk throughout the first year for her health of that of her baby.

Return to Work or School

A mother’s return to work or school can be a major challenge for continued successful breastfeeding; however, it is possible and encouraged. If a nursing mother returns to work or school, it is best to wait until breastfeeding is going well and a good milk supply has been established. Babies placed in child care experience a higher chance of becoming ill

TABLE 15-18 Storage of Human Milk for Healthy Full-term Infants

STORING FRESH BREASTMILK			
Location	Temperature	Maximum Time	Comments
Outside refrigerator	Room temperature (60° F-85° F)	3-4 hours (optimal) 6-8 hours (maximum)	Containers should be covered; discard leftover milk within 1-2 hours after feeding
Small cooler with blue-ice pack	59°F	24 hours	Ice packs should be in contact with containers; keep cooler closed—open only when needed
Refrigerator	≤39°F	≤72 hours (optimal) 5-8 days (maximum)	Keep milk in rear of refrigerator for maximal cooling
Freezer	≤0°F	≤6 months (optimal) ≤12 months (maximum)	Store in back of freezer for constant temperature
STORING THAWED BREASTMILK			
	Room temperature (60° F-85° F)	Refrigerator (≤39° F)	Freezer
Thawed breastmilk	≤1-2 hours (optimal) ≤3-4 hours (maximum)	24 hours	Do not refreeze

Adapted from USDHHS, Office on Women's Health: *Breastfeeding: Pumping and Milk Storage* (website): <http://www.womenshealth.gov/breastfeeding/pumping-and-milk-storage/>, 2014. Accessed February 2014.

when exposed to other children; however, breastmilk offers protection against germs the child is likely to be exposed to in these environments.

An exclusive diet of human milk continues to provide optimal nutrition through the baby's first 6 months. After that time, when appropriate solid foods are introduced into the baby's diet, mother's milk is the milk of choice at least through the baby's first year, and even beyond. The mother also experiences rewards if she is able to continue to breastfeed after her return to work or school. This helps to maintain an emotional connection with her baby because she will be reminded physically throughout the day of the need to express milk from her breasts. She also can continue to preserve the breastfeeding relationship with her baby when at home. Because of the advance in quality of breast pumps on the market today, mothers are able to express milk and maintain their supply effectively and comfortably. See Table 15-18 for breastmilk storage guidelines for healthy full-term infants and Table 15-19 for guidelines for hospitalized infants.

TABLE 15-19 Human Milk Storage Recommendations for Hospitalized Infants

Storage Method	Recommended Storage Time
Freezer (home unit combined with refrigerator)	3 months
Freezer (-20° C, -4° F)	6-12 months
Freezer (-70° C, -94° F)	≥12 months
Refrigerator (4° C, 40° F), fresh milk	48-96 hours*
Refrigerator (4° C, 40° F), thawed milk	24 hours
Refrigerator (4° C, 40° F) fortified milk	24 hours
Refrigerator (4° C, 40° F), thawed pasteurized donor milk	48 hours
Cooler with ice packs (15° C, 59° F), fresh milk	24 hours
Room temperature (25° C, 77° F)	<4 hours

Adapted from Academy of Nutrition and Dietetics: *Infant feedings: guidelines for preparation of human milk and formula in health care facilities*, ed 2, 2011, ADA.

*Applies to fresh milk unit-dosed at time of expression when expressed under clean conditions before infant feeding.

Many mothers are able to obtain breast pumps using their health insurance or through the WIC program. Federal and state laws also offer protection for the lactating worker so that she is ensured a private, clean space (other than a restroom) to express her milk while away from her baby. Mothers should talk to school personnel or their work supervisor before their maternity leave so that a plan is in place upon her return, and so that all parties involved will have an understanding of what to expect. A woman who expresses her milk regularly throughout the day with an effective pump can maintain a full milk supply for as long as she desires while at work or school full time. A mother facing this situation can find more help with this by discussing any questions or challenges with a lactation professional.

Common Nutrition Diagnosis Statements in Pregnant or Lactating Women

- Limited access to food related to low income and misunderstanding of the use of WIC vouchers as evidenced by other family members using the WIC foods in the household
- Obesity related to frequent meals and snacking during pregnancy as evidenced by weight gain of 30 pounds in second trimester
- Intake of unsafe foods related to storing fresh milk on the counter as evidenced by home visit by social worker and discussions with client
- Inconsistent carbohydrate intake related to management of gestational diabetes as evidenced by nutritional history of skipping breakfast and sometimes lunch
- Abnormal gastrointestinal function related to heartburn as evidenced by complaints of reflux after every meal and excessive use of antacids
- Inadequate food and beverage intake related to irregular income as evidenced by discussion about migrant status and the challenges during pregnancy
- Breastfeeding difficulty related to frequent nipple soreness as evidenced by mother's hesitancy to continue nursing her 6-month-old
- Food- and nutrition-related knowledge deficit of breastfeeding management related to frequent infant crying and slow infant weight gain as evidenced by a mother's report of keeping baby on a strict feeding schedule
- Undesirable food choices as related to mother's desire for rapid weight loss while breastfeeding as evidenced by dietary recall showing excessive intake of diet drinks and low calorie food items.

CLINICAL CASE STUDY 1

Carol is a 34-year-old woman who was pregnant recently for the first time, but the baby had anencephaly and died at birth. She has a sister who has spina bifida and an older brother who had a stroke when he was 14. Carol has now been tested and found to have a genetic defect known as a 677C>T polymorphism in the methylenetetrahydrofolate reductase (MTHFR) gene.

Of course, she and her husband were devastated with the loss of their first child, but they also very much want to be parents. She has gone to genetic counseling but is also coming to you to find out what she can do to lower the chances that this happens again. She is worried about using the traditional prenatal vitamin-mineral supplement because she has been cautioned that she is unable to metabolize folic acid from diet and supplements.

Nutrition Diagnostic Statement

Altered nutrient (folic acid) metabolism related to a genetic alteration as evidenced by positive results for C>T in the MTHFR gene and family history of spina bifida and stroke

Nutrition Care Questions

1. What advice would you give Carol about any special dietary changes?
2. Carol knows that there is a special prenatal vitamin-mineral supplement available but does not know how to obtain it. How will you help Carol find this supplement?
3. What are the risks for a successful pregnancy outcome if Carol cannot find this special prenatal supplement?
4. What other concerns do you have regarding her pregnancy?

CLINICAL CASE STUDY 2

Cecilia is 3 months postpartum after a normal labor and full-term delivery. She tells you that she is exclusively breastfeeding her baby about eight times a day but is very tired and is not getting much sleep because her baby always seems fussy between feedings—day and night. She has been determined to lose her “baby weight” and for the past 6 weeks, she has been restricting her caloric intake to around 1200 calories/day, including approximately six diet drinks every day. She reports that the pediatrician told her that the baby’s weight gain has slowed over the past month and she would like her to begin supplementing the baby with formula. She is hesitant to do this because her goal is to continue breastfeeding exclusively until the baby is 6 months old, and then possibly continue until at least the baby’s first birthday.

Nutrition Diagnostic Statement

Difficulty breastfeeding related to poor maternal dietary intake as evidenced by mother’s report of inappropriate diet and baby’s poor weight gain

Nutrition Care Questions

1. What would you tell Cecilia regarding her concern about losing her “baby weight”?
2. What would you tell her to do to improve her dietary intake?
3. How would you address her baby’s fussiness and inadequate weight gain?
4. What advice would you give her to preserve her breastfeeding and achieve her breastfeeding goals?

whey proteins

During the first 2 years of life, which are characterized by rapid physical and social growth and development, many changes occur that affect feeding and nutrient intake. The adequacy of infants' nutrient intakes affects their interaction with their environment. Healthy, well-nourished infants have the energy to respond to and learn from the stimuli in their environment and to interact with their parents and caregivers in a manner that encourages bonding and attachment.

PHYSIOLOGIC DEVELOPMENT

The length of gestation, the mother's prepregnancy weight, and the mother's weight gain during gestation determine an infant's birth weight. After birth, the growth of an infant is influenced by genetics and nourishment. Most infants who are genetically determined to be larger reach their **growth channel**, a curve of weight and length or height gain throughout the period of growth, at between 3 and 6 months of age. However, many infants born at or below the tenth percentile for length may not reach their genetically appropriate growth channel until 1 year of age; this is called **catch-up growth**. Infants who are larger at birth and who are genetically determined to be smaller grow at their fetal rate for several months and often do not reach their growth channel until 13 months of age. This phenomenon during the first year of life is called **lag-down growth**.

Growth in infancy is monitored with the routine collection and monitoring of anthropometric data, including weight, length, head circumference, and weight-for-length for age. These are plotted on the appropriate World Health Organization (WHO) growth chart shown in Appendices 4, 5, 8, and 9. The WHO growth charts are used for the first 2 years of life and consist of a series of percentile curves that show the distribution of

body measurements in infants and children in optimal growth conditions. When the anthropometric data are plotted on the growth charts, the percentiles rank the infant by showing what percentage of the reference population the infant would equal or exceed. For example, a 7-month-old infant girl who has a weight-for-age at the 75th percentile weighs the same or more than 75% of the reference population for 7-month-old girls and weighs less than 25% of the same population. It is important to monitor growth trends over time and not focus on one measurement.

Infants may lose approximately 7% of their body weight during the first few days of life, but their birth weight usually is regained by the seventh to tenth day. Weight loss of more than 10% in the newborn period indicates need for further assessment regarding adequacy of feeding. Growth thereafter proceeds at a rapid but decelerating rate. Infants usually double their birth weight by 4 to 6 months of age and triple it by the age of 1 year. The amount of weight gained by the infant during the second year approximates the birth weight. Infants increase their length by 50% during the first year of life and double it by 4 years. Total body fat increases rapidly during the first 9 months, after which the rate of fat gain tapers off throughout the rest of childhood. Total body water decreases throughout infancy from 70% at birth to 60% at 1 year. The decrease is almost all in extracellular water, which declines from 42% at birth to 32% at 1 year of age.

The stomach capacity of infants increases from a range of 10 to 20 ml at birth to 200 ml by 1 year, enabling infants to consume more food at a given time and at less frequent intervals as they grow older. During the first weeks of life, gastric acidity decreases and for the first few months remains lower than that of older infants and adults. The rate of emptying is relatively slow, depending on the size and composition of the meal.

Fat absorption varies in the neonate. Human milk fat is well absorbed, but butterfat is poorly absorbed, with fecal excretions of 20% to 48%. The fat combinations in commercially prepared infant formula are well absorbed. The infant's lingual and gastric lipases hydrolyze short- and medium-chain fatty acids in the

Sections of this chapter were written by Cristine M. Trahms, MS, RD, CD, FADA

stomach. Gastric lipase also hydrolyzes long-chain fatty acids and is important in initiating the digestion of triglycerides in the stomach. Most long-chain triglycerides pass unhydrolyzed into the small intestine, where they are broken down by pancreatic lipase. The bile salt–stimulated lipase present in human milk is stimulated by the infant’s bile salts and hydrolyzes the triglycerides in the small intestine into free fatty acids and glycerol. Bile salts, which are effective emulsifiers when combined with monoglycerides, fatty acids, and lecithin, aid in the intestinal digestion of fat.

The activities of the enzymes responsible for the digestion of disaccharides—maltase, isomaltase, and sucrase—reach adult levels by 28 to 32 weeks’ gestation. Lactase activity (responsible for digesting the disaccharide in milk) reaches adult levels by birth. Pancreatic amylase, which digests starch, continues to remain low during the first 6 months after birth. If the infant consumes starch before this time, increased activity of salivary amylase and digestion in the colon usually compensate.

The neonate has functional but physiologically immature kidneys that increase in size and concentrating capacity in the early weeks of life. The kidneys double in weight by 6 months and triple in weight by 1 year of age. The last renal tubule is estimated to form between the eighth fetal month and the end of the first postnatal month. The glomerular tuft is covered by a much thicker layer of cells throughout neonatal life than at any later time, which may explain why the glomerular filtration rate is lower during the first 9 months of life than it is in later childhood and adulthood. In the neonatal period the ability to form acid, urine, and concentrate solutes is often limited. The renal concentrating capacity at birth may be limited to as little as 700 mOsm/L in some infants. Others have the concentrating capacity of adults (1200 to 1400 mOsm/L). By 6 weeks, most infants can concentrate urine at adult levels. Renal function in a normal newborn infant is rarely a concern; however, difficulties may arise in infants with diarrhea or those who are fed formula that is too concentrated (Butte et al, 2004).

NUTRIENT REQUIREMENTS

Nutrient needs of infants reflect rates of growth, energy expended in activity, basal metabolic needs, and the interaction of the nutrients consumed. Balance studies have defined minimum acceptable levels of intakes for a few nutrients, but for most nutrients the suggested intakes have been extrapolated from the intakes of normal, thriving infants consuming human milk. The dietary reference intakes (DRIs) for infants are shown in the inside front cover.

Energy

Full-term infants who are breast-fed to satiety or who are fed a standard infant formula generally adjust their intake to meet their energy needs when caregivers are sensitive to the infants’ hunger and satiety cues. An effective method for determining the adequacy of an infant’s energy intake is to monitor carefully gains in weight, length, head circumference, and weight-for-length for age and plot these data on the WHO growth charts shown in Appendix Tables 4, 5, 8, and 9. During the first year a catch-up or lag-down period in growth may occur.

If infants begin to experience a decrease in their rate of weight gain, do not gain weight, or lose weight, their energy and nutrient intake should be monitored carefully. If the rate of growth in length decreases or ceases, potential malnutrition, an undetected disease, or both should be investigated thoroughly.

If the weight gain proceeds at a much more rapid rate than growth in length, the energy concentration of the formula, the quantity of formula consumed, and the amount and type of semisolid and table foods offered should be evaluated. The activity level of the infant also should be assessed. Infants who are at the highest end of the growth charts for weight-for-length, or who grow rapidly in infancy, tend to be at greater risk for obesity later in life (Druet et al, 2012).

The equations to calculate the estimated energy requirement (EER) for infants 0 to 12 months of age are in Table 16-1. The EER includes the total energy expenditure plus energy needed for growth for healthy infants with normal growth (see Chapter 2).

Protein

Protein is needed for tissue replacement, deposition of lean body mass, and growth. Protein requirements during the rapid growth of infancy are higher per kilogram of weight than those for older children or adults (see Table 16-2). Recommendations for protein intake are based on the composition of human milk, and it is assumed that the efficiency of human milk use is 100%.

Infants require a larger percentage of total amino acids as essential amino acids than do adults. Histidine seems to be an essential amino acid for infants, but not for adults, and tyrosine, cystine, and taurine may be essential for premature infants (see Chapter 42).

Human milk or infant formula provides the major portion of protein during the first year of life. The amount of protein in human milk is adequate for the first 6 months of life, even though the amount of protein in human milk is considerably less than in infant formula. From 6 months of age the diet should be supplemented with additional sources of high-quality protein, such as yogurt, strained meats, or cereal mixed with formula or human milk.

Infants may not receive adequate protein if their formula is excessively diluted for a prolonged period, or if they have multiple food allergies and are placed on a restricted diet without appropriate medical or nutritional supervision (see Chapter 26).

TABLE 16-1 Equations for Calculating Estimated Energy Requirement (EER) for Infants

Age	Calculation
0-3 months	$(89 \times \text{Weight of infant [kg]} - 100) + 175$
4-6 months	$(89 \times \text{Weight of infant [kg]} - 100) + 56$
7-12 months	$(89 \times \text{Weight of infant [kg]} - 100) + 22$

Lipids

The current recommendation for infants younger than 1 year of age is to consume a minimum of 30 g of fat per day. This quantity is present in a normal intake of human milk and infant formulas. Significantly lower fat intakes (e.g., with skim-milk feedings) may result in an inadequate total energy intake. An infant may try to correct the energy deficit by increasing the volume of milk ingested but usually cannot make up the entire deficit this way.

Human milk contains the essential fatty acids linoleic acid and alpha-linolenic acid, as well as the longer-chain derivatives **arachidonic acid (ARA)** (C20:4 ω -6) and **docosahexaenoic acid (DHA)** (C22:6 ω -3). They are found in a wide range of concentrations in human milk, depending on the maternal diet (see Chapter 15 - *Focus On: Omega-3 Fatty Acids in Pregnancy and Lactation*). Infant formulas are supplemented with linoleic acid and alpha-linolenic acid, from which ARA and DHA are derived. Except for a few specialty products, standard formulas for term infants in the United States now also are supplemented with ARA and DHA, although there are no regulatory requirements for their inclusion.

Linoleic acid, which is essential for growth and dermal integrity, should provide 3% of the infant's total energy intake, or 4.4 g/day for infants younger than 6 months of age and 4.6 g/day for infants 7 months to 1 year of age. In human milk 5% of the kilocalories and 10% in most infant formulas are derived from linoleic acid. Smaller amounts of alpha-linolenic acid should be included. The current recommendation for alpha-linolenic acid is 0.5 g/day during the first year of life.

The concentration of DHA in human milk varies, depending on the amount of DHA in the mother's diet. DHA and ARA are the major omega-3 and omega-6 long-chain polyunsaturated fatty acids (LCPUFAs) of neural tissues, and DHA is the major fatty acid of the photoreceptor membranes of the retina. Some studies suggest that supplementation of DHA and ARA positively affects visual acuity and psychomotor development, especially in premature infants. However, other studies have shown no differences in cognitive development later in childhood between supplemented and unsupplemented infants (Willatts et al, 2013). The American Academy of Pediatrics (AAP) has not taken an official stand on the addition of LCPUFAs to infant formula. The Academy of Nutrition and Dietetics (AND) recommends that infants who are not breast-fed receive infant formula that contains DHA and ARA (ADA, 2007).

Carbohydrates

Carbohydrates should supply 30% to 60% of the energy intake during infancy. Approximately 40% of the energy in human milk and 40% to 50% of the energy in infant formulas is derived from lactose or other carbohydrates. Although rare, some infants cannot tolerate lactose and require a modified formula in their diet (see Chapters 28 and 43).

Botulism in infancy is caused by the ingestion of *Clostridium botulinum* spores, which germinate and produce toxin in the bowel lumen. Infant botulism has been associated with eating the carbohydrate honey that contains the bacterial spores. Light and dark corn syrups also have been reported to contain the spores, although cases of infant botulism have not been linked to corn syrup. The spores are extremely resistant to heat treatment and are not destroyed by current methods of processing. Thus honey and corn syrup should not be fed to infants younger than 1 year of age because they have not yet

developed the immunity required to resist botulism spore development.

Water

The water requirement for infants is determined by the amount lost from the skin and lungs and in the feces and urine, in addition to a small amount needed for growth. The recommended total water intake for infants, based on the DRIs, is 0.7 L/day for infants up to 6 months and 0.8 L/day for infants 6 to 12 months of age. Note that total water includes all water contained in food, beverages, and drinking water. Fluid recommendations per kilogram of body weight are shown in Table 16-3.

Because the renal concentrating capacity of young infants may be less than that of older children and adults, they may be vulnerable to developing a water imbalance. Under ordinary conditions, human milk and formula that is properly prepared supply adequate amounts of water. However, when formula is boiled, the water evaporates and the solutes become concentrated; therefore boiled milk or formula is inappropriate for infants. In very hot, humid environments, infants may require additional water. When losses of water are high (e.g., vomiting and diarrhea), infants should be monitored carefully for fluid and electrolyte imbalances.

Water deficits result in hypernatremic dehydration and its associated neurologic consequences (e.g., seizures, vascular damage). Hypernatremic dehydration has been reported in breast-fed infants who lose greater than 10% of their birth weight in the first few days of life (Leven and MacDonald, 2008). Because of the potential for hypernatremic dehydration, careful monitoring of volume of intake, daily weights, and hydration status (e.g., number of wet diapers) in all newborns is warranted.

Water intoxication results in hyponatremia, restlessness, nausea, vomiting, diarrhea, and polyuria or oliguria; seizures also can result. This condition may occur when water is provided as a replacement for milk, the formula is excessively diluted, or bottled water is used instead of an electrolyte solution in the treatment of diarrhea.

Minerals

Calcium

Breast-fed infants retain approximately two thirds of their calcium intake. The recommended adequate intake (AI), the mean intake, is based on calcium intakes in healthy breast-fed infants. The AI for infants 0 to 6 months of age is 200 mg/day; for infants 6 to 12 months of age the AI is 260 mg/day; formulas are enhanced accordingly.

Fluoride

The importance of fluoride in preventing dental caries has been well documented. However, excessive fluoride may cause dental fluorosis, ranging from fine white lines to entirely chalky teeth (see Chapter 25). To prevent fluorosis, the tolerable upper in-

TABLE 16-3 Maintenance Fluid Requirements of Infants and Children

Body Weight	Fluid Requirement
0-10 kg	100 ml/kg
11-20 kg	1000 ml + 50 ml/kg for each kg >10 kg
>20 kg	1500 ml + 20 ml/kg for each kg >20 kg

take level for fluoride has been set at 0.7 mg/day for infants up to 6 months and 0.9 mg/day for infants 6 to 12 months of age. Fluoride concentration of 0.7 ppm (0.7 mg/L) in drinking water has been proposed as being optimal for safety and caries prevention (AND, 2012). Fluoride content of water supplies can be obtained through local public health departments or water utilities. Fluoride containing toothpaste should be used sparingly – just a smear on a toothbrush (AAPD, 2015).

Human milk is very low in fluoride. Infants who exclusively consume infant formula reconstituted with fluoridated water may be at increased risk of developing mild fluorosis (CDC, 2013). Using water that is free of or low in fluoride, which are waters labeled “purified,” “demineralized,” “deionized,” “distilled,” or “produced through reverse-osmosis,” may decrease this risk. Other dietary sources of fluoride during infancy include commercially prepared infant cereals and wet pack cereals processed with fluoridated water. Fluoride supplementation is not recommended for infants younger than 6 months of age, and after 6 months of age is recommended only if an infant is at high risk of developing dental caries and drinks insufficiently fluoridated water (AND, 2012). After tooth eruption it is recommended that fluoridated water be offered several times per day to breast-fed infants, those who receive cow’s milk, and those fed formulas made with water that contains less than 0.3 mg of fluoride/L (AAP, 2014b).

Iron

Full-term infants are considered to have adequate stores of iron for growth up to a doubling of their birth weight. This occurs at approximately 4 months of age in full-term infants and much earlier in prematurely born infants. Recommended intakes of iron increase according to age, growth rate, and iron stores. At 4 to 6 months of age, infants who are fed only human milk are at risk for developing a negative iron balance and may deplete their reserves by 6 to 9 months. Iron in human milk is highly bioavailable; however, breast-fed infants should receive an additional source of iron by 4 to 6 months of age (AAP, 2012). For breast-fed term infants, the AAP recommends iron supplementation of 1 mg/kg/day starting at 4 months of age and continuing until appropriate complementary foods have been introduced (Baker and Greer, 2010). Complementary foods high in iron include strained meats and iron-fortified infant cereals. In addition, by 6 months of age offering one serving of vitamin C-rich foods per day enhances iron absorption from nonheme sources. Formula-fed infants receive adequate iron from formula. Cow’s milk is a poor source of iron and should not be given before 12 months of age.

Iron deficiency and iron deficiency anemia are common health concerns for the older infant. Between 6 and 24 months of age, because of rapid growth, iron requirements per kilogram of body weight are higher than at any other period of life. Risk factors associated with a higher prevalence of iron deficiency anemia include low birth weight, low intake of iron-rich complementary foods, high intake of cow’s milk, low socioeconomic status, and immigrant status.

Monitoring iron status is important because of the long-term cognitive effects of iron deficiency in infancy. There is consistent association between iron deficiency anemia in infancy and long-lasting poor cognition, developmental deficits, and behavioral performance (Domellöf et al, 2014). Thus it is important dietary advice reaches high-risk groups to prevent these significant long-term effects.

Zinc

Newborn infants are immediately dependent on a dietary source of zinc. Zinc is better absorbed from human milk than from infant formula. Human milk and infant formulas provide adequate zinc (0.3 to 0.5 mg/100 kcal) for the first year of life. Other foods (e.g., meats, cereals) should provide most of the zinc required during the second year. Infants who are zinc deficient can exhibit growth retardation (Cole and Lifshitz, 2008) (see Appendix 53).

Vitamins

Vitamin B₁₂

Milk from lactating mothers who follow a strict vegan diet may be deficient in vitamin B₁₂, especially if the mother followed the regimen for a long time before and during her pregnancy. Vitamin B₁₂ deficiency also has been diagnosed in infants breast-fed by mothers with pernicious anemia (Roumeliotis et al, 2012) (see Chapter 32). Symptoms of vitamin B₁₂ deficiency include lethargy, hypotonia, developmental regression, vomiting, and diarrhea.

Vitamin D

The vitamin D content of breast milk is correlated directly to the vitamin D status of the mother. Studies of lactating mothers who were supplemented with anywhere from 2000 IU to 6400 IU of vitamin D per day achieved sufficient vitamin D status in their exclusively breast-fed infants without directly supplementing the infant (Uriu-Adams et al, 2013). However, the current RDA for vitamin D for lactating mothers is 600 IU per day, and the tolerable upper limit is 4000 IU per day. Coupled with the AAP’s recommendation to keep all infants under the age of 6 months out of direct sunlight, exclusively and partially breast-fed infants are at high risk for vitamin D deficiency (Balk, 2011). For the prevention of rickets and vitamin D deficiency, the AAP recommends a minimum vitamin D intake of 400 IU per day shortly after birth for all infants. All breast-fed infants need a vitamin D supplement of 400 IU per day. Formula-fed infants who consume less than 1000 ml of formula per day also need supplementation (Wagner and Greer, 2008).

There appears to be a higher risk of rickets among unsupplemented, breast-fed infants and children with dark skin (Uriu-Adams et al, 2013). Because a variety of environmental and family lifestyle factors can affect sunlight exposure and absorption of vitamin D, the AAP recommendations to provide supplemental vitamin D are appropriate for all infants. Supplementation up to 800 IU of vitamin D per day may be needed for infants at higher risk, such as premature infants, dark-skinned infants and children, and those who reside in northern latitudes or at higher altitudes (Misra et al, 2008).

The Food and Drug Administration (FDA) states that some droppers that come with liquid vitamin D supplements could hold more than the 400 IU per day recommended by the AAP. Thus it is important that parents or caregivers provide only the recommended amount. Excessive vitamin D can cause nausea and vomiting, loss of appetite, excessive thirst, frequent urination, constipation, abdominal pain, muscle weakness, muscle and joint aches, confusion, fatigue, or damage to kidneys (see Appendix 45).

Vitamin K

The vitamin K requirements of the neonate need special attention. Deficiency may result in bleeding or hemorrhagic disease of the newborn. This condition is more common in breast-fed infants than in other infants because human milk contains only 2.5 mcg/l of vitamin K, whereas cow’s milk-based formulas

contain approximately 20 times this amount. All infant formulas contain a minimum of 4 mcg of vitamin K per 100 kcal of formula. The AI for infants is 2 mcg/day during the first 6 months and 2.5 mcg/day during the second 6 months of life. This can be supplied by mature breast milk, although perhaps not during the first week of life. For breast-fed infants, vitamin K supplementation is necessary during that time to considerably decrease the risk for hemorrhagic disease. Most hospitals require that infants receive an injection of vitamin K as a prophylactic measure shortly after birth.

Supplementation

Vitamin and mineral supplements should be prescribed only after careful evaluation of the infant's intake. Commercially prepared infant formulas are fortified with all necessary vitamins and minerals; therefore formula-fed infants rarely need supplements. Breast-fed infants need additional vitamin D supplementation shortly after birth, and iron by 4 to 6 months of age (see *Focus On: Vitamin and Mineral Supplementation Recommendations for Full-Term Infants*). Chapter 42 discusses the feeding of premature or high-risk infants and their special needs.

FOCUS ON

Vitamin and Mineral Supplementation Recommendations for Full-Term Infants

Vitamin D

Supplementation shortly after birth of 400 IU/day for all breast-fed infants and infants consuming less than 1000 ml (33 oz) of vitamin D-fortified formula each day

Vitamin K

Supplementation soon after birth to prevent hemorrhagic disease of the newborn

Iron

Breast-Fed Infants

Approximately 1 mg/kg/day by 4 to 6 months of age, preferably from supplemental foods, and only iron-fortified formulas for weaning or supplementing breastmilk

Formula-Fed Infants

Only iron-fortified formula during the first year of life

Modified from American Academy of Pediatrics Committee on Nutrition: *Pediatric nutrition*, ed 7, Elk Grove Village, Ill, 2014, American Academy of Pediatrics, 2014.

MILK

Human Milk

Human milk is unquestionably the food of choice for the infant. Its composition is designed to provide the necessary energy and nutrients in appropriate amounts. It contains specific and nonspecific immune factors that support and strengthen the immature immune system of the newborn and thus protect the body against infections. Human milk also helps prevent diarrhea and otitis media (AAP, 2012). Allergic reactions to human milk protein are rare. Moreover, the closeness of the mother and infant during breast-feeding facilitates attachment and bonding (see Fig 15-6) and breast milk provides nutritional benefits (e.g., optimal nourishment in an easily digestible and

bioavailable form), decreases infant morbidity, provides maternal health benefits (e.g., lactation amenorrhea, maternal weight loss, some cancer protection), and has economic and environmental benefits (ADA, 2009; see Chapter 15).

During the first few days of life, a breastfeeding infant receives **colostrum**, a yellow, transparent fluid that meets the infant's needs during the first week. It contains less fat and carbohydrate, but more protein and greater concentrations of sodium, potassium, and chloride than mature milk. It is also an excellent source of immunologic substances.

Note that breastfeeding may not be appropriate for mothers with certain infections or those who are taking medications that may have untoward effects on the infant. For example, a mother who is infected with human immunodeficiency virus can transmit the infection to the infant, and a mother using psychotropic drugs or other pharmacologic drugs may pass the medication to the infant through her breastmilk (AAP, 2012; see Chapter 15).

The Academy of Nutrition and Dietetics (AND) and the AAP support exclusive breastfeeding (EBF) for the first 6 months of life and then breastfeeding supplemented by complementary foods until at least 12 months (AAP, 2012; Lessen and Kavanaugh, 2015). It is important to note the ages of the infants in these recommendations; adding other foods at too young of an age decreases breastmilk intake and increases early weaning. There is some evidence that early introduction of complementary foods increases the chances of picky eating behavior (Shim et al, 2011). Healthy Children 2020 objectives propose to support breastfeeding among mothers of newborn infants (see *Focus On: Healthy Children 2020 Objectives: Nourishment of Infants*).

FOCUS ON

Healthy Children 2020 Objectives: Nourishment of Infants

Healthy People 2020 is a comprehensive set of health objectives for the United States to achieve during the second decade of the twenty-first century. Healthy People 2020 identifies a wide range of public health priorities and specific, measurable objectives. The objectives have 42 focus areas, one of which is Maternal, Infant, and Child Health. The objectives related to nourishment of infants are as follows:

GOAL: Improve the health and well-being of women, infants, children, and families.

Objective: Increase the proportion of infants who are breast-fed to 81.9% in the early postpartum period, to 60.6% at 6 months, and to 34.1% at 1 year of age. Increase the proportion of infants that are exclusively breast-fed to 46.2% through 3 months of age and 25.5% through 6 months of age.

Objective: Reduce the proportion of breast-fed newborns who receive formula supplementation within the first 2 days of life to 14.2%.

GOAL: Promote health and reduce chronic disease risk through the consumption of healthful diets and achievement and maintenance of healthy body weights.

Objective: Eliminate very low food security among children.

Objective: Reduce iron deficiency among children ages 1 to 2 years to less than 14.3%.

GOAL: Prevent and control oral and craniofacial diseases, conditions, and injuries and improve access to preventive services and dental care.

Objective: Reduce the proportion of young children with dental caries in their primary teeth.

The complete text of the Healthy People 2020 Objectives can be found at www.healthypeople.gov/2020/topicsobjectives2020/default.aspx

Composition of Human and Cow's Milk

The composition of human milk is different from that of cow's milk; for this reason, unmodified cow's milk is not recommended for infants until at least 1 year of age. Both provide approximately 20 kcal/oz; however, the nutrient sources of the energy are different. Protein provides 6% to 7% of the energy in human milk and 20% of the energy in cow's milk. Human milk is 60% **whey proteins** (mainly lactalbumins) and 40% casein; by contrast, cow's milk is 20% whey proteins and 80% casein. **Casein** forms a tough, hard-to-digest curd in the infant's stomach, whereas **lactalbumin** in human milk forms soft, flocculent, easy-to-digest curds. Taurine and cystine are present in higher concentrations in human milk than in cow's milk; these amino acids may be essential for premature infants. Lactose provides 42% of the energy in human milk and only 30% of the energy in cow's milk.

Lipids provide 50% of the energy in human and whole cow's milk. Linoleic acid, an essential fatty acid, provides 4% of the energy in human milk and only 1% in cow's milk. The cholesterol content of human milk is 10 to 20 mg/dl compared with 10 to 15 mg/dl in whole cow's milk. Less fat is absorbed from cow's milk than from human milk; a lipase in human milk is stimulated by bile salts and contributes significantly to the hydrolysis of milk triglycerides.

All of the water-soluble vitamins in human milk reflect maternal intake. Cow's milk contains adequate quantities of the B-complex vitamins, but little vitamin C. Human milk and supplemented cow's milk provide sufficient vitamin A. Human milk is a richer source of vitamin E than cow's milk.

The quantity of iron in human and cow's milk is small (0.3 mg/L). Approximately 50% of the iron in human milk is absorbed, whereas less than 1% of the iron in cow's milk is absorbed. The bioavailability of zinc in human milk is higher than in cow's milk. Cow's milk contains three times as much calcium and six times as much phosphorus as human milk, and its fluoride concentration is twice that of human milk.

The much higher protein and ash content of cow's milk results in a higher **renal solute load**, or amount of nitrogenous waste and minerals that must be excreted by the kidney. The sodium and potassium concentrations in human milk are about one third those in cow's milk, contributing to the lower renal solute load of human milk. The osmolality of human milk averages 300 mOsm/kg, whereas that of cow's milk is 400 mOsm/kg.

Antiinfective Factors

Human milk and colostrum contain antibodies and antiinfective factors that are not present in infant formulas. **Secretory immunoglobulin A (sIgA)**, the predominant immunoglobulin in human milk, plays a role in protecting the infant's immature gut from infection. Breastfeeding should be maintained until the infant is at least 3 months of age to obtain this benefit.

The iron-binding protein **lactoferrin** in human milk deprives bacteria of iron and thus slows their growth. Lysozymes, which are bacteriolytic enzymes found in human milk, destroy the cell membranes of bacteria after the peroxides and ascorbic acid that are also present in human milk have inactivated them. Human milk enhances the growth of the bacterium *Lactobacillus bifidus*, which produces an acidic gastrointestinal (GI) environment that interferes with the growth of certain pathogenic organisms. Because of these antiinfective factors, the incidence of infections is lower in breast-fed infants than in formula-fed infants.

The Microbiome and Probiotics and Prebiotics

Colonization with nonpathogenic microbiota is important for infant health and probably affects health in later life. By the time a mother weans her infant, the baby's GI tract has established its normal flora or microbiome. This ecosystem in early life is influenced by such factors as mode of birth, environment, diet, and use of antibiotics (Marques et al, 2010).

Probiotics are microorganisms that, when administered as an oral supplement or as part of food, may confer health benefits to the host by changing the gut microbiome. Prebiotics are nondigestible food ingredients that promote the growth of the gut's bacteria. Studies have looked at the effects of postnatal probiotic supplementation on the prevention of atopic disease such as asthma, eczema, and allergic rhinitis. Results have been mixed, depending on the strain of probiotics used, and whether the mother also was supplemented during pregnancy (Elazab et al, 2013). Evidence is emerging that supplementing term infants with the probiotic *Lactobacillus reuteri* (*L. reuteri*) may decrease their risk of colic, gastroesophageal reflux, and constipation (Indrio et al, 2014). However, supplementation with *L. reuteri* does not appear to be effective in treating colic. In fact, a well-controlled study found no reduction in crying or fussiness in colicky infants receiving the probiotic. Interestingly the formula-fed infants who were given *L. reuteri* actually fussed more than formula-fed infants given placebo (Sung et al, 2014). The effectiveness of supplemental probiotic use is still under study. Although probiotics have been found generally to be safe, their content is not regulated (Van den Nieuwboer et al, 2014). Similar caution should be used as when using other nutrition supplements.

Human milk contains prebiotics in the form of **oligosaccharides**, which by some estimates can be as much as 12 to 15 g/L (Jeurink et al, 2013). The addition of short-chain gluco-oligosaccharides and long-chain fructo-oligosaccharides to infant formula results in gut microflora more similar to those of human milk-fed infants (Oozeer et al, 2013). The AAP has no official stance on the addition of probiotics or prebiotics to infant formula; however, some infant formulas in the United States are now supplemented with probiotics or prebiotics. The addition of oligosaccharides to infant formula has been deemed to be of no major concern in Europe (Thomas et al, 2010).

Formulas

Infants who are not breast-fed usually are fed a formula based on cow's milk or a soy product. Many mothers also may choose to offer a combination of breastmilk and formula feedings. Those infants who have special requirements receive specially designed products.

Commercial formulas made from heat-treated nonfat milk or a soy product and supplemented with vegetables fats, vitamins, and minerals are formulated to approximate, as closely as possible, the composition of human milk. They provide the necessary nutrients in an easily absorbed form. The manufacture of infant formulas is regulated by the FDA through the Infant Formula Act (Nutrient Requirements for Infant Formulas, 1985). By law, infant formulas are required to have a nutrient level that is consistent with these guidelines (see Table 16-4). Refer to individual manufacturers' websites to obtain the most accurate information and compare the composition of various infant formulas and feeding products.

Formulas are also available for older infants and toddlers. However, typically "older infant" formulas are unnecessary unless toddlers are not receiving adequate amounts of infant or table foods.

TABLE 16-4 Nutrient Levels in Infant Formulas as Specified by the Infant Formula Act

Specified Nutrient Component	Minimum Level Required (per 100 kcal of energy)
Protein (g)	1.8
Fat (g)	3.3
Percentage of calories	30
Linoleic acid (mg)	300
Percentage of calories	2.7
Vitamin A (IU)	250
Vitamin E (IU)	0.7
Vitamin D (IU)	40
Vitamin K (mcg)	4
Thiamin (mcg)	40
Riboflavin (mcg)	60
Niacin (mcg)	250
Ascorbic acid (mg)	8
Pyridoxine (mcg)	35
Vitamin B ₁₂ (mcg)	0.15
Folic acid (mcg)	4
Biotin (mcg) (non-milk-based formulas only)	1.5
Pantothenic acid (mcg)	300
Choline (mg) (non-milk-based formulas only)	7
Inositol (mg) (non-milk-based formulas only)	4
Calcium (mg)	60
Phosphorus (mg)	30
Iron (mg)	0.15
Zinc (mg)	0.5
Magnesium (mg)	6
Manganese (mcg)	5
Sodium (mg)	20
Potassium (mg)	80
Iodine (mcg)	5
Chloride (mg)	55
Copper (mcg)	60

From Food and Drug Administration: Nutrient requirements for infant formulas, Final Rule (21 CFR 107), *Fed Reg* 50:45106, 1985.

The declining prevalence of anemia in infants is credited to the use of iron-fortified formula. The AAP recommends iron-fortified formulas for all formula-fed infants. The widespread theory that iron-fortified formula may cause constipation, loose stools, colic (severe abdominal pain), and spitting up has not been confirmed by clinical studies (AAP, 1999).

Various products are available for infants who cannot tolerate the protein in cow's milk-based formulas. Soy-based infant formulas are recommended for (1) infants in vegetarian families, and (2) infants with galactosemia or hereditary primary lactase deficiency. Soy formulas are not recommended for children known to have protein allergies because many infants who are allergic to cow's milk protein also develop allergies to soy protein (Bhatia and Greer, 2008; see Chapter 26).

Infants who cannot tolerate cow's milk-based or soy products can be fed formulas made from a **casein hydrolysate**, which is casein that has been split into smaller components by treatment with acid, alkali, or enzymes. These formulas do not contain lactose. For infants who have severe food protein intolerances and cannot tolerate hydrolysate formulas, free amino acid-based formulas are available. Other formulas are

available for children with problems such as malabsorption or metabolic disorders (e.g., phenylketonuria) (see Box 26-9 in Chapter 26).

Soy-based formulas are under regular scrutiny. Full-term infants ingesting soy formulas grow and absorb minerals as well as infants fed cow's milk-based formulas, but they are exposed to several thousand times higher levels of phytoestrogens and isoflavones. The biologic effect of these elevated isoflavone levels on long-term infant development is not yet clear (National Toxicology Program, 2010). Mental, psychomotor, and language development have been found to be similar in infants fed soy-based formula compared with infants fed breastmilk and cow's milk-based formula (Andres et al, 2012). Soy-based formulas are not recommended for pre-term infants because of the increased risk for osteopenia (Bhatia and Greer, 2008).

The protein in soy infant formula is soy protein isolate supplemented with L-methionine, L-carnitine, and taurine. Contaminants include phytates, which bind minerals and niacin; and protease inhibitors, which have antitrypsin, antichymotrypsin, and antielastin properties. Aluminum from mineral salts is found in soy infant formulas at concentrations of 600 to 1300 ng/ml, levels that exceed aluminum concentrations in human milk of 4 to 65 ng/ml. This does not appear to put term infants with normal renal function at risk of developing aluminum toxicity (Bhatia and Greer, 2008).

Whole Cow's Milk

Some parents may choose to transition their infant from formula to fresh cow's milk before 1 year of age. However, the AAP Committee on Nutrition has concluded that infants should not be fed whole cow's milk during the first year of life (AAP, 2014a). Infants who are fed whole cow's milk have been found to have lower intakes of iron, linoleic acid, and vitamin E, and excessive intakes of sodium, potassium, and protein. Cow's milk may cause a small amount of GI blood loss.

Low-fat (1% to 2%) and nonfat milk are also inappropriate for infants during the first 12 months of life. The infants may ingest excessive amounts of protein in large volumes of milk in an effort to meet their energy needs, and the decreased amount of essential fatty acids may be insufficient for preventing deficiency (AAP, 2014a). Substitute or imitation milks such as soy, rice, oat, or nut milks are also inappropriate during the first year of life. When introduced, only pasteurized cow milk and milk products should be offered (AAP, 2014a).

Formula Preparation

Commercial infant formulas are available in ready-to-feed forms that require no preparation, as concentrates prepared by mixing with equal parts of water, and in powder form that is designed to be mixed with 2 oz of water per level scoop of powder.

Infant formulas should be prepared in a clean environment. All equipment, including bottles, nipples, mixers, and the top of the can of formula, should be washed thoroughly. Formula may be prepared for up to a 24-hour period and refrigerated. Formula for each feeding should be warmed in a hot water bath. Microwave heating is not recommended because of the risk of burns from formula that is too hot or unevenly heated. Any formula offered and not consumed at that feeding should be discarded and not reused later, because of bacterial contamination from the infant's mouth.

FOOD

Dry infant cereals are fortified with **electrolytically reduced iron**, which is iron that has been fractionated into small particles for improved absorption. Four level tablespoons of cereal provide approximately 5 mg of iron, or approximately half the amount the infant requires. Therefore infant cereal is usually the first food added to the infant's diet. In recent years, concern has been raised about the arsenic content in rice. The Food and Drug Administration (FDA) has determined the arsenic content in rice and rice products, such as infant rice cereal, is too low to cause any immediate or short-term adverse health effects. The FDA recommends offering infants a variety of grains and to avoid the excessive intake of any one food (FDA, 2013).

Strained and “junior” vegetables and fruits provide carbohydrates and vitamins A and C. Vitamin C is added to numerous jarred fruits and all fruit juices. In addition, tapioca is added to several of the jarred fruits. Milk is added to the creamed vegetables, and wheat is incorporated into the mixed vegetables.

Most strained and junior meats are prepared with water. Strained meats, which have the highest energy density of any of the commercial baby foods, are an excellent source of high-quality protein and heme iron.

Numerous dessert items are also available such as puddings and fruit desserts. The nutrient composition of these products varies, but all contain excess energy in the form of sugar and modified cornstarch or tapioca starch. Most infants do not need this excess energy.

Various commercially prepared foods and organically grown products are available for infants. See *Clinical Insight: Is Organic Produce Healthier?* in Chapter 9 for a discussion of organic foods. These products vary widely in their nutrient value. Foods for infants should be thoughtfully selected to meet their nutritional and developmental needs.

Mothers who would like to make their own infant food can do so easily by following the directions in **Box 16-1**. Home-prepared foods generally are more concentrated in nutrients than commercially prepared foods because less water is used. Salt and sugar should not be added to foods prepared for infants.

FEEDING

Early Feeding Patterns

Because milk from a mother with an adequate diet is designed uniquely to meet the needs of the human infant, breastfeeding for the first 6 months of life is recommended strongly. Most chronic medical conditions do not contraindicate breastfeeding.

A mother should be encouraged to nurse her infant immediately after birth. Those who care for and counsel parents during the first postpartum days should acquaint themselves with ways in which they can be supportive of breastfeeding. Ideally, counseling and preparation for breastfeeding starts in the last few months or weeks of pregnancy (see Chapter 15).

Regardless of whether infants are breast-fed or formula fed, they should be held and cuddled during feedings. Once a feeding rhythm has been established, infants become fussy or cry to indicate they are hungry, whereas they often smile and fall asleep when they are satisfied (see **Table 16-5**). Infants, not adults, should establish the feeding schedules. Initially, most infants feed every 2 to 3 hours; by 2 months of age most feed every 4 hours. By 3 to 4 months of age infants have usually matured enough to allow the mother to omit night feedings.

BOX 16-1 Directions for Home Preparation of Infant Foods

1. Select fresh, high-quality fruits, vegetables, or meats.
2. Be sure that all utensils, including cutting boards, grinder, knives, and other items, are thoroughly cleaned.
3. Wash hands before preparing the food.
4. Clean, wash, and trim the food in as little water as possible.
5. Cook the foods until tender in as little water as possible. Avoid overcooking, which may destroy heat-sensitive nutrients.
6. Do not add salt or sugar. Do not add honey to food intended for infants younger than 1 year of age.*
7. Add enough water for the food to be easily puréed.
8. Strain or purée the food using an electric blender, a food mill, a baby food grinder, or a kitchen strainer.
9. Pour purée into an ice cube tray and freeze.
10. When the food is frozen hard, remove the cubes and store in freezer bags.
11. When ready to serve, defrost and heat in a serving container the amount of food that will be consumed at a single feeding.

**Clostridium botulinum* spores, which cause botulism, have been reported in honey; young infants do not have the immune capacity to resist this infection.

TABLE 16-5 Hunger and Satiety Behaviors in Infants

Approximate Age	Hunger Cue	Satiety Cue
Birth through 5 months	Wakes and tosses Sucks on fist Fusses or cries Opens mouth while feeding to show wants more	Falls asleep Turns head away Seals lips together Decreases rate of sucking or stops sucking Purses lips, bites nipple, or spits nipple out or smiles and lets go
4 months through 6 months	Fusses or cries Smiles, coos, gazes at caregiver during feeding Moves head toward spoon Tries to swipe food toward mouth	Distracted or pays more attention to surroundings Turns head away Bites nipple or spits it out Decreases rate of sucking or stops sucking Obstructs mouth with hands
5 months through 9 months	Reaches for food Points to food	Rate of feeding slows down Pushes food away Keeps mouth tightly closed Changes posture Uses hands more actively
8 months through 11 months	Gets excited when food is presented Reaches for food Points to food	Clenches mouth shut Pushes food away Rate of feeding slows down Shakes head to say “no more” Plays with utensils, throws utensils
10 months through 12 months	Expresses desire for specific food with words or sounds	Hands bottle or cup to caregiver Shakes head to say “no more” Sputters with tongue and lips

Modified from U.S. Department of Agriculture: *Infant Nutrition and Feeding: a Guide for Use in the WIC And CSF Programs* (website): <http://www.nal.usda.gov/wicworks/Topics/FG/CompleteIFG.pdf>, 2009. Accessed December 2014.

Bisphenol A (BPA) is a chemical that was present in many hard plastic bottles, such as baby bottles and reusable cups, and metal food and beverage containers, including canned liquid infant formula. Concern has been raised about the potential effects of BPA on the brain, behavior, and prostate gland in fetuses, infants, and young children. Since 2012, U.S. manufacturers have stopped producing BPA-containing bottles and infant feeding cups for the U.S. market. BPA has not been used in packaging for infant formula in the United States since 2013 (FDA, 2014).

Development of Feeding Skills

At birth, infants coordinate sucking, swallowing, and breathing, and are prepared to suckle liquids from the breast or bottle but are not able to handle foods with texture. During the first year, typical infants develop head control, the ability to move into and sustain a sitting posture, and the ability to grasp, first with a **palmar grasp** and then with a refined **pincer grasp** (see Figure 16-1, B). They develop mature sucking and rotary chewing abilities and progress from being fed

FIGURE 16-1 Development of feeding skills in infants and toddlers. **A**, This 7-month-old boy shows the beginnings of involvement with feeding by anticipating the spoon. **B**, This 8-month-old girl is using a refined pincer grasp to pick up her food. **C**, This 19-month-old boy is beginning to use his spoon independently, although he is not yet able to rotate his wrist to keep food on it.

FIGURE 16-2 This 14-month-old boy is learning to self-feed; it's normal to be messy.

to feeding themselves using their fingers. In the second year, they learn to feed themselves independently with a spoon (see Figure 16-2).

Addition of Semisolid Foods

Developmental readiness and nutrient needs are the criteria that determine appropriate times for the addition of various foods. During the first 4 months of life, the infant attains head and neck control, and oral motor patterns progress from a suck to a suckling to the beginnings of a mature sucking pattern. Puréed foods introduced during this phase are consumed in

the same manner as are liquids, with each suckle being followed by a tongue-thrust swallow. Table 16-6 lists developmental landmarks and their indications for semisolid and table food introduction.

Between 4 and 6 months of age, when the mature sucking movement is refined and munching movements (up-and-down chopping motions) begin, the introduction of strained foods is appropriate. Infant cereal usually is introduced first. To support developmental progress, cereal is offered to the infant from a spoon, not combined with formula in a bottle (see Figure 16-1, A). Thereafter various commercial or home-prepared foods may be offered. The sequence in which these foods are introduced is not important; however, it is important that one single ingredient food (e.g., peaches, not peach cobbler, which has many ingredients) be introduced at a time. Introducing a single new food at a time at 2- to 7-day intervals enables parents to identify any allergic responses or food intolerances. Introducing vegetables before fruits may increase vegetable acceptance.

Infants demonstrate their acceptance of new foods by slowly increasing the variety and quantity of solids they accept. Breast-fed infants seem to accept greater quantities than do formula-fed infants. Dietary flavors from the maternal diet transfer through breastmilk and may facilitate the introduction of new foods in breast-fed infants (Hausner et al, 2008). Parents who thoughtfully offer a variety of nourishing foods are more likely to provide a well-balanced diet and help their children learn to accept more flavors.

As oral-motor maturation proceeds, an infant's rotary chewing ability develops, indicating a readiness for more textured foods such as well-cooked mashed vegetables, casseroles, and pasta from the family menu. Learning to grasp—with the palmar

TABLE 16-6 Feeding Behaviors: Developmental Landmarks During the First 2 Years of Life

Developmental Landmarks	Change Indicated	Examples of Appropriate Foods
Tongue laterally transfers food in the mouth Shows voluntary and independent movements of the tongue and lips Sitting posture can be sustained Shows beginning of chewing movements (up and down movements of the jaw)	Introduction of soft, mashed table food	Tuna fish; mashed potatoes; well-cooked, mashed vegetables; ground meats in gravy and sauces; soft, diced fruit such as bananas, peaches, and pears; flavored yogurt
Reaches for and grasps objects with palmar grasp Brings hand to mouth Voluntarily releases food (refined digital [pincer] grasp)	Finger feeding (large pieces of food) Finger feeding (small pieces of food)	Oven-dried toast, teething biscuits; cheese sticks (should be soluble in the mouth to prevent choking) Bits of cottage cheese, dry cereal, peas, and other bite-size vegetables; small pieces of meat
Shows rotary chewing pattern	Introduction of food of varied textures from family menu	Well-cooked, chopped meats and casseroles; cooked vegetables and canned fruit (not mashed); toast; potatoes; macaroni, spaghetti; peeled ripe fruit
Approximates lips to rim of the cup	Introduction of cup for sipping liquids	
Understands relationship of container and its contents	Beginning of self-feeding (though messiness should be expected)	Food that when scooped adheres to the spoon, such as applesauce, cooked cereal, mashed potatoes, cottage cheese, yogurt
Shows increased movements of the jaw Shows development of ulnar deviation of the wrist Walks alone	More skilled at cup and spoon feeding May seek food and obtain food independently	Chopped fibrous meats, such as roast and steak; raw vegetables and fruit (introduced gradually) Mixed textures, food from the family meal; foods of high nutritional value
Names food, expresses preferences; prefers unmixed foods Goes on food jags Appetite appears to decrease		Balanced food choices, with child permitted to develop food preferences (parents should not be concerned that these preferences will last forever)

TABLE 16-7 Suggested Ages for the Introduction of Semisolid and Table Foods

Food	AGE (MO)		
	4-6	6-8	9-12
Iron-fortified cereals for infants	Add		
Vegetables		Add strained.	Gradually eliminate strained foods and introduce table foods.
Fruits		Add strained.	Gradually eliminate strained foods; introduce chopped, well-cooked, or canned foods.
Meats		Add strained or finely chopped table meats.	Decrease the use of strained meats; increase the varieties of table meats offered.
Finger foods, such as arrowroot biscuits, oven-dried toast		Add foods that can be secured with a palmar grasp.	Increase the use of small finger foods as the pincer grasp develops.
Well-cooked mashed or chopped table foods prepared without added salt or sugar			Add and introduce use of spoon.

Modified from Trahms CM, Pipes P: *Nutrition in infancy and childhood*, ed 6, New York, 1997, McGraw-Hill.

grasp, then with an inferior pincer grasp, and finally with the refined pincer grasp—indicates a readiness for finger foods such as oven-dried toast, arrowroot biscuits, or cheese sticks (see [Figure 16-1, B](#)). [Table 16-7](#) presents recommendations for adding foods to an infant's diet. Foods with skins or rinds and foods that stick to the roof of the mouth (e.g., hot dogs, grapes, nut butters) may cause choking and should not be offered to young infants.

During the last quarter of the first year, infants can approximate their lips to the rim of the cup and can drink if the cup is held for them. During the second year they gain the ability to rotate their wrists and elevate their elbows, thus allowing them to hold the cup themselves and manage a spoon (see [Figure 16-1, C](#)). They are very messy eaters at first (see [Figure 16-2](#)), but by 2 years of age most typical children skillfully feed themselves (see [Figure 16-3](#)).

Weaning from Breast or Bottle to Cup

The introduction of solids into an infant's diet begins the weaning process in which the infant transitions from a diet of only breastmilk or formula to a more varied one. Weaning should proceed gradually and be based on the infant's rate of growth and developmental skills. Weaning foods should be chosen carefully to complement the nutrient needs of the infant, promote appropriate nutrient intake, and maintain growth.

Many infants begin the process of weaning with the introduction of the cup at approximately 6 to 9 months of age and complete the process when they are able to ingest an adequate

FIGURE 16-3 This 2-year-old is skilled at self-feeding because he has the ability to rotate his wrist and elevate his elbow to keep food on the spoon.

amount of milk or formula from a cup at 18 to 24 months of age. Parents of infants who are breast-fed may choose to transition the infant directly to a cup or have an intermittent transition to a bottle before the cup is introduced.

Early Childhood Caries

Dental caries is the most common chronic disease of childhood ([AAP, 2014c](#)). **Early childhood caries (ECC)**, or “baby bottle tooth decay” is a pattern of tooth decay that involves the upper anterior and sometimes lower posterior teeth. ECC is common among infants and children who are allowed to bathe their teeth in sugar (sucrose or lactose) throughout the day and night. If infants are given sugar-sweetened beverages or fruit juice in a bottle during the day or at bedtime after teeth have erupted, the risk of dental caries increases (see [Chapter 25](#)).

To promote dental health, infants should be fed and burped and then put to bed without milk, juice, or food. Juice should not be introduced into the diet before 6 months of age. Juice should be limited to 4 to 6 oz/day for infants and young children and offered to children only from a cup ([AAP, 2013](#)). Parents and caregivers can be taught effective oral health practices for infants, not only by dentists but also by other paraprofessionals ([MacIntosh et al, 2010](#)).

Feeding Older Infants

As maturation proceeds and the rate of growth slows down, infants' interest in and approach to food changes. Between 9 and 18 months of age most reduce their breastmilk or formula intake. They can become finicky about what and how much they eat.

In the weaning stage infants have to learn many manipulative skills, including the ability to chew and swallow solid food and use utensils. They learn to tolerate various textures and flavors of food, eat with their fingers, and then feed themselves with a utensil. Very young children should be encouraged to feed themselves (see [Clinical Insight: A New Look at the Food Practices of Infants and Toddlers](#)).

CLINICAL INSIGHT***A Look at the Food Practices of Infants and Toddlers***

The Feeding Infants and Toddlers Study was a national random sample of more than 2500 infants and toddlers from 4 to 24 months of age and their mothers.

- Assuming that a variety of nutritious foods are offered to infants and toddlers, parents and caregivers should encourage self-feeding without concern for compromising energy intake and nutrient adequacy (Carruth et al, 2004b).
- Parents and caregivers should offer a variety of fruits and vegetables daily; sweets, desserts, sweetened beverages, and salty snacks should be offered only occasionally. Because family food choices influence the foods offered to infants, family-based approaches to healthy eating habits should be encouraged (Fox et al, 2004).
- By 24 months of age, 50% of toddlers were described as picky eaters. When offering a new food, caregivers must be willing to provide 8 to

15 repeated exposures to enhance acceptance of that food (Carruth et al, 2004a).

- Infants and toddlers have an innate ability to regulate energy intake. Parents and caregivers should understand the cues of hunger and satiety and recognize that coercive admonitions about eating more or less food can interfere with the infant's or toddler's innate ability to regulate energy intake (Fox et al, 2006).
- On average, infants and toddlers were fed seven times per day, and the percentage of children reported to be eating snacks increased with age. Snack choices for infants and toddlers could be improved by delaying the introduction of and limiting foods that have a low nutrient content and are energy dense (Skinner et al, 2004).

At the beginning of a meal, children are hungry and should be allowed to feed themselves; when they become tired, they can be helped quietly. Emphasis on table manners and the fine points of eating should be delayed until they have the necessary maturity and developmental readiness for such training.

The food should be in a form that is easy to handle and eat. Meat should be cut into bite-size pieces. Potatoes and vegetables should be mashed so that they can be eaten easily with a spoon. Raw fruits and vegetables should be in sizes that can be picked up easily. In addition, the utensils should be small and manageable. Cups should be easy to hold, and dishes should be designed so that they do not tip over easily.

Type of Food

In general, children prefer simple, uncomplicated foods. Food from the family meal can be adapted for the child and served in child-size portions. Children younger than 6 years of age usually prefer mild-flavored foods. Because a young child's stomach is small, a snack may be required between meals. Fruit, cheese, crackers, dry cereal, fruit juices, and milk contribute nutrients and energy. Children ages 2 to 6 years often prefer raw instead of cooked vegetables and fruits.

Infants should be offered foods that vary in texture and flavor. Infants who are accustomed to many kinds of foods are less likely to limit their variety of food choices later. To add variety to an infant's diet, vegetables and fruits can be added to cereal feedings. It is important to offer various foods and not allow the infant to continue consuming a diet consisting of one or two favorite foods. Older infants generally reject unfamiliar foods the first time they are offered. When parents continue to offer small portions of these foods without comment, infants become familiar with them and often accept them. It may take 8 to 15 repeated exposures before acceptance of the food (Carruth et al, 2004a). It is important that fruit juice does not replace more nutrient-dense foods. If excessive amounts of juice are consumed, children may fail to thrive.

Serving Size

The size of a serving of food offered to a child is very important. At 1 year of age infants eat one third to one half the amount an adult normally consumes. This proportion increases to one half an adult portion by the time the child reaches 3 years of age and increases to about two thirds by 6 years of age. Young children should not be served a large plateful of food; the size of the plate

and the amount should be in proportion to their age. A tablespoon (not a heaping tablespoon) of each food for each year of age is a good guide to follow. Serving less food than parents think or hope will be eaten helps children eat successfully and happily. They will ask for more food if their appetite is not satisfied.

Forced Feeding

Children should not be forced to eat; instead, the cause for the unwillingness to eat should be determined. A typical, healthy child eats without coaxing. Children may refuse food because they are too inactive to be hungry or too active and overtired. To avoid overfeeding and underfeeding, parents should be responsive to the cues for hunger and satiety offered by the infant. A child who is fed snacks or given a bottle too close to mealtime (within 90 minutes) is not hungry for the meal and may refuse it.

Parents who support the development of self-feeding skills respond to the infant's need for assistance and offer encouragement for self-feeding; they also allow the infant to initiate and guide feeding interactions without excessive pressure on the infant for neatness in self-feeding or amount of food consumed. If a child refuses to eat, the family meal should be completed without comment, and the plate should be removed. This procedure is usually harder on the parent than on the child. At the next mealtime, the child will be hungry enough to enjoy the food presented.

Eating Environment

Young children should eat their meals at the family table; it gives them an opportunity to learn table manners while enjoying meals with a family group. Sharing the family fare strengthens ties and makes mealtime pleasant. However, if the family meal is delayed, the children should receive their meals at the usual time. When children eat with the family, everyone must be careful not to make unfavorable comments about any food. Children are great imitators of the people they admire; thus, if the father or older siblings make disparaging remarks about squash, for example, young children are likely to do the same.

The Bright Futures materials and guidelines (www.brightfutures.org/nutrition/) provide information and support to families as they guide their children to healthy eating habits and nourishment.

CLINICAL CASE STUDY

Ethan is an 8-month-old male who was born vaginally at 37 weeks' gestational age. The pregnancy and delivery were uncomplicated. This was his mother's second pregnancy. Ethan's brother, who is now 4 years old, was born prematurely at 27 weeks' gestational age.

Ethan's mother is concerned that Ethan is underweight and not eating enough food. Ethan was born small for gestational age and weighed less than 5 lb at birth. His weight and length percentiles have since increased: His weight has followed the 5th percentile for age and his length has followed roughly the 50th percentile for age since 2 months of age. His weight-for-length has consistently been between the 2nd and 5th percentiles.

Ethan's mother offers him Similac Advance formula mixed at standard dilution (1 scoop of powder mixed with 2 oz. water) 6 to 8 times daily. Ethan's mother has a hard time reading Ethan's hunger cues. She is so concerned about his growth that she offers him a bottle frequently, every 1½ to 2 hours. He consumes 26 to 30 ounces (780 to 900 ml) of formula daily. She offers him homemade purées of fruits or vegetables mixed with grains twice a day; he eats a couple of tablespoons at a time. When she feels he has not eaten enough food, she offers him a bottle.

Nutrition Diagnostic Statement

Food- and nutrition-related knowledge deficit related to age-inappropriate frequency of formula feeding as evidenced by formula offered every 1½ to 2 hours

Nutrition Care Questions

1. What additional information is needed to get an accurate assessment of this infant's intake?
2. When you assess Ethan's growth, what are your expectations for his growth rate? Do you have concerns about his rate of growth?
3. What is a typical eating pattern for an infant Ethan's age? Is Ethan's eating pattern appropriate? Comment on his food and formula intake.
4. How would you assess Ethan's readiness for more textured foods? For self-feeding?

Other Common Nutrition Diagnostic Statements in Infants:

Inadequate energy intake related to mother diluting formula to save money as evidenced by slowed growth pattern and small head circumference

Underweight related to dietary restrictions to address multiple food allergies without medical supervision as evidenced by decrease of weight-for-length from the 50th percentile to the 25th percentile over 1 month

Inadequate vitamin B₁₂ intake related to exclusively breast-fed by vegan mother without vitamin supplementation as evidenced by serum B₁₂ levels below normal range and lethargy

Excessive oral intake related to using foods to soothe baby as evidenced by weight-for-length at the 95th percentile for age

KEY TERMS

adiposity rebound
catch-up growth
failure to thrive (FTT)

food jags
growth channels
growth deficiency

pediatric undernutrition
primarily wasted
stunted growth

The period that begins after infancy and lasts until puberty often is referred to as the *latent* or *quiescent* period of growth—a contrast to the dramatic changes that occur during infancy and adolescence. Although physical growth may be less remarkable and proceed at a steadier pace than it did during the first year, these preschool and elementary school years are a time of significant growth in the social, cognitive, and emotional areas.

GROWTH AND DEVELOPMENT

Growth Patterns

The rate of growth slows considerably after the first year of life. Increments of change are small compared with those of infancy and adolescence; weight typically increases an average of 1.6 to 3.3 kg (3½ to 7 lb) per year until the child is 9 or 10 years old. Then the rate increases, signaling the approach of puberty. Height increase increments average 5 to 9 cm (2 to 3½ inches) per year until the individual growth spurt seen in puberty.

Growth is generally steady and slow during the preschool and school age years, but it can be erratic in individual children, with periods of no growth followed by growth spurts. These patterns usually parallel similar changes in appetite and food intake. For parents, periods of slow growth and poor appetite can cause anxiety, leading to mealtime struggles.

Body proportions of young children change significantly after the first year. Head growth is minimal, trunk growth slows substantially, and limbs lengthen considerably, all of which create more mature body proportions. Walking and increased physical activity of the now-erect child lead to the legs straightening and increased muscle strength in the abdomen and back.

The body composition of preschool and school age children remains relatively constant. Fat gradually decreases during the early childhood years, reaching a minimum between 4 and 6 years of age. Children then experience the **adiposity rebound**, or increase in body fatness in preparation for the pubertal growth spurt. Earlier adiposity rebound has been associated with increased adult body mass index (BMI) (Williams and Goulding, 2009). Sex differences in body composition become increasingly apparent: boys have more lean body mass per

centimeter of height than girls. Girls have a higher percentage of weight as fat than boys, even in the preschool years, but these differences in lean body mass and fat do not become significant until adolescence.

Assessing Growth

A complete nutrition assessment includes the collection of anthropometric data. This includes length or stature, weight, and weight-for-length or BMI, all of which are plotted on the recommended growth charts (see Appendixes 4 through 11). Other measurements that are less commonly used but that provide estimates of body composition include upper-arm circumference and triceps or subscapular skin folds. Care should be taken to use standardized equipment and techniques for obtaining and plotting growth measurements. Charts designed for birth to 24 months of age are based on length measurements and nude weights, whereas charts used for 2- to 20-year-olds are based on stature (standing height) and weight with light clothing and without shoes (see Chapter 7).

The proportion of weight to length or height is a critical element of growth assessment. This parameter is determined by plotting the weight-for-length on the WHO birth to 24-month growth charts or calculating BMI, and plotting it on the 2- to 20-year-old CDC growth charts. Growth measurements obtained at regular intervals provide information about an individual's growth pattern. One-time measurements do not allow for interpretation of growth status. Growth channels are not well established until after 2 years of age. Children generally maintain their heights and weights in the same **growth channels** during the preschool and childhood years, although rates of growth can vary within a selected period.

Regular monitoring of growth enables problematic trends to be identified early and intervention initiated so that long-term growth is not compromised. Weight that increases rapidly and crosses growth channels may suggest the development of obesity (**Figure 17-1**). Lack of weight gain over a period of months or weight loss may be a result of undernutrition, an acute illness, an undiagnosed chronic disease, or significant emotional or family problems (**Figure 17-2**). However, many

FIGURE 17-1 Growth chart and BMI chart for an 8-year-old boy who gained excessive weight after having leg surgery and being immobilized in a body cast for 2 months. The surgery and immobilization were followed by a long period of stress caused by family problems. At the age of 11 years, he became involved in a weight management program. (Source of growth charts only: Centers for Disease Control and Prevention: Growth Charts [website]: <http://www.cdc.gov/growthcharts/>, 2014. Accessed December 2014.)

children are evaluated by health care professionals only when they are ill, so growth evaluation and development may not be a focus of care.

Catch-Up Growth

A child who is recovering from an illness or undernutrition and whose growth has slowed or ceased experiences a greater than expected rate of recovery. This recovery is referred to as **catch-up growth**, a period during which the body strives to return to the child's normal growth channel. The degree of growth suppression is influenced by the timing, severity, and duration of the precipitating cause, such as a severe illness or prolonged nutritional deprivation.

Initial studies supported the thesis that malnourished infants who did not experience immediate catch-up growth would have permanent growth retardation. However, studies of malnourished children from developing countries who subsequently received adequate nourishment, as well as reports of children who were malnourished because of chronic disease such as celiac disease or cystic fibrosis, have shown that these children caught up to their normal growth channels after the first year or two of life when their disease was managed.

The nutritional requirements for catch-up growth depend on whether the child has overall **stunted growth** (height and weight are proportionally low) and is chronically malnourished, or is **primarily wasted**, meaning that the weight deficit exceeds the height deficit. With renourishment, expectations for weight gain vary. A chronically malnourished child may not be expected to gain more than 2 to 3 g/kg/day, whereas a child who is primarily wasted may gain as much as 20 g/kg/day.

Nutrient requirements, especially for energy and protein, depend on the rate and stage of catch-up growth. For instance, more protein and energy are needed during the initial period of very rapid weight gain and for those in whom lean tissue is the major component of the weight gain. In addition to energy, other nutrients are important, including vitamin A, iron, and zinc.

Current growth parameters are used to evaluate the child's weight in relation to age and stature and to estimate a "desirable" or goal weight. Formulas are then used to estimate the minimum and maximum energy needed for catch-up growth. After a child who is wasted catches up in weight, dietary management must change to slow the weight gain velocity and avoid

A

FIGURE 17-2 Growth charts for a 2-year-old girl who experienced significant weight loss during a prolonged period of diarrhea and feeding problems. After being diagnosed with celiac disease, she began following a gluten-free diet and entered a period of catch-up growth. (Source of growth charts only: Centers for Disease Control and Prevention: *Growth Charts* [website]: <http://www.cdc.gov/growthcharts/>, 2014. Accessed December 2014.)

B

excessive gain. The catch-up in linear growth peaks approximately 1 to 3 months after treatment starts, whereas weight gain begins immediately.

NUTRIENT REQUIREMENTS

Because children are growing and developing bones, teeth, muscles, and blood, they need more nutritious food in proportion to their size than do adults. They may be at risk for malnutrition when they have a poor appetite for a long period, eat a limited number of foods, or dilute their diets significantly with nutrient-poor foods.

The dietary reference intakes (DRIs) are based on current knowledge of nutrient intakes needed for optimal health. (See inside front cover.) Most data for preschool and school age children are values interpolated from data on infants and adults. The DRIs are meant to improve the long-term health of the population by reducing the risk of chronic disease and preventing nutritional deficiencies. Thus, when intakes are less than the recommended level, it cannot be assumed that a particular child is inadequately nourished.

Energy

The energy needs of healthy children are determined by basal metabolism, rate of growth, and energy expenditure of activity. Dietary energy must be sufficient to ensure growth and spare protein from being used for energy, while not allowing excess

weight gain. Suggested intake proportions of energy are 45% to 65% as carbohydrate, 30% to 40% as fat, and 5% to 20% as protein for 1- to 3-year-olds, with carbohydrates the same for 4- to 18-year-olds, 25% to 35% as fat, and 10% to 30% as protein.

The DRIs for estimated energy requirement (EER) are average energy requirements based on life-stage groupings for healthy individuals of normal weight. Toddlers 13 through 35 months are grouped together; for older children the EERs are divided by sex and age (3 to 8 years and 9 to 18 years). The EER includes the total energy expenditure plus energy needed for growth (see Chapter 2). The DRIs are applied to child nutrition programs and other guidelines (Otten et al, 2006). Box 17-1 provides examples of determining EER for two children. On an individual basis, it can be useful to estimate energy requirements using kilocalories per kilogram of weight or per centimeter of height.

Protein

The need for protein decreases from approximately 1.1 g/kg in early childhood to 0.95 g/kg in late childhood (Table 17-1). Protein intake can range from 5% to 30% of total energy, depending on age. Protein deficiency is uncommon in American children, partly because of the cultural emphasis on high-protein foods. National surveys show that less than 3% of children fail to meet the recommended dietary allowance. Children who are most at risk for inadequate protein intake are those on strict vegan diets,

BOX 17-1 Determining Estimated Energy Requirements

(Examples using data from Box 2-1, Chapter 2)

1. For 13- to 35-month-old children:

$$\text{EER (kcal)} = (89 \times \text{wt [kg]}) - 100 + 20$$

An 18-month-old boy has a length of 84 cm and weighs 12.5 kg

$$\text{EER (kcal)} = (89 \times 12.5) - 100 + 20$$

$$\text{EER (kcal)} = 1113 - 100 + 20$$

$$\text{EER (kcal)} = 1033$$

2. For girls 3 through 8 years:

$$\text{EER (kcal)} = 135.3 - ([30.8 \times \text{age in yrs}] + \text{PA} \times ([10 \times \text{wgt in kg}] + [934 \times \text{hgt in m}])) + 20$$

A 6½-year-old girl is 112 cm tall, weighs 20.8 kg, and has moderate activity (PA coefficient of 1.31)

$$\text{EER (kcal)} = 135.3 - (30.8 \times 6.5) + 1.31 \times ([10 \times 20.8] + [934 \times 1.12]) + 20$$

$$\text{EER (kcal)} = 135.3 - 200.2 + 1.31 \times (208 + 1046.1) + 20$$

$$\text{EER (kcal)} = 135.3 - 200.2 + 1642.9 + 20$$

$$\text{EER (kcal)} = 1598$$

EER, Estimated energy requirement; PA, physical activity.

TABLE 17-1 Protein Dietary Reference Intakes (DRIs) for Children Through Age 13 Years

Age	Grams/Day*	PROTEIN
		Grams/Kilogram/Day
1-3 yr	13 g/day	1.05 g/kg/day
4-8 yr	19 g/day	0.95 g/kg/day
9-13 yr	34 g/day	0.95 g/kg/day

*Recommended dietary allowance for reference individual (g/day).

those with multiple food allergies, or who have limited food selections because of fad diets, behavioral problems, or inadequate access to food.

Minerals and Vitamins

Minerals and vitamins are necessary for normal growth and development. Insufficient intake can cause impaired growth and result in deficiency diseases. The DRIs are listed inside the front cover.

Iron

Children between 1 and 3 years of age are at risk for iron deficiency anemia, which can affect development. The rapid growth period of infancy is marked by an increase in hemoglobin and total iron mass. National Health and Nutrition Examination Survey (NHANES) data indicate that children with prolonged bottle feeding and those of Mexican American descent are at highest risk for iron deficiency (Moshfegh et al, 2005). Recommended intakes must factor in the absorption rate and quantity of iron in foods, especially those of plant origin.

Calcium

Calcium is needed for adequate mineralization and maintenance of growing bone in children. The RDA for calcium for children 1 to 3 years old is 700 mg/day, for children 4 to 8 years it is 1000 mg/day, and for those 9 to 18 years it is 1300 mg per day. Actual need depends on individual absorption rates and dietary factors such as quantities of protein, vitamin D, and phosphorus. Because milk and other dairy products are primary sources of calcium, children who consume limited amounts of these foods are often at risk for poor bone mineralization. Other calcium-fortified foods such as soy and rice milks and fruit juices are also good sources (see Appendix 46).

Zinc

Zinc is essential for growth; a deficiency results in growth failure, poor appetite, decreased taste acuity, and poor wound healing. Because the best sources of zinc are meat and seafood, some children may regularly have low intakes (see Appendix 53). Diagnosis of zinc deficiency, especially marginal deficiency, may be difficult because laboratory parameters, including plasma, serum erythrocyte, hair, and urine, are of limited value in determining zinc deficiency. There is a positive influence of zinc supplementation on growth and serum zinc concentrations.

Vitamin D

Vitamin D is needed for calcium absorption and deposition of calcium in the bones; other functions within the body, including prevention of chronic diseases such as cancer, cardiovascular disease, and diabetes, are important areas of current investigation. Because this nutrient also is formed from sunlight exposure on the skin, the amount required from dietary sources depends on factors such as geographic location and time spent outside (see Appendix 45).

The DRI for vitamin D for infants is 400 IU (10 mcg) per day and for children is 600 IU (15 mcg) per day. Vitamin D-fortified milk is the primary dietary source of this nutrient, and breakfast cereals and nondairy milks often are fortified with vitamin D (see Appendix 45). Dairy products such as cheese and yogurt, however, are not always made from fortified milk. Milks other than cow milk (e.g., goat, soy, almond, or rice) may not be fortified with vitamin D. For young children the current DRI for vitamin D is higher than what may be consumed from a typical diet. Supplementation may be needed after a careful assessment or measurement of vitamin D status. It is becoming more common to measure serum 25(OH) vitamin D in children; however, there is some controversy regarding what constitutes optimal levels (Rovner and O'Brien, 2008).

Vitamin-Mineral Supplements

Forty percent of preschool children are given a multivitamin-mineral supplement; this percentage decreases in older children (Butte et al, 2010; Picciano et al, 2007). Families with more education, health insurance coverage, and higher incomes generally have higher rates of supplement use, although these may not be the families who are at greatest risk for having inadequate diets.

Evidence shows that fluoride can help prevent dental caries. If a community's water supply is not fluoridated, fluoride supplements are recommended from 6 months until 16 years of age. However, individual family practices should be assessed, including the child's primary source of fluids (e.g., drinking water, juices, or other beverages) and fluoride sources from child care, school, toothpaste, and mouthwash (see Chapter 25).

The AAP does not support giving healthy children routine supplements of any vitamins or minerals other than fluoride. However, children at risk for inadequate nutrition who may benefit include those (1) with anorexia, inadequate appetite, or who consume fad diets; (2) with chronic disease (e.g., cystic fibrosis, inflammatory bowel disease, hepatic disease); (3) from food-deprived families or who suffer parental neglect or abuse; (4) who participate in a dietary program for managing obesity; (5) who consume a vegetarian diet without adequate dairy products; (6) with faltering growth (failure to thrive); (7) with developmental disabilities.

Children who routinely take a multiple vitamin or a vitamin-mineral supplement usually do not experience negative effects if the supplement contains nutrients in amounts that do not exceed the DRIs, especially the tolerable upper intake level. However, some nutrients can be “missed” by general multiple vitamin supplements. Although many children consume less than the recommended amount of calcium, children’s vitamin-mineral supplements typically do not contain significant amounts of calcium. For example, among children ages 2 to 18 years who took supplements, one third did not meet recommendations for calcium and vitamin D intakes even with supplements. In addition, supplement use was associated with increased prevalence of excessive intakes of iron, zinc, vitamin A, and folic acid (Bailey et al, 2012). In addition, an analysis of supplements marketed for infants and children indicated that available supplements do not necessarily meet recommendations for intake; for some nutrients, not enough is provided, and for others, the supplements provide excessive amounts (Madden et al, 2014). Children should not take

megadoses, particularly of the fat-soluble vitamins because large amounts can result in toxicity. Careful evaluation of each pediatric supplement is suggested because many types are available but incomplete. Because many vitamin-mineral supplements look and taste like candy, parents should keep them out of reach of children to avoid excessive intake of nutrients such as iron.

Complementary nutrition therapies are becoming more common for children, especially for those with special health care needs such as children with Down syndrome, autism spectrum disorder (ASD), or cystic fibrosis (see Chapters 34 and 44). As part of the nutrition assessment, practitioners should inquire as to the use of these products and therapies, be knowledgeable about their efficacy and safety, and help families determine whether they are beneficial and how to use them (see Chapter 12).

PROVIDING AN ADEQUATE DIET

The development of feeding skills, food habits, and nutrition knowledge parallels the cognitive development that takes place in a series of stages, each laying the groundwork for the next. Table 17-2 outlines the development of feeding skills in terms of Piaget’s theory of child psychology and development.

Intake Patterns

Children’s food patterns have changed over the years. Although they drink less milk, more of it is low-fat or nonfat milk. The total fat as a percent of energy intake has decreased, but remains above recommendations of 25% to 40% of total

TABLE 17-2 Feeding, Nutrition, and Piaget’s Theory of Cognitive Development

Developmental Period	Cognitive Characteristics	Relationships to Feeding and Nutrition
Sensorimotor (birth-2 yr)	Neonate progresses from autonomic reflexes to a young child with intentional interaction with the environment and the beginning use of symbols. Food is used primarily to satisfy hunger, as a medium to explore the environment, and as an opportunity to practice fine motor skills.	Progression involves advancing from sucking and rooting reflexes to the acquisition of self-feeding skills.
Preoperational (2-7 yr)	Thought processes become internalized; they are unsystematic and intuitive. Use of symbols increases. Reasoning is based on appearances and happenstance. The child’s approach to classification is functional and unsystematic. The child’s world is viewed egocentrically.	Eating becomes less the center of attention and is secondary to social, language, and cognitive growth. Food is described by color, shape, and quantity, but the child has only a limited ability to classify food into “groups.” Foods tend to be categorized into “like” and “don’t like.” Foods can be identified as “good for you,” but reasons why they are healthy are unknown or mistaken.
Concrete operational (7-11 yr)	The child can focus on several aspects of a situation simultaneously. Cause-and-effect reasoning becomes more rational and systematic. The ability to classify, reclassify, and generalize emerges. A decrease in egocentrism permits the child to take another’s view.	The child begins to realize that nutritious food has a positive effect on growth and health but has a limited understanding of how or why. Mealtimes take on a social significance. The expanding environment increases the opportunities for influences on food selection; for example, peer influence increases.
Formal operational (11 yr and beyond)	Hypothetical and abstract thought expand. The child’s understanding of scientific and theoretical processes deepens.	The concept of nutrients from food functioning at physiologic and biochemical levels can be understood. Conflicts in making food choices may be realized (i.e., knowledge of the nutritious value of foods may conflict with preferences and nonnutritive influences).

energy intake depending on age. More energy comes from snacks, and portion sizes have increased. In addition, more food is consumed in environments other than the home (Nicklas and Hayes, 2008). Foods with low nutrient density (soft drinks, baked and dairy desserts, sweeteners, and salty snacks) often displace nutrient-dense foods. National food intake studies of children and adolescents indicate that most of their diets do not meet the national recommendations for food groups.

Like physical growth patterns, food intake patterns are not smooth and consistent. Although subjective, appetites usually follow the rate of growth and nutrient needs. By a child's first birthday, milk consumption begins to decline. In the next year vegetable intake decreases; intakes of cereals, grain products, and sweets increase. Young children often prefer softer protein sources instead of meats that are harder to chew.

Changes in food consumption are reflected in nutrient intakes. The early preschool years show a decrease in calcium, phosphorus, riboflavin, iron, and vitamin A compared with infancy. Intakes of most other key nutrients remain relatively stable. During the early school years, a pattern of consistent and steadily increased intakes of most nutrients is seen until adolescence. In healthy children a wide variability of nutrient intake is seen at any age. Children are most likely to consume inadequate amounts of calcium, vitamin D, fiber, and potassium (Bailey et al, 2010; Kranz et al, 2012). However, clinical signs of malnutrition in American children are rare.

Factors Influencing Food Intake

Numerous influences, some obvious and others subtle, determine the food intake and habits of children. Habits, likes, and dislikes are established in the early years and carried through to adulthood. The major influences on food intake in the developing years include family environment, societal trends, the media, peer pressure, and illness or disease.

Family Environment

For toddlers and preschool children the family is the primary influence in the development of food habits. In young children's immediate environment, parents and older siblings are significant models. Food attitudes of parents can be strong predictors of food likes and dislikes and diet complexity in children of primary school age. Similarities between children's and their parents' food preferences are likely to reflect genetic and environmental influences (Savage et al, 2007).

Contrary to common belief, young children do not have the innate ability to choose a balanced, nutritious diet; they can choose one only when presented with nutritious foods. A positive feeding relationship includes a division of responsibility between parents and children. The parents and other adults are to provide safe, nutritious, developmentally appropriate food as regular meals and snacks. The children decide how much, if any, they eat (Eneli et al, 2008).

Eating together at family meals is becoming less common, partly because of family schedules, more time eating in front of a screen, and the decreasing amount of time devoted to planning and preparing family meals. School age children and adolescents who eat more dinners with their families consume more fruits and vegetables, less soda, and fewer fried foods than those who rarely eat dinner with their families (Larson et al, 2007). Family meals have other influences, including a positive influence on nutrition beliefs and possibly prevention of overweight (Chan and Sobal, 2011).

The atmosphere around food and mealtime also influences attitudes toward food and eating. Unrealistic expectations for a child's mealtime manners, arguments, and other emotional stress can have a negative effect. Meals that are rushed create a hectic atmosphere and reinforce the tendency to eat too fast. A positive environment is one in which sufficient time is set aside to eat, occasional spills are tolerated, and conversation that includes all family members is encouraged (Figure 17-3).

Societal Trends

Because almost three fourths of women with school age children are employed outside the home, children may eat one or more meals at a child care center or school. In these settings all children should have access to nutritious meals served in a safe and sanitary environment that promotes healthy growth and development (Benjamin Neelon et al, 2011; Bergman and Gordon, 2010). Because of time constraints, family meals may include more convenience or fast foods. However, having a mother who is employed outside the home does not seem to affect children's dietary intakes negatively. Food service in group settings such as child care centers, Head Start programs, preschool programs, and in elementary schools is regulated by federal or state guidelines. Many facilities and some in-home child care centers may participate in the U.S. Department of Agriculture (USDA) Child and Adult Care Food Program. However, the quality of meals and snacks can vary greatly; parents should investigate food service when considering child care options. In addition to providing children with optimal nutrients, a program should offer food that is appealing, safely prepared, and appropriate, incorporating cultural and developmental patterns (Benjamin Neelon et al, 2007).

Approximately one in five American children lives in a family with an income below the poverty line; in 2012 nearly 16 million children lived in poverty (DeNavas-Walt et al, 2013). The increasing numbers of single-parent households predominantly headed by women have lower incomes and less money for all expenses, including food, than households headed by men. This

FIGURE 17-3 Three generations of a family share a meal. Eating together gives meals a place of prominence in the home—meals that will not be replaced with fast foods eaten on the run. (From Photo@istock.com.)

phenomenon makes these families increasingly vulnerable to multiple stressors such as marginal health and nutritional status partly because of lack of jobs, child care, adequate housing, and health insurance.

In 2013, 11.3% of U.S. households experienced food insecurity. Federal food and nutrition assistance programs (including National School Lunch, Food Stamp Program, and Special Supplemental Nutrition Program for Women, Infants and Children [WIC]) provided benefits to about 60% of food-insecure households (Coleman-Jensen, et al, 2013; see Chapter 9). The food stamp allotment for families, based on the USDA Thrifty Food Plan, does not provide adequate funds to purchase food based on the government's nutrition guidelines, especially when labor is considered (Davis and You, 2010). Food insecurity also increases the risk for children younger than age 3 years to be iron-deficient with anemia. Studies suggest that intermittent hunger in American children is associated with increased developmental risk (see *Focus On: Childhood Hunger and Its Effect on Behavior and Emotions*) (Rose-Jacobs et al, 2008). Even marginal food insecurity, which is often thought not to be an indicator of nutrition risk in adults, is associated with adverse health outcomes in children (Cook et al, 2013).

FOCUS ON

Childhood Hunger and Its Effect on Behavior and Emotions

It is well accepted that malnourished children are less responsive, less inquisitive, and participate in less exploratory behavior than well-nourished children. Specific nutrient deficiencies such as iron deficiency anemia also can result in a decreased ability to pay attention and poorer problem-solving skills. Less clear is the effect of periodic hunger or food insecurity on a child's behavior and functioning. With recent federal welfare reform legislation and economic downturns, an increasing number of children from low-income families are at risk for limited food resources (Stang and Bayerl, 2010).

In the 1990s the Community Childhood Hunger Identification Project conducted surveys using standardized questions and large, rigorously selected samples to categorize families as "hungry," "at risk for hunger," or "not hungry" (Kleinman et al, 1998). It was estimated that each year 8% of children younger than 12 years of age in the United States experienced prolonged periods in which they had insufficient food. Data from 2012 indicated that 10% of U.S. households with children were food-insecure. In 2012, 49.0 million people in the United States lived in food-insecure households; 15.9 million of those people (11.3%) were children (Food and Research Action Center, 2014). A longitudinal study following approximately 21,000 children from kindergarten through third grade found that persistent food insecurity was predictive of impaired academic outcomes, poorer social skills, and a tendency to increased BMI (Ryu and Bartfeld, 2012).

Although these studies have limitations because of other factors that may affect a child's functioning (e.g., stress, family dysfunction, or substance abuse), a correlation exists between children's lack of sufficient food and their behavioral and academic functioning. As future studies provide more evidence of this relationship, it will be clear that social policies must ensure the provision of children's basic needs for optimal growth and development.

Media Messages

Food is marketed to children using a variety of techniques, including television advertising, in-school marketing, sponsorship, product placement, Internet marketing, and sales promotion. Television advertising and in-school marketing are regulated to

some degree. By the time the average American child graduates from high school, he or she has watched 15,000 hours of television and spent 11,000 hours in the classroom. In a sample of television advertising to children, more than 40% of commercials were for food. Of these, 80% to 95% were for items high in saturated fat, trans fat, sugar, and sodium (Powell et al, 2013).

Screen time can be detrimental to growth and development because it encourages inactivity and passive use of leisure time. Television viewing and its multiple media cues to eat have been suggested as a factor contributing to excessive weight gain in school age children and adolescents, especially when there is a television in the child's bedroom (Gilbert-Diamond et al, 2014). Increases in hours of television viewing are associated with rising BMIs in boys and girls, with females also affected by watching DVDs/videos and electronic games. For those already at risk with higher BMIs, limits on uneducational viewing may be part of intervention strategies (Falbe et al, 2013).

The types of food eaten during television viewing can contribute to increased dental caries resulting from the continued exposure of the teeth to dense carbohydrate- and sugar-laden foods (Ghimire and Rao, 2013). Children ages 2 to 11 are viewing less food-related advertising than in the past, with the largest decrease in ads for sweet foods; foods shown are still high in saturated fat, sodium, and/or sugar (Powell et al, 2011).

Preschool children are generally unable to distinguish commercial messages from regular programs. In fact, they often pay more attention to the commercials. As children get older, they gain knowledge about the purpose of commercial advertising and become more critical of its validity but are still susceptible to the commercial message. Media literacy education programs teach children and adolescents about the intent of advertising and media messages and how to evaluate and interpret their obvious and subtle influences. Comprehensive and consistent regulation approaches plus monitoring the use of the most common persuasive marketing techniques (premium offers, promotional characters, nutrition- and health-related claims, taste and fun appeal) is suggested (Jenkin et al, 2014).

Significant decreases have occurred in beverage and food vending in schools, but both forms of sales still occur. Elementary-age students often are given coupons to encourage their families to purchase food, whereas those in upper grades may be exposed to in-school exclusive beverage contracts and other types of marketing (Terry-McElrath et al, 2014). The USDA has established nutrition standards for snack foods and beverages available for sale in schools but does not address food marketing. Standards that can be enforced are still needed to clarify the nutrition content of all foods and beverages marketed in school settings.

Fortunately, some media messages are beneficial. For example, public health messages about eating fish versus the risks of acquiring mercury are important. (See *Focus On: Childhood Methylmercury Exposure and Toxicity: Media Messaging.*)

Peer Influence

As children grow, their world expands and their social contacts become more important. Peer influence increases with age and affects food attitudes and choices. This may result in a sudden refusal of a food or a request for a currently popular food. Decisions about whether to participate in school meals may be made more on the basis of friends' choices than on the menu. Such behaviors are developmentally typical. Positive behaviors such as a willingness to try new foods can be reinforced. Parents

FOCUS ON

Childhood Methylmercury Exposure and Toxicity: Media Messaging

Mercury toxicity can cause neurologic problems, which can lead to cognitive and motor deficits. Toxicity related to prenatal exposure is documented, and there is evidence that postnatal exposure is dangerous as well (Myers et al, 2009; Oken and Bellinger, 2008). Exposure to mercury can occur through environmental contact and eating contaminated foods. Methylmercury, the most toxic form of mercury, accumulates in fish.

Public health agencies have looked at balancing the benefits of minimizing exposure to this neurotoxin with the risk of limiting intake of docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA) as well as a source of high biologic value protein. DHA and EPA are essential omega-3 fatty acids and have received much attention because of their importance in cognitive and vision development and their cardiovascular benefits (Mahaffey et al, 2008). In addition, fish advisories are available in certain states. The U.S. Environmental Protection Agency's (EPA) reference dose for methylmercury is based on body weight: 0.1 mcg/kg/day. For a 20-kg child, this is approximately 14 mcg/week (U.S. EPA, 2004). The methylmercury content of 3 ounces of albacore tuna is approximately 29.7 mcg, canned light tuna approximately 10 mcg, and fresh or frozen salmon approximately 1.2 mcg. The Food and Drug Administration (FDA) and EPA have made recommendations for fish intake by young children:

- Do not eat shark, swordfish, king mackerel, or tilefish because they contain high levels of mercury.
- Eat up to 12 oz (two average meals) a week of a variety of fish and shellfish that are lower in mercury.
- Five of the most commonly eaten fish that are low in mercury are shrimp, canned light tuna, salmon, pollock, and catfish.
- Another commonly eaten fish, albacore ("white") tuna has more mercury than canned light tuna. So, when choosing two meals of fish and shellfish, eat up to 6 ounces (one average meal) of albacore tuna per week, but only 3 ounces for a child.
- Check local advisories about the safety of fish caught by family and friends in local lakes, rivers, and coastal areas. If no advice is available, eat up to 6 ounces (3 oz for a child) per week of fish caught from local waters, but do not consume any other fish during that week.
- Follow these same recommendations when feeding fish and shellfish to young children, but serve smaller portions.

Revised fish consumption guidelines from U.S. EPA and FDA are expected in 2016. See: <http://www2.epa.gov/fish-tech/epa-fda-advisory-mercury-fish-and-shellfish>. Accessed November 2015.

must set limits on undesirable influences but also must be realistic; struggles over food are self-defeating.

Illness or Disease

Children who are ill usually have a decreased appetite and limited food intake. Acute viral or bacterial illnesses are often short-lived but may require an increase in fluids, protein, or other nutrients. Chronic conditions such as asthma, cystic fibrosis, or chronic renal disease may make it difficult to obtain sufficient nutrients for optimal growth. Children with these types of conditions are more likely to have behavior problems relating to food. Children requiring special diets (e.g., those who have diabetes or phenylketonuria) not only have to adjust to the limits of foods allowed but also have to address issues of independence and peer acceptance as they grow older. Some rebellion against the prescribed diet is typical, especially as children approach puberty.

Feeding Preschool Children

From 1 to 6 years of age children experience vast developmental progress and acquisition of skills. One-year-old children primarily use fingers to eat and may need assistance with a cup. By

2 years of age, they can hold a cup in one hand and use a spoon well but may prefer to use their hands at times. Six-year-old children have refined skills and are beginning to use a knife for cutting and spreading.

As the growth rate slows after the first year of life, appetite decreases, which often concerns parents. Children have less interest in food and an increased interest in the world around them. They can develop **food jags**, which can be periods when foods that were previously liked are refused, or there are repeated requests to eat the same food meal after meal. This behavior may be attributable to boredom with the usual foods or may be a means of asserting newly discovered independence. Parents may have concerns with their child's seemingly irrational food behavior. Struggles over control of the eating situation are fruitless; no child can be forced to eat. This period is developmental and temporary (Figure 17-4).

A positive feeding relationship includes a division of responsibility between parents and children. Young children can choose a balanced nutritious diet if presented with nutritious foods. The parents and other adults provide safe, nutritious, developmentally appropriate food as regular meals and snacks; and the children decide how much, if any, they eat (Satter, 2000). Parents maintain control over what foods are offered and have the opportunity to set limits on inappropriate behaviors. Neither rigid control nor a laissez-faire approach is likely to succeed. Parents and other care providers should continue to offer a variety of foods, including the child's favorites, and not make substitutions a routine.

FIGURE 17-4 Use of alternative eating utensils can increase a preschooler's interest in trying new foods and development of fine motor skills.

With smaller stomach capacities and variable appetites, preschool children should be offered small servings of food four to six times a day. Snacks are as important as meals in contributing to the total daily nutrient intake. Carefully chosen snacks are those dense in nutrients and least likely to promote dental caries. A general rule of thumb is to offer 1 tablespoon of each food for every year of age and to serve more food according to the child's appetite. Table 17-3 is a guide for food and portion size.

Senses other than taste play an important part in food acceptance by young children. They tend to avoid food with extreme temperatures, and some foods are rejected because of odor rather than taste. A sense of order in the food presentation often is preferred; many children do not accept foods that touch each other on the plate, and mixed dishes or casseroles with unidentifiable foods are not popular. Broken crackers may go uneaten, or a sandwich may be refused because it is "cut the wrong way."

The physical setting for meals is important. Children's feet should be supported, and chair height should allow a comfortable reach to the table at chest height. Sturdy, child-size tables and chairs are ideal, or a high chair or booster seat should be used. Dishes and cups should be unbreakable and heavy enough to resist tipping. For very young children, a shallow bowl is often better than a plate for scooping. Thick, short-handled spoons and forks allow for an easier grasp.

Young children do not eat well if they are tired; this should be considered when meal and play times are scheduled. A quiet activity or rest immediately before eating is conducive to a relaxed, enjoyable meal. However, children also need active, large-motor activities and time in the fresh air to stimulate a good appetite.

Fruit juices and juice drinks are common beverages for young children; they frequently replace water and milk in children's diets. In addition to altering the diet's nutrient content, excessive intake of fruit juice can result in carbohydrate malabsorption and chronic, nonspecific diarrhea. This suggests that juices, especially apple and pear, should be avoided when using liquids to treat acute diarrhea. For children with chronic diarrhea, a trial of restricting fruit juices may be warranted before more costly diagnostic tests are done.

When children aged 2 to 11 years consume 100% juice, their diets have significantly higher intakes of energy, carbohydrates, vitamins C and B₆, potassium, riboflavin, magnesium, iron, and folate, and significantly lower intakes of total fat, saturated fatty acids, discretionary fat, and added sugar; this 100% juice intake does not correlate with overweight later (Nicklas et al, 2008). However, excess juice intake (12 to 30 oz/day) by young children may decrease a child's appetite, resulting in decreased food intake and poor growth. Here, a reduction in juice intake results in improved growth (American Academy of Pediatrics [AAP], Committee on Nutrition, 2001). Fruit juice intake should be

TABLE 17-3 Suggested Portion Sizes for Children*

These suggestions are not necessarily appropriate for all children (and may be inappropriate for some children with medical conditions that greatly affect nutrient needs). They are intended to serve as a general framework that can be individualized based on a child's condition and growth pattern.

	1- to 3-Year-Olds	4- to 6-Year-Olds	7- to 12-Year-Olds	Comments
Grain Products	Bread: ½ to 1 slice Rice, pasta, potatoes: ¼ to ½ cup Cooked cereal: ¼ to ½ cup Ready-to-eat cereal: ¼ to ½ cup Tortilla: ½ to 1	Bread: 1 slice Rice, pasta, potatoes: ½ cup Cooked cereal: ½ cup Ready-to-eat cereal: ¾ to 1 cup Tortilla: 1	Bread: 1 slice Rice, pasta, potatoes: ½ cup Cooked cereal: ½ cup Ready-to-eat cereal: 1 cup Tortilla: 1	Include whole grain foods and enriched grain products.
Vegetables	Cooked or pureed: 2-4 tablespoons Raw: few pieces, if child can chew well	Cooked or pureed: 3-4 tablespoons Raw: few pieces	Cooked or pureed: ½ cup Raw: ½ to 1 cup	Include one green leafy or yellow vegetable for vitamin A, such as spinach, carrots, broccoli, or winter squash.
Fruit	Raw (apple, banana, etc.): ½ to 1 small, if child can chew well Canned: 2-4 Tablespoons Juice: 3-4 ounces	Raw (apple, banana, etc.): ½ to 1 small, if child can chew well Canned: 4-8 tablespoons Juice: 4 ounces	Raw (apple, banana, etc.): 1 small Canned: ¾ cup Juice: 5 ounces	Include one vitamin C-rich fruit, vegetable, or juice, such as citrus juices, an orange, grapefruit sections, strawberries, melon in season, a tomato, or broccoli.

Modified from Lowenberg ME: Development of food patterns in young children. In Trahms CM, Pipes P: *Nutrition in infancy and childhood*, ed 6, St Louis, 1997, WCB/McGraw-Hill and Harris; Harris AB et al: *Nutrition strategies for children with special needs*, 1999, USC University Affiliated Program, Los Angeles.

*This is a guide to a basic diet. Fats, oils, sauces, desserts, and snack foods provide additional energy to meet the needs of a growing child. Foods can be selected from this pattern for meals and snacks.

limited to 4 to 6 oz/day for children 1 through 6 years of age and 8 to 12 oz/day (in two servings) for older children and adolescents (AAP, 2014).

Large volumes of sweetened beverages, combined with other dietary and activity factors, may contribute to overweight in a child. High intake of fructose, especially from sucrose and high-fructose corn syrup in processed foods and beverages, may lead to increased plasma triglycerides and insulin resistance. In several studies, low calcium intake and obesity have been correlated with high intake of sugar-sweetened beverages in preschool children (Keller et al, 2009; Lim et al, 2009). High milk and low sweetened-beverage intake is associated with improved nutrient intake, including calcium, potassium, magnesium, and vitamin A (O'Neil et al, 2009). Children should be offered milk, water, and healthy snacks throughout the day instead of sugar-sweetened choices.

Excess sodium is another concern. An increase in sodium or salt intake results in an increase in systolic blood pressure and diastolic blood pressure (Bergman et al, 2010). A reduction in the use of processed foods may be warranted for children with elevated blood pressure. The Dietary Approaches to Stop Hypertension (DASH) diet is useful for all age groups because it increases potassium, magnesium, and calcium in relation to sodium intake (see Appendix 26).

Meal time in group settings is an ideal opportunity for nutrition education programs focused on various learning activities around food (Figure 17-5). Experiencing new foods, participating in simple food preparation, and planting a garden are activities that develop and enhance positive food habits and attitudes.

Feeding School Age Children

Growth from ages 6 to 12 years is slow but steady, paralleled by a constant increase in food intake. Children are in school a greater part of the day; and they begin to participate in clubs, organized sports, and recreational programs. The influence of peers and significant adults such as teachers, coaches, or sports idols increases. Except for severe issues, most behavioral problems connected with food have been resolved by this age, and children enjoy eating to alleviate hunger and obtain social satisfaction.

School age children may participate in the school lunch program or bring a lunch from home. The National School Lunch Program (NSLP), established in 1946, is administered by the

FIGURE 17-5 Children who eat with each other in an appropriate environment often eat more nutritiously and try a wider variety of foods than when eating alone or at home. (Courtesy of Ana Raab.)

USDA. Children from low-income families are eligible for free or reduced-price meals. In addition, the School Breakfast Program (SBP), begun in 1966, is offered in approximately 85% of the public schools that participate in the lunch program. The USDA also offers the Afterschool Snacks and Summer Food Service for organized programs, the Fresh Fruit and Vegetable Program in selected schools, and the Special Milk program for children not participating in school lunch (see Chapter 9).

Guidelines for the meals provided by the NSLP and SBP are based on the Institute of Medicine (IOM) report, *School Meals, Building Blocks for Healthy Eating* and legislated by the 2010 Healthy, Hunger-Free Kids Act (IOM, 2009; McGuire, 2009). In addition to guidelines to align meals patterns with the Dietary Guidelines and to address other childhood health concerns, the Act makes resources and technical assistance available. Nutrition standards for the NSLP and SBP that follow the IOM recommendations and made significant changes to meal patterns were published in 2012 ([Food and Nutrition Service, 2012](#)).

Efforts have been made to decrease food waste by altering menus to accommodate student preferences, allowing students to decline one or two menu items and offering salad bars. Efforts to increase participation in school lunch require consistent messages that support healthful eating.

School wellness policies were required by the school year 2006 to 2007 in institutions participating in school lunch and school breakfast programs. The school, including the administration, teachers, students, and food service personnel, in cooperation with families and the community, are encouraged to work together to support nutrition integrity in the educational setting (Bergman et al, 2010).

Consumption of school meals also is affected by the daily school schedule and the amount of time allotted for children to eat. When recess is scheduled before lunch rather than after, intake is better. A Montana “Recess Before Lunch” pilot study documented improvement in the mealtime atmosphere and students’ behavior. Discipline problems on the playground, in the lunchroom, and in the classroom decreased ([Montana Office of Public Instruction, 2010](#)).

Children who require a special diet because of certain medical conditions such as diabetes, celiac disease, or documented food allergy are eligible for modified school meals. Children with developmental disabilities are eligible to attend public school from ages 3 to 21 years, and some of them need modified school meals (e.g., meals that are texture modified, or with increased or decreased energy density). To receive modified meals, families must submit written documentation by a medical professional of the diagnosis, meal modification, and rationale. For children receiving special education services, the documentation for meals and feeding can be incorporated as objectives in a child’s individual education plan (IEP) (see Chapter 44).

Studies of lunches packed at home indicate that they usually provide fewer nutrients but less fat than school lunch meals. Favorite foods tend to be packed, so children have less variety. Food choices are limited to those that travel well and require no heating or refrigeration. A typical well-balanced lunch brought from home could include a sandwich with whole-grain bread and a protein-rich filling; fresh vegetables, fruit, or both; low-fat milk; and possibly a cookie, a graham cracker, or another simple dessert. Food safety measures (e.g., keeping perishable foods well chilled) must be observed when packing lunches for school.

Today many school age children are responsible for preparing their own breakfasts. It is not uncommon for children to skip this meal altogether, even children in the primary grades. Children who skip breakfast tend to consume less energy and other nutrients than those who eat breakfast (Wilson et al, 2006). Reviews of the effects of breakfast on cognition and school performance indicate a positive association between breakfast and school performance (Adolphus et al, 2013) (see *Focus On: Breakfast: Does It Affect Learning?*).

FOCUS ON

Breakfast: Does It Affect Learning?

The educational benefits of school meal programs and especially the role of breakfast in better school performance have been debated and discussed for decades. Overall, breakfast consumption has been associated with better on-task classroom behavior (i.e., attention in class, and engagement in learning activities) regardless of nutritional and/or socioeconomic status. A literature review indicates associations between school performance and breakfast consumption, especially among children who were at nutritional risk (i.e., had wasted and stunted growth) and or were from low socioeconomic backgrounds (Adolphus et al, 2013). School-based breakfast experiments in 9- to 11-year-old and 6- to 8-year-old children found similar positive results with breakfast consumption (i.e., enhanced short-term memory, better spatial memory, and improved processing of complex visual stimuli), but other reports are less supportive (Adolphus et al, 2013). These studies suggest that brain functioning is sensitive to short-term variations in nutrient availability. A short fast may impose greater stress on young children than on adults, resulting in metabolic alterations as various homeostatic mechanisms work to maintain circulating glucose concentrations.

In addition to potential positive effects on academic performance, breakfast contributes significantly to the child's overall nutrient intake. These studies underscore the potential benefits—not only for low-income and at-risk children but also for all school children—of a breakfast at home or school meal programs that include breakfast. In the 2012 to 2013 school year, 10.8 million low-income children, or 51.9%, participated in a school breakfast program on an average day (FRAC, 2014). This is an increase from about 42 out of 100 children in 2002 to 2003.

Snacks are commonly eaten by school age children, primarily after school and in the evening. As children grow older and have money to spend, they tend to consume more snacks from vending machines, fast-food restaurants, and neighborhood grocery stores. Families should continue to offer wholesome snacks at home and support nutrition education efforts in the school. In most cases, good eating habits established in the first few years help children through this period of decision making and responsibility. Developing and supporting programs and policies that ensure access to better-quality food, larger quantities of food, and better living conditions for low-income children help to reduce health disparities where present.

Nutrition Education

As children grow, they acquire knowledge and assimilate concepts. The early years are ideal for providing nutrition information and promoting positive attitudes about all foods. This education can be informal and take place in the home with parents as models and a diet with a wide variety of foods. Food can be used in daily experiences for the toddler and preschooler and to promote the development of language, cognition, and self-help behaviors (i.e., labeling; describing size, shape, and color; sorting; assisting in preparation; and tasting).

More formal nutrition education is provided in preschools, Head Start programs, and public schools. Some programs such as Head Start have federal guidance and standards that incorporate healthy eating and nutrition education for the families involved. Nutrition education in schools is less standard and frequently has minimum or no requirements for inclusion in the curriculum or the training of teachers. Recommendations include policies in schools promoting coordination between nutrition education; access to and promotion of child nutrition programs; and cooperation with families, the community, and health services (Bergman et al, 2010).

Teachers attempting to teach children nutrition concepts and information should take into account the children's developmental level. The play approach, based on Piaget's theory of learning, is one method for teaching nutrition and fitness to school age children. Activities and information that focus on real-world relationships with food are most likely to have positive results. Meals, snacks, and food preparation activities provide children opportunities to practice and reinforce their nutrition knowledge and demonstrate their cognitive understanding. Involving parents in nutrition education projects can produce positive outcomes that are also beneficial in the home. Many written and electronic resources on nutrition education for children exist, such as at the National Center for Education in Maternal and Child Health.

NUTRITIONAL CONCERNS

Overweight and Obesity

Overweight and obesity among children is a significant public health problem. The prevalence of obesity and overweight increased rapidly in the 1990s and 2000s, plateaued between 2007 to 2008 and 2009 to 2010 and may be decreasing during the first part of the 2010 decade. Obesity rates in some populations, for example Hispanic and non-Hispanic white children and adolescents, are continuing to increase.

The most recent NHANES (2011 to 2012) reported an obesity (BMI-for-age above the 95th percentile) prevalence of 16.9% in children ages 2 to 19 years, and high BMI (BMI-for-age above the 85th percentile) prevalence of 31.8%, relatively unchanged from rates in 2003 to 2004. For children 2 to 5 years of age, the prevalence of obesity decreased from 14% in 2003 to 2004 to 8.4 in 2011 to 2012 (Ogden et al, 2012).

The Expert Committee report suggests the following terms to describe risk based on BMI: *obesity* as BMI-for-age at or above the 95th percentile and *overweight* as BMI-for-age between the 85th and 94th percentiles (Barlow and Committee, 2007). Determining whether growing children are obese is difficult. Some excess weight may be gained at either end of the childhood spectrum; the 1-year-old toddler and the prepubescent child may weigh more for developmental and physiologic reasons, but this extra weight is often not permanent. BMI, a useful clinical tool for screening for overweight, has limitations in determining obesity because of variability related to sex, race, body composition, and maturation stage.

The CDC growth charts allow tracking of BMI from age 2 into adulthood; thus children can be monitored periodically, and intervention provided when the rate of BMI change is excessive. The BMI charts show the **adiposity rebound**, which normally occurs in children between 4 and 6 years of age (see Appendices 12 and 16). Children whose adiposity rebound

occurs before 5½ years of age are more likely to weigh more as adults than those whose adiposity rebound occurs after 7 years of age. The timing of the adiposity rebound and excess fatness in adolescence are two critical factors in the development of obesity in childhood, with the latter being the most predictive of adult obesity and related morbidity (Williams and Goulding, 2009).

Although genetic predisposition is an important factor in obesity development, the increases in the prevalence of overweight children cannot be explained by genetics alone. Factors contributing to excess energy intake for the pediatric population include ready access to eating and food establishments, eating tied to sedentary leisure activities, children making more food and eating decisions, larger portion sizes, and decreased physical activity. In addition, American children snack three times a day, with chips, candy, and other low-nutrient foods providing more than 27% of their daily energy intake; this contributes 168 kcal per day (Piernas and Popkin, 2010).

Inactivity plays a major role in obesity development, whether it results from screen time, limited opportunities for physical activity, or safety concerns that prevent children from enjoying free play outdoors. Although increased television viewing and computer and handheld game use have been associated with childhood overweight, a review suggests that the greater risk of overweight is related to television viewing plus a low activity level (Ritchie et al, 2005). The need to use automobiles for short trips limits children's opportunities to walk to local destinations, a phenomenon particularly relevant to children in the suburbs.

Obesity in childhood is not a benign condition, despite the popular belief that overweight children will outgrow their condition. The longer a child has been overweight, the more likely the child is to be overweight or obese during adolescence and adulthood. Consequences of overweight in childhood include psychosocial difficulties such as discrimination, a negative self-image, depression, and decreased socialization. Many overweight children have one or more cardiovascular risk factors such as hyperlipidemia, hypertension, or hyperinsulinemia (Daniels, 2009). An even more dramatic health consequence of overweight is the rapid increase in the incidence of type 2 diabetes in children and adolescents, which has a serious effect on adult health, development of other chronic diseases, and health care costs (see Chapter 30).

The AAP has developed guidelines for overweight screening and assessment for children from age 2 through adolescence (Barlow and Committee, 2007). In addition to growth parameters, other important information includes dietary intake and patterns, previous growth patterns, family history, physical activity, and family interactions. The U.S. Preventive Services Task Force (USPSTF) recommends obesity screening for 6- to 18-year-olds and referral to treatment programs, if appropriate (USPSTF, 2010).

A 2010 paper described a lower prevalence of obesity among children who were exposed to the following routines: regularly eating the evening meal as a family, obtaining adequate nighttime sleep, and having limited screen-viewing time (Anderson and Whitaker, 2010). Interventions for obesity in children have had limited effect on the childhood obesity problem, especially for black, Hispanic, and Native American populations. Success is most likely to result from programs that include comprehensive behavioral components such as family involvement, dietary modifications, nutrition information, physical activity, and behavioral strategies (Barlow and Committee, 2007). Incorporating behavioral intervention in obesity treatment improves

outcomes and is most effective with a team approach. Depending on the child, goals for weight change may include a decrease in the rate of weight gain, maintenance of weight, or, in severe cases, gradual weight loss (see Chapter 21). An individualized approach should be tailored to each child, with minimum use of highly restrictive diets or medication, except if there are other significant diseases and no other options.

Intervention strategies require family involvement and support. Incorporating motivational interviewing and stages of change theory into the comprehensive program will likely be more successful (see Chapter 14). Changes to address overweight should include the child's input, with choices and plans that modify the family's food and activity environment, not just the child's. Adequate energy and other nutrients are needed to ensure maintenance of height gain velocity and nutrient stores. The hazards of treating overweight children too aggressively include alternate periods of undereating and overeating, feelings of failure in meeting external expectations, ignoring internal cues for appetite and satiation, feelings of deprivation and isolation, an increased risk for eating disorders, and a poor or an increasingly poor self-image.

Some children with special health care needs, such as those with Down syndrome, Prader-Willi syndrome, short stature, and limited mobility, are at increased risk for being overweight. Their size, level of activity, and developmental status must be considered when estimating energy intake and providing dietary guidance to their families (see Chapter 44).

Prevention of childhood obesity is an important public health priority in the United States. The Institute of Medicine (IOM) has published recommendations that target families, health care professionals, industry, schools, and communities (IOM, 2012). The recommendations include schools (improved nutritional quality of food sold and served, increased physical activity, wellness education), industry (improved nutrition information for consumers, clear media messages), health care professionals (tracking BMI, providing counseling for children and families), and communities and government (better access to healthy foods, improved physical activity opportunities). Schools are a natural environment for obesity prevention, which can include nutrition and health curricula, opportunities for physical education and activity, and appropriate school meals. Efforts have resulted in school nutrition policies that limit the kinds of products sold in vending machines and food and beverages sold for fundraising. Cross-sectional data indicate that policies that limit the sale of competitive foods and beverages (foods sold outside the school meal programs) are associated with changes in consumption and availability of foods. More research is needed to understand long-term health effects of these policies (Chriqui et al, 2014). More research also is needed to develop effective prevention strategies that address the needs of diverse populations.

Families are essential for modeling food choices, healthy eating, and leisure activities for their children. Parents influence children's environment by choosing nutrient-rich foods, having family meals (including breakfast), offering regular snacks, and spending time together in physical activity, all of which can be critical in overweight prevention. Reducing sedentary behaviors can increase energy expenditure and reduce prompts to eat; the AAP recommends limiting television and video time to no more than 2 hours per day (Krebs and Jacobson, 2003). Parents exerting too much control over their child's food intake or promoting a restrictive diet may cause children to be less able to

self-regulate and more likely to overeat when the opportunity is available (Ritchie et al, 2005). Health professionals should support positive parenting within the child's developmental level.

Underweight and Failure to Thrive

Weight loss, lack of weight gain, or **failure to thrive (FTT)** can be caused by an acute or chronic illness, a restricted diet, a poor appetite (resulting from constipation, medication, or other issues), feeding problems, neglect, or a simple lack of food. Some experts prefer the terms **pediatric undernutrition** or **growth deficiency**. Infants and toddlers are most at risk for poor growth, often as a result of prematurity, medical conditions, developmental delays, inadequate parenting, or a combination of these. Dietary practices also can contribute to poor growth, including food restrictions in preschool children stemming from parents' concerns about obesity, atherosclerosis, or other potential health problems.

A careful assessment is critical and must include the social and emotional environment of the child and any physical findings. If neglect is documented to be a contributing factor, health professionals are obligated to report the case to the local child protective services. Because of the complexity of growth failure, an interdisciplinary team is ideal for assessments and interventions.

The provision of adequate energy and other nutrients and nutrition education should be one part of an overall interdisciplinary plan to assist children and their families. Attempts should be made to increase children's appetites and modify the environment to ensure optimal intake. Frequent small meals and snacks should be offered at regular times, using developmentally appropriate, nutrient-dense foods. This optimizes the smaller stomach capacity of the young child and provides structure and predictability for the eating environment. Families should receive support for positive parent-child interactions, with respect for the division of responsibility in feeding and avoidance of any pressure or coercion on the child's eating. Severe malnutrition may require carefully planned interventions and close monitoring to prevent refeeding syndrome.

Chronic constipation can result in poor appetite, diminished intake, and FTT. Ensuring adequate fluid and fiber intake can help relieve constipation, improve appetite, and eventually promote weight gain. Because the fiber intake of children is often low, especially in children who are picky eaters, fiber intake always should be addressed in the evaluation. Fiber can be increased by adding legumes, fruits (especially dried fruits), vegetables, high-fiber breakfast cereals, bran muffins, or all of these to the diet.

Iron Deficiency

Iron deficiency is one of the most common nutrient disorders of childhood. The highest prevalence of anemia in children occurs in those younger than 2 years of age. Iron deficiency is less of a problem among older preschool and school age children.

Infants with iron deficiency, with or without anemia, tend to score lower on standardized tests of mental development and pay less attention to relevant information needed for problem solving. Poorer cognitive performance and delayed psychomotor development have been reported in infants and preschool children with iron deficiency. Deficiency can have long-term consequences, as demonstrated by poorer performance on developmental tests in late childhood and early adolescence (Lozoff et al, 2007). Iron intake should be considered during assessments of

individual diets and in policy decisions intended to address the nutrition needs of low-income, high-risk children.

In addition to growth and the increased physiologic need for iron, dietary factors also play a role. For example, a 1-year-old child who continues to consume a large quantity of milk and excludes other foods may develop anemia. Some young preschool children do not eat much meat, so most of their iron is consumed in the nonheme form from fortified cereals, which is absorbed less efficiently (see Chapter 32).

Dental Caries

Nutrition and eating habits are important factors affecting oral health. An optimal nutrient intake is needed to produce strong teeth and healthy gums. The composition of the diet and an individual's eating habits (e.g., dietary carbohydrate intake, eating frequency) are significant factors in the development of dental caries (see Chapter 25).

Allergies

Food allergies during infancy and childhood are more likely when a child has a family history of allergies. Allergic symptoms are seen most often as respiratory or gastrointestinal responses as well as skin responses but may include fatigue, lethargy, and behavior changes. There can be confusion about over the definitions of *food allergy*, *food intolerance*, and *food sensitivity*, and some tests for food allergies are unspecific and equivocal. See Chapter 26 for management of food allergies in children.

Attention Deficit Hyperactivity Disorder

ADHD is one of the most common disorders of childhood. It usually is diagnosed first in childhood and often lasts into adulthood. ADHD is defined by academic or behavioral problems and symptoms of inattention, hyperactivity, or impulsivity that are inappropriate for a child's developmental level. The diagnosis is based on information about the child's behavior at home, school, and other settings. Various dietary factors have been suggested as a cause of this disorder, including artificial flavors and colors, sugar, altered fatty acid metabolism, and allergies. Several studies have suggested that artificial food colors and a food preservative, sodium benzoate, were associated with some negative behaviors in both those children with a diagnosis of ADHD and some children who did not have this diagnosis. However, for a complete answer, more evidence is needed (Bateman, 2004; McCann, et al, 2007). Research looking at the effects of artificial food colors and sodium benzoate, exposure to pesticides, and fatty acid supplementation are ongoing (Rytter et al, 2015). Sugar shows no effect on behavior or cognition in most children with ADHD. See Chapter 44 for further discussion of ADHD.

Autism Spectrum Disorder

Autism spectrum disorder (ASD) affects 1 in 68 children. All children should receive developmental screening in early childhood during routine well child visits and specifically at 18 and 24 months of age. If significant delays or concerns are noted in social interaction, communication, and behavior a more comprehensive diagnostic evaluation is needed (see Chapter 44).

These concerns can affect nutrient intake and eating behaviors if a child accepts only specific foods, refuses new or unfamiliar foods, or has increased hypersensitivities (e.g., to texture, temperature, color, and smell) or difficulty making transitions. Children with ASD often refuse fruits and vegetables and may

eat only a few foods from the other food groups. Although most children have normal growth parameters, their restricted diets make them at risk for marginal or inadequate nutrient intake. They may be resistant to taking a vitamin-mineral supplement, even though they could benefit from one.

Popular nutrition advice for children with ASD includes elimination diets (e.g., gluten-free or casein-free), essential fatty acid supplements, large doses of vitamins, and other alternative therapies. Despite anecdotal reports of benefits, few well-designed controlled studies have been done to test the effectiveness of these interventions, and currently there is no strong evidence of benefits (Dosman et al, 2013). Behavioral nutrition interventions may increase the types of food accepted at home and school. If families want to try alternative dietary therapies, nutrition professionals can help them ensure that the child's diet is adequate and any supplements are safe (see Chapter 12).

PREVENTING CHRONIC DISEASE

The roots of chronic adult diseases such as heart disease, cancer, diabetes, and obesity are often based in childhood—a phenomenon that is particularly relevant to the increasing rate of obesity-related diseases such as type 2 diabetes. To help decrease the prevalence of chronic conditions in Americans, government and nonprofit agencies have been promoting healthy eating habits for children. Their recommendations include the Dietary Guidelines for Americans, the USDA MyPlate, the National Cholesterol Education Program (NCEP), and the National Cancer Institute Dietary Guidelines (see Chapter 11).

Cardiovascular Health

Compared with their counterparts in many other countries, American children and adolescents have higher blood cholesterol levels and higher intakes of saturated fatty acids and cholesterol. Early coronary atherosclerosis begins in childhood and adolescence. Risk factors include family history, breastfeeding and perinatal factors, nutrition and diet, physical activity, tobacco exposure, hypertension, hyper- and dyslipidemia, overweight and obesity, and diabetes. These were explored by an expert panel (National Heart Lung and Blood Institute, 2011); selected recommendations with nutrition implications are briefly summarized as follows:

For most healthy children limiting total fat to 30% of total energy, saturated fat to 7% to 10%, and dietary cholesterol to 300 mg/day is recommended. Use of fat-free milk is appropriate for most children ages 2 years and older. A balanced energy intake, increased intake of fruits and vegetables, and limiting “extra calories” to 5% to 15% total intake also is recommended for most children. Fiber intake of at least “age + 5 grams” (e.g., for a 4-year-old, 4 + 5 = 9 g per day) or 14 g fiber/1000 kilocalories is suggested.

For children with dyslipidemia, who are overweight or obese, or who have “risk factor clustering” or high-risk medical conditions, the Expert Panel recommends consideration of the Cardiovascular Health Integrated Lifestyle Diet (CHILD-1) as the first stage in dietary change (National Heart Lung and Blood Institute, 2012). This is a DASH-style pattern with emphasis on fat-free/low-fat dairy and increased intake of fruits and vegetables.

For all children, the approach to modifying risk factors, especially related to dietary fat intake, should be individualized (see Chapter 33).

Calcium and Bone Health

Osteoporosis prevention begins early by maximizing calcium retention and bone density during childhood and adolescence, when bones are growing rapidly and are most sensitive to diet and the important effects of physical activity (see Chapter 24). However, mean dietary intakes of calcium are lower than the AI, with 20% to 30% of pubertal girls having intakes less than 500 mg/day. One longitudinal study of white children from infancy to 8 years of age found that bone mineral content was positively correlated with intake of protein and several minerals, suggesting that many nutrients are related to bone health in children (Bounds et al, 2005). Because food consumption surveys show that children are drinking more soft drinks and noncitrus juices and less milk, education is needed to encourage young people to consume an appropriate amount of calcium from food sources and possibly supplements (see Appendix 46).

Fiber

Education about dietary fiber and disease prevention has mainly been focused on adults, and only limited information is available on the dietary fiber intake of children. Dietary fiber is needed for health and normal laxation in children. National survey data indicate that preschool children consume a mean of 11 to 12 g/day of dietary fiber; school age children consume approximately 13 to 14 g/day (U.S. Department of Agriculture, 2012). This is lower than the DRI for children, which is based on the same 14 g/1000 kcal as adults because of lack of scientific evidence for the pediatric population (Otten et al, 2006). Generally, higher fiber intakes are associated with more nutrient-dense diets in young children (Kranz et al, 2012).

The Gut Microbiome

The gut microbiome is an emerging topic in nutrition, including pediatric nutrition. It is clear that dietary and other factors affect the number and type of bacteria that colonize the gut. Factors that can affect the gut microbial community include dietary fiber, prebiotics, probiotics, and the use of antibiotic medication (see Chapter 1).

The gut bacteria profile seems to be associated with short- and long-term health outcomes. In addition to effects on GI disorders, research continues to explore the relationship between the gut microbiome and short- and long-term health outcomes, including obesity, inflammation, and cancers (Peregrin, 2013).

Physical Activity

A decreased level of physical activity in children has been noted for several decades. Participation in school physical education programs has declined over time and generally decreases with increasing age. Regular physical activity not only helps control excess weight gain but also improves strength and endurance, enhances self-esteem, and reduces anxiety and stress. Activity, combined with an optimal calcium intake, is associated with increased bone mineral density in children and adolescents. Current physical activity recommendations for those ages 6 through 17 years of age are 60 minutes or more of physical activity every day with the majority at a moderate or vigorous aerobic intensity. Children and adolescents should do vigorous intensity activity at least 3 days per week and include muscle-strengthening and bone-strengthening activity on at least 3 days per week. Information regarding activities that

will meet these recommendations and are appropriate for children is available (U.S. Department of Health and Human Services, 2008). Screen time (active games, exercise or dance videos, or TV exercise programs) can be a beneficial source of activity for youth. Three in 10 youth ages 9 to 18 engaged in at least 1 hour of active screen time weekdays, and 4 in 10 youth did the same on weekends (Wethington et al, 2013). MyPlate's *Eat Smart to Play Hard* materials promote the recommendation for 60 minutes of physical activity each day (Figure 17-6). The Dietary Guidelines for Americans and MyPlate also have been applied to children and their parents (www.choosemyplate.gov/kids).

CLINICAL CASE STUDY

Brian is a 7-year, 4-month-old male who gained 15 pounds during the past school year. His height is 50½ inches, and his weight is 75 pounds. Brian moved to a new home and began a new school a year ago after his parents' divorce. After-school care has been provided by a retired neighbor, who loves to bake for Brian. He has few friends in the neighborhood, and his main leisure activities have been watching television and playing video games. When he gets bored, he often looks for a snack. His mother reports that they often rely on take-out and fast-food meals because of the time constraints of her full-time job, and she has gained weight herself. She recently started an aerobics class with a friend and is interested in developing healthier eating habits for herself and Brian.

After joint sessions with Brian and his mother, the following goals were identified by the family: (1) explore after-school care at the local community center, which has a physical activity component; (2) alter grocery and menu selection to emphasize the MyPlate and low-fat choices while still meeting the family's time and resource constraints; (3) begin to incorporate physical activities (Brian identified swimming and bicycling as things he would like to do) on the weekends; and (4) limit television and video games to no more than 2 hours daily.

After 4 months, Brian has enrolled in the local community center's afterschool program and participates in organized soccer and "pick-up" basketball. Weekends are a challenge. Brian and his mother have not yet incorporated physical activity into their weekend routine, and Brian finds it tough to limit screen time to 2 hours on the weekends. Brian has lost 4 pounds and is taller; he is 51 inches tall and weighs 66 pounds.

Nutrition Diagnostic Statement

Overweight/obesity as evidenced by BMI-for-age above the 95th percentile or more related to infrequent physical inactivity, large amounts of sedentary activity, and estimated excessive energy intake.

Nutrition Care Questions

1. Calculate and plot Brian's BMI over time. Discuss the changes.
2. What recommendations should be made to prevent Brian and his mother from resuming their old habits?
3. What other activities can Brian try to help him avoid or reduce the tendency to eat when he is not hungry?
4. What would you suggest to promote a positive feeding relationship between Brian and his mother, considering his age and level of development?
5. What recommendations can you make to decrease Brian's energy intake and make it more consistent with MyPlate recommendations? Consider ideas to alter Brian's favorite recipes (e.g., his favorite meal is fried chicken with gravy, mashed potatoes, and ice cream), select healthy options from take-out or fast-food options, and modifications to snack options.
6. Are there any nutrient-related concerns because Brian's diet is being altered to help with weight management? Or because of his age? Or other factors?

and Tashara Leak, PhD, RDN*

KEY TERMS

adolescence
body image
disordered eating
growth spurt
gynecologic age

menarche
peak height gain velocity
physiologic anemia of growth
pubarche
puberty

sexual maturity rating (SMR)
Tanner staging
thelarche

Adolescence is one of the most exciting yet challenging periods in human development. Generally thought of as the period of life that occurs between 12 and 21 years of age, adolescence is a period of tremendous physiologic, psychologic, and cognitive transformation during which a child becomes a young adult. The gradual growth pattern that characterizes early childhood changes to one of rapid growth and development, affecting physical and psychosocial aspects of health. Changes in cognitive and emotional functioning allow teens to become more independent as they mature. Peer influence and acceptance may become more important than family values, creating periods of conflict between teens and parents. Because all of these changes have a direct effect on the nutrient needs and dietary behaviors of adolescents, it is important that health care providers develop a full understanding of how these developmental changes of adolescence can affect nutritional status.

GROWTH AND DEVELOPMENT

Puberty is the period of rapid growth and development during which a child physically develops into an adult and becomes capable of reproduction. It is initiated by the increased production of reproductive hormones such as estrogen, progesterone, and testosterone and is characterized by the outward appearance of secondary sexual characteristics, such as breast development in females and the appearance of facial hair in males.

Psychologic Changes

Adolescence often is depicted as a time of irrational behavior. The physical growth of puberty transforms the teen body into an adult-like form, leading adults to believe that adolescent development is complete. However, the social and emotional development of adolescence lags behind. The mismatch between how teens look and how they act may lead adults to deduce that the adolescent is “not acting his or her age.” The rebellion that is associated with the teen years is actually the manifestation of their search for independence and a sense of

autonomy. Food can be, and often is, used as a means of exerting autonomy. Adolescents may choose to become vegetarian as a way to differentiate themselves from their meat-eating parents or to express their moral and ethical concerns over animal welfare or the environment.

Cognitive and emotional development may vary greatly among adolescents, with some adolescents maturing faster than others. In general, adolescence is a time of impulsivity as a result of slow development in regions of the brain that govern cognitive control combined with a heightened reward response. Cognitive ability, including abstract reasoning, expands during adolescence; however, teens are more likely to base decisions on emotional as opposed to rational contexts (Blakemore and Robbins, 2012; Steinberg, 2010). Psychosocial development can affect health and nutritional status in many ways, including the following:

- Preoccupation with body size, body shape, and **body image** (the mental self-concept and perception of personal body size), resulting from the rapid growth and development that has occurred, may lead to dieting and possibly disordered eating behaviors
- Diminishing trust and respect for adults as authority figures, including nutrition and health professionals
- Strong influence of peers, especially around areas of body image and appearance, with the influence of a few select peers becoming more important than that of large groups as adulthood approaches
- More pronounced social, emotional, and financial independence, leading to increased independent decision making related to food and beverage intake
- Significant cognitive development as abstract reasoning is nearly complete and egocentrism decreases; however, teens may still revert to less complex thinking patterns when they are stressed
- Developed future orientation, which is required to understand the link between current behavior and chronic health risks

- Development of social, emotional, financial, and physical independence from family as teens leave home to attend college or seek employment
- Development of a core set of values and beliefs that guides moral, ethical, and health decisions

The psychosocial development of adolescents has a direct bearing on the foods and beverages they choose. Food choices are more likely to be based on taste, cost, and peer behaviors than on health benefits because these influences satisfy a teen's innate preference for immediate reward. Nutrition education and counseling methods that focus on how adolescents look, such as improving skin appearance or promoting hair growth, are most likely to be effective with young teens because these reinforce emotional influences.

Sexual Maturity

Sexual maturity rating (SMR), also known as **Tanner staging**, is used to assess clinically the degree of sexual maturation during puberty (Tanner, 1962). Among males, SMR is based on genital and pubic hair development (see Figure 18-1 and Table 18-1). Among females SMR is assessed by breast and pubic hair development. SMR is measured through a series of five stages, with stage 1 marking prepubertal development and stage 5 marking

the completion of physical growth and development (see Appendix Tables 12 and 13). The five stages of SMR correlate with other markers of growth and development during puberty, such as alterations in height, weight, body composition, and endocrine functioning. A thorough understanding of the relationship between physical growth and development and SMR enables health care professionals to assess an adolescent's potential for future growth.

In general, females enter puberty earlier than males. An example of ethnic variation in female development is shown in data from the National Health and Nutrition Examination Study III (NHANES III). The data suggest that most non-Hispanic black and Mexican American females reach breast development stage 2 (**thelarche**) at 9.6 years of age, 8 months earlier than non-Hispanic white females (Rosenfield et al, 2009). Racial and ethnic differences in maturation are also seen for pubic hair stage 3 (**pubarche**), which occurs earlier among most non-Hispanic black females (10.6 years) compared with Mexican American and white females (11.6 years). Most females enter puberty at least 2.5 years earlier than their male counterparts, with Mexican American youth showing the greatest gender variance in age at pubarche (Rosenfield et al, 2009).

Data from NHANES III also suggest variation in the timing of pubarche among males of different racial and ethnic backgrounds (Rosenfield et al, 2009). The median age among non-Hispanic white and black males (12.3 and 12.5 years) is approximately 6 months earlier than among Mexican American males (13.2 years).

Adolescent females with a body mass index (BMI) in the 85th percentile or higher are four times more likely to have reached thelarche by age 8 and twice as likely by 9.6 years of age than normal weight females (Rosenfield et al, 2009). Excessive body weight plays a larger role in the timing and duration of puberty among females than among males (Pinkney et al, 2014).

Menarche, the onset of menses or menstruation, often is considered the hallmark of puberty among females (at 12.5 years in the average girl). However, the onset of menses can occur anywhere between the ages of 8 and 17 years (Tanner, 1962; Rosenfield et al, 2009). The median age of menarche is 12.1 years for black, 12.3 years for Mexican American, and 12.6 years for white females (Rosenfield et al, 2009).

Excessive body weight among females is associated with earlier onset of puberty and earlier menses among females of all racial and ethnic groups. Females with a BMI in the 85th percentile or higher are four times as likely to have experienced menses by 10.6 years of age. The timing of menarche increases micronutrient requirements among females; thus it is imperative that the timing of menarche be evaluated during a full nutrition assessment.

In summary, puberty may begin earlier but last longer for nonwhite females (Rosenfield et al, 2009). Although racial and ethnic differences in the age of pubarche occur among males, the differences are not as pronounced. No significant relationship between weight status and pubarche is observable among males.

Linear Growth

The velocity of physical growth during adolescence is much higher than that of early childhood (see Figure 18-2). On average, adolescents gain approximately 20% of their adult height during puberty. There is a great deal of variability in the timing

FIGURE 18-1 Sequence of events during puberty in females (*upper chart*) and males (*lower chart*). Breast, genitalia, and pubic hair development are numbered 2 to 5 based on the Tanner developmental stages. (From Marshall WA, Tanner JM: Variations in the pattern of pubertal changes in males, *Arch Dis Child* 45:13, 1970.)

TABLE 18-1 Ratings of Sexual Maturation*

	Pubic Hair	Genitalia	Corresponding Changes
Males			
Stage 1	None	Prepubertal	
Stage 2	Small amount at outer edges of pubis, slight darkening	Beginning penile enlargement Testes enlarged to 5-ml volume Scrotum reddened and changed in texture	Increased sweat gland activity
Stage 3	Covers pubis	Penis longer Testes enlarged to 8-10 ml Scrotum enlarged	Voice changes Faint mustache and facial hair Axillary hair Beginning of peak height gain velocity (growth spurt of 6-8 inches)
Stage 4	Adult type, does not extend to thighs	Penis wider and longer Testes enlarged to 12 ml Scrotal skin darker	End of peak height gain velocity More facial hair Darker hair on legs Voice deeper Possibly severe acne
Stage 5	Adult type, spreads to thighs	Adult penis Testes enlarged to 15 ml	Significantly increased muscle mass
Females			
Stage 1	None	No change from childhood	
Stage 2	Small amount, downy, on medial labia	Breast buds	Increased sweat gland activity Beginning of peak height gain velocity (growth spurt of 3-5 inches)
Stage 3	Increased, darker, curly	Larger, but no separation of the nipple and the areola	End of peak height gain velocity Beginning of acne
Stage 4	More abundant, coarse texture	Larger Areola and nipple form secondary mound	Axillary hair Possibly severe acne
Stage 5	Adult, spreads to medial thighs	Adult distribution of breast tissue, continuous outline	Menarche begins Increased fat and muscle mass

Modified from Tanner JM: *Growth at adolescence*, ed 2, Oxford, 1962, Blackwell Scientific Publications.

*See Appendixes 12 and 13.

FIGURE 18-2 Typical individual velocity curves for supine length or height in males and females. Curves represent the growth velocity of the typical boy and girl at any given age.

and duration of growth among adolescents as illustrated in [Figure 18-3](#) by a group of 13-year-old males.

Linear growth occurs throughout the 4 to 7 years of pubertal development in most teens; however, the largest percentage of height is gained during an 18- to 24-month period commonly referred to as the **growth spurt**. The fastest rate of growth during the growth spurt is labeled the **peak height gain velocity**. Although growth slows after the achievement of sexual maturity, linear growth and weight acquisition continue into the late teens for females and early 20s for males and young men. Most females gain no more than 2 to 3 inches after menarche, although females who have early menarche tend to grow more after its onset than do those having later menarche. Longitudinal data suggest that the velocity of linear growth among males may be reduced or delayed by the prolonged use of stimulant medications such as those for attention deficit hyperactivity disorder (ADHD). These effects are most pronounced among 14- to 16-year-old males, with a dose-response pattern noted. Stimulant medication use among females is not as well studied, and thus it is not clear if this phenomenon also occurs among girls ([Poulton et al, 2013](#)).

Increases in height are accompanied by increases in weight during puberty. Teens gain 40% to 50% of adult body weight during adolescence. The majority of weight gain coincides with increases in linear height. However, it should be noted that teens may gain more than 15 pounds after linear growth has ceased. Changes in body composition accompany changes in weight and height. Males gain twice as much lean tissue as females, resulting in differentiation in percent body fat and lean body mass.

FIGURE 18-3 These males are all 13 years old, but their energy needs vary according to their individual growth rates.

Body fat levels increase from prepuberty averages of 15% for males and 19% for females, to 15% to 18% in males and 22% to 26% in females. Differences in lean body mass and body fat mass affect energy and nutrient needs throughout adolescence and differentiate the needs of females from those of males.

NUTRIENT REQUIREMENTS

The dietary reference intakes (DRIs) for adolescents are listed by chronologic age and gender (see inside front cover). Although the DRIs provide an estimate of the energy and nutrient needs for an individual adolescent, actual need varies greatly between teens as a result of differences in body composition, degree of physical maturation, and level of physical activity. Therefore health professionals should use the DRIs as a guideline during nutritional assessment but should rely on clinical judgment and indicators of growth and physical maturation to make a final determination of an individual's nutrient and energy requirements.

Energy

Estimated energy requirements (EERs) vary greatly among males and females because of variations in growth rate, body

composition, and physical activity level (PAL). EERs are calculated using an adolescent's gender, age, height, weight, and PAL, with an additional 25 kilocalories (kcal) per day added for energy deposition or growth (Institute of Medicine [IOM], 2006). To determine adequate energy intake, physical activity assessment is required. The energy requirements allow for four levels of activity (sedentary, low active, active, and very active), which reflect the energy expended in activities other than the activities of daily living. Tables 18-2 and 18-3 show the EER for each activity level based on PALs.

Adequacy of energy intake for adolescents is assessed best by monitoring weight and BMI. Excessive weight gain indicates that energy intake is exceeding energy needs, whereas weight loss or a drop in BMI below an established percentile curve suggests that energy intake is inadequate to support the body's needs. Groups of adolescents who are at elevated risk for inadequate energy intake include teens who "diet" or frequently restrict caloric intake to reduce body weight; individuals living in food-insecure households, temporary housing, or on the street; adolescents who frequently use alcohol or illicit drugs, which may reduce appetite or replace food intake; and teens with chronic health conditions such as cystic fibrosis, Crohn's disease, or muscular dystrophy.

Recent concerns about excessive energy intake among youth have centered on intake of solid fats and added sugars. The mean daily intake of solid fats and added sugars among young people ages 12 to 18 years represents 34% of total energy consumption or approximately 740 kcal (Slining and Popkin, 2013). Solid fats account for a greater proportion of these empty calories with about 18% of total energy consumption coming from solid fats and 15% of total energy coming from added sugars. The main food and beverage sources of solid fats are milk, grain-based desserts, pizza, cheese, processed meats, and fried potatoes. Grain-based desserts are also a main source of added sugar intake along with sugar-sweetened beverages, candy, and other sweet snacks, ready-to-eat cereals, dairy-based desserts, and sweeteners and syrups. Sugar-sweetened beverages are of particular concern as a source of added sugar intake; soft drinks contribute nearly 30% and fruit drinks contribute 15% of added sugars consumed by youth ages 2 to 18 years (Keast et al, 2013). NHANES data revealed that 77% of 12- to 18-year-olds consume a sugar-sweetened beverage on a given day (Han and

TABLE 18-2 Estimated Energy Requirements for Adolescent Males

Age	Reference Weight (kg [lb])	Reference Height (m [in])	ESTIMATED ENERGY REQUIREMENTS (KCAL/DAY)

18	56.2 (123.8)	1.63 (64.2)	1690	2024	2336	2858

Data from Institute of Medicine, Food and Nutrition Board: *Dietary reference intakes for energy, carbohydrate, fiber, fat, fatty acids, cholesterol, protein, and amino acids*, Washington, DC, 2002, National Academies Press.

PAL, Physical activity level.

*PAL categories, which are based on the amount of walking per day at 2-4 mph are as follows: sedentary, no additional activity; low active, 1.5-2.9 miles/day; active, 3-5.8 miles/day; and very active, 7.5-14 miles/day (see Table 2-3).

Powell, 2013). The proportion of energy from solid fats and added sugars is similar for foods and beverages obtained from stores (33%), schools (32%), and fast-food restaurants (35%) (Poti et al, 2014).

Counseling related to excessive energy intakes among adolescents should focus on intake of discretionary calories, especially those from added sweeteners consumed through soft drinks and candy and from solid fats consumed through snack foods and fried food. Tips should be provided for selecting nutrient-dense foods and beverages at all locations where teens spend their time.

Protein

During adolescence protein requirements vary with degree of physical maturation. The DRIs for protein intake are estimated to allow for adequate pubertal growth and positive nitrogen balance (IOM, 2006). Table 18-4 illustrates the protein requirements for adolescents. Actual protein needs are best determined based on a per kilogram of body weight method during puberty to account for differences in rates of growth and development among teens.

Insufficient protein intake is uncommon in the U.S. adolescent population. However, as with energy intake, food security issues, chronic illness, frequent dieting, and substance use may compromise protein intakes among adolescents. Teens who follow vegan or macrobiotic diets are also at elevated risk for inadequate protein intake.

TABLE 18-4 Protein: Estimated Average Requirements and Recommended Dietary Allowances for Adolescents

Age (yr)	EAR (g/kg/day)	RDA (g/kg/day)
9-13	0.76	0.95 or 34 g/day*
14-18 Males	0.73	0.85 or 52 g/day*
14-18 Females	0.71	0.85 or 46 g/day*

Data from Institute of Medicine, Food and Nutrition Board: *Dietary reference intakes for energy, carbohydrate, fiber, fat, fatty acids, cholesterol, protein, and amino acids*, Washington, DC, 2002, National Academies Press.

EAR, Estimated average requirement; RDA, recommended dietary allowance.

*Based on average weight for age.

When protein intake is inadequate, alterations in growth and development are seen. In the still-growing adolescent, insufficient protein intake results in delayed or stunted increases in height and weight. In the physically mature teen, inadequate protein intake can result in weight loss, loss of lean body mass, and alterations in body composition. Impaired immune response and susceptibility to infection also may be seen.

Carbohydrates and Fiber

Carbohydrate requirements of adolescents are estimated to be 130 g/day (IOM, 2006). The requirements for carbohydrates, as for most nutrients, are extrapolated from adult needs and should be used as a starting point for the determination of an individual adolescent's actual need. Teens who are very active or actively growing need additional carbohydrates to maintain adequate energy intake, whereas those who are inactive or have a chronic condition that limits mobility, may require fewer carbohydrates. Whole grains are the preferred source of carbohydrates because these foods provide vitamins, minerals, and fiber. Intake of carbohydrate is adequate in most teens; data from the 2009 to 2010 What We Eat in America survey, a component of the NHANES, suggest that average daily intakes of carbohydrate are 335 g for teenage males and 242 g for females (U.S. Department of Agricultural [USDA], Agricultural Research Service [ARS], 2012b).

However, fiber intakes of youth are low because of poor intake of whole grains, fruits, and vegetables. The adequate intake (AI) values for fiber intake among adolescents are 31 g/day for males 9 to 13 years old, 38 g/day for males 14 to 18 years old, and 26 g/day for 9- to 18-year-old females (IOM, 2006). These values are derived from calculations that suggest that an intake of 14 g/1000 kcal provides optimal protection against cardiovascular disease (CVD) and cancer (IOM, 2006). Adolescents who require less energy intake because of activity restrictions may have needs that are lower than the AI values.

What We Eat in America survey data suggest that average daily intakes of fiber are 16.4 g for teenage males and 12.6 g for females (USDA, ARS, 2012b). The disparities between fiber recommendations and actual intakes suggest that more emphasis must be placed on educating adolescents about optimal sources of carbohydrates, including whole grains, fruits, vegetables, and legumes.

Fat

DRI values for total fat intake have not been established for adolescents. Instead it is recommended that total fat intakes not exceed 30% to 35% of overall energy intake, with no more than 10% of calories coming from saturated fatty acids. Specific recommendations for intakes of omega-6 and omega-3 fatty acids have been set in an attempt to ensure that teens consume adequate essential fatty acids to support growth and development, as well as to reduce chronic disease risk later in life. The AI for omega-6 polyunsaturated fatty acids (linoleic acid) is 12 g/day for 9- to 13-year-old males, 10 g/day for 9- to 13-year-old females, 16 g/day for 14- to 18-year-old males, and 11 g/day for 14- to 18-year-old females. Estimated requirements for omega-3 polyunsaturated fatty acids (alpha-linolenic acid) among teens are 1.2 g/day for 9- to 13-year-old males, 1 g/day for 9- to 13-year-old females, 1.6 g/day for 14- to 18-year-old males, and 1.1 g/day for 14- to 18-year-old females (IOM, 2006).

Minerals and Vitamins

Micronutrient needs of youth are elevated during adolescence to support physical growth and development. The micronutrients involved in the synthesis of lean body mass, bone, and red blood cells are especially important during adolescence. Vitamins and minerals involved in protein, ribonucleic acid, and deoxyribonucleic acid synthesis are needed in the greatest amounts during the growth spurt. Needs decline after physical maturation is complete; however, the requirements for vitamins and minerals involved in bone formation are elevated throughout adolescence and into adulthood, because bone density acquisition is not completed by the end of puberty.

In general, adolescent males require greater amounts of most micronutrients during puberty, with the exception of iron. Micronutrient intakes during adolescence are often inadequate among some subgroups of teens, especially among females. Data from the National Growth and Health Study, which followed a cohort of more than 2300 girls over 10 years, suggest that the majority of teenage girls have inadequate intakes of calcium, magnesium, potassium, and vitamins D and E (Moore et al, 2012). The proportion of girls with inadequate intakes tends to increase with age. What We Eat in America survey data also can be used to monitor the adequacy of micronutrient intakes among U.S. adolescents. Compared with DRI recommendations this survey data suggests intakes of vitamin E and calcium are often too low among males and females (see Tables 18-5 and 18-6) (USDA, ARS, 2012b).

Calcium

Because of accelerated muscular, skeletal, and endocrine development, calcium needs are greater during puberty and adolescence than during childhood or the adult years. Bone mass is acquired at much higher rates during puberty than any other time of life. In fact, females accrue approximately 37% of their total skeletal mass from ages 11 to 15 years, making adolescence a crucial time for osteoporosis prevention (IOM, 2011).

The RDA for calcium is 1300 mg for all adolescents with an upper level intake of 3000 mg/day (IOM, 2011). Calcium intake declines with age during adolescence, especially among females. Research suggests that high soft drink consumption in the adolescent population contributes to low calcium intake by displacing milk consumption (Ranjit et al, 2010). Interventions to promote calcium consumption among youth should be initiated early and focus not only on increasing dairy product intake

TABLE 18-5 Mean Intakes of Select Nutrients Compared with DRIs: Adolescent Males

	Mean Intake	9- to 13-year-old RDA/AI	14- to 18-year-old RDA/AI

but also on decreasing intakes of soft drinks and increasing intakes of calcium-rich foods such as fortified orange juice and ready-to-eat cereals, enriched breads and other grains, dark leafy green vegetables, and tofu prepared with calcium sulfate.

Iron

Iron requirements are increased during adolescence to support the deposition of lean body mass, increase in red blood cell

volume, and need to replace iron lost during menses among females. Iron needs are highest during periods of active growth among all teens and are especially elevated after the onset of menses in adolescent females. The DRI for iron among females increases from 8 mg/day before age 13 (or before the onset of menses) to 15 mg/day after the onset of menses (IOM, 2006). Among adolescent males recommended intakes increase from 8 to 11 mg/day, with higher levels required during the growth spurt. Iron needs remain elevated for women after age 18 but fall back to prepubescent levels in men once growth and development are completed (IOM, 2006).

Median intakes of iron among adolescents in the United States are less than desirable. Increased needs for iron, combined with low intakes of dietary iron, place adolescent females at risk for iron deficiency and anemia. Rapid growth may temporarily decrease circulating iron levels, resulting in **physiologic anemia of growth**. Other risk factors for iron deficiency anemia are listed in Box 18-1. During adolescence, iron deficiency anemia may impair the immune response, decrease resistance to infection, and decrease cognitive functioning and short-term memory (see Appendix 49).

Folic Acid

The DRI for folate intake among teens is 300 mcg/day for 9- to 13-year-old males and females, increasing to 400 mcg/day for 14- to 18-year-olds (IOM, 2006). The need for folate increases during later adolescence to support accretion of lean body mass and to prevent neural tube defects among females of reproductive age. Food sources of folate should include naturally occurring folate, found in dark green leafy vegetables and citrus fruit, and folic acid found in fortified grain products (see Appendix 40).

BOX 18-1 Risk Factors for Iron Deficiency

Inadequate Iron Intake/Absorption/Stores

- Vegetarian eating styles, especially vegan diets
- Macrobiotic diet
- Low intakes of meat, fish, poultry, or iron-fortified foods
- Low intake of foods rich in ascorbic acid
- Frequent dieting or restricted eating
- Chronic or significant weight loss
- Meal skipping
- Substance abuse
- History of iron-deficiency anemia
- Recent immigration from developing country
- Special health care needs

Increased Iron Requirements and Losses

- Heavy or lengthy menstrual periods
- Rapid growth
- Pregnancy (recent or current)
- Inflammatory bowel disease
- Chronic use of aspirin, nonsteroidal antiinflammatory drugs (e.g., ibuprofen), or corticosteroids
- Participation in endurance sports (e.g., long-distance running, swimming, cycling)
- Intensive physical training
- Frequent blood donations
- Parasitic infection

Average intakes of folate reported in the 2009 to 2010 What We Eat in America survey suggest that adolescent females are at greater risk for inadequate intake than are males (USDA, ARS, 2012b). This is a cause for concern among adolescent females who have achieved menses and are sexually active, as having adequate folic acid status before conception is important for the prevention of birth defects such as spina bifida (see Chapter 15).

Vitamin D

Vitamin D plays an important role in facilitating calcium and phosphorus absorption and metabolism, which has important implications for bone development during adolescence (IOM, 2011). The current recommended dietary allowance (RDA) for vitamin D requirements among adolescents is 600 IU/day (IOM, 2011). Natural food sources of vitamin D include cod liver oil and fatty fish and milk is fortified to 100 IU per 8-ounce serving. Vitamin D also can be synthesized by the exposure of skin to sunlight (vitamin D₂) or ingested through supplements in the form of vitamin D₂ or D₃ (see Appendix 45). Activation of these biologically inert forms begins in the liver where 25-hydroxyvitamin D (25-OH-D) is formed. The second step occurs in the kidneys, where 25-OH-D is converted to the biologically active form, 1,25-dihydroxyvitamin D (calcitriol), which exerts its action in the small intestine and bone to raise serum calcium and phosphorus levels. Despite its important role, calcitriol has limited value as a marker of vitamin D status because it has a half-life of only 4 hours; a serum level of 25-OH-D is the most accurate measure of vitamin D stores.

A recent IOM report concluded that a serum 25-OH-D level of 20 ng/ml covers the requirement of 97.5% of the population (IOM, 2011). However, it is recommended that individuals at risk for vitamin D deficiency maintain a higher level of 30 ng/ml (Holick et al, 2011).

Based on these guidelines, there is a prevalence of vitamin D deficiency among U.S. adolescents. Among youth ages 12 to 19 years, approximately one third have serum 25-OH-D levels below 10 ng/ml and three quarters have levels below 30 ng/ml (Ganji et al, 2012). There also have been noted declines in vitamin D status over the past two decades. NHANES data collected during the preceding few decades established that serum 25-OH-D levels decreased by 15% to 16% (Ganji et al, 2012). The reductions were especially obvious among non-Hispanic black participants and those in the highest BMI quintile.

Several factors may contribute to the recent increases and prevalence of vitamin D deficiency (Ma and Gordon, 2012). Increased use of topical sunblock lotions has been advocated to prevent premature aging of the skin and some skin cancers, but its use also decreases vitamin D synthesis. Some evidence suggests that individuals with a higher BMI more readily sequester cutaneous vitamin D in adipose tissue, making it less bioavailable. Further, overweight youth may be less likely to engage in regular physical activity outdoors and thus have less exposure to sunlight. Other risk factors for vitamin D deficiency include malabsorption syndromes such as cystic fibrosis, long-term use of medications which increase its catabolism (e.g., corticosteroids), lactose intolerance or milk allergy, having darkly pigmented skin, and residence at northern geographic latitudes where youth may spend little time outdoors during colder months. Low vitamin D intake is an important health risk for adolescents and deserves attention during nutrition assessment, education, and intervention (see Appendix 55).

Supplement Use by Adolescents

The consumption of moderate portions of a wide variety of foods is preferred to nutrient supplementation as a method for obtaining adequate nutrient intake. Despite this recommendation, studies show that adolescents do not consume nutrient-dense foods and usually have inadequate intakes of many vitamins and minerals; thus supplements may be beneficial for many teens (Keast et al, 2013; Moore et al, 2012). National surveys show that 28% of adolescents report using vitamin or mineral supplements (Dwyer et al, 2013). The adolescents most likely to use supplements are those in good health with a higher household income and health insurance.

The use of herbal and other nonvitamin, nonmineral dietary supplements is not well documented. National data suggest that 5% of adolescents consume nonvitamin, nonmineral supplements; however, this estimate is based on parental report and the actual prevalence of use is likely higher as adolescents may not disclose all supplement use to their parents (Wu et al, 2013). Echinacea, fish oil, and combination herbal pills are the most commonly taken herbal supplements. Adolescents most likely to use nonvitamin, nonmineral supplements are those who report non-Hispanic white race, a higher household income, activity limitations resulting from chronic health conditions, long-term prescription use, or relatively heavy use of physician services. Many adolescent athletes also use or may consider the use of dietary supplements to improve sport performance (see Chapter 23). The short- and long-term effects of such nonnutritional supplement use by adolescents are not known. Health professionals should screen adolescents for supplement use and should counsel them accordingly (see Chapter 12).

FOOD HABITS AND EATING BEHAVIORS

Food habits of concern that are seen more frequently among teens than other age groups include irregular consumption of meals, excessive snacking, eating away from home (especially at fast-food restaurants), dieting, and meal skipping. Many factors contribute to these behaviors, including decreasing influence of family, increasing influence of peers, exposure to media, employment outside the home, greater discretionary spending capacity, and increasing responsibilities that leave less time for teens to eat meals with their families. Most adolescents are aware of the importance of nutrition and the components of a healthy diet; however, they may have many barriers to overcome.

Teens perceive taste preferences, hectic schedules, the cost and accessibility of different foods, and social support from family and friends to be key factors that affect their food and beverage choices (Berge et al, 2012; Gellar et al, 2012). For example, parents may positively influence the food and beverage choices of teens by modeling healthy eating habits, selecting healthy foods for family meals, encouraging healthy eating, and setting limits on the consumption of unhealthy snack foods. Friends influence each other through modeling and shared activities, such as eating out at fast-food restaurants and purchasing snacks at convenience stores near school.

Developmentally, many teens lack the ability to associate current eating habits with future disease risk. Teens often are more focused on “fitting in” with their peers. They adopt health behaviors that demonstrate their quest for autonomy and make them feel more like adults such as drinking alcohol, smoking, and engaging in sexual activity. Nutrition education and counseling

should focus on short-term benefits, such as improving school performance, looking good, and having more energy. Messages should be positive, developmentally appropriate, and concrete. Specific skills such as choosing water or milk over sugar-sweetened drinks, ordering broiled rather than fried meats, and choosing baked rather than fried snack chips are key concepts to discuss.

Irregular Meals and Snacking

Meal skipping is common among adolescents. Meal skipping increases throughout adolescence as teens try to sleep longer in the morning, try to lose weight through calorie restriction, and try to manage their busy lives. Breakfast is the most commonly skipped meal. National data suggest that one quarter of adolescents (12 to 19 years) skip breakfast on a given day (USDA, ARS, 2012a). Breakfast skipping has been associated with poor health outcomes, including higher BMI; poorer concentration and school performance; and increased risk of inadequate nutrient intake (De la Hunty et al, 2013; Hoyland et al, 2009). Adolescents who skip breakfast tend to have a higher intake of added sugars and poorer intake of key nutrients (e.g., calcium, vitamin A) compared with those who eat breakfast, especially when the breakfast meal is composed of healthy foods that may be fortified such as ready-to-eat cereal (Deshmukh-Tasker et al, 2010).

Teens who skip meals often snack in response to hunger instead of eating a meal. Most teens (92% of males, 94% of females) consume at least one snack per day, and the majority of teens who report snacking consume two or more snacks per day (USDA, ARS, 2012c). Snack foods consumed by teens are often high in added fats, sweeteners, and sodium. Soft drinks and other sugar-sweetened beverages are consumed commonly, accounting for a substantial proportion of daily caloric intake and representing an important source of caffeine consumption (see *Focus On: Caffeine and Substance Use by Teens*). Teens consume a daily average of 286 calories from sugar-sweetened beverages, and 16% report heavy consumption of 500 or more calories (Han and Powell, 2013). Frequent snacking may promote higher total energy intake and a higher proportion of energy provided by added and total sugars (Larson and Story, 2013). However, national data indicate that snacks also make positive contributions to intake of key nutrients. For example, 2009-2010 NHANES data for male and female adolescents indicate that foods and beverages consumed at snack occasions provide 17% to 20% of folate intake, 27% to 35% of vitamin C intake, 17% to 19% of vitamin D intake, 23% to 26% of calcium intake, and 18% to 21% of iron intake (USDA, ARS, 2012d). Because snacks are prevalent and often consumed in place of meals, teens should be encouraged to make healthy choices when choosing these snack foods and beverages. **Box 18-2** provides ideas for healthy snacks or meal alternatives for teens.

Fast Foods and Convenience Foods

Convenience foods include foods and beverages from vending machines, canteens, school stores, fast-food restaurants, and convenience stores. As adolescents spend considerable amounts of time in and around schools, convenience foods available at school and in the surrounding neighborhood are likely to influence their eating patterns. National data indicate vending machines are available in 72% of middle schools and 87% of high schools (Fox et al, 2012). One in five middle schools and

BOX 18-2 Teen-Friendly Healthy Snacks

- Nonfat yogurt layered with berries and granola
- Instant oatmeal made with skim milk and sliced fruit
- Pudding made with skim milk
- Glass of skim milk with a teaspoon of chocolate or strawberry syrup
- Soft pretzel topped with mustard or salsa
- Sliced apples dipped in peanut butter or fat-free caramel dip
- Whole-wheat English muffins topped with low-fat cream cheese and diced fresh vegetables
- Mini-bagel topped with one tablespoon of peanut butter or almond butter
- Air-popped popcorn
- Whole-wheat pita wedges topped with 1-2 tablespoons of hummus
- String cheese and crackers containing no trans fat
- Baked tortilla chips with bean dip or salsa
- Baked potato topped with salsa or broccoli and melted low-fat cheese
- Graham crackers containing no trans fat
- Frozen yogurt or juice bars
- Fruit drink spritzer (half juice and half seltzer water)
- Trail mix (dried fruit with nuts and seeds)
- Baby carrots and low-fat ranch dressing
- Low-fat granola bars
- Mini-rice cakes or popcorn cakes
- Tortilla wraps filled with slices of turkey, cheese, lettuce, and tomato

Adapted with permission from Stang J, Story M, editors: *Guidelines for adolescent nutrition services*, Minneapolis, 2010, Center for Leadership Education and Training in Maternal and Child Nutrition, Division of Epidemiology and Community Health, School of Public Health, University of Minnesota.

stores are socially acceptable places for teens to eat, spend time with their friends, and even work.

Convenience foods tend to be low in vitamins, minerals, and fiber, but high in calories, added fat, sweeteners, and sodium. National data suggest that 46% of adolescents (12 to 18 years) consume at least one item from a fast-food restaurant, and 44% to 55% consume at least one convenience food item at school on a given day (Fox et al, 2009; Poti et al, 2014). Few teens are willing to stop purchasing convenience foods; the low price, convenient access, and taste appeal to them. Instead of asking teenagers to not eat these foods, health professionals should counsel them on how to make healthy choices and work with schools to implement the U.S. Department of Agriculture nutrition standards for convenience foods sold in schools (see Figure 18-4). Counseling teens with concrete guidelines that are easy to remember, such as choosing snacks or vending and fast-food options with fewer than 5 g of fat per serving, can be particularly effective. Teens also can be encouraged to check labels to determine whether foods are made from whole grains or are high in added sweeteners or sodium.

Family Meals

The frequency with which adolescents eat meals with their families decreases with age (Child Trends, 2013). Nearly half of 12- to 14-year-olds eat meals with their families at least 6 days per week compared with just more than one third of 15- to 17-year-olds. Adolescents who eat meals with their families

FOCUS ON

Are Teenagers Who Consume Energy Drinks More Likely to Become Substance Abusers?

Three out of four adolescents consume caffeine on a given day, mostly from soft drinks, tea, and coffee (Branum et al, 2014). Although average caffeine intake among adolescents does not exceed the recommended daily limit of 100 mg, energy drinks are becoming increasingly popular, and the amount of caffeine in these drinks is not regulated by the Food and Drug Administration (FDA) (Branum et al, 2014; Seifert et al, 2011). The FDA has imposed a limit on caffeine of 71 mg per 12-ounce serving for soft drinks, whereas energy drinks have been found to contain nonnutritive stimulants (e.g., caffeine, guarana, taurine) in amounts that range from 2.5 to 171 mg per ounce (Terry-McElrath et al, 2014). Of further concern, recent evidence suggests that energy drink users are more likely than their peers to report alcohol, cigarette, and illicit drug use.

The relationship between energy drink consumption and substance abuse was explored using a 2010-2011 survey. In this survey data were collected from a nationally representative sample of 21,995 secondary school students (grades 8, 10, and 12) who were participating in the Monitoring the Future study (Terry-McElrath et al, 2014). Students self-reported how many energy drinks they consumed on an average day. Substance use data was also self-reported, including frequency of alcohol, cigarette, marijuana, and amphetamine use in the past 30 days. Energy drink consumption was related to greater use of each substance for students in all grades. This research suggests that certain groups of adolescents may be particularly likely to consume energy drinks and to be substance users, and nutrition educators should inform parents and adolescents about the masking effects of caffeine in energy drinks on alcohol- and other substance-related impairments.

approximately one quarter of all high schools have a school store where students can purchase food or beverages (Fox et al, 2012). In addition, middle schools and high schools often have a fast-food restaurant or convenience store within walking distance (Forsyth et al, 2012). Fast-food restaurants and convenience

SMART SNACKS IN SCHOOL

The Healthy, Hunger-Free Kids Act of 2010 requires USDA to establish nutrition standards for all foods sold in schools — beyond the federally-supported meals programs. This new rule carefully balances science-based nutrition guidelines with practical and flexible solutions to promote healthier eating on campus. The rule draws on recommendations from the Institute of Medicine, existing voluntary standards already implemented by thousands of schools around the country, and healthy food and beverage offerings already available in the marketplace.

• Equals 1 calorie ○ Shows empty calories*

FIGURE 18-4 Smart Snacks in School: U.S. Department of Agriculture nutrition standards for convenience foods sold in schools.

USDA is an equal opportunity provider and employer.

have been found to have better academic performance and to be less likely to engage in risky behaviors such as drinking alcohol and smoking compared with peers who do not frequently engage in family meals (Neumark-Sztainer et al, 2010).

Developing healthful eating patterns at family meals during adolescence may improve the likelihood that individuals will choose to consume nutritious foods in adulthood and possibly also protect them from the future development of overweight (Berge et al, 2015; Fulkerson et al, 2014). Family meals not only allow for more communication between teens and their parents but also provide an ideal environment during which parents can model healthy food and beverage choices and attitudes toward eating. Teens who eat at home more frequently have been found to consume fewer soft drinks and more calcium-rich foods, fruit, and vegetables (Fulkerson et al, 2014; Larson et al, 2013) (see *Focus On: Family Meals and Nutritional Benefits for Teens*).

FOCUS ON

Family Meals and Nutritional Benefits for Teens

When teens regularly share dinners with their families, they are more likely to have diets of higher nutritional quality, and some evidence suggests the practice may protect them against the future development of overweight in young adulthood (Berge et al, 2015; Fulkerson et al, 2014). However, different schedules and difficulty finding time to eat together are common barriers to sharing the evening meal. One recent study examined whether there are similar benefits associated with eating breakfast together (Larson et al, 2013). Students at 20 public middle schools and high schools in the Minneapolis-St. Paul metropolitan area of Minnesota were surveyed about their dietary practices and how often they have a family meal at breakfast and at dinner. Approximately 71% of students at these schools qualified for free or reduced-price school meals and 81% represented a racial/ethnic background other than non-Hispanic white. Among these students, family breakfast meals occurred on average less often than family dinners (1.5 breakfast meals versus 4.1 dinner meals per week) and less than 10% of students ate together daily with “all or most” of their family at breakfast. However, participation in more frequent family breakfast meals was linked to several markers of better diet quality (e.g., more fruits, whole grains, and fiber) as well as lower risk for overweight. These associations were found while accounting for family dinner frequency as well as structural and organizational characteristics of families and thus suggest, when it is not always possible to eat dinner together, coming together for other meals such as breakfast can provide benefits. Health professionals should encourage families to eat together at breakfast as well as at dinner, and provide supports for addressing challenges such as lack of time, food security, and limited food preparation skills.

Media and Advertising

Marketing to teenagers has become a multi-billion dollar business, as the nation’s largest food and beverage companies spend \$1.8 billion per year to market their products to youth (Federal Trade Commission [FTC], 2012). Food and beverage companies promote their products to youth using a number of different techniques (e.g., contests, product placements, sponsorships, celebrity endorsements, viral marketing) and multiple platforms; however, television is the dominant advertising medium, representing 35% of all youth-directed marketing expenditures (FTC, 2012).

American youth spend 7.5 hours per day with media and, given the amount of time they spend using more than one medium at a time, they are exposed to more than 10.5 hours of media content (Rideout et al, 2010). Outside of school work, on an average day, youth spend 4.5 hours watching television and movies, 2.5 hours listening to the radio or recorded music,

1.5 hours using a computer, 1.2 hours playing video games, and 38 minutes reading magazines or books. The majority of youth (71%) have a television, and 33% have Internet access in their bedroom. As the time that youth spend with media has increased, so has the ability for advertisers to influence their eating behaviors (Rideout et al, 2010). Teenagers (12 to 17 years) view an estimated 14 television advertisements for food products on an average day (Powell et al, 2010). Despite some recent evidence of improvement in the nutritional quality of advertised products, most viewed food advertisements are for products high in fat, sugar, or sodium, and fast-food restaurant advertisements are the most frequently viewed food advertisements at an average of four per day (Powell et al, 2010, 2013). In addition, the majority of the nation’s largest food and beverage companies market their products to youth online (FTC, 2012). Media literacy education can and should be taught to teens to assist them in determining the accuracy and validity of media and advertising messages.

Dieting and Body Image

Body image concerns are common during adolescence. Many teens describe themselves as being overweight despite being of normal weight, signifying a disturbance in their body image. Poor body image can lead to weight control issues and dieting. The Youth Risk Behavior Surveillance System data from 2011 show that 46% of U.S. high school students were attempting to lose weight. The prevalence of dieting was higher among female (61%) than male (32%) students. Hispanic females had the highest prevalence of dieting at 66%, followed by white females (61%), black females (55%), Hispanic males (40%), white males (29%), and black males (27%) (Eaton et al, 2012).

Eating nutrient-dense foods (e.g., skim milk, fruits, and vegetables) to limit calories and getting regular exercise can be viewed as healthy weight loss behaviors when used in moderation and can be a starting point for nutrition education and counseling to improve eating behaviors. However, not all dieting behaviors have the potential to improve health. High-risk dieting practices are used by many teens and carry with them the risk of poor nutritional status and increased risk for **disordered eating** (see Chapter 22). Fasting, or refraining from eating for more than 24 hours, was practiced by 17% of female and 7% of male U.S. high school students in the past month as a means of dieting (Eaton et al, 2012). Furthermore, 6% of females and 4% of males had used diet pills to lose weight; the prevalence of this behavior was highest among Hispanic students and increased with age. The use of purging methods, including vomiting and laxative or diuretic use, was reported by 6% of females and 3% of males. White and Hispanic students were more likely to report purging behaviors than African American students.

NUTRITION SCREENING, ASSESSMENT, AND COUNSELING

The American Academy of Pediatrics recommends that adolescents have an annual health screening to address priority issues, including physical growth and development, social and academic competence, emotional well-being, risk reduction (e.g., for substance use, sexually transmitted infections), and violence and injury prevention (Hagan et al, 2008). The supervision of physical growth and development should involve an assessment of nutrition risk and the provision of anticipatory guidance.

Nutrition screening should include the assessment of height, weight, and BMI to determine weight status; evaluation for the presence of iron deficiency anemia (females only); review of oral health behaviors (e.g., regular dental visits, intake of high-sugar foods); and assessment of physical fitness and media use (Holt et al, 2011). Anticipatory guidance should further address healthy eating behaviors and building a positive body image.

Weight, height, and BMI should be plotted using the Centers for Disease Control and Prevention (CDC) National Center for Health Statistics BMI tables to determine appropriateness of weight for height (see Appendix Tables 6, 7, 10, and 11). A BMI below the fifth percentile may signal the presence of chronic or metabolic disease, growth failure, or an eating disorder. A BMI at or above the 85th percentile, but below the 95th percentile, indicates that an adolescent is overweight, whereas a BMI at or above the 95th percentile indicates the presence of obesity. All BMI values that indicate the presence of overweight should be corroborated with a direct measure of body fat to determine that excessive fat, or obesity, is truly indicated (see Chapter 7).

When nutrition screening indicates the presence of nutritional risk, a full assessment should be conducted. Nutrition assessment should include a complete evaluation of food intake through a 24-hour recall, dietary records, or brief food frequency questionnaire (see Chapter 4). The adequacy of energy, fiber, macronutrients, and micronutrients should be determined, as well as excessive intake of any dietary components such as sodium or sweeteners. Nutritional assessments also should include an evaluation of the nutritional environment, including parental, peer, school, cultural, and personal lifestyle factors. The attitude of the adolescent toward food and nutrition is important; helping them overcome their perceived barriers to eating well is an essential component of nutrition counseling.

Teens who live in food-insecure households, temporary housing, or shelters, or who have run away from home are at especially high nutritional risk, as are adolescents who use alcohol and street drugs. It is important that health professionals working with high-risk teens develop partnerships with community-based food assistance programs to ensure that youth have access to a steady, nutritious food supply. Homeless teens, as well as those living in temporary shelters, benefit from nutrition counseling focusing on lightweight, low-cost, prepackaged foods that do not require refrigeration or cooking facilities. Dried fruit, nuts, granola bars, cereal bars, tuna in pouches, and meat jerky are foods that should be available for runaway or homeless teens.

Education and counseling should be tailored to meet any specific nutrition diagnoses identified during the assessment. A teen who has been found to be overweight with type 2 diabetes requires a different type and intensity of counseling than a teen who has been diagnosed with iron deficiency anemia. Knowledge, attitude, and behavior must be addressed when guiding adolescents toward acquiring healthful food habits. For a plan to succeed the adolescent must be willing to change; therefore an assessment of a teenager's desire to change is essential. Encouraging the desire to change usually requires much attention (see Chapter 14).

Information can be provided in various settings ranging from the classroom to the hospital (see Figure 18-5). The clinician must understand the change process and how to communicate it meaningfully. Parents may be included in the process and are encouraged to be supportive. Recommended eating plans based on recommended energy intakes for adolescents are shown in Table 18-7.

FIGURE 18-5 Teenagers who help to prepare safe, nutritious meals become engaged in the healthy eating process.

SPECIAL CONCERNS

Vegetarian Dietary Patterns

As adolescents mature, they begin to develop autonomous social, moral, and ethical values. These values may lead to vegetarian eating practices because of concerns about animal welfare, the environment, or personal health. Concerns about body weight also motivate some adolescents to adopt a vegetarian diet because it is a socially acceptable way to reduce dietary fat. Recent data confirm that adolescents who consume vegetarian diets are less likely to be overweight or obese than their omnivorous peers (Robinson-O'Brien et al, 2009). Well-planned vegetarian diets that include a variety of legumes, nuts, and whole grains can provide adequate nutrients for teens who have completed the majority of their growth and development (Craig et al, 2009).

Vegetarian diets that become increasingly more restrictive should be viewed with caution, because this may signal the development of disordered eating, with the vegetarian diet used as a means to hide a restriction of food intake (Craig et al, 2009). Teen males and females who adopt vegetarian dietary patterns have been found to use more high-risk weight control behaviors, especially vomiting, to lose weight (Robinson-O'Brien et al, 2009). This increased risk for unhealthy weight control behaviors seems to persist even after the vegetarian eating style is discontinued, suggesting that although the issues are related, vegetarian diets likely do not cause disordered eating and instead may serve as an early symptom.

Vegetarian adolescents often have high intakes of iron, vitamin A, and fiber and low intakes of dietary cholesterol. Vegetarian diets that include eggs or dairy products are consistent with the Dietary Guidelines for Americans and can meet the DRIs for all nutrients. A sample eating plan to assist vegetarian teens in achieving adequate energy and nutrient intakes is listed in Table 18-8.

Vegan and macrobiotic diets, which do not include animal products of any kind, do not provide natural sources of vitamin B₁₂ and may be deficient in calcium, vitamin D, zinc, iron, and long-chain omega-3 fatty acids (Craig et al, 2009). Therefore vegan adolescents must choose foods fortified with these nutrients or take a daily multivitamin-mineral supplement. Adolescents and their caregivers should be instructed on the planning of well-balanced vegetarian diets and fortified foods that can prevent potential nutrient deficiencies.

oz-eq, one ounce-equivalent is: 1 slice (1 ounce) of bread; 1 ounce uncooked pasta or rice; ½ cup cooked rice, pasta, or cereal; 1 tortilla (6" diameter); 1 pancake (5" diameter); 1 ounce ready-to-eat cereal (about 1 cup cereal flakes)

*Activity level categories are defined as follows: *sedentary*, a lifestyle that includes only the light physical activity associated with typical day-to-day life; *moderately active*, a lifestyle that includes physical activity equivalent to walking about 1.5 to 3 miles per day at 3 to 4 miles per hour, in addition to the light physical activity associated with typical day-to-day life; and *active*, a lifestyle that includes physical activity equivalent to walking more than 3 miles per day at 3 to 4 miles per hour, in addition to the light physical activity associated with typical day-to-day life.

[†]Number of servings of whole grains are not in addition to but are included in the number of servings of grains.

Acne

The appearance of acne most often peaks during adolescence and affects 80% to 90% of U.S. teens (Burris et al, 2013). Effective treatment for the condition is important because acne can significantly affect quality of life and in some cases lead to social withdrawal, anxiety, or depression (Burris et al, 2013). Research suggesting the potential value of incorporating medical nutrition therapy in the treatment of acne continues to emerge. For example, a recent study among 250 young adults (ages 18 to 25) in New York City found evidence that dietary factors may influence or aggravate acne development by comparing the self-reported usual dietary patterns of participants who reported no or mild acne to those with moderate to severe acne (Burris et al, 2014). Young adults with moderate to severe acne reported higher glycemic index diets, including more added sugars, total sugars, milk servings, saturated fat, and trans fatty acids and fewer servings of fish. The majority of all participants (58%) additionally reported the perception that diet aggravates or influences their acne.

The evidence from this study combined with other epidemiologic, observational, and experimental research does not demonstrate that diet causes acne but indicates it may aggravate or influence the condition to some degree (Burris et al, 2013). Medical nutrition therapy as an adjunct to dermatology therapy may be beneficial for some young people with acne.

However, a number of questions remain that must be addressed by additional research before the efficacy and clinical relevance of diet therapy can be established and evidence-based guidelines developed to guide dietitian nutritionist in practice.

Currently, the most reasonable approach to practice is to approach each young person with acne on an individual basis to determine whether dietary counseling may be beneficial. The evidence base most consistently supports guiding individuals with acne toward a healthful, low-glycemic load diet that is low in saturated fat and high in whole grains, fruit, and vegetables (see Chapter 30 and Appendix 37). An additional dietary intervention that may similarly offer multiple health benefits is to recommend increasing consumption of omega-3 fatty acids (see Appendix 34). As long as intake of calcium and vitamin D are sufficient, it may further be beneficial to recommend a diet lower in dairy but as yet the quantity of milk necessary to exacerbate acne has not been established.

Disordered Eating and Eating Disorders

An estimated 10% to 20% of teens engage in disordered eating behaviors, such as binge-purge behavior, compensatory exercise, laxative and diuretic abuse, and binge eating (Neumark-Sztainer et al, 2012). These behaviors do not occur with enough regularity

*Activity level categories are defined as follows: *sedentary*, a lifestyle that includes only the light physical activity associated with typical day-to-day life; *moderately active*, a lifestyle that includes physical activity equivalent to walking about 1.5 to 3 miles per day at 3 to 4 miles per hour, in addition to the light physical activity associated with typical day-to-day life; and *active*, a lifestyle that includes physical activity equivalent to walking more than 3 miles per day at 3 to 4 miles per hour, in addition to the light physical activity associated with typical day-to-day life.

or frequency to be diagnosed as an eating disorder, but may still have significant health implications for teens. Symptoms that may signal the presence of disordered eating behaviors include recurring gastrointestinal complaints, amenorrhea, or unexplained weight loss. Overweight females have been found to be twice as likely to engage in disordered eating behaviors. A screening for disordered eating can easily be done and should include questions about body dissatisfaction, fear of weight gain, frequency of dieting and fasting, use of laxatives and diuretics, use of diet pills, fear of certain foods (e.g., foods containing fat or sugar), vomiting, bingeing, and compensatory exercise.

Eating disorders occur in adolescent females and males and across all socioeconomic, racial, and ethnic groups (see Chapter 22). In general, anorexia nervosa is characterized by a dangerously low body weight, preoccupation with thinness, and restrictive dietary behaviors. Bulimia nervosa is characterized by a body weight that is close to normal, episodes of uncontrollable eating (bingeing), and efforts to eliminate calories or food from the body (purging). Binge eating disorder is characterized by frequent, recurrent episodes of binge eating and loss of control over eating. Although prevalence rates are difficult to estimate, national data suggest that bulimia nervosa and binge eating disorder are somewhat more common than anorexia nervosa (Ozier et al, 2011).

Diagnostic criteria for eating disorders provided by the *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition,

must be used judiciously with adolescents because of issues surrounding normal growth and development (American Psychiatric Association [APA], 2013). The wide variability in the rate, timing, and velocity of height and weight gain during normal puberty; the absence of menstrual periods in early puberty combined with the unpredictability of menses soon after menarche; and the cognitive inability to understand abstract concepts can make application of the diagnostic criteria challenging in adolescents. Adolescents are particularly vulnerable to the complications of eating disorders. The effect of malnutrition on linear growth, brain development, and bone acquisition can be persistent and irreversible. Yet with early and aggressive treatment, adolescents have the potential for a better outcome than adults who have had the disease longer (Steinhausen, 2008).

Overweight and Obesity

Overweight and obesity in adolescence have short- and long-term health consequences. Adolescents who are overweight and particularly those with more severe obesity are at higher risk for hyperlipidemia, hypertension, insulin resistance, and type 2 diabetes compared with normal weight peers (Kelly et al, 2013). Epidemiologic studies of obesity and disease risk demonstrate an increased risk of premature mortality and morbidity from diabetes, hypertension, coronary heart disease, stroke, asthma, and polycystic ovary syndrome among individuals who were overweight or obese during adolescence (Reilly and Kelly, 2011).

Adolescent weight status is evaluated based on BMI (weight/height² [kg/m²]) as shown in Appendices 7 and 11. Among 12- to 19-year-olds in the United States, the prevalence of overweight, characterized by a BMI higher than the 85th percentile, is 32.6% (Ogden et al, 2012). The prevalence of obesity (BMI of at least the 95th percentile) is 17.1%, and it is estimated that severe obesity (120% of the 95th percentile) afflicts 4% to 6% of youth (Kelly et al, 2013; Ogden et al, 2012). Obesity is a complex, multifactorial health issue that is influenced by genetics, metabolic efficiency, PAL, dietary intake, and environmental and psychosocial factors (see Chapter 21). Adolescents who are found to be overweight should have a fasting lipid profile completed and should be assessed for additional risk factors for chronic disease, such as personal history of hypertension, hyperlipidemia, tobacco use, and family history of hypertension, early cardiovascular death, stroke, hyperlipidemia, and type 2 diabetes mellitus (Krebs et al, 2007). If risk factors are noted, aspartate aminotransferase and alanine aminotransferase measurements to assess liver function should be obtained as well.

A fasting glucose level should be drawn on any overweight adolescent with two or more risk factors for CVD, or with a family history of diabetes. Obese teens should undergo the same

laboratory assessments as overweight children, with the addition of microalbumin/creatinine or microalbumin/creatinine ratio. Additional assessments for conditions such as sleep apnea, orthopedic disorders, polycystic ovary disease, and hormonal abnormalities should be performed based on presenting symptoms.

Recent guidelines for adolescent overweight and obesity suggest a staged care treatment process (see Box 18-3) based on a teen's BMI, age, motivation, and the presence of comorbid conditions (Hoelscher et al, 2013). Four stages are recommended, with progress through the stages based on age, biologic development, level of motivation, weight status, and success with previous stages of treatment. Advancing to the next stage of treatment may be recommended if insufficient progress is made to improve weight status or resolve comorbid conditions after 3 to 6 months.

Concern has been expressed regarding the use of bariatric surgery in adolescents. Recommendations for bariatric surgery suggest that it can be justified only by the combination of severe obesity and the existence of comorbid medical conditions (Kelly et al, 2013). Difficulty in complying with dietary restrictions after surgery may lead to complications such as dumping syndrome after high carbohydrate intake, voluntary excessive food intake, digestion of meat affected in a gastrojejunal anastomosis,

BOX 18-3 Staged Care Treatment for Overweight and Obesity

Four treatment stages are recommended, with progress through the stages based on the adolescent's age, biologic development, level of motivation, weight status, and success with previous stages of treatment. Advancing to the next stage of treatment may be recommended if insufficient progress is made to improve weight status or resolve comorbid conditions after 3 to 6 months.

Stage 1 is appropriate for overweight adolescents with no comorbid conditions and/or SMR of 4 or less. This stage of obesity treatment consists of general nutrition and physical activity advice and can be provided by a single health care provider, including physicians, nurses, and dietitians who have training in pediatric weight management. Weight loss should be monitored monthly by the provider and not exceed 1 to 2 pounds per week. Achieve 1 hour of moderate-to-vigorous physical activity each day. Limit daily screen time to no more than 2 hours.

Guidelines for Stage 1

- Remove television and other forms of screen media from the bedroom.
- Consume five fruit and vegetable servings per day, but limit intake of juice.
- Limit eating occasions away from home with the exception of school meals.
- Participate in family meals on most days of the week.
- Consume at least three meals per day rather than frequently snacking.
- Eat mindfully, only when hungry and only until satiated.
- Reduce consumption of most energy-dense foods and beverages and eliminate consumption of sugar-sweetened beverages.
- Select appropriate portion sizes when eating at home and away from home.

Stage 2 includes the same concepts as Stage 1, but provides more structure. This stage of obesity treatment can be provided by a single health care provider with training in motivational counseling. However, referrals for additional services such as physical therapy or counseling may be necessary for some adolescents. Stage 2 treatment is considered successful if weight maintenance or weight loss of up to two pounds per week is achieved. Assessment of progress should be monitored monthly.

Guidelines for Stage 2

- Monitor food and beverage intake through daily food and exercise journals or record books.

- Set goals for food and physical activity behavior changes and monitor progress toward goals.
- Limit time spent with screen media to no more than 60 minutes per day.
- Follow a structured meal plan with scheduled meal and snack times.
- Plan and monitor physical activity to ensure 60 minutes of moderate-to-vigorous activity is achieved each day.
- Reinforce successful lifestyle changes through the use of age-appropriate, nonfood rewards such as tickets to a local event or museum, jewelry, clothing, or music.

Stage 3 is more structured than Stage 2. Youth with a BMI at or above the 99th percentile for age and gender may start treatment in Stage 3. Treatment services are provided by a multidisciplinary team that includes a physician or pediatric nurse practitioner, a counselor (psychologist or social worker), a registered dietitian/nutritionist, and an exercise physiologist or physical therapist. Stage 3 treatment is considered successful when BMI no longer exceeds the 85th percentile for age and gender; however, weight loss should be monitored to not exceed 2 pounds per week. If no improvement is seen after 3 to 6 months, or if comorbid conditions worsen, it is recommended that treatment advance to stage 4.

Guidelines for Stage 3

- The treatment program provides at least 50 hours and ideally more than 70 hours of intervention within 2 to 6 months.
- A family component and an adolescent-only component are offered.
- A highly structured meal plan is developed and monitored.
- A highly structured physical activity plan is developed and monitored.
- A formal behavior modification program is instituted by a counselor, with parent involvement as appropriate.

Stage 4 treatment is a tertiary care service and is reserved for severely obese adolescents or those who have a BMI at or above the 95th percentile for age and gender and who have significant comorbidities that require concerted intervention. This treatment stage is available only in clinical settings that employ a full range of health professionals who are trained specifically in the behavioral and medical management of pediatric obesity.

Guidelines for Stage 4

- Intensive dietary regimens, such as meal replacement, protein-sparing modified fasts, oral medication
- Bariatric surgery may be used

Adapted from Spear B et al: Recommendations for treatment of child and adolescent overweight and obesity, *Pediatrics* 120:S254, 2007 and U.S. Preventative Services Task Force; Barton M: Screening for Obesity in Children and Adolescents: U.S. Preventive Services Task Force Recommendation Statement, *Pediatrics* 125:361, 2010.

and B vitamin deficiencies caused by poor compliance with vitamin-mineral supplementation (see Chapter 21).

Hyperlipidemia and Hypertension

Hyperlipidemia and hypertension, risk factors for CVD, are apparent in adolescence and have been shown to be predictive of

CVD risk in later life. Components of a health screening assessment aimed at the identification and prevention of risk for CVD and other chronic diseases are listed in Table 18-9. Table 18-10 lists the classification criteria for the diagnosis of hyperlipidemia among youth. National data suggest that one in five adolescents 12 to 19 years old has elevated blood lipid levels

TABLE 18-9 Suggested Health Screening Schedule for Health Promotion and Chronic Disease Prevention

Risk Factor	Ages 12-17 Years	Ages 18-21 Years
Family history of premature cardiovascular disease	<ul style="list-style-type: none"> Update previous family history at each visit. Provide dietary counseling and referral based on family history as necessary. 	<ul style="list-style-type: none"> Assess changes in family history at least annually. Provide dietary counseling and referral based on family history as necessary.
Eating behaviors and patterns	<ul style="list-style-type: none"> Assess diet using appropriate methods. Provide education and counseling as needed. 	<ul style="list-style-type: none"> Review eating behaviors and provide education to improve dietary intake and nutritional status.
Growth and weight status	<ul style="list-style-type: none"> Weigh and measure teen at each visit. Plot height, weight, and BMI. Review with adolescent and parent(s). If adolescent is overweight, provide Step 1 counseling to adolescent and parent(s) and schedule follow-up visit. If adolescent is obese, provide Step 2 counseling and refer to a comprehensive weight management program. 	<ul style="list-style-type: none"> Weigh and measure client at each visit. Calculate BMI based on height and weight measurements. If overweight or obese, thoroughly assess diet and physical activity patterns and provide counseling as appropriate. If overweight or obese, refer to primary health provider for full health assessment.
Blood lipids	<ul style="list-style-type: none"> Refer adolescent with family history of premature heart disease, family history of dyslipidemia, or those who are overweight/obese to primary care provider and request a blood lipid panel. Review blood lipid levels with adolescent and parent(s). Provide nutrition counseling as appropriate. If adolescent is overweight, provide dietary counseling in accordance with Step 1. If adolescent is obese, provide dietary counseling in accordance with Step 2 and refer to comprehensive weight management program. The addition of plant sterols or stanols at no more than 2 g/day can be recommended for teens with familial hyperlipidemia. If dietary management is not effective, refer to primary care provider for physical examination and management of dyslipidemia by medication as needed. 	<ul style="list-style-type: none"> Refer adolescent with family history of premature heart disease, family history of dyslipidemia, or those who are overweight/obese to primary care provider and request a blood lipid panel. Review blood lipid levels with adolescent and parent(s). Provide nutrition counseling as appropriate. If client is overweight or obese, provide dietary counseling as appropriate and refer to weight management program. The addition of plant sterols or stanols at no more than 2 g/day can be recommended for clients with familial hyperlipidemia. If dietary management is not effective, refer to primary care provider for physical examination and management of dyslipidemia by medication as needed.
Blood pressure	<ul style="list-style-type: none"> Review blood pressure results with adolescent and parent(s). Provide counseling in accordance with the DASH diet. Request follow-up visit. If adolescent is overweight, provide dietary counseling in accordance with Step 1. If adolescent is obese, provide dietary counseling in accordance with Step 2 and refer to comprehensive weight management program. If dietary management is not effective, refer to primary care provider for physical examination and management of hypertension by medication as needed. 	<ul style="list-style-type: none"> Review blood pressure results with client. Provide counseling in accordance with the DASH diet. Request follow-up visit. If client is overweight or obese, provide dietary counseling as appropriate and refer to weight management program. If dietary management is not effective, refer to primary care provider for physical examination and management of hypertension by medication as needed.
Diabetes	<ul style="list-style-type: none"> Refer adolescent with family history of diabetes, signs of acanthosis nigricans, symptoms consistent with diabetes or those who are overweight/obese to a primary care provider and request a fasting blood glucose. Review fasting blood glucose levels with adolescent and parent(s). Provide nutrition counseling as appropriate. If adolescent is overweight, provide dietary counseling in accordance with Step 1. If adolescent is obese, provide dietary counseling in accordance with Step 2 and refer to comprehensive weight management program. 	<ul style="list-style-type: none"> Refer client with family history of diabetes, signs of acanthosis nigricans, symptoms consistent with diabetes or those who are overweight/obese to primary care provider and request a fasting blood glucose. Review fasting blood glucose levels with client. Provide nutrition counseling as appropriate. If client is overweight or obese, provide dietary counseling and refer to comprehensive weight management program.
Physical activity	<ul style="list-style-type: none"> Review physical activity pattern and behaviors with adolescent and parent(s). Reinforce need for 60 min or more of moderate-to-vigorous physical activity per day. Reinforce limiting sedentary and screen time to no more than 2 hours per day. 	<ul style="list-style-type: none"> Review physical activity pattern and behaviors with client. Reinforce need for 60 min or more of moderate-to-vigorous physical activity each day. Reinforce limiting sedentary and screen time to no more than 2 hours per day.

Summary report*, NIH Publication No 12-7486A, October 2012.

TABLE 18-10 Classification Criteria for the Diagnosis of Hyperlipidemia in Adolescents (10- to 19-years-old)^a

	Acceptable	Borderline	Unacceptable
Total cholesterol (mg/dl)	≤170	170-199	≥200
LDL cholesterol (mg/dl)	<110	110-129	≥130
Non-HDL cholesterol (mg/dl)	<120	120-144	>145
HDL cholesterol (mg/dl)	>45	40-45	<40
Triglycerides (mg/dl)	<90	90-129	>130
Apolipoprotein A-1 (mg/dl)	>120	115-120	<115
Apolipoprotein B (mg/dl)	<90	90-109	>110

Adapted from U. S. Department of Health and Human Services (USDHHS), National Institutes of Health (NIH), National Heart, Lung and Blood Institute (NHLBI): *Expert panel on integrated guidelines for cardiovascular health and risk reduction in children and adolescents. Summary report*, NIH Publication No 12-7486A, October 2012.

HDL, High-density lipoprotein; LDL, low-density lipoprotein.

^aBased on the average of two measurements.

(CDC, 2010). The prevalence of hyperlipidemia among adolescents varies according to adolescent weight status from 14% among normal weight to 22% among overweight and 43% among obese teens. The prevalence of low high-density lipoprotein (HDL) cholesterol and high triglyceride levels appeared to increase with age. Adolescent males were almost three times more likely to have low HDL cholesterol levels compared with females at any age. These youth are considered candidates for therapeutic lifestyle counseling with emphasis on nutrition and physical activity intervention.

The National Heart, Lung and Blood Institute (NHLBI) has recommended that all youth with elevated blood lipids be referred to a registered dietitian or nutritionist for medical nutrition therapy. The dietary recommendations for youth up to 21 years of age with elevated low-density lipoprotein (LDL) cholesterol are listed in [Box 18-4](#), and those for elevated triglycerides and non-HDL cholesterol are listed in [Box 18-5](#).

BOX 18-4 Dietary Recommendations for Elevated Low-Density Lipoprotein Cholesterol in Adolescents

- Limit total fat intake to no more than 25% to 30% of calories.
- Limit saturated fat intake to no more than 7% of calories.
- Dietary cholesterol intake should not exceed 200 mg/day.
- Plant sterol esters and/or stanol esters can replace usual fat intake up to 2 g/day for children with familial hypercholesterolemia.
- Up to 12 g of psyllium fiber can be added to the diet each day as cereal enriched with psyllium.
- At least 1 hour of moderate to vigorous exercise should be obtained daily.
- Sedentary and/or screen time should be limited to less than 2 hours each day.

Adapted from U.S. Department of Health and Human Services, National Institutes of Health, National Heart, Lung and Blood Institute: *Expert panel on integrated guidelines for cardiovascular health and risk reduction in children and adolescents. Summary report*, NIH Publication No 12-7486A, October 2012.

BOX 18-5 Dietary Recommendations for Adolescents with Elevated Triglyceride or Non-High-Density Lipoprotein Cholesterol Levels

- Limit total fat intake to no more than 25% to 30% of calories.
- Limit saturated fat intake to no more than 7% of calories.
- Reduce intake of added and natural sugars in the diet.
- Replace simple carbohydrates with complex carbohydrate and whole grains.
- Avoid sugar-sweetened beverages.
- Increase the intake of fish high in omega-3 fatty acids.

Adapted from U.S. Department of Health and Human Services, National Institutes of Health, National Heart, Lung and Blood Institute: *Expert panel on integrated guidelines for cardiovascular health and risk reduction in children and adolescents. Summary report*, NIH Publication No 12-7486A, October 2012.

National screening criteria for blood pressure levels among adolescents are listed in [Tables 18-11](#) and [18-12](#). Teenagers 17 years of age and younger are determined to have prehypertension if their average blood pressure readings fall between the 90th and 94th percentiles. Hypertension is diagnosed when the average of three blood pressure measurements exceed the 95th percentile for age, gender, and height.

Dietary counseling and weight management are integral components of hypertension treatment. The Dietary Approaches to Stop Hypertension (DASH) eating pattern has been shown to be effective in reducing blood pressure in many individuals (see [Chapter 33](#) and [Appendix 26](#)). In addition to the DASH diet, teens with elevated blood pressure should be counseled to reduce sodium intake to less than 2000 mg/day and to achieve and maintain a healthy body weight.

The NHLBI has developed the CHILD 1 (Cardiovascular Health Integrated Lifestyle Diet) diet and nutrition guidelines which integrate dietary approaches to prevent hypertension, hyperlipidemia, and obesity (see [Table 18-13](#)). These guidelines include the DASH dietary guidelines as well as recommendations for upper limits for total and saturated fatty acids and dietary cholesterol intake. The CHILD 1 guidelines recommend the avoidance of sweetened beverages, limiting juice intake and increasing fiber intake to a level of 14 g/1000 kcal.

Metabolic syndrome is not well defined in the adolescent population, and therefore it is not consistently considered a separate risk factor for CVD. Rather it is considered to be a clustering of risk factors that, taken together, signal a need to intensify the depth and breadth of prevention measures that are recommended. It is estimated that between 2.0% and 9.4% of all U.S. adolescents have metabolic syndrome; the rates are much higher among obese teens, in whom they are estimated at 12.4% to 44.2% (U.S. Department of Health and Human Services [USDHHS], National Institutes of Health [NIH], NHLBI, 2012).

Diabetes

The exact prevalence of diabetes among adolescents is not known. Approximately 215,000 people under the age of 20 have diabetes, with the majority of the cases being type 1 diabetes (CDC, 2011). The CDC estimates that type 1 diabetes occurs in 1.7 per 1000 youth (younger than 19 years old) in the United States. Type 2 diabetes can be hard to detect in adolescents

TABLE 18-11 90th and 95th Percentiles for Blood Pressure for Adolescent Males by Height Percentiles

*Height percentile determined by standard growth curves.

†Blood pressure percentile determined by a single measurement.

because they may show no symptoms and even when they do, differentiating between type 1 and type 2 can be difficult. Adolescents who are diagnosed with type 2 diabetes usually have a strong family history for diabetes and are obese. Recommendations for type 2 diabetes screening are listed in [Box 18-6](#). The risk of type 2 diabetes among adolescents varies among racial/

ethnic groups with 15- to 19-year-old American Indian youth having the highest rates (4.5/1000 among all U.S. American Indian youth; 50.9/1000 among Pima Indian youth). The prevention of type 2 diabetes includes following the CHILD 1 dietary guidelines and additional physical activity at a level to reduce body weight ([USDHHS, NIH, NHLBI, 2012](#)).

TABLE 18-13 Cardiovascular Health Integrated Lifestyle Diet (CHILD 1) Recommendations, Ages 11 to 21 Years

Fat-free unflavored milk should be the primary beverage consumed. Sugar-sweetened beverages should be limited or avoided. Water intake should be encouraged. A range of 25% to 30% of daily energy needs should come from total fatty acids. No more than 8% to 10% of daily energy needs should come from saturated fatty acids. Monounsaturated and polyunsaturated fatty acids should provide no more than 20% of daily energy intake. Trans fatty acids should be avoided. Dietary cholesterol intake should not exceed 300 mg/day. Foods high in dietary fiber should be encouraged. A goal of 14 g of dietary fiber per 1000 kcal should be encouraged. Intake of naturally sweetened juices (no added sugar) should be limited to 4 to 6 oz/day. Sodium intake should be limited. Breakfast should be eaten each day. Family meals should be encouraged. Fast food meals should be limited. The use of the Dietary Approaches to Stop Hypertension eating plan should be encouraged. Energy intake should be based on estimated energy requirements and adjusted for growth and physical activity as needed.

Adapted from U.S. Department of Health and Human Services (USDHHS), National Institutes of Health (NIH), National Heart, Lung and Blood Institute (NHLBI): *Expert panel on integrated guidelines for cardiovascular health and risk reduction in children and adolescents. Summary report*, NIH Publication No 12-7486A, October 2012.

BOX 18-6 Recommendations for Screening Adolescents for Type 2 Diabetes Mellitus

Youth who are overweight or obese and exhibit two of the following risk factors are at high risk:

- First- or second-degree relative with a history of type 2 diabetes
- Member of a racial/ethnic group considered at higher risk (American Indian, African American, Latino, Asian American/Pacific Islander)
- Dyslipidemia
- Hypertension
- Acanthosis nigricans
- Polycystic ovary syndrome

Screening should begin at age 10 or the onset of puberty, whichever occurs first. Screening should occur every 2 years.

Adapted from U.S. Department of Health and Human Services, National Institutes of Health, National Heart, Lung and Blood Institute: *Expert panel on integrated guidelines for cardiovascular health and risk reduction in children and adolescents. Summary report*, NIH Publication No 12-7486A, October 2012.

Physical Activity

National recommendations for physical activity suggest that all youth should be active at least 60 minutes each day, including participation in vigorous activity at least 3 days each week (USDHHS, Physical Activity Guidelines Steering Committee, 2008). In addition, muscle-strengthening and bone-strengthening activities should each be included in the 60 minutes of

physical activity at least three times a week. However, many youths do not meet these recommendations. Only half of U.S. high school students report being physically active for at least 60 minutes per day on 5 days or more per week, with males nearly twice as likely to meet these recommendations as females (Eaton et al, 2012).

Teenage athletes have unique nutrient needs. Adequate fluid intake to prevent dehydration is especially critical for young athletes. Young adolescents are at higher risk for dehydration because they produce more heat during exercise but have less ability to transfer heat from the muscles to the skin. They also sweat less, which decreases their capacity to dissipate heat through the evaporation of the sweat (see Chapter 23).

Athletes who participate in sports that use competitive weight categories or emphasize body weight are at elevated risk for the development of disordered eating behaviors. A concern among female athletes is the female athlete triad relationship, a constellation of low body weight and inadequate body fat levels, amenorrhea, and osteoporosis (see Chapter 23). The female athlete triad may lead to premature bone loss, decreased bone density, increased risk of stress fractures, and eventual infertility (Javed, 2013). Nutrition assessment and education for teenage athletes should focus on obtaining adequate energy, macronutrients, and micronutrients to meet the needs for growth and development and to maintain a healthy body weight. The use of anabolic agents (such as steroids or insulin) and other ergogenic supplements also should be included in nutrition screening. Survey data suggest the use of muscle-enhancing substances should be a concern for adolescent males and females; one study found that steroids were used by 6% of males and 5% of females, whereas other substances such as creatine and growth hormone were used by 10% of males and 5% of females (Eisenberg et al, 2012).

Pregnancy

Although birth rates among females 15 to 19 years have declined over the past few decades and reached a low of 29.4 births per 1000 adolescents in 2012, adolescent pregnancy remains a significant public health issue (Hamilton et al, 2013). Adolescent females who become pregnant are at particularly high risk for nutritional deficiencies because of elevated nutrient needs. Pregnant adolescents with a **gynecologic age** (the number of years between the onset of menses and current age) of less than 4 and those who are undernourished at the time of conception have the greatest nutritional needs. As with adult women, pregnant teens require additional folic acid, iron, zinc, and other micronutrients to support fetal growth (see Chapter 15). Calcium and vitamin D are also important nutrients in pregnancy, because both are necessary for growth and development of the adolescent mother and fetus (Young et al, 2012). Pregnant teens should have a full nutrition assessment done early in pregnancy to determine any nutrient deficiencies and to promote adequate weight gain. Weight gain recommendations for pregnancy are listed in Table 15-11 in Chapter 15. Referral to appropriate food assistance programs such as the Special Supplemental Nutrition Program for Women, Infants and Children is an important part of prenatal nutrition education.

CLINICAL CASE STUDY

Cherise is an 18-year-old girl and high school senior who saw a nurse at the school-based clinic. While taking her medical history, the school nurse noted that Cherise had frequent headaches and fatigue. Cherise's blood pressure reading fell into the 92nd percentile. The school nurse referred her to a local community clinic for a more thorough evaluation.

A physician's assistant (PA) at the community clinic took a social history and performed a physical examination on Cherise. An SMR stage of 5 was noted. The PA noted that Cherise's BMI was at the 94th percentile for her age and gender. Her blood pressure registered at the 94th percentile. The family history revealed a strong family history of cardiovascular disease, diabetes and renal disease. Cherise thought her father may be taking medication for his cholesterol and blood pressure, but reported no health issues for her mother. No signs of acanthosis nigricans were noted on the physical examination.

Laboratory results show that Cherise had elevated total, non-HDL, and LDL cholesterol levels along with a marginally low HDL level. The liver enzyme and blood glucose values were at the upper end of normal. A referral was made for Cherise to see a registered dietitian/nutritionist for diet and exercise counseling.

The outpatient dietitian/nutritionist (RDN) reviewed Cherise's medical history, confirmed her family history of cardiovascular disease, and measured her height and weight. Cherise's BMI value plotted at the 94th percentile. The RDN completed a 24-hour dietary recall with Cherise, beginning with the last thing she had eaten that day and working backward to facilitate a complete and accurate recall. The RDN also inquired about usual dietary patterns and physical activity as well as the presence of any food allergies/intolerances and avoidances.

Cherise reported that she usually skipped breakfast because she didn't have time to eat in the morning, but she often buys a caramel macchiato from the school store at 7:15 AM. The first food Cherise ate most days was usually a snack from the vending machine at 10:30 AM, which consisted of a granola bar or a bag of chips and a juice drink. Occasionally she would purchase a la carte lunches of tacos or a burger, but generally she skipped lunch. Cherise was out of school at 2 pm each day, at which time she went to work as a clothing sales clerk at the local mall. She had a half-hour break in the late afternoon or early evening, when she would go to the food court for dinner. Her evening meal usually consisted of one to two slices of pepperoni pizza, two tacos, or one to two pieces of fried chicken with a soft drink. About half of the time she also ordered fries or nachos. When Cherise returned home from work at 10:15 PM, she usually had a snack of ice cream, tortilla chips, spicy cheese puffs, or microwave popcorn while doing her homework. A large glass of juice or lemonade usually accompanied her snack. On weekends, Cherise worked as many hours at the mall as she could, often meeting friends for pizza or fast food on her nights off. Her physical activity consisted of walking between the house and bus stop in the morning and evening, walking around school between classes and being on her feet in the evenings at her sales job.

The RDN counseled Cherise regarding a healthy diet and physical activity. A follow-up visit was scheduled 4 weeks in the future.

Cherise did not return to see the RDN for her follow-up appointment and did not keep her follow-up appointments with the PA. Five months later, she returned to see the PA at which time her health status was reassessed. Cherise's blood pressure was still at the 94th percentile and her BMI now at the 95th percentile. When questioned about her dietary habits and physical activity, Cherise reported that she had tried to follow the recommendations of the RDN but found it hard because of time constraints. She reported that she wanted to lose weight and thought she could do this because she would graduate in a few weeks and would have more time to devote to exercise and cooking. The PA suggested she see the RDN again for more dietary and physical activity counseling.

The RDN reviewed the previous dietary recommendations with Cherise and suggested she attend the clinic's 12-week weight management program. Cherise attended the first five sessions of the program, then stopped. She had lost 12 pounds during the five sessions. Several months later Cherise was once again seen by the PA. Her blood pressure continued to be elevated and her BMI was plotted at the 94th percentile. When questioned about the weight loss program, Cherise reported that her mother had changed jobs and lost her health insurance benefits, so she could no longer participate in the program. The RDN connected Cherise with the local YMCA, which offered a weight management program for adults on a sliding fee scale. Five months later Cherise's BMI was assessed at 26.8 and a weight loss of 19 pounds from previous levels was noted.

Nutrition Diagnostic Statements

1. Excessive energy intake as evidenced by dietary history and BMI at 94th %tile. (NI-1.3)
2. Excessive fat intake as evidenced from dietary history. (NI – 5.6.2)
3. Obesity as evidenced by BMI of 94th %tile. (NC 3.3.1)
4. Limited adherence to nutrition-related recommendations as evidenced by BMI up 1 %tile at followup visit. (NB-1.6)

Nutrition Care Questions

1. How would you classify Cherise's blood pressure based on the reading at the school nurses office?
2. How would you classify Cherise's weight based on the readings at the first visit at the community clinic? Based on this classification, what laboratory tests would you order to be consistent with the NHLBI recommendations?
3. What type of diet should the RDN recommend Cherise follow, based on her blood pressure, weight and laboratory results?
4. What specific strategies would be beneficial for the RDN to recommend to Cherise regarding improving her dietary intake?
5. What strategies would you recommend for Cherise to change her level of physical activity?
6. Based on the staged treatment recommendations for weight, what type of program would the RDN recommend for Cherise?

phytonutrients

prebiotics
premenstrual syndrome (PMS)
probiotics
wellness

This chapter emphasizes the background and tools for encouraging adults to set nutrition-related lifestyle goals that promote positive health and reduce risk factors. Other chapters of this text provide a focus on the present and potential role of medical nutrition therapy (MNT) on prevention and intervention for major chronic diseases and conditions that affect food and nutrition choices in the adult years, such as cardiovascular disease (CVD), diabetes, cancer, weight control, and osteoporosis. Added to these are health-related conditions such as arthritis, Alzheimer's disease, renal disease, and inflammatory-related conditions, which research is indicating may have a link to lifestyle and food and nutrition choices. Although these links are mentioned here, other chapters and ongoing research provide the core of information. The focus of this chapter is that the adult years are a time for nutrition and dietetics professionals to be leaders and team members helping adults achieve and maintain positive health. The goals for Healthy People 2010 and 2020 provide the framework ([Centers for Disease Control and Prevention \[CDC\], 2011c, 2013b](#)). The evidence is convincing that decisions for a healthy lifestyle must be early in life to build the road for health promotion and disease prevention ([Academy of Nutrition and Dietetics \[AND\], 2013b](#)).

SETTING THE STAGE: NUTRITION IN THE ADULT YEARS

This chapter focuses on nutrition and food-related behaviors for the years after adolescence but before one is deemed an "older adult," often defined as age 65, based on traditional retirement age. Admittedly this is a wide range of ages, and, like all population groups, the adult years are heterogeneous. The description of what constitutes being an "older adult" is in constant flux as people change their retirement age, as life expectancy projections are adjusted and as medical science and lifestyle alterations extend life spans and opportunities for an optimum quality of life. A life expectancy of 80 and above is a reality backed up by Centers for Disease Control statistics with life expectancy in 2013 at 78.8 ([CDC, 2013a](#)). Evidence

continues to indicate that the adult years set the framework for quality of life as well as life expectancy. Nutrition and food-related behaviors are key factors, and the earlier prevention becomes the goal, the better the outcome ([AND, 2013b](#)).

The dietary reference intakes (DRIs) on the inside cover of this text provide an overview of the nutrient recommendations for age groups under the DRI umbrella. Staying current on changes in DRI is a critical part of the dietetics and nutrition professionals tools because changes are made as research is validated ([Institute of Medicine \[IOM\], National Academy of Sciences \[NAS\], 1984-2004](#)). Nutrient needs in the adult life cycle are similar but, as in all life stages, are affected by gender, state of health, genetics, medications, and lifestyle choices such as eating behaviors, smoking, and activity. These are markers, determined through assessment, that a nutrition and health professional can use to determine this population's needs. Other markers are less evident and include the adult's perceptions of quality of life and motivation in the areas of nutrition and health.

When the objectives are prevention and behavior change, such markers become critical. Research continues to indicate that positive changes at any age and lifestyle behaviors can make a difference in total health and life expectancy. Making these changes early in life, rather than later, and maintaining them throughout the adult years should be goals. Genetics always has been a consideration in assessment of nutrition status and life potential, but the evolving science of **nutritional genomics** has become an important marker in nutrition and dietetics practice ([AND, 2014b](#)).

SETTING THE STAGE: MESSAGES

A first step for nutrition and dietetics professionals is to recognize that many adults are prime targets for nutrition and health information that offers positive guidance that is understandable and implementable. However, this translates into growing evidence that adults can be willing targets for misinformation and guidance based on promises and quick-fixes rather than

evidence-based MNT. Rebekah Nagler, PhD, studied the potential role of consumer reaction to what appeared to be contradictory nutrition information or guidance. According to Nagler, confusion and backlash may make people more likely to ignore not only the contradictory information but also the widely accepted nutritional advice such as eating more fruits and vegetables. Nagler also noted that those with the greatest exposure to contradictory information expressed the most confusion with nutrition (Nagler, 2014).

As with any group, adults must be approached with strategies and guidance that fit their health and education needs as well as their capability to implement them. An appreciation that research constantly is altering and changing should be firmly fixed in the minds of the messenger (the nutrition professional) and the receiver (the patient or client). It is the role of the nutrition professional to verify messaging, separating current evidence based messages from those based on preliminary or single studies. What is reported as news or guidance to the consumer may appear to be contradictory to current practice when in fact the basis is preliminary research rather than evidence based.

The challenge to nutrition and dietetics professionals is staying current on research and guidelines while acknowledging the potential motivations of their audience or clients and their sources of their information. In a technologically savvy world with instant access to nutrition and health advice by self-proclaimed as well as credentialed professionals, this becomes even more of a challenge.

The Academy of Nutrition and Dietetics (AND, formerly American Dietetic Association, or ADA) Trends surveys have set the stage for communication. These surveys included a representative sampling of adult Americans with a focus on food, nutrition, and activity messages and consumers' reactions to these messages. Because this survey was conducted every 2 years for 12 years and was repeated in 2008 and 2011, Trends provides a snapshot of evolving attitudes about the importance of nutrition, activity, and sources of information. Trends 2008 indicated that respondents noted they were making positive steps to meeting nutrition and activity guidelines (AND, 2008). The 2011 snapshot indicated a slight drop in the number of respondents who already had made changes or identified that they should make changes. Many of the remaining questions provided clues that for some adults, reaching health goals was difficult (AND, 2011).

Like the Trends information, other surveys support the idea that adults are seeking nutrition information and using it to make positive lifestyle changes but are finding that making these changes is a challenge. Time, lack of willpower, apparent mixed messages, and identifying the efficacy of the messages are cited as barriers (International Food Information Council [IFIC], 2013). The 2015 IFIC Foundation Food and Health Survey continued with identifying barriers and noted that consumer confusion is emerging as a key concern. Of interest is the remark that consumers are wanting to hear "what to eat" rather than what to avoid (IFIC, 2015). Although women continue to lead men in these efforts, the influence of men is growing in such areas as wellness initiatives, meal planning, and shopping with health in mind. According to the ADA/AND's Trends survey, half of consumers believe they are already doing what they can to achieve balanced nutrition and a healthy diet. Younger adults were less likely than older adults to rate diet and nutrition as "very important," whereas exercise and physical activity
