This article is a revision of the previous edition article by H. Hogeveen and W. Ouweltjes, Volume 3, pp 1735–1940, © 2002, Elsevier Ltd.

Introduction

There are many aspects to milk quality. Mastitis is associated with two of the milk quality aspects that are used in most dairy-producing countries: somatic cell count (SCC) and, if mastitis is clinical, visibly abnormal milk (in the remaining part of this article referred to as abnormal milk). In most dairy systems, it is assumed that the farmer, informed by the official organizations in his country, has the responsibility to deliver milk of sufficient quality. In order to deliver milk with a low SCC, the focus should be on adequate detection and prevention of mastitis. Efficient detection of clinical mastitis is therefore important. A well-established method to detect clinical mastitis is to strip before milking and check the foremilk for abnormalities. Discarding of abnormal milk is part of the EU Milk Hygiene Directive (EC/92/46). Milk from diseased cows or milk that is visually abnormal should not be delivered. Discarding of abnormal milk is also mandatory in the United States, according to the Grade ‘A’ Pasteurized Milk Ordinance. Checking of foremilk is thus important to detect clinical mastitis, depending on the regulations of a country, to meet regulations (*see* **Milk Quality and Udder Health**: Test Methods and Standards; Effect on Processing Characteristics. **Milking and Handling of Raw Milk**: Milking Hygiene).

From the mid-1980s, work has been carried out in order to automate the detection of mastitis by means of sensors. When detection of clinical mastitis is carried out automatically, the task of the milker becomes easier and the capacity of milking parlors can be increased. Although sensors for detection of mastitis became commercially available in the beginning of the 1990s, they were never applied on a large scale. Because of the fact that with automatic milking no milker is present at the time of milking, the need for sensors to detect clinical mastitis and abnormal milk was high when automatic milking systems were commercially introduced. Moreover, because the number of milking clusters in an automatic milking system is much lower than in a comparable milking parlor, the cost of application of sensors is also lower in an automatic milking system. Therefore, interest in the application of sensors to detect mastitis and abnormal milk is gaining importance (*see* **Milking Machines**: Robotic Milking).

This article describes the current status of sensors to detect abnormal milk and mastitis (subclinical as well as clinical).

Demands for Automatic Detection of Mastitis and Abnormal Milk

Test Requirements

Sensors for detection of mastitis and/or abnormal milk can be seen as diagnostic tests, which can be characterized by epidemiological parameters. The two most important parameters are sensitivity and specificity. The sensitivity refers to the probability that a milking with abnormal milk (or a cow with clinical mastitis) will be classified as such (positive test result). The specificity refers to the probability that a milking without abnormalities (or a cow without clinical mastitis) will be classified as normal (negative test result). Sensitivity and specificity are interdependent. If the threshold of a test is increased, the number of positive outcomes and thus the sensitivity will decrease. On the other hand, the specificity will increase. Therefore, thresholds have to be set in such a way that the performance of a sensor in terms of sensitivity and specificity is optimized. However, for practical evaluation, the predictive values (positive and negative) of a test are more important. The predictive value depends on sensitivity, specificity, and prevalence of a disease. When discussing methods to detect clinical mastitis and abnormal milk, the test characteristics described above should be taken into account. Moreover, the goal for which the test is used is important in the evaluation of the test characteristics. Therefore, the usefulness of tests may differ for the detection of clinical mastitis to treat the cow and the detection of abnormal milk to automatically separate this milk. The prevalence of clinical mastitis, subclinical mastitis, and abnormal milk is very low. The prevalence of clinical mastitis and abnormal milk is approximately 0.04% (4 cases per 10 000 milkings). The prevalence of subclinical mastitis is much higher: 100–5000 cases per 10 000 milkings. This low prevalence, especially for clinical mastitis, will have effects on the interpretation of sensor data. In the following three sections, the demands for tests to detect clinical mastitis, subclinical mastitis, and abnormal milk are described.

Clinical Mastitis

The primary goal of online detection of clinical mastitis is to be able to cure the diseased cow. After an alert signal, the herdsman will check the cow first to confirm the mastitis before deciding on treatment. The advantage of using a sensor system to detect clinical mastitis is the management by exception principle. Only those cows requiring attention will get it. Because mastitis case will be confirmed first, a reasonable amount of false-positive test results will not be a problem. The only costs that are incurred are the labor costs of the herdsman performing checks. Alerts can be given directly in the milking parlor, decreasing the time that is needed to milk one cow. When the person applying treatments is not in the milking parlor (as is the case with automatic milking), the alerts of the sensor system may be placed on an alert list. The herdsman checks this list regularly and checks the cows on it. It is important that as many cows with clinical mastitis as possible (preferably all) be identified, requiring a high sensitivity. At least cows with severe clinical mastitis (grave systemic and local symptoms) must be detected (*see* **Mastitis Therapy and Control**: Management Control Options).

Subclinical Mastitis

Treatment of subclinical mastitis during lactation is not a common practice. However, in controlled experiments, the efficacy of treatment improves when cows with an intramammary infection are treated before the occurrence of signs of clinical mastitis (preclinical mastitis). When treating cows based on alerts of a sensor system before clinical signs appear, a very low proportion of false-positive test results can be allowed. Treating a cow when there is really no need for treatment is a waste of antibiotics, milk, and labor. On the other hand, there are no very high demands for sensitivity. A high sensitivity is useful, but will not be necessary. In order to define demands for a test for subclinical mastitis, it is important to know what the actions are to be undertaken when a case of subclinical mastitis is found (*see* **Mastitis Therapy and Control**: Management Control Options).

Abnormal Milk

Almost all abnormal milk is a result of clinical mastitis. Abnormal milk might also be caused, for instance, by the presence of blood in milk. While the goal of detection of clinical mastitis is to be able to cure a diseased cow, the goal of detection of abnormal milk is to discard this milk, as is required by regulations in most milk-producing countries. If the task of discarding abnormal milk has to be carried out automatically as is the case with an automatic milking system, it is not sufficient to use alert lists. A signal of abnormal milk must be followed directly by automatic separation of the milk. The management information system must detect as much milkings with abnormal milk as possible (preferably all), requiring a high sensitivity. Since each milking that is unnecessarily separated costs money, the number of false positives should be low.

Sensors to Detect Mastitis and Abnormal Milk

Because of the pathophysiological changes in the udder, intramammary infections lead to major alterations in the composition of milk. Clinical mastitis is as per definition an intramammary infection where visible changes in the appearance of the milk, the udder, or both occur as an effect of the inflammation process. Among others, a rapid influx of polymorphonuclear leukocytes leads to an increase of the SCC. The SCC is the basis of many milk quality programs worldwide. Besides the influx of polymorphonuclear leukocytes, there are other changes in milk composition. Sensors have been developed that can detect some of these changes online. This article presents the current knowledge on sensors that have been developed for online detection of mastitis, abnormal milk, or both.

Electrical Conductivity

General

Electrical conductivity (EC) is a measure of the resistance of a particular material to an electric current. In milk, ions present are the main components conducting electricity. Active and passive transport systems in the secretory cells of the mammary gland keep the sodium to potassium ratio in the milk at approximately 1:3, whereas it is 30:1 in the extracellular fluid or blood. The chloride concentration in milk is much lower than in blood. The mammary ducts are impermeable to ions (**Figure 1** (**a**)). Mastitis leads to a change in blood capillary permeability, destruction of tight junctions, and destruction of the active ion-pumping systems. As a result, the ion concentrations in milk change. Since milk is iso-osmotic with blood, the secretory cells of the mammary gland will stabilize the osmotic pressure leading to a change in EC (**Figure 1** (**b**)) (*see* **Mammary Gland**: Anatomy).

Because the principle of measuring EC is relatively simple, sensors for measuring EC are commercially available for a number of years. Basically, two types of systems are available: (1) systems that measure the conductivity of the whole milk, located for instance in the electronic milk meter, and (2) systems measuring the conductivity per udder quarter, located in the claw of the milking cluster (traditional milking systems) or in the long milk tube (automatic milking systems). Since mastitis is an event that occurs on udder quarter, EC measurements at the quarter level give the possibility to compare udder quarters, thus increasing the test characteristics.

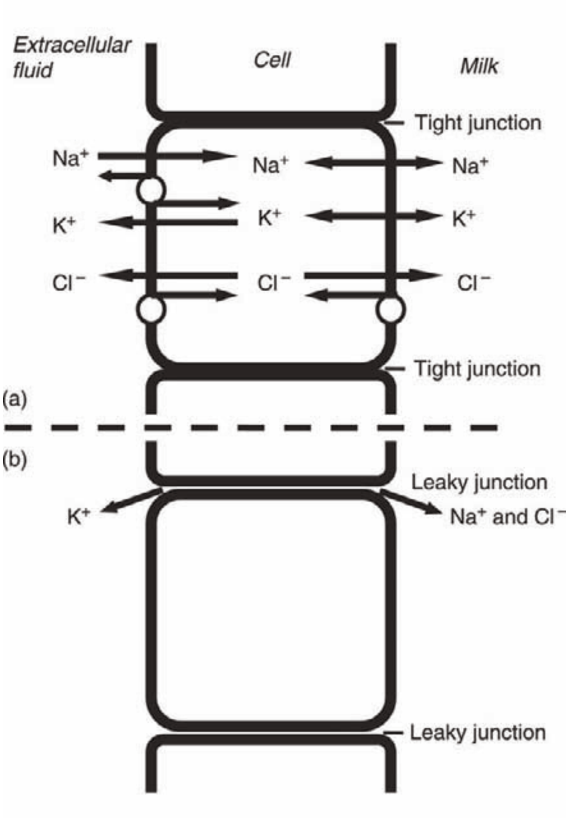

Figure 1 Schematic overview of the pathways of ion transport in the mammary secretory epithelium. (a) Situation in a normal functioning mammary gland and (b) some of the changes caused, among others, by mastitis. Based on Linzell JL and Peaker M (1971) Mechanism of milk secretion. *Physiological Reviews* 51: 564–597.

Many studies have been carried out to evaluate the use of EC to detect mastitis. **Table 1** gives results from two meta-analyses. It can be noticed that there is a large variation in results between the studies. Moreover, the test characteristics seem to differ between the reference methods used. The best results in sensitivity as well as specificity were found when bacteriology was used as a reference.

Clinical mastitis

Although some laboratory studies found a sensitivity of 100% when using EC to detect clinical mastitis, average test results given in **Table 1** are not very good. Especially the sensitivity is too low. The average sensitivity for clinical mastitis signs was 68%, varying from 34 to 95%. However, the studies summarized in **Table 1** were rather diverse, and the algorithms used could be improved (see further in this article for more on this subject).

Subclinical mastitis

The performance of EC to detect subclinical mastitis (defined as increased SCC, positive bacteriology, or both) varies between studies. Although subclinical mastitis can be detected, the specificity is not more than 95%. With the relatively low prevalence of subclinical mastitis, in practice this will lead to an unacceptable high number of false-positive test results. To make treatment (with antibiotics or in another way) based upon EC efficient, the number of false-positive test results should be lowered. For the same reason, early treatment of clinical mastitis (before clinical signs occur) based upon EC is not efficient. Small-scale application of new algorithms (fuzzy logic) showed a large reduction of false-positive test results. When this type of algorithms give the same performance online, the number of false-positive test results might be reduced to such an extent that treatment of early mastitis or subclinical mastitis based upon EC could become an efficient option.

Abnormal milk

There is not much work done on the use of EC to detect abnormal milk. For instance, detection of abnormal milk, using commercially available EC sensors and software on six dairy farms, has been reported with an average sensitivity of 39%, varying from 13 to 50%. When decreasing

Brussels, Belgium: IDF.

the detection threshold, the sensitivity would improve greatly, but the number of false-positive test results would increase to unacceptable levels. Although this study was rather limited (138 cows were followed for 48 h), the results are not unexpected. After all, there is a large correlation between abnormal milk and clinical mastitis, and the results for detection of abnormal milk will probably not deviate very much from the results presented above. With those results, EC is not sufficient to withhold abnormal milk automatically. Too many milkings with abnormal milk will still be delivered and too much milk will be discarded unnecessarily leading to economic losses. Improvement of sensors and algorithms might make automatic separation of abnormal milk possible in the future.

L-Lactate dehydrogenase

L-Lactate dehydrogenase (LDH) is an enzyme found in the cytoplasm of all cells and tissues in the body and it plays an important role in the glycolytic pathway. LDH is a responsive indicator of mastitis. A biosensor, based on LDH and using dry-stick technology, is commercially available. A model, using LDH, milk yield, EC, and cow-specific information, has been developed. This model appears to be robust and gave a sensitivity and specificity of 82 and 99%, respectively.

Color

A direct measure of the physical characteristics of abnormal milk (mostly due to clinical mastitis) will most likely offer better detection results than measurement of an indirect indicator of mastitis or abnormal milk. One of the visible aspects of milk is its color. Recently, a sensor for online color measurement is on the market.

The principle of the sensor is based on the reflection of light generated by a light-emitting diode (LED). The whiter the milk, the more the light reflected. Three different wavelengths of light are measured by the sensor: red, green, and blue.

In a first study under laboratory circumstances, using homogenized quarter milk samples from eight cows with clinical mastitis, the potential to detect mastitis from color measurements was estimated. The milk samples of the suspected quarters of all eight cows with clinical mastitis showed lower color values than homogenized milk.

In a detailed study on the predictive potential of EC and color measurements, it became clear that most information to distinguish udder quarters with abnormal milk and clinical mastitis from other udder quarters could be found in EC measurements. The potential of color measurements did add but not very much. This means that color sensors should always be used in combination with other sensors.

Somatic Cell Count

The best-known and most widely applied parameter related to mastitis and used for its detection is the SCC. Rapid reliable measurement of SCC is carried out routinely in laboratories, and can be used to monitor udder health. Therefore, SCC is used as an important tool for the control of (subclinical) mastitis. There are a few results of online measurement of SCC by means of near-infrared (NIR) technology. The results of these limited experiments are promising for future application of NIR.

Sensors that measure SCC online are commercially available on automatic milking systems. One of these sensors utilizes the gel formation process of the Californian mastitis test (**Figure 2**). The potential value of this sensor has been studied at the cow level in

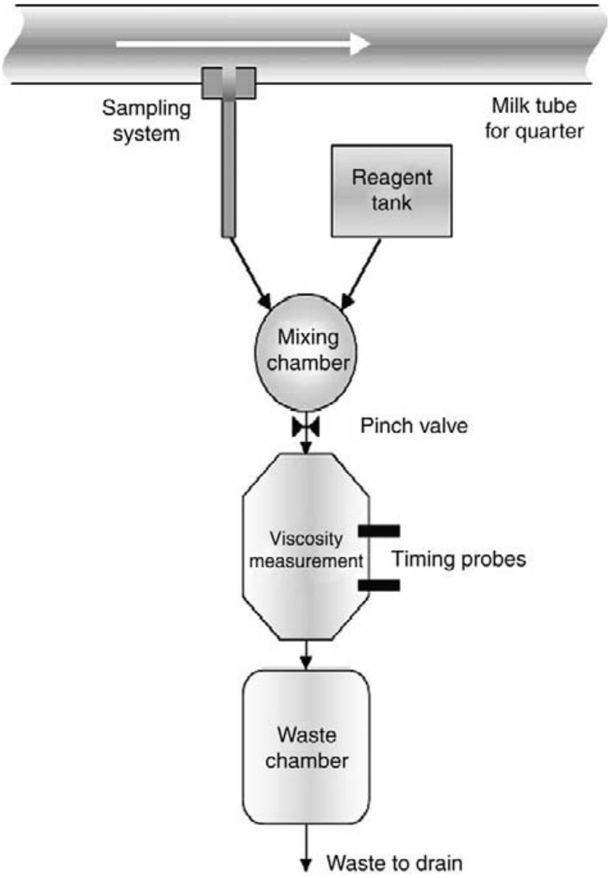

Figure 2 Representation of online somatic cell count sensor based on gel formation as utilized by the Californian mastitis test.

combination with quarter-based EC. With thresholds set in such a way that the sensitivity of the test was 80%, online SCC measurement gave similar results as EC (using standard algorithms). The test based on online SCC measurement gave a probability of 13% that a positive sensor outcome was a case of clinical mastitis. When combining EC and SCC measurements, the probability that a positive sensor outcome was a case of clinical mastitis increased to 33%. These results suggested that estimating SCC from a composite cow milking contributes to an automatic sensing system for the detection of clinical mastitis by reducing the number of false-positive attentions while keeping the sensitivity of detection at a reasonable level. Recent, not yet published, data show that measuring SCC at the quarter level gives better detection performance than measuring SCC at the cow level (*see* California Mastitis Test; Somatic Cell Count).

Other Methods for the Detection of Abnormal Milk and Mastitis

Mastitis has effects on the body temperature of the cow, and thus on the milk, activity of the cow, and milk yield. Equipment to measure these parameters online in milk is commercially available. However, these parameters are not distinctive enough for detection of mastitis or abnormal milk. More recent work describes the use of thermal cameras to measure the temperature of the udder. Temperature changes of 1–1.5 °C can be detected this way. However, most of the clinical mastitis cases do not affect the general condition of the cow.

Besides EC, there are many other changes in milk composition, caused by the disease-combating response of the cow, the reduced synthetic ability of the mammary gland, or tissue damage and blood capillary permeability. Changes in anion and cation concentration in milk are the basis for EC measurement. But also changes in the levels of enzymes such as catalase and *N*-acetyl-β-D-glucosaminidase (NAG-ase) are of interest.

Recently, a large number of new possibilities to detect mastitis online are described. Among these is a chemical array-based sensor that was able to detect chloride, potassium, and sodium ions released during mastitis. Another development is the measurement of volatile metabolites produced by mastitis pathogens in milk. Biosensors have also been developed to detect NAG-ase, haptoglobin, and hemoglobin in milk. Besides these recently described developments, outside the dairy industry biosensors are developed for a wide range of compounds and applications. The commercial success of some of these applications indicates that this is a viable and robust technology that might be very useful for the dairy industry, and in the future new developments are being expected.

Many sensors for detection of mastitis and abnormal milk measure an indirect indicator of mastitis. Any change in milk composition, caused by mastitis, either clinical or subclinical, can be used as the basis for a sensor. However, especially for the discarding of abnormal milk, a direct indicator might be useful. Abnormal milk, in the sense that it is meant in European and American legislation, is visibly abnormal. Visible abnormality of the milk occurs also in most clinical mastitis cases. Color is one part of visible abnormalities. A method to detect deviations in milk color has been described above. The other part is the appearance of milk emulsion: clots and flocks in the milk are abnormal and this is a sign of clinical mastitis. Patents have been filed for direct clot sensors but so far they have not been implemented in a commercial milking system (*see* Analysis of Milk and Dairy Products; **Analytical Methods**: Biosensors; Somatic Cells in Milk; Spectrophotometric Techniques).

Algorithms

Sensors, how advanced they might be, deliver data. Many online sensors deliver a large amount of data. There are

Figure 3 The path from data to decision.

many measurements per milking, sometimes per udder quarter and during many milkings. These data in themselves are not informative. These data should be processed to generate information (**Figure 3**). An example of information is the probability that this cow has mastitis during this milking (alerts). Many algorithms have been proposed, developed, and described to perform this task. A very straightforward example of an algorithm is the use of a threshold: if the measurement is above that threshold, an alert is generated. Because of the low prevalence of the event that has to be detected (clinical mastitis, abnormal milk, or subclinical mastitis), there are high demands on the processing of sensor data. A good algorithm is essential to optimize the online sensor data in an interpretable value. Algorithms can make a huge difference in the performance of a sensor system. Described algorithms include the use of thresholds, moving averages, dynamic linear models (Kalman filters), fuzzy logic, and data mining. The information should finally be processed into action. Many times this latter step is carried out by the herdsman, although there are possibilities to support this with automation (automated decision support).

Because mastitis is associated with many changes in the cow and milk, a combination of more than one sensor has been proven to be useful. For instance, the combination of EC with LDH or SCC measurements has been shown to give better performance than the use of EC, LDH, or SCC alone. A final suggestion is the combination of sensor outcomes with cow-specific information such as mastitis history, age of the cow, and lactation stage. The usefulness of this latter combination is not yet proven.

To evaluate the performance of a mastitis detection algorithm, the alerts created by the algorithm used and sensor output must be compared to a gold standard describing the animal status to be detected (clinical mastitis, subclinical mastitis, or abnormal milk). When comparing the alert with the observation of the gold standard, the time between the alert and the observation of the gold standard is important. In published studies on performance of sensors to detect mastitis, time windows between 0 and 28 days are found. It is obvious that the performance of the sensors improves with a larger time window. However, it should be noted that the usefulness of alerts decreases with increasing time windows.

Besides the development of algorithms to evaluate the outcome of a sensor, for a practical implementation of sensors, it is also important that calibration schemes are made and systems are developed that detect malfunctioning sensors. Maintenance is often underestimated.

Conclusion

Automated online detection of mastitis and abnormal milk is an important subject in the dairy industry, especially because of the introduction of automatic milking systems. Because of the demands for performance, automatic detection systems should be evaluated separately for clinical mastitis, subclinical mastitis, and abnormal milk. EC is the most applied sensor to detect mastitis. The use of EC might be sufficient to produce alert lists for clinical mastitis. The herdsman then has to interpret the results and check cows manually. The use of EC is insufficient to detect and separate abnormal milk automatically. New sensors, measuring the color of milk, SCC, or LDH, are commercially available. These sensors can be especially useful when combining them with EC. The increasing complexity of sensors requires complex algorithms to optimize the utilization of the data measured by the sensors.

Management Control Options

S C Nickerson, LSU Agricultural Center, Homer, LA, USA

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Even though therapy with antimicrobials is beneficial in curing existing infections during lactation and at drying off, the goal of any mastitis control program is to prevent the occurrence of new infections. The dairyman has several management control options that have proven useful in reducing the rate of new cases of mastitis; these include genetic selection for disease resistance, proper nutrition, alleviation of stress, and promoting proper hygiene.

Genetic Selection

Breeding for mastitis resistance is difficult because this characteristic is regulated by genes at numerous loci and is greatly influenced by environmental factors. Likewise, although the resistance is based on the status of the immune system, which is controlled by the major histocompatibility complex (MHC), other genes outside the MHC may also affect disease resistance.

Breeding programs in dairy cows have resulted in great genetic improvement for milk yield but have led to increased susceptibility to mastitis owing to a negative correlation between yield and disease resistance. Assuming a genetic correlation between yield and mastitis of 0.30, mastitis incidence increases ∼0.4% per year as a result of the current trends for milk yield. Although this yearly rate is low, it becomes quite high over the long term; thus, mastitis resistance should be considered in breeding programs.

Somatic cell count (SCC) data are used as an indirect measure of this disease because intramammary infection is associated with an increase in SCC. The genetic correlation between SCC and mastitis is 60–80%; thus, selection for cows with low SCC reduces the incidence of this disease. Somatic cell score (SCS) is a logarithmic transformation of SCC and has been in use as a trait for selection. Disease traits have relatively low heritability; however, reasonable estimates of transmitting ability can be obtained for artificial insemination (AI) bull sires. Based on estimates of genetic variation, the incidence of mastitis in daughters of the worst 5% of bulls would range 10–15% higher than that in daughters of the best 5% of bulls. Thus, consideration should be given to removing bulls from breeding programs when their daughters are predisposed to elevated SCS.

Anatomical mechanisms also play a role in defense against mastitis. For example, pendulous udders are susceptible to inflammation, and selecting against this trait, that is, selecting AI bulls that sire heifers with shallow, well-attached udders, reduces the incidence of the disease. Similarly, cows with short teat canal length and wide canal diameter have higher incidences of mastitis than those with a longer teat canal length and narrower canal diameter. Estimates of heritability for continuous markers such as udder and teat traits are high (**Table 1**). The genetic interrelationship between these traits and mastitis is given in **Table 2**, which indicates that the coefficients of genetic correlation are negative between teat tip to floor distance for all mastitis parameters, suggesting that the shorter the distance (i.e., pendulous udder), the greater the chances for mastitis.

The bovine lymphocyte antigen (BoLA) genes may be suitable markers to include as selection criteria, and associations between specific BoLA alleles and mastitis have been reported. One study reported an association between a bull's breeding value on the progeny test for disease resistance and BoLA Class II alleles, for example, the DQ^{1A} haplotype, which is associated with increased susceptibility to clinical mastitis. Also, cows with BoLA-w16 are susceptible to mastitis, whereas cows with BoLA-w2 are resistant to this disease. In one study, it was concluded that the presence of the BoLA Class I allele CA42 increased the susceptibility of cows to *Staphylococcus aureus* mastitis; however, heritability estimates of susceptibility to *Staph. aureus* infection were low.

Biochemical markers that may be used to predict susceptibility to mastitis are available. The M blood group system may be closely linked to the BoLA system, and its presence is associated with an increased incidence of mastitis. Cows carrying the M-factor (M/M and M/-) exhibit higher frequencies of mastitis than exhibited by cows lacking this factor. Likewise, M-positive cows have higher SCC than that observed in M-negative cows.

Nutrition

Diet plays a role in resistance to udder infection because certain micronutrients affect mammary defense mechanisms such as leukocyte function, and deficiencies in these micronutrients are related to an increase in incidence, duration, and severity of mastitis. Leukocytes are a

[a] Significantly different ($P < 0.01$).

major defense mechanism of the bovine mammary gland, and nutritional effects on leukocyte function can have a profound effect on mammary immunity. Antioxidants have been implicated as critical to the promotion of efficient leukocytes. Following oxidation-dependent bacterial killing, oxygen radicals enter the cytosol, resulting in oxidative damage to the host cell. In response, an array of antioxidant defenses derived from micronutrients protects the host cells. Cytosolic enzymes such as selenium (Se)-dependent glutathione peroxidase (GSH-Px) and copper (Cu)- and zinc (Zn)-dependent superoxide dismutases protect leukocytes from oxidation by degrading the potential substrates for oxygen radical production. Vitamins E and C, and β-carotene also reduce oxygen radicals, augmenting the cytosolic enzyme systems.

The Cu plasma protein, ceruloplasmin, is an acute-phase protein, and cows with clinical mastitis exhibit elevated concentrations of plasma ceruloplasmin as compared with nonmastitic cows. Ceruloplasmin reduces *in vitro* adhesion of activated neutrophils to endothelial cells and scavenges extracellular superoxide as well. Neutrophils from Cu-deficient animals exhibit reduced ability to kill *Staph. aureus.*

Vitamin E and Se supplementation of dairy cattle diets enhances the ability of blood neutrophils to kill ingested *Staph. aureus* and *Escherichia coli.* Whole blood concentrations of vitamin E and Se, and GSH-Px activity tend to be higher in low-SCC herds than in high-herds (**Table 3**) and are associated with reduced incidence of clinical mastitis. In the udder, peak bacterial concentrations in milk and duration of infection were found to be higher in Se-deficient than in Se-supplemented heifers. In addition, milk loss resulting from coliform infection was significantly higher in Se-deficient than in Se-supplemented heifers. Dietary supplementation with vitamin E (50–100 ppm) and Se (0.3 ppm) 60 days prepartum and throughout lactation in addition to an injection of 50 mg Se 3 weeks prepartum reduced staphylococcal and coliform infections at calving by 42.2%; duration of infection by organisms other than *Corynebacterium bovis* was reduced by 40–50%. Clinical mastitis was reduced in early lactation (57.2%) as well as throughout lactation (32.1%), and mean SCC was lower.

Vitamin A is a colorless, fat-soluble, long-chain unsaturated alcohol (retinol) involved in maintaining a functional epithelium (which provides a physical barrier to the entrance of pathogens) and in enhancement of cellular and humoral immunity. β-Carotene (provitamin A) also has been shown to enhance immune function and disease resistance. Results of several studies suggest that the highest incidence of mastitis coincides with a period of poor vitamin A and β-carotene status in dairy cows, and that vitamin A and/or β-carotene play a role in regulating host defense system during periods of increased disease susceptibility. In one study, β-carotene concentrations in healthy cows (SCC $<100 \times 10^3$ cells ml^{-1}) averaged 6.1 μg ml^{-1}, whereas the values in mastitic cows (SCC $>500 \times 10^3$ cells ml^{-1}) averaged 3.66 μg ml^{-1}. Another experiment showed a lower incidence of intramammary infection in cows supplemented with a low level of vitamin A and β-carotene (27% incidence), when compared with cows supplemented with a higher level of vitamin A (50% incidence) alone. Exogenous β-carotene stimulates *in vitro* phagocytosis in blood neutrophils and stimulates killing of *Staph. aureus*. However, phagocytosis or killing of *Staph. aureus* does not differ between phagocytes collected from cows fed adequate vitamin A (53 000 IU day^{-1}), supplemental

Table 2 Genetic correlations between mastitis diagnosis and continuous markers

vitamin A (213 000 IU day^{-1}), or a combination of vitamin A (53 000 IU day^{-1}) and β-carotene (400 mg day^{-1}).

Zinc deficiency leads to increased susceptibility to infections in dairy cattle, and use of organic Zn complexes in the diet has been found to decrease SCC. Zinc is required for the maintenance of a healthy skin and is instrumental in the synthesis of the keratin plug that provides a protective barrier at the teat end against mastitis-causing organisms. Zinc methionine is typically included in the diet to provide 180 mg of Zn and 360 mg methionine, so as to yield 20 ppm of Zn in the diet. The amount of Zn methionine is doubled temporarily to provide 360 mg Zn and 720 mg methionine in herds experiencing elevated SCC. In one study, SCC decreased from 560×10^3 to 282×10^3 ml^{-1}, and in another study, SCC decreased from 242×10^3 to 115×10^3 ml^{-1} owing to a twofold increase in the amount of daily dietary Zn.

Research indicates that supplemented chromium (Cr) may also have immunostimulating properties and some production-enhancing abilities. Dairy cows fed diets supplemented with chelated Cr (0.5 ppm day^{-1}) from 6 weeks prior to calving until 16 weeks postcalving showed significantly higher antibody responses to a number of antigens and a higher lymphocyte proliferation upon mitogen stimulation compared with nonsupplemented controls. In addition, Cr supplementation was associated with increased milk yield, particularly among primiparous cows.

Studies with the iron (Fe) chelator deferoxamine indicate that Fe binding may have a possible benefit in reducing tissue damage resulting from ischemic events in the mammary gland, but the effect of Fe chelator therapy on the severity of acute mastitis remains speculative.

Stress

The dairy industry imposes severe stress on cows: animals calve once every year, are pregnant and lactating for 7 months, and are machine milked 2 or 3 times daily for 305 days. As dairymen demand more from their animals by increasing milk yield and improving efficiency, greater stress is placed upon the productive capacity of the bovine. Hot and humid environmental conditions along with solar radiation, animal crowding, insect pests, and poor ventilation add to this stress and are associated with a reduction in milk production and increased mastitis.

As the environmental temperature and relative humidity rise, heat loss from the cow via radiation, conduction, and convection decreases. Thus, body temperature rises and other mechanisms of heat loss, for example, decreased feed intake, increased sweating and respiration, and behavioral changes become observable in attempts to maintain thermoneutrality. For instance, a cow may seek shade to control radiation, move into the wind to control convection, or lie down in a cold wet spot to control conduction. These mechanisms are necessary to maintain homeostasis but negatively impact feed intake, milk yield, and mastitis resistance.

Thermal stress significantly affects milk yield and indirectly leads to an elevation in mastitis and SCC during the summer months. Mean SCC for the hot summer months of June to August increases dramatically owing to the temperature–humidity index, and there is a carryover effect into the cooler months of September, October, and November.

This seasonal increase is likely owing to differences in exposure of teat ends to bacteria during hot and humid conditions, which favor bacterial growth and teat end contamination. However, herd SCC increases do not necessarily indicate a response of healthy quarters to heat stress, and although various forms of thermal stress cause depression in yields, SCC is not affected in uninfected quarters. Serum corticoid concentrations are elevated, along with circulating leukocytes, in response to heat stress and are known to suppress immune function. These hormones interfere with neutrophil adhesiveness, chemotaxis, receptor activity, lysosomal enzyme release, bactericidal activity, and phagocytosis, which may explain, in part, why incidence of infection is higher during periods of thermal stress.

Flies are vectors of bacterial diseases, and biting flies greatly contribute to the level of stress in a herd of cows and may cause milk production to drop as well as spreading mastitis. Flies are instrumental in the establishment of *Staph. aureus* and coagulase-negative staphylococcal teat canal colonizations in dairy heifers, which lead to intramammary infections with these organisms. Therefore, fly control is especially important during hot, humid weather, when conditions are optimal for insect multiplication.

Methods to Manage Stress

Shade

Trees provide a good source of shade, and their leaves absorb heat from cows' body. However, high cow density can kill trees in a matter of months, and muddy, wet areas around trees where manure accumulates are a good source of environmental mastitis pathogens. In corral systems, locating shade structures over the feed mangers is problematic because cows occupy the area for feeding as well as for shade; thus, the area becomes overloaded with manure, cows become dirty, and mastitis results. Hence, it is recommended that additional shaded areas be provided away from feed mangers.

Cooling

Cows drink 50% more water when the temperature is 26.7 °C, than when it is 4.4 °C. In addition, this elevated temperature requires them to cool themselves through respired moisture and body sweat. Chilling drinking water to 10 °C alleviates heat stress, resulting in increased feed intake, milk yield, and rumen mobility, with decreased respiration and body temperature.

Commercial coolers combine air turbulence and high-pressure water injectors to effectively lower temperature under shades. One study showed that coolers increased milk production by about 10% and lowered the death rate, as cooled cows recovered more rapidly from mastitis when heat stress was tempered. The use of corral manger misters on heat-stressed cows may increase milk production and reduce death loss among fresh cows having had recent cases of mastitis. In humid environments, use of low-speed fans with misting is highly recommended to carry away the humid air.

A shower-and-fanning station adjacent to the milking parlor has been quite successful. Water is sprayed with high-capacity overhead sprinklers for about 30 s every 5 min or with low-capacity sprinklers operating continuously; fans remove the warm humid air from animal surfaces to dry them. Cows can also be wet down again in the exit lane, spraying only the top and sides so that the postmilking germicidal teat dip is not washed off. In this way, cows are temporarily relieved from the sun, and, instead of returning immediately to the shade, they follow their normal cool-weather practice of eating and drinking after each milking. This practice keeps animals on their feet and allows time for teat duct closure before contact with soil and manure, which may lead to mastitis.

Another management strategy for cooling cows and reducing mastitis involves the use of cooling ponds. During periods of maximal heat stress, well water is continuously pumped into ponds and the overflow is carried into contained settling areas. Reduction in mastitis occurs probably owing to enhanced resistance to infection resulting from reduced heat stress, as well as from improved udder preparation afforded by cleaner cows at milking time. Cows from pond access are cleaner upon entering milking parlors and require less premilking preparation. In addition, cows with pond access are less likely to seek relief from the heat by lying down in the mud.

Hygiene

The underlying principle on which the control of mastitis rests involves prevention of the disease. This is best accomplished by minimizing the number of mastitis pathogens to which teats are exposed during the premilking, milking, postmilking, and intermilking periods. Transmission often occurs during the milking process via milker's hands, udder cloths or sponges, and teat cup liners. Microorganisms most likely to be transmitted at this time are contagious pathogens such as *Staph. aureus*, *Streptococcus agalactiae*, and *Mycoplasma* species. Transmission of the environmental streptococci (e.g., *Streptococcus uberis*) and coliforms (e.g., *E. coli)* occurs during the intervals between milkings.

Disinfection of Milker's Hands

Hands are an important means of transmitting mastitis pathogens to the teats of cows. Contamination of hands can occur when stripping foremilk to detect clinical mastitis, handling and attaching teat cups, or touching any contaminated object in the milking center. Rinsing hands in a disinfectant eliminates many mastitis pathogens, but not all. The wearing of disposable, surgical-type, plastic gloves, combined with the practice of rinsing hands frequently in disinfectant, further reduces the transfer of microorganisms during udder preparation.

Disinfection of Teats and Predipping

The primary objective of premilking udder preparation and teat sanitation is to achieve an acceptable level of decontamination, which reduces the spread of microorganisms and the incidence of mastitis. It is important to use a minimum amount of water, if any, and to concentrate attention primarily on cleaning and sanitizing only the portion of the teats actually touched by teat cup liners. Forestripping, or the removal of 2–3 ml of milk prior to machine attachment, reduces new infections by flushing mastitis organisms from teat canals. Teats should be dried subsequently with single-service paper or cloth towels prior to teat cup attachment. If water is present on the flanks or udder of cows, it drains down and pools at the top of teat cup liners, collecting additional microorganisms and leading to mastitis.

Predipping is a practice in which teats are immersed in a germicide (such as iodophor, chlorhexidine, and sodium chlorite) prior to milking to reduce the mastitis-causing bacterial load on teat skin. Recommended predipping procedure is as follows: clean the teats, forestrip, predip, wait for 20–30 s as recommended by the product manufacturer, dry teats with a single-service paper towel or a clean cloth towel, and attach the teat cups. Research on predipping has shown that the incidence of new infections caused by environmental streptococci and coliforms is reduced by about 50%. Care must be exercised to prevent germicide residues from contaminating the milk supply, but if the teats are dried carefully after predipping, the amount of additional residue present in the milk is negligible.

Adjusting Milking Units and Teat Cup Removal

During milking, units should be observed closely while attached to the udders to ensure that they are adjusted correctly and to aid in preventing liner slips. Liner slips are the result of improper liner design, absence of hose support arms, overmilking of individual quarters, milking wet teats, milking short or small teats, cluster weight, vacuum level, and vacuum fluctuations. If liner slips occur at the same time the liner opens, milk droplets impact against the teat end, which may contain mastitis-causing organisms and penetrate the teat canal. Also, teat cups seated excessively high on teats cause irritation to the lining of the teats and may contribute to the development of mastitis.

At the end of milking, the goal should be to remove the teat cups just as the last quarter milks out, but the vacuum should always be shut off before detaching teat cups; an increased risk of infection exists when teat cups are removed while under vacuum.

Postdipping

If the incidence of mastitis is to be reduced, it is important that the vast majority of organisms present on teats after milking be destroyed. The dipping of teats after milking (postdipping) in a suitable germicidal product (such as chlorhexidine, iodophor, and sodium chlorite) is the single most important practice to prevent new intramammary infections, especially those caused by contagious pathogens such as *Staph. aureus* and *Strept. agalactiae.* The correct application of a good teat postdip will reduce the rate of new infection by at least 50%.

Teat spraying is as effective as teat dipping if it is done properly, but, to be as effective, the entire barrel of the teat contacting the teat cup liner must be covered with germicide. This is rarely accomplished because milkers usually apply teat spray only on one side of the teats rather than to the entire surface. Moreover, teat spraying requires more time and more disinfectant than required by dipping; thus, most authorities recommend dipping rather than spraying.

The two basic types of teat dips are germicidal and barrier products. Germicidal products enjoy the major share of the teat dip market, and products are highly effective in reducing populations of mastitis organisms remaining on teats at the end of milking. The persistency of germicidal activity is limited when used as a postdip, however, because it is partially neutralized by milk and by organic matter in the environment. The theory behind barrier teat dips is that they form a physical obstruction between the teats and the environment, thus reducing infections during the intermilking period, especially with microorganisms of environmental origin.

Disinfection of Teat Cup Liners

Teat cup liners are a potential means for spreading microorganisms both within and among cows. One method for reducing the number of microorganisms is to immerse teat cups into a disinfectant two at a time to permit the disinfectant solution to have contact with the full length of the liners. However, the most effective method for disinfecting liners between cows is backflushing, which incorporates a water rinse to flush milk residues from the inside surface of the liners, claw, and milk hose; a rinse with a disinfectant solution; a short time delay to destroy microorganisms; another rinse with water to remove disinfectant residues; and a blast of air to remove residual water.

Importance of Excellent Environmental Hygiene

Regardless of whether cows are placed in pastures, open corrals, free stalls, open housing, or other types of housing, with or without bedding, the provision of a clean and comfortable environment will increase milk production, assist with maintaining a healthy immune system, and reduce mastitis. When cows lie down in their environment, teats are exposed to mastitis pathogens, especially *Strept. uberis* and *E. coli*, which may be present in concentrations ranging from 1000 to 1 billion per gram of bedding. Udders should be clipped or singed as necessary to remove long hair and to reduce the amount of bacteria in adhered dirt, manure, and bedding.

Conclusion

The objective of a mastitis control program is the prevention of new infections. In efforts to (1) breed dairy cows for disease resistance, (2) supply appropriate nutrition including micronutrients, (3) reduce the level of environmental stress imposed, and (4) provide proper milking time hygiene, the dairyman is taking the necessary steps to reduce the susceptibility of his herd to mastitis-causing bacteria, promote herd health, and increase milk quality.

Introduction

The control of bovine mastitis is best accomplished by a preventative program including pre- and postmilking teat antisepsis, proper maintenance of milking equipment, control of environmental exposure to mastitis pathogens, management of environmental stress on animals, and vaccination against certain pathogens. Despite the proven effectiveness of these procedures, new intramammary infections (IMIs) will occur and must be managed properly to prevent a herd mastitis problem from developing.

Once an infection is established, the task is to eliminate the infection from the individual cow, if possible, and to protect other cows in the herd from infection. Options for eliminating infections from the herd include (1) culling of infected animals, (2) treating with antibiotics during lactation, (3) treating with antibiotics at the beginning of the dry period, and (4) supportive care and management of the infection to enhance spontaneous cure. Of these, antibiotic therapy is the principal method used to treat IMIs.

The primary aim of antibiotic therapy is to cure the existing infection and return the cow to profitability as soon as possible. Additional goals include reducing the sources of new infection in the herd, preventing existing chronic cases from worsening, preventing cow mortality in severe cases, minimizing damage to secretory tissue, and preventing new infections from developing during the dry period.

Treatment during Lactation

When mastitis occurs during lactation, the dairy farmer can hope for a spontaneous cure, cull the infected animal, treat the infection during lactation with antibiotic therapy, or terminate lactation early and treat with a nonlactating cow antibiotic preparation.

Factors to consider in deciding whether to treat during lactation include the economic worth of the cow, whether the organism is one that can reasonably be expected to respond to treatment, and whether the risk of antibiotic residues in milk can be minimized to an acceptable level.

Therapy of *Streptococcus agalactiae*

Treatment in lactation is always indicated when cows are infected with *S. agalactiae*. This organism is highly contagious and is spread from cow to cow during milking. Fortunately, this organism responds well to antibiotic therapy during lactation, with cure rates usually in the range 90–95%. This organism is generally considered to be susceptible to all of the antibiotics commercially available to treat mastitis.

Identification of all infected quarters in the herd is of paramount importance when treating a *S. agalactiae* problem. If infected cows are left untreated, they will serve as sources of bacteria for infecting other cows. Because of this, *S. agalactiae* is often treated by 'blitz' therapy whereby all infected cows are treated in all quarters simultaneously in an attempt to eliminate all infections from the herd. This procedure can be effective; however, care must be taken to ensure that all infected quarters are treated and follow-up culturing is performed to identify treatment failures. Those cows failing to respond to therapy should be culled from the herd. In addition to antibiotic therapy during lactation, in herds infected with *S. agalactiae*, strict milking time hygiene, effective teat dipping program, and dry cow antibiotic therapy must be followed on all quarters of all cows at the end of each lactation.

Therapy of *Staphylococcus aureus*

Staphylococcus aureus is another contagious mastitis pathogen that is spread during milking. Unlike *S. agalactiae*, however, *S. aureus* does not respond well to treatment during lactation. Conventional therapy with commercially available mastitis preparations generally results in cure rates between 20 and 30% following label instructions. Because of this poor success, it is generally not recommended to treat *S. aureus* mastitis during lactation. This organism is best treated during the dry period with an approved dry cow antibiotic. There are times, however, when it becomes necessary for the dairyman to consider treatment of *S. aureus* infections during lactation. When high somatic cell counts (SCCs) threaten the milk market and other options such as culling and early dry-off have been exhausted, it may be necessary to attempt treatment of *S. aureus* infections during lactation.

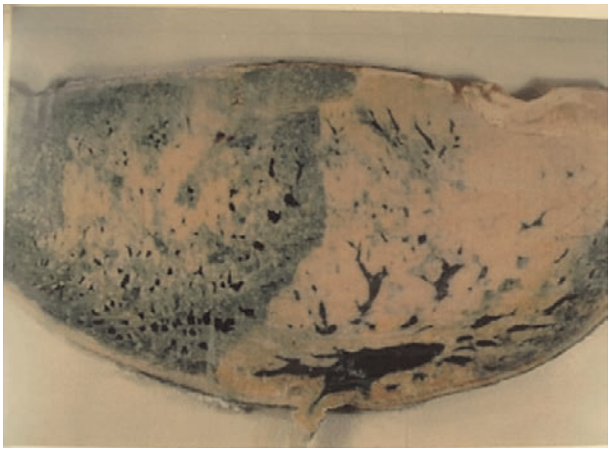

Figure 1 Cross-sectional view of a mammary gland chronically infected with *Staphylococcus aureus*. The gland has been infused with green dye and the unstained areas indicate portions of the gland inaccessible to antibiotic due to blockage of milk ducts.

The poor response of *S. aureus* to lactational therapy is believed to be caused by the combination of several factors. This organism tends to produce a chronic type of mammary inflammation, with foci of infection deep within the mammary tissue, resulting in scarring, clot formation, and swelling. This in turn results in the occlusion of milk ducts draining the infected area, which impedes the distribution of infused antibiotic to the site of infection. Contact between the antibiotic and the infecting bacteria is minimized, and thus treatment failures occur. **Figure 1** shows a cross-sectional view of a mammary gland chronically infected with *S. aureus*. The gland has been infused with green dye and the unstained areas indicate portions of the gland inaccessible to antibiotic due to blockage of milk ducts. To enhance the effectiveness of antibiotic therapy against *S. aureus*, several new strategies that increase the chances of cure have been devised (discussed below).

Combination Therapy

A combination of intramuscular injections together with intramammary infusions has resulted in much higher tissue antibiotic concentrations and a higher cure rate. In one study, 49 cows with 78 quarters subclinically infected with *S. aureus* were tested. One group of cows received intramammary infusion at each milking for six milkings with a lactating cow product containing 62.5 mg amoxicillin. Another group of cows received the same intramammary infusion regimen plus intramuscular injections of 6 million units of procaine penicillin G after each milking for 3 days.

The combination of intramammary and intramuscular treatment cured 51% of quarters compared with 25% of quarters treated by intramammary infusion alone. Thus, combination therapy was twice as effective as conventional infusion alone, and it allowed more antibiotic to penetrate deep areas of infection, and increased the cure rate. The SCCs taken prior to initiation of therapy from milk of cured quarters averaged 2 500 000 ml^{-1} and they were less than SCCs from quarters that failed therapy (4 000 000 ml^{-1}). By 8 days after treatment, SCC for cured quarters was 340 000 ml^{-1} compared with 1 900 000 ml^{-1} for failed quarters, and at 21 days, SCC was 224 000 ml^{-1} for cured compared with 1 975 000 ml^{-1} for failed quarters.

Extended Therapy

Another alternative for enhancing cure rates when treating chronic mastitis involves the use of pirlimycin hydrochloride and is called extended therapy. Pirlimycin has excellent activity against *S. aureus* and it penetrates scar tissue quite well. Approximately 50% of the drug is absorbed from the udder into the bloodstream and 50% of that amount is then re-excreted back into the udder. This helps the drug in reaching infected tissues.

A treatment protocol using three series of on-label treatments, separated by 36-h milk discard periods, was developed. Milk was salable for human consumption 36 h following the third series of treatments. In one investigation in a research herd using the three-treatment regimen, the drug was administered to quarters that had failed repeated therapy attempts. The results showed that 41% of quarters were cured. In a second investigation using a commercial dairy herd in which extensive treatment of subclinical *S. aureus* infections had not been practiced during lactation, 86% of quarters were cured using the three-treatment regimen. The SCCs were monitored in the infected quarters in both investigations, and a decrease from 3 400 000 to 280 000 ml^{-1} was observed by 10 days after treatment in quarters that cured. Similar improvement in cure rates using this treatment regimen was noted with a penicillin–novobiocin product, but no improvement was seen with this regimen using an erythromycin-containing product.

Combining Antibiotic Therapy with Vaccination

More recently, vaccination has been employed to amplify the cow's immune system against *S. aureus* antigens and augment the effectiveness of antibiotic therapy. In one study, vaccination in combination with intramammary therapy was evaluated over a 1-year period in a 48-cow herd with a *S. aureus* prevalence of 58.3%. After selected *S. aureus*-infected cows were dried off or culled, 20 animals were vaccinated at 2 and 14 days prior to antibiotic therapy. Vaccinations were subcutaneous in the area of the supramammary lymph node with a bacterin containing an encapsulated strain of *S. aureus* plus an autogenous strain isolated from the herd. Each cow was then treated using extended therapy with pirlimycin as described above and vaccinated again 7 days later. The results demonstrated that all but three quarters responded to this vaccine/treatment program, and by 5 months after trial initiation, *S. aureus* was eliminated from the herd. The herd SCC was reduced to $492 \times 10^3\,\text{ml}^{-1}$ 1 year later. All herds would not be expected to exhibit this degree of success, but this strategy may be extremely useful for certain *S. aureus*-infected herds.

No matter what treatment strategy is used, the probability of curing existing infections is reduced under the following conditions: older cows, high SCC, rear quarters infected, cows in early- to mid-lactation, and presence of multiple quarter infections within an udder. Because of the low probability of cure, it is important for dairy producers and veterinarians to take great care in selecting *S. aureus*-infected cows for treatment in lactation.

Therapy of Acute Clinical Mastitis

Acute clinical mastitis is characterized in the cow by systemic symptoms resulting from the toxic effects of the bacteria causing the infection. The primary cause of this severe form of mastitis is the coliform group of organisms including *Escherichia coli* and *Klebsiella pneumoniae*. These Gram-negative bacteria produce endotoxin, which results in systemic symptoms typified by dehydration, depression, inability to stand, diarrhea, and shock. Therapy must be directed toward alleviating these symptoms and countering the effects of the endotoxin. In most cases, the bacteria reach very high numbers in the mammary gland quickly and then die off rapidly. Often the bacteria that are responsible for the infection are no longer viable when symptoms begin to become apparent, resulting in cultures that are negative for bacteria despite obvious clinical symptoms. As the bacteria die, the endotoxin component of their cell wall is released and this causes the toxic effects. Because the bacterial cause of the symptoms is often no longer present, antibiotic therapy is often of little or no benefit. Therapy must be supportive and directed to counter the effects of the endotoxin in the bloodstream, and includes frequent stripping of the quarter and administering electrolytes, anti-inflammatory agents, glucose, bicarbonate, and calcium. Often large amounts of fluids are needed, and severely affected cows may require 40–60 l of fluids to be administered intravenously on the first day of the onset of symptoms.

Care must be taken when using anti-inflammatory products to manage toxemia, inflammation, and shock associated with acute clinical mastitis. Products such as prednisone, prednisolone, methylprednisolone, and isoflupredone can be effective but should be administered for no longer than 2 or 3 days. These products can suppress the immune system and can induce premature calving, retained placenta, and uterine infection when used in the third trimester of pregnancy.

Oxytocin is another product that may be considered as an adjunct to therapy of acute clinical mastitis. This hormone is normally released from the brain into the bloodstream in response to milking stimuli. Oxytocin causes contractions of the alveoli in the mammary gland, resulting in expulsion of milk. The therapeutic administration of exogenous oxytocin is believed to cause additional contraction of alveoli in infected and inflamed mammary tissue, resulting in increased expulsion of clots, bacteria, inflammatory products, and toxins.

The therapeutic recommendations for oxytocin include frequent stripping of infected quarters (6–8 times per day) following oxytocin administration (40–50 units intramammarily). Clinical studies with oxytocin have yielded variable results. Often a clinical response is noted initially only to be followed in some cases by relapse. In one study, relapses were observed more often in clinical cases caused by environmental streptococci than by coliforms.

Therapy of Subacute Clinical Mastitis

The majority of clinical mastitis cases do not progress to the acute toxic form discussed above and are characterized as subacute. In most clinical cases, the milk is visibly abnormal and exhibits clots, flakes, or a watery consistency. The quarter may be swollen, but no systemic signs are apparent.

Antibiotic therapy with an approved infusion product is generally recommended for cases of subacute clinical mastitis. Therapy should be continued for a minimum of 3 days and should continue for at least 1 day beyond obvious clinical improvement. Discontinuation of therapy too soon can result in relapses that may evolve into chronic cases that will not respond to further treatment. Successful antibiotic therapy of clinical mastitis is dependent on several factors including the severity of the infection, how long the infection has persisted, the organism causing the infection, and the overall health of the cow.

Culture of the milk from the infected quarter to identify the causative organism is important in cases of clinical mastitis. Knowing which organisms are present can help determine which treatment procedures have the best chance of success. If routine culture methods fail to identify the cause of the infection, alternative culture techniques may be necessary. Often mastitis pathogens are present in low numbers in clinical cases and routine culture methods are not sensitive enough to detect the organisms. Alternatively, some mastitis pathogens require specialized media and culture conditions. The coliform organisms that are responsible for many clinical mastitis cases are often present in detectable numbers for the first

12–18 h of an infection. Milk samples collected after this time often contain no or very low numbers of these pathogens, resulting in culture-negative clinical samples. Increasing the volume of milk cultured can enhance the recovery of pathogens present in low numbers. The presence of numerous culture-negative milk samples (50%) may indicate the presence of *Mycoplasma* species. These organisms cause a highly contagious type of mastitis that is unresponsive to antibiotic therapy. *Mycoplasma* species will not grow on routine culture media and require specialized media, enhanced CO_2 atmosphere, and typically 5–10 days to grow.

Treatment at Dry-Off

Dry cow therapy is a major component of a comprehensive mastitis control program. Infusion of an approved dry cow antibiotic into every quarter of every cow at the end of each lactation is the most effective use of antibiotic therapy against mastitis. The advantages of dry cow therapy are as follows: cure rates are higher than for treatment in lactation, higher concentrations of antibiotics can be used, the incidence of new infections is reduced, number of clinical mastitis cases at calving are reduced, salable milk is not discarded, unrecognized infections are treated, laboratory culturing is not required, and damaged tissue has time to redevelop prior to the next lactation if therapy is successful. Treatment at dry-off not only treats existing infections, but also provides protection from new infections during the early dry period. Some dairy farmers use selective dry cow therapy in which they treat only quarters of cows with known cases of mastitis. This often proves to be false economy because it is difficult to know the presence of all infections in a herd and some undiagnosed infections will go untreated. Also, the protection from new infections that may occur in the early dry period is lost when no dry cow therapy is administered. Research has shown that treatment of all quarters of all cows is the most effective method for using dry cow antibiotics. Some concern has been expressed that the constant exposure of microorganisms to the antibiotics commonly used to treat mastitis will encourage the emergence of strains of bacteria that are resistant to these antibiotics. However, despite widespread use of these products for many years, no evidence of resistance development associated with these practices has emerged.

Recently, a new procedure for dry cow treatment has been developed, called teat sealing. An inert paste-type product made of 65% bismuth subnitrate in heavy liquid paraffin is infused into the gland at dry-off. The product forms an inert seal in the lower portion of the teat cistern and in the teat canal, and this prevents new IMIs by serving as a physical barrier. Data indicate that the product is effective at preventing new IMIs when used in uninfected mammary glands.

Current recommendations are to use this product immediately after administration of a dry cow antibiotic product, and is not intended as a replacement for dry cow antibiotic therapy. Also, care must be taken at calving to ensure complete removal of the sealant before returning the cow to the milking herd.

Heifer Mastitis

The realization in recent years that dairy heifers are at risk of contracting mastitis prior to their first lactation has led to research aimed at treating and eliminating these infections during the prepartum period. The results of this research indicate that IMIs present in dairy heifers respond well to administration of nonlactating cow antibiotic preparations infused intramammarily >45 days prior to calving. The staphylococci are the predominant organisms isolated from heifer secretions and *S. aureus* can account for a substantial number of these infections. Left untreated, these infections may persist into the first lactation where they become much more difficult to cure. In addition, the presence of IMI prior to and during the first lactation can damage developing mammary tissue, reducing potential milk production in subsequent lactations.

Cure rates for *S. aureus* IMI in heifers treated prepartum with approved dry cow products exceed 90%. Prepartum therapy of heifers is more effective, in part, due to the smaller volume of tissue in the developing heifer mammary gland compared to the adult cow, which results in much higher concentrations of antibiotic and greater contact with the infecting bacteria. **Figure 2** shows a cross-sectional comparison of a heifer gland relative to that of an adult cow. Recent research aimed at determining the

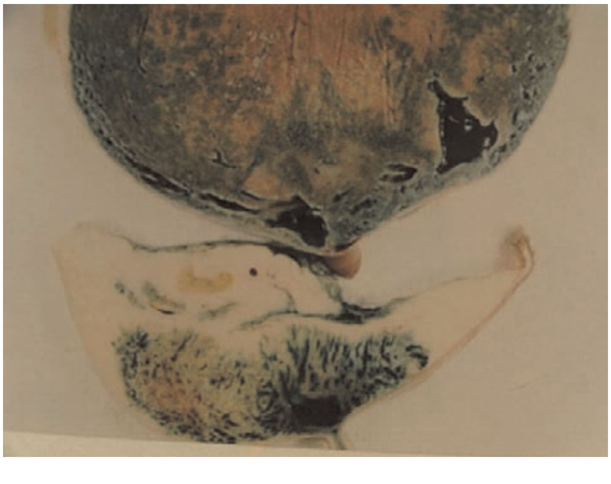

Figure 2 Cross-sectional comparison of a heifer gland to an adult cow.

optimum time prepartum to treat heifers found no difference in treatment efficacy when treatment was administered during the first, second, or third trimesters. However, treating during the third trimester resulted in fewer new infections occurring after treatment and prior to calving, suggesting that treatment in the third trimester reached the most infections. Dry cow treatment of heifers is an effective way to control *S. aureus* mastitis in herds with high numbers of heifers calving with mastitis. If a problem is suspected, secretion samples should be collected from a representative number of heifers and cultured to determine if the problem exists and if therapy is warranted.

Treatment Procedures

Care must be taken to follow correct procedures when infusing antibiotics into the mammary gland via the teat end. A cotton ball soaked in 70% alcohol or a prepackaged alcohol pledget is used to thoroughly cleanse the teat end prior to infusion. The teat end often contains large numbers of bacteria that may have originated from the environment; these organisms can be pushed into the mammary gland via the treatment syringe cannula during treatment if the teat end is not properly sanitized. Some of these organisms such as *Nocardia* spp., *Bacillus* spp., *Prototheca* spp., and fungi can cause severe mastitis that does not respond to antibiotic therapy.

It is recommended that gloves be worn when treating cows if highly contagious microorganisms, such as *S. agalactiae* or *Mycoplasma bovis*, are present in the herd. In addition, hands should be dipped in a sanitizing solution between treating animals.

The method of drug infusion can actually cause mastitis by inadvertently introducing microorganisms through the teat canal. Full insertion of the conventional mastitis tube syringe cannula can result in temporary dilation of the teat sphincter muscle. In addition, the keratin plug that normally occludes the teat canal is either pushed aside or partially removed. Both of these situations create a larger than normal teat canal opening, allowing entry of microorganisms. The syringe cannula may also push microorganisms that are colonized in keratin into the teat cistern. If microorganisms gaining access to the teat cistern by these routes are resistant to the infused antibiotic, then a new infection may result, which may be more severe than the one for which treatment was intended.

Studies designed to compare conventional full insertion with partial insertion of only the first 2–3 mm of the cannula tip at drying off have demonstrated that mastitis at calving was reduced markedly by using the partial insertion technique. Several types of syringe cannulas have since been developed to aid in inserting only the tip of the cannula into the teat canal and to form a seal against the teat opening to provide support during infusion. The use of the partial insertion technique may reduce new infections by major mastitis-causing microorganisms at calving by 50% or more.

Treated animals must be clearly identified in some obvious manner with neck chains or leg bands. In addition, they should be kept separate from untreated animals to aid in preventing their milk from being commingled with milk from untreated animals.

Role of Milking Machines in Control of Mastitis

F Neijenhuis, Livestock Research, Lelystad, The Netherlands

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Machine milking plays a role in the incidence of mastitis. The milking machine is an important vector of bacteria, both between cows and within the cow, from teat to teat, and can play an active role in the penetration of bacteria into the teat canal, teat sinus, or gland sinus, and may cause trauma to the teat rendering it more susceptible to colonization and infection (**Table 1**). With the current knowledge, it is not possible to quantify the effects of the different infection mechanisms on new intramammary infection (*see* **Milking Machines**: Principles and Design).

Transfer of Bacteria

The milking process offers multiple opportunities for bacteria to be transferred between cows and quarters. The number of pathogenic bacteria on the teat skin and particularly the teat orifice will affect the rate of new infections. Bacteria may be transferred from one cow to another and between quarters via the hands of the milker, liners, clusters, and towels (**Figure 1**). Poor barn hygiene in between milkings and improper teat preparation increase contamination and transmission of bacteria (*see* **Milking and Handling of Raw Milk**: Milking Hygiene).

During milking, vacuum fluctuations in the claw cause milk to move between teat cups. If the cow being milked has one or more infected quarters, this process transfers pathogenic bacteria to the surfaces of other teats. After a cow has been milked, the liner surfaces carry bacteria originating from the teat surface and milk of that cow. These bacteria are transferred to the next cow when the machine is applied. Mastitis-infected cows should be milked last or in separate milker units used only for infected cows.

Proper premilking teat preparation and the use of predipping can lower the number of bacteria at the teat end. Teat cup flushing between milkings can reduce the amount of bacteria on liners and claws; however, the effect on new infection rate is not clear (*see* **Mastitis Therapy and Control**: Management Control Options and **Milking and Handling of Raw Milk**: Milking Hygiene).

Increase Bacterial Penetration of Teat Duct

The action of the milking machine can cause bacteria to be propelled directly from the exterior of the teat into the teat sinus. Vacuum fluctuations in the claw can cause impacts: air and droplets of milk, including pathogens, are propelled toward the teat tip. The impact mechanism is the only known means by which vacuum fluctuations are capable of increasing infection rate under both experimental and field conditions. Vacuum fluctuations can be characterized in terms of rate of change and magnitude and are the result of milk flowing in the system, pulsation, and admission of air. Large fluctuations in vacuum have earlier been shown to increase intramammary infections, but the rate of change and magnitude were not well defined in these older studies.

During cluster attachment or removal, air is admitted through the teat cup and this air is sucked toward the claw. Liners should be applied to teats with minimal vacuum leakage by keeping the short milk tube bent over the claw ferrule until the liner slides onto the teat. Cluster takeoff should be done after vacuum shutoff. Liner slippage is an important cause of vacuum fluctuations, which occurs primarily at the end of milking. The long milk hose should be adjusted during the milking process to avoid liner slippage and/or uneven milkout. Milking with high vacuum and the use of liners with a good grip on the teat result in less liner slippage. Some udder and teat conformations increase the probability of liner slip: rear quarters lower than front quarters, wider teats, larger teat diameters, and longer teats.

Vacuum stability in milkline systems can be achieved by using adequate claw air bleeds, pipeline diameters, claw volume, vacuum pump capacity as well as a well-functioning vacuum regulator. Shields in the liner or valved claws intercepts impact and reduce new infection rates. However, they have never been a success in practice.

Besides factors associated with the milking machine, factors related to the cow also play a role; for example, quarters with a high peak flow rate ($>1.6\,\mathrm{kg\,min^{-1}}$) are more susceptible to infection probably because of larger teat canal diameter.

Besides vacuum fluctuations, reverse pressure gradients (RPGs) between liner space and teat cistern may cause milk contaminated with pathogens to move from the exterior into the teat, but the effect of this mechanism is not known.

Table 1 Machine milking mechanisms potentially affecting new infection

Mode of infection	*Main milking-related mechanisms*	*General evidence*
1. Transfer of bacteria	Transfer of bacteria from (a) Environment to teat (b) Cow to cow (c) Teat to teat (same cow)	Teat disinfection reduces bacterial numbers on the teat skin and orifice and decreases new infection rate (NIR) Experimental bacterial challenges increase NIR
2. Increase bacterial penetration of teat duct	By causing impacts of bacteria-laden milk droplets and dispersing pathogens from (a) Teat canal to the teat sinus (b) Teat sinus to the gland sinus and/or ducts	Endotoxin, *Escherichia coli*, and dyes have been jetted through the teat canal Shields or valves reduced NIR High-velocity air/liquid flows toward the teat end increased NIR Few infections occur if bacteria placed within the teat sinus are carefully removed by stripping but bacteria placed within the gland sinus frequently cause NIR In some experiments, presquirting of teats before milking reduced milking
3. Frequency and/or degree of udder evacuation	By changing (a) Susceptibility of the gland to invading pathogens (b) Concentrations of pathogens on the teat end (c) Duration of exposure to pathogens	NIRs are higher in dried off cows at the start of the dry period Incomplete milking or omittance of milking tends to increase NIR
4. Resistance of teat to bacterial invasion	By affecting (a) Teat canal integrity (b) Teat congestion and/or edema (c) Increasing skin and/or orifice lesions	NIR is increased by reaming keratin from the teat canal and by visible teat canal injuries NIR is increased when pulsation is ineffective Clinical mastitis is increased with increasing teat end callosity or lesions

Adapted from Bramley AJ, Dodd FH, Mein GA, and Bramley JA (1992*) Machine Milking and Lactation*. Berkshire, UK: Insight Books; IDF (1987) Machine milking and mastitis. *International Dairy Federation Bulletin No. 215*.

Frequency and/or Degree of Udder Evacuation

Good premilking procedures and adequate lag-time before attachment of the teat cups will allow cows with a milk yield of 10 kg milk per milking to milk in about 5 min (±0.5 min). To make optimum use of milk letdown and to ensure that milking of empty teats is avoided, the lag-time between first teat manipulation during premilking treatment and applying the teat cups must be 30–90 s. Attachment of teat cups, before milk letdown occurs, results in teat cup crawling up during the first minutes of milking and less complete and efficient harvest of milk.

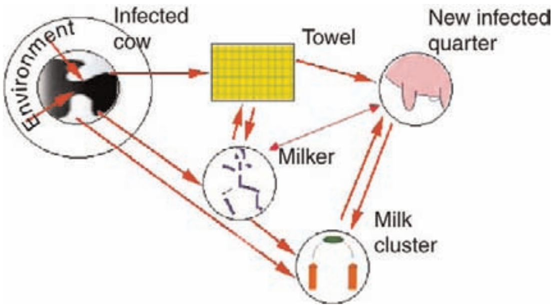

Figure 1 Role of machine milking in the transmission of bacteria.

Cases of poor type or condition of the liner, mismatch between claw inlet and short milk tube, a too light cluster, not evenly hanging cluster, high milking vacuum levels, or malfunctioning pulsators may lead to inadequate milk removal and this incompleteness of milking can cause problems. Incomplete milking or omitted milking tends to increase new infection rates or the progression of subclinical infections to clinical stage. Many bacteria are removed by the flushing action of milk as it moves through the teat duct during milking.

Increasing cluster weight and the use of a mechanical device to align the unit squarely on the udder reduce strip yields. Early removal of the milking unit (at a flow rate of 400 vs. 200 g min^{-1}) does not affect milk yield or composition, and the incidence and prevalence of subclinical mastitis, but machine-on time is shortened and teat condition improved.

Although overmilking can damage the epithelial lining of the teat sinus as a result of teat tissue being rubbed together during liner collapse, little teat damage occurs from moderate overmilking when milking machines are installed correctly and operated properly. Overmilking in combination with inadequate pulsation, high vacuum, or excessive vacuum fluctuation increases new infection rate.

Resistance of Teat to Bacterial Invasion

Teat Condition

The teat canal is a strong and important primary barrier against invasion of mastitis pathogens into the udder. Teat tissue changes by machine milking can be seen as teat swelling (teat end, base, or top), teat flattening, color changes, openness of the teat orifice, vascular damage (hemorrhages), teat lesions, teat end callosity, and loss of teat canal keratin (*see* **Mammary Resistance Mechanisms**: Anatomical).

Changes of the teat canal integrity and teat tissue pliability may favor penetration of bacteria into the udder. Trauma to the mucous membranes lining the teat sinus may provide an environment favoring bacterial colonization or multiplication. Local pain may lead to neurohormonal responses that suppress immune function and increase the likelihood of disease.

Teat swelling

Vacuum opens the teat canal and milk flows out but also blood and lymph are drawn into the teat tissue. The collapsing liner exerts a mechanical force on the teat end (compressive load), causing the teat canal closure and transport of blood and lymph back to the udder.

During milking, the thickness of the teat ends decreases during the high flow rate phase, increases during the low flow rate and overmilking phases, and again decreases as soon as milking is finished. The differences in the increase of teat end thickness are influenced by overmilking, use of wide-bore liners, high vacuum, pulsation failure, insufficient rest phase of pulsation, short A- and C-phases of pulsation, or liner mouthpiece chamber. Vacuum level seems to have a greater effect than the duration of milking.

For teats milked without pulsation or with liner-less teat cups, the increase in teat end thickness is significantly greater than for conventional liners and pulsation settings. Decreases in teat end thickness have been observed for positive pulsation, calf suckling, and hand milking. Milking with narrow-bore liners that have a soft mouthpiece lip reduces congestion and edema. It is generally agreed that the internal diameter of the liner should be at least 1 mm smaller than the average teat diameter in a herd before milking.

Teat orifice openness

Factors associated with greater openness of the teat orifice include high milking vacuum, overmilking, design of the liner mouthpiece, or unusually heavy cluster weight, or excessively high mounting tension of the liner.

Teat lesions

Injured teat skins are a common site for bacteria and viruses to multiply. Bacteria, in particular *Staphylococcus aureus*, *Streptococcus agalactiae*, and *Streptococcus dysgalactiae*, are often associated with teat lesions. The risk of infection is amplified when lesions are at, or near, the teat orifice.

Overmilking, pulsation ratios above 70%, inappropriate housing conditions, and insufficient hoof care are associated with an increased incidence of teat lesions. The associations of pulsation ratio and overmilking suggest that factors that predispose to teat end edema and/or irritation during milking might cause teat lesions.

Vascular damage

The proportion of teats with petechial hemorrhages gives an indication of the extent of any vascular damage. Vascular damage usually reflects some type of pulsation failure, wide pulsation ratios (>80%) often associated with high vacuum and/or prolonged overmilking.

Teat end callosity

The long-term effects of repeated use of the milking machine are changes in teat end tissue, resulting in a callous ring around the teat orifice. Changes in teat end tissue result from mechanical forces exerted by vacuum and the collapsing liner during machine milking. Teat end callosity increases during lactation and parity. High-yielding cows are more often affected, probably because machine-on time is longer. The differences between farms can be explained in part by the differences between the cows and in part by the differences in the characteristics of the milking machine and management like use of high vacuum, wide pulsation ratios, use of teat dip, and so on.

Most of the systems that have been developed to classify teat end condition either do not differentiate between smooth and rough callosity rings or do include scabs or lesions. The adapted classification system of The Netherlands shows marked differences in the thickness of the callosity ring, which is transformed into five classes: none (N), slight (A), moderate (B), thick (C), and extreme (D). Additionally, the ring is classified as smooth (1) or rough (2) (**Figure 2**). A more practical classification is to define teat end callosity into four categories: none (N), smooth (S), rough (R), and very rough (VR).

Teat end callosity involves hyperkeratosis (stratum corneum) (**Figure 3**). Thicker callosity rings show parakeratosis and nuclei are observed in the cells. Teats with a higher score of teat end callosity show perivascular reaction: infiltration of lymphocytes, granulocytes, or erytrocytes.

With thick callosity, the outside portion of the teat canal cannot close tightly and microorganisms may penetrate the teat easily. On rough callosity, it is easier for bacteria to anchor and reproduce, contributing to the incidence of mastitis. Mild hyperplasia is a basic physiological response to the forces imposed by milking.

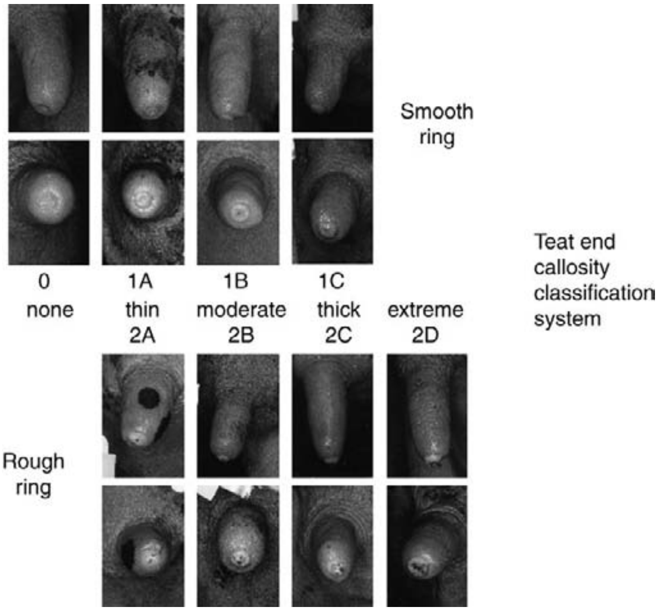

Figure 2 Teat end callosity classification system. Adapted from Neijenhuis F, Barkema HW, Hogeveen H, and Noordhuizen JPTM (2000) Classification and longitudinal examination of callused tead ends in dairy cows. *Journal of Dairy Science* 83:2795–2804.

Teat canal keratin

Milking removes keratin out of the teat canal, and this may adversely affect teat canal defense as keratin has a protective role. Loose keratin traps invading bacteria and these are removed by the flushing action of milking. Up to 40% of the keratin is lost from the teat canal wall during milking. The loss is greater for milking with pulsation than for milking without pulsation. But milking without pulsation increases new infection rates, apparently removing an inadequate amount of keratin. Higher losses of keratin can also increase new infection rates, as occurring in very high flow rates. Under the right milking conditions, there will be a healthy balance between the degree of desquamation per milking and the rate of regeneration.

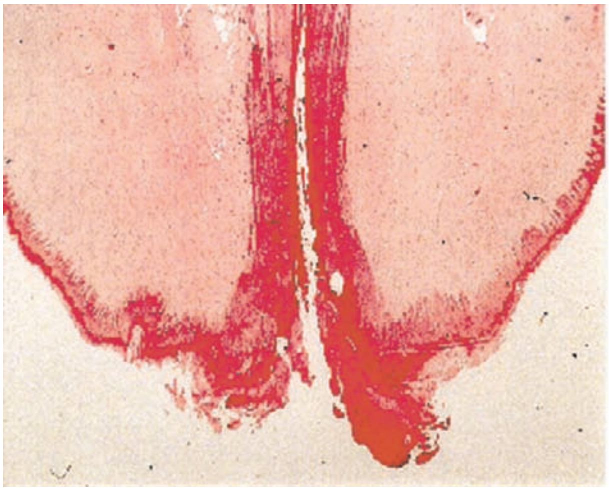

Figure 3 Microscopic view of a teat end with a thick rough callosity ring (2C). Courtesy of Dr. A de Man, Dr. YH Schukken, and Dr. JP Koeman, Utrecht University.

Practical guide to teat condition

An international group of teat condition experts made a list of teat conditions and their target criteria (**Table 2**). It is recommended to score at least all teats of 80 randomly selected cows or 20% of the herd, whichever is larger. If the target criteria are not met, further investigations to find the cause of deterioration of teat condition should be made.

Machine Milking Factors Affecting Teat Condition

The mechanical forces during machine milking that result in changes in teat end tissue are milking vacuum, pulsation vacuum, and liner type in combination with teat shape and milking time. **Table 3** summarizes the common

Table 2 Teat condition measures and criteria to be met

Teat condition measure	*Criteria*
1. Color	>20% visibly reddened or blue
2. Swelling at the teat base	>20% swelling or palpable rings
3. Swelling at the teat end	>20% firm, hard, or swollen
4. Openness	>20% classified as open
5. Vascular damage	>10% petechiations
6. Teat end roughness	>20% rough and very rough
7. Open lesions	>5% open lesions or cracked skin

primary causes of the short-, medium-, and long-term teat condition (*see* **Milking Machines**: Principles and Design).

Liner and teat

The pressure of the liner on the teat during the d-phase of pulsation is believed to relieve congestion of the teat tissue but excessive pressure seems to contribute to the development of teat end callosity or hyperkeratosis.

The compressive load of the liner on the teat can be estimated from the shape of the curved liner and the pressure difference across the liner just underneath the teat (**Figure 4**):

$$pR = Pr, \quad \text{i.e.,} \quad p = \frac{Pr}{R} \text{ kPa}$$

$$\text{if } P = 50\,\text{kPa}, \quad \text{then } p = \frac{50r}{R} \text{ kPa}$$

where R is the radius of curvature of the liner around the teat (mm), p the pressure (kPa above atmosphere) between the liner and the teat, r the radius of curvature of the liner just underneath the teat (mm), and P the pressure difference across the liner just under the teat (kPa).

On average, r:R ratio can be assumed to be 1:5; thus, the pressure on the teat would be around 10 kPa. Very soft, thin-walled liners will show a ratio of 1:15, indicating a compressive load of 3 or 4 kPa. Thick-walled liners under high tension show a ratio of 1:2, indicating a compressive load of 25 kPa. The compressive load applied by the liner on the teat should be 8–12 kPa. This approximates the bovine arterial pressure of about 12 kPa.

Another way to estimate the effect of the liner and vacuum on the teat is by measuring the pulsation vacuum at which the milk flow starts or stops. This is called overpressure or liner compression. Another important factor that determines the response of the teat to milking is milking time.

Vacuum

Increasing the milking vacuum at the teat end results in shortened milking times. On the other hand, milking at high vacuum can increase strip yields, teat end callosity, and teat thickness. Local trauma of the mucous membranes lining the teat sinus by excessive vacuum may provide an environment that favors bacterial colonization or multiplication. Milking at low vacuum increases machine-on time and the frequency of liner slip and decreases milk flow rate, but has a positive influence on teat condition and udder health compared to milking at high vacuum. Vacuum underneath the teat should not exceed 40–42 kPa (<13 inches) during the peak milk flow. This results in nominal vacuum setting of 40–46 kPa for low lines and 47–50 kPa for high lines.

Pulsation

If the duration of liner collapse is inadequate or if the liner is too short so that collapse does not occur at the teat end, there will be an increase in infection possibly through loss of mature stratum corneum and the exposure of an immature (desmosome-bound) surface. The closing phase of the liner (d-phase) should be more than 150 ms per cycle.

MICROORGANISMS ASSOCIATED WITH MILK

A N Hassan and J F Frank, South Dakota State University, Brookings, SD, USA, University of Georgia, Athens, GA, USA

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Milk is a good growth medium for many microorganisms because of its near-neutral pH, complex biochemical composition, and high water content. Although in the absence of mastitis it is secreted free of microorganisms, it is subject to microbial contamination from a number of sources (**Figure 1**). Some microorganisms move up the teat canal causing aseptically drawn milk to be contaminated. These contaminants, called udder commensals, are present in small numbers and are mainly lactic acid bacteria. Their numbers are limited by the animal's immune system and antimicrobial agents secreted into the milk. Therefore, contaminants external to the udder from locations such as udder skin, hide, milking equipment, and utensils form the vast majority of microorganisms in raw milk. Although technology has allowed the production of milk with very low microbial levels, product quality still depends on controlling entry and growth of microorganisms in milk from farm to the consumer.

The number and types of microorganisms present in milk are influenced by season, farm hygiene, feed, and efficiency of cooling. The number of bacteria in milk ranges from a few hundred to thousands per milliliter of freshly drawn milk from healthy cows. Four physiological groups of spoilage bacteria are commonly found in raw milk: producers of lactic acid, propionic acid, butyric acid, and degradative enzymes (primarily proteases and lipases). In addition, raw milk may contain pathogens whose multiplication depends mainly on the temperature and competing microflora. The main criteria for high-quality raw milk are the presence of a low number of spoilage microorganisms and the absence of animal pathogens. The sources of microorganisms found in milk, their characteristics, and their growth are discussed below.

Microorganisms Found in Milk

The microorganisms found in milk can be divided into three groups: animal pathogens and toxin producers, spoilage agents (saprophytes), and microorganisms used to produce fermented products. Some overlap among these groups occurs; for example, *Bacillus cereus* is a toxin producer and is also involved in spoilage, and lactic acid bacteria can cause spoilage and be used in fermentations. **Figure 2** shows the different morphological groups commonly found in raw milk.

Pathogenic Microorganisms

Pathogenic bacteria are those capable of causing infection or intoxication. Milk is a good growth and protective medium for most pathogens. The growth of pathogens in milk is inhibited by cooling and the growth of nonpathogenic competing microorganisms. Many pathogens, such as *Mycobacterium tuberculosis* and *Brucella* species, grow very slowly in milk, and others, such as viruses, do not multiply at all. Therefore, the threat associated with their presence in milk will depend on the initial load of milk contamination. Although the potential hazard of pathogens has been minimized by modern milk production and technology practices, disease outbreaks caused by *Listeria monocytogenes*, *Campylobacter jejuni*, *Yersinia enterocolitica*, and *Escherichia coli* O157:H7 have occurred in recent years.

Staphylococcus spp.

Staphylococcus spp. are nonmotile, non-spore-forming, Gram-positive, catalase-positive cocci. They grow well in media containing 10% NaCl and produce proteases, lipases, and esterases. *Staphylococcus aureus* is the most important species of this genus associated with milk. It produces heat-stable enterotoxins that are responsible for food poisoning. Its natural habitat includes the skin and mucous membranes of mammals. Most contamination occurs during milking and originates with the cow. About 40% of bulk tank milk from a nationally representative sample of 542 dairies tested positive for *Staph. aureus*. It has been reported that 16 and 18% of the cows from organic and conventional farms, respectively, harbored oxacillin-resistant staphylococci, which indicated the presence of the methicillin-resistant gene (*mecA*). Although the presence of *Staph. aureus* in milk is difficult to prevent, appropriate cleaning and sanitation of the cow and milking equipment controls initial numbers and

cooling the milk prevents growth, toxin production, and spreading of bacteria to humans via the milk chain. *Staphylococcus hyicus* has been isolated from the skin of cows and from the milk of cows with mastitis. Some strains are enterotoxigenic.

Streptococcus spp.

Streptococcus pyogenes is pathogenic to humans and some animals. It resists phagocytosis and produces an erythrogenic toxin that causes scarlet fever. *Streptococcus agalactiae* belongs to group B streptococci (GBS) and is an important agent of bovine mastitis in some countries and a cause of diseases in humans. The gastrointestinal tract is the main human reservoir. *Streptococcus dysgalactiae* belongs to Lancefield group C streptococci. It is found mainly in mastitic bovine udders. *Streptococcus uberis* is found in the lips and skin of cows, udder tissue, and milk. It is the main cause of mastitis in some countries, especially during the winter. The only phenotypic criterion that differentiates between *Sc. uberis* and *Sc. parauberis* is the ability of the former to produce β-D-glucuronidase. *Streptococcus equi* subsp. *equi* and *Sc. equi* subsp. *zooepidemicus* are β-hemolytic group C *Streptococcus* species that infect animals and humans, respectively.

Campylobacter jejuni

Campylobacter jejuni is a common cause of human gastroenteritis. It is a Gram-negative, curved, slender, motile rod and is found in food, feces, and water. Although it does not grow in milk, the consumption of fresh raw milk has caused numerous outbreaks of gastroenteritis (*see* **Pathogens in Milk**: *Campylobacter* spp.). Results from NAHMS Dairy 2002 indicated that the percentage of cows shedding *Campylobacter* spp. was 51.4%, while the percentage of dairy herds with at least one cow shedding *Campylobacter* was 97.9%.

Yersinia spp.

The genus *Yersinia* belongs to the family Enterobacteriaceae. Members of this genus are Gram-negative, motile rods, facultatively anaerobic at 28–29 °C but strictly aerobic at 37 °C, which can grow at 2–4 °C. *Yersinia enterocolitica* is the only species of importance in milk. The most common source of contamination is the rinsing water used at the farm. *Yersinia* species grow well in milk and cause an enteric infection that mimics appendicitis (*see* **Pathogens in Milk**: *Yersinia enterocolitica*).

Salmonella spp.

The genus *Salmonella* (family Enterobacteriaceae) consists of small, Gram-negative, non-spore-forming rods. Most strains are motile. The primary habitat is the intestinal tract. Cows suffering from salmonellosis can excrete large numbers of salmonellae in their feces and occasionally directly into milk. Milk can be contaminated with *Salmonella* from feces, livestock feed, humans, water, and dust. Direct contact from other herds can result in the introduction of *Salmonella* spp. into dairy farms. Many outbreaks of salmonellosis have been attributed to milk and milk products. Unlike staphylococcal food poisoning, the ingestion of viable cells of *Salmonella* is necessary for salmonellosis. Raw milk or dairy products made from raw milk have been the cause of outbreaks of salmonellosis in the Western world. Nontyphoid *Salmonella enterica* infects an estimated 2–4 million people every year in the United States. Growth of *Salmonella* in milk is not necessary as ingestion of only a few cells can cause the disease (*see* **Pathogens in Milk**: *Salmonella* spp.).

Escherichia coli

Escherichia coli is a member of the family Enterobacteriaceae. It is a facultatively anaerobic, Gram-negative rod, and ferments lactose. Four categories of pathogenic *E. coli* are recognized: enteropathogenic, enterotoxigenic, enteroinvasive, and enterohemorrhagic. Enterotoxigenic *E. coli* produces enterotoxins that cause diarrhea. Humans are the main reservoir. To cause diarrhea, sufficient numbers of toxigenic *E. coli* must be ingested and they must adhere to the small intestine. In recent years, enterohemorrhagic *E. coli*, mainly *E. coli* O157:H7, have caused milk-borne illness. These pathogens cause hemorrhagic colitis (bloody diarrhea), an illness that can lead to renal failure in children. The dairy cow gut is a reservoir for *E. coli* O157:H7. Hemorrhagic strains of *E. coli* do not ferment sorbitol and the incubation temperature used to detect fecal coliforms (44–45 °C) will not allow *E. coli* O157:H7 to grow (*see* **Pathogens in Milk**: *Escherichia coli*). Non-O157 shiga toxin-producing *E. coli* (STEC) was also associated with raw milk and raw milk cheese.

Listeria spp.

Within the genus *Listeria*, only *Li. monocytogenes* and *Li. ivanovii* are considered virulent, with *Li. monocytogenes* being the only species of public health concern. *Listeria innocua* is the most frequently encountered nonpathogenic *Listeria* species. *Listeria monocytogenes* is a Gram-positive, short rod with rounded ends that occurs singly, in parallel, or in V shapes. It grows slowly in milk at refrigeration temperature. *Listeria monocytogenes* causes mastitis and abortion in animals. In humans, it causes miscarriages and meningitis in its severe form and flu-like symptoms in its mild form. Raw milk can be contaminated with *Li. monocytogenes* from feces, cows suffering from mastitis, poor-quality silage, and milking equipment (*see* **Pathogens in Milk**: *Listeria monocytogenes*).

Mycobacterium spp.

Mycobacterium avium subsp. *paratuberculosis* (MAP) is one of the most heat-resistant pathogenic microorganisms likely to be present in milk. *Mycobacterium tuberculosis* may gain access to milk from infected animals through milk secretion and fecal contamination or from milkers and other environmental sources such as cow alleyways, manure storage, calving area, sick cow pen, water runoff, and postweaned calves areas. The organism does not multiply in milk but survives in unpasteurized milk and milk products.

MAP causes the infection commonly known as Johne's disease. Detectable numbers of this organism have been reported in the milk of both clinically affected and asymptomatic cattle. Pasteurization inactivates MAP when present at levels associated with milk from asymptomatic cattle. It is unknown whether this microorganism is pathogenic for man.

Mycobacterium bovis causes infection in animals and humans. Compared with *M. tuberculosis*, growth of *M. bovis* is less luxuriant and it adapts to aerobic growth after repeated subculturing. Contaminated milk, feces, soil, and water are the main sources of infection (*see* **Diseases of Dairy Animals**: Infectious Diseases: Johne's Disease; Infectious Diseases: Tuberculosis).

Brucella spp.

Brucella species are Gram-negative, aerobic, short rods that do not ferment carbohydrates. They survive well in milk and dairy products and are pathogenic to humans and animals. The most important causes of brucellosis in milk are *Br. abortus* and *Br. melitensis* (*see* **Pathogens in Milk**: *Brucella* spp.).

Coxiella burnetii

Coxiella burnetii is a rickettsia (family Rickettsiaceae), which causes Q fever in humans. Rickettsiae are obligate intracellular parasites. *Coxiella burnetii* is a small pleomorphic, sometimes filamentous, nonmotile rod that produces a capsule-like structure. It is highly resistant to chemical and physical disinfectants and is the most heat-resistant pathogen found in milk (*see* **Pathogens in Milk**: *Coxiella burnetii*).

Aeromonas spp.

Aeromonas species are facultatively anaerobic, Gram-negative, motile cocci or rods that grow in media containing up to 5% salt. *Aeromonas hydrophila* is an opportunistic pathogen found in the feces of healthy animals.

Bacillus spp.

Bacillus species are Gram-positive, aerobic, spore-forming rods belonging to the family Bacillaceae. Their spores make them resistant to heat and other destructive agents. Strains can be psychrotrophic, mesophilic, or thermophilic. *Bacillus cereus* is a common soil bacterium that is often found in raw milk. It is capable of producing enterotoxins (especially in starchy foods), which cause food poisoning. *Bacillus anthracis* causes anthrax, which is a deadly acute infectious disease. Purposeful contamination of foods by *B. anthracis* was considered a potential biological weapon. The presence of *Bacillus* in raw milk shows marked seasonal variation. Soil, feces, bedding, air, silage (possibly via feces), and the milking equipment are the main sources of *Bacillus* in milk (*see* **Pathogens in Milk**: *Bacillus cereus*).

Clostridium spp.

Clostridia are Gram-positive, spore-forming rods, which are usually found in sediments, the intestinal tract of humans and animals, soil, dust, feces, and silage. They are anaerobic and often poisoned by atmospheric oxygen unless in the spore form.

Clostridium perfringens causes food poisoning and gas gangrene in humans and a variety of diseases in animals. Milk and milk products provide a ready medium for transmission of *Cl. perfringens*. Vegetative cells sporulate in the gut and release exterotoxin, which is responsible for symptoms such as profuse diarrhea, sudden acute inflammation of the abdomen, and severe abdominal pain. Large numbers of cells must be consumed for illness to occur.

Botulism is an intoxication attacking the nervous system caused by ingestion of toxins produced by *Cl. botulinum*. Very low levels (<1 spore ml^{-1}) of these organisms are common in milk. They do not germinate or grow in raw or pasteurized milk, but cheese and cheese products can support growth if they are not sufficiently acidic (*see* **Pathogens in Milk**: *Clostridium* spp.).

Xanthomonas maltophilia

Xanthomonas maltophilia, previously known as *Pseudomonas maltophilia*, is an aerobic rod of the family Pseudomonadaceae. It is one of several pseudomonad-like organisms in hospital laboratories associated with serious infections. It has been isolated from milk and water.

Klebsiella pneumoniae

Klebsiella pneumoniae belongs to the family Enterobacteriaceae and is an agent for pneumonia, urinary tract infection, and gastroenteritis and mastitis. It is present in animal bedding materials and water. Fecal shedding of *Kl. pneumoniae* is considered one of the sources of this microorganism in milk. Inorganic bedding such as sand reduces its occurrence.

Serratia spp.

Serratia species are Gram-negative, facultative, anaerobic rods of the family Enterobacteriaceae. They are distributed in soil, air, water, and plants. Some strains produce hemolysins and infected animals produce contaminated milk. Their presence in pasteurized dairy products indicates poor sanitation practices since they are heat sensitive. *Serratia marcescens* is the most important species and causes mastitis.

Proteus spp.

Proteus species are Gram-negative, non-spore-forming rods belonging to the family Enterobacteriaceae. They are commonly found in the feces of humans and animals, soil, and plants. They frequently cause a variety of infections in humans, especially urinary tract infections. *Proteus mirabilis* is the most common species followed by *Pr. vulgaris* and *Pr. penneri*.

Enterobacter sakazakii

Enterobacter sakazakii belongs to the family Enterobacteriaceae. Although rarely found, it can cause life-threatening neonatal meningitis. It does not survive pasteurization but is found in ultra-high temperature (UHT) milk and milk powder that have been subjected to postprocessing contamination. Its natural habitat is not known.

Hafnia alvei

Hafnia alvei, which belongs to the family Enterobacteriaceae, resembles *Salmonella*. Some strains cause mild gastroenteritis. It is found in sewage, soil, water, and feces. *Hafnia* species can grow on the surface of Camembert cheese (*see* **Pathogens in Milk**: Enterobacteriaceae).

Actinomyces spp.

Actinomyces species are irregular, non-spore-forming, Gram-positive rods that occur mainly in the oral cavity and on the mucous membranes of warm-blooded vertebrates. They cause pyogenic infections. *Actinomyces bovis* and *Ac. pyogenes* are the important species in milk.

Leptospira spp.

Species of the genus *Leptospira* (family Leptospiraceae) are Gram-negative, flexible, helicoidal rods. *Leptospira interrogans* causes leptospirosis in animals and humans. The kidney is the natural habitat and contaminated urine is the main source of contamination.

Molds and Yeasts

Many different genera of molds such as *Aspergillus*, *Penicillium*, and *Fusarium* produce mycotoxins in milk and dairy products. Mycotoxins are secondary metabolites that are acutely toxic, carcinogenic, emetic, estrogenic, hallucinogenic, mutagenic, or teratogenic. *Aspergillus flavus* and some other *Aspergillus* species produce aflatoxins when growing on cheeses. Some strains of *Geotrichum* might cause infection in humans. *Candida albicans* is pathogenic to humans and animals (*see* **Yeasts and Molds**: Spoilage Molds in Dairy Products; **Yeasts and Molds**: Yeasts in Milk and Dairy Products).

Viruses

Viruses are genetic elements that replicate inside cells and also have an extracellular nonreplicating state. Replication of the virus often destroys the host cell causing illness. The extracellular form of the virus is a submicroscopic particle and can be transmitted between hosts. Viruses do not multiply in milk but some may survive for long periods. Viruses can be infective at very low doses and most that are found in milk produce gastroenteritis and originate with the cow. Viruses in milk are inactivated by pasteurization.

Rotaviruses can produce severe gastrointestinal illnesses. Milk may be a vector for this virus but detection in raw milk is prevented by the presence of antiviral antibodies (immunoglobulins; IgG). The antibody/virus complex is dissociated in the highly acidic conditions of the stomach.

Hepatitis A virus enters milk through fecal contamination or polluted water. This virus causes symptoms of fever, vomiting, nausea, and abdominal discomfort. The virus eventually affects the liver, causing enlargement and jaundice.

Poliovirus causes the acute infectious disease poliomyelitis, which is characterized by fever, vomiting, and headache. The poliovirus might infect the central nervous system and cause paralysis. It can be transmitted to milk through fecal contamination.

Milk can serve as a vector for the spread of the foot-and-mouth disease virus. This virus, which is nonenveloped, belongs to the Picornaviridae family, which also includes rhinoviruses and enteroviruses.

Protozoa

Toxoplasma gondii is a parasite of humans and many warm-blooded animals, especially dairy goats. Infection occurs as a result of ingestion of foods or water contaminated with oocysts. Contaminated milk is considered a potential source of human toxoplasmosis.

Cryptosporidiosis is an infection caused by *Cryptosporidium muris* and *Cr. parvum.* Diarrhea is the primary symptom of infection. Cows can shed *Cr. muris* oocysts in their feces, which may lead to contamination of milk. Drinking water is the most common vehicle for transmission of this disease.

Entamoeba histolytica is a protozoan that causes amoebiasis, the third most common cause of death by parasites in the world. Transmission occurs via ingestion of cysts in contaminated foods or water or through poor personal hygiene.

Giardia intestinalis is a flagellated protozoan that inhabits the intestinal tracts of humans and animals. Cysts survive well in the environment and are transmitted via contaminated hands, drinking water, and food contaminated with feces.

Spoilage Microorganisms

Spoilage of milk and dairy products is manifest as off-flavors and odors and changes in texture and appearance. The most important spoilage microorganisms of milk and dairy products are the Gram-negative, rod-shaped bacteria (e.g., *Pseudomonas* and coliforms), Gram-positive, spore-forming bacteria (*Bacillus* and *Clostridium*), lactic acid bacteria, members of coryneform group, yeasts, and molds.

Psychrotrophic Bacteria

Most psychrotrophic bacteria present in raw milk belong to the family Pseudomonadaceae, which includes Gram-negative, non-spore-forming, nonfermentative, aerobic rods. *Pseudomonas fluorescens* is the species most commonly isolated from milk, with *Ps. fragi* and *Ps. putida* being of less importance. Soil, water, animals, and plant material are the natural habitat of psychrotrophic bacteria found in milk. Contaminated milk equipment and air provide an additional source of contamination, especially after processing. As little as 1 cfu ml^{-1} of raw milk may be enough to spoil milk during cold storage within 5 days. Some *Pseudomonas* spp. grow at cold and warm temperatures, and others found in milk cannot propagate at temperatures greater than 25 °C. Defects associated with the growth of these organisms in milk include development of bitter and fruity off-flavors. Although psychrotrophic, Gram-negative bacteria are not heat resistant, they produce heat-stable extracellular proteolytic and lipolytic enzymes that can spoil heat-treated products. However, not all Gram-negative isolates from raw milk display proteolytic activities at 7 or 20 °C. Other spoilage Gram-negative rods include *Acinetobacter*, *Psychrobacter*, *Flavobacterium*, *Shewanella putrefaciens*, and *Alcaligenes* spp. Cold-tolerant endospore-forming bacteria such as *Bacillus* and *Paenibacillus* spp. in raw milk are considered a major cause of spoilage of pasteurized milk.

Family Moraxellaceae

Moraxellaceae are Gram-negative, psychrotrophic, non-pigmented, nonmotile, aerobic coccobacilli. There are three genera: *Acinetobacter* are nonmotile, oxidase-negative organisms, *Moraxella* are similar but oxidase-positive, and the third genus is *Psychrobacter*. Moraxellaceae seldom spoil milk because they lack sufficient biochemical activities such as proteolysis and lipolysis that cause off-odors. In addition, they are overgrown by *Pseudomonas* during cold storage.

Shewanella putrefaciens

Shewanella putrefaciens, previously known as *Pseudomonas putrefaciens* or *Alteromonas putrefaciens*, is a Gram-negative rod. It is found in water and soil and contaminates milk and milk products causing spoilage such as surface taint in butter.

Flavobacterium spp.

Flavobacterium species are Gram-negative organisms found in water, soil, and milk. They hydrolyze casein and cause spoilage in milk and dairy products during cold storage. Important species are *Fb. maloloris*, *Fb. aquatile*, and *Fb. lutensis*.

Alcaligenes spp

Alcaligenes species are Gram-negative, short, motile rods. They are aerobic and do not use lactose. They are found in water, soil, and milk. *Alcaligenes faecalis* produces the exopolysaccharide curdlan and is a potential contaminant of dairy products. *Alcaligenes* can grow under refrigeration conditions, producing off-flavors and reducing the shelf life of milk.

Coliforms

Coliforms are Gram-negative, oxidase-negative, non-spore-forming rods that grow aerobically or facultatively anaerobically in the presence of bile salts. They also ferment lactose to produce acid and gas within 48 h at 37 °C. Coliforms include the genera *Escherichia*, *Enterobacter*, *Klebsiella*, *Proteus*, *Serratia*, and *Citrobacter*. They do not survive pasteurization. Gas production may result in early blowing of hard cheese and a poor curd structure in Cottage cheese. Approximately 10^7 cfu g^{-1} of coliforms is needed for a gassy defect to be noticed. Other types of spoilage include acid production, slime production in Cottage cheese, bitter flavors, and grassy, unclean, medicinal, or fecal odors. Cheese varieties in which acid production is delayed are more susceptible to coliform growth. *Klebsiella* (*Kl. pneumoniae* and *Kl. oxytoca*) and *Enterobacter aerogenes* are responsible for gas formation in cheese, which can lead to swelling of the package. *Serratia marcescens* produces proteolytic enzymes that might cause gelation of UHT milk. In addition, they produce methanethiol in Cheddar cheese. Soiled udders and teats are common sources of coliforms. Coliforms can also grow and contaminate milk from poorly sanitized milk contact surfaces and equipment.

Spore-Forming, Gram-Positive Rods

Two genera in this group are associated with milk: *Bacillus* and *Clostridium*. They are unique spoilage microorganisms because of their ability to form heat- and chemical-resistant spores and their ability to grow over a wide temperature range (>0–75 °C). Their main habitat is soil, but they can also be found in water, air, fodder, and feed. New subtyping methods for DNA sequencing of the *rpoB* gene have reclassified some *Bacillus* into new genera such as *Paenibacillus* and *Alicyclobacillus*.

Bacillus cereus causes defects in high-temperature-treated milk and cream including sweet curdling (curd formation with no acid production). It also produces lecithinase, an enzyme that degrades fat globule membranes resulting in fat aggregation in cream (bitty cream). *Bacillus subtilis* survives pasteurization, and milk concentration and perhaps UHT treatment and produces a variety of enzymes that are capable of hydrolyzing casein and polysaccharides. *Bacillus licheniformis* is a common cause of spoilage in UHT and pasteurized milk. *Geobacillus stearothermophilus* (formerly *Bacillus stearothermophilus*) is extremely heat resistant; it is more resistant than *Cl. botulinum* spores. It can survive canning and can cause flat sour spoilage and sweet curdling defects with little or no gas formation. This microorganism is also used to detect antibiotics in milk through growth inhibition assays. *Bacillus coagulans* has also been implicated in the spoilage of UHT and concentrated milk; it also produces chymosin-like enzymes, which cause sweet curdling. *Bacillus circulans* is a psychrotrophic bacterium, which causes an acid defect in aseptically packaged heat-treated milk. *Bacillus macerans* causes a flat sour defect in canned condensed milk.

Clostridium species are important spoilage microorganisms in cheese and canned milk products. Late blowing of some cheese varieties that have a relatively high pH, a high moisture content, and a low interior salt content, such as Emmental, Gouda, and Edam, is caused by these microorganisms. *Clostridium tyrobutyricum* and, occasionally, *Cl. sporogenes* and *Cl. butyricum* are involved. These clostridia produce carbon dioxide, hydrogen gas, and butyric and acetic acids.

Lactic Acid Bacteria and Related Organisms

Many species of lactic acid bacteria cause souring, off-flavors, and texture defects (ropiness, curdling) in milk and dairy products. The general characteristics of lactic acid bacteria will be discussed later.

Lactobacillus spp.

Heterofermentative lactobacilli such as *Lb. brevis* and *Lb. casei* subsp. *pseudoplantarum* cause an open texture in Cheddar and Mozzarella cheeses due to gas production. Lactobacilli also convert L(+)-lactate to D(−)-lactate, which reacts with calcium to form calcium lactate, which appears as white insoluble crystals in ripened Cheddar and other cheeses. Salt-tolerant lactobacilli produce phenolic and putrid sulfide-like flavors during ripening. *Lactobacillus casei* subsp. *casei* causes a soft body in Mozzarella cheese due to proteolysis. *Lactobacillus delbrueckii* subsp. *bulgaricus* can produce a pink discoloration in Italian cheese. *Lactobacillus casei* species sometimes produce a phenolic flavor in Cheddar cheese.

Lactococcus spp.

Lactococcus lactis is commonly used as a starter culture for cheese and fermented milks. These strains are carefully selected so that they do not produce off-flavors or other defects. Wild strains of lactococci often contaminate raw milk, and if the milk is not kept sufficiently cold they will produce sourness and other off-flavors and odors. One variant, *Lc. lactis* subsp. *lactis* var. *maltigenes*, produces a malty flavor in fluid milk due to the production of 3-methylbutanal. Wild strains of lactococci may also contaminate cheeses and grow during manufacture and aging. Some of these strains produce fruity flavors due to the production of esters such as ethyl hexanoate and ethyl butyrate.

Propionibacterium spp.

Pigmented strains of *Propionibacterium* cause pink spots in Swiss cheese. Split formation is influenced by *Prop. freudenreichii* subsp. *shermanii* strains used in making Swiss cheese.

Enterococcus spp.

Enterococcus faecalis, *Ec. faecium*, and *Ec. durans* are part of the normal microflora of many cheeses and are sometimes used as starter cultures. Some strains produce undesirable flavors and high levels of amines during cheese ripening.

Some *enterococci* are also considered probiotic. Two species, *Ec. faecalis* and *Ec. faecium*, were formerly classified as fecal streptococci (*see* **Lactic Acid Bacteria**: *Enterococcus* in Milk and Dairy Products).

Micrococcus spp.

Some strains of *Micrococcus* species are able to survive pasteurization, but spoilage of heat-treated products is also caused by postprocessing contamination. *Micrococcus* species can produce swelling in UHT milk packs and have the ability to grow on some cheese varieties. Their growth may be either beneficial or detrimental to cheese flavor, depending on the cheese variety and strains involved.

Yeasts

The presence of large numbers of yeasts on a cheese surface may result in a slimy rind, discolored appearance, and undesirable flavors. Non-lactose-fermenting *Saccharomyces* produce gas in fruit yogurt. Their source is usually a contaminated processing plant environment or unpasteurized fruits. *Saccharomyces cerevisiae* can spoil sweetened and acid dairy products.

Kluyveromyces marxianus var. *lactis*, *K. marxianus* var. *marxianus*, *Debaryomyces hansenii*, and *Yarrowia lipolytica* spoil acidified refrigerated dairy products such as yogurt. *Yarrowia lipolytica* does not utilize lactose but metabolizes fat, protein, and organic acids, allowing it to spoil high-fat products such as butter and cream. It liberates amino and fatty acids and usually causes off-odors and softening of cheese curd. In addition, it produces melanin pigment from tyrosine and causes discoloration of cheese surfaces.

Candida species are potential dairy spoilage organisms because of their ability to digest casein and fat, grow at storage temperatures, and ferment lactose and sucrose. They form surface slime on cream cheese. In yogurt, they cause yeasty and bitter flavors and a gassy texture. The important spoilage species in cheese is *Can. famata* and in yogurt *Can. famata*, *Can. versatilis*, and *Can. lusitaniae.*

Molds

Mucor, *Rhizopus*, *Penicillium*, and *Aspergillus* grow at the yogurt–air interface of undisturbed packages. One mold spore can spoil a carton of yogurt by producing a visible colony. Molds also produce off-flavors in contaminated dairy products. *Scopulariopsis brevicaulis* causes odor defects in mold-ripened cheese. *Sporendonema sebi* grows on sweet condensed milk forming discrete colonies (mold buttons). *Geotrichum* grows on most dairy products, especially cheese and butter. Cheese varieties with low salt content are often spoiled by *Mucor* species.

Beneficial Microorganisms in the Dairy Industry

Selected lactic acid bacteria and other microorganisms are used by the dairy industry to produce fermented products such as yogurt and cheese. Commercially available starter cultures have been selected for a variety of desirable properties such as flavor production, lack of associated off-flavors, fast acid production, bacteriophage resistance, salt tolerance, exopolysaccharide production, bacteriocin production, and heat sensitivity. These microbial preparations may consist of different species of lactic acid bacteria, propionibacteria, surface-ripening bacteria, yeasts, and molds.

Lactococcus spp.

Lactococci are the major acid-producing microorganisms used for dairy fermentations, *Lc. lactis* being the main species of importance. *Lactococcus lactis* is homofermentative and weakly proteolytic. There are two subspecies: *Lc. lactis* subsp. *lactis* and *Lc. lactis* subsp. *cremoris*. Citrate-positive strains of *Lc. lactis* (*Lc. lactis* subsp. *lactis* biovar *diacetylactis*) utilize citrate to produce diacetyl, carbon dioxide, and other compounds in cheeses and cultured milks. Some strains are highly ropy.

Streptococcus spp.

Streptococcus thermophilus is used to produce acid in dairy products subjected to high temperatures during fermentation (yogurt and Mozzarella cheese). It is weakly proteolytic and some strains produce extracellular polysaccharides.

Leuconostoc spp.

Leuconostoc species are heterofermentative, Gram-positive cocci. They produce flavor compounds such as diacetyl and acetoin, and some strains produce exopolysaccharides. *Leuconostoc mesenteroides* subsp. *cremoris* is used in the production of cottage and cream cheese and cultured milks. *Leuconostoc mesenteroides* subsp. *mesenteroides* and *Ln. mesenteroides* subsp. *dextranicum* often produce slime (glucan, formerly known as dextran) from sucrose. *Leuconostoc paramesenteroides* does not produce glucan and is used in making brined cheese. *Leuconostoc lactis* is also found in milk and dairy products. *Leuconostoc* species reduce an undesirable 'green' flavor in cultured dairy products by converting acetaldehyde to diacetyl, but grow only slowly in milk.

Lactobacillus spp.

Lactobacillus species are a genetically and physiologically diverse group of rod-shaped lactic acid bacteria. They are the most acid tolerant of the lactic acid bacteria and produce numerous proteolytic enzymes. There are three groups based on the type of fermentation end products: homofermentative (*Lb. delbrueckii* subsp. *bulgaricus*, *Lb. delbrueckii* subsp. *lactis*, *Lb. acidophilus*, *Lb. helveticus*, and *Lb. helveticus* subsp. *jugurti*), facultatively heterofermentative (*Lb. casei*, *Lb. curvatus*, and *Lb. plantarum*), and obligately heterofermentative (*Lb. kefir*, *Lb. fermentum*, and *Lb. brevis*). Some lactobacilli, such as *Lb. acidophilus*, are claimed to confer health benefits. Homofermentative lactobacilli are usually thermophilic and are used to produce fermented milk and some cheese varieties that require the use of high temperature during manufacturing. *Lactobacillus casei* and *Lb. plantarum* cannot grow at high temperatures (at 45 °C). They are involved in the ripening of Cheddar and other cheese varieties.

Propionibacterium spp.

Propionibacteria produce propionic and acetic acids and carbon dioxide from sugars and lactic acid. They are responsible for eye formation in Swiss cheese. *Propionibacterium freudenreichii*, *Prop. jensenii*, *Prop. thoenii*, and *Prop. acidipropionici* are the species commonly found in cheese.

Coryneform Bacteria

Coryneform bacteria are a group of irregular, non-spore-forming, Gram-positive rods, often found growing on the surface of surface-ripened cheese. From a taxonomic viewpoint, dairy species differ from the reference pathogenic species. Cheese smear coryneform bacteria are mostly psychrotrophic and do not grow at 37 °C, whereas pathogenic coryneform bacteria are facultative anaerobes and grow at 37 °C. The cheese smear group includes *Brevibacterium*, *Arthrobacter*, *Microbacterium*, *Aureobacterium*, *Brachybacterium*, *Rhodococcus*, and *Corynebacterium*. These microorganisms are responsible for the viscous, red-orange surface (smear) on surface-ripened cheese varieties. They survive high salt concentrations and produce various proteolytic enzymes. Their presence in large numbers causes a slimy rind, discolored appearance, and undesirable flavors in cheese. Currently, the genus *Brevibacterium* is restricted to four species: *Brev. linens*, *Brev. iodinum*, *Brev. casei*, and *Brev. epidermidis*. *Arthrobacter* species include *Ab. globiformis*, *Ab. nicotianae*, *Ab. protophormiae*, *Ab. agilis*, *Ab. sulphurous*, and *Ab. citreus*. The genus *Microbacterium* contains *Microb. lacticum*, *Microb. laevaniformans*, *Microb. imperiale*, and *Microb. arborescens*. The genus *Aureobacterium* contains *Au. liquefaciens* and *Au. testaceum*. *Brachybacterium alimentarium* and *Brach. tyrofermentans* are two new species of coryneform bacteria isolated from the surface of Gruyère and Beaufort cheeses and they tolerate up to 20% salt. *Corynebacterium* species found in dairy products include *C. ammoniagenes* and *C. variabilis*. *Rhodococcus fascians* was also isolated from cheese. The habitats of coryneform bacteria are cheese and human skin (*see* **Bacteria, Beneficial**: *Brevibacterium Linens*, *Brevibacterium Aurantiacum* and Other Smear Microorganisms).

Bifidobacterium spp.

Bifidobacterium species are inhabitants of the intestinal tract, which are added to dairy products for probiotic applications. The species most often used are *Bif. longum*, *Bif. bifidum*, and *Bif. animalis*. *Bifidobacterium* species grow poorly in milk (*see* **Bacteria, Beneficial**: *Bifidobacterium* spp.: Applications in Fermented Milks; *Bifidobacterium* spp.: Morphology and Physiology).

Pediococcus spp.

Pediococcus species are salt-tolerant members of the family Streptococcaceae, which usually grow as tetrads of cells. Most species can grow at 4–6.5% NaCl. They produce acetic acid and small amounts of lactic acid when growing aerobically and mostly lactic acid when growing anaerobically. The most important species used in the dairy industry are *Pc. acidilactici* and *Pc. pentosaceus* (*see* **Lactic Acid Bacteria**: *Pediococcus* spp.).

Micrococcus spp.

Micrococcus species are the predominant microorganisms found in raw milk drawn aseptically from the udder. They are the constituents of the natural microflora of teat skin and have also been isolated from soil, water, and dust. Based on phylogenetic and chemotaxonomic analysis, many micrococci (except *Mc. luteus* and *Mc. lylae*) have been renamed. The new names are *Kocuria varians*, *Kc. roseus*, *Kc. kristinae*, *Dermacoccus nishinomiyaensis*, *Kytococcus sedentarius*, *Ab. agilis*, and *Nesterenkonia halobia*. *Micrococcus* species have proteolytic, lipolytic, and esterase activities, which make them important in the ripening of various cheeses, especially those that are surface-ripened.

Molds

Penicillium species are widely distributed in the environment. This genus includes four subgenera. The surface of soft white cheese can be colonized by *P. camemberti* Thom to produce many different cheese varieties such as Brie and Camembert. This mold produces a white layer of the mycelium on the cheese surface, while spores (candida) are embedded in the curd. The mold metabolizes some of lactic acid thereby raising the pH, which allows growth of *Brev. linens* and other ripening microflora. In blue-veined cheese varieties, *P. roqueforti* (blue mold) is used in cheese ripening. *Penicillium roqueforti* has a relatively low oxygen requirement for growth (<4.2%) and tolerates 6–10% salt. Both *P. camemberti* and *P. roqueforti* produce lipolytic and proteolytic enzymes. They produce additional compounds that give cheese its distinctive flavor and aroma. *Penicillium casei* is similar to *P. roqueforti* and is found in Swiss cheese. *Penicillium nalgiovense* (Lava), another white mold, tolerates up to 8% salt and is used in some cheese varieties.

Aspergillus niger and *A. awamori* produce lipase and contribute to the flavor of some cheese varieties. *Geotrichum candidum* is often found in raw milk, on milking and dairy processing equipment, and on the surface of ripened cheese. It can be used in starter cultures for Brie and Camembert cheese when combined with *Penicillium* species. *Rhizomucor miehei* and *Rm. pusillus* produce chymosin-like enzymes, which are used in cheese manufacture.

Yeasts

Saccharomyces species are ascosporogenous yeasts with a capability for vigorous anaerobic or semianaerobic fermentation of sugar to produce ethanol and carbon dioxide. None of them utilizes lactose. *Saccharomyces cerevisiae* is the most important species and can be found on the surface of mold-ripened cheeses. *Saccharomyces cerevisiae* metabolizes hexoses, lactic acid, and other organic acids. The optimum pH for the growth of *Saccharomyces* species is 4.5–6.5. Oxygen is important to maintain viability but they survive under microaerophilic conditions.

Kluyveromyces marxianus and *K. lactis* can ferment lactose and produce various hydrolytic enzymes. *Kluyveromyces* species are often isolated from Nordic fermented milks. They produce lactase, which can be used to reduce the lactose content of milk and assist in the digestion of milk by lactose maldigesters.

Debaryomyces species are isolated from soil, water, and plants. *Debaryomyces hansenii* is involved in the ripening of mold-ripened soft cheeses. It tolerates high salt concentrations, utilizes lactic acid, produces protease and lipase, and grows well at low temperature. *Candida kefyr* is present in the microflora of the fermented milk kefir.

Microbial Population Dynamics in Milk

Microbial populations in milk are continually changing and interacting with the milk components and with each other. The Pasteurized Milk Ordinance in the United States requires grade A milk to have a total bacterial count of less than 100 000 cfu ml^{-1}. The initial microbial population of raw milk is affected by factors such as equipment and animal cleanliness, season, feed, and cow health. The initial microflora of good quality milk mainly consists of organisms found within the udder and the normal teat skin flora. These microorganisms include non-thermoduric micrococci and streptococci, which do not grow well at low temperatures. Pathogens will predominate in milk from mastitic cows. Seasonal factors include feed source and housing, both of which influence the level of bacterial spores in milk. Psychrotrophic bacteria (those that grow at low temperatures) are at low or even undetectable levels in the best quality fresh raw milk. They originate from the water and milking equipment. After collection, milk is cooled, which initiates a change in microbial population from Gram-positive rods and cocci, which do not grow, to Gram-negative rods, which can grow slowly at low temperatures. These Gram-negative rods are primarily *Pseudomonas* spp. and are capable of causing various off-flavors when populations exceed 10^6 cells ml^{-1}.

When raw milk is not kept cold, lactic acid bacteria will grow. The resulting increase in acidity will inhibit the growth of many other microorganisms including spore-forming *Bacillus* and *Clostridium* species and Gram-negative *Pseudomonas* species and coliforms. Growth of lactic acid bacteria is rapid at 20 °C and slows as the temperature decreases. Many strains of lactic acid bacteria produce bacteriocins, which inhibit other lactic acid bacteria as well as some pathogens such as *Listeria* and *E. coli*.

Both the lactic acid bacteria and the psychrotrophic bacteria that grow in raw milk are heat sensitive, so when milk is pasteurized, microorganisms that have previously grown in the product are greatly reduced in number. The surviving microflora mainly consists of spore-forming bacteria, micrococci, and lactobacilli. Pasteurized milk that is not recontaminated with microorganisms will often keep at refrigeration temperature for 3 weeks or longer, because these surviving microorganisms grow slowly or not at all in the cold milk. Spoilage may occur more rapidly if significant numbers of psychrotrophic *B. cereus* are present in the raw milk. Most pasteurized milk is recontaminated with low numbers of psychrotrophic bacteria, resulting in a shorter shelf life.

Introduction

Milk is a fluid secreted by the female of all mammals, of which there are about 4500 species, for the nutrition of its offspring. In addition to meeting the complete nutritional requirements of the neonate, milk serves several physiological functions: immunoglobulins and other antibacterial agents present in milk have a protective effect; enzymes and enzyme inhibitors, and binding or carrier proteins of the milk aid digestion; and growth factors/ hormones of milk have growth-promoting activity. Because the nutritional and physiological requirements of each species are more or less unique, there are marked interspecies differences in the composition of milk; however, the milks of only about 200 species have been analyzed and, of these, the data for only about 50 species are considered to be reliable (due to sufficient number of samples, representative sampling, adequate coverage of the lactation period and health and stress status of the animal). Not surprisingly, the milks of the principal dairying species – cow, goat, sheep, and water buffalo – and humans are among those that are well characterized. The gross composition of milk from some species, selected to demonstrate the diversity, is shown in **Table 1**. Its gross composition belies the great complexity of milk. For example, it has been reported that bovine milk fat contains up to 400 fatty acids (FAs; more than any other fat), resulting in several thousand triglycerides (TGs) and complex lipids. In addition to the eight main proteins (α_{S1}-, α_{S2}-, β-, and κ-caseins, β-lactoglobulin, α-lactalbumin, blood serum albumin, and immunoglobulins), there are at least 80 minor proteins, including about 60 enzymes. Milk contains at least 30 inorganic elements, which are important from technological, stability, and nutritional viewpoints. It contains all known vitamins, some at quite high concentrations, presumably reflecting the needs of the particular species. There are separate articles in this encyclopedia on all important constituents of milk and on the milk of all major and minor commercial dairy species, as well as some extreme species

Table 1 Composition (%) of the milk of selected species

Species	*Total solids*	*Fat*	*Protein*	*Lactose*	*Ash*
Human	12.2	3.8	1.0	7.0	0.2
Chimpanzee	10.4	1.1	1.0	8.0	-
Cow	12.7	3.7	3.4	4.8	0.7
Buffalo	16.8	7.4	3.8	4.8	0.8
Goat	12.3	4.8	2.9	4.1	0.8
Sheep	19.3	7.4	4.5	4.8	1.0
Camel	15.0	5.4	3.8	5.2	0.7

Since milk supplies all the nutritional requirements of the neonatal mammal during the period of its most rapid growth, it is not surprising that milk is the most nearly complete natural food; only the whole carcass of an animal, including bones, meets the nutritional requirements of humans better than milk. The early antecedents of *Homo sapiens* were probably vegetarians but became omnivorous at an early stage in evolutionary history – anthropologists suggest that the practice of eating meat was one of the factors that facilitated human evolution because meat provided a concentrated source of nutrients that was largely independent of the season. Until relatively recently, human beings were hunter-gatherers who killed small, and occasionally larger, animals, probably ate carrion, and collected roots, fruits, and nuts when available. It is very unlikely that humans consumed the milk of other species until animals had been domesticated, that is, about 8000 BC. Sheep and goats were domesticated early during the agricultural revolution, 8000–10 000 years ago. Cattle were domesticated later but have become the principal dairying species in the most intense dairying areas, although sheep and goats are very important in arid regions, especially around the Mediterranean. Buffaloes are especially important in India, Pakistan, and Egypt and less important elsewhere. Equine milk is used extensively in central Asia and is receiving attention in Europe for special dietary purposes since its composition is closer to that of human milk than is bovine milk. Donkey milk, the composition of which is also relatively close to that of human milk, is attracting attention for special dietary purposes. Donkey milk appears to have been used for cheese production in classical Greece and was considered preferable to cows' milk for the artificial feeding of infants in the eighteenth and nineteenth centuries, and probably earlier. Other dairying species include the camel, which is quite important in the desert areas of North and East Africa and the Middle East, yak in Mongolia and Tibet, and the reindeer in Lapland. The husbandry of these minor species will be discussed in separate articles in this encyclopedia (*see* **Animals That Produce Dairy Foods**: Camel; Donkey; Horse; Reindeer; Water Buffalo; Yak).

Classification of Mammals

Mammals evolved from premammalian egg-laying reptiles about 200 million years ago. It has been suggested that premammalian reptiles secreted a fluid from sebaceous glands to maintain their shell-less eggs moist and to prevent microbial infection. The hatchlings would have licked off and ingested some of this fluid, which provided nutritional benefits, eventually becoming the principal function of such secretions, leading ultimately to milk production (*see* **Mammals**). The essential distinguishing characteristic of mammals is the ability of the female of the species to produce milk in specialized organs (mammary glands) for the nutrition of its newborn.

It is estimated that about 80% of all mammalian species are extinct (*see* **Mammals**).

The class Mammalia is divided into two subclasses: Prototheria and Theria.

Prototheria

This subclass contains only one order, Monotremata, the species of which are egg-laying mammals, that is, the duck-billed platypus and four species of echidna, all of which are indigenous only to the Australian mainland, Tasmania, and New Guinea. Monotremes were the earliest mammals and, presumably, many species have become extinct. They possess perhaps as many as 200 mammary glands grouped in two areas of the abdomen; the glands do not terminate in a teat and the secreted milk is licked by the young from the surface of the gland. Not surprisingly, the milk of monotremes is very different from that of most other mammals and is described, along with that of marsupials, in the article **Milk**: Milk of Monotremes and Marsupials.

Theria

The young of the subclass Theria are born live (viviparous) and fall into two groups: Metatheria and Eutheria.

Metatheria (Marsupials)

Marsupials (about 200 species) do not have a placenta and the young are born alive after a short gestation and are very premature at birth, to a greater or lesser degree, depending on the species. After birth, the young are transferred to a pouch where they reach maturity. Marsupials include kangaroo, wallaby, and koala.

In marsupials, the mammary glands, which vary in number, are located within the pouch and terminate in a teat. The mother may nurse two offspring, differing widely in age, simultaneously from different mammary glands that secrete milk of very different composition, designed to meet the different specific requirements of each offspring (*see* **Milk**: Milk of Monotremes and Marsupials).

Eutherians (True Placental Mammals)

About 95% of all mammals belong to this group. The developing embryo *in utero* receives nourishment via the placental blood supply (hence, they are referred to as placental mammals) and is born at a high, but variable, species-related state of maturity. Although all eutherians secrete milk, the young of some species are born sufficiently mature to survive and develop without milk.

The number and location of mammary glands vary with the species, from 2 (human, goat, and sheep) to 14–16 for the pig or up to 22 in primitive insectivores. Each gland is anatomically and physiologically separate and is emptied via a teat (*see* **Mammary Gland**: Anatomy; Gene Networks Controlling Development and Involution; Growth, Development, and Involution).

The wide interspecies variations in the composition of milk (**Table 1**) and in the chemistry of its constituents render milk species-specific, that is, designed to meet the requirements of the young of that species. However, in spite of the large interspecies differences, the milk of one species is tolerated moderately well by the young of other species after the first few critical days postpartum. There is also a good relationship between milk yield and maternal body weight; species bred for commercial milk production, for example, dairy cow and goat, fall above the line. The modern dairy cow is the result of selective breeding for high milk yield and produces several times more milk than is required, or even can be consumed, by its offspring.

Structure and Development of Mammary Tissue

The mammary gland of all species has the same basic structure and in all species it is located external to the body cavity, which facilitates research on milk biosynthesis. The structure, development, and control of the mammary gland are quite well understood (*see* **Mammary Gland**: Anatomy; Growth, Development, and Involution).

The principal constituents of milk are synthesized in the specialized cells (mammocytes) in the mammary gland from components obtained from the blood and transported across the basal (outer) membrane of the secretory cell. Within the mammocytes, these components are modified, rearranged, and/or polymerized as they pass inward through the cell; the finished milk constituents are excreted into the lumen across the luminal (apical) membrane. Some constituents are transferred unchanged from the blood to milk, for example, immunoglobulins, blood serum albumin, and vitamins, sometimes against a concentration gradient, indicating active transport. Various techniques have been developed to study the biosynthesis of milk constituents, for example, arteriovenous concentration differences, isotope studies, perfusion of excised gland, tissue slices, cell homogenates, and tissue culture, each of which has advantages and limitations. The synthesis of principal constituents of milk is well established and is discussed in several articles in this encyclopedia (*see* **Mammary Gland, Milk**

Biosynthesis and Secretion: Lactose; Milk Fat; Milk Protein; Secretion of Milk Constituents).

The constituents of milk can be grouped into four general classes according to their source:

- organ- (mammary gland) and species-specific constituents (most proteins and lipids)
- organ- but not species-specific constituents (lactose)
- species- but not organ-specific constituents (some proteins)
- neither organ- nor species-specific constituents (water, salts, vitamins)

The lactating mammary gland is by far the most metabolically active organ of the body of many species. For many small mammals, the energy input required for the milk secreted in a single day may exceed that required to develop a whole litter *in utero*. A cow yielding 50 kg of milk per day secretes approximately 2.4 kg of lactose, 1.8 kg of fat, and 1.7 kg of protein per day. This compares with the daily weight gain for a beef animal of 1–1.5 kg day^{-1}, 60–70% of which is water. In large measure, a high-yielding mammal is subservient to the needs of its mammary gland, to which it must supply not only the precursors for the synthesis of milk constituents but also an adequate level of high energy-yielding substrates (adenosine triphosphate, uridine triphosphate, etc.) required to drive the necessary synthetic reactions. In addition, minor constituents (vitamins and minerals) must be supplied.

Constituents and Variability of Milk

With the exception of water and vitamins, the principal constituents of milk are unique to milk and were designed for nutritional purposes. However, milk is an important raw material for the production of a wide range of foods, the production and properties of which depend on certain characteristics of the macroconstituents of milk, which have been studied in depth. Most natural foods contain the same types of constituents, water, lipids, proteins, and carbohydrates, but at very different concentrations and proportions, and the physicochemical properties of the constituents vary widely. The physicochemical and technological properties of foods are determined by the properties of their main constituents, especially the carbohydrates and proteins, which are unique to each group of foods.

Lactose is the principal (0–10%) carbohydrate in the milk of most species and it is unique to milk; why lactose, rather than some other sugar, is the principal sugar in milk is a matter of conjecture, as discussed in the article **Lactose and Oligosaccharides**: Lactose: Chemistry, Properties. However, milk contains several other sugars in addition to lactose, either as components of glycoproteins or glycolipids or as oligosaccharides, which are major components of the milk of some species, for example, humans, and are considered to be very important from nutritional and physiological viewpoints (*see* **Lactose and Oligosaccharides**: Indigenous Oligosaccharides in Milk).

The milk of all species that have been examined contains lipids (~1 to >50%), of which the principal class is TGs (~98% for most species). The FAs in milk lipids are not synthesized in the mammary gland but are obtained, via the blood, from dietary lipids or are synthesized in the liver. The FA profile is unique at the species level and especially at the genus level; the lipids of ruminants are the only natural lipids that contain butanoic acid (C4:0). The mammary gland is the only organ of the animal body that excretes large quantities of lipids from the secretory cells. Since the hydrophobic lipids are exported into an aqueous hydrophilic system, milk serum, with which they are incompatible, they must be formed into a stable emulsion for colloidal stability. This is done as the TGs are exported from the mammocytes by surrounding them with the apical cell membrane, which consists of special proteins and polar lipids. The composition and structure of the membrane are discussed in the article **Husbandry of Dairy Animals**: Predator Control in Goats and Sheep. The lipids of milk supply the neonate with essential FAs, fat-soluble vitamins, and energy; they are important for the flavor and textural properties of dairy products.

The total concentration of protein in milk ranges from ~1 to ~25%; there are eight principal proteins and perhaps 80 others at low or trace levels. The principal proteins fall into two groups: caseins and whey (serum) proteins (WPs). The caseins, a family of phosphoproteins that are insoluble at their isoelectric points (at pH ~4.5), are unique to milk, in which their function is to supply amino acids, calcium, and phosphates to the neonate and to prevent pathological calcification of the mammary gland. Most of the WPs have some biological function (in addition to supplying amino acids). In addition to differences in the total concentration of proteins, there are marked interspecies differences in the ratio of caseins to WPs and in the concentration of individual proteins. The technological properties of milk are mainly due to the proteins, which are described in the articles **Milk Proteins**: Analytical Methods; Casein Nomenclature, Structure, and Association; Caseins, Micellar Structure; Heterogeneity, Fractionation, and Isolation; Immunoglobulins; Inter-Species Comparison of Milk Proteins: Quantitative Variability and Molecular Diversity; α-Lactalbumin; β-Lactoglobulin; Lactoferrin; Minor Proteins, Bovine Serum Albumin, Vitamin-Binding Proteins; Nutritional Quality of Milk Proteins; Proteomics; **Milk Protein Products**:; Bioactive Peptides; Caseins and Caseinates, Industrial Production, Compositional Standards, Specifications, and Regulatory

Aspects; Functional Properties of Milk Proteins; Membrane-Based Fractionation; Milk Protein Concentrate; Whey Protein Products.

The minor constituents of milk, especially the vitamins and inorganic elements, are disproportionately important from a nutritional viewpoint and many of them from the technological viewpoint also. They are discussed in the articles **Milk Salts**: Distribution and Analysis; Interaction with Caseins; Macroelements, Nutritional Significance; Trace Elements, Nutritional Significance; **Vitamins**: Biotin (Vitamin B_7); Folates; General Introduction; Niacin; Pantothenic Acid; Riboflavin; Thiamine; Vitamin A; Vitamin B_{12}; Vitamin B_6; Vitamin C; Vitamin D; Vitamin E; Vitamin K.

The principal constituent in the milk of most species is water, the significance of which is considered in the articles **Water in Dairy Products**: Analysis and Measurement of Water Activity; Water in Dairy Products: Significance.

Milk is a very variable biological fluid. In addition to interspecies differences (**Table 1**), the milk of any particular species varies with the individual animal, breed (in the case of commercial dairying species), health (mastitis and other diseases), nutritional status, stage of lactation, age, interval between milkings, and other factors. In a bulked factory milk supply, variability due to many of these factors is evened out but some variability persists and may be quite large when milk production is seasonal. In addition to variations in the concentrations of the principal and minor constituents due to the above factors, the actual structure of some of the constituents also varies, for example, the FA profile is influenced strongly by diet. Variations in the concentration and properties of the constituents of milk cause variations in the processing properties of milk and hence in the quality of dairy products. Some of the variability in the nature of milk can be minimized, adjusted, or counteracted by animal husbandry practices or processing technology but some differences may persist. The variability of milk and the consequent problems will become apparent from several articles throughout the encyclopedia.

From a physicochemical viewpoint, milk is a very complex fluid, the constituents of which occur in three phases. About 40% of the dry matter of bovine milk is in true solution, that is, lactose (sugar), organic and inorganic salts, vitamins, and other small molecules in water. In this aqueous solution are dispersed proteins, some (WPs) at a molecular level, others (the caseins) as large colloidal aggregates (micelles), ranging in diameter from 50 to 300 nm, and lipids, which exist in an emulsified state, as globules ranging in diameter from 0.1 to 20 μm and stabilized by a lipoprotein membrane, the milk fat globule membrane (MFGM). Milk has a slightly sweet taste due to lactose, which has a low level of sweetness in comparison with other common sugars, for example, fructose, glucose, galactose, sucrose, or maltose. The concentration of lactose in milk ranges from 0 to ~10% but the four commercially important milks – cow, goat, sheep, and buffalo milks – contain 4.5–5.0%; human milk contains 7% lactose. The pleasant mouthfeel of milk is due to its colloidal constituents, casein and fat. The white color (appearance) of milk is due to the scattering of light by the colloidal particles, especially the casein micelles. The rheological properties and surface activity of milk and dairy products also are determined primarily by the colloidal constituents. Other physical properties of milk, for example, freezing point, boiling point, osmotic pressure, electrical conductivity, pH, and redox potential (E_h), are determined mainly by the low-molecular-mass compounds present in true solution.

Milk is a dynamic system owing to

- the instability of many of its structures, for example, the MFGM and casein micelles
- changes in the solubility of many constituents, especially inorganic salts, but also proteins, with temperature and/or pH
- the presence of various enzymes, which can modify constituents through lipolysis, proteolysis, or oxidation/reduction
- the growth of microorganisms, which can cause major changes, either directly through their growth, for example, changes in pH or E_h, or through enzymes they excrete
- the interchange of gases with the atmosphere, especially CO_2

Milk was intended to be consumed directly from the mammary gland and to be expressed from the gland at frequent intervals. However, in dairying operations, milk is stored for various periods, ranging from a few hours to several days, during which it is cooled (and perhaps heated) and agitated to various degrees. These treatments will cause at least some physical changes and permit some enzymatic and microbiological changes, which may alter the processing properties of milk. It may be possible to counteract some of these changes.

History of Dairy Science and Technology

Milk is probably the best characterized of the principal food groups in terms of chemical and physicochemical properties. Research on milk dates from the eighteenth century and dairy science/technology is a well-established discipline for technological study and is serviced by several professional societies and associations (*see* **Dairy Science Societies, and Associations**). There is a very ancient and now voluminous literature on various aspects of dairy science. Several Roman writers, for example, Cato, Varo, Pliny the Elder, and Columella, wrote on various aspects of agriculture, including dairying and dairy products. Books on various aspects of dairying were published at the end of the nineteenth century, perhaps the oldest of which is *Lehrbuch der Milchwirtschaft* by W Fleischmann, published in 1870. The early interest and progress in dairy science can be attributed to many factors, and some are listed below:

1. While milk can be consumed without any treatment or processing, its principal constituents separate during storage, without human intervention, creating the opportunity for the production of new products.
2. The principal constituents of milk (lipids, proteins, and lactose) can be fractionated and purified rather easily in comparison with other major food groups, for example, meat or cereals, and were amenable to the application of new analytical techniques as these were developed.
3. The perishability of milk necessitated and encouraged the development of methods to conserve it, which, in turn, encouraged the study of the properties of milk.
4. The properties of some milk constituents are very interesting – in fact, unique – which has encouraged their study. The properties of some constituents permit the manufacture of new products; for example, coagulability of caseins by enzymes or acids permits the production of cheeses and fermented milks; the very high heat stability of milk permits the manufacture of a wide range of pasteurized and sterilized products without major physical changes.
5. The fact that milk is a liquid that can be readily converted to a solid renders milk a very flexible raw material.

As will become apparent from several articles throughout this encyclopedia (*see* **Lactose and Oligosaccharides**: Lactose: Chemistry, Properties; Lactose: Production, Applications; **Milk Lipids**: General Characteristics; **Milk Proteins**: Heterogeneity, Fractionation, and Isolation), the constituents of milk are well characterized at the chemical, physical, and genetic levels. Certainly, knowledge of the chemical and physical properties will be extended and refined in the future but the greatest opportunities for advancement are in the area of molecular genetics, through which the yield of milk will be increased, its composition modified (e.g., lactose deleted, replaced, or modified), properties of milk constituents modified (properties of milk proteins modified via point mutations), or new constituents introduced. Genetic engineering opens up the possibility of converting the cow from a food-producing animal to a producer of pharmaceuticals (*see* **Molecular Genetics and Dairy Foods**).

Dairy cows have been scientifically bred for at least 150 years and casually for much longer. The objectives of such breeding programs have been to increase milk yield and fat content and recently protein content also. Inadvertently, some technological properties may have been improved (and perhaps disimproved) but there has been no concerted effort in this regard. Advances in classical genetics are discussed in the articles **Genetics**: Selection: Concepts; International Flow of Genes; Selection: Economic Indices for Genetic Evaluation; Selection: Evaluation and Methods. Developments in molecular biology make it possible to design milk for specific nutritional or technological applications, including milk as a source of nutraceuticals; these developments are described in the article **Molecular Genetics and Dairy Foods**.

Production and Utilization of Milk

Probably, some milk and dairy products are consumed in all regions of the world but they are major dietary items in Europe, North and South America, Australia, New Zealand, India, and some Middle Eastern countries. Total recorded milk production is about 600 million tonnes. In addition to domestic consumption, there is a substantial international trade in dairy products, aspects of which are discussed in the articles **Policy Schemes and Trade in Dairy Products**: Trade in Milk and Dairy Products, International Standards: Harmonized systems; Trade in Milk and Dairy Products, International Standards: World Trade Organization. Data on the consumption of milk and dairy products in member countries are published at regular intervals by the Food and Agriculture Organization (FAO) and the International Dairy Federation (IDF). Milk and dairy products are quite important in several other countries that are not members of the IDF. Approximately 85, 11, 2, and 2% of global milk production is produced from cows, water buffaloes, sheep, and goats, respectively; camel, yak, reindeer, horse, and donkey are important in certain regions, but are of very little significance globally.

Milk and dairy products are major dietary items in Europe and North America, where they contribute 20–30% of dietary protein, 15% of dietary lipids, and 80% of calcium. An adequate intake of calcium, especially in childhood, is critical for bone development and the prevention of osteoporosis in later life, especially in women; hence, milk and calcium-rich dairy products, for example, rennet-coagulated cheeses, are very important (**Milk Salts**: Macroelements, Nutritional Significance). Milk plays a key role in infant nutrition. While human milk is probably best for human infants, most survive and grow very well on bovine milk. Although bovine milk was probably fed to human infants in medieval and even ancient times, the first formulated infant food was produced by Justus von Liebig in 1856. The development of sweetened condensed milk and sterilized evaporated milk in the mid-nineteenth century was a major factor in reducing infant mortality during the early years of the twentieth century. The production of modified (humanized) formulae is now a widespread, important, and profitable sector of the dairy industry (*see* **Dehydrated Dairy Products**: Infant Formulae).

Because milk is perishable and its production was traditionally seasonal, milk that was surplus to immediate requirements was converted to more stable products, traditional examples being butter or ghee, fermented milk, and cheese; small amounts of dried milk were produced by sun-drying. These traditional products are still very important, their production is expanding, and many new variants thereof have been introduced. In addition, several new products have been developed during the past 150 years, for example, sweetened condensed milk, sterilized concentrated milk, a range of milk powders, ultraheat-treated (UHT) sterilized milk, ice creams, infant foods, and milk protein products.

One of the important developments in dairy technology in recent years has been the fractionation of milk into its principal constituents, for example, lactose, milk fat fractions, and milk protein products (caseins, caseinates, WP concentrates, WP isolates, mainly for use as functional proteins but more recently as nutraceuticals, that is, proteins for specific physiological and/or nutritional functions, e.g., lactotransferrin, immunoglobulins). All these products will be considered in individual articles in this encyclopedia (*see* **Lactose and Oligosaccharides**: Lactose: Chemistry, Properties; Lactose: Production, Applications; **Milk Protein Products**: Whey Protein Products; **Milk Proteins**: Casein Nomenclature, Structure and Association; Immunoglobulins; Lactoferrin; **Nutrition and Health**: Nutraceuticals from Milk).

As a raw material, milk has many attractive features:

1. Milk was designed for animal nutrition and hence contains the necessary nutrients in easily digestible forms (although the balance is designed for the young of a particular species) and free of toxins. No other single food, except the whole carcass of an animal, including the bones, contains the complete range of nutrients at adequate concentrations.
2. The principal constituents of milk – lipids, proteins, and carbohydrates – can be fractionated readily and purified by relatively simple methods for use as food ingredients.
3. Milk itself is readily converted into products with highly desirable organoleptic and physical characteristics and its constituents have many very desirable and some unique physicochemical (functional) properties.
4. The modern dairy cow is a very efficient converter of plant material; average national yields of about 8000 kg per annum are common, with individual cows producing up to 20 000 kg per annum. In terms of kilograms protein that can be produced per hectare, milk production, especially by modern cows, is much more efficient than meat production but less efficient than some plants (e.g., cereals and soybeans). However, the functional and nutritional properties of milk proteins are superior to those of soy protein and since cattle, and especially sheep and goats, can thrive under farming conditions not suitable for growing cereals or soybeans, dairy animals need not be competitors with humans for use of land, although high-yielding dairy cows are fed products that could be used for human foods. In any case, dairy products improve the quality of life, which is a desirable objective *per se*.
5. One of the limitations of milk as a raw material is its perishability – it is an excellent source of nutrients for microorganisms as well as for humans. However, this perishability is readily overcome by a well-organized, efficient dairy industry at both the farm and factory levels. Milk is probably the most adaptable and flexible of all food materials, as will be apparent from **Table 2**, which shows the principal families of milk-based foods. Some of these families, for example, cheese, contain several hundred different products. However, a few families of products dominate the dairy sector, for example, 40% of total milk production is used as beverage (liquid) milk, 35% is converted into cheese, and 10% is converted into whole-milk powder.

Many of the processes to which milk is subjected cause major changes in the composition, physical state, stability, and nutritional and sensory attributes of the product; some of these changes will be discussed in separate articles (*see* **Analytical Methods**: Principles and Significance in Assessing Rheological and Textural Properties; Rheology of Liquid and Semi-Solid Milk Products).

Conclusion

Milk is a unique biological fluid, intended for a specific purpose, that is, the nutrition of neonatal mammals. However, due to its high nutritional value and its suitability as a raw material for the production of some unique products, it is a major item in the human diet in many regions of the world and is a major item of international trade.

Table 2 Diversity of dairy products

Process	*Primary product*	*Further products*
Centrifugal separation	Cream	Butter, anhydrous milk fat, ghee, creams of various fat content (10–50%) (pasteurized, ultraheat-treated sterilized, in-container stabilized) Cream cheeses
	Skim milk	Powders, casein, cheese, milk protein concentrates
Concentration by thermal evaporation or reverse osmosis		In-container or ultraheat-sterilized concentrated milks; sweetened condensed milk
Concentration and drying		Whole-milk powders; infant formulae; dietary products
Enzymatic coagulation	Cheese	Numerous varieties; further products, for example, processed cheese, cheese-based ingredients
	Rennet casein	Cheese analogues
	Whey	Whey powders, demineralized whey powders, whey protein concentrates, whey protein isolates, individual whey proteins, whey protein hydrolysates, nutraceuticals Lactose and lactose derivatives
Acid coagulation	Cheese	Fresh cheeses and cheese-based products
	Acid caseins/ caseinates	Functional applications, for example, coffee creamers, meat extenders; nutritional applications
	Whey	As for enzymatic coagulation
Fermentation		Various fermented milk products, for example, yogurt, buttermilk, acidophilus milk, bioyogurt
Freezing		Ice cream (numerous types and formulations)
Miscellaneous		Chocolate products

Physical and Physico-Chemical Properties of Milk

O J McCarthy, Massey University, Palmerston North, New Zealand

This article is reproduced from the previous edition, Volume 3, pp 1812–1821, © 2002, Elsevier Ltd.

Introduction

Milk is a complex colloidal dispersion of fat globules, casein micelles, and whey proteins in an aqueous solution of lactose, minerals, and a number of minor compounds. Its physical and physico-chemical properties depend on intrinsic compositional and structural factors, extrinsic factors such as temperature, and postmilking treatment.

There is no clear dividing line between physical properties and physico-chemical properties. However, physical properties may be thought of as measures of the bulk behavior of milk and of how milk interacts with energy, while physico-chemical properties are measures of how bulk behavior and energy interactions depend on milk's constituent colloidal particles, molecules, atoms, and ions.

Knowledge of physical properties is of importance particularly in the technological and engineering design and control of milk processes and processing equipment. Knowledge of physico-chemical properties provides a basis for the design of modern methods of milk analysis, determination of milk microstructures, and elucidation of the complex chemical reactions that occur in milk.

In this article, recognizably physical properties, such as rheological properties, density, and thermal properties, are discussed first. Then, properties that fall within the realms of both physics and physical chemistry are described: surface tension, acoustic properties, electrical and dielectric properties, and optical properties. Finally, recognizably physico-chemical properties – the colligative properties, and acid–base and oxidation–reduction equilibria – are discussed.

Rheological Properties

The rheological behavior of milk is in accord with that of emulsions and suspensions in general. Milk may exhibit Newtonian or non-Newtonian behavior depending on composition, prior treatment, and measurement conditions (especially shear rate and temperature).

At moderate to high shear rates, Newtonian behavior is exhibited by skim milk, by whole milk at temperatures >40 °C (milk fat completely molten, no cold agglutination), and by whole milk at temperatures <40 °C when cold agglutination is absent.

Non-Newtonian behavior manifests itself in raw whole milk under conditions that favor cold agglutination (temperatures <40 °C) and at low shear rates. Shear thinning is the predominant rheological behavior. Skim milk shows shear-thinning behavior at low shear rates and at temperatures <30 °C.

As milk is concentrated by heat evaporation or by membrane processes, viscosity increases, shear thinning becomes more pronounced, and deviation from Newtonian behavior persists to higher shear rates. Thixotropy (time-dependent shear thinning) appears at a sufficiently high concentration, or after a sufficiently long storage time (at concentrations and temperatures above certain minima), during which structure development occurs. Such structure development, and the consequent steady viscosity increase, is known as age thickening.

Viscosity of milk is greatly influenced by the concentration and state of the fat and casein, and thus on factors that affect these. Such factors include temperature, and technological treatments such as homogenization, heat treatment, renneting, and acidification.

A full discussion of the rheological properties of milk may be found in the article **Rheology of Liquid and Semi-Solid Milk Products**.

Density and Specific Gravity (Relative Density)

The density ($\mathrm{kg\,m^{-3}}$) of milk is identified for a given measurement temperature as, for example, ρ^{20}, where the superscript is the temperature in °C. Specific gravity (SG), defined as $\rho_{\text{milk}}/\rho_{\text{water}}$, is identified in a similar way, for example, SG_{20}^{20} or SG_{4}^{20}, where the superscript is the temperature at which the milk density was measured, and the subscript the temperature at which the density of water was determined. Density and specific gravity (more properly called 'relative density') are related by the equation

$$\rho^{\theta_1} = \mathrm{SG}_{\theta_2}^{\theta_1} \times \rho_{\text{water}}^{\theta_1} \qquad (1)$$

where θ is the temperature (°C) and, usually, $\theta_1 = \theta_2$.

ρ^{20} of whole milk is about $1030\,\mathrm{kg\,m^{-3}}$ and usually ranges from 1027 to $1033\,\mathrm{kg\,m^{-3}}$ depending mainly on fat content. $\mathrm{SG}_{15.5}^{15.5}$ ranges from 1.030 to 1.035 for mixed-herd milk, and a commonly quoted average value is 1.032. Inter-breed variations in density and specific gravity are small.

The density and specific gravity of milk depend on composition, temperature, and, in the melting point range of the milk triglycerides (–40 to +40 °C), thermal history; thermal history determines the ratio of liquid fat (lower density) to solid fat (higher density). Other factors, such as the stage of lactation and nutritional status of the cow, are important only insofar as they affect composition.

Density data are needed for converting mass to volume and vice versa, and for calculating the values of physical properties such as kinematic viscosity and thermal diffusivity. The density of milk may be predicted, if the milk's proximate composition is known, by using the equation

$$\frac{1}{\rho} = \sum\left(\frac{x_i}{\rho_i}\right) \qquad (2)$$

where x_i and ρ_i are the mass fraction and density, respectively, of the ith component; $\Sigma(x_i) = 1$ for the non-gaseous components. One of the non-gaseous components will be ice if the temperature is below the (initial) freezing point of the milk.

The value of ρ^{20} of milk can be calculated using the values of component densities given in **Table 1**. The value of 918 kg m^{-3} for milk fat given in the table assumes that the fat is a supercooled liquid, but allows for the higher density of the milk fat globule membrane.

If milk contains dispersed gas, such as air, the actual density will be lower than that predicted by eqn [2]:

$$\rho^{\theta}_{\text{actual}} = (1 - \varepsilon_a)\,\rho^{\theta}_{\text{predicted}} \qquad (3)$$

where ε_a is the volume fraction occupied by dispersed gas, which is assumed to have zero mass. θ is the temperature of measurement or prediction. Dispersed gas considerably lowers density, which then becomes pressure dependent.

There have been many attempts to develop empirical equations relating milk density to fat content and temperature, the two most important determining variables. One such equation is as follows:

$$\begin{aligned}\rho = {} & (-2.307\times10^{-3}\theta^2) - (0.2655\theta) + 1040.51 \\ & -[F(-4.78\times10^{-5}\theta^2 + 9.69\times10^{-3}\theta + 0.967)] \\ & (\text{kg m}^{-3})\end{aligned} \qquad (4)$$

Table 1 Density of milk components at 20 °C

Milk component	*ρ^{20} (kg m^{-3})*
Water	998.2
Fat	918
Protein	1400
Lactose	1780
Residual components	1850

From Walstra P and Jenness R (1984) *Dairy Chemistry and Physics*. New York: Wiley.

where θ is the temperature (°C) and F is the % fat (w/w). Equation [4] is valid for milk and cream with fat contents in the range 0–15% (w/w), at temperature in the range 65–140 °C. The temperature dependence of milk's specific gravity is very slight, which is the principal advantage of expressing density in this way.

Processing operations such as homogenization, pasteurization, and sterilization have negligible effects on milk density.

Thermal Properties

Specific Heat Capacity and Enthalpy

The specific heat capacity of milk determines the quantity of thermal energy that has to be added to or removed from milk to effect a given temperature change according to the following equation:

$$q = \Delta h = \int_{\theta_1}^{\theta_2} c(\theta)\,\mathrm{d}\theta\,(\text{J kg}^{-1}) \qquad (5)$$

where q is the quantity of heat energy per kg (J kg^{-1}), Δh is the change in milk enthalpy (J kg^{-1}), θ is the temperature (°C), $(\theta_2 - \theta_1)$ is the temperature change (θ_1 to θ_2 or θ_2 to θ_1), and $c(\theta)$ is the specific heat capacity (J kg^{-1} K^{-1}) expressed as some function of temperature. $c(\theta)$ is the specific heat capacity at constant pressure, rather than at constant volume. As milk is a liquid, the two can be considered equal, except perhaps under the conditions used in high-pressure processing. The equality of q and Δh is valid under isobaric conditions and in the absence of phase transitions, chemical reactions, changes in composition, and forms of work other than displacement.

Equation [5] is valid for temperatures >40 °C, the upper end of the milk fat melting point range. At temperatures between the (initial) freezing point of milk and 40 °C, sensible heat demands are confounded with the latent heat demands caused by phase changes in the milk fat, and eqn [5] must be written as

$$\Delta h = \int_{\theta_1}^{\theta_2} c_{\text{app}}(\theta)\,\mathrm{d}\theta \qquad (6)$$

where $c_{\text{app}}(\theta)$ is the apparent specific heat capacity (J kg^{-1}) expressed as some function of temperature. $c_{\text{app}}(\theta)$ depends on fat content, triacylglycerol composition, and thermal history. There is a maximum (~4000 J kg^{-1} K^{-1}) in the temperature range 15–20 °C and a minimum (~3880 J kg^{-1} K^{-1}) at about 40 °C. At temperatures away from the maximum, specific heat capacity is inversely related to fat content. At temperatures above 40 °C, where the milk fat is completely molten and there are no phase changes, specific heat capacity increases gradually with temperature, reaching ~3940 J kg^{-1} K^{-1} at 100 °C and ~4000 J kg^{-1} K^{-1} at 140 °C.

The specific heat capacity of skim milk, which includes no significant latent heat effects due to phase changes in milk fat, increases essentially linearly but slowly with temperature over a wide range. Representative values are 3899 and 3988 J kg^{-1} K^{-1} at 0 and 50 °C, respectively.

For skim milk, and for whole milk with 4% fat, specific heat capacity may be predicted as a function of temperature (at temperatures above the milk fat melting point range) by the following equations:

$$\text{Skim milk at } 52-143\ ^{\circ}\text{ C: } c = 2.814\theta + 3942 \ \ (\text{J kg}^{-1}\text{K}^{-1}) \tag{7}$$

$$\text{Whole milk at } 53-153\ ^{\circ}\text{C: } c = 2.976\theta + 3692 \ \ (\text{J kg}^{-1}\text{K}^{-1}) \tag{8}$$

The ability to predict the enthalpy change between two chosen temperatures is, from a technological or engineering point of view, more useful than the ability to predict specific heat capacity at specific temperatures. The following general expression is valid for any temperature range, any fat content, and any total solids content:

$$\Delta h_{\theta_1 \leftrightarrow \theta_2} = \Delta h_{\text{fat}} x_{\text{fat}} + \Delta h_{\text{nonfat}} x_{\text{nonfat}} \tag{9}$$

where Δh_{fat} is the enthalpy change (J kg^{-1}) in milk fat between θ_1 and θ_2, Δh_{nonfat} is the enthalpy change in the non-fat portion of the product between θ_1 and θ_2, x_{fat} is the fraction of milk fat in the product, and $x_{\text{non-fat}}$ is the mass fraction of the nonfat portion.

Δh_{fat} must be found from a suitable set of published empirical data. $\Delta h_{\text{non-fat}}$ can be predicted from

$$\begin{aligned}\Delta h_{\text{nonfat}} &= \Delta h_{\text{milk plasma}} = \int_{\theta_1}^{\theta_2} \sum (c_i x_i)\, \mathrm{d}\theta \\ &= \sum (c_i x_i)(\theta_1 - \theta_2)\end{aligned} \tag{10}$$

where c_i is the specific heat of the ith component, x_i is the mass fraction of the ith component, and $\Sigma(c_i x_i)$ is the specific heat of milk plasma. Suitable values of c_i for water, lactose, protein, and ash are 4200, 1400, 1600, and 800 J kg^{-1} K^{-1}, respectively. The slight temperature dependence of the specific heat capacity of these non-fat components may usually be ignored for practical purposes, as indicated by eqn [10].

When milk is heat-concentrated, the enthalpy demand is almost wholly the latent heat of evaporation of water (h_{fg}) that must be supplied. This demand can be expressed as kilograms of water evaporated per kilogram of unconcentrated milk × h_{fg} (J kg^{-1}), where h_{fg} is read from steam tables at the pressure at which evaporation occurs. (There is an additional, though relatively small, sensible heat demand, as milk boiling point increases during concentration, but this demand is moderated by a concomitant decrease in specific heat capacity.)

In calculating enthalpy changes over a temperature range that straddles or lies below the initial freezing point of milk, it is necessary to account for latent heat effects due to phase change in the water substance (water or ice) as well as in the milk fat. There are ways of doing this, but milk is rarely frozen.

Thermal Conductivity and Thermal Diffusivity

The thermal conductivity of skim milk, whole milk, and cream increases slowly with increasing temperature. It decreases with increasing %TS or increasing fat content, the effects being generally greater at higher temperatures. The following semi-empirical relationship, although developed specifically for creams of fat content ≥20% (w/w), is accurate to within 10% for milk and cream with a fat content in the range 0.1–42% (w/w), and for the temperature range 5–75 °C:

$$\begin{aligned}\lambda = {} & (0.5279 + 2.13 \times 10^{-3}\theta - 7.32 \times 10^{-6}\theta^2) \\ & [1 - (0.843 + 1.9 \times 10^{-3}\theta)\,\phi_{\text{fat}}](\text{W m}^{-1}\text{ K}^{-1})\end{aligned} \tag{11}$$

where λ is the thermal conductivity (W m^{-1} K^{-1}), ϕ_{fat} is the fat volume fraction, and θ is the temperature (°C). Representative values of thermal conductivity at 20 °C calculated using eqn [11] are compared with the thermal conductivity of water in **Table 2**.

The thermal conductivity of whole milk heat concentrates may be predicted using the following equation:

$$\lambda = (0.59 + 0.0012\theta)\ (1 - 0.0078\text{TS})\ \ (\text{W m}^{-1}\text{ K}^{-1}) \tag{12}$$

The equation is valid for the temperature range $40 < \theta < 90$ °C and the %TS range $37 < \text{TS} < 72\%$; it is accurate to ±0.88%.

The thermal diffusivity of milk may be calculated using the equation:

$$\alpha = \frac{\lambda}{\rho c} \quad (\text{m}^2\text{ s}^{-1}) \tag{13}$$

Table 2 Representative values of the thermal conductivity of fluid milk products compared with the thermal conductivity of water, at 20 °C

Fluid	*Thermal conductivity (W m^{-1} K^{-1})*
Water	0.603
Skim milk (0.1% fat)	0.568
Whole milk (3.9% fat)	0.548
Cream (42% fat)	0.357

From Fernandez-Martin F and Montes F (1972) *Milchwissenschaft* 27: 772–776.

where α is the thermal diffusivity ($\mathrm{m^2\,s^{-1}}$), ρ is the density ($\mathrm{kg\,m^{-3}}$), and c is the specific heat capacity ($\mathrm{J\,kg^{-1}\,K^{-1}}$). λ, ρ, and c can be predicted as described above, and α, then, can be calculated. For example, at 20 °C, $\lambda \approx 0.548\,\mathrm{W\,m^{-1}\,K^{-1}}$, $\rho \approx 1030\,\mathrm{kg\,m^{-3}}$, and $c \approx 3980\,\mathrm{J\,kg^{-1}\,K^{-1}}$, giving a value for α of $\sim 1.34 \times 10^{-7}\,\mathrm{m^2\,s^{-1}}$.

Surface Tension

The surface tension of milk lies in the range 40–60 $\mathrm{mN\,m^{-1}}$ (average: $\sim 52\,\mathrm{mN\,m^{-1}}$) at 20 °C. Comparable values for some milk fractions are 72.8 (water), 51–52 (rennet whey), 52–52.5 (skim milk), 42–45 (25% fat cream), and 39–40 (sweet-cream buttermilk).

Surface tension decreases with increasing temperature. For whole milk, the relationship is

$$\gamma = 1.8 \times 10^{-4}\theta^2 - 0.163\theta + 55.6 \qquad (14)$$

where γ is the surface tension ($\mathrm{mN\,m^{-1}}$) and θ is the temperature (°C).

Surface tension is influenced by fat content, homogenization, and temperature history. It decreases with increasing fat content up to ~4%, but no further decrease occurs at higher fat contents. Homogenization of pasteurized milk increases surface tension. Homogenization of raw milk, however, can lead to a decrease in surface tension owing to the release of free fatty acids by lipase activity. The surface tension of milk held at 5 °C and brought to 20 °C is lower than that of milk cooled to 20 °C when measured immediately. Heat treatment of milk at sterilization temperatures can cause a small increase in surface tension, probably the result of denaturation of whey proteins, a change that reduces their surface activity.

Acoustic Properties

Acoustics is the science of sound (mechanical vibrations at frequencies in the range 1.6×10^{-2} to 20 kHz, which are detectable by the human ear), infrasound (frequencies of $<1.6 \times 10^{-2}$ kHz), and ultrasound (frequencies of >20 kHz). Only low-power ultrasound (which involves power levels $<1\,\mathrm{W\,cm^{-2}}$) is of significance in dairy science and technology. It is used principally as an analytical tool for indirectly measuring food characteristics and as an in-line method for measuring flow rate.

The ultrasonic properties of a material most frequently measured are the ultrasonic velocity ($\mathrm{m\,s^{-1}}$), the attenuation coefficient ($\mathrm{Np\,m^{-1}}$), and the acoustic impedance ($\mathrm{kg\,m^{-2}\,s^{-1}}$). These depend on other physical properties of the material.

The ultrasonic velocity (the distance traveled by an ultrasonic wave in unit time) is related to the elastic modulus, E, and density, ρ:

$$\left(\frac{k}{\omega}\right) = \frac{\rho}{E} \qquad (15)$$

Here, ω is the angular frequency ($\mathrm{rad\,s^{-1}}$) and k is the complex wave number $= (\omega/c) + \mathrm{i}\alpha$, where c is the ultrasonic velocity ($\mathrm{m\,s^{-1}}$), α is the attenuation coefficient ($\mathrm{Np\,m^{-1}}$), and $\mathrm{i} = \sqrt{-1}$.

For low-attenuating materials (i.e., $\alpha << \omega/c$), eqn [15] can be written as

$$\frac{1}{c^2} = \frac{\rho}{E} \qquad (16)$$

where ρ is the density ($\mathrm{kg\,m^{-3}}$) and E is the modulus of elasticity (Pa).

In the case of milk, E is the bulk modulus, as liquids are normally subjected to a compressive (as opposed to a shearing) ultrasonic wave.

The attenuation coefficient, α, is a measure of the decrease in the amplitude of an ultrasound wave as it travels through the material. It is given by the equation

$$A = A_0\,\mathrm{e}^{-\alpha x} \qquad (17)$$

where A_0 is the initial amplitude of the wave and A is the amplitude after the wave has traveled a distance x through the material. Attenuation results from absorption and scattering.

The acoustic impedance is a measure of the fraction of an ultrasonic wave reflected from a material's surface. The (complex) specific acoustic impedance, Z, is defined as

$$Z = \frac{\omega\rho}{k} \qquad (18)$$

where $Z = R_Z + \mathrm{i}X_Z$, with R_Z being the resistive (real) part of the complex impedance and X_Z the reactive (imaginary) part of the complex impedance.

For low-attenuating materials (i.e., $\alpha << \omega/c$), eqn [18] can be written as

$$Z = R_Z = \rho c \qquad (19)$$

Values of the three ultrasonic properties of skim milk (at 1 mHz and 28 °C) are as follows:
velocity, $c = 1522\,\mathrm{m\,s^{-1}}$,
attenuation coefficient, $\alpha = 23\,\mathrm{Np\,m^{-1}}$, and
impedance, $Z = 1.5 \times 10^{-6}\,\mathrm{kg\,m^{-2}\,s^{-1}}$.

Ultrasonic properties, which are frequency and temperature dependent, are most commonly measured using the pulse-echo technique. Enhanced information about the characteristics of the sample can be gained by carrying out measurements over a range of frequencies and also a range of temperatures.

The ultrasonic properties of milk are fundamental properties, but they are not of interest by themselves. Their measurement is useful only insofar as it is possible to establish relationships between them and other physico-chemical characteristics such as composition, structure, and state – characteristics that determine how ultrasound interacts with the sample. Such relationships can be developed empirically by means of calibration experiments, or theoretically.

Ultrasound has been used to measure the composition of milk in terms of fat and solids-not-fat, the particle size distributions of milk fat globules and casein micelles, and the rate of coagulation of milk by chymosin. Ultrasonic imaging has been used to measure teat milk flow rate, and to non-invasively monitor the microbial spoilage of packaged UHT milk. The measurement of creaming profiles, the principle of which is the measurement of the ultrasound velocity and/or attenuation coefficient as a function of sample height and time, has obvious potential for milk and other liquid dairy products.

Apart from being non-invasive and non-destructive, ultrasound can be used to analyze opaque as well as concentrated systems, and is inexpensive, rapid, and accurate.

Electrical and Dielectric Properties

Electrical Conductivity

Electrical conductivity (EC), σ, is a measure of a material's ability to carry an electrical current. It ranges in value from 10^{-18} to $10^{7}\,\mathrm{S\,m^{-1}}$ (Siemen per meter), depending on the material. The EC of normal whole milk is about $0.460\,\mathrm{S\,m^{-1}}$.

EC is most easily measured by applying a known DC voltage across a pair of parallel electrodes immersed in the sample, measuring the current produced, and calculating the resistance of the specimen (the volume bounded by the electrodes):

$$\sigma = \frac{1}{R}\frac{l}{A} = G\frac{l}{A}\,(\mathrm{S\,m^{-1}}) \qquad (20)$$

where R is the resistance (Ω), G the conductance (S), l the distance between the electrodes (m), and A the electrode area ($\mathrm{m^2}$).

Equation [20] shows that EC and electrical conductance (the reciprocal of resistance) are related via the dimensions of the specimen.

EC is generally measured in practice by impedance (or, admittance) spectroscopy, in which an AC rather than a DC voltage is applied to the sample. Impedance and admittance (the reciprocal of impedance) are complex properties, the real parts of which are, respectively, resistance and conductance. Measurements are best carried out at frequencies >10 kHz; at and above this frequency the measured value is a property of the bulk milk and not of the milk–electrode interface.

The EC of milk is determined mainly by the charged species present, particularly the salts. There is very little contribution from lactose; casein, also, makes a much smaller contribution than do the milk salts. The main effect of milk proteins in general is to hinder the migration of ions and thus depress EC. However, the release of calcium ions from the casein micelles as a result of a decrease in pH, caused by either deliberate acidification or bacterial growth, results in an increase in EC. A drop in milk pH to about 5 causes all of the colloidal calcium phosphate to dissolve, and the equilibria of milk buffer systems to change, resulting in saturation of the EC to a constant maximum value. This phenomenon is the basis of the automatic monitoring of the growth of lactic acid bacteria by conductimetric methods.

Mastitis in a quarter of a cow's udder results in decreases in the concentrations of lactose and $\mathrm{K^+}$ in the milk secreted, and corresponding increases in the concentrations of $\mathrm{Na^+}$ and $\mathrm{Cl^-}$ that preserve the milk's isoosmolality with the cow's blood. The net effect is an increase in the milk's EC. This phenomenon has led to much research over the last 60 years aimed at finding a reliable way of using in-line EC measurement at milking to detect both subclinical and clinical mastitis in the quarters of individual cows. Although the EC of milk from individual quarters can be monitored easily and accurately, achieving this aim has been hampered by the fact that variation in EC depends not only on the level of infection, but also on numerous other factors such as breed, parity, estrus, lactation stage, presence of other diseases, milking interval, time of day, and milk composition. In 1998, an extensive analysis of published data carried out by the International Dairy Federation concluded that EC measurement could not identify mastitic quarters or mastitic cows, nor detect subclinical mastitis, with sufficient accuracy to be useful. Currently, most automatic milking systems and some manual systems incorporate sensors for measuring the EC of quarter milk and software for processing the data generated. The development of sophisticated statistical modeling of the data, which involves comparisons between the quarters of the individual cow over successive milkings, has led to an improvement in the sensitivity of detection of subclinical and clinical mastitis. In the case of automatic milking systems, the farmer is dependent on EC measurement for detecting mastitic cows.

The EC of fresh milk and cream decreases with increasing fat content because the fat globules (themselves nonconducting) occupy volume that would otherwise be filled with the conducting aqueous phase of the product, thus impeding the mobility of the conducting ions and increasing the distance that migrating ions have to travel. For a fat content in the range

0.15–51% (w/w), the EC of milks and creams is related to the volume fraction of fat, ϕ_{fat}, as follows:

$$\sigma = \sigma_{\text{skim}}(1-\phi_{\text{fat}})^{\delta}\,(1+q\,\phi_{\text{fat}}^{2})^{\delta} \tag{21}$$

where $\delta = 1.56 \pm 0.04$, and q varies between 3.0 and 3.5, depending on the batch of milk.

Measurement of the admittance of milk has the potential to allow estimation of milk fat content if milk water content is known, and vice versa. The latter utility of the measurement could provide a means of detecting adulteration of milk with water.

The EC of stored whole milk reaches a higher saturation value than that of stored skim milk, because for whole milk the EC-depressing effect of the presence of fat is more than compensated for by the production of free fatty acids and the release of phosphate ions from the milk fat globule membrane.

The EC of milk increases markedly with temperature, as illustrated by the following empirical relationship for buffalo milk, valid for the temperature range 5–70 °C:

$$\sigma = 1.71\times10^{-1} + 6.32\times10^{-3}\theta + 9.01\times10^{-6}\theta^{2} \quad (\text{S m}^{-1}) \tag{22}$$

The EC and the viscosity of milk have been shown to be related. This relationship is thought to be due to the fact that the ion content of milk affects both the EC and the conformation of milk proteins, the latter influencing viscosity.

Dielectric Properties

The dielectric properties of a material, the permittivity (ε') and the dielectric loss factor (ε''), are the real and imaginary parts, respectively, of the complex permittivity (ε):

$$\varepsilon(\omega) = \varepsilon'(\omega) - j\varepsilon''(\omega) \tag{23}$$

where ω is the frequency (Hz) and j $=\sqrt{-1}$.
$\varepsilon'$is a measure of the ability of the material to store electromagnetic energy. ε'' is a measure of the material's ability to dissipate electromagnetic energy as heat. The latter phenomenon is exploited in microwave and radio frequency heating.

Permittivity and loss factor are frequency and temperature dependent. Representative values of ε' and ε'' for whole milk (3.25% fat) at 20 °C and 2.45 GHz (the frequency most commonly used for microwave heating) are 67.9 and 17.6, respectively, relative to the values for free space. Corresponding values for water are 80.2 and 13.4.

The permittivity at 20 °C of skim milk, low-fat milk, and whole milk decreases with increasing frequency in the range 1–20 GHz. The loss factor, on the other hand, exhibits a net increase with frequency over this range, but goes through a minimum near the lower end and a maximum near the higher end. At a given frequency, the permittivity of whole milk decreases slowly with increasing temperature, whereas the loss factor is almost temperature-independent.

The dielectric property spectra of whole milks of varying total solids content can be modeled using the following theoretical equations:

$$\varepsilon'(\omega) = \varepsilon'_{\infty} + \frac{\varepsilon'_{S} - \varepsilon'_{\infty}}{1+\omega^{2}\tau^{2}} \tag{24}$$

$$\varepsilon''(\omega) = \frac{(\varepsilon'_{S} - \varepsilon'_{\infty})\,(\omega t)}{1+\omega^{2}\tau^{2}} + \frac{\sigma}{\omega\varepsilon_{0}} \tag{25}$$

where ε'_{∞} is the real permittivity at very high frequencies, ε'_{S} is the real static (low frequency) permittivity, $\tau = 1/2\pi f_{R}$, where f_{R} is the relaxation frequency, σ the electrical conductivity, and ε_{0} the permittivity of free space ($= 8.854\times10^{-12}$ F m^{-1}).
Modeling shows that the complex permittivity of milk is essentially that of water, with perturbations caused by the ionic and nonionic milk components. Analysis of the spectral data relating to permittivity (ε'_{S}, ε'_{∞}, and τ) and those relating to loss factor (($\varepsilon'_{S} - \varepsilon'_{\infty}$), τ , and σ) shows that the perturbations are sensitive to the presence of fat, carbohydrate, protein, and ionic species. For example, permittivity is depressed by the nonionic components fat, lactose, and casein. Measurement of dielectric property spectra could potentially be useful in monitoring the gross composition of large quantities of milk in real time.

Optical Properties

The term 'optical properties' comprises properties with respect to electromagnetic radiation not only in the visible region of the spectrum (380–760 nm), but also in the infrared (IR, 760 nm to 1 mm) and ultraviolet (UV, 5–380 nm) regions that lie on either side of it. Visible, IR, or UV light incident on milk is absorbed, absorbed and reemitted (producing fluorescence), scattered, or transmitted, depending on wavelength.

Milk, as a complex colloidal dispersion of fat globules, casein micelles, and whey proteins in an aqueous solution containing a number of solutes, not only absorbs light at several wavelengths but also scatters light, as well as transmitting it. In the visible region, riboflavin in milk absorbs strongly near 470 nm (giving the yellow-green color of whey) and emits fluorescent radiation with a maximum at 530 nm. The β-carotene in milk fat absorbs near 460 nm, which is responsible for the yellow color of the fat.

In the UV region, aromatic amino acid residues of proteins (tyrosine and tryptophan) absorb strongly near 280 nm, and a part of the UV radiation is emitted as fluorescence at 340 nm. Measurement of the intensity of this fluorescence has been used to quantify the protein content of milk. The double bonds of the milk fat absorb very strongly near 220 nm.

In the IR region, absorption is primarily by the amide (II) groups (CONH) of proteins at 6465 nm, the hydroxyl groups (OH) of lactose at 9610 nm, and the ester carbonyl groups (C=O) of lipids at 5723 nm. This is the basis for the instrumental compositional analysis of milk using infrared analyzers. Milk samples are first homogenized to reduce the size of fat globules to <1 μm, to prevent their presence interfering with the measurement.

Both fat globules and casein micelles scatter light. It is possible to measure the intensities of both the scattered light and the light transmitted by the sample. Both measurements form the basis of the determination of the fat content of milk and of the size distributions of fat globules and casein micelles. Instruments for fat determination are based on measurement of turbidity, that is, the attenuation of the incident beam, usually expressed as optical density or absorbance.

The surface light scattering (diffuse reflection) and absorption properties of milk strongly affect the visual appearance of milk. The creamy color of whole milk is due to the β-carotene in the fat. Casein micelles scatter blue light (shorter wavelength) more effectively than they scatter red (longer wavelength), giving skim milk its bluish color. Homogenization of whole milk makes milk whiter by increasing the diffuse reflection (e.g., by some 19% at 550 nm). Heating has the same effect initially, but severe heating causes nonenzymic browning.

The penetration of light into milk can be important with respect to light-induced reactions. At 580 nm, light incident on whole milk loses 90 and 99% of its intensity at penetration depths of 8 and 24 mm, respectively.

The refractive index of milk varies with temperature and wavelength. The value for bovine milk at 589.3 nm (the D line of the sodium spectrum) at 20 °C, n_{D}^{20}, lies in the range 1.344 0–1.348 5. This may be compared with the value of 1.333 0 for water. The difference (Δn) between the values of n_{D}^{20} for milk and water reflects the presence of dissolved substances (lactose, minerals, etc.) and colloidal substances (casein micelles and whey proteins):

$$\Delta n = \rho \Sigma (mr) \tag{26}$$

where ρ is the density of the aqueous part of milk (kg m^{-3}), and m and r are, respectively, the mass fractions and specific refractive increments (m^3 kg^{-1}) of the individual substances. Values of r for the main determinants of Δn are 2.07×10^{-4} (casein micelles; m^3 kg^{-1} of dry casein), 1.87×10^{-4} (whey proteins), 1.40×10^{-4} (lactose), and $\sim 1.70 \times 10^{-4}$ (other dissolved substances). Fat globules and air bubbles do not contribute to the refractive index of milk.

Colligative Properties: Freezing Point, Boiling Point, and Osmotic Pressure

The part of milk comprising water and low molecular weight solutes obeys Raoult's law approximately. This law in one form states that the relative lowering of the solvent vapor pressure resulting from the presence of a solute is equal to the mole fraction of the solute in the solution. Consequences of the lowering of vapor pressure (the equilibrium relative humidity of milk at ambient temperature is ~99.3%) are a depression of freezing point ($\Delta\theta_{\mathrm{f}}$) and an elevation of boiling point ($\Delta\theta_{\mathrm{b}}$). In addition, the presence of the solute gives rise to an osmotic pressure.

For very dilute solutions

$$\Delta\theta_{\mathrm{f}} = K_{\mathrm{f}} M \tag{27}$$

and

$$\Delta\theta_{\mathrm{b}} = K_{\mathrm{b}} M \tag{28}$$

where K_{f} and K_{b} are the cryoscopic constant and ebullioscopic constant, respectively, and M is the molality of the solution.

The freezing point of milk is less than 0 °C, and the boiling point higher than 100 °C (at atmospheric pressure). Equations [27] and [28] can be used to roughly calculate the freezing point depression and boiling point elevation of milk as functions of the concentrations of water-soluble milk components.

Lactose, chloride salts, and other components (calcium, potassium, magnesium, lactate, phosphate, citrate, etc.) contribute about 55, 25, and 20%, respectively, to the freezing point depression. The freezing point of the vast majority of individual milks lies in the range −0.512 to −0.550 °C, and few fall outside the range −0.520 to −0.512 °C. The constancy of the freezing point depression is a reflection of the constant osmolality of milk. Although the concentrations of individual water-soluble components can vary, the total molality of fully dissociated species remains fairly constant. As the milk secretion process dictates that the osmotic pressure of milk be kept equal to that of blood (~687 kPa), a constant osmolality is maintained in milk by the passage of blood constituents into the mammary gland; any change in the concentration of lactose in milk is compensated for by changes in the concentrations of sodium and chloride. Milk with a freezing point of −0.53 °C has an osmolality of 0.285 osmol kg^{-1} water.

The determination of freezing point is extensively used to assess whether or not milk has been adulterated by the addition of water, and to quantify the amount added. Milk with a freezing point ≤ -0.525 °C is usually assumed to be unadulterated.

Acid–Base Equilibria

pH of Milk

The pH of bovine milk at 25 °C usually lies in the range 6.5–6.7, with 6.6 being the most common value. The pH decreases with increasing temperature. This implies temperature-induced changes in milk's complex buffering system rather than an increase in milk's acidity. At a given temperature, differences in pH and buffering capacity between individual lots of fresh milk reflect compositional variation. The pH of colostrum can be as low as 6.0 and that of mastitic and end-of-lactation milks as high as 7.5. High pH can be due to increases in $[\mathrm{Na}^{+}]$ and $[\mathrm{Cl}^{-}]$ (and possibly in the concentrations of other ions), a reduction in the lactose content, and a reduction in the concentration of soluble inorganic P – changes that alter buffering capacity in this pH range.

Buffering Constitutents of Milk

Milk, because of its buffering system, resists change in pH when it is titrated against a strong acid or a strong base. The extent of resistance, that is, the buffering action, at a given pH is called the 'buffering index'. The buffering index, $\mathrm{d}B/\mathrm{dpH}$, is the derivative (slope) of the titration curve (the plot of moles of strong acid or strong base added to milk vs. pH). It is calculated as follows:

$$\frac{\mathrm{d}B}{\mathrm{dpH}} = \frac{(\text{volume of acid or base solution added}) \times (\text{normality of solution})}{(\text{average volume of sample}) \times (\text{pH change produced})} \tag{29}$$

The resulting value of $\mathrm{d}B/\mathrm{dpH}$ is assigned to the pH at the mid-point of the pH change that has occurred.

Buffering action is due to the presence in milk of acid buffers (weak acid–conjugate base pairs) and base buffers (weak base–conjugate acid pairs). Milk contains many acidic and alkaline groups that result in buffering action over a wide pH range. The main groups are listed in **Table 3**. The principal buffer components in milk are soluble phosphate, colloidal calcium phosphate (CCP), citrate, bicarbonate, and casein.

The relationship between pH and $\mathrm{p}K_{\mathrm{a}}$ (the negative logarithm of the acidity constant K_{a}) for the titration of a weak acid against a strong base is given by the Henderson–Hasselbalch equation:

$$\mathrm{pH} \approx \mathrm{p}K_{\mathrm{a}} + \log\frac{[\mathrm{A}^{-}]}{[\mathrm{HA}]} \tag{30}$$

Maximum buffering occurs at $\mathrm{pH} = \mathrm{p}K_{\mathrm{a}}$. In the case of a weak base–conjugate acid buffer, maximum buffering action likewise exists when $\mathrm{pH} = \mathrm{p}K_{\mathrm{a}}\ (= 14 - \mathrm{p}K_{\mathrm{b}})$. K_{b} is the basicity constant and $\mathrm{p}K_{\mathrm{b}}$ is its negative logarithm.

In some cases several values are given for $\mathrm{p}K_{\mathrm{a}}$ in **Table 3**; values for many milk constituents are uncertain because of the complexity of the overall system.

Table 3 Principal buffering groups in milk

Group	*Approximate concentration (mmol l^{-1})*	*Expected pK_a*	*pK_a (in milk)*
Salts			
Inorganic phosphate	21.0	2.1, 7.2, 12.3	3, 5.8, 6.6
Citrate	9.0–9.2	3.1, 4.7, 5.4	3, 4.1, 4.8
Organic phosphate esters	2.5–3.5	1.4, 6.6	1.7, 5.9
Carbonate	2.0	6.4, 10.1	6.4, 10.1
Lactic acid	<0.4	3.9	3.9
Formic acid	0.2–1.8	3.6	3.6
Acetic acid	0.05–0.8	4.7	4.8
Various amines	1.5	~7.6	7.6
Protein-bound residues	*Titratable group*	*Expected pK_a*	*pK_a (in milk)*
Aspartic acid	β-COOH	4.6	4.1
Glutamic acid	α-COOH	4.6	4.6
Histidine	Imidazole	6.1	6.5
Tyrosine	Phenol	9.7	-
Lysine	ϵ-NH_3^+	10.4	10.5
Phosphoserine	Phosphate	1.5, 6.5	2, 6
N-Acetylneuraminic acid	COOH	2.6	5.0
Terminal carboxyl	α-COOH	3.6	3.7
Terminal amino	α-NH_3^+	7.9	7.9

From McCarthy OJ and Singh H (2009) Physico-chemical properties of milk. In: McSweeney PLH and Fox PF (eds.) *Advanced Dairy Chemistry, Vol. 3: Lactose, Water Salts and Minor Constituents*, 3rd edn., pp. 691–758. New York: Springer.

The shape of a titration curve, and consequently the relationship between buffering index and pH, depends on the experimental methodology used; titration and back-titration curves of milk do not coincide (**Figures 1** and **2**). When milk is acidified (**Figure 1**), maximum buffering (a maximum in d*B*/dpH) occurs at about pH 5.1, but when acidified milk is back-titrated with a base, a low extent of buffering exists at pH 5.1 and a maximum at pH ~6.3. The acid part of the titration curve is important because milk is acidified in the manufacture of products such as yogurt.

When milk is titrated to pH 11.0 (**Figure 2**), buffering action is relatively slight at pH 8–9 but increases at higher pH values. There is little difference between the curves for titration with alkali and back-titration with acid. On back-titration, a buffering peak is not observed at pH 6.3 (cf. **Figure 1**). Although there is a peak at about pH 5.1, it is weaker and less distinct than the peak obtained when normal milk is first acidified (**Figure 1**).

The maximum at pH 5.1 on acidification is due to dissolution of CCP and the consequent formation of HPO_4^{2-} and $H_2PO_4^-$. On back-titration, buffering action is low at this pH because the CCP is already solubilized. The maximum at pH 6.3 is due to the formation of calcium phosphate, resulting in the release of H^+ (from HPO_4^{2-} and $H_2PO_4^-$), which can combine with OH^-.

The buffering action of milk at high pH values is probably due to lysine residues and carbonate. When milk is titrated to high pH, all of the calcium phosphate precipitates. The precipitate dissolves again on subsequent acidification, resulting in buffering action over a wide pH range.

Colostrum has a much higher buffering capacity than that of normal milk over the pH range 6.6–3.0. The buffering peak at pH ~5.1 for mastitic milk is slightly higher than that for normal milk.

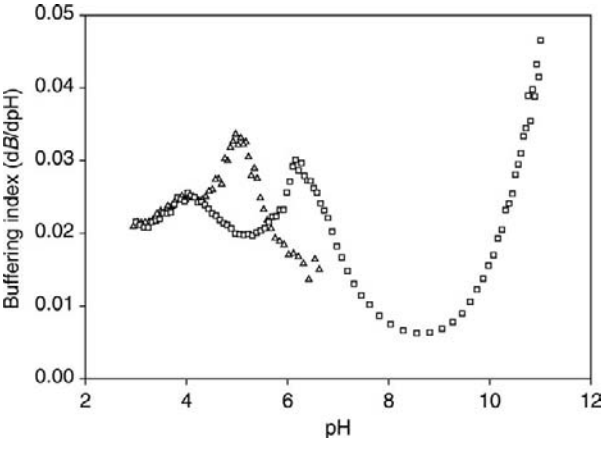

Figure 1 Buffering curves of milk titrated from the initial pH (6.6) to pH 3.0 with 0.1 M HCl (Δ) and then back-titrated to pH 11.0 with 0.5 M NaOH (□). Data supplied by J. A. Lucey, Department of Food Science, University of Wisconsin–Madison.

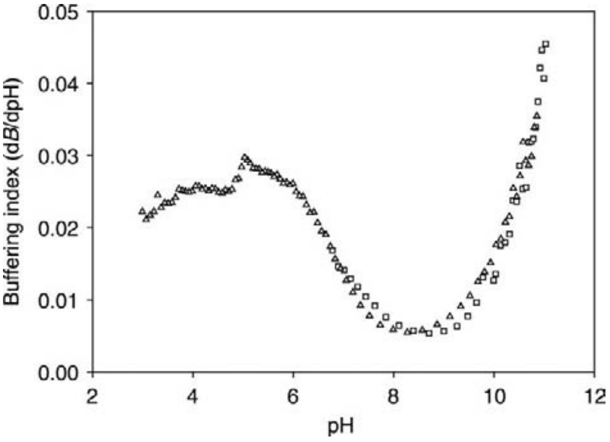

Figure 2 Buffering curves of milk titrated from the initial pH (6.6) to pH 11.0 with 0.5 M NaOH (□) and then back-titrated to pH 3.0 with 0.5 M HCl (Δ). Data supplied by J. A. Lucey, Department of Food Science, University of Wisconsin–Madison.

Titratable Acidity of Milk

The alkaline range of the titration curve is important because of the widespread use of titratable acidity to characterize milk. The titratable acidity is the buffering capacity of milk between its own pH (6.6) and pH 8.3 (the phenolphthalein end point). The measurement of titratable acidity (usually expressed, somewhat arbitrarily, as percentage lactic acid) is useful for determining the freshness of milk and for controlling the manufacture of fermented dairy products. The titratable acidity of fresh milk seldom falls outside the range 0.14–0.16%.

Effects of Milk Treatment on Acid–base Equilibria

Heating

Heat treating milk (e.g., by holding at 100 °C for 10 min) results in an increase in buffering action at pH ~5.0 during acid titration. This is probably caused by an increase in the concentration of CCP owing to the formation of heat-precipitated calcium phosphate. More severe heat treatment causes a shift of the peak from pH 5.0 to pH 4.4, and the buffering action in the pH range 5.0–4.0 is much stronger than that of unheated or less severely heated milk. The shift in the pH of the peak may be due to a change in the structure and composition of CCP during the severe heat treatment.

Freezing

The pH of milk decreases to as low as 5.8 during slow freezing, probably owing to the precipitation of calcium phosphate and the consequent release of H^+ in the unfrozen phase as this phase becomes increasingly concentrated.

Little change occurs on rapid freezing, possibly owing to insufficient time available for precipitation to occur.

Dilution and concentration

Concentration of milk lowers milk pH owing to precipitation of calcium phosphate; dilution has the opposite effect.

During the ultrafiltration concentration of milk, the buffering capacity of the retentate increases steadily owing to the increasing concentrations of casein, whey proteins, and milk salts.

Oxidation–Reduction Equilibria

Oxidation and reduction are, respectively, the loss and gain of electrons. The potential of a system to transfer electrons, that is, the oxidation–reduction or redox potential (E_h), is measured relative to the hydrogen electrode, and expressed in volts. For a simple binary oxidation–reduction system, E_h is related to the concentrations of the oxidized and reduced forms of the substance involved by the Nernst equation:

$$E_h = E_0 + \frac{RT}{nF}\ln\left(\frac{[\mathrm{Ox}]}{[\mathrm{Red}]}\right) \tag{31}$$

where E_0 is the standard redox potential (V) (i.e., the potential when both the oxidized and reduced forms are at unit activity); [Ox] and [Red] are the activities of the oxidized and reduced forms, respectively; n is the number of electrons transferred per molecule; R is the gas constant ($8.314\,\mathrm{J\,K^{-1}\,mol^{-1}}$); T is the absolute temperature (K); and F is the Faraday constant ($96.5\,\mathrm{kJ\,V^{-1}\,mol^{-1}}$). Systems with a positive value of E_h are oxidizing systems, whereas those with a negative value are reducing ones.

At 25 °C and for a one-electron transfer, eqn [23] becomes

$$E_h = E_0 + 0.059\log\left(\frac{[\mathrm{Ox}]}{[\mathrm{Red}]}\right) \tag{32}$$

In many biological systems, H^+ are involved in the overall oxidation reaction. In this case, again, for a one-electron transfer,

$$E_h = E_0 + 0.059\log\left(\frac{[\mathrm{Ox}]}{[\mathrm{Red}]}\right) - 0.059\mathrm{pH} \tag{33}$$

An oxidation system exhibits poising capacity, analogous to buffering capacity, at values of [Ox]/[Red] close to unity, that is, at E_h values close to the E_0 value.

The redox potentials of individual milk samples in equilibrium with air fall in the range +0.25 to +0.35 V at 25 °C at the normal milk pH. The redox potential is inversely related to pH, ranging from about +0.20 at pH 10 to about +0.395 at pH 3.5 for raw milk. Little information is available on the considerable poising capacity of milk, because of measurement difficulties. These difficulties are the result of sluggishness of some oxidation–reduction systems in milk in coming to equilibrium (redox potentials pertain to equilibrium conditions), incomplete reversibility of some systems, and back- diffusion of oxygen during measurement.

O_2, ascorbate, and riboflavin are the principal systems determining the E_h of milk. The thiol–disulfide system contributes to the E_h of heated milk. All the ascorbate in freshly drawn milk is in the reduced form, but reversible oxidation to dehydroascorbate occurs at a rate dependent on the concentrations of Cu^{2+}, Fe^{3+}, and O_2; the E_h values of all three of these are higher than that of ascorbate. Preservation of ascorbate depends on deaeration and prevention of contamination by copper.

Oxidation–reduction reactions in milk are influenced by heat treatment, bacterial activity, and exposure to light, as well as by O_2 and the presence of metal ions. Heating lowers the E_h of milk, the more so if high temperature–short time conditions are used and prior deaeration carried out; the result is better retention of reducing substances such as ascorbic acid.

Bacterial activity reduces the E_h by consumption of available oxygen in the milk. The decrease in potential can lead to the reduction and loss of color of certain added dyes, and is the basis of the methylene blue test for the bacterial status of fresh milk.

The riboflavin in milk does not contribute significantly to E_h or to poising. However, the absorption of visible light by riboflavin (at 470 nm) results in excitation. Excited-state riboflavin can oxidize a number of compounds in milk, thereby itself becoming reduced. This is an example of photooxidation, and it results in the production of off-flavors in milk exposed to sufficiently intense visible light, for example, direct sunlight.

Conclusions

Some of the physical and physico-chemical properties of milk, such as density, thermal properties, freezing point, acid–base equilibria, and oxidation–reduction equilibria, have been well studied and are well understood. Others, such as acoustic properties and dielectric properties, have been studied to a relatively limited extent. This is a reflection of the relative importance, historically, of the different properties with respect to production, analysis, handling, and processing of milk.

Milk, a complex biological fluid, is by no means fully understood. There is no doubt that future advances in our understanding of its nature and attributes will depend to a significant extent on the use of measurement techniques whose development will be built upon and will extend our current knowledge of physical and physico-chemical properties.

Bovine Milk

P F Fox, University College, Cork, Ireland

© 2011 Elsevier Ltd. All rights reserved.

Introduction

While milk for human consumption is obtained from several species, breeds of the genus *Bos*, especially *Bos taurus* (*see* **Animals that Produce Dairy Foods**: Major *Bos taurus* Breeds; Minor and Dual-Purpose *Bos taurus* Breeds), predominate in milk production. Bovine milk represents about 85% of all milk offered for sale, compared to 11% represented by buffalo milk and 2% each by ovine and caprine milk. For several hundred years, some breeds of *B. taurus* have been selected and bred specifically for milk production, and consequently are now extremely efficient for this purpose. Owing to its commercial importance, bovine milk has been the subject of research for more than 100 years and is now the most thoroughly characterized food system. The word milk, when unqualified, is assumed to refer to bovine milk.

The milks of all species have similar constituents and those of the commercial dairying species are quite similar, but there are significant interspecies, even interbreed, differences, which affect the processability of milk. The general characteristics of milk are described in the article **Milk**: Introduction. The specific unique properties of bovine milk are described in an introductory way in this article, while the milks of other commercially important or interesting species are described in the articles **Milk**: Buffalo Milk; Camel Milk; Equid Milk; Goat Milk; Human Milk; Milk of Marine Mammals; Milks of Non-Dairy Mammals; Milks of Other Domesticated Mammals (Pigs, Yaks, Reindeer, etc.); Sheep Milk. This set of articles is intended to provide overviews, and especially interspecies comparisons, of milk. The properties of milk constituents, especially those of bovine milk, and the effects thereof on milk processing are considered in several articles throughout this encyclopedia.

Milk contains several hundred compounds, mostly at trace levels. These constituents can be classified into four categories:

- organ- and species-specific constituents (lipids and the principal proteins)
- organ- but not species-specific constituents (lactose)
- species- but not organ-specific constituents (some whey proteins (WPs))
- neither organ- nor species-specific constituents, although the profile and concentrations are species specific (water, salts, vitamins)

Like the milk of probably all species, the composition, and hence the properties, of bovine milk varies with several factors, especially breed, stage of lactation, and health, nutritional status, and individuality of the animal – the differences observed may be very large and consequently milk should be selected carefully for processing. The influence of animal husbandry practices on the production and composition of milk is described in several articles throughout this encyclopedia. Although the modern dairy cow is very highly bred and selected, intrabreed differences persist, even within single herds under essentially identical management.

The principal and some of the minor constituents of milk are the subject of at least one dedicated article. This article presents a brief general overview of the principal constituents, lactose, lipids, proteins, and salts, and properties of bovine milk.

Lactose

Lactose, one of the principal constituents of the milk of most species, is a reducing disaccharide unique to milk. Bovine milk typically contains ~4.8% lactose, a value that decreases with advancing lactation and mastitic infection. The concentration of lactose in the milk of the principal dairying species, cow, buffalo, goat, and sheep, is approximately the same, at 4.5–5.0%, and there is little effect of breed or individuality or nutrition of the animal on the lactose content of its milk, owing to the relationship between lactose concentration and the osmotic pressure of blood, which is fixed (*see* **Lactose and Oligosaccharides**: Lactose: Chemistry, Properties).

Lactose is a slightly sweet-reducing disaccharide, which occurs in the milk of most species. Because of its low solubility, crystallization behavior, and hygroscopicity, it causes problems in concentrated, dehydrated, and frozen products; these problems are largely confined to bovine milk since very little of such products are produced from the milk of other species. The chemistry, technologically important properties, production, and applications of lactose are described in the articles **Lactose and Oligosaccharides**: Lactose: Chemistry, Properties; Lactose: Derivatives; Lactose: Galacto-Oligosaccharides; Lactose Intolerance; Lactose: Production, Applications; Maillard Reactions.

Oligosaccharides

Oligosaccharides (OSs) containing 3–10 monosaccharides, including fucose and *N*-acetylneuraminic acid, are believed to have been the principal carbohydrates in milk during the early stages of mammalian evolution; they are considered to have had a protective rather than a nutritional role (*see* **Lactose and Oligosaccharides**: Indigenous Oligosaccharides in Milk). In comparison to the milk of many other species (e.g., humans, elephants, bears, marsupials, and monotremes), bovine milk contains low levels of OSs, which have no known technological significance but are believed to be nutritionally and physiologically significant. The OSs partition into the whey during cheese production and there is commercial interest in isolating them for the supplementation of infant formulae. They can be concentrated and purified by membrane fractionation, and the charged OSs, recovered by ion-exchange chromatography.

Lipids

Until recently, the lipids of bovine milk were considered to be its most valuable constituents, being used for the production of butter and ghee and being very important to the quality of cheese, liquid milk, and ice cream. The use of milk fat in spreads has now declined and has been replaced by hydrogenated plant oils. The significance of milk fat in various dairy products is discussed in several articles throughout this encyclopedia (*see* **Butter and Other Milk Fat Products**: Anhydrous Milk Fat/Butter Oil and Ghee; Fat Replacers; Modified Butters; Milk Fat-Based Spreads; Properties and Analysis; The Product and Its Manufacture; **Cream**: Manufacture; Products).

Bovine milk contains ~3–6% lipids, the value depending on breed, individuality, stage of lactation, interval between milking, point during milking at which the sample is taken, nutritional and health status of the animals, and other minor factors. The milk of Jersey and Guernsey cows has the highest fat content and that of Friesian and Holstein the lowest; within any breed, there is considerable variation between individual animals in the fat content of milk. Since the fat content of milk is genetically controlled, breeding programs strive to increase it. The fat content of bovine milk decreases during the first 4–6 weeks postpartum, but then increases considerably, especially toward the end of lactation. The point during milking at which a sample is taken has a very large effect on its fat content, which increases from ~1% at the start of milking to about 10% at the end; this effect is attributed to the retardation of fat globules in the small ducts of the mammary gland – a similar effect is not observed for the soluble constituents, proteins and lactose. Assuming that the cow is thoroughly milked, this factor is not commercially significant. If the interval between milkings is different, the fat content of milk is inversely related to the interval between milkings; this effect may be commercially important, especially if an incorrect sampling procedure is used. If the animal suffers from malnutrition, the fat content of its milk will be reduced, especially if the diet is deficient in roughage, because about 50% of the fatty acids (FAs) in milk are synthesized by rumen microbes acting on cellulose; a diet rich in lipids, especially unsaturated lipids, depresses the fat content of milk (*see* **Feed Ingredients**: Feed Concentrates: Cereal Grains; Feed Concentrates: Cereal Grains; Feed Concentrates: Oilseed and Oilseed Meals; **Feeds, Prediction of Energy and Proteins**: Feed Energy; Feed Proteins; **Feeds, Ration Formulation**: General Nutritive Requirements of Sheep and Goats; Lactation Rations for Dairy Cattle on Dry Lot Systems; Models in Nutritional Management; Models in Nutritional Research; Systems Describing Nutritional Requirements of Dairy Cows; **Feed Supplements**: Feed Supplements: Anionic Salts; Feed Supplements: Fats and Protected Fats; Feed Supplements: Macrominerals; Feed Supplements: Microminerals; Feed Supplements: Organic-Chelated Minerals; Feed Supplements: Ruminally Protected Amino Acids; Vitamins).

The lipids in milk are principally (98%) triglycerides, with smaller amounts of phospholipids, other polar lipids, diglycerides, sterols (principally cholesterol), carotenoids, fat-soluble vitamins, and traces of FAs and hydrocarbons.

The FAs in milk lipids are not synthesized in the mammary gland but originate from the diet or from blood lipids synthesized *de novo* in the liver; in the case of ruminants, β-hydroxybutanoic acid, produced by rumen bacteria, supplies a substantial part of the lipid carbon, being converted to butanoic acid and incorporated directly into triglycerides or converted to butanyl CoA used instead of acetyl CoA in the biosynthesis of FAs (*see* **Mammary Gland, Milk Biosynthesis and Secretion**: Milk Fat). Hence, ruminant milk fats contain substantial (~20 mol%) amounts of C4:0, C6:0, C8:0, and C:10:0 – they are the only lipids that contain C4:0. The proportions of these short-chain FAs, which vary with the species of ruminants, have major effects on the physical properties and flavor-generating aspects of these lipids. Ruminant milk fats contain low levels of polyunsaturated fatty acids (PUFAs) because dietary PUFAs are biohydrogenated in the rumen. Ruminant milk fats contain a relatively high level of saturated FAs, which are considered to be nutritionally undesirable. However, opinions on the nutritional significance of FAs are changing (*see* **Milk Lipids**: Bioactive Lipids; **Nutrition and Health**: Nutritional and Health-Promoting Properties of Dairy Products: Fatty Acids of Milk and Cardiovascular Disease). However, contain substantial amounts of Δ 9, 11 *cis, trans* octadecadienoic acid (conjugated linoleic acid (CLA)), produced by incomplete biohydrogenation of linoleic acid in the rumen. The level of CLA, which has anticarcinogenic properties, in ruminant milk fats is affected by the levels of PUFAs in the diet and is higher in bovine than in other ruminant milk fats (*see* **Milk Lipids**: Conjugated Linoleic Acid).

Cattle transfer dietary carotenoids to milk, at a level that is strongly dependent on the breed of animal, the plants in the forage, and season of the year; other ruminants do not do this. Consequently, bovine milk and products produced therefrom are markedly yellow in comparison with buffalo, sheep, or goat milk. The yellow color of products produced from bovine milk is unattractive to many consumers accustomed to products produced from buffalo, sheep, or goat milk. The carotenoids may be bleached by benzoyl peroxide or masked using TiO_2 or chlorophyll.

Lipids are insoluble in the aqueous environment of milk; they occur as an emulsion stabilized by a special membrane, the milk fat globule membrane (MFGM), which consists of polar lipids and special proteins, acquired during the expression of fat globules from the mammocytes (*see* **Milk Lipids**: Milk Fat Globule Membrane). One of the special proteins is xanthine oxidoreductase (XOR), which is present on the inner surface of the MFGM and somehow initiates blebbing of the fat globules through the apical membrane of the mammocyte. The mechanism of this action of XOR is unknown but it is not enzymatic. Bovine milk possesses much higher XOR activity than the milk of any other species studied, apparently due to a very low level of molybdenum in the milk of the other species studied – how this affects the release of fat globules is not known. The fat globules in bovine milk range in diameter from 0.1 to 20 µm, with an average of 3–4 µm. The average diameter decreases throughout lactation and is higher in high-fat (Jersey and Guernsey) milk than in Friesian or Holstein milk. The MFGM partitions into buttermilk on churning for butter manufacture, which is, therefore, rich in phospholipids and other polar lipids which have good emulsifying and nutritional properties (*see* **Milk Lipids**: Buttermilk and Milk Fat Globule Membrane Fractions).

The fat globules in milk are less dense than the skim milk phase and, consequently, would be expected to rise to the surface and form a cream layer in accordance with Stokes' Law. However, the fat globules in bovine milk cream much faster and more copiously than Stokes' Law predicts. The difference is due to the presence of certain globulins (referred as cryoglobulins) that are insoluble at low temperatures and precipitate onto the fat globules, causing them to form clumps, which cream very rapidly due to their large diameter. The milk of the other dairying species lacks cryoglobulins and consequently creams very slowly. The nutritional and physiological significance, if any, of cryoglobulins in bovine milk is not known.

The MFGM contains mucoproteins (mucins), MUC 1 and MUC 15, which in human and equine milk form long (5–20 µm) tendrils; in the case of bovine milk, these tendrils are very unstable and are shed quickly. Pathogenic bacteria attach to the mucins of the tendrils, which appear to have an antibacterial function; they may also improve the digestibility of lipids. The stability of the tendrils of the MFGM of other species has not been reported.

Proteins

Bovine milk contains ~3.5% protein, but this level varies substantially with breed, individuality, stage of lactation, and health and nutritional status of the animal. The technological properties of milk, indeed the very existence of most dairy products, are determined mainly by the unique properties of some of its proteins, which have been very well characterized.

The milk proteins of all species that have been studied fall into two groups: caseins (phosphoproteins that are insoluble at pH ~4.6 and 20 °C, and which are unique to milk) and whey (serum) proteins, the principal of which are milk-specific, with several minor ones derived from the blood (*see* **Milk Proteins**: Heterogeneity, Fractionation, and Isolation). The ratio of caseins to WPs is characteristic of the species. In bovine, ovine, caprine, and buffalo milk, and probably in the milk of other ruminants, the caseins represent ~80% of total proteins, while in human, equine, asinine, porcine, and elephant milk, they are 50% or less. However, the milk of rodents, cats, dogs, and rabbits also has a high proportion of casein and there seems to be no obvious pattern among species, although species that produce a high level of protein in their milk have a high proportion of casein, which presumably reflects the high growth rate of the neonate; animals that grow rapidly tend to have a high casein content in their milk. In addition to supplying amino acids to the neonate, the caseins supply calcium and phosphorus (see below), which are essential for the rapidly growing neonate.

Caseins

Bovine casein comprises four proteins, α_{s1}-, α_{s2}-, β-, and κ-caseins, in the approximate proportions of 38, 10, 35, and 12, respectively, each of which exhibits microheterogeneity owing to genetic polymorphism, variations in the degree of phosphorylation or glycosylation and perhaps deamidation, and in the case of α_{s2}- and κ-caseins, disulfide-linked polymerization. The milk of buffalo, sheep, and goat and many other ruminants also contains these four caseins but human milk contains little or no α_s-casein and equine milk contains little κ-casein. The caseins are relatively small (20–25 kDa) molecules with many rather unique characteristics. All are phosphorylated but the level of phosphorylation varies from 1 to 13; some equine and human caseins are not phosphorylated. All caseins, regardless of species, have a high level of proline (16% for bovine β-casein), which interrupts secondary structures, resulting in the caseins being unstructured, open, rheomorphic proteins; this renders the caseins very surface active and readily digestible, which conforms with the natural function of the caseins as sources of amino acids. The caseins are amiphatic and have high surface activity (*see* **Milk Proteins**: Casein Nomenclature, Structure, and Association).

α_{s1}-, α_{s2}-, and β-caseins bind Ca^{2+} and other polyvalent cations strongly and are rendered insoluble at $[Ca^{2+}]$ >6 mmol l^{-1} at 20 °C. However, the solubility of κ-casein is not affected by Ca^{2+} and it can stabilize up to 10 times of its mass of Ca-sensitive caseins by forming micelles (*see* **Milk Proteins**: Caseins, Micellar Structure). The stability, and destabilization under certain circumstances, of the micelles is critical to dairy technology; in fact, the dairy industry depends on certain properties of the casein micelles. Therefore, the structure and properties of the casein micelles have been studied intensely over the past 100 years and there is general agreement thereon (*see* **Milk Proteins**: Caseins, Micellar Structure). The caseins in the milk of all species appear to form micelles, which are generally similar to those of bovine milk but there are significant differences, as will be apparent from the species-specific articles (*see* **Milk**: Buffalo Milk; Camel Milk; Colostrum; Equid Milk; Goat Milk; Human Milk; Milk of Marine Mammals; Milks of Nondairy Land Mammals; Milks of Other Domesticated Mammals (Pigs, Yaks, Reindeer, etc.); Sheep Milk; Seasonal Effects on Processing Properties of Cows' Milk).

Whey Proteins

The WPs are typical globular proteins, with high levels of secondary, tertiary, and, in some cases, quaternary structures. Bovine milk contains four principal WPs, β-lactoglobulin (β-Lg), α-lactalbumin (α-La), blood serum albumin (BSA), and immunoglobulins (Igs), which represent ~60, 20, 10, and 10% of total WP, respectively, and several minor proteins, mostly at trace levels, many of which have a biological function, including ~60 indigenous enzymes. The WPs of bovine milk are generally similar to those of other species, although there are many minor interspecies differences in amino acid sequences and properties. Human and rodent milk contains no β-Lg and the milk of some marine mammals lacks α-La; the properties and significance of α-La and β-Lg are described in the articles **Milk Proteins**: α-Lactalbumin; β-Lactoglobulin, respectively.

BSA is a leakage protein from blood and has no biological or technological significance in milk. The principal Ig in bovine, ovine, caprine, and buffalo milk is IgG1, which is transported selectively from the blood and is present at ~10% in colostrum and bestows passive immunity on the young of these species who do not receive Ig *in utero*; Ig has no special significance in mature milk. The minor proteins include lactoferrin, vitamin-binding proteins, peptide hormones, and enzymes, and are probably common to most species although the concentration of many shows large interspecies differences; only a few minor proteins in non-bovine milks have been studied. For unknown reasons, the indigenous enzymes are probably the most variable constituents in milk. Bovine milk contains high levels of XOR, lactoperoxidase (LPO), and ribonuclease but a low level of lysozyme. Several of the indigenous enzymes have significant functions: for example, deterioration of quality (e.g., lipase, plasmin, acid phosphatase, XOR), preservation of quality (lysozyme, superoxide dismutase, LPO), as indicators of thermal history (e.g., alkaline phosphatase, catalase, γ-glutamine-transpeptidase, LPO), or as indicators of mastitis (e.g., *N*-acetylglucosaminidase, catalase).

Milk Salts

When bovine milk is heated at a very high temperature, >500 °C, a residue, ash, representing 0.7–0.8% (w/w) of the milk remains. Some of the ash derives from the proteins, a little from the phospholipids, and a trace from sugar phosphates, but the majority is derived from inorganic salts, especially chlorides, phosphates, sulfates, and carbonates of Na, K, Ca, and Mg (macroelements). In addition, milk contains ~30 elements at trace concentrations (microelements). The inorganic elements are present in the milk as salts, some of which are in true solution, some associated with proteins, especially caseins (i.e., colloidal), and a small proportion in the MFGM as a component of some proteins. The inorganic elements are important for nutrition, spoilage (lipid oxidation), structure, and properties of many of the proteins and the activity of several enzymes. Although the inorganic salts are quantitatively minor constituents, they are very important from a nutritional viewpoint and for the technological properties of milk, as discussed in the articles **Milk Salts**: Distribution and Analysis; Interaction with Caseins; Macroelements, Nutritional Significance; Trace

Elements, Nutritional Significance. Qualitatively, bovine milk contains the same range of inorganic elements as the milk of other species but there are very substantial quantitative differences, which affect the processability of milk.

Technological Properties of Bovine Milk

It will be evident from the preceding discussion that although there are interspecies differences in the composition and chemical and physical properties of milk, these differences are quite small, especially between the milk of species of the same family, for example, Bovinae. However, these small differences are reflected in the processing properties of milk. Perhaps the most important technological differences are FA profile of the lipids, rate of creaming, rennet coagulability, syneresis of rennet-induced gel, and heat stability of milk. These properties are discussed more extensively in separate articles in this encyclopedia.

As described earlier, bovine milk creams much faster than the milk of other species due to the aggregation of the fat globules. This property is not important today (in fact creaming is often prevented by homogenizing the milk) but in the past it was important for the preparation of cream for buttermaking, prior to the invention of the centrifugal cream separator by Gustav de Laval in 1878. Milk was designed to coagulate in the neonatal stomach, which is achieved through limited proteolysis of the micelle-stabilizing protein, κ-casein, by a specific gastric proteinase, chymosin (*see* **Cheese**: Rennet-Induced Coagulation of Milk); coagulation delays discharge from the stomach into the intestine and thereby improves digestibility and levels out the supply of nutrients. The firmness of the coagulum is strongly dependent on the protein content of the milk – human, camel, and equine milks form protein flocks rather than a gel and are probably more readily digested than bovine, caprine, and ovine milks.

The rennet-induced coagulation of milk is exploited in the production of cheese, 75% of which is produced from rennet-coagulated casein. Bovine milk has good rennet coagulability, as do the milks of goat, sheep, and buffalo, due partly to their relatively high casein content (*see* **Milk**: Buffalo Milk; Goat Milk; Sheep Milk).

Milk also gels on acidification to pH ~4.6, that is, to the isoelectric point of the caseins. This property is exploited in the production of acid-coagulated (fresh) cheeses, fermented milks, and acid casein (an important functional protein) (*see* **Cheese**: Swiss-Type Cheeses; **Fermented Milks**: Asian Fermented Milks; Buttermilk; Health Effects of Fermented Milks; Kefir; Koumiss; Middle Eastern Fermented Milks; Nordic Fermented Milks; Starter Cultures; Types and Standards of Identity; Yogurt: Role of Starter Culture; Yogurt: Types and Manufacture; **Milk Protein Products**: Caseins and Caseinates, Industrial Production, Compositional Standards, Specifications, and Regulatory Aspects). As for the rennet-induced coagulation of milk, the firmness of an acid-induced milk gel is strongly related to the casein content of the milk, and the four principal dairying species, especially sheep, are very suitable for this application.

Bovine milk is a very heat-stable system (*see* **Heat Treatment of Milk**: Heat Stability of Milk), which permits the production of a range of heat-treated products without major apparent changes in the appearance and properties of milk. The heat stability of milk is highly dependent on its composition; bovine milk is more heat stable than the milk of other dairying species due, at least in part, to the concentration of calcium in the milk.

Conclusion

Bovine milk is a very complex and very well-characterized biological system. Most of the topics introduced in this article will be explained in greater detail in other articles throughout the encyclopedia.

Introduction

Goats' (*Capra hircus*) milk ranks fourth after cows', buffaloes', and sheep's milks in terms of world milk production. Although goats' milk production (14.80 metric ton (MT), for 2007) accounts for only 2.2% of the total world milk production, goat-keeping has a significant economic importance in countries where climatic conditions are not favorable for cattle-keeping. The world leaders in goats' milk production are listed in **Table 1**.

The production of goats' milk is likely to be much greater than the official statistics indicate because a large amount of milk that is used for home consumption goes unreported. Especially in developing countries, the production of this type of milk has become a useful strategy to deal with malnutrition, especially among the infant population. Europe, which produced 2.58 Mt of goats' milk in 2007, contributes about 17.5% of the world's goats' milk supply. Countries around the Mediterranean region have the most developed dairy goat industries, with France, Greece, Spain, and Italy among the main goats' milk-producing countries. In recent years, there has been an increased interest in goats' milk production and conversion to value-added products, encouraged within the European Union countries by the introduction of quotas on cows' milk in 1984. Moreover, there are four aspects to the increase in goats' milk production compared to other farm animals: (1) domestic consumption; (2) the connoisseur interest in goats' milk products, especially cheeses and yogurt, in many developed countries; (3) the affliction of people with cows' milk allergies and other gastrointestinal problems; and (4) the potential health benefits associated with the consumption of goats' milk, related to, for example, its higher oligosaccharide and nucleotide content.

Composition and Physical Properties of Goats' Milk

The composition of goats' milk varies widely and is influenced by breed, nutritional and environmental factors, stage of lactation, parity, and season. To add to this complexity, there is a wide variability in composition among individual animals of the same breed attributed to an extensive and complex genetic polymorphism of the goats' milk caseins. **Table 2** shows the average gross composition of goats' milk as well as the ranges of the main constituents. The composition of goats' milk is similar to that of cows' milk in terms of total solids (TS), fat, crude protein, lactose, and ash contents, but there are important differences in the individual components, as detailed below.

The density of goats' milk is comparable to that of cows' milk but is lower than that of sheep's milk, whereas both goats' and sheep's milks have higher specific gravity, viscosity, and titratable acidity but lower refractive index and freezing point than cows' milk (**Table 3**).

Carbohydrates

Lactose is the major carbohydrate in goats' milk, but it is approximately 0.2–0.5% less than that in cows' milk. Other carbohydrates in goats' milk include oligosaccharides, glycopeptides, glycoproteins, and nucleotide sugars. Goats' milk has a remarkably high oligosaccharide content, and the diversity found in goats' milk oligosaccharides is important. Cows' milk contains low levels of monosaccharides and oligosaccharides. Milk oligosaccharides have considerable antigenic properties and are valuable in promoting the growth of the intestinal flora of the newborn. Oligosaccharides promote the growth of bifidobacteria in the neonate and play a role as intestinal mucosal cell protectors against pathogens. Finally, they may play a role in neonatal brain development. There is 4 times as much sialic acid in goats' milk (~230 mg sialic acid per kg fresh milk) as in cows' milk (60 mg sialic acid per kg fresh milk). Moreover, nucleotide sugars in milk are of particular interest since they are the glycosyl donors for glycosyltransferase in milk and mammary gland, and are the precursors of glycoproteins, glycolipids, and oligosaccharides in the biosynthesis of milk. Goats' milk has a high nucleotide content, about 154 μmol $100\,\mathrm{ml}^{-1}$ milk, followed by sheep's milk (93 μmol $100\,\mathrm{ml}^{-1}$) and cows' milk (68 μmol $100\,\mathrm{ml}^{-1}$), while human mik contains only 5 μmol $100\,\mathrm{ml}^{-1}$.

Table 1 Top 10 goats' milk-producing countries in the world during 2007

Goats' milk production		
Position	*Country*	*Mt*
1	India	3.82
2	Bangladesh	2.01
3	Sudan	1.45
4	Pakistan	0.70
5	France	0.59
6	Greece	0.50

Table 2 Gross composition of goats' milk

	Average	*Range*
	(%, w/w)	*(%, w/w)*
Total solids	12.90	9.95–21.5
Fat	4.10	2.46–7.76
Crude protein[a]	3.50	2.49–5.06
Casein	2.90	2.33–4.63
Lactose	4.50	3.62–6.30
Ash	0.80	0.69–0.89

[a] Protein values represent crude protein, that is, total nitrogen multiplied by 6.38, and thus are approximately 0.25% higher than true protein (total nitrogen minus nonprotein nitrogen).
Ranges are based on the results from different authors.

Lipid Fraction

Fats are one of the most important components of goats' milk in terms of cost, nutrition, and the physical and sensory characteristics that they impart to goat dairy products. The fatty acid (FA) composition of goats' milk shows substantial differences from that of cows' milk. Goats' milk fat is rich in short-chain fatty acids (SCFAs) (e.g., caproic ($C_{6:0}$), caprylic ($C_{8:0}$), and capric ($C_{10:0}$) acids) and medium-chain fatty acids (MCFAs) (e.g., lauric acid ($C_{12:0}$)). SCFAs represent up to 15–18% of the FAs in goats' milk, but only 5–9% in cows' milk, because of differences in the polymerization of the acetate produced by the rumen bacteria in goat, and are associated with the characteristic odor and flavor of goats' milk cheeses (**Table 4**).

Another noteworthy aspect concerning the FA profile of goats' milk is its content of branched-chain free FAs with less than 11 atoms of carbon, which are virtually non-existent in cows' milk and which give the characteristic goaty flavors to goat dairy products. The most novel aspect reported to date concerning the composition of ruminant milk fats concerns their content of conjugated linoleic acids (CLAs). These are a series of positional and geometric isomers of linoleic acid, which contain a conjugated double bond system. Data from animal models have been used to suggest that the main CLA isomer, *cis*-9 *trans*-11 $C_{18:2}$, is responsible for the anticarcinogenic properties of CLA, as well as antiatherogenic effects.

The triacylglycerol (TAG) structure of milk fat is responsible for its rheological properties and its melting and crystallization behavior. Although the composition and particularly the dominant position of the triacylglycerides are not unlike those of cows' milk, a larger concentration of free FAs is found in goats' milk. The free FAs are the result of hydrolysis and their presence could lead to the development of desirable or undesirable flavors, depending on their type and concentration. In goats' milk, the free FAs are the main source of the characteristic flavor. A number of lipases have been identified and are considered responsible for the hydrolysis. **Table 5** shows the average TAG composition of goats' milk fat, which presents a wide range of molecular weights and chain lengths with acyl carbon atom numbers between C_{26} and C_{54}. The distribution of acyl carbon numbers shows a maximum at C_{40}–C_{42}. The percentage

of C_{38}–C_{44} TAG is much higher in goats' milk fat than in cows' milk fat (49 vs. 36%, respectively), which is related to the need for a TAG composition with appropriate melting points for fat secretion. Goats' milk fat is rich in medium-chain triacylglycerides (MCTs), made up preferentially of SCFAs. Therefore, the MCTs of goats' milk are of special interest, indeed, from a therapeutic point of view, because of their particular metabolism and hence their application for certain cases of metabolic illness.

Analysis of the positional distribution of FAs in goats' milk triglycerides shows that a majority of the SCFAs are esterified at the *sn*-3 position of the glycerol, whereas the long chain FAs are esterified at *sn*-2 position. This specific placement of FAs implies that triglycerides are synthesized from a pool of long-chain 1,2-diglycerides.

Lipids in goats' milk are present in the form of globules, which naturally do not aggregate upon cooling because they lack agglutinin, responsible for the aggregation of fat globules in cows' milk. Besides, the goats' milk fat globules are characteristically abundant and smaller than those of cows' milk. The average diameter of the individual fat globules in goats' milk is 2.76 μm and is smaller than the mean diameter of 3.51 μm for cows' milk. This is advantageous for digestibility and a more efficient lipid metabolism compared with cows' milk fat.

The milk fat globule membrane (MFGM) consists of plasma membrane of the secretory cell and contains protein constituents (some of which are enzymes), phospholipids, cerebrosides, and gangliosides. So far, studies suggest that the protein and phospholipid compositions of the MFGM are similar in goats and cows. About 60% of the total phospholipids in goats' milk are on the MFGM. All the classes found in cows' milk are present – phosphatidylcholine, phosphatidylethanolamine, phosphatidylserine, phosphatidylinositol, and sphingomyelin.

Goats' milk fat contains significant concentrations of aliphatic δ-lactones or their hydroxy acid precursors. These compounds are associated with the development of flavors in heated and stored dairy products.

Proteins

The principal proteins in goats' milk are the same as in the milk of other species, namely the caseins (κ-, β-, α_{s1}-, α_{s2}-, and γ-CN) and the whey proteins, β-lactoglobulin (β-Lg), α-lactalbumin (α-La), serum albumin, and immunoglobulins.

The amino acid composition and sequence of the goat caseins and whey proteins have been determined from analyses of the cDNA sequence and are shown in **Table 6**.

A homology of 80–90% exists between goats' and cows' milk proteins. The relative proportion of the four

major caseins in caprine milk varies widely between individual animals. This variation is due largely to an unusual and complex genetic variability that exists on the casein loci (**Table 7**). In the polymorphism of α_{s1}-CN, more than 18 alleles have been identified, which are distributed among ten different classes of protein variants (α_{s1}-CN A, B1, B2, B3, C, D, E, F, G and O) and associated with four levels of α_{s1}-CN expression. Variant α_{s1}-CN B1 is believed to be the original type of the species because it has the closest homology with the bovine and ovine counterparts. The allele frequencies at the α_{s1}-CN locus vary with breed. In French and Italian Alpine and Saanen goats, alleles E and F predominate. In the Italian goat breed, Sarda, the strong A and B alleles predominate, whereas the majority of Verzaschese goats have the weak F variant. In French and Spanish breeds, allele E is the most frequently encountered, whereas in Swiss breeds there is a high frequency of the defective mutants E, F, and O in the order of decreasing frequency. This has enormous implications because the genes of the Alpine, Saanen, and Toggenburg breeds have been spread worldwide.

Table 7 Protein composition of goats' milk

	Concentration
Protein	*(%)*
Total casein	2.33–4.63
β-Casein[a]	0[b]– 64.0
κ-Casein[a]	15.0–29.0
α_{s1}-Casein[a]	0[b]–28.0
α_{s2}-casein[a]	10.0–25.0
Whey proteins	0.37–0.70
β-Lactoglobulin[c]	39.2–72.1
α-Lactalbumin[c]	17.8–33.3
Serum albumin/lactoferrin[c]	5.1–21.5
Immunoglobulins[c]	4.6–21.4

[a] Percentage of total casein.
[b] Absence of β- or α_{s1}-caseins in milk from animals carrying the respective null alleles.
[c] Percentage of total whey.
Individual caseins and whey proteins are expressed as percentage of the total casein and total whey, respectively.

There is also polymorphism at the α_{s2}-CN locus, for which seven alleles have been identified, and which are also associated with three different levels of casein synthesis.

Caprine β-CN is encountered at two different phosphorylation levels, β_1-CN and β_2-CN, with six and five phosphoseryl residues, respectively. β-CN is the main casein fraction in goats' milk, and for a long time was considered monomorphic. However, a null allele was detected in the Garganica, Creole de Guadeloupe, and Granadina breeds.

So far, seven variants of goat κ-CN have been identified. Alleles A and B are the most frequent variants, occurring in the majority of breeds, with the highest prevalence of the B variant, except for the Canarian breed, where the A allele is more frequent. Sequence data suggest that the F variant is the original type of goat κ-CN, other alleles being derived from it, following two different tracks by successive mutations. Variants F and G are found only in the Italian breeds Teramana, Girgentana, and Sarda, at a relatively high frequency.

Compared with cows' milk, goats' milk has a higher β-CN and a lower α_{s1}-CN content. However, there are a number of important differences in the individual caseins between the two milks, which affect their processing properties and are responsible for the characteristic textural and sensory attributes of goats' milk products.

Two genetic variants of goat β-Lg have been identified. Goat β-Lgs have a lower net charge than the bovine counterparts. Differences also occur in the charged amino acids of α-La, and two variants have been reported having Lys or Ala as N-terminal residues, although the B variant is rare. Recently, an additional silent allele at the goat α-La locus has been detected.

The percentage of β-Lg in goat acid whey is lower than in sheep or cow acid whey, and the goat whey also has a low percentage of α-La. The α-Las in sheep's and goats' milks are closely homologous to α-La in cows' milk.

Minor Proteins and Non-protein Nitrogen Compounds

Goats' milk, like cows' milk, contains 20–200 mg l^{-1} of lactoferrin and transferrin. Prolactin has also been isolated (~44 μg l^{-1}) as well as immunoglobulins (IgGs, IgA, IgM). A minor whey protein (glycoprotein) that binds folate has also been identified.

The non-protein nitrogen (NPN) contents of goat and human milks are higher than that of cows' milk. NPN is composed of several nitrogenous compounds, including nucleosides and nucleotides; goats' and sheep's milks principally contain UMP, AMP, and CMP but also some UDP.

Enzymes

The lysozyme content of goats' milk averages 25 μg l^{-1}, which is in the low-range characteristic of the milk of artiodactyls. Ribonuclease, lipase, and xanthine oxidase activities in goats' milk are lower than those in cows' milk. The levels of lactic hydrogenase and malic dehydrogenase in goats' milk are comparable to those of cows' milk. Raw goats' milk contains substantially lower levels of alkaline phosphatase than cows' milk. Inactivation of this enzyme serves as the basis for the evaluation of the effectiveness of pasteurization in cows' milk. The low level of alkaline phosphatase in goats' milk precludes its use as an effective index of pasteurization of goats' milk.

Minerals and Trace Elements

The mineral composition of goats' milk is shown in **Table 8**. There is great variability in the reported values as a result of genetic effects, diet, stage of lactation, and analytical procedures. Overall, goats' milk has a higher level of calcium, phosphorus, potassium, magnesium, and chlorine, and a lower level of sodium than cows' milk. However, the repartition of calcium, phosphorus, and magnesium between the soluble and colloidal phases of milk is similar for cows' and goats' milks. Goats' milk generally contains more magnesium than cows' milk and lower or comparable levels of iodine and copper. More than 50% of the magnesium is found in the soluble phase. Trace elements are part of essential substances such as hemoglobin and vitamin B_{12}. Many enzymes also require specific metallic activators. Colostrum has much higher levels of trace elements than mid-lactation milk. The concentration of some elements, such as zinc, molybdenum, and strontium, varies greatly with their concentration in the diet. Zinc and manganese are found largely in the micellar phase, whereas copper and iron are most abundant in the soluble phase of milk.

Vitamins

Goats' milk contains a higher level of vitamin A than cows' milk because goats convert all carotenes into vitamin A, which gives the milk a whitish color. In contrast, goats' milk is poor in folic acid and vitamin E.

Variability in Milk Composition

Factors Affecting Milk Yield

Milk yield is closely linked to the breed, lactation number and lactation period, season of kidding, and litter size. Genetic selection has resulted in improved breeds, such as Alpine and Saanen, with yields several orders of magnitude higher than local unimproved breeds. Maximum yield is usually attained during the third to fourth lactations, and early kidding favors milk production.

Litter size is also positively correlated to milk yield. Nutritional and environmental factors, such as a diet supplemented with concentrate, husbandry conditions, and flock management can influence milk yield. Milk yield is inversely related to the fat content, TS, and crude protein content in milk.

Lactation

In most of the relevant studies, the lactation effects are confounded with nutritional and seasonal effects. During the first month after parturition, milk has a higher content of fat, TS, protein, and nonfat solids than milk at later stages of lactation. As a general consensus, a curvilinear response in total milk solids, fat, total casein, and total whey protein content during the lactation period has been reported (**Figures 1** and **2**). There is a gradual decrease in total milk solids, fat, and protein content, reaching a minimum around week 20–25 of lactation, followed by an increase toward the end of lactation. The proportion of the individual caseins does not seem to change during lactation but among the whey proteins, β-Lg seems to vary more than α-La.

The total fat content is highest on the first days after parturition, and then declines until day 110 of lactation. The fat composition changes greatly during lactation. After parturition, when body fat deposits start to be mobilized, a high content of $C_{18:0}$ and $C_{18:1}$ FAs and a relatively low content of $C_{16:0}$ FAs are found in milk. A high proportion of $C_{14:1}$ and $C_{16:1}$ FAs in the colostrum is probably of the same origin. As lactation advances, there is a shift in metabolism to utilize substrates derived entirely from the diet rather than from body stores. The proportion of milk fat derived from the *de novo* synthesis then increases and citrate decreases.

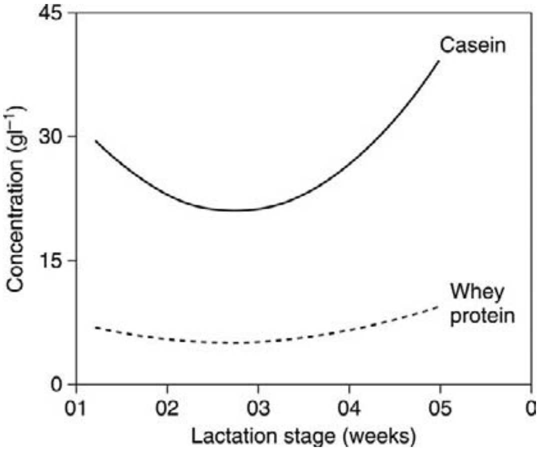

Figure 1 Changes in the concentration of the major goats' milk proteins during lactation.

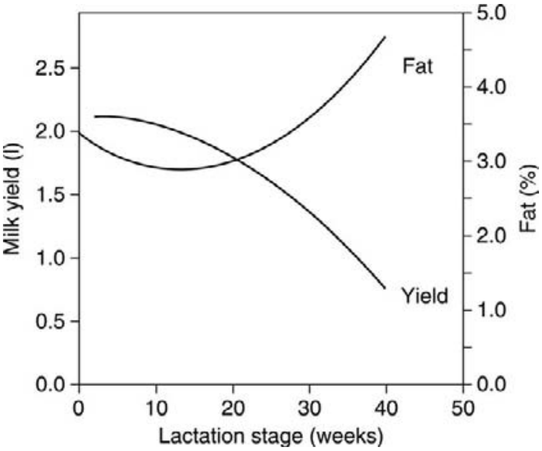

Figure 2 Changes in the milk yield and fat content of goats' milk during lactation.

The SCFAs $C_{4:0}$, $C_{6:0}$, and $C_{8:0}$ decrease during lactation as well as the long-chain FAs $C_{18:1}$ and $C_{18:3}$ while the levels of $C_{10:0}$ and $C_{14:0}$ FAs increase.

Diet

Dietary manipulation constitutes a natural and economical way to markedly and rapidly change the milk FA composition. There is a great challenge for farmers and for scientists working on ruminants to be able to modulate the milk FA composition, increasing those FAs of greatest interest for human nutrition such as *cis* monounsaturated FAs (MUFAs) and polyunsaturated FAs (PUFAs), including CLA. The largest changes can be obtained either by changing the forages in the diets of ruminants, particularly pasture, or by adding plant or marine lipid supplements to the diet. These dietary FAs are metabolized extensively and biohydrogenated in the rumen, resulting in the production of a wide range of isomers of PUFAs and MUFAs, especially *trans* FAs and CLAs. Some FA intermediates biohydrogenated in the rumen, for example, *trans* vacenic acid ($t11\text{-}C_{18:1}$, TVA), are transformed by body tissues, especially by the mammary gland where the δ-9 desaturase acts by adding a *cis*-9-double bond to different FAs, which partly reduces the saturation level and the melting point of milk fat.

The goat responds very differently to dietary factors compared to the cow, both in milk fat secretion and in some aspects of milk FA composition, which are of interest for consumers of goat dairy products. Unlike the situation in dairy cows, there is no decrease in milk fat content when diets supplemented with PUFAs are fed to dairy goats. It has been suggested that the inhibition of acetyl-CoA carboxylase and *de novo* lipogenesis elicited by long-chain FAs (especially with a high level of unsaturation) seems less strong in goat mammary gland metabolism. Therefore, potential inhibitors of lipogenesis present in the rations would be less active in goats than in dairy cows. With regard to milk protein, it has been observed that the addition of fat to the diet of goats results in no change in milk protein content and may, in fact, lead to an increase.

Although the CLA content in dairy products is affected by many factors, animal feeding strategies and specifically diets with oil seed or oil supplements rich in PUFAs have been effective in enriching the milk of dairy goats with CLA. Effects of feeding fresh forages and free oils and the seasonal changes of Mediterranean natural pastures on FAs, especially on CLA composition and its precursors, in goats' milk have been reported. Generally, free oils are more effective than whole or treated oilseeds.

A slight increase in the level of *n*-3 FAs in goats' milk fat occurred when goats were fed fish oil, but the levels of these supplements in the diet should be low and protected against ruminal biohydrogenation in order to avoid a decrease in milk yield and fat and protein contents. To date, data on CLA enhancement in goats' milk by adding fish oil supplements are, however, limited.

Breed

Goats' milk composition varies within breeds (**Table 9**). Undoubtedly, some of the variation in the reported values arises also from differences in sampling and analytical procedures. The casein number (casein N/total N) ranges from 0.69 to 0.82, with an average of 0.76, which is similar

Table 9 Variation in the gross composition of goats' milk from different breeds

to that of cows' milk. The greatest variation is observed in the TS level and fat content.

Unusually high levels of fat, TS, and protein content have been reported for the West African dwarf goat, Pygmy goat of Oregon, and Black Bengal and Barbari in India. Indigenous goats in Greece (*Capra prisca*) and Sardinian have been reported to produce milks richer in TS, fat, and protein content. Generally, Alpine and Saanen milks have a lower fat, protein, and casein content. This is not unexpected given the higher milk yields of these breeds. Statistical analysis of the composition of the milk fat of individual goats suggests the existence of genetic differences in FA composition.

Nubian and Anglo-Nubian goats produce milk with higher fat and protein levels than animals of the Alpine breed kept at the same experimental station.

In Libyan goats (Maltese cross), it has been reported that the concentrations of C_6–C_{18} FAs are similar to those found in the Masri breed of South Arabia (which they resemble closely).

Genotype

It is well established that the casein composition in goats' milk is influenced by genetic polymorphism on the casein loci. Polymorphism of α_{s1}-CN is the most interesting and extensively studied because it controls the level of α_{s1}-CN excretion in milk. Four levels of α_{s1}-CN expression ranging from 0 (null allele α_{s1}-CN^0) to 3.5 g l^{-1} per copy of each A, B, or C (strong) allele have been reported. Alleles F and G (weak) are associated with low contents of α_{s1}-CN (0.45 g l^{-1} per allele) and alleles E and I (medium) are associated with an intermediate content of α_{s1}-CN (1.1–1.7 g l^{-1} per allele).

The α_{s1}-CN genotype influences the total protein, total casein, and fat contents and is linked to the technological behavior of goats' milk. Milk from animals with the strong alleles has higher levels of fat, TS, and protein. However, α_{s1}-CN genatype does not interfere with the level of expression of the other caseins or whey proteins. Differences have been found in the micellar size distribution and their calcium content in milks from animals of different α_{s1}-CN genotypes. Thus, F-type milk has, on average, larger micelles than milks with α_{s1}-CN A, B, or E.

Technologically, milk from animals with the strong alleles is considered superior to milk from animals with weak alleles, with higher cheese yields and firmer curds. Organoleptically, cheeses made from F-type milks are characterized by a 'strong' goaty flavor.

There is also polymorphism at the α_{s2}-CN locus, which is associated with three different casein synthesis levels. A, B, C, E, and F alleles produce 'normal' α_{s2}-CN contents (2.5 g l^{-1}), the D allele causes reduced α_{s2}-CN contents, and the 0 allele has no detectable amounts of this casein in goats' milk.

Moreover, the total casein content in the milk of animals with the null allele for goat β-CN has been reported to be extremely low and its clotting ability poor.

Characteristic Properties of Goats' Milk

An important characteristic of goats' milk is the unique 'goaty' flavor. This is attributed to differences in the fat fraction of goats' milk. Other investigators attributed the characteristic 'goaty' flavor to the relatively higher proportion of SCFAs and MCFAs.

From the technological point of view, it is clear that the differences in chemical composition and particularly the impact of casein genotype on the structure of the goat casein micelles are sufficiently pronounced to explain the differences in the textural characteristics of cheeses and fermented milk products. Goats' milk has better digestibility and buffering capacity than cows' or human milk, as well as certain therapeutic values in medicine and human nutrition. Recently, goat β-Lg and α_{s2}-CN have been reported as sources of bioactive peptides with angiotensin converting enzyme (ACE) inhibitory properties.

Use of Goats' Milk in the Production of Dairy Products

In the Mediterranean and many eastern European countries, goats' milk has gained economic importance mainly via its utilization in cheese making. In the European Community, the originality of goats' and sheep's milk products is protected by the legislation on the Protected Designation of Origin (PDO) and the Protected Geographic Indications (PGI). International rules are opportune in order to protect the typical products, their specific characteristics, and their biodiversity, encouraging the permanent residence of the population in the rural areas, especially in the less favorite areas. Greece and France have by far the largest goat cheese production and, along with Italy and Spain, are also noted for their sheep milk cheeses. Excellent cheeses are made from sheep's or goats' milk or from mixtures of the two. Differences in the FA composition of the fat give a unique flavor to the cheeses. Ripened goats' milk cheeses are characterized by a piquant and peppery-sharp flavor, while sheep milk cheese is smooth, mellow, and aromatic. Goat cheeses are white because goats' milk lacks carotene. Best cheeses are obtained from early lactation milks. **Table 10** gives some compositional

Sheep Milk

M Ramos and M Juarez, Instituto de Investigatión en Ciencias de la Alimentaćion (CSIC-UAM), Madrid, Spain

© 2011 Elsevier Ltd. All rights reserved.

Introduction

On a global scale, the annual production of sheep's milk, approximately eight million tonnes, is of marginal importance when compared to cow's milk in quantitative terms (2% of the total); nevertheless, it is of major importance in the Middle Eastern and Mediterranean countries, such as France, Italy, Spain, and Greece. The numbers of sheep do not fully reflect the amount of milk produced, as sheep are often used for other purposes such as meat and wool. Although sheep milk is richer in nutrients than cow's milk, it is rarely used for consumption as liquid milk. In general, sheep's milk is essentially used for cheese making, but in some countries a part of it is used for making yogurt or whey cheeses.

Chemical Composition and Physical Properties

Milk is a mixture in equilibrium of proteins, fat, lactose, and minerals in various states of dispersion in water, such as emulsions, colloidal suspensions, and true solutions. Sheep's milk is more viscous than cow's milk and is more resistant to the proliferation of bacteria in the first hours after milking, thanks to its greater immunological activity. It has a smell that is characteristic of the animal that produces it, and is an opaque white in color.

Table 1 shows the typical composition of sheep's milk, which generally contains higher amounts of total solids and major nutrients than goat and cow milks. Sheep's milk is an excellent source of high-quality protein, calcium, phosphorus, and lipids. There is a good balance between the protein, fat, and carbohydrate components, each being present in approximately similar amounts. The supply of nutrients is high in relation to the calorie content of the food. Fat and protein are the principal components of the dry matter, constituting 69% in sheep's milk as compared to 56% in cow's milk. The levels of fat and protein are higher than in cow's milk, and therefore the yield of cheese is also higher (approximately 15% for sheep's milk as compared with 10% for cow's milk).

As has been reported for cow's milk, the composition of sheep milk varies with diet, breed, animals within breed, parity, season, feeding, management and environmental conditions, locality, and stage of lactation. The principal factor is breed; breeds selected for their high milk yield produce milk with a lower level of total solids. Fat shows greater variation within a breed than do proteins. Another factor to consider is the stage of lactation. Sheep colostrum in the early post-partum period also contains approximately 13.0% fat, 11.8% protein, 3.3% lactose, 0.9% minerals, and 28.9% total solids, and thus has a much higher basic nutrient concentration than cow colostrum. The fat and protein contents of the milk itself decline during the first few weeks, then gradually increase after the first month until lactation ends and the yield decreases. At the end of seven months of lactation, the fat content may be as high as 8.1–10% and the protein content as high as 6.8–8.9%. The lactose content falls slightly throughout lactation, and more sharply at the end (4.1 to 3.4%).

Sheep milk has higher specific gravity, viscosity, and titratable acidity, but lower refractive index and freezing point than typical cow milk (**Table 2**). Sheep's milk is slightly more acidic than cow's milk, possibly due to its higher protein content.

Proteins in Sheep Milk

Sheep's milk contains 0.7–1% nitrogen. This is distributed in fractions, the importance of which varies in terms of dairy technology and nutrition. Proteins account for approximately 95% of the total nitrogen, and 5% is non-protein nitrogen. The principal proteins in sheep are the same as those in cow milk. Milk proteins occur in two distinct phases. One is a micellar phase composed of caseins, the micelles averaging about 190 nm in diameter. The submicelles are interlinked by calcium phosphate and small amounts of magnesium, sodium, and potassium citrate, which diffuse light and give skimmed milk its opaque white appearance. The other type of protein is the soluble whey proteins. The caseins precipitate at pH 4.6 at room temperature, whereas under the same conditions the whey proteins (β-lactoglobulin, α-lactalbumin, and serum albumin) remain soluble.

Caseins in Sheep Milk

Caseins (CNs) are the majority proteins in sheep milk (76–83% of total proteins) and are also present in most types of its cheeses. The denomination 'casein' embraces

Table 1 Composition of ewe's milk

Component	*Average content (%)*	*Range (%)*	*Average of dry matter (%)*
Water	81.60	79.27–83.80

four types of polypeptide chains: α_{s1}-CN, α_{s2}-CN, β-CN, and κ-CN. The heterogeneity of caseins is determined either by the presence of genetic variants or by other factors such as a discrete level of phosphorylation, variation in the extent of glycosylation of the κ-CN fraction, and the coexistence of protein forms having different chain lengths.

It has been demonstrated that four ovine casein genes, α_{s1}-CN, α_{s2}-CN, β-CN, and κ-CN, are polymorphic and are linked on both ovine and bovine genomes. In recent years, five variants of α_{s1}-CN have been described in bovine caseins, designated A, B, C, D, and E, and the corresponding nomenclature is proposed for goat milk caseins. α_{s1}-CN D was described initially and was called the Welsh variant because of its discovery in the Welsh mountains by King in 1966. This is the least phosphorylated variant. The lower number of phosphate groups explains the longer migration time of this variant by capillary electrophoresis at acid pH and the slow migration in alkaline polyacrylamide gels. The variant α_{s1}-CN C differs from the variant α_{s1}-CN A by the substitution of Ser for Pro at position 13, which explains the loss of the phosphate group on site 12 of the protein chain. Two variants of α_{s2}-CN, A and B, have been described, and they differ in that Asn_{49} and Lys_{200} are replaced by Asp_{49} and Asn_{200}. In addition, a variant with high electrophoretic mobility and low molecular weight has been found in the Manchega breed.

Ovine β-CN consists of 209 amino acids. For β-CN, there is a nongenetic polymorphism due to varying degree of phosphorylation, with six and five phosphate groups found in β_1-CN and β_2-CN, respectively. In addition, three genetic variants, designated A, B and C, have been described. The only sequence difference found between A and C is the substitution of the Glu at position 2 in variant A for Gln in variant C – no sequence data for the variant B are available yet. Both the stability of the casein micelle, and the availability and distribution of Ca are affected by the extent of phosphorylation of the caseins.

Ovine κ-casein contains 171 amino acid residues. No genetic variants have been found for ovine κ-CN, but it shows non-genetic polymorphism due to varying degrees of glycosylation at three different Thr residues (positions 135, 137, and 138) and two phosphorylation sites (Ser P^{151} and Ser P^{168}). The casein fraction also contains γ-caseins,

Table 3 Positions and amino acid differences in genetic variations of ovine milk proteins

		Position and amino acid in the protein

the product of the breakdown of β-caseins by plasmin. **Table 3** shows the positions and the differences in genetic variations of sheep's milk proteins.

Whey Proteins

Sheep milk whey proteins account for 17–22% of the total proteins. The major whey proteins are β-lactoglobulin (β-Lg) and α-lactalbumin (α-La). Immunoglobulins, serum albumin, and proteose-peptones are present at lower concentrations. The latter are products of the breakdown of β-casein by plasmin. Another soluble protein found in small amounts and possessing antibacterial properties is lactoferrin. Serum albumin and immunoglobulins are not specific to milk and are considered to be the same as those found in blood. In the case of rennet whey, caseinomacropeptide is also present, produced by chymosin action on bond 105–106 of κ-CN.

β-Lactoglobulin, the major protein in whey, consists of a polypeptide chain of 162 amino acids. Three genetic variants have been described in sheep's milk: β-Lg A, β-Lg B, and β-Lg C. Ovine β-Lg B and A variants differ only by a single amino acid exchange, His for Tyr at position 20. β-Lg C is a subtype of ovine β-Lg A with a single exchange, Arg for Gln at position 14. The three variants can be resolved by isoelectric focusing and by capillary electrophoresis. Of the three variants described for ovine β-Lg, alleles A and B were present in almost all breeds analyzed, whereas allele C is rather rare and confined to specific breeds. α-Lactalbumin is closely homologous to bovine α-lactalbumin. It is a metalloprotein containing one atom of Ca per molecule and is important from a biological standpoint in that it is involved in lactose synthesis. Two genetic variants, A and B, have been described, although the B variant is very uncommon.

Non-protein Nitrogen

Non-protein nitrogen accounts for 5–6.8% of the total nitrogen in sheep milk. Non-protein nitrogen compounds are urea (45%), free amino acids (16%), creatine (2.4%), creatinin (1.7%), ammonium nitrogen (1%), uric acid (2.1%), and other indeterminate compounds. Sheep's milk contains more urea and uric acid than found in cow's milk. Among the free amino acids taurine and carnitine are important because of their essential physiological functions in the newborn. Sheep's milk contains significantly more taurine (14 μmol/100 ml) than that contained in cow's milk (1 μmol/100 ml) but less than that contained in human milk (30 μmol/100 ml).

Lipid Fraction

Lipids are one of the most important components of milk in terms of cost, nutrition, and the physical and sensory characteristics they impart to dairy products. They are present in the form of globules and are characteristically abundant in sizes of less than 3.5 μm. No appreciable differences have been found in the mechanism of fat globule secretion in sheep and cows; the structure and composition of the membrane are similar in both species and represent approximately 1% of the total milk fat volume. The phospholipid profile in both species is similar to that of the plasma membrane, which tends to confirm their common origin.

Along with triacylglycerols, other simple lipids (diacylglycerols, monoacylglycerols), complex lipids (phospholipids), and lipo-soluble compounds (sterols, cholesterol esters, hydrocarbons) are contained in the lipid fraction of sheep's milk. Triacylglycerols constitute the largest group (nearly 98%), including a large number of esterified fatty acids.

Fatty Acids

Most fatty acids, from butanoic to eicosanoic acid, contain an even number of carbon atoms. The five most important fatty acids in quantitative terms ($C_{16:0}$, $C_{18:1}$, $C_{10:0}$, $C_{14:0}$, and $C_{18:0}$) account for >75% of the total fatty acids in sheep's milk. Sheep's milk contains more caproic ($C_{6:0}$; 2.9%), caprylic ($C_{8:0}$; 2.6%), and capric ($C_{10:0}$; 7.8%) acids than does cow milk. These fatty acids are associated with the characteristic flavor of cheeses and can also be used to detect mixtures of milk from different species (**Table 4**).

The most important factor among the intrinsic and extrinsic variables that modulate milk fatty acid composition is the feed, in particular, adding lipid supplement to the diet.

To increase the polyunsaturated fatty acid content in milk fat, a high forage-to-concentrate ratio or the inclusion of a polyunsaturated oil-seed rich in polyunsaturated fatty acids or a rich, protected fat are recommended for

Table 4 Mean values and the minimum (Min) and maximum (Max) contents of the main fatty acids in sheep's and cow's milk fat (% in total fatty acid methyl esters)

sheep feed. Changes in the fatty acid profile of ovine milk fat should not substantially differ from the pattern previously described for cow milk.

Other minor components of milk fat are branched-chain and odd-numbered chain saturated fatty acids. The main point of quantifying these components is that volatile branched-chain fatty acids give characteristic flavors to many dairy foods. The amount of these compounds contained in a cheese is dependent largely on the composition of the milk fat substrate. The concentration of branched-chain fatty acids reported in sheep's milk fat (2% of the total fatty acids) was made up of six different acids: *iso*-C14, *iso*- and *anteiso*-C15, *iso*- and *anteiso*-C17, and *iso*-C16. These branched-chain fatty acids are also predominant in bovine milk.

Monounsaturated *trans* fatty acids in milk fat range from 2.5 to 5% of the total fatty acids, depending on the species and the season. In general, sheep's milk contains the highest quantities, followed by cow's and, finally, goat's milk fat. The pattern of *trans* C18:1 isomer distribution is quantitatively identical in the three species, and the individual *trans* fatty acid isomers could have differing physiological effects. The importance of *trans*-11 C18:1, vaccenic acid, the predominant *trans* fatty acid in milk, lies in its role as a precursor of the main isomer of conjugated linoleic acid (CLA), rumenic acid (*cis*−9 *trans*−11 C18:2), physiologically the most relevant bioactive compound present in milk fat. This synthesis occurs not only in the bovine mammary gland but also in human tissues.

Milk CLA concentration in different ruminant species seems to decrease in the order sheep > cow > goat milk fat, accounting for 1.08, 1.01, and 0.65% of the total fatty acids, respectively, and varies with the season, mainly due to variations in feeding factors. The greatest seasonal differences in CLA content were measured in sheep's milk, 1.28% in summer and 0.54% at the end of winter. The relative composition of CLA isomers in sheep's milk is similar to that reported in cow's milk. Data from *in vitro* studies and animal models suggest that the rumenic acid isomer is responsible for the anticarcinogenic and anti-atherogenic properties of CLA, as well as for a multiplicity of potentially beneficial effects on human health.

Triacylglycerols

The triacylglycerol structure of milk fat is responsible for the rheological properties of the fat and its behavior during melting and crystallization. Their composition is also of interest given that it can be used to verify the authenticity of milk fat.

Triacylglycerols are almost invariably accompanied by small amounts of di- and mono-acylglycerols, mainly at positions 1 and 2, which are therefore probably intermediates in the biosynthesis of triacylglycerols. The distribution of fatty acids in the triacylglycerol molecule, as determined by stereospecific analysis, differs slightly from that in cow's milk, but the distribution of acids in the molecule is not random. On the other hand, in both sheep's and cow's milk, butyric acid ($C_{4:0}$) and other short-chain fatty acids ($C_{6:0}$–$C_{8:0}$) are esterified mainly at position 3 of the glycerol molecule and only one short-chain acid ($C_{4:0}$ or $C_{6:0}$) occurs per triacylglycerol molecule; the distribution of the other fatty acids (C_{10} or greater) exhibits no such marked specificity for positions 1 or 2.

Table 5 shows the average triacylglycerol composition of sheep's milk as compared with cow's milk. The triacylglycerols in sheep's milk show a wide range of molecular weights when distributed according to the number of carbon atoms (taking into account the carbon atoms of the three acyl radicals), with two peaks at C38–C40 and C50–C52, and a minimum at C44–C46. The chromatographic triacylglycerol profile of sheep's milk shows similarities to that reported for cow's milk. However, as a result of the differences in fatty acid composition between the two species, sheep milk fat has a higher percentage of short-chain triacylglycerols (C26–C36) than cow's milk (24 vs. 21%). Percentage of medium-chain triacylglycerols (C38–C44) is also higher in sheep's milk than in cow's milk (42 vs. 36%). However, percentages of long-chain triacylglycerols (C46–C54) and unsaturated triacylglycerols are lower in sheep's than in cow's milk (34 vs. 43% and 51 vs. 55%, respectively). These differences relate to the

[c] Cholesterol included.

need for a triacylglycerol composition with an appropriate melting point to allow the fat to be secreted.

It has been established that the principal triacylglycerols in sheep's milk fat are composed largely of three fatty acids C_{14}, $C_{16,}$ and $C_{18:1}$ combined with the short-chain fatty acids $C_{4:0}$ and $C_{6:0}$. The largest triacylglycerols are composed primarily of three fatty acids $C_{4:0}$, $C_{16:0}$, and $C_{18:1}$, the same as those in cow's milk.

Unsaponifiable Lipids

The unsaponifiable fraction of milk fat is composed largely of sterols, with a smaller proportion of hydrocarbons, basically squalene, and trace amounts of a number of normal- and branched-chain hydrocarbons in the range C_{17}–C_{48} with odd and even numbers of carbon atoms, lipo-soluble vitamins, and aliphatic alcohols. Ovine milk contains virtually no tocopherol or β-carotene.

Sterols are a minor fraction of the total milk fat, the main component being cholesterol (270–350 mg per 100 g of fat, equivalent to approx. 20 mg per 100 ml of sheep's milk), but small amounts of other sterols, implicated in cholesterol biosynthesis, have also been found in ovine milk: lanosterol (5–15 mg per 100 g of fat) and, in still smaller proportions, dihydrolanosterol, desmosterol, and lathosterol. The variation is wide but comparable to that found in cow's milk fat. The minor sterols represent 3–5% of the total sterol fraction.

Phospholipids

The major phospholipids in both sheep's and cow's milk are phosphatidyl-ethanolamine, phosphatidyl-choline, phosphatidyl-serine, phosphatidyl-inositol, and sphingomyeline. These account for roughly 0.8% of the total lipid fraction, and the proportions of corresponding phospholipid classes in sheep milk are remarkably similar to those in the milks of other ruminants.

Carbohydrates

Lactose, the major carbohydrate in ovine milk, is composed of glucose and galactose bonded by a β 1–4 glycosidic linkage. The lactose content in sheep milk is similar to that in bovine milk. Sheep's milk contains 4.5–5.0 g lactose per kilogram of milk, and lactose accounts for 22–27% of dry matter versus 33–40% in cow's milk. The lower lactose content does not present a problem in cheesemaking, as enough lactose is available to ensure lactic fermentation.

Lactose is a valuable nutrient because it favors intestinal absorption of calcium, magnesium, and phosphorus, and the utilization of vitamin C. Carbohydrates other than lactose, such as glycopeptides, glycoproteins, and oligosaccharides are also found in ovine milk. The amount of oligosaccharides in ovine milk is in the range 20–30 mg l^{-1}, and their content, as in other mammalian milks, is considerably higher in colostrums. Three neutral milk oligosaccharides, isomers of galactosyllactose, Gal (α1-3) Gal (β1-4) Glc, Gal (β1-3) Gal (β1-4) Glc, and Gal (β1-6) Gal (β1-4) Glc, and three acidic milk oligosaccharides from the ovine colostrums have been isolated and identified by ^{1}H-NMR. These acidic milk oligosaccharides contain sialic acid. Oligosaccharides promote the growth of bifidobacteria in the newborn and play a role as intestinal mucosal cell protectors against pathogens.

Mineral Elements and Vitamins

Sheep's milk contains mineral salts (around 0.9% of ash). The most abundant elements are Ca, P, K, Na, and Mg. Ca and P are the most important of the major constituents, both in nutritional terms and for their role in the structure of casein micelles and hence in the behavior of the caseins during milk processing. The most abundant of the trace elements are Zn, Fe, Cu, and Mn. **Table 6** shows the average concentrations of major elements and

trace elements in sheep's milk. With the exception of Na, the concentrations of these elements are higher than those found in cow's milk. Sheep's milk contains an average of 2 g Kg^{-1} of citrate, which is slightly higher than that in cow's milk. The mineral content of sheep's milk is much higher than that of human milk. The concentrations of minerals are not constant but are influenced by a number of factors such as stage of lactation, nutritional status of the animal, and environmental and genetic factors due to feeding differences and seasonal variations.

The percentages of Ca and P in the soluble phase are, respectively, 20–25% and 35–40% of the total. These proportions are lower than those in cow's milk, but the absolute concentrations in the soluble phase are comparable for the two species. Therefore, the concentrations of both elements in the colloidal phase of sheep milk are much higher than those in cow's milk, given the higher levels of casein found in sheep's milk. Na and K are the major elements in the soluble phase. Of the trace elements mentioned, Zn, Mn, Fe, and Cu, the first two are associated mainly (around 90%) with the colloidal fraction of the milk, whereas Fe and Cu are associated to a lesser extent (70 and 64%, respectively). In addition, of all the elements considered here, Fe is probably the one that is bound in the highest proportion to the lipid fraction. About the rest of the trace elements, it should be noted that availability of Se in sheep milk appears to be significantly lower than that in bovine milk.

Most of the known vitamins are contained in ovine milk, and for some of them this foodstuff is a rich source. From the literature it is concluded that sheep's milk is richer than cow's milk in most of the vitamins. However, documented research data on vitamins in sheep's milk are too sparse to offer a definitive picture.

The average values and the ranges of variation are shown in **Table 6**.

Enzymes

Enzymes are constituents of the mammary gland that pass into the milk during the secretion process. The enzymes found in milk are highly specific and are chiefly oxidoreductases, transferases, and hydrolases. Particularly important for technological purposes are proteases and lipases. Lipase, lysozyme, ribonuclease, and xanthinoe-oxidase are less active in sheep's milk, whereas alkaline phosphatase, despite possessing the same molecular weight and the same properties, is more active than in cow's milk. The most abundant enzyme is lactoperoxidase, which has proved impossible to distinguish from the bovine form but appears to be more thermolabile.

The native proteinases include aminopeptidases, thermolabile neutral acid proteinases, and heat-resistant serine proteinases. Serine proteinase, also known as alkaline or plasmin proteinase, is heat-stable and hydrolyzes Lys–Xy and Arg–X bonds. It becomes more active after thermal treatment.

Renneting Properties

The renneting properties of sheep's milk are affected by a number of factors such as pH, physicochemical composition, micellar system, salts equilibria, calcium concentration, temperature and time of heating. Sheep's milk coagulates well and is indeed very suitable for making high-quality cheeses. Coagulation is faster than in cow's milk, and less rennet is needed to coagulate in the same time as for cow's milk. Curd formation is also faster than in cow's milk, but syneresis takes longer. The reason for this difference may be that sheep's milk contains more casein, ionic calcium, and colloidal calcium than those contained in cow's milk. Renneting time and rate of firming are practically unaffected by the addition of calcium.

The coagulation properties of sheep's milk are less affected than those of cow's milk by storage at 4 °C or by heat treatment. In fact, although severe treatments (90 °C, 10 min) delay coagulation of sheep's milk, gelation does take place. In cow's milk, on the other hand, heating for 1 min at 90 °C prevents gelation. The reason for this difference in the behavior of cow's and sheep's milks could be that in the latter, when heated to 85 or 90 °C, the micelles grow considerably in size, attaining 1.75 times the size of the micelles in fresh milk.

Bioactive Components

Enzymatic hydrolysis of milk proteins can release fragments able to exert specific biological activities, such as antihypertensive, antimicrobial, opioid, antioxidant, immunomodulatory, or mineral-binding. Such protein fragments, known as bioactive peptides, are formed from the precursor inactive proteins during gastrointestinal digestion and/or during food processing. Owing to their physiological and physicochemical versatility, milk peptides are regarded as highly prominent components for health-promoting foods or pharmaceutical applications. Research in the field of bioactive peptides has focused mainly on milk proteins of bovine origin. However, during recent years, research has been extended to milk proteins from other mammals, including ovine and caprine species.

A proline-rich peptide, called colostrinin, which was originally found as a fraction accompanying ovine immunoglobulins, was found to promote T cell maturation. This peptide promotes procognitive functions in experimental animal models, indicating prevention of pathological processes in the central nervous system. In humans, the therapeutic benefit of colostrinin in Alzheimer's disease patients, by delaying the progress of the disease, has been demonstrated.

Cheeses

Practically all sheep's milk is used to make cheeses, most of which are craft products. Some have an appellation of origin, so that production is confined to specific regions , and only a minority are made on an industrial basis. There are six categories of sheep's milk cheese based on the technology used: fresh, white brined (pickled), blue-veined, semi-hard, hard, and whey cheeses. **Table 7** shows some of the principal sheep's milk cheeses produced in different countries, indicating the type of consistency and the global characteristics of composition.

The world's principal sheep milk cheese in terms of output and general availability is Roquefort. This is a blue-veined cheese made from raw milk inoculated with *Penicillium roqueforti* spores. It undergoes high levels of proteolysis, 50% water-soluble nitrogen (WSN) in total nitrogen, and lipolysis, 8–10% of total fatty acids, after 5 months of ripening. Spain produces a blue-veined variety with similar characteristics: Cabrales cheese. This has a very good reputation, although the raw material is a mixture of cow's, sheep's, and goat's milk.

Feta cheese is a white-brined cheese originally from Greece, and is one of the most popular internationally. Traditionally, it is made from raw milk and is ripened in barrels with brine (6–8% NaCl) for around 1 month at 8–10 °C; it is then kept chilled for at least 2 months prior to consumption. It is now made mainly from pasteurized milk. There is a variety similar to Feta called Teleme cheese, originally from Romania, which is generally made from a mixture of milks of all three species. The white-brined category also includes Halloumi, a cheese produced chiefly in Cyprus from raw sheep's milk.

Pecorino is an Italian semi-hard or hard cheese. There are several varieties with appellations of origin, including Roma, Sicilia, and Fiore Sardo. The Roma variety accounts for 50% of all production. This cheese is made with raw or pasteurized milk, in most cases coagulated with lamb or kid rennet paste. Proteolysis is moderate (≈20% WSN), but there is intense lipolysis due to the use of pregastric esterases in the traditional curd pastes used. Kefalotiri is a variety similar to Pecorino produced in Greece, although curd pastes are not normally used for coagulation.

Kachkaval has been produced in various European countries, particularly in the Balkans, at least since the eleventh century. This is a stretched-curd cheese which undergoes moderate proteolysis even after 3 months of ripening (≈13% WSN).

The most characteristic Spanish semi-hard/hard sheep's milk cheeses are Manchego, Zamorano, Roncal, and Idiazabal, traditionally made from raw milk. These are generally ripened for 3–6 months, although Manchego is matured in olive oil for a longer period. Proteolysis is medium/high, 20–45% WSN, whereas lipolysis is low. Idiazabal cheese is ripened for 1–2 months and then smoked.

Some sheep's milk cheeses are made in Portugal and Spain using vegetable rennet extracted from the flower of the chard *Cynara cardunculus*. Examples include Serra da Estrela in Portugal, and La Serena, Los Pedroches, and Torta del Casar in Spain. These are marketed after relatively short ripening (30–60 days), but proteolysis levels are high (40–50% WSN) due to the strong proteolytic activity in the curds.

Spain produces two highly popular fresh cheeses, Burgos and Villalón. These are now made from pasteurized milk using animal rennet, but without a starter culture. They must be kept in chilled storage and consumed within less than 6 days.

Finally, in various countries, the whey from sheep's milk cheesemaking is used on its own or mixed with milk to manufacture products of high nutritional value. The whey contains mainly water-soluble proteins (≈1%), fat

Table 7 Average content of fat, protein, calcium, and phosphorus in cheeses from ewe's milk in different countries

Country	*Name*	*Type of cheese*	*Fat content (% total solids)*	*Protein (%)*	*Ca (%)*	*P (%)*
Bulgaria	Kaschkaval	Stretched curd	45	20		
Cyprus	Halloumi	Brined	48	24		
France	Roquefort	Blue-veined	50	21	0.62	0.42
Greece	Feta	Brined	40	18	0.65	0.40
Italy	Pecorino	Hard	42	29	0.40	0.32
Portugal	Serra da Estrela	Semihard	56	196	0.65	0.53
Romania	Teleme	Brined	50	18	0.53	0.40
Spain	Manchego	Semi-hard	50–55	23	0.68	0.54

Average values calculated on the results given by different authors.

(<1%), lactose, minerals, non-nitrogen substances, and vitamins. These whey cheeses are the result of heat-induced coagulation of the whey protein (which occludes fat). The best-known whey cheeses are Ricotta from Italy, Manouri and Myzithra from Greece, and Requesón from Spain.

Besides the cheeses mentioned here, many countries produce cheeses, generally semihard varieties, in which the raw material is a mixture of sheep's, cow's, and goat's milk.

Buffalo Milk

J S Sindhu and S Arora, National Dairy Research Institute, Karnal, Haryana, India

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Buffalo milk constitutes over 12% of the global milk production, which is second only to cow's milk; however, in hot and humid regions of the world, buffaloes contribute more significantly than cows to the total milk production because of their ability to thrive under more severe conditions, being more hardy and disease-resistant, and being better converters of coarse roughages. In the Indian subcontinent, the greater part of the milk produced is by buffaloes. Buffalo milk represents >53% of the total milk production in India, increasing at a rate of ~3.6% per annum, and >68% in Pakistan; this growth rate will continue for the immediate future. India and Pakistan together account for ~90% of the total worldwide production of buffalo milk. Buffalo milk is also produced in other Asian countries, but outside Asia only around 2 million tonnes is produced in Egypt and small volumes in Europe (notably in Italy, Bulgaria, Romania, and Germany). Buffalo milk provides more energy per unit volume than provided by cow's milk due to its higher fat and protein content, and it is more economical for producers, processors, and consumers. Planners, researchers, and development agencies of the world are now paying more attention to the efficient utilization of this previously neglected resource.

Gross Composition

Buffalo milk is known for its richness and creaminess. Its composition is influenced by a number of factors that may be genetic, physiological, nutritional, seasonal, or related to the stage of lactation and animal husbandry practices. The general chemical composition of buffalo milk in comparison to the milk of zebu and western cattle is given in **Table 1**. Buffalo milk contains 82–83% water, 6–12% fat, 4–5% proteins, 4–5.5% lactose, and 0.80% ash; it contains higher total solids, fat, proteins, and ash than found in cow's milk.

Milk Proteins

Buffalo milk contains about 4.0% casein and 0.9% whey proteins (**Table 2**). Of the 4.0% total casein, 1.4–1.8% is α_{S1}-casein, 0.2–0.28% α_{S2}-casein, 1.25–1.6% β-casein, 0.15–0.16% γ-casein, and 0.4–0.5% κ-casein. Of the 0.9% whey proteins, about 0.15% is α-lactalbumin, 0.40% β-lactoglobulin, 0.32% proteose-peptone, 0.03% serum albumin, and 0.03% lactoferrin. In comparison to cow's milk, both caseins and whey proteins are present at higher concentrations in buffalo milk. The average proportions of α_{S1}-, α_{S2}-, β-, and κ-caseins in buffalo milk are 40, 6.3, 35, and 12%, respectively. The concentration of nitrogen, calcium, and phosphorus in buffalo casein is about 12.0, 3.5, and 4.5%, respectively. The sialic acid content is 2.0 mg g^{-1}, hexose 2.54 mg g^{-1}, and hexosamine about 1.81 mg g^{-1} of casein. Almost all the casein in buffalo milk is in micellar form. The diameter of the micelles is 80–250 nm, the majority of the micelles being 110–160 nm as compared to 70–110 nm in bovine milk. The voluminosity of the micelles is 2.68–3.72 ml g^{-1} in the temperature range of 25–37 °C. Solvation of the micelles, calculated from voluminosity, is 2.60–2.90 g water g^{-1} casein. This is much lower than the solvation of the casein micelles in cow milk. The opacity of buffalo milk micelles is higher than that of cow's milk casein micelles.

α_{S1}-Casein

Buffalo α_{S1}-casein is a single polypeptide and has no disulfide bridges. Its amino acid composition is similar to that of bovine α_{S1}-casein. The C-terminal and N-terminal sequences are alike in the two species, except that the N-terminal sequence of buffalo α_{S1}-casein has lysine at the fourth position, whereas it is histidine in bovine milk casein. The reverse is true at position 8. The C-terminal sequence of α_{S1}-casein is Leu-Trp-Thr. Like its bovine counterpart, water buffalo α_{S1}-casein has 199 amino acid residues with a theoretical molecular mass of 22 798 Da. The nitrogen and phosphorus content of the protein is 15 and 1.1%, respectively. No genetic polymorphism has been observed in buffalo α_{S1}-casein. On the basis of the number of phosphoserine residues, it can be separated into α_{S1}-Frac.I (six phosphate groups molecule^{-1}) with a molecular mass of 23 276.2 ± 6.1 Da; α_{S1}-Frac.II (seven phosphate groups molecule^{-1}) with a molecular mass of 23 360.6 ± 4.6 Da; and α_{S0}-CN (eight phosphate groups molecule^{-1}) with a molecular mass of 23 437.9 ± 4.1 Da.

α_{S2}-Casein

Two subfractions of buffalo α_{S2}-casein have been identified, containing 10 and 11 phosphoserine residues, respectively. The two fractions are similar in amino acid composition except for lysine and glutamic acid. The

Table 1 Concentration (% w/w) of the major constituents in buffalo's and cow's milk

		Cow's milk	
Nutrient	*Buffalo's milk*	*Indian (Zebu)*	*Western*
Water	83.2	85.3	87.2
Total solids	16.3	13.8	12.8

Protein	4.7	3.3	3.5
Lactose	4.6	4.4	4.9
Total ash	0.8	0. 7	0.7

Table 2 Concentration of various protein fractions in buffalo's and cow's milk casein fractions

	Concentration in milk ($g\ 100\,ml^{-1}$)	
Polypeptide	*Buffalo's milk*	*Cow's milk*
α_{s1}-Casein	1.44–1.8	1.04–1.3
α_{s2}-Casein	0.22–0.28	0.26–0.34
β-Casein	1.26–1.58	0.94
γ-Casein	0.16	0.15
κ-Casein	0.43–0.54	0.3–0.37
β-Lactoglobulin	0.39	0.31–0.38
α-Lactalbumin	0.14	0.071–0.1
Proteose-peptone	0.33	0.24
Serum albumin	0.029	
Lactoferrin	0.032	0.005

calcium sensitivity of the protein at 30 °C is maximum at 2–4 mmol l^{-1} calcium. There is no genetic polymorphism in α_{S2}-casein.

β-Casein, γ-casein, and proteose-peptone

The primary structures of β-casein, γ-casein, and proteose-peptone (PP) are known. The γ-casein and PP-5, PP-8F, and PP-8S are fragments of β-casein; therefore, it is recommended that these should be called β-casein fragments. Chymosin action on buffalo milk produces three peptides from β-casein, namely, β-casein I, β-casein II, and β-casein III. Buffalo β-casein is more sensitive to calcium than bovine β-casein. Its amino acid composition is similar to that of bovine β-casein; it is devoid of carbohydrates, and no genetic polymorphism has been observed. Its pI is 5.3, the absorbance of a 1% solution in a 1-cm cell at 280 mm is 4.9, and its partial specific volume is 0.764 ml g^{-1}. The β-casein content of serum casein and smaller micelles is lower than that of large micelles. Buffalo β-casein is more sensitive to heat in the presence of calcium than bovine β-casein. The hydrolysis of buffalo β-casein by trypsin is slower than that of bovine β-casein. Buffalo β-casein gives three subfractions on anion exchange chromatography and two bands on gel electrophoresis. Recently, genetic polymorphism of buffalo β-casein has been reported; the molecular mass of the A and B variants is 24 048.8 ± 2.2 and 23 981.2 ± 1.3 Da and they have six and five phosphate groups per molecule, respectively. Buffalo β-casein A and B variants differ by three amino acid substitutions.

The proteose-peptone content of buffalo milk is about 330 mg 100 ml^{-1} compared to about 240 mg 100 ml^{-1} in bovine milk. Heating the milk and hydrolysis with trypsin lead to an increase in the concentration of proteose-peptone in buffalo milk. PP-3, PP-5, and PP-8 – like polypeptides with molecular weights of 25 120, 23 170, and 20 980 Da, respectively – have been isolated from buffalo milk. These fractions are low in aromatic amino acids and have arginine as the N-terminal amino acid. Component 3 is rich in carbohydrates but poor in phosphorus.

γ-Casein represents 4.7% of the total casein in buffalo milk; it gives three bands on SDS-PAGE corresponding to molecular weights of 23 300, 16 400, and 11 200 Da, respectively.

κ-Casein

Buffalo κ-casein is heterogeneous; eight subfractions have been isolated from colostrum. All the fractions are similar in phosphorus content but differ in carbohydrate content; no genetic polymorphism has been observed. Its amino acid composition is similar to that of bovine κ-casein, but its sialic acid content is lower. The release of sialic acid from buffalo κ-casein on rennet action is less than that from bovine milk. The stabilizing capacity of κ-casein for α-casein is low. However, its aggregation and disaggregation in the presence of $CaCl_2$ during heating are similar to bovine κ-casein. This fraction contains almost all the carbohydrates of casein and is rich in nitrogen but poor in phosphorus. Its pI value is 5.8–6.4, its extinction value at pH 8.6 (1% solution in a 1-cm cell at 280 nm) is 10.75, and its partial specific volume is 0.689 ml g^{-1}. Its concentration is higher in serum casein and in smaller micelles than in large micelles. In buffalo colostrum, this fraction is highly glycosylated and is devoid of carbohydrate-free κ-casein.

Whey proteins

Although the concentration of whey proteins in buffalo milk is higher than that in bovine milk, the proportions of different proteins are similar. The individual whey proteins are discussed below.

β-Lactoglobulin

The amino acid composition of buffalo β-lactoglobulin is identical to that of bovine β-lactoglobulin. However, buffalo β-lactoglobulin does not exhibit genetic polymorphism and is identical to bovine β-lactoglobulin B in electrophoretic mobility, sedimentation, and titration behavior. Sedimentation data under different conditions of pH and protein concentration show little difference from those obtained with bovine β-lactoglobulin. Based on the sedimentation coefficient, the molecular weight of buffalo β-lactoglobulin is 38 500 Da, that is, it exists as a dimer. The intrinsic viscosity of a solution of the protein at pH 5.2 and 37 °C is 0.034–0.035 dl g^{-1}, and is independent of pH. The molecule exists as a dimer at pH 5.2, but as a monomer at pH below 3.5 or above 6.5. At a low temperature and at a pH of 4.5, the molecule is present as a tetramer. At pH 12, the molecule is completely denatured and aggregates to form dimers, trimers, tetramers, pentamers, and hexamers. The surface tension of a 0.2% solution of the protein is 40–45 dyn cm^{-1}; at high concentrations, the surface tension is independent of concentration.

α-*Lactalbumin*

There is no genetic polymorphism in buffalo α-lactalbumin, which corresponds to the A variant of bovine α-lactalbumin. Chromatofocusing resolves buffalo α-lactalbumin into one major and three minor components. The Stoke's radius, as determined by gel filtration, is 1.86 nm and the degree of hydration, determined viscometrically, is very low (0.52 g g^{-1}). The partial specific volume is 0.73 ml g^{-1} and the molecular weight, determined by SDS-PAGE, is 14 400–14 500 Da, but gel filtration indicates that it is 2000–3000 units higher. The major component and one of the minor components with a slower electrophoretic mobility are devoid of carbohydrates, while the two other minor components are similar in hexose and hexosamine content; but only one of these fractions contains sialic acid. All the components are active in modifying the activity of galactosyl transferase in the synthesis of lactose. The physicochemical properties of buffalo and bovine α-lactalbumin are similar: they have the same crystalline form, and a similar nitrogen content, specific extinction coefficient at 280 nm, and tyrosine and tryptophan content. Their sedimentation coefficient is within the range of $1.87–1.99 \times 10^{-13}$ s.

Immunoglobulins

Buffalo milk contains about 10 mg of immunoglobulins per 100 ml of milk. In colostrum, their concentration is very high, being 43 and 32% of the total proteins in the first and second milking, respectively. The immunobiological role of buffalo immunoglobulins has generated considerable interest. Due to the high levels of these proteins in buffalo colostrum, efforts are being made to isolate and utilize them in infant foods as bioprotective additives. Four classes of these proteins, namely, IgG, IgA$_1$, IgA$_2$, and IgM, have been identified in buffalo colostrum, and IgG predominates.

Lactoferrin

Buffalo milk contains about 32 mg 100 ml^{-1} lactoferrin, compared with 15 mg 100 ml^{-1} for bovine milk; buffalo colostrum contains about 750 mg 100 ml^{-1} lactoferrin. The molecular weight of the protein is 73 500–74 000 Da. Total binding sites and other properties of the protein are similar to those of bovine lactoferrin.

Enzymes

Over 20 enzymes have been isolated from bovine milk and characterized. However, information on enzymes in buffalo milk is very limited. The important enzymes that have been characterized in some detail are given in **Table 3**. The major difference is in the activity of lactoperoxidase, which is nearly 1.76-fold higher in buffalo milk than in bovine milk.

Lipids

The proportions of mono-, di-, and tri-glycerides in buffalo milk fat are 0.7, 0.4, and 95%, respectively, which is similar to those in bovine milk fat. Significantly lower levels of free fatty acids have been found in buffalo milk and ghee (anhydrous milk fat) as compared to cow's milk and ghee.

The unsaponifiable matter is less in buffalo milk (390–400 mg 100 ml^{-1}) than in bovine milk (416–450 mg 100 ml^{-1}). Its content is higher in spring than in summer or winter.

Table 3 Concentration or activity of some enzymes in buffalo and bovine milk

	Activity/concentration in milk	
Enzyme	*Buffalo milk*	*Bovine milk*
Lipase (units ml^{-1})	0.16–1.13	0.1–0.6
Alkaline phosphatase (units ml^{-1})	0.12–0.18	0.08–0.12
Xanthine oxidase (units ml^{-1})	0.075	0.092
Lysozyme (μg ml^{-1})	0.152	0.18
Lactoperoxidase (units ml^{-1})	5.2–9.8	4.36–7.16
Ribonuclease (μg ml^{-1})	9.78	8.23
Protease (units ml^{-1})	0.78	0.68

Cholesterol

Buffalo milk fat has a lower concentration of total ($275\,mg\,100\,g^{-1}$) and free cholesterol ($212\,mg\,100\,g^{-1}$) than bovine milk fat (330 and $280\,mg\,100\,g^{-1}$, respectively). On the other hand, there are about $64\,mg\,100\,g^{-1}$ esterified cholesterol in buffalo milk fat compared to $48\,mg\,100\,g^{-1}$ in bovine milk fat. The cholesterol content is higher in foremilk than in strippings. On heating ghee (milk fat), thermal oxidation of cholesterol occurs, resulting in a lowered cholesterol level. Colostrum and mastitis milk contain more cholesterol than normal milk.

Phospholipids

The concentrations of phospholipids in bovine and buffalo milk are the same (about $39\,mg\,100\,ml^{-1}$ milk). However, due to the much higher fat content in buffalo milk, the phospholipid content of buffalo milk fat is much lower than that of bovine milk fat. Therefore, buffalo butter and ghee are poor in phospholipids. Winter ghee and the solid fraction obtained at 29 °C are rich in phospholipids.

Minor components

Buffalo milk fat contains about $8\,\mu g\,g^{-1}$ squalene compared to $5.9\,\mu g\,g^{-1}$ in cow's milk fat. Buffalo milk fat is also rich in ubiquinone, about $6.5\,\mu g\,g^{-1}$ compared to $5\,\mu g\,g^{-1}$ in cow's milk fat. However, buffalo milk fat is a poor source of lutein and lanosterol, which are present at 3.0 and $83\,\mu g\,g^{-1}$, respectively, compared to 4 and $93\,\mu g\,g^{-1}$ in bovine milk fat. The concentration of ethers is also lower in buffalo milk fat, about $0.8\,\mu g\,g^{-1}$, compared to $0.9\,\mu g\,g^{-1}$ in bovine milk fat. The concentration of total carbonyls is $9.8\,\mu g\,g^{-1}$ fat in buffalo milk. Alkanols (ethanol, methanol, and butanol) are present in lower concentrations in buffalo milk fat, being $1.85\,\mu g\,g^{-1}$ compared to $2.29\,\mu g\,g^{-1}$ in bovine milk fat. Ketoglycerides are also present in buffalo milk fat.

Fatty acid composition

The fatty acid composition of buffalo and bovine milk fat is given in **Table 4**. The proportions of $C_{4:0}$, $C_{16:0}$, $C_{17:0}$, and $C_{18:0}$ fatty acids are higher but those of $C_{6:0}$, $C_{8:0}$, $C_{10:0}$, $C_{12:0}$, $C_{14:0}$, and $C_{14:1}$ fatty acids are lower in buffalo milk fat than in bovine milk fat. In summer, the proportions of monounsaturated fatty acids, namely, $C_{14:1}$, $C_{16:1}$, and $C_{18:1}$, are higher, but the proportions of saturated fatty acids, namely, $C_{4:0}$, $C_{12:0}$, $C_{14:0}$, and $C_{16:0}$, are lower than the corresponding proportions in winter. Colostrum and late-lactation milk are rich in unsaturated fatty acids but poor in saturated fatty acids. Buffalo milk fat is richer in tetraenoic and pentaenoic acids but poorer in dienoic and trienoic fatty acids than bovine milk fat (**Table 4**).

Table 4 Fatty acid composition (% w/w) of buffalo and bovine milk fat

Fatty acid	*Buffalo milk*	*Bovine milk*
$C_{4:0}$	4.36	3.20

Pentaenoic		
Conjugated	0.002	0.0
Nonconjugated	0.105	0.062
Total	0.107	0.062

Colostrum and late-lactation milk are rich in polyunsaturated fatty acids (PUFA) (**Table 5**).

Glyceride structure

Separation of triglycerides based on crystallization behavior into high-melting triglycerides (HMT), medium-melting triglycerides (MMT), and low-melting triglycerides (LMT) reveals that buffalo milk fat contains a higher proportion (9–12%) of HMT than cow's milk fat (5–6%). Separation of triglycerides on the basis of molecular weight into higher-molecular-weight triglycerides (HMWT), medium-molecular-weight triglycerides (MMWT), and lower-molecular-weight triglycerides (LMWT) reveals that their proportions in buffalo milk fat are 42.5, 17.0 and, 40.5%, respectively, compared to 52.9, 18.9, and 28.2% in bovine milk fat. About 90% of the fatty acids in HMWT are $C_{14:0}$, $C_{16:0}$, $C_{18:1}$, and $C_{18:2}$. The principal fatty acids in MMWT are $C_{6:0}$, $C_{14:0}$, $C_{16:0}$, and $C_{18:1}$, and those in LMWT are $C_{4:0}$, $C_{14:0}$, $C_{16:0}$, and $C_{18:1}$.

Physicochemical constants

Buffalo milk fat has a higher melting point, specific gravity, saponification value and Reichert–Meissl value and larger grain size, but lower BR reading, refractive index, acid value, iodine value, and Polenske value compared to cow's milk fat.

Fat globules and fat globule membrane

The fat globules in buffalo milk are bigger, with an average volume of 4.15–4.6 μm compared to 3.36–4.15 μm for bovine milk. Buffalo milk fat globules are rendered chargeless at a much higher pH (4.5–4.6) as compared to bovine milk fat globules (pH 4.3). Buffalo fat globule membrane has an average lipid content of 38.5% compared to 35.7% in bovine milk. The total neutral lipids are higher in buffalo milk (74.4%) than in bovine milk (65.7%) fat globule membrane. On the other hand, the phospholipid content is almost the same in both species. Except for triglycerides and diglycerides, which are higher in buffalo milk (52.7 and 7.4%, respectively) than in bovine milk (35.5 and 5.5%), the concentration of other fractions is similar in both the milks.

Minerals

Major minerals

Buffalo milk is rich in calcium and magnesium (divalent cations) but poor in monovalent cations (sodium and potassium) and monovalent anions (chloride) as compared to bovine milk. However, the concentration of divalent anions (phosphate and citrate) is similar in both the milks. The average concentration and the partitioning of different salts between the dissolved and the colloidal phases in buffalo milk and bovine milk are given in **Table 6**. The concentrations of calcium and magnesium in the dissolved phase of buffalo and cow's milk are almost similar (about 39–40 mg of calcium and 8 mg of magnesium per 100 ml of milk). However, due to the higher concentrations of these minerals in buffalo milk, only about 20–22% of calcium and 45–46% of magnesium are in the dissolved state in buffalo milk, compared to about 33% of calcium and 75% of magnesium in bovine milk. On the other hand, in buffalo milk nearly twice as much divalent cations (about 172 mg 100 ml^{-1}) are present in the colloidal state, compared to 78 mg 100 ml^{-1} in bovine milk. The proportions of phosphate and citrate are also higher in the colloidal phase of buffalo milk than in bovine milk.

Trace elements

The trace elements in buffalo milk have not been studied as extensively as the major minerals. However, their concentrations reported in the literature are iron (1.3–1.94 mg kg^{-1}), copper (0.29–0.35 mg kg^{-1}), zinc (4.96–5.9 mg kg^{-1}), boron (0.52–1.36 mg kg^{-1}), and sulfur (157–314 mg kg^{-1}).

Table 6 Concentration of salt constituents in milk and its dissolved phase

Parameter		*Buffalo*	*Cow*
Calcium	Total (mg 100 ml^{-1})	182.6	114.2
	Dissolved (mg 100 ml^{-1})	39.75 (22)	39.2 (34)
Magnesium	Total (mg 100 ml^{-1})	18.04	11.0
	Dissolved (mg 100 ml^{-1})	8.30 (46)	7.8 (10)
Sodium	Total (mg 100 ml^{-1})	43.85	50
	Dissolved (mg 100 ml^{-1})	41.59 (95)	47 (94)
Potassium	Total (mg 100 ml^{-1})	106.6	148
	Dissolved (mg 100 ml^{-1})	100.96 (95)	143 (98)
Phosphorus	Total (mg 100 ml^{-1})	82.39	84.8
	Dissolved (mg 100 ml^{-1})	26.20 (31)	38.4 (45)
Citric acid	Total (mg 100 ml^{-1})	159.2	166.0
	Dissolved (mg 100 ml^{-1})	114.69 (84)	152.0 (96)
Chloride	Total (mg 100 ml^{-1})	57.69	106.3
	Dissolved (mg 100 ml^{-1})	57.03 (99)	106.2 (100)

Values in parentheses are the percentage of total in the dissolved phase.

Vitamins

The concentrations of vitamins in buffalo and bovine milk are given in **Table 7**. Except for vitamin A and tocopherol, the concentrations of vitamins in buffalo milk are similar to their concentrations in bovine milk. However, due to the absence of carotenoids and the high fat content of buffalo milk, its total potential level of vitamin A is lower than that of bovine milk. Similarly, there is a higher concentration of tocopherol in buffalo milk, but due to its higher fat content buffalo milk fat is poorer in tocopherol (about 26 μg g^{-1}) as compared to cow's milk fat (about 35 μg g^{-1}).

Pigments in Buffalo Milk

Buffalo milk contains a blue-green pigment, biliverdin IX alpha, which is not found in cow's milk. The average concentrations of biliverdin in skim milk of Murrah and Surti buffalo are about 52 and 65 μg 100 ml^{-1}, respectively, and are influenced by the stage of lactation. Biliverdin in buffalo milk is associated with the caseins. On souring of milk, the pigment is dissociated and undergoes a rapid chemical reduction to a fat-soluble yellow pigment, bilirubin IX alpha. This pigment binds milk lipids and imparts the characteristic greenish-yellow appearance to ghee and butter prepared by the traditional method.

Table 7 Concentration of vitamins in buffalo and bovine milk

	Concentration in milk	
Vitamin	*Buffalo*	*Bovine*
Vitamin A (IU ml^{-1})	340	230
Thiamine (μg ml^{-1})	0.2–0.5	0.2
Riboflavin (μg ml^{-1})	1.59	2.33
Pyridoxine (μg ml^{-1})	3.25	2.6–3.0
Ascorbic acid (mg 100 g^{-1})	2.2	1.94
Tocopherol (μg g^{-1})	334.2	312.2

Miscellaneous Constituents

Non-protein nitrogen

About 5% of the total nitrogen in buffalo milk is non-protein nitrogen, the same as in bovine milk. Non-protein nitrogen compounds in buffalo milk include amides, urea, amino acids, creatine, creatinine, uric acid, and ammonia. The concentrations of these compounds in buffalo milk are similar to their concentrations in bovine milk except for urea, which is present at a much lower concentration (17–22 mg 100 ml^{-1}) than in bovine milk (37–40 mg 100 ml^{-1}). Buffalo milk has an average taurine content of 23 mg l^{-1}.

Physicochemical Properties of Buffalo Milk

Due to quantitative and qualitative differences in various constituents, buffalo milk differs from bovine milk in physicochemical properties. The physicochemical properties of buffalo and bovine milk are compared in **Table 8**.

Heat Stability

The heat stability of buffalo milk is similar to that of bovine milk, and no correlation has been observed between its heat stability and its natural pH or between heat stability and any of its constituents. However, alteration in its natural pH due to souring or addition of acid or alkali leads to a considerable change in heat stability. All buffaloes produce type A milk with its natural pH coinciding with the pH of maximum stability. Therefore, any alteration in its pH results in the destabilization of buffalo milk. Addition of urea, glyceraldehyde, glyoxal, and deoxyribose stabilizes buffalo milk in the region of maximum stability while the addition of acid causes its destabilization. Colostrum, dry secretion, mastitic milk,

Table 8 Physical properties of bovine and buffalo milk

Property	*Buffalo milk*	*Cow's milk*
Specific gravity (at 20 °C)	1.0323	1.0317
Viscosity (cP at 27 °C)	2.245	1.450
Curd tension (g)	32.85	28.54
Surface tension (dyn cm^{-1} at 20 °C)	45.50	42.50
Freezing point (°C)	−0.545 4	−0.530
pH (at 20 °C)	6.7	6.6

Thermal conductivity (kcal h^{-1}m^{-1} °C^{-1} at 37 °C)	0.569	0.46
Heat capacity (cal g^{-1} °C^{-1} at 30 °C)	0.852	0.93–0.95
Heat stability (min at 130 °C)	31	32
Rennet stability (min)	25.6	28.2

and milk from tuberculosis-infected animals are very unstable. No correlation between the heat stability of buffalo milk and its casein number, casein solvation, and voluminosity has been observed.

Comparatively much less work has been done on the heat stability of concentrated buffalo milk. Concentrated buffalo milk is much less stable than cow's milk at its natural pH due to a greater shift in its pH of maximum stability toward the acidic side. In the case of concentrated bovine milk, the pH of maximum stability is usually on the alkaline side of the natural pH. Therefore, addition of substances that cause an increase in its pH, such as disodium phosphate or trisodium citrate, leads to stabilization. On the other hand, due to the location of the pH of maximum stability on the acidic side of the natural pH, the above compounds, instead of stabilization, cause very strong destabilization of concentrated buffalo milk. Similarly, removal of calcium by cation exchangers destabilizes buffalo milk concentrates. For these reasons, problems were encountered in the manufacture of evaporated milk from buffalo milk. However, with the addition of an optimum amount of either NaH_2PO_4 or $CaCl_2$, evaporated milk can be prepared from buffalo milk. The heat stability of buffalo milk concentrate at the pH of maximum stability is as good as that of cow's milk, except that cow's milk is on the acidic side of the natural pH while cow's milk concentrate is on the alkaline side. The heat coagulation time (HCT) versus pH curves of buffalo milk and its concentrate are presented in **Figures 1** and **2**.

Rennet and Ethanol Stability

Under similar conditions, the rennet coagulation time of buffalo milk is shorter than that of cow's milk and is inversely proportional to its calcium content.

Ethanol stability, expressed as the concentration of ethanol in aqueous solution that coagulates an equal volume of milk, is 60–72%, which is lower than 70–80% for the milk of Zebu cattle. Addition of ethylenediaminetetraacetic acid (EDTA), disodium phosphate, and trisodium phosphate; forewarming at 90 °C for 30 min; and dilution with water increase the ethanol stability of buffalo milk. On the other hand, addition of calcium chloride reduces ethanol stability.

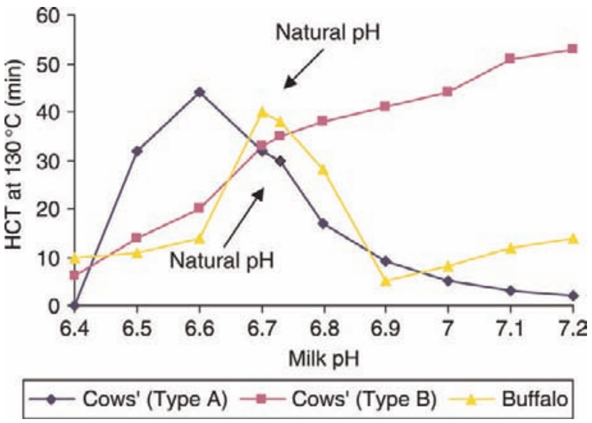

Figure 1 Effect of pH on the heat stability of buffalo's and cow's milk.

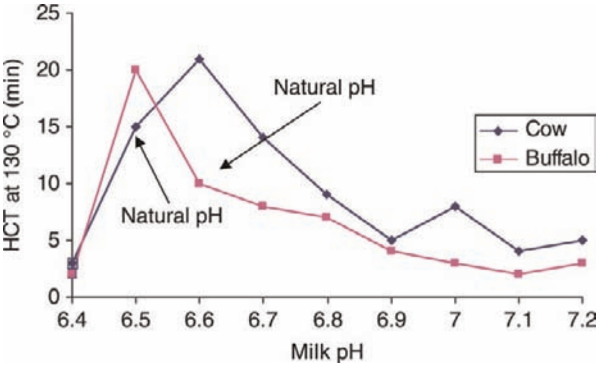

Figure 2 Effect of pH on the heat stability of concentrated milk (buffalo's and cow's).

Density and Specific Gravity

The density of buffalo milk at 20 °C is about 1.034 1 kg l^{-1}, which decreases to 1.027 2 and 1.026 3 kg l^{-1} at 27 and 29 °C, respectively. The specific gravity of the milk is about 1.032 3 at 20 °C and 1.031 9 at 30 °C.

pH, Acidity, and Buffering Capacity

The pH of fresh buffalo milk is in the range of 6.63–6.8. It is highest during January and lowest during May–June. The titratable acidity of buffalo milk is 0.16%, compared to 0.15% for cow's milk. The development of acidity is faster in buffalo milk than in cow's milk. The buffering capacity of buffalo milk is highest in the acidic pH range, with the peak at pH 4.8–5.2; on either side of this range it shows a steep fall. The buffering capacity at 60 °C is maximum at about pH 4.6, which shifts to around pH 5.7 at 20 °C. The addition of disodium phosphate or trisodium citrate causes an increase in buffering capacity but the addition of calcium chloride reduces it.

Freezing Point

The freezing point of buffalo milk is in the range of −0.545 4 to −0.544 3 °C. This range is higher for milk from the Egyptian buffaloes, being −0.552 to −0.558 °C. These values for the freezing point are much lower than the freezing point of cow's milk, which is −0.522 °C.

Viscosity and Surface Tension

The viscosity of buffalo milk at 20 °C is about 2.245 cP, which is much higher than that of cow's milk (1.450 cP at 20 °C). This is due to the higher protein and fat content of buffalo milk. The surface tension of buffalo milk at 20 °C is in the range of 45.5–48.7 dyn cm^{-1}, which is somewhat higher than the surface tension of cow's milk (42.3–42.5 dyn cm^{-1}).

Curd Tension

The curd tension of buffalo milk is 32–85 g, which is much higher than that of cow's milk, which is in the range of 28–54 g. The higher curd tension of buffalo milk may be due to its higher total solids, particularly the casein and calcium.

Oxidation–Reduction Potential and Electrical Conductivity

The oxidation–reduction potential (Eh) of buffalo milk is in the range of +0.129 to +0.469 V, with an average of +0.310 V at 30 °C. This value is higher than the Eh of cow's milk, which is +0.258 V. There is no appreciable difference in the electrical conductivity of milk from the two species; for buffalo milk the value is 3.22 m℧ and for cow's milk it is 4.0–5.5 m℧.

Thermal Expansion and Thermal Conductance

The volume of buffalo milk increases by 1.26% when heated from 4 to 40 °C and by 6% when heated up to 95 °C. The increase in volume is less for skim milk than for whole milk. Furthermore, the increase is greater for buffalo milk than for cow's milk. For whole milk the coefficient of thermal expansion is 4.106×10^{-4} °C^{-1} in the temperature range of 20–25 °C. The thermal conductance of buffalo milk is in the range of 0.548 7–0.593 7 kcal h^{-1} m^{-1} °C^{-1} with an average of 0.568 9 kcal h^{-1} m^{-1} °C^{-1} at 37 °C. This value is much higher than the thermal conductance of 0.46 kcal h^{-1} m^{-1} °C^{-1} for cow's milk.

Heat Capacity

The heat capacity of buffalo milk is 0.852 0 cal g^{-1} °C^{-1} at 30 °C and is lower than that of cow's milk, which is in the range of 0.933–0.954 cal g^{-1} °C^{-1} at the same temperature.

Color and Flavor

Fresh buffalo milk is whiter than cow's milk and has a slight blue-green hue. This may be attributed to the larger size of casein micelles and fat globules, the presence of biliverdin, and the absence of carotenoids in buffalo milk. Buffalo milk has a smoother, more pleasant, slightly sweeter, and richer flavor than cow's milk apparently due to higher total solids and fat content.

Inherent Advantages and Problems Encountered during the Processing of Buffalo Milk

Inherent Advantages of Buffalo Milk

Due to higher levels of total solids, fat, proteins, and colloidal calcium, and the larger fat globules in buffalo milk, fermented products like dahi (curd), lassi, shrikhand, shrikhand wadi (indigenous Indian products), leben, cermir (Iraq), lule kaymagl (Turkey), zabadi (Egypt), buttermilk (Bulgaria), and yogurt made from buffalo milk have a better body and texture than similar products made from cow's milk. For yogurt, the need to concentrate milk or to add milk powder is avoided due to the higher total solids content. The yield of cream, butter, and ghee from buffalo milk is higher due to higher fat, and the separation of cream and its churning into butter are easier due to the larger size of the fat globules and the higher proportion of solid fat. The fat losses in skim milk and buttermilk are lower. The texture of ghee is better due to the bigger grain size, which, in turn, may be due to the higher proportions (9–12%) of HMT compared to only 5% in cow's milk fat. The quality of khoa (a heat desiccated indigenous Indian product) from buffalo milk is superior to that of khoa from cow's milk, which has a moist surface, a sticky and sandy texture, and a salty taste. Similarly, the quality of buffalo milk paneer (an acid-coagulated unripened cheese) is superior, as the cow's milk product is too soft, weak, and fragile, and after cooking, its pieces lose their identity. The yield of these products is also higher from buffalo milk than from cow's milk.

The manufacture of edible casein and caseinate is easier from buffalo milk due to its higher casein content. The yield of these products is also higher than the yield from cow's milk, as the losses in the whey are less due to larger size, less hydration, and lower voluminosity of the casein micelles in buffalo milk.

Better absorption of fat due to superior emulsifying capacity; a higher calcium-to-phosphorus ratio; higher concentrations of whey proteins, calcium, magnesium, lactoferrin, esterified cholesterol, and taurine; and lower concentrations of sodium, potassium, chloride, urea, and total and free cholesterol in buffalo milk as compared to cow's milk are beneficial in human nutrition. These attributes make buffalo milk superior to cow's milk as an ingredient for health foods and, with slight modification, for infant foods.

Certain varieties of cheese, like Mozzarella and Domiati, are superior in quality when made from buffalo milk. Other prominent varieties of cheese made from buffalo milk are Feta, Bjalo salamureno sirene (Bulgaria), Beli-sir-u-kriskama (Yugoslavia), Teleme (Romania), Lori, Imeretinskii, Limanskii, Osetinskii (Russia), and Brizna (Israel).

Problems during the Processing of Buffalo Milk

Due to the quantitative and qualitative differences of various constituents and physicochemical properties of the milk from the two species, the processing technology developed in Western countries for cow's milk is not suitable for processing buffalo milk. Therefore, buffalo milk poses some problems during processing to some products; a brief description of these problems is given below.

The lower heat capacity, higher thermal conductivity, and higher thermal expansion of buffalo milk clearly indicate that a lower quantum of heat energy is required to achieve certain desired heat effects in buffalo milk. Therefore, time–temperature combinations for its processing may have to be standardized and suitably modified.

Buffalo milk is considered not suitable for the manufacture of certain ripened cheese varieties, namely, Cheddar, Gouda, and Emmental. These ripened varieties of cheeses are characterized by their soft, mellow and velvety body and texture and a rich pleasing flavor. The cheese made from buffalo milk has a flat flavor and a hard, rubbery and dry body and texture. These problems in buffalo milk cheese may be due to slower acidity development, a lower retention of moisture, and a lower rate of glycolysis, proteolysis, and lipolysis, as compared to cow's milk cheeses. However, with modifications in the process, Cheddar, Gouda, and Emmental cheeses of acceptable quality can be made from buffalo milk.

The quality of buffalo milk chhana (an acid-coagulated Indian product used as an ingredient in sweetmeats) is not comparable to that of cow's milk chhana as its texture is hard and cohesiveness is lower, which makes it unsuitable for making rasogolla. Also, butter made from buffalo milk is harder than cow's milk butter. As a result it creates problems during working and has poor spreadability on bread. The oxidative stability of buffalo ghee is poor because the amounts of tocopherol and phospholipids present are low.

Camel Milk

Z Farah, Swiss Federal Institute of Technology, Zürich, Switzerland

© 2011 Elsevier Ltd. All rights reserved.

Introduction

According to FAO (Food and Agriculture Organization of the United Nations) statistics, there are about 19 million camels in the world, of which 15 million are found in Africa and 4 million in Asia. Of this estimated world population, 17 million are believed to be one-humped dromedary camels (*Camelus dromedarius*) and 2 million two-humped (*Camelus bactrianus*). Approximately 15 million dromedaries, representing two-thirds of the world camel population, are in the arid areas of Africa, particularly in northeast Africa, that is, Somalia, Sudan, Ethiopia, and Kenya. This article is concerned entirely with the one-humped camels. The term 'camel' should therefore be taken to refer to this species unless specifically stated otherwise.

Camels are kept by pastoralists in subsistence production systems. They are very reliable milk producers during dry seasons and drought years when milk from cattle, sheep, and goats is scarce. At such times, camel can contribute up to 50% of the nutrient intake of the pastoralists. Camel meat is also an important by-product mainly as a source of income. Sale of live camels, usually males and unproductive females for slaughter, is very common in East Africa and there are now increasing numbers of camel butcheries in many urban centers. There is also a growing export trade of slaughter camels to the Arabian Peninsula. The camel is also a means of transportation and serves domestic needs such as drawing water from wells, rivers, and dams.

From a global perspective, the economic significance of camel production is minimal in comparison with that of other domestic animals. Nevertheless, in Africa, especially in East Africa and Sahel countries, the camel population makes a significant contribution to national economies. However, it is difficult to evaluate this economic contribution as most of the camel products are traded in the informal sector. Owing to the increasing human population and declining per caput production of food, there is an urgent need to develop marginal resources, such as arid land, and optimize their utilization through appropriate livestock production systems of which camel production is the most suitable without doubt.

Milk Production

It is difficult to estimate the daily milk yield of a camel under pastoralist conditions, owing to the inconsistency of milking frequency. Milk yield also varies with species, breed, stage of lactation, feeding, and management conditions.

The length of lactation can vary from 9 to 18 months. This depends mainly on the husbandry practices, which are determined largely by the need for milk, more being required in the dry months than in the wet months when other sources of food are available. In general, both udder halves are milked at the same time by two herdsmen, but before milking, the calf is allowed to suckle until the milk starts to flow and the camel can be milked. Without this stimulation, the dam cannot be milked. If the calf dies, the dam dries up if milking is not stimulated. Often it is sufficient for the dam to see the skin of her calf for milk secretion to be stimulated.

Estimates of milk yields from various countries are given in **Table 1**. The data should be considered as guidelines for milk yields under pastoral conditions. It must also be noted that throughout lactation calves are still suckling and therefore the actual volume of milk secreted is higher than the figures presented in the table.

Camels are slow reproducers. A female camel is sexually mature at the age of 4–5 years. Pregnancy is just over 12 months and the calving interval in pastoral production systems is normally 24 months or more. Female camels can remain fertile up to the age of 25 years and it is often reported that they produce 8–10 calves during a lifetime. In pastoral production systems, however, only a small fraction of the breeding female can reach this production performance.

Besides this natural productivity limitation, the main factor affecting milk production is calf mortality. Newborn mortality in camels is very common and losses as high as 50% have been reported in different parts of eastern and northern Africa.

In the surveyed areas, deaths of newborn and calves up to 1 month were sixfold compared to grown-up camels with 3% of losses. The main reason given by the herders was feeding of colostrum, which leads, according to their belief, to diarrhea. For this reason, the colostrum is milked onto the ground, leaving only a relatively small quantity for suckling by the calf. This indicates that low colostrum

Table 1 Milk yield of camels reported from various sources

Country	*Average daily yield (kg)*	*Lactation length (months)*	*Calculated yield (kg yr^{-1})*
Algeria	3.0	9–16	1460
Ethiopia	5.0	12–18	1825
India	6.8	18	2482
Kenya	4.5	11–16	1643
Pakistan	10.0	16–18	2920
Somalia	5.0	9–18	1825
Tunisia	4.0	9–16	1460

intake, and consequently low immunization, of the newborn calf is presumably one of the main causes of early calf mortality.

Camel milk is generally opaque white. It has a sweet and sharp taste, but sometimes it can be salty. The taste generally depends on the type of fodder and availability of drinking water. The pH of camel's milk ranges from 6.2 to 6.5 and the density from 1.026 to 1.035. Both density and pH are lower than those of cow's milk.

Compared to cow's milk, camel's milk sours very slowly and can be kept longer without refrigeration.

Milk Composition and Main Components

The composition of camel milk quoted from various sources and the corresponding values from other animal species are presented in **Table 2**. There are greater variations in the constituents of camel milk than in cow milk. Camels are known to produce diluted milk in hot weather when water is scarce. The main difference between cow's and camel's milk lies in the different physicochemical characteristics of the individual components.

Proteins

The average casein content and the whey protein content of camel milk vary between 1.9 and 2.3%, and 0.7 and 1.0%, respectively. Comparison with bovine milk proteins reveals pronounced differences in the quantitative distribution of casein and whey proteins. β-Casein is found in higher concentration (65% of total casein) than in bovine milk (39% of total casein), whereas κ-casein, which is about 13% of total caseins, in bovine milk amounts to only 3.5% of the casein fraction of camel milk (**Figure 1**).

Camel milk casein differs from cow milk casein in terms of micellar size distribution. Electron microscopic studies showed a relatively broad size distribution of casein micelles in camel milk with a greater number of large micelles than cow milk.

Most casein particles in cow milk have a diameter of 40–160 nm. In camel milk, casein particles range in diameter from 20 to more than 300 nm (**Figure 2**).

Nearly 90% of the whey proteins consist of α-lactalbumin, serum albumin, immunoglobulin, and lactophorin, the rest being minor proteins such as peptidoglycan recognition proteins (PGRPs), lactoferrin, and whey acidic protein.

β-Lactoglobulin, the main whey protein of bovine milk, is not found in camel milk.

Milk Fat

The fat content of camel milk varies between 2.9 and 5.4% and the average size of the fat globules is about the same as fat globules of cow milk. According to our present knowledge, the main differences in fat between cow milk and camel milk are as follows:

1. Natural creaming of camel milk differs markedly from that of cow milk. On standing, camel milk creams less rapidly and less completely than cow milk and no skimmable cream can be obtained even after standing for several days.

Table 2 Gross composition (%) of milk from various animal species

Species	*Moisture*	*Fat*	*Lactose*	*Protein*	*Ash*
Camel	86–88	2.9–5.4	3.3–5.8	3.0–3.9	0.6–1.0
Cow	86–88	3.7–4.4	4.8–4.9	3.2–3.8	0.7–0.8
Goat	87–88	4.0–4.5	3.6–4.2	2.9–3.7	0.8–0.9
Sheep	79–82	6.9–8.6	4.3–4.7	5.6–6.7	0.9–1.0
Human	80–88	3.3–4.7	6.8–6.9	1.1–1.3	0.2–0.3

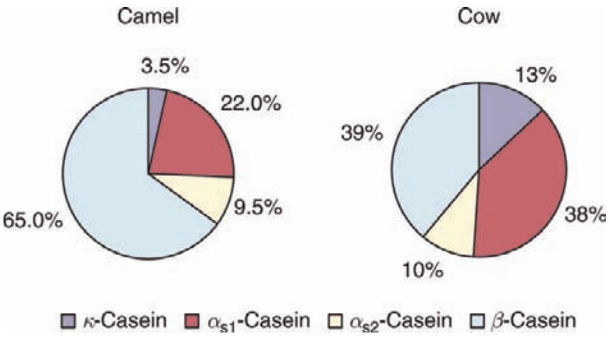

Figure 1 Proportion of individual caseins in camel and cow milk.

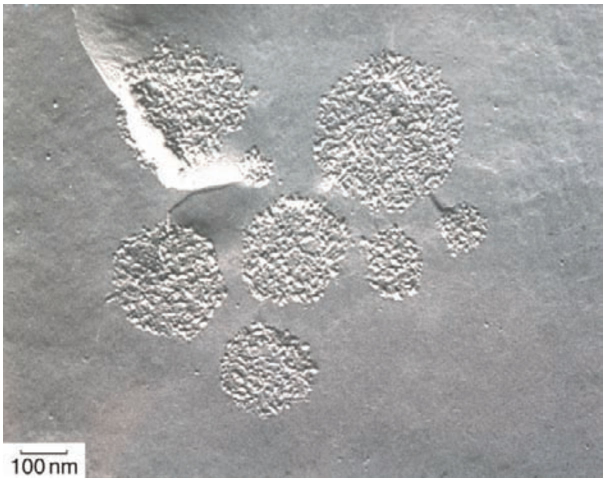

Figure 2 Electron micrograph (×75 000) of freeze-fractured casein micelles in camel milk. Scale = 100 nm.

2. Compared to cow milk fat, camel milk fat contains less short-chain fatty acids. Long-chain unsaturated fatty acids occur to about the same extent in both.
3. Butter can be obtained from camel milk only at a high churning temperature of 20–25 °C. These values are considerably higher than the value for cow milk, which normally varies between 8 and 12 °C.
4. The mean melting point of camel milk butter is around 41.5 °C and is on average 8 °C higher than the corresponding value for cow milk butter.

Lactose

Lactose is the major carbohydrate in the milk of all mammals and it is generally accepted that there are no non-mammalian sources of lactose.

The lactose content of camel milk ranges from 4.8 to 5.8% and is slightly higher than the lactose content of cow milk. It seems that the lactose content of camel milk is relatively constant throughout lactation.

Studies on the effect of drought on the composition of camel milk found that the lactose content was low at birth being around 2.8% but within 24 h it was increased to 3.8%. There was a further increase up to 5% as long as drinking water was available. Dehydration of the animals led to a decline in milk lactose content to as low as 2.6%. According to these studies, this change in lactose concentration would account for the milk being described sometimes as sweet and other times as bitter.

Mineral Salts and Vitamins

Only fragmentary information is available on minerals and vitamins in camel milk.

Milk mineral salts are mainly chlorides, phosphates, and citrates of potassium sodium, calcium, and magnesium. Although salts comprise less than 1% of the milk, they influence the physical state and stability of milk proteins, particularly the phosphocaseinate complex. The mineral content of camel milk expressed as ash ranges from 0.6 to 0.8%. Although the salt composition of milk is influenced by factors such as health status of the udder and stage of lactation, the major salt constituents of camel milk seem to be similar to those of cow milk.

Camel milk contains less vitamin A and E, thiamine, riboflavin, folic acid, and pantothenic acid than cow milk, while the content of pyridoxine and B_{12} is about the same. The content of niacin and vitamin C is higher than that of cow milk. The availability of a relatively fair amount of vitamin C (range reported in the literature is 25–60 mg l^{-1}) in camel milk is significant from the nutritional standpoint in arid areas.

Technologically Relevant Properties of Milk

Enzymatic Coagulation

Most attempts to make cheese from camel milk have revealed major difficulties in getting the milk to coagulate. With the same amount of calf rennet, the coagulation time of camel milk is two- to threefold longer than cow milk. The action of rennet on camel milk leads to coagulation in the form of flocks, with no firm coagulum. Typical formagraph recordings of duplicate cow and camel milk samples are shown in **Figure 3**.

The coagulation time (*R*) is determined by measuring the distance from the origin to the point where the baseline begins to increase in width and curd formation is expressed as the time from the start of gel development until a width of 20 mm is reached. Following this definition, no curd firmness could be measured in camel milk as this width of formagraph was not reached, due to the failure of curd formation.

One reason for this weak coagulum is presumably the low amount of κ-casein in camel milk, which can lead to weak curd formation. Another possible reason is the fact that the mean diameter of camel casein micelles is larger than

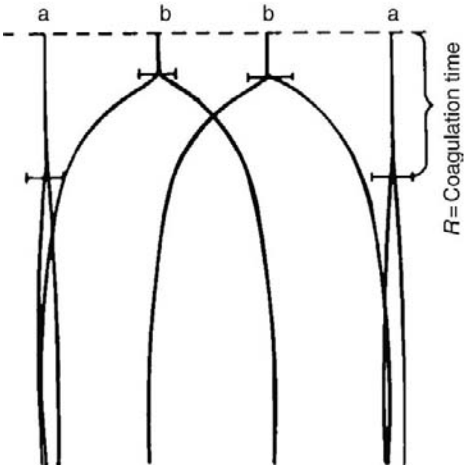

Figure 3 Formagram of duplicate camel (a) and cow (b) milk samples (*R* cow = 330 s, *R* camel = 930 s).

that of casein micelles in bovine milk. This can contribute to the formation of weak coagulum, as normally smaller diameter micelles give firmer curd than larger micelles.

It is well known that the clotting enzyme from one species is more effective and specific for milk from the same species. For example, chymosin from lamb was found to be more effective on sheep milk than on cow milk. This suggests an adaptation between the proteolytic specificities of the gastric proteases and the structure of the caseins. Accordingly, it can be expected that camel chymosin would be more effective on camel milk than calf chymosin.

In a recent study, the production of camel chymosin was reported. In the first step, the genetic information (in the form of the so-called mRNA) needed for the production of chymosin was obtained from the stomach of a young camel. This information was then inserted into a so-called expression vector, a piece of genetic sequence needed for introduction (transformation) of the chymosin information into a fungus. The fungus was now able to produce and secrete camel chymosin. The high-yielding fungal strains were selected for production of the enzyme. After centrifugation of the fungus and purification of the supernatant, the enzyme was ready for use. The process is patented. Field and laboratory studies for making cheese from camel milk were successfully carried out in different countries and the camel chymosin in now available on the market (**Figure 4**).

Effect of Heat on Milk

There are very few studies on the effect of heat treatment on camel milk proteins. Available data indicate that the whey proteins in camel milk are more heat resistant than those in cow milk. In this study, the milk was pasteurized to 63, 80, and 90 °C for 30 min, and the effect of heat on the whey proteins was determined by polyacrylamide gel electrophoresis. Under the selected experimental conditions, the rate of heat denaturation of camel milk whey proteins was approximately twofold lower than cow milk whey proteins. This indicates that camel milk can be pasteurized. In fact, there are commercial small- and middle-scale camel milk processing plants for the production of pasteurized milk in Mauritania, Kenya, and Gulf states.

Figure 4 Fresh cheese from camel milk manufactured using camel chymosin.

Reported investigations aiming to study the ability of camel milk to withstand ultra-high temperature (UHT) processing showed phase separation and the formation of deposit after storage. This heat instability of camel milk at high processing temperatures can be due to the low content of κ-casein and the total absence of β-lactoglobulin in camel milk. Both proteins play an important role in the heat stability of bovine milk.

Milk Commercialization and Hygiene

In eastern African countries (Kenya, Somalia, Sudan, and Ethiopia) where most of the world's camel populations are kept, camel milk plays a central role in food security.

In the context of advancing urbanization, camel milk, in the form of raw or fermented milk, is increasingly commercialized and consumed in urban areas. The camel milk suppliers are nomadic pastoralists. Traditionally, nomadic settlements are transient and their movements depend on where they can find adequate pasture and water for their herds. However, this picture of 'moving' nomads has changed in recent decades. With growing urbanization, the demand for milk among the city population has been increasing. On the other hand, the demand for a number of goods such as grain, oil, sugar, and clothes has increased among the pastoralists and milk sales have become the most important source of cash income for many camel-owning pastoralists. Studies on the camel milk market in some eastern African countries showed how camel milk outweighed other milk types in rural pastoral areas during the dry season.

In these studies, two types of camel-oriented dairy systems are described. One consists of wide-ranging nomadic herders who from time to time during their seasonal migratory movement pass through the 'milk catchment areas' surrounding settlements, where they sell their surplus milk. The other is more intensive camel dairying and is based on semi-stationary camel herds established near urban centres around towns in regions with adequate pasture and water. In a herd, there are approximately 10–100 lactating camels and the milk is marketed through urban milk traders who collect the milk and sell it in the urban centers. These semi-stationary herds regularly exchange camels with dry herds that utilize more remote grazing areas to ensure that limited pasture near markets is used by lactating camels.

Camel milk production areas are often located far from markets. Distances to provincial markets range from 20 to 90 km and may be up to 400 km for distant urban markets. During periods of milk surplus (rainy season), transport on dirt roads is unreliable, resulting in breakdowns and delays in milk delivery. Storage in unhygienic containers, pooling of milk from different suppliers, prolonged transport times, and high environmental temperatures all increase contamination and spoilage of milk.

This results in considerable losses in marketed camel milk caused by frequent spoilage due to the absence of appropriate conservation and storage methods. In addition, the presence of zoonotic infectious diseases in camels results in a potentially high health risk to the public.

The monitoring of hygienic quality of camel milk from pastoral production areas has serious logistical problems because of distances to the laboratory.

Field studies showed that raw milk directly milked into clean containers has a total bacterial count (TBC) of about 10^4–10^5 cfu ml^{-1}, but it deteriorates rapidly as it enters the informal marketing chain, turning sour in less than 24 h at 25 °C or in less than 12 h under hot conditions (35 °C).

Optimizing milk hygiene under pastoral conditions is difficult; however, the introduction of simple interventions showed measurable results in field studies. One of the most promising methods is the activation of the lactoperoxidase system (LPS) in milk.

The LPS is composed of lactoperoxidase, thiocyanate, and hydrogen peroxide.

Lactoperoxidase is always present in milk at an adequate concentration. The concentration of thiocyanate is more variable as it is dependent on feed and stage of lactation. The third component of the system, hydrogen peroxide, is not normally detected in milk. When active, the LPS produces hypothiocyanite ions, a strong antimicrobial agent. The system can be activated by adding a defined quantity of thiocyanate and hydrogen peroxide to milk.

In field tests performed in rural Kenya using an FAO- and WHO-approved LPS kit, TBC of untreated fresh milk was 1×10^5 cfu ml^{-1}. After LPS treatment and transport for 6 h at 30 °C, the TBC of untreated milk increased to 3×10^7 cfu ml^{-1}, while LPS-treated milk remained unchanged.

Based on these results, it was concluded that lactoperoxidase treatment can be effective in extending the shelf life of raw camel milk following the same procedure as for cow milk.

Furthermore, the introduction of the following simple milk handling techniques proved to be effective:

- replacement of cheap plastic with quality stainless steel containers for storage and transport;
- filtration of milk through disposable clean gauze/paper filters;
- rotation of sealed sanitized containers between production areas and dairy processors;
- short heating/flash boiling of raw milk at primary collection sites;
- reduction of milk temperature at collection sites using solar- or gas-powered refrigerators, by evaporative cooling from charcoal-walled cooling chambers, or simply by wrapping milk containers in a moist cloth; providing shade/cooling boxes during vehicle transport;
- training and extension to increase awareness among producers on clean milking and handling practice; accelerated transport from production to market;
- exclusion of milk from processing if the animal is infected with brucellosis, mastitis, or tuberculosis. Also, the milk must not be used if it contains colostrum or veterinary drug residues and if the animal has been vaccinated within the previous 24 h;
- before milking, washing the udder of the animal with lukewarm water and disinfectant and wiping clean-dry with a cloth used for this and no other purpose. The milker's hands must also be washed and disinfected.

Concluding Remarks

Camel husbandry is becoming increasingly important in the arid zones. The camel has long been the mainstay of pastoral societies due to its drought tolerance, reliable milk supply, and ability to feed on a wide variety of plants.

The interest in research on camel milk is gradually increasing; however, much of the research work so far is being carried out by individuals from different institutions with little impact on the development efforts.

Attention must be given to practically oriented research by developing market-oriented milk products of high quality and prolonged shelf life.

This will get the support of the private investors interested in the development of camel dairies in countries with large camel populations and satisfy the demand for camel milk among the growing urban population.

Introduction

More than 200 species of ungulate (hoofed) animals exist today and are grouped into two orders Artiodactyla (even-toed ungulates) and Perissodactyla (odd-toed ungulates). There are about 190 species of Artiodactyla and 15 species of Perissodactyla; the latter includes three families, Equidae, Rhinocerotidae, and Tapiridae (**Figure 1**). Four of the equidae species, the African ass, onager, mountain zebra, and Grévy's zebra (**Figure 2**), are considered endangered, while the kiang and plains zebra are threatened in the wild. *Equus przewalskii* is often listed as a subspecies of the domestic horse or as the last surviving wild horse *Equus ferus przewalskii*. The domestic donkey (*Equus asinus*) is often classified as a subspecies of its presumed wild ancestor, the African wild ass (*Equus africanus*). The fact that the horse is spread throughout the world, has been domesticated, is relatively easily handled, and produces large amounts of milk, which can be obtained relatively easily, makes equine milk a relatively easy subject for research. Although the donkey is now less widely distributed than the horse, its milk, also, can be obtained readily. However, the zebra has not been domesticated and although it is widespread in the wild in Africa and in captivity elsewhere, apparently it is very difficult to obtain milk from zebras, even from captive animals. As far as is known, the zebra has never been used for milk production, nor have the onager and kiang.

The horse is a nonruminant herbivore and initially digests food enzymatically in the foregut and then ferments it in the very large sacculated hindgut. The equine digestive system is designed to process small amounts of food consumed frequently. Equids rarely fast for more than 2–4 h and naturally forage for 16–18 h per day. Donkeys, like horses, generally survive on a diet high in fiber and low in soluble carbohydrates and proteins. While donkeys are not as efficient as ruminants at digesting cell wall components, they are far more efficient than horses and can increase forage intake to compensate for a low-quality diet. Donkeys have a much lower requirement for water per unit weight than any other mammal, except the camel, and can rehydrate quickly by consuming a large volume of water, without complications. The zebra, on the other hand, needs a constant supply of water for survival.

Composition of Equid Milks

Young mammals are born at very different stages of maturity and their mothers' milk differs greatly in composition, although milk from species in the same taxonomic order tends to be reasonably similar. Horses produce milk that is low in protein and fat but high in lactose and has a low energy value (**Table 1**). Among species studied, only the rhinoceros produces milk with a lower level of total solids, protein, and gross energy than equid species. All equid species studied to date produce milk containing 10–11% total solids, 1–2% fat, 1.6–1.8% true protein, and 6–7% lactose, with little difference between the species throughout lactation (**Table 1**). The high metabolic needs of the foal are met through frequent feeding. The average weight gain for a foal weighing 40–50 kg at birth is about 1 kg per day and its birth weight doubles in 40–60 days, depending on the breed. Equine colostrum contains >15 g protein (primarily immunoglobulin (Ig)) per 100 g immediately postpartum, but the concentration decreases to <4 g per 100 g after 24 h and to <2 g per 100 g after 4 weeks. The casein to whey protein ratio in equine colostrum is 0.2:1 immediately postpartum and this changes to ~1.1:1 within 1 week. Equid milks are relatively rich in lactose and the concentration more than doubles during the first 24 h postpartum and subsequently increases steadily throughout lactation, a trend that is different from that observed for bovine milk, in which the lactose content decreases with advancing lactation. The lipid content of equine milk decreases with advancing lactation, whereas that of bovine milk shows a distinct minimum after ~3 months of lactation and increases thereafter.

Lactose

Although the lactose content of equid milks is high, the physicochemical properties of lactose that cause problems in the processing of bovine milk are of no consequence for equid milks, which are consumed either fresh or in fermented form. Lactose intolerance is less of a problem with fermented equine milk, koumiss, as some lactose is converted into lactic acid, ethanol, and carbon dioxide during microbial fermentation.

Oligosaccharides

The oligosaccharides identified in equine colostrum are summarized in **Table 2**. The oligosaccharides in mature equine milk have not been reported but it can be assumed that levels are considerably lower than in colostrum. The neutral oligosaccharides lacto-*N*-neotetraose and lacto-*N*-neohexaose identified in equine colostrum are also abundant in human milk, while iso-lacto-*N*-neotetraose and lacto-*N*-novopentanose 1 are not, but have been identified in bovine colostrum; lacto-*N*-novopentanose 1 has been identified also in the milk of the Tammar wallaby and brown capuchin monkey.

Proteins of Equid Milk

Like the milk of all species that have been studied, equine milk contains two principal classes of proteins: caseins and whey proteins. While caseins are the predominant group of proteins in bovine milk (~80% of total milk protein), equine milk contains much less casein and more whey proteins. The casein to whey protein ratio in equine milk is ~0.2:1 immediately postpartum but changes to ~1.1:1 during the first week of lactation. The concentrations of caseins and whey proteins in equine and asinine milk are shown in **Table 3**, with comparative data for human and bovine milk.

Whey Proteins

The principal whey proteins in equine milk are β-lactoglobulin (β-Lg), α-lactalbumin (α-La), Igs, serum albumin, lactoferrin (LF), and lysozyme, all of which are also present in bovine milk and all, except β-Lg, in human milk; the relative amounts differ considerably between equine, bovine, and human milk. Equine and asinine milk have a high content of lysozyme compared to bovine milk (**Table 3**).

β-Lactoglobulin

β-Lg is the major whey protein in the milk of most mammals but is absent from the milk of humans, lagomorphs, rodents, and camels. Two distinct forms of equine β-Lg have been isolated, designated β-Lg I and II, which contain 162 and 163 amino acids, respectively. Asinine milk also has two forms of β-Lg, β-Lg I and II, although a recent study on Sicilian donkey milk found that >23% of the animals lacked β-Lg II. Two genetic variants of asinine β-Lg I, A and B, and three genetic variants of asinine β-Lg II, A, B, and C, have been identified. Equine β-Lg I has a molecular mass of 18 500 Da and an isoelectric pH of 4.85, whereas equine β-Lg II has a molecular mass of 18 262 Da, despite having an extra amino acid, and an isoelectric pH of 4.7. Unlike bovine β-Lg, equine β-Lg contains no free sulfhydryl group. In ruminant milk, β-Lg exists as a dimer at natural pH, whereas in equine milk, β-Lg occurs in the monomeric form.

α-Lactalbumin

α-La occurs in the milk of most mammals and is homologous with type C lysozymes. It is a calcium metalloprotein, in which the Ca^{2+} plays a crucial role in

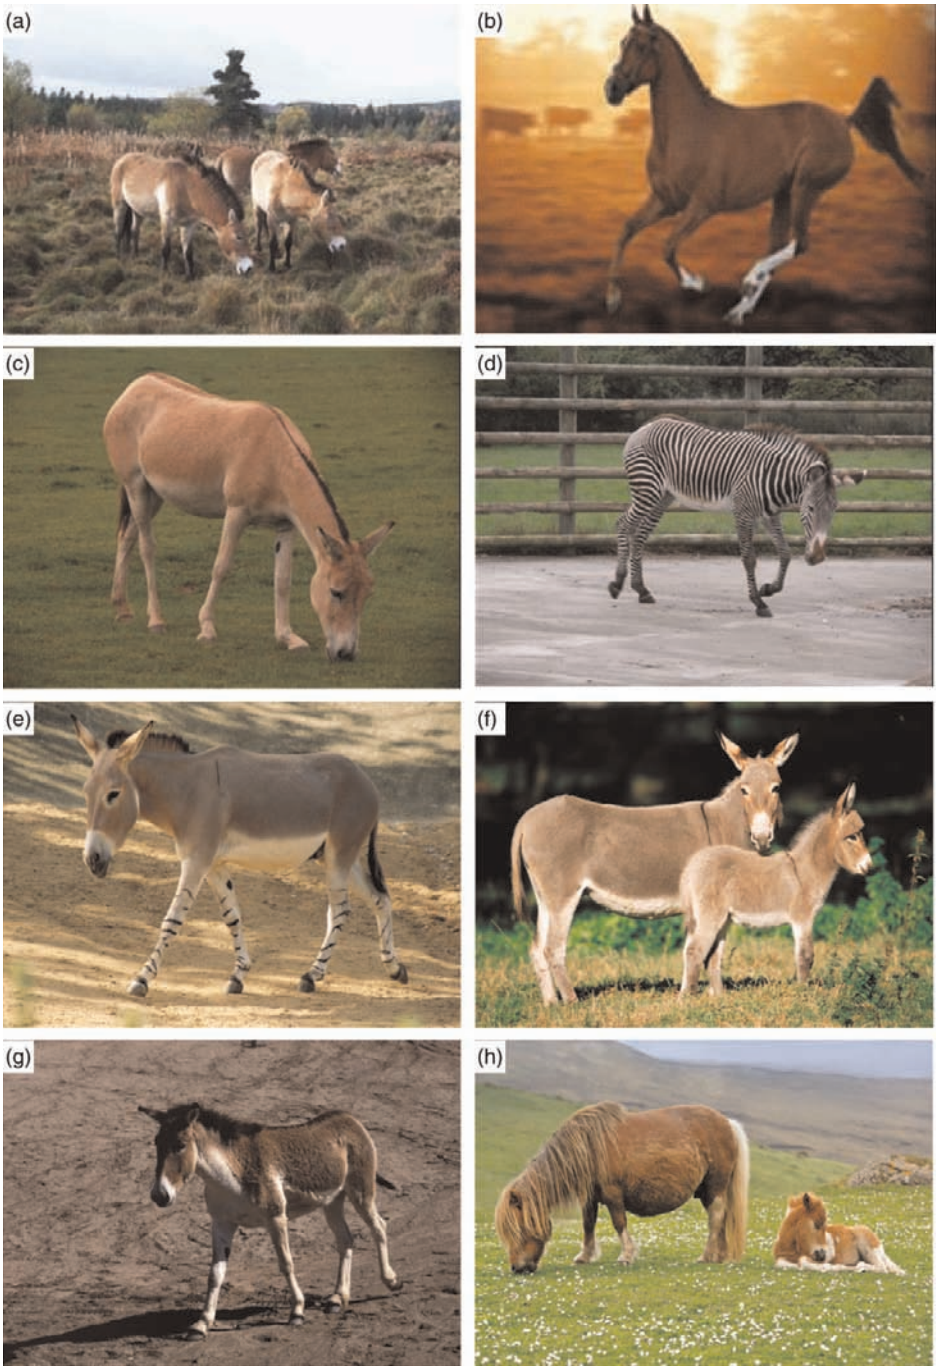

Figure 2 Equid species: (a)Przewalski's horse (*Equus przewalskii*); (b) horse (*Equus caballus*); (c) onager (*Equus hemionus*); (d) Grévsy's zebra (*Equus grevyi*); (e) Kiang or Tibetan wild ass (*Equus kiang*); (f) donkey (*Equus asinus*); (g) African wild ass (*Equus africanus*); (h) Shetland pony (*Equus caballus*). folding and structure. α-La regulates the synthesis of lactose in the lactating mammary gland. α-La of the cow, buffalo, sheep, goat, horse, donkey, camel, and human contains 123 amino acids. The primary structures of equine, bovine, and human α-La differ by only a small number of single amino acid replacements, as a result of which the proteins have similar properties. Equine α-La occurs as three genetic variants, A, B, and C. The A variant differs from the B variant at positions 7, 33, 54, 78, and 95, at which equine α-La A contains Glu, Ser,

Table 1 Gross composition (g per 100 g) of the milks of some equid species (bovine and human milk are included for comparison)

	Total solids	*Fat*	*Protein*	*Casein/whey ratio*	*Lactose*	*Ash*

Casein micelle diameter (nm)	255		64	182

The data are compiled from 14 references from 1984 to 2008.

Gln, Asp, and Ile residues, respectively, and equine α-La B contains Gln, Asp, Glu, Asn, and Asp residues, respectively. The B and C variants of equine α-La differ only at position 95, where the C variant contains Ile. Equine α-La A, B, and C have an isoelectric point at pH 4.95, 4.95, and 5.11, respectively. Two forms of asinine α-La have been identified with isoelectric points differing by 0.23 pH units. Bovine, equine, asinine, and human α-La contain four intramolecular disulfide bonds and lack a sulfhydryl group.

Lactoferrin

The level of LF in equine milk is similar to that in human milk and considerably higher than that in asinine and bovine milk (**Table 3**). Equine LF contains 689 amino acid residues, similar to bovine LF, whereas human LF contains 692 residues. Equine and human LF contain 17 and 16 intramolecular disulfide bonds, respectively. Compared to most other milk proteins, LF has a high isoelectric point, that is, at pH 8.32, 8.67, and 8.47 for equine, bovine, and human LF, respectively. Consequently, LF is positively charged at the natural pH of milk and may associate with negatively charged proteins via electrostatic interactions. The iron-binding capacity of equine, bovine, and human LF is equivalent, although the pH dependence of the iron-binding capacity of bovine LF differs from that of the equine and human proteins.

Immunoglobulins

Igs form part of the humoral-mediated aspect of the immune system. In some species, for example, man, maternal IgG is responsible for neonatal passive systemic immunity and is transferred to the fetus from maternal circulation *in utero*; the intestines of a full-term baby are relatively impermeable to maternal proteins. In ruminants, pig, and the horse, IgGs are not transferred *in utero* but are contained in colostrum and transferred through the intestine, which remains permeable to proteins for 2–3 days after birth; the intestine then ‘closes’ and further significant passage of proteins is prevented. Three classes of Igs are commonly found in milk, IgG, IgA, and IgM, the relative proportions of which differ between species (**Table 3**).

Denaturation of Whey Proteins

Whey proteins are thermolabile. Equine LF and serum albumin are the most heat sensitive of the equine whey proteins that have been studied (no reports are available on the thermal sensitivity of equine Igs) and have similar thermal sensitivities to their bovine counterparts; in both species, a temperature of up to 130 °C for 1 min is required for complete denaturation of the whey proteins. Equine β-Lg and α-La are much more thermostable than their bovine counterparts and do not undergo significant denaturation at temperatures <100 °C. The high thermal stability of equine β-Lg may be related to its lack of a sulfhydryl group. Equine lysozyme is very heat stable and retains 68% of its antimicrobial activity after 15 min at 82 °C and undergoes significant denaturation only at >90 °C.

Caseins

The caseins are the principal protein class in the milk of ruminants and that of most other mammals. The caseins of most species are four gene products: α_{s1}-, α_{s2}-, β-, and κ-caseins. Of these, α_{s1}-, α_{s2}-, and β-caseins are calcium-sensitive proteins. All the caseins exhibit microheterogeneity caused by genetic polymorphism and posttranslational modifications, for example, phosphorylation, glycosylation, and proteolytic cleavage. Equine β-casein and α-La undergo spontaneous deamidation, which has been reported also for canine milk lysozyme and human LF. Caseins represent ~55% of the total protein in mature equine milk, the principal proteins being α- and β-caseins (~50:50), both of which are very heterogeneous due to variations in the degree of phosphorylation; however, equine milk contains little or no κ-casein. As in the milk of other species, the caseins in equine milk occur as large colloidal aggregates, called micelles, the properties of which have been studied only superficially.

α_{s1}-Casein

Equine α_{s1}-casein contains 205 amino acids and has a molecular mass of 24 614.4 Da prior to posttranslational modification: that is, it is slightly larger than its bovine counterpart. Equine α_{s1}-casein contains six potential phosphorylation sites, five of which are in very close proximity and can form a phosphorylation center, which is important in the structure of casein micelles. Bovine α_{s1}-casein contains eight or nine phosphorylation sites in two groups. Like bovine α_{s1}-casein, equine α_{s1}-casein has three hydrophobic regions, including the N-terminal region, and therefore, it has properties similar to those of bovine α_{s1}-casein.

α_{s2}-Casein

Only the 12–15 amino acids of the N-terminal region of equine α_{s2}-casein have been identified and the sequences reported thus far differ between different studies. Isoelectric focusing of equine α_{s2}-casein shows two major bands, with isoelectric points in the pH range 4.3–5.1.

β-Casein

The amino acid sequence of equine β-casein, deduced from its cDNA, comprises 226 amino acids with a molecular mass of 25 496.3 Da. Bovine and human β-casein contain 209 and 211 amino acid residues, respectively. Two smaller genetic variants of equine β-casein, which probably result from exon skipping during transcription, have been reported. In equine β-casein, the first 28 C-terminal amino acids contain 7 potential phosphorylation sites (Ser$_9$, Ser$_{15}$, Ser$_{18}$, Ser$_{23}$, Ser$_{24}$, Ser$_{25}$, Ser$_{28}$), 3–7 of which are phosphorylated, giving a family of proteins with pI values varying from 4.74 to 5.30. Extensive deamidation of equine β-casein occurs at Asn$_{135}$; deamidation of bovine or human β-casein has not been observed. γ-Casein and proteose peptone 5 have been identified in equine milk. Bovine plasmin readily hydrolyzes the Lys$_{55}$-Ile$_{56}$ bond of equine β-casein, but the corresponding Lys$_{48}$-Ile$_{49}$ bond in bovine β-casein has not been reported to be hydrolyzed by plasmin. Equine β-casein is readily hydrolyzed by chymosin at Leu$_{198}$-Tyr$_{199}$.

κ-Casein

The presence of κ-casein in equine milk has been an issue of debate for several years; several authors have reported its absence but recent studies indicate its presence, albeit at a very low level. The primary structure of equine κ-casein, deduced from its cDNA sequence, contains 165 amino acid residues, that is, 4 less than bovine κ-casein but 3 more than human κ-casein. The molecular mass of equine κ-casein prior to posttranslational modification is 18 844.7 Da. Equine and human κ-casein have a considerably higher pI, 8.03 and 8.68, respectively, than bovine κ-casein at 5.93, indicating that the former have a net positive charge at physiological pH, whereas bovine κ-casein has a net negative charge. Equine κ-casein appears to be less hydrophilic than its bovine counterpart, which has a hydrophilic C-terminus, which is important for the stability of bovine casein micelles. No direct information is available on the glycosylation of equine κ-casein, but lectin-binding studies suggest that equine κ-casein is glycosylated at Thr$_{123}$, Thr$_{127}$, Thr$_{131}$, Thr$_{149}$, and Thr$_{153}$.

Casein Micelles

Like the milk of (probably) all species, the caseins in equine milk occur as large aggregates, called micelles. Equine casein micelles are larger than bovine or human casein micelles (**Table 3**). Electron microscopic studies have shown that bovine and equine micelles have a similar 'spongy' appearance, while human micelles seem to have a much 'looser', more open structure. There are no specific reports on the substructure of the equine casein micelle although equine milk does contain ~10.1 mmol l^{-1} micellar calcium and ~2.6 mmol l^{-1} micellar inorganic phosphorus, suggesting a micellar calcium:casein ratio of >20:1, which, on a molar basis, far exceeds the calcium-binding capacity of equine casein molecules. Hence, it may be assumed that equine micelles, like bovine casein micelles, contain nanoclusters of calcium phosphate. Since equine milk contains little or no κ-casein, dephosphorylated β-casein may play a role in micellar stability.

Casein Micelle Stability

Equine casein micelles at natural pH are not susceptible to rennet-induced gelation although it has been reported that isolated equine κ-casein is hydrolyzed slowly by calf chymosin at the Phe$_{97}$-Ile$_{98}$ bond. On renneting, equine milk forms fine flocs after several hours, but it does not form a gel. Preliminary research suggests that asinine milk is coagulable by chymosin, forming a very weak gel (G' of 10–15 Pa, after 60 min at 30 °C, compared to 180–200 Pa for bovine milk coagulum under similar conditions). No cheese is produced from equine or asinine milk. Acidifying equine milk to pH 4.2 (the point of minimum solubility of equine caseins) causes very limited flocculation and no gelation and as a consequence, no yogurt-type products are produced from equine milk.

At 140 °C, the heat coagulation time (HCT) of equine milk increases with pH, giving a sigmoidal pH–HCT profile with a midpoint around pH 6.7; the HCT is <2 min at pH 6.3–6.9, but is >60 min at pH 7–7.3. The low heat stability of equine milk at pH <6.8 is probably related to its very high level of ionic calcium, ~2.6–3.0 mmol l^{-1}, compared to bovine milk, ~1.8 mmol l^{-1}, and its very low level of κ-casein.

The ethanol stability of bovine milk, defined as the minimum concentration of added aqueous ethanol that causes it to coagulate, at its natural pH (~6.7), is 70–75% (added 1:1 to milk), whereas the ethanol stability of equine milk (pH ~7.2) is 40–45%. The high concentration of ionic calcium and low level of κ-casein in equine milk probably contribute to its low ethanol stability.

Nonprotein Nitrogen

Nonprotein nitrogen (NPN) constitutes 10–15% of the total nitrogen in mature equine milk, which is intermediate between values for human (~25%) and ruminant (~3–5%) milk (**Table 3**). The NPN is composed primarily of urea, creatine, creatinine, small peptides, amino acids, and ammonia.

Indigenous Enzymes

Milk contains many indigenous enzymes, which originate from the milk fat globule membrane (MFGM), mammary cell cytoplasm, or blood. The indigenous enzymes in bovine and human milk have been studied extensively, but the enzymes in the milk of other species have been studied only sporadically. Equine milk probably contains all the enzymes that have been identified in bovine milk, but relatively few studies have been reported. Lactoperoxidase (LPO), catalase, amylase, proteinase (plasmin), lipase, lactate dehydrogenase (LDH), and malate dehydrogenase (MDH) have been reported in equine milk. Bovine milk is a rich source of xanthine oxidoreductase (XOR), but the milks of other species for which data are available have much lower XOR activity, because in nonbovine species, most (up to 98%) of the enzyme molecules lack Mo and are inactive. XOR activity has not been reported in equine milk, but considering the role of XOR in the excretion of fat globules from the secretory cells, it is highly likely that the MFGM in equine milk contains XOR. Equine milk contains quite a high level of Mo, which presumably is present exclusively in XOR.

Lysozyme (EC 3.1.2.17) occurs at high levels in equine, asinine, and human milk (**Table 3**). Human and equine milk contain 3000 and 6000 times more lysozyme, respectively, than bovine milk; lysozyme represents 4 and 3%, respectively, of the total protein in human and equine milk. Equine milk lysozyme contains 129 amino acid residues and, like the lysozyme of other species, is highly homologous with α-La. Unlike α-La, most lysozymes cannot bind Ca^{2+}, but equine lysozyme is an exception in this regard and binds Ca^{2+} tightly, making it particularly stable. Equine milk has very good antibacterial activity, presumably due to its high level of lysozyme.

Lipids

The milk of all equidae contains a low level of lipids, and lactose, rather than lipids, is the principal source of energy. Human and bovine milk, which are relatively rich in fat, provide about 53 and 51%, respectively, of energy as fat, compared to ~25% for equine milk. The fat content of equine milk decreases during lactation to about 50% of its initial value. Triglycerides (TGs) represent only 80–85% of the lipids in equine milk compared with ~98% in most other milks; ~9.4% are free fatty acids (FFAs) and phospholipids account for ~5% (**Table 4**).

The levels of monounsaturated (MUFAs) and polyunsaturated (PUFAs) fatty acids in the milk fat of some species are shown in **Table 5**. The milk fat of nonruminants contains substantially higher levels of PUFAs than ruminant milk, and equine milk has a considerably higher level of PUFAs than asinine milk. The higher content of conjugated linoleic acid (CLA) in ruminant milk fat compared to that of nonruminants is inversely correlated with the level of PUFAs and weakly correlated with the content of MUFAs.

Table 4 Lipid classes in human, bovine, and equine milk

	Equine	*Bovine*	*Human*
Total lipids (g per 100 g)	1.21	3.61	3.64
Constituents (percentage of total lipids)			
Triglycerides	81.1	97	98
Phospholipids	5.0	1.5	1.3
Unsaponifiable matter (sterols)	4.5	1.5	0.7
Free fatty acids	9.4	Trace	Trace

Table 5 Monounsaturated and polyunsaturated fatty acids (percentage of total fatty acids) in the milk fat of some ruminants and nonruminants

	MUFAs	*PUFAs*	*CLA*
Nonruminants			
Equine	31.20	22.70	0.09
Asinine	15.30	16.00	
Porcine	51.80	12.40	0.23
Human	39.40	15.27	0.39
Ruminants			
Caprine	26.90	2.58	0.65
Bovine	24.65	5.82	1.01
Ovine	23.00	3.85	1.08

CLA, conjugated linoleic acid; MUFA, monounsaturated fatty acid; PUFA, polyunsaturated fatty acid.

The fatty acid profile of equid milk differs from that of bovine and human milk fat in a number of respects (**Table 6**). It contains virtually no butyric acid (C_4), which is present at high levels in bovine and other ruminant milk fats. All equid milks contain high proportions of middle-chain fatty acids (20–35% of all fatty acids contain <16C) but are poor in both short- and long-chain saturated fatty acids. Equid milk fats contain a very high level of α-linolenic acid (ALA), which reflects the high level of PUFAs in the diet and the lack of biohydrogenation, as occurs with ruminants.

Equine and asinine milk have similar fatty acid profiles, although equine milk has a significantly higher content of MUFAs (**Tables 5** and **6**). The ratio of $n-6{:}n-3$ (1.16:1) in asinine milk compared to 3.14:1 in equine milk makes it an interesting product for human nutrition. Small amounts of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) occur in asinine milk, whereas equine milk has only trace amounts. EPA and DHA are important in infant nutrition but their absence from equine milk is not considered to be a problem as an infant's liver can desaturate linoleic acid (LA) and ALA to form EPA and DHA. Furthermore, the ratio of LA to ALA in equine milk is regarded as optimal for absorption by the human neonate, who can quickly convert them into EPA and DHA.

Table 6 Average fatty acid composition in the milks of some species (percentage of total fatty acids)

Structure of Triglycerides

The distribution of fatty acids in animal TGs is nonrandom, apparently so that the TGs will be liquid at body temperature. Interspecies comparison of the positional distribution of fatty acids has been made, using fatty acid and stereospecific analysis, for 11 species, the echidna, koala, Tammar wallaby, guinea pig, dog, cat, Weddell seal, horse, pig, cow, and human. Generally, the positional distribution of fatty acids is similar, except for the echidna, with short-chain fatty acids preferentially esterified at *sn*-3, saturated fatty acids at *sn*-1, and unsaturated fatty acids generally found at *sn*-2. In equine milk fat, $C_{10:0}$ occurs at the *sn*-3 position, whereas in bovine milk fat, more $C_{10:0}$ is found at the *sn*-2 than at the *sn*-3 position. In human and equine milk, $C_{16:0}$ is located preferentially at the *sn*-2 position, which is regarded as favorable for assimilation by infants and children, whereas in bovine milk, $C_{16:0}$ is equally distributed between the *sn*-1 and *sn*-2 positions. In the milk fat of the Weddell seal and horse, $C_{18:1}$ is esterified preferentially at *sn*-1, but for all other species studied it occurs mainly at *sn*-3.

Fat Globules

The fat in milk is emulsified as globules, 2–3, 3–5, and 4 μm in diameter, in equine, bovine, and human milk, respectively. The fat globules are surrounded and stabilized by a very complex emulsifying layer, consisting of phospholipids and proteins, called the MFGM. Many of the indigenous enzymes in milk are concentrated in the MFGM. The glycoproteins in the MFGM of human, rhesus monkey, chimpanzee, dog, sheep, goat, cow, gray seal, camel, horse, and alpaca have been studied; large intra- and interspecies differences have been found. Very highly glycosylated proteins occur in the MFGM of primates, horse, donkey, camel, and dog. Long (0.5–1 mm) filamentous structures, comprised of mucins (highly glycosylated proteins), extend from the surface of the fat globules in equine and human milk. These filaments dissociate from the surface into the milk serum on cooling and are lost on heating. For unknown reasons, the filaments on bovine milk fat globules are lost much more easily than those in equine and human milk. The filaments facilitate the adherence of fat globules to the intestinal epithelium and probably improve the digestion of fat. The mucins prevent bacterial adhesion and may protect mammary tissue against tumors (mammary tumors are very rare in the cow).

The temperature-dependent melting characteristics of bovine milk fat have been studied thoroughly, but since equid milk is not used for the production of butter, the spreadability, rheology, and melting characteristics of these fats have not been studied in detail. Considering the rather unusual fatty acid profile of equid milk fat, it should have interesting melting and rheological properties. One study has shown that equine milk fat has a lower melting point than bovine milk fat (20–22 vs. 26–34 °C), a higher iodine number (92–101 vs. 25–40), and a lower saponification value (209 vs. 232).

No studies on the chemical spoilage of equid milk fat have been reported. Considering the high content of PUFAs in these fats, they are probably quite susceptible to oxidation. Since equine milk contains lipase, hydrolytic rancidity would be expected under certain conditions.

Vitamins

Vitamin levels in the milks of some species are shown in **Table 7**. Equine milk contains a significantly higher level of vitamin C than other milks shown, except for ovine milk. The levels of vitamins A, D_3, K, and C are affected by stage of lactation and are significantly higher in equine colostrum compared to equine milk, whereas vitamin E concentration remains unchanged throughout lactation. Fat-soluble vitamin concentrations are generally similar in equine and bovine milk (**Table 7**).

Minerals

The ash content of equine milk is higher than that of human milk but only about half that of bovine milk (**Table 1**). As in the milk of other species studied to

The data are compiled from various sources.

date, the principal salts in equine milk are phosphates, chlorides, carbonates, and citrates of potassium, sodium, calcium, and magnesium. However, there are considerable quantitative interspecies differences (**Table 8**). Compared to human milk, calcium and phosphorus levels in equine and especially asinine milk are high. For human infant nutrition, a Ca:P ratio of ~2:1 is considered optimal; in bovine milk, the ratio is ~1:1, but in equine milk it is about 2:1, and very close to that of human milk. The concentrations of all macroelements, except potassium, are higher in equine milk than in human milk, but all are considerably lower than the concentrations in bovine, caprine, ovine, or porcine milk.

The concentration of macroelements in equid milks is strongly influenced by the stage of lactation; the concentrations of calcium, magnesium, phosphorus, sodium, and potassium decrease progressively as lactation advances. A comparison of the concentrations of trace elements in equine, bovine, and human milk is shown in **Table 9**. Compared to bovine milk, equine milk contains noticeably higher levels of aluminum, copper, iron, and titanium but lower levels of boron, barium, lithium, molybdenum, manganese, silicon, and zinc.

Table 9 Concentrations (mg l^{-1}) of trace elements in equine, bovine, and human milk

Physical Properties of Equid Milk

The physical properties of the milk of some species are compared in **Table 10**. The lower freezing point of equine milk compared to bovine milk is related to its

Table 10 Physical properties of the milk of some species

Property	*Equine milk*	*Equine colostrum*	*Bovine milk*	*Human milk*	*Asinine milk*
Freezing point (°C)	−0.554 to −0.548		−0.512 to −0.550		
pH (25 °C)	7.1–7.3		6.5–6.7	6.8	7.0–7.2
Density (kg m^{-3}) (20 °C)	1032	1080	1027–1033	1031	1029
Refractive index, $n_D{}^{20}$	1.3394	1.340–1.354	1.344–1.349		
Viscosity (mPa s)	1.5031		1.6314		
Zeta potential (mV)	−10.3		−20.0		
Color, L^*, a^*, b^*	86.52,−2.34, −0.15		79.12,−7.46, 2.31		80.88,−2.27, −3.53

higher lactose content. The density of equine colostrum shows a significant linear correlation with its IgG content, and is higher than that of equine milk. The higher refractive index of equine colostrum compared to that of equine milk is probably related to the higher total solids content of colostrum, since refractive index increases with the increasing mass fraction of each solute. Differences in the pH of equid and bovine milk are presumably related to differences in protein and salt composition. Equid milks are less viscous than bovine milk due to a lower total solids content. Bovine casein micelles have a net negative charge of approximately −20 mV, which contributes to their stability and is dependent on pH and temperature. Equine casein micelles have a lower average zeta potential, approximately −10.3 mV, probably due to their larger micellar size, compared to bovine micelles, and a very low, if any, surface coverage of κ-casein.

Equid milk should be less white than bovine milk due to its low protein content and large casein micelles but this is not the case and equid milk appears considerably whiter; this is due to the presence of β-carotene in bovine milk fat, which confers a yellow color to the milk.

Equid Milks in Human Nutrition

Currently, 84% of recorded milk production is bovine, 12.3% is buffalo, 2% is caprine, 1.3% is ovine, and ~0.2% is from other species, that is, horses, donkeys, camels, yaks, and reindeer. Equine milk for human consumption is an ancient practice and can be traced back to ~2000 BC in early Chinese records, which describe the preparation of koumiss, fermented equine milk. Equine milk is regarded as having nutritional and therapeutic properties that are beneficial to the elderly, convalescents, and infants. Similar to human milk, it is low in protein, has a low casein to whey protein ratio, high concentrations of lactose and PUFAs, and low levels of cholesterol. In patients with compromised digestive systems, equine milk is often recommended due to its ease of digestion; in the stomach, high-casein milks, such as bovine milk, form firm clots that are digested relatively slowly (3–5 h), whereas the coagulum formed from human or equine casein is soft and flocculant, with an evacuation time of ~2 h. Equine milk and products therefrom (e.g., koumiss) have, traditionally, been used widely in Russia (for the treatment of tuberculosis) and eastern and central Asia. In Mongolia, koumiss (Airag) is the national drink and distilled or double-distilled versions are also produced. Per caput consumption of koumiss in Mongolia is about 50 l per annum.

Koumiss belongs to the yeast–lactic fermentation group of beverages, where alcoholic fermentation using yeasts is used in combination with lactic acid fermentation and is the principal product from equine milk. Koumiss is thought to be more effective than raw equine milk in disease treatment due to the additional peptides and bactericidal substances produced by microbial metabolism.

A decade ago, equine milk was produced only in isolated small holdings in parts of eastern Europe and Mongolia, but now there are large-scale operations in France, Belgium, Germany, Austria, and the Netherlands. Estimates suggest that more than 30 million people worldwide drink equine milk regularly, with that figure increasing significantly in recent years. Currently, there is considerable interest in the use of equine milk in human nutrition in western Europe where supply now falls short of demand.

Asinine milk is consumed mainly in countries where donkeys are bred traditionally (Asia, Africa, and eastern Europe), but consumption in western European countries is increasing due, like equine milk, to the similarity of its composition to human milk. Both milks are considered good substitutes for bovine milk for children with severe IgE-mediated cows' milk allergy (CMA). The high lactose content of these equid milks improves palatability and the absorption of calcium, which is essential for bone mineralization in children.

In health food shops and some pharmacies in western Europe, equine milk is sold frozen or in the form of capsules of lyophilized milk. Powdered equine milk, which may be fortified with vitamins, is also widely available in pharmacies in Germany, France, and Italy, where it is consumed directly or after rehydration. Producers of equine milk in Belgium and the Netherlands sell equine milk fresh or as a koumiss-type product. Supporting literature for many of the products claim relief from metabolic and intestinal problems, help in gut cleansing and 'repair' of the intestinal flora, prevent stomach ulcers, high blood pressure, high cholesterol, and liver problems, and serve as a complementary aid in the treatment of cancer patients. For healthy individuals, the products are recommended as a preventative for the ailments listed. The recommended dose is ∼250 ml day^{-1}. No cheese products are produced from equine milk because, as discussed earlier, it is not coagulable by the methods traditionally used for bovine milk. The production of cosmetics incorporating equine milk is a recent innovation, and soaps, creams, shampoos, and moisturizers are now available commercially.

Milks of Other Domesticated Mammals (Pigs, Yaks, Reindeer, etc.)

Y W Park, Fort Valley State University, Fort Valley, GA, USA

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Information on the milk of domesticated species is not readily available, since the milk of some of these mammals is produced for human consumption only in certain regions of the world and only limited studies have been conducted. However, their milk is important for human consumption, or nutritional and health research.

Reports on the composition of milk of wild and domesticated minor species vary in accuracy due to the lack of sample numbers, difficulties in defining stage of lactation, bias introduced during sampling, and different analytical procedures. The objective of this article is to discuss the milk of sow, yak, reindeer, musk ox, llama, alpaca, and other minor dairy species.

General Composition of Milk of Minor Domesticated or Wild Mammals

The chemical composition of the milk of different species is designed by natural selection to provide the nutritional needs of the neonate of the specific species. There are considerable differences in the basic composition of milk among different domesticated and wild mammals (**Table 1**). Frequently, little is known about the stage of lactation and milk sampling time from the gland, which can result in misleading interspecies differences. Even under standard conditions of milk sampling, there are substantial short-term (diurnal and day-to-day) variations in composition, which are due to environmental conditions, feeding, management, season, locality, disease, and yield per day, as is also the case for the major domestic milk producers – the cow, buffalo, camel, goat, and sheep.

Colostrum contains much higher levels of total solids, protein, and ash than mature milk obtained 2 or 3 weeks after parturition in all species. The high protein level in colostrum is due to the globulins, which contain the antibodies. Since the antibody titer of blood of the newborn is low, mammals such as cows, sheep, goats, horses, and pigs acquire passive immunity from colostrum and its immunoglobulins.

The amount of dietary intake of roughage is important for the level of milk fat in ruminants. A decrease in roughage intake depresses the milk fat content and causes changes in rumen fermentation and parakeratosis. The daily ruminant diet should contain at least 17% crude fiber in order to prevent the decrease in the molar percentage of acetic acid and the increase in propionic acid in the rumen, which results in a low fat content in the milk.

Production and Composition of Milk from Minor Species

Sow Milk

Little has been documented on the production and utilization of sow milk, while a large amount of data have been reported on the composition of sow milk. Since humans and pigs have similar digestive and physiological systems, research data on the production and composition of sow milk are useful and applicable for the nutritional and medical well-being of humans.

The yield of sow milk is affected by the stage of lactation, suckling frequency, sow body weight, metabolic state, litter size, ambient temperature, and amount of mammary tissue. The daily yield of sow milk may range from 400 to 2000 ml. Peak milk yield is at about 3 weeks post-partum and then declines. Increased suckling frequency plays a role in increased mammary gland mass and milk production.

The composition and quantity of sow milk depend on the body condition of the sow at farrowing and early lactation. The efficiency of utilizing dietary nutrients depends on litter size, suggesting that sows nursing large litters utilize dietary nutrients more efficiently than sows nursing small litters. Since ambient temperature influences the proportion of blood flow into skin capillaries for dissipation of body heat, it also affects the composition and yield of milk during nursing.

The fat and protein levels of sow milk vary in a curvilinear manner during lactation. Sow milk fat is highest at the onset of lactation and lowest at around day 20 (**Figure 1**). The level of proteins in sow milk follows a similar pattern, but does not vary as much as fat content. The fat and protein levels in the milk of ruminants, such as cows, sheep, and goats, follow a somewhat different trend, usually increasing with advancing lactation (**Figure 2**).

The essential and semi-essential amino acids of sow milk constitute 45.5% of the total amino acid content, and the ratio of Lys to Met plus Cys is 1:0.5. The amino acid composition of sow and bovine caseins (CNs) is shown in **Table 2**. Bovine CN contains lower levels of Glu, Pro, Val, Ala, Phe, Lys, Tyr, and His than sow CN, while human milk proteins are reported to have less Glu, Met,

Table 1 Average composition (g per 100 ml) of milk of minor mammalian species

Mammals	*Days of lactation*	*No. of samples*	*Total solids*	*Protein*	*Lactose*	*Fat*	*Ash*

Met, Tyr, Lys, and His and more Cys and Trp than sow milk proteins.

In light of fatty acid composition, the differences between sow and bovine milks are primarily in short-chain fatty acid levels and the degree of saturation. Sow milk fat contains C4–C12 fatty acids at barely detectable levels and these fatty acids represent only 0.2% of the total, whereas in bovine milk these fatty acids represent 8% of the total. Bovine milk fat contains more myristic, palmitic, and stearic acids, and far less palmitoleic, oleic, linoleic, and linolenic acids than sow milk.

There is little information available on the effect of genetics on mineral concentrations in sow milk. The level of cholesterol is less than 0.5% of total lipids in cow and sow milk. Somatic cell counts in sow milk are affected by litter replacement and oxytocin administration and may increase from about 8×10^6 cells ml^{-1} milk on day 2 to more than 12×10^6 cells ml^{-1} on day 51 post-partum.

Yak Milk

Origin and distribution of yak

Yak is called 'the ship of cold regions' and serves many needs related to food, fiber, and transportation of the people in the cold mountainous regions of northern China, Mongolia, Tajikistan, Uzbekistan, Russia, Nepal, and Bhutan. Yaks are members of the subfamily of Bovinae and are classified as *Bos grunniens* or *Poephagus grunniens*. They originated in the Qinghai-Tibetan Plateau and were first domesticated about 4500 years ago. Yak have a unique ability to live under extreme environmental conditions and are able to survive unsheltered through the winter months, exposed to harsh snowstorms and temperatures below −40 °C at high altitudes, 3000–5000 m above sea level. China has an estimated 13 million yaks, with the largest numbers in the Sichuan Province, followed by Qinghai Province, the Tibet Autonomous Region, Gansu, Xinjiang, Inner Mongolia, and Yunnan Province. Outside of China, the largest yak

Table 2 Amino acid composition of sow and bovine casein (g per 100 g protein)

Amino acid	*Sow casein*[a]	*Bovine casein*[b]

population is in Mongolia with approximately 600 000 head. Wild populations of yak are estimated to be about 150 000.

Yak breeds and milk production

On average, yaks produce less milk than dairy cows, approximately 1.5 kg day^{-1} after suckling the calf, or 300 kg per lactation, with a lactation period of 5–6 months. Milk production by the Chauri and Jom yak breeds exceeds the yield of pure-bred yak. Jom can produce 1.5–3 l milk per day. When yaks are artificially inseminated to Brown Swiss (BS) cattle, the female hybrids (BS Joms) produce about 3–4 l day^{-1}. Chauri are considered more versatile than pure-bred yak throughout Nepal and are more manageable draught and pack animals, tolerating lower altitudes. Jhopkyo yak can carry between 60 and 80 kg loads.

Yak milk composition

Yak milk is high in total solids and has a sweet fragrance and golden rich color. Because of its higher fat and protein content than bovine milk, yak milk quality is often referred as ‘thick’ or ‘rich’. Research data on the composition of yak milk produced in China, Mongolia, and Nepal are shown in **Table 3**. The fat content of yak milk is about twice that of average cow milk, ranging from 5.45 to 8.60%, depending on season, time of milking, stage of lactation, and availability of supplementary feeds.

Yak milk contains lower levels of short- and medium-chain fatty acids than caprine or bovine milks. The major fatty acids in yak milk are C16:0, C18:1, C18:0, and C14:0; oleic acid is the most abundant among the unsaturated fatty acids. Semihard cheeses made from yak milk reared in the highlands of the Nepalese Himalayas contain lower myristic and palmitic acids, higher total long-chain

Table 3 Composition (range) of normal milk and colostrum of yak at different regions

	Normal milk		*Colostrum*	
	China	*Mongolia*	*Nepal*	*China*
Total solids (%)	15.70–18.36	16.00	17.40	33.01

Silk TM, Guo MR, Haenlein GFW, and Park YW (2006) Yak milk. In: Park YW and Haenlein GFW (eds.) *Handbook of Milk of Non-Bovine Mammals*. pp. 345–354. Ames, Lowa; Oxford, England: Blackwell Publishers.

saturated fatty acids, and much higher polyunsaturated fatty acids than Cheddar cheese made from cow milk.

The levels of protein and total solids in yak milk from China and Nepal range from 4 to 7% and 16 to 18%, respectively. As in bovine milk, there is an inverse relationship between milk yield and fat and protein levels. Lactose and ash contents of yak milk range from 3 to 6% and 0.4 to 0.9%, respectively (**Table 3**).

Yak milk has six major proteins comparable with bovine: α-lactalbumin (α-La), β-lactoglobulin (β-Lg), β-CN, α_s-CN, bovine serum albumin (BSA), and lactoferrin. The major proteins in yak milk are CNs, which account for over 60% of total proteins. The relative percentage of α-La in yak milk is significantly lower ($P < 0.05$) than that in bovine milk, while differences in other proteins between yak and bovine milk including CNs, immunoglobulins, lactoferrin, BSA, and β-Lg are not significant. Yak milk has a good level of essential amino acids. Mean lysine and methionine contents are 80.0 and 30.6 (mg^{-1} g protein), respectively, and glutamic acid is the most abundant (184 mg^{-1} g protein) amino acid in Mongolian yak milk.

Yak milk products

Yak milk has been a major traditional staple food for yak herders and their families in the highland plains of Tibet. Yak milk is consumed as full-fat milk by children and the elderly, and is used to manufacture butter, ghee, cheese, and yogurt. In some areas, it is processed into powder, which can provide up to 60% of the total income for yak herders. 'Milk tea', a mixture of boiled tea and yak milk, is popular and is consumed throughout the year. It is made by boiling tea leaves (cut from a tea brick) in water and then adding yak milk and boiling for a few more minutes.

A Swiss Gruyere-type cheese has been made from yak milk since 1952, supported by the Food and Agriculture Organization (FAO) of the United Nations, transferring Swiss cheese technology from the Alps to Nepal.

Butter is a major product from yak milk, and it represents one of the staple foods of yak-raising people in China. Milk is first heated to about 35 °C and then filtered to separate cream. The cream is naturally fermented for a 1 or 2 days and then transferred to a wooden churn, where it is stirred/churned by rotating the stick until the fat solidifies. 'Butter tea' is especially popular with yak herders in China and Tibet.

Yak milk cake is made from whole yak milk or sometimes skimmed yak milk. It is hard in texture and looks like a cake. It is usually consumed with butter and sugar, which are used to enhance flavor, by yak herdsmen and their guests. Milk curd is also widely consumed as a dessert by yak herdsmen on the Tibetan Plateau. Yak milk whey is used as pig feed or for traditional leather processing.

Reindeer

Reindeer husbandry and milking evolved at least 2000 years ago on the Taiga region of eastern Siberia around Lake Baikal and spread to nearby ethnic groups. Reindeer milking regimen developed along the borders of Russia, Mongolia, and China. This was probably triggered by cultural exchange and expansion of pastoral nomads living on the northern fringe of the Asian steppe. The Yakuts, famous horse and cattle breeders, adapted reindeer raising as they pushed north and introduced an advanced milking culture into the region.

Reindeer (*Rangifer tarandus tarandus*) and caribou (*Rangifer tarandus granti*) are closely related in species and ancient associations in northern lands. For indigenous Northern Americans, caribou have provided meat, skins for clothing and shelter of exceptional warmth and lightness, and implements made from bones and antlers. The fur trade led to early exploitation of North American caribou.

Reindeer milking also evolved in Scandinavia independently by the Nordic Saami people of Lapland. Saami reindeer herding families in the late 1800s practiced small-scale reindeer pastoralism, and the milk was used to manufacture cheese and butter for their own consumption and for sale. As new technology developed, intensive production in larger herds became possible by using snow mobiles.

Reindeer milking starts usually a month after calving during May, depending on latitude and environmental conditions, and continues up to the rut in late September and early October. Among advanced southeastern Siberian reindeer herders, the calves and females are normally tethered during alternate periods to ensure that both remain close to the campsite, but are kept separated during part of the day. The females are milked up to 3 times daily and the separation time of the calves from their mother varies with the stage of lactation. The most efficient but labor-intensive form of Saami milking regime is called 'kjevle' of the calf, in which small herds are driven into a restricted or fenced compound, where the calves are caught and a small wooden stick is placed in their mouth to prevent them from sucking, but this does not hamper grazing seriously after milking.

Yield of Reindeer milk

The pattern of the lactation curve of reindeer is similar to that of other ungulates (**Figure 3**), where the peak of lactation occurs during weeks 2–4 with a daily output of around 1 l, depending on the weight of the animal, with a total milk yield of about 100 kg, but also less depending on the nutritional state of the female. Isotope tracer techniques have been used to study the potential milk production of reindeer and caribou, which are accurate, but elaborate and expensive.

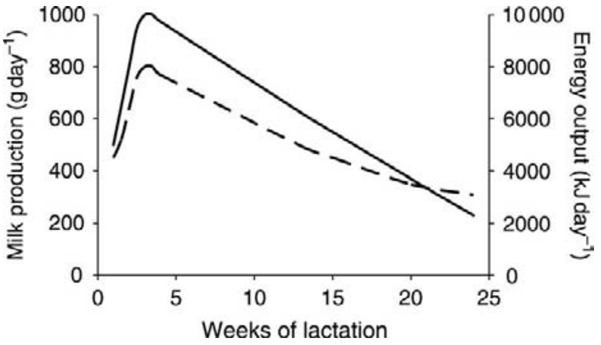

Figure 3 Lactation curves of reindeer for potential daily mean milk production (solid line) and energy output (dotted line) of an average female (75 kg) through lactation. Adapted from Holand Ø, Aikio P, Gjøstein H, Nieminen M, Hore K, and White RG (2002) Modern reindeer dairy farming – the influence of machine milking on udder health, milk yield and composition. *Small Ruminant Research* 44: 65–73.

The lactation curve of reindeer has been determined on the basis of milk yield during a few selected stages of lactation. The estimated total milk yield of reindeer is lower than that of red deer (150 kg) and Iberian red deer (224 kg), but slightly higher than that of black-tailed deer (93 kg).

Composition of Reindeer milk

It is difficult to give a typical composition of reindeer milk, due to limited sample size, individual variation, difference in sampling techniques, feeding regime, and variations in the lactation stage among different studies. In general, wild and semi-domestic ruminants give richer milk, particularly in late lactation, than the domesticated species. Reindeer milk at peak and mid-lactation has a relatively high level of fat (11–15%) and protein (7–10%), but a moderately low level of lactose (about 3.5%) (**Table 4**).

The protein content of reindeer milk increases from around 9% in early lactation to about 11% in late lactation, while the relative levels of different amino acids are rather constant throughout lactation. The amino acid profile resembles those in sheep and goats, except for low cysteine and high tyrosine contents. CN is the predominant protein fraction in reindeer milk, with a content of 7–9%. β-Lg is the main whey protein: it contains 162 amino acids. Reindeer milk contains high levels of non-protein nitrogen (NPN), urea, ammonium, and carnitine (at 84–118 mg per 100 ml). Urea content is about 48 mg per 100 ml and free carnitine 71 mg kg^{-1}.

Fat is the major energy component in reindeer milk, representing 67% of the energy content at peak lactation and 75% at late lactation. Fatty acids of reindeer milk are dominated by palmitic acid (16:0), accounting for one-third of the total fat, and stearic (18:0), oleic (18:1), and myristic acids (14:0), contributing around 13%. The levels of short-chain fatty acids, especially butyric (4:0) and capric (6:0) acids, are higher in reindeer than in red deer, roe deer, and fallow deer milk. Reindeer milk contains about 3–3.5% lactose at peak lactation, which is lower than in other wild ungulates, and also has small amounts of oligosaccharides.

The mineral content of reindeer milk is moderate to high (1–1.5%), compared to most other ungulates. Reindeer milk is high in fat- and water-soluble vitamins. Vitamin C content is around 2 mg per 100 ml, which is similar to that in red deer and fallow deer milk. Reindeer milk is several times higher in vitamin D_3 (0.5–2.0 mg kg^{-1}) as compared to cow milk.

Utilization of reindeer milk

Reindeer milk is consumed as fluid and processed products. Children drink fresh milk and adults consume it in tea and coffee. The milk is also dried and processed into cheese, butter, and sour cream, as well as used in medications (**Table 5**). The milk is curdled and often mixed with tasty herbs (*Oxyria* spp. and *Angelica* spp.). Reindeer milk is also stored frozen and often mixed with berries (*Vaccinium* spp., *Empetrum nigrum*).

Normally, reindeer milk from the first part of lactation is consumed fresh, the second part is mainly used for cheese production, and the last part of lactation is used more appropriately for churning butter. Reindeer milk and its products are highly priced, and are also used for medical purposes such as cures for digestive problems, owing to its anti-diarrheic properties and for healing wounds. Fat oozed by heat from reindeer cheese is used to cure nursing pains, frostbites, and other injuries. Colostrum is used for children's ailments.

Table 4 Gross composition (%) of reindeer milk at peak lactation, 3–5 weeks post-partum

Weeks of lactation	*No.*	*Total solids*	*Fat*	*Protein*	*Lactose*	*Ash*
4–5	8	27.1	11.1	11.1	3.0	1.5
4	3	23.7	10.2	7.5	3.7	1.2
5	5	38.1	19.6	13.0	3.7	2.7
3–5	7	31.6	15.5	10.7	3.7	1.3
5	2	32.8	17.1	10.9	2.8	1.5

Holand Ø, Gjøstein H, and Nieminen M (2006) Reindeer milk. In: Park YW and Haenlein GFW (eds.) *Handbook of Milk of Non-Bovine Mammals*, pp. 355–370. Ames, IA; Oxford, UK: Blackwell Publishing.

Table 5 Traditional products and uses of reindeer milk

Fresh milk	Consumed by children (often diluted with water), used in tea and coffee and in medical treatments
Stored milk	
Frozen	Stored for consumption during winter, ice cream mixed with berries
Fermented	
Short	Sour cream and cultured milk inoculated with a bacterial starter, for consumption
Long	Stored in wooden containers often mixed with herbs, curdled, consumed during winter and spring migration, both the liquid and solid phases
Dried	Dried in stomach compartment, reticulum, for winter consumption
Manufactured milk product	
Cheese	Curdled by heating or by adding dried abomasum, dried and stored for consumption and sale
Butter	Churned from both fresh and fermented milk, for consumption and sale
Other products	Buttermilk and whey, consumed fresh and reduced and eaten as soup

Holand Ø, Gjøstein H, and Nieminen M (2006) Reindeer milk. In: Park YW and Haenlein GFW (eds.) *Handbook of Milk of Non-Bovine Mammals*, pp. 355–370. Ames, IA; Oxford, UK: Blackwell Publishing.

Musk Ox

Musk ox ranges across northern Alaska, Canada, and Greenland. Musk ox was extinct in Alaska by the mid-1800s, possibly due to hunting by native people, explorers, and whalers. In the early 1900s, the musk oxen population in the world was estimated to be as few as 5000 animals, which was considered to be in danger of extinction. Beginning in 1917, the Canadian Government enforced protection of the species from hunting and made efforts to save musk oxen. The species was translocated from Greenland to Alaska and held in captivity in Fairbanks for feeding, growth, and breeding studies until 1935–36, and then released into the wild on Nunivak Island.

Although the lactational strategies differ in length, musk oxen and caribou live in similar arctic environments, and often eat similar forages. Healthy musk oxen continue to nurse their young throughout the rutting period, until December to February, and they may lactate throughout the winter in the field.

Musk oxen have three recognized subspecies: *Ovibos moschatus moschatus*, *Ovibos moschatus niphoecus*, and *Ovibos moschatus wardi*. Musk oxen in Alaska are descendants of animals transplanted from Greenland (*O. moschatus wardi*). A comparative study of allozyme electrophoresis has shown that little genetic variation exists within and between populations of Alaskan and Greenlandic Musk Oxen.

The gross composition of musk ox milk is shown in **Tables 1** and **6**. Although there are some variations between reports, musk ox milk contains a much higher level of total solids than cow milk. This is due to the higher fat and protein, which is a common characteristics of the milk of Arctic and sub-Arctic species. The gross composition of musk ox milk such as total solids, solid-not-fat, and lactose contents increases from day 1 to 3 months of lactation. Musk oxen have the highest milk production at 3 weeks postpartum, and production remains high for about 1 month and then tapers off gradually.

Table 6 Gross composition of musk ox milk

	Study 1[a]	*Study 2*[b]
Total solids (%)	27.1	21.5
Water (%)	72.9	78.5
Fat (%)	10.9	11.0
Solid-not-fat (%)	16.2	10.6
Ash (%)	1.20	1.8
Protein (%) ($N \times 6.38$)	11.9	5.3
Lactose (%)	2.1	3.6
Specific gravity	1.023	-
pH	5.4	-
Vitatmin B_{12} ($\mu g\, l^{-1}$)	-	3.4

[a] Baker BK, Cook HW, and Teal JJ (1970) musk ox (*Ovibos Moschatus*) milk. I. Gross composition, fatty acid, and mineral constitution. *Canadian Journal of Zoology* 48:1345–1347.

[b] Tener JS (1956) Gross composition of musk ox milk. *Canadian Journal of Zoology* 34:569–571.

The fatty acid composition of musk ox milk reveals that approximately 38% of the total fatty acids is oleic acid, and only a trace amount of butyric acid is detected. The levels of small- and medium-chain fatty acids (C4–C14) of musk ox milk range from 9.8 to 17.4%, which are significantly lower than those of bovine or caprine milk. Must ox milk also contains lower levels of long-chain fatty acids (above C18) compared to the milk of other Arctic species.

Llama Milk

Milk Yield

Llama has a milk secretory system consisting of four mammary glands, similar in structure to the cow, with four teats each having two streak canals, which enter into separate teat and gland cisterns. Milk is collected by variable numbers and sizes of milk ducts from the gland and emptied into the gland cistern. The amount of milk produced daily by individual llamas varies significantly and ranges from 16 to 413 ml per animal, with a median of 62 ml per animal.

Milk composition

Llama milk contains an average of 13.1% total solids, 6.5% lactose, 3.4% protein, and 2.7% fat. The energy content of llama milk varies between 50.0 and 95.8 kcal per 100 g with an average of 70.0 kcal per 100 g, which is lower than that of bovine (85.2 kcal per 100 g), caprine (103.6 kcal per 100 g), and ovine milk (155.6 kcal per 100 g). Llama milk has a density of 1.033 g ml^{-1}, a milk fat density of 0.935 g ml^{-1}, and a pH of 6.52 at 20 °C.

The mineral content of llama milk is different from human and bovine milk, in which potassium is the most abundant mineral, while calcium is the main mineral in llama milk, followed by phosphorus and potassium. The calcium content of llama milk is higher (1310–2210 mg kg^{-1}) than that of human, cow, and goat milk (280, 1120, and 1400 mg kg^{-1}, respectively), but similar to that of camel milk. The concentration of sodium in llama milk (193–413 mg kg^{-1}) is lower than in cow milk (530 mg kg^{-1}), but higher than in human milk (180 mg kg^{-1}).

The most abundant trace element in llama milk is zinc, similar to that in milk of other species. The mean zinc content of llama milk (about 4.2 mg kg^{-1}) is higher than that of human milk (1.2 mg kg^{-1}), but similar to cow milk (3.9 mg kg^{-1}) and camel milk (4.0–5.0 mg kg^{-1}). Barium concentration in llama milk (0.278 mg kg^{-1}) is higher than that of cow milk (188 mg kg^{-1}). The mean copper concentration of llama milk (0.109 mg kg^{-1}) appears to be lower than that of mare (0.155 mg kg^{-1}), human (0.250–0.314 mg kg^{-1}), or guinea pig (0.500 mg kg^{-1}) milk. The relatively low copper concentration in llama milk agrees with low blood serum copper concentration of llamas compared to other domestic animals. Mean iron concentration of llama milk (0.65 mg kg^{-1}) is comparable to that of cow milk (0.50 mg kg^{-1}), but higher than that of human milk (0.3 mg kg^{-1}) and lower than that of camel milk (1.3–2.5 mg kg^{-1}). Llama milk proteins contain significant proportions of phosphorus, being 0.36, 0.45, 0.30, and 0.15% for α-CN, β-CN, γ-CN, and the proteose peptone fraction, respectively.

Alpaca

There are four species of South American camelids: vicuna, guanaco, llamas, and alpacas. The vicuna and guanaco are wild species. The vicuna is native to the altiplano regions of Chile, Bolivia, and Peru. The guanaco is native to the Patagonia regions of southern Chile and Argentina. Llamas and alpacas are the two domesticated species in this camelid family.

Alpacas are highly important for the village economy in Chile, Bolivia, Peru, Ecuador, and Argentina. Alpacas are an essential source of income and provide food and wool for the native people, who live on the high altiplano regions. Alpaca-producing regions in these countries have a conception rate of 50% or lower and a 20% mortality rate of the young called ‘cria’. Nutritional inadequacies, infectious diseases, and changes in the environment may cause these reproductive problems.

Studies on the composition of alpaca colostrum at 48 h postpartum for Andean high plateau and Patagonia regions (**Table 7**) showed 21 and 19% total solids, 9.8 and 9.2% protein, 4.8 and 2.7% fat, 4.4 and 5.3% lactose, 1.6 and 1.8% ash, respectively. The colostrum of Andean altiplano alpaca has higher dry matter, protein, and fat, but lower lactose than Patagonia region alpaca. A similar trend was observed for the major constituents of mature of milk alpaca from 1 to 5 months of lactation (**Table 7**). The higher fat content of alpaca milk at the Andean high plateau compared to the lower altitude Patagonia region may suggest that the animals at the higher altitude may

Table 7 Comparison of gross compositions of colostrum and mature milk of alpaca from two regions of Chile

	Dry matter	*Protein*	*Fat*[a]	*Lactose*[a]	*Ash*
Colostrum					
AHP[b]	20.66 ± 1.3	9.84 ± 0.6	4.80 ± 1.2	4.41 ± 0.1	1.63 ± 0.0
Patagonia[c]	19.06 ± 0.5	9.24 ± 0.5	2.71 ± 0.6	5.33 ± 0.1	1.78 ± 0.1
Mature milk					
AHP[b]	16.8 ± 0.7	6.9 ± 0.3	3.8 ± 0.6	4.4 ± 0.5	1.7 ± 0.3
Patagonia[c]	15.8 ± 0.6	6.5 ± 0.3	2.6 ± 0.5	5.2 ± 0.5	1.4 ± 0.1

[a] Differences in fat and lactose contents of both colostrum and mature milk between the two regions are significant ($P < 0.05$).

[b] AHP: Andean high plateau region (4400 m above sea level); 24 alpacas were tested.

[c] Patagonia: Patagonia region (12 m above sea level); 18 alpacas were tested.

Data were reorganized from Parraguez VH, Thenot M, Latorre E, Fernando G, and Raggi LA (2003) Milk composition in alpaca (*Lamo pacos*): Comparative study in two regions of chile. Archivos de Zootechia 52:431–439.

require more energy for body maintenance by natural selection compared to those at the lower altitude. The differences in fat and lactose composition between the two regions could also be explained by the pasture composition and availability of the regions as well as the grazing behavior of the alpacas.

The main immunoglobulin of colostrum found in alpaca crias is IgG. Mean IgG concentrations are similar in llama (2370 mg per 100 ml) and alpaca crias (2340 mg per 100 ml), and are not different between males and females. Llama and alpaca crias are born agammaglobulinemic, with IgG concentrations increasing after suckling.

Milks of Non-Dairy Mammals

G Osthoff, University of the Free State, Bloemfontein, South Africa

Introduction

The use of milk and dairy products is such a daily routine that mankind does not realize that it is using the milk from another species. Knowledge therefore reaches no further than the assumption that milk from all species is the same. Furthermore, mankind has become so used to dairy products such as butter, cheese, and yogurt, which have been discovered merely by chance, owing to abusive handling and storage of milk, that no thought is given about the consequences that would have been faced if milk had a different composition. Only when malnutrition among humans has been observed during feeding of infants with cow's milk, and when differences in dairy product properties have been observed when milks from different domestic species are used, has an interest sprouted in the composition of the milks of non-dairy species. Although the milks of all mammals contain the same components – water, salts, vitamins, fat, carbohydrates, and proteins – it was realized that this does not imply that all milks are the same.

The objective of this article is to provide a brief comparison of milks, and to describe certain characteristics that are unique to milks from certain animals, which are not to be expected by extrapolation of the knowledge of well-studied species. Very little data are available on milks of non-dairy animals, because studies in this area have been limited. Further limitations are the inaccuracy of data for many species owing to the small numbers of samples, small sample volumes, difficulties in defining the stage of lactation, biases during sampling, and flaws in analytical procedures. It is therefore attempted here to present the data from multiple samples of which the stage of lactation was specified; the analytical procedures used are currently regarded as accurate.

Gross Composition of Milk

By comparing the milk composition of different species (**Table 1**) it may be concluded that, in general, the milks of some primates and Perissodactyla (horses and rhinoceroses) are dilute, low-fat milks, whereas bears, Pinnipedia, and Cetacea produce high-fat and energy-dense milks. The milks of marsupials are rich in carbohydrates, especially oligosaccharides, whereas in the milks of Pinnipedia these carbohydrates are present in trace amounts. Deviations from these general observations are noticed, and may be ascribed to adaptation to special needs, such as to the environment or special dietary requirements. Among the Bovidae, the total dry matter of the milks of ibex, dall sheep, muskox, dorcas gazelle, and springbok is above 20%, as compared to the figures of 12–20% for the other members, possibly owing to the adaptation to arid environments. Among the Felidae, the total dry matter may vary; for serval milks it is 29.5%, whereas for cheetah milk it is 16.6%. Adaptation to the environment cannot be considered as the reason, as these two cats coexist in the same regions. Each milk, therefore, provides nutrients and bioreactive components in the correct amount and form, which is the result of adaptation to environmental circumstances and physiological constraints.

Proteins

Of all the milk nutrients, proteins are the least studied in species other than humans and a few domestic mammals. The proteins of all milks are subdivided into whey proteins and caseins. 'Whey protein' is a collective description for a wide variety of proteins and includes enzymes and immunoglobulins, as well as the major proteins β-lactoglobulin and α-lactalbumin. The caseins are α_{s1}-, α_{s2}-, β-, and κ-caseins, of which different subtypes may occur.

The proteins occur in different amounts. In cow's milk caseins are the major proteins at 2.6%, with whey proteins at 0.7%. In human milk, the respective amounts are 0.2 and 0.6%. Subfractionation of milk proteins of only a few species has been reported; so phylogenetic relationships cannot be established. In the milks of all ruminants, a ratio of whey proteins to caseins similar to that in cow's milk is observed. In non-ruminant species, the whey proteins are not always the major fraction. A major problem in subfractionation lies in the methods applied, which are based on selective precipitation of the caseins with acid and subsequent separation of the whey proteins. It is then assumed that milk proteins from other species will react in the same manner as the bovine proteins for which the methods were developed, which is the case quite often, but not always. Actually a separation method should be developed for the milk proteins of each species; however, this is not possible when only small quantities of milk are available from wild animals.

Table 1 Gross composition of mammalian milks

Species		*Dry matter (%)*	*Fat (%)*	*Crude protein (%)*	*Lactose and sugars (%)*
Monotremata					
Tachyglossidae

Part B* 150: 74–84; Osthoff G, Hugo A, and De Wit M (2009) Comparison of the milk composition of free-ranging blesbok, black wildebeest and blue wildebeest of the subfamily Alcelaphinae (family: Bovidae). *Comparative Biochemistry and Physiology* 154: 48–54; Park YW and Haenlein FW (2006) *Handbook of Milk of Non-Bovine Mammals*. Oxford: Blackwell.

Milk proteins may be separated further by polyacrylamide gel electrophoresis (PAGE). The technique may be adapted to effect separation by size, charge, or both. When the proteins are stained, quantification by densitometry is possible. However, this method is also not foolproof, as unrelated proteins with similar molecular weight or charge may not be separated, and furthermore not all proteins are stained at equal intensity. In **Figure 1**, the electrophoretic separation of milk proteins by urea-PAGE of a number of species is shown. Among the Bovidae the electrophoretic migration of the caseins is very similar, whereas that of the whey proteins, α-lactalbumin for example, varies to a great extent. Variation in electrophoretic mobility is the result of differences in amino acid composition or post-translational modification. The migration of β-caseins is very similar when compared to cow's milk protein, whereas the migration of the α-type caseins is slightly different. The κ-casein of cow's milk is clearly separated from the β-caseins; an almost similar separation is observed for kudu milk and springbok milk. This is indicative of only minor differences in amino acid composition or post-translational modification of these proteins. For the other five antelopes, the κ- and β-caseins are not clearly separated. Among all these example species, the migration of the α-lactalbumin band may also be slower or faster than its bovine equivalent.

Apart from these major protein bands, many other bands that are distinct for each species are visible. These may be enzymes and globulins which occur at different concentrations in each species. Among closely related species similarities may occur, but also there are differences. Good examples in **Figure 1** are the three representatives from the subfamily Alcelaphinae. Although the genetic distance between the two wildebeest species is 0.02 ± 0.014 (determined with 29 protein encoding loci), and between these and the blesbok is 0.121 ± 0.066, the electrophoretograms seem to contradict this, especially regarding the migration of α-lactalbumin. The same is observed for the κ-casein of kudu and eland of the subfamily Bovinae.

The electrophoretograms of non-ruminant species differ substantially from those of the ruminants. The β-caseins have a slower mobility, while some proteins,

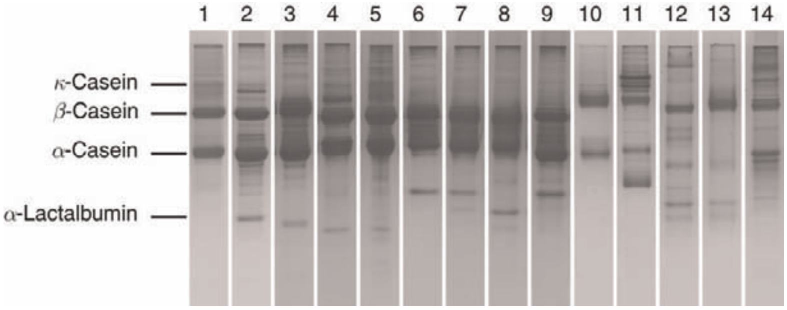

Figure 1 Urea–polyacrylamide gel electrophoretograms of sodium caseinate (lane 1), and milk of cow (2), springbok (3), kudu (4), eland (5), blesbok (*Damaliscus dorcas phillipsi*) (6), black wildebeest (7), blue wildebeest (8), sable antelope (9), white rhinoceros (10), African elephant (11), vervet monkey (12), rhesus macaque (13), and human (14).

such as the α-type casein, may be absent. The African elephant milk has a short migration distance for β-casein and contains high amounts of other (whey) proteins, while the α-caseins of the white rhinoceros have a similar migration distance as their bovine equivalent.

Comparison of the electrophoretograms of the primate milks shows the β-casein at a shorter migration distance than the bovine equivalent. However, among the primate milks shown, the electrophoretic migration of the β-casein does not vary as much as that of the whey proteins – a similar observation as for the Bovidae described above. It has been established that the α-type casein is absent in human milk. The protein bands at the migration position equivalent to that of the bovine α-type casein have been identified as lactoglobulin and lactoferrin. High amounts of immunoglobulins are present in human milk. Owing to their high molecular weights they migrate short distances. When the milks of vervet monkey and macaque are compared to human milk, the absence of α-type casein becomes obvious. The migration of the lactalbumin bands is similar, which seems logical considering the close relationship between these species within the Cercopithecidae family. In spite of this close relationship, however, differences in the electrophoretic properties of the proteins in general are also observed.

A more specific comparison of the caseins regarding molecular mass and post-translational modification may be explained by the amino acid sequence, phosphorylation, and glycosylation of the caseins from some marsupials and ruminants. The caseins of the marsupials differ substantially from those of eutherian species (**Figure 2**). Marsupial milk contains only one type of α-casein, of which the amino acid sequence shows low levels of similarity with that of eutherian species, and, furthermore, it is glycosylated. The β-caseins have no similarity to their eutherian equivalents.

Among the eutherian species, high levels of amino acid sequence identity for the α_{s1}-casein are observed within closely related species. Among ruminants, the identity is >85%, and among rodents >80%. Lower levels of identity are observed between unrelated groups, for example, 45% between bovine and pig, and 29% between bovine and rat α_{s1}-caseins. This explains the difference in electrophoretic migration of these proteins from those of Bovidae and other species (**Figure 1**). Multiple forms of these proteins may occur, which have been described for bovine and goat species. The β-caseins show a similar degree of divergence across species as the α_{s1}-caseins, and multiple forms have also been reported. The multiple forms of these two caseins are indicative of hereditary lineage, which in cattle may be traced to *Bos indicus* or

Figure 2 Alignment of the amino acid sequences of the α_{s1}-caseins of possum (*Trichosurus vulpecula*), mouse (*Mus musculus*), and cow (*Bos taurus*) to show the difference between marsupial and eutherian proteins, and partial similarity between eutherian proteins. From Ginger MR and Grigor MR (1999) Comparative aspects of milk caseins. *Comparative Biochemistry and Physiology. Part B* 124: 133–145.

Bos taurus lineages. In general, the α_{s2}-like caseins are more disparate among different species. The level of sequence identity between bovine and pig proteins is 64%, and between rabbit and mouse it is <40%.

The α- and β-type caseins share several common properties, which include partial amino acid sequence and calcium sensitivity, which suggests that they may have originated from a common protein ancestor. κ-Casein is not related to the above proteins. It is the only eutherian casein that contains carbohydrate moieties, does not display calcium sensitivity, and is susceptible to cleavage by the aspartate protease, chymosin (rennin). Human milk κ-casein is more highly glycosylated than bovine and ovine proteins and it differs from these with the presence of fucose and *N*-acetylglucosamine.

In terms of the cleavage of κ-casein by chymosin, mammals may be separated in two groups. In group I, κ-casein is cleaved at a specific Phe–Met bond, and this group is found mainly in the ruminants Cervidae, Giraffidae, and Bovidae. In group II, κ-casein is cleaved at Phe–Ile or Phe–Leu, and this group is mainly found in non-ruminants such as Primata, Cetacea, Perissodactyla, Suidae, Tayassuidae, and Camelidae. It seems the division on the basis of ruminant or non-ruminant is not definite. Both the κ-casein groups are represented in the Rodentia, with the guinea pig (Caviidae) producing group I, and the mouse and rat (Muridae) producing group II κ-caseins, while the rabbit (Lagomorpha) also produces group I κ-caseins. The resulting difference in cleavage affects the clotting mechanism of the two milks. Milks of the Equidae family contain very low levels of κ-casein, the effect being that equine milks do not coagulate on renneting or form very weak curd.

Of the whey proteins, α-lactalbumin has been characterized in great detail. It occurs in the milk of most mammals and is involved in the synthesis of lactose. The amounts of this protein in the mammary gland differ among species, which in turn governs the amounts of lactose in the milk. Small amounts are found in monotremes and marsupials, while high amounts are observed in most eutherians. While there is a homology between the α-lactalbumins of monotremes, marsupials, and eutherians, the protein of the former two also shows a high degree of homology with eutherian lysozyme with regard to amino acid sequence, secondary and tertiary structure, as well as arrangement of the genes. It was therefore proposed that α-lactalbumin has evolved from lysozyme. In spite of the homology of lysozymes between species, substantial differences occur, which may explain the large variation in electrophoretic mobility of this protein observed in **Figure 1**.

The difference of proteins between species is of course not restricted only to the milk proteins, but also extends to other functional proteins such as enzymes. Consequently, there will be differences in the reaction products produced by such enzymes, which, in milk, will be reflected in the composition of fats and saccharides, as is described next.

Lipids

Fatty Acid Composition

The triacylglycerides in milk are synthesized in the mammary cells. The fatty acids are obtained from three sources: (1) *de novo* synthesis of fatty acids from metabolites such as NADPH and acetate, (2) direct uptake from fatty acids circulated in blood, and (3) further modification of fatty acids in the mammary gland by desaturation and elongation. In monogastric animals, the fatty acid composition of the milk reflects to a high degree the circulating fatty acids, most of which normally stem from the diet of the mother. This is not the case in species with foregut fermentation, such as ruminants, where the ingested fatty acids are changed by microbial fermentation.

In *de novo* synthesis the length of the fatty acids produced depends on several factors such as the ability to utilize specific molecules as sources and the specific properties of enzymes. While glucose is the source for fatty acid synthesis in non-ruminants, it is not used effectively in ruminants. Instead, lactate, acetate, and 3-hydroxybutyrate, which are metabolites of the fermentation of carbohydrates by the rumen bacteria, are utilized. The medium-chain fatty acids (8:0–12:0) are synthesized *de novo* by the mammary tissue. Fatty acids are synthesized by fatty acid synthetase in an elongation process. In the liver and adipose tissue, the fatty acids attain a chain length of 16 or more. In the mammary gland, the synthesis process is terminated by a thioesterase after the addition of up to 16 carbons. In some mammals this termination is effected after the addition of 8 to 14 carbons. Short-chain fatty acids (4:0 and 6:0) are characteristic of ruminant milk.

Fatty acids from the diet are obtained from triacylglycerols, which are carried to the mammary cells by lipoproteins, where the fatty acids are released. Generally, these fatty acids are more than 14 carbons long, mainly 16 or 18 carbons. In ruminants, approximately half of the fatty acids in milk are derived in this way, including about one-third of the 16-carbon acids and most of the 18-carbon acids. Plant foods contain high amounts of unsaturated fatty acids. In ruminants, these are altered by the rumen bacteria through hydrogenation to produce more saturated fatty acids, resulting in more saturated ones being incorporated in milk fat than found in nonruminant milks.

In the liver and adipose tissue, fatty acids are normally not elongated beyond the length of 16 carbons. However, in some species 16- and 18-carbon acids are used as substrates to be elongated up to 24 carbons in the liver and mammary gland. A further modification process of fatty acids is desaturation. In ruminants, 18:0 and 16:0 may get changed to 18:1 and 16:1. Unsaturated fatty acids such as linoleic acid ($18{:}2n-6$) and α-linoleic acid ($18{:}3n-3$) cannot be synthesized *de novo*, and have to be obtained through the diet such as plant material. In ruminants α-linoleic acid may also be produced by the rumen bacteria. Through elongation and further desaturation of these two fatty acids, unsaturated fatty acids up to 22 carbons long are formed. The substrates for elongation and desaturation may be obtained from plant material.

A phylogenetic relationship has been noted for the preference of which lipid synthesis mechanisms are used. Milk of Artiodactyla, specifically the ruminant families Cervidae, Giraffidae, and Bovidae, is characterized by the presence of up to 15% short-chain fatty acids (4:0 and 6:0) (**Table 2**). In the Camelidae these fatty acids constitute approximately 1%, and in the Suidae they are absent. Medium-chain fatty acids (8:0–12:0) are present in different amounts, and occur along family lines. The milk of goat and sheep (subfamily Caprinae) may contain up to 19% of these, whereas the milk of blesbok and the black and blue wildebeest (subfamily Alcinaphinae) contain 20–30%. The milks of the latter three animals also contain up to 20% $C_{14:0}$, which in almost all other species occurs at amounts below 13%. The single sample of okapi milk analyzed may suggest that higher amounts of medium-chain fatty acids are also found in the milk of the Giraffidae.

The milks of non-ruminant mammals may have varying amounts of medium-chain fatty acids. Among the Rodentia, the species seem to vary in their secretion of these fatty acids, and phylogenetic trends are not clear. While they may be absent in the milk of gerbil, cloud rat, guinea pig, and acouchi, they may reach 16–37% in the Norway rat and wood rat, and within the genus *Peromyscus* (deer mouse) they may be present or absent.

Some non-ruminant herbivores have extraordinarily high contents of medium-chain fatty acids (8:0–12:0). Of the Lagomorpha, rabbit milk was found to contain more than 62% of these fatty acids, and hare milk 25%. Of the Perissodactyla, the horse, tapir, and rhinoceros synthesize large proportions of medium-chain fatty acids, the content of which may change over lactation time; in the Indian rhinoceros, 10:0 was found to change from 18 to 36%.

Elephants (Proboscidae) produce most of their milk fatty acids by *de novo* synthesis of medium chain, which may reach amounts of up to 90%. The levels of these change drastically over lactation time. The amounts of 8:0 and 10:0 increase from, respectively, 3 and 30% to 12 and 60%, while 12:0 and 14:0 decrease from approximately 25 to 10%. These are the highest level of change in fatty acid composition over lactation observed for any mammal and are not related to changes in the diet. It is not known what the reason of this change in medium-chain fatty acid composition over lactation is, that is, what the benefit is to the mother animal or to nutrition.

Synthesis of medium-chain fatty acids is also a property of the primates, and specific phylogenetic relationships are found. The milks of lemurs and lorises seem to contain no 8:0, but relatively high amounts of 12:0 (4–19%) and 14:0 (6–20%), while the Callitrichidae may contain up to 2% 8:0 and higher levels of 10:0 (8–22%) and 12:0 (8–17%). Milk of the Cebidae seems to contain high amounts of 8:0 (3%) and 10:0 (12–23%) and less of 12:0 and 14:0. The Cercopithecidae and Hylobatidae seem to secrete the highest levels of 8:0 and 10:0 and low levels of 12:0 and 14:0. In the Hominidae, the bonobo, chimpanzee, Bornean orangutan, gorilla, and human low amounts of 8:0 and 10:0 are observed, which shows that there is less emphasis on *de novo* synthesis of fatty acids. In all primates, the diet plays a significant role in the fatty acid composition of the milk, and great variation in long-chain fatty acids are observed accordingly.

The milks of all the other mammalian orders not discussed above do not appear to contain short- or medium-chain fatty acids, and the fatty acid composition is highly dependent on the diet. Marine mammals such as the Pinnipedia and Cetacea are characterized by high amounts of long-chain polyunsaturated fatty acids which are obtained from fish, and the insectivorous Monotremata, Insectivora, and Chiroptera contain high levels of $18{:}3n-3$. The milk fatty acid composition of the Carnivora follows the same trend of being affected by the diet, which is best illustrated by the level of $18{:}3n-3$, which is normally low, but may reach 15% in black bear when consuming vegetable material.

Melting Properties of Fat

The above discussion and **Table 2** show that the milk fat composition of animals varies extensively with regard to chain length and degree of unsaturation. This has a great effect on the physical properties of the fat. Animal fats, including milk fat, contain more saturated fatty acids than plant fats do. The effect of fatty acid composition on the physical properties is best demonstrated with plant fats being liquid oils at room temperature while the animal fats, butter and lard, are solid. However, in the living mammal, the milk fat is not in a solid state because of the high body temperature (~ 37 °C) being maintained. The melting properties of the different milk fats give insight into the degree of fluidity at different temperatures as affected by the fatty acids. In **Figure 3** the melting thermograms of a few representative species as determined by differential scanning calorimetry (DSC) are shown, and compared to butterfat.

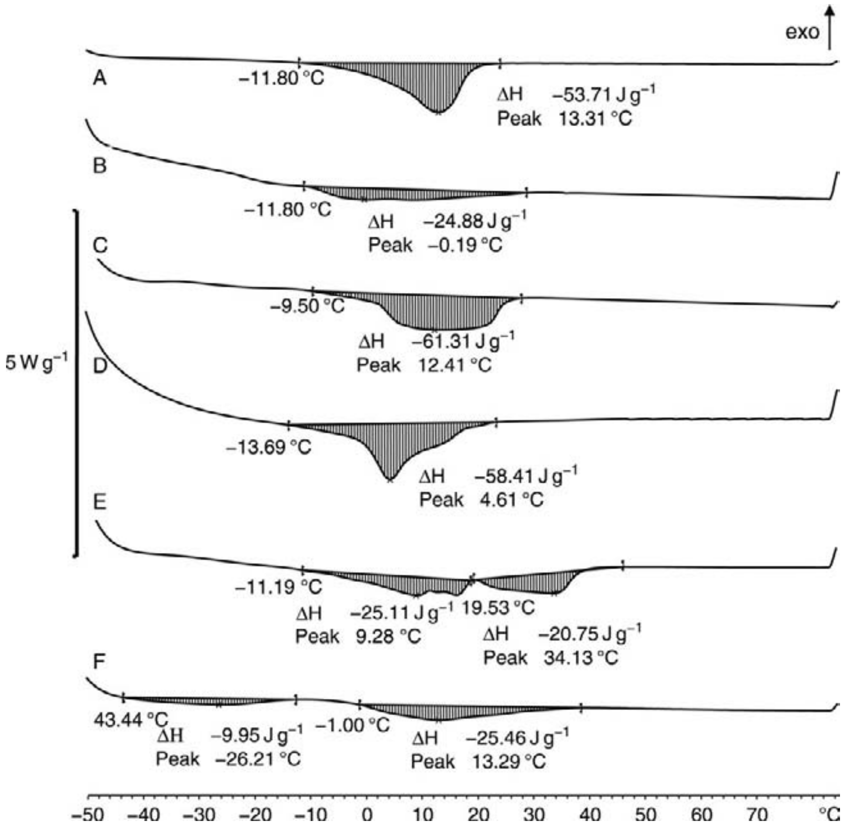

Figure 3 Differential scanning calorimetry thermograms of milk fat from African elephant (A), cheetah (B), blue wildebeest (C), vervet monkey (D), domestic cow (E), and bottlenose dolphin (F).

A distinct melting curve is observed for each species. The first aspect to be noted is the initial and final melting points. A high initial, as well as final, melting point is indicative of high amounts of saturated long-chain fatty acids, and a low initial, as well as final, melting point is the result of high amounts of short-chain or polyunsaturated fatty acids. The final melting point of all milk fats is below 40 °C, but for a few species, such as the cow, a small percentage of the fat may be solid above that temperature. This shows that milk fat in all species is in a liquid state at body temperature.

The second aspect is the different melting peaks observed for the same milk fat, which is the result of triglycerides containing different types of fatty acids. Elephant milk fat shows only one melting peak between −11 and 24 °C, owing to the lipids containing up to 90% medium-chain fatty acids. The lipids in cow's milk occur in two groups. One group contains high amounts of polyunsaturated fatty acids and the other more of saturated ones. The effect is that these two groups of molecules melt between −11 and 20 °C, and between 20 and 46 °C, respectively. Similarly, two groups are observed for the milk fat of the bottlenose dolphin, which melt between −48 and −4 °C, and between −1 and 38 °C, the low melting peak being ascribed to the high levels of polyunsaturated fatty acids. As the milk fats of most ruminants have a very similar fatty acid composition (**Table 2**), similar melting properties are observed. The milk fat of ruminants such as the blue wildebeest, however, contains higher amounts of medium-chain fatty acids, which results in a lower maximum melting point. Furthermore, if the fatty acids are more evenly distributed among the lipid molecules, a narrower melting range, resembling that of the elephant milk fat, is observed.

The technological implication of the fatty acid composition and melting properties is that cow's milk fat results in a butter that is hard at 4 °C due to approximately 75% of the fat being in a solid state, but soft and spreadable at 25 °C, due to approximately 60% of the lipids being in a liquid state and being entrapped by the 40% solid molecules. In comparison, the other milk fats whose melting properties are discussed above do not result in butter with the same properties? The milk fats of elephant, blue wildebeest, and vervet monkey have the same solid character as cow's milk fat at 4 °C, but are liquid oils at 25 °C. The milk fat of cheetah is soft at 4 °C and liquid at 25 °C, and that of bottlenose dolphin is very soft at 4 °C and almost completely liquid at 25 °C. Concurrently, will these fats also present (structural characteristics and mouthfeel) to food products such as ice cream and baked goods as cow's butterfat?

Carbohydrates

Carbohydrates that are found in milk are lactose and oligosaccharides, and the monomer constituents, namely, galactose, glucose, fucose, and to a lesser extent sialylic acid and *N*-acetylglucosamine. The major carbohydrate in the milk of most eutherian species is lactose.

Of over 200 species the milks of which have been analyzed, the specific contents of lactose and the other saccharides have been determined for only a few, the reason being the specificity and sensitivity of the methods of analysis that have been used. Older methods, such as the phenol–sulfuric acid method, were nonspecific and not very sensitive. The total carbohydrate content was actually recorded, while the lactose content was reported based on the assumption that lactose is the only carbohydrate in all milks. The latest techniques rely on chromatographic separation, such as gas chromatography and high-performance liquid chromatography, and quantification relative to standards, which enables specific quantification. Nevertheless, it was recognized with the aid of paper chromatography that milk of a broad range of species contains carbohydrates of larger molecular weight than lactose. In the milk of monotremes and marsupials, and also a few eutherian species, the major carbohydrates were shown to be oligosaccharides.

These observations initiated the research on the mechanism of oligosaccharide synthesis in the mammary gland. Lactose is synthesized by lactose synthase, which consists of a complex of β-4-galactosyltransferase I and α-lactalbumin. The latter controls the rate of lactose synthesis. Oligosaccharide synthesis is catalyzed by a variety of glucosyl transferases which transfer monosaccharide residues (galactose, glucose, fucose, sialylic acid, or *N*-acetylglucosamine) either to free lactose or to another saccharide residue attached to lactose. In species with high levels of milk oligosaccharides, α-lactalbumin is present at a very low level.

Based on the homology of α-lactalbumin to lysozyme, it was proposed that the ability to secrete lactose is linked to the evolutionary development of α-lactalbumin. Prior to the presence of α-lactalbumin in the mammary gland, the rate of lactose synthesis was not controlled and almost all of the lactose was utilized for the synthesis of oligosaccharides by glycosyl transferases. This is observed in monotremes and marsupials. The biological role of the oligosaccharides in milk also seems to have changed. Oligosaccharides are not only a source of energy, but act mainly as anti-infection factors against pathogenic organisms. In eutherian species, this role has been lost to a large extent where oligosaccharides have been replaced by lactose, which acts as a source of energy.

The milks of most eutherian species contain lactose as the dominant saccharide. The concentration of lactose changes over the lactation period. In general an increase is observed in early lactation, after which it may stay stable or decrease slightly over a prolonged time. In the milk of the African elephant, a steady decrease is observed. The highest lactose concentrations (5–9%) are found in the milk of primates, Perissodactyla, and some ruminants; intermediate levels (3–5%) in Chiroptera and Rodentia; and very low levels in Pinnipedia, Cetacea, bears, monotremes, and marsupials. Great variation in lactose content is observed among, as well as within, the Carnivora families. This has best been demonstrated for the felines, where the milk lactose of the lion was determined as 3.6%, of the cheetah 4.0%, and of the serval 6.9%.

In monotremes and marsupials, the lactose content is low, but the oligosaccharide content is high (2–12%) owing to the preferred synthesis of oligosaccharides over lactose, because of the absence of α-lactalbumin. Milk of eutherian species also contains oligosaccharides, the varying amounts of which have a phylogenetic relationship. Elephant milk contains up to 2.6% oligosaccharides, which decrease over the lactation period to around 1%. This decrease is surpassed by the decrease of lactose; so oligosaccharides become the major saccharide fraction during later lactation. Human and other hominid ape milks contain substantial amounts of oligosaccharides. Human colostrum and mature milk contain 2.2–2.4% and 1.2–1.3% oligosaccharides, respectively, while in gorilla milk, 0.7% was detected. The milks of other anthropoids which have been analyzed for oligosaccharides – Hylobatidae, Cercopithecidae, and Cebidae – contain less than 0.1% of these sugars. Ruminant milks, in general, contain 0.1% oligosaccharides or less, although 0.4% has been recorded for the sable antelope.

Bears are exceptional among eutherian species, as their milk contains little lactose and a relatively high concentration (2–3%) of oligosaccharides. Among the Pinnipedia, it was found that milk of the hooded seal, a phocid pinniped, contains small amounts of lactose together with oligosaccharides, while those of the Australian and northern fur seals and Californian sea lion, otariid pinnipeds, contain no saccharides. In the latter group, saccharides are not being synthesized; this is due to the absence of α-lactalbumin, which is not expressed. In these species the nutritional role of lactose has been lost, and lactose has been replaced by fat as the energy source.

Phylogenetic relationships are observed not only in the amounts of oligosaccharides in milk, but also in their structure. The oligosaccharides may consist of 3–10 monomeric units, and their structures may be linear or branched. Phylogenetic comparison shows that oligosaccharides in the milk of marsupials are represented by three structural groups, one of which consists of sialyl oligosaccharides, which have two *N*-acetyllactosamine

(Gal(β1-4)GlcNAc) branched units, while a second one consists of β(1-3)Gal sequences. Some of the oligosaccharides are found exclusively in marsupial milks.

In the milks of eutherian species, the oligosaccharides are divided into 12 groups. Phylogenetic differences in the occurrence of oligosaccharides have been noted. Further, the exclusive occurrence of certain oligosaccharides in some species has been noted, although this exclusiveness seems to become less as more species are being studied. A great number of oligosaccharides and chain types seem to be present in most milks, but a specific difference between human and other eutherian species is notable. In human milk oligosaccharides containing the type I chain (Gal(β1-3)GlcNAc) are more prominent than those containing the type II chain (Gal(β1-4)GlcNAc), whereas the milks of some other species, including some great apes, may even contain only the type II chain oligosaccharides.

The knowledge gained thus far shows that milk saccharides play a role not only in the provision of energy, but also in protection. It seems the need for the latter role differs between species, inferred from the amounts of saccharides present in the milk, as well as the oligosaccharide chain types. In humans, the oligosaccharides act as prebiotics to promote the establishment of beneficial intestinal bacteria, lactobacilli and bifidobacteria. The oligosaccharide structures are similar to glycoconjugates on the surface of gastrointestinal cells to which pathogenic organisms may attach. When the free milk oligosaccharides bind to the pathogens, attachment is prevented. It is suggested that lacto-*N*-tetraose, as well as fucosylated oligosaccharides, specifically promotes the establishment of bifidobacteria in the human intestine. Since oligosaccharides in general, and fucosylated oligosaccharides in particular, occur at low levels, and lacto-*N*-tetraose is absent in the ruminant milks consumed by humans, they cannot provide the same protection to human infants. One of the aims of improving dairy products is therefore enrichment with prebiotic oligosaccharides, and finding sources of oligosaccharides other than milk that can fulfill the role of the natural product.

Conclusion

The composition of the milk of each species is complex and unlikely to be duplicated. This uniqueness in composition stems from evolutionary development and adaptation to provide nutrients and protection for the offspring as demanded by the circumstances experienced by each species. Regarding proteins, lipids, and carbohydrates, the most unique properties may perhaps be observed in the following examples. Milk of the Equidae contains a very low level of κ-casein. Elephants (Proboscidae) produce most of their milk fatty acids by *de novo* synthesis of medium-chain length, which may reach levels of up to 90%, the contents of which change drastically over the lactation period, independent of the diet. Milks of monotremes and marsupials, and of eutherians, the bears and seals, contain very small amounts of lactose due to the absence of α-lactalbumin, but high levels of oligosaccharides for protective purposes.

If one or more of these properties were characteristic of the milk of the known domestic species, the impact on technological aspects would have been severe. Without κ-casein, such as in the Equidae, milk does not coagulate on renneting or forms a very weak curd. Without lactose, as in monotremes, marsupials, bears, and seals, fermentation is not possible. Milk fat with high levels of medium-chain fatty acids, as found in elephant milk, would not only affect the taste of dairy products, but would govern melting properties, which in turn affect mouthfeel. With this in mind it seems to be a real coincidence that, from all the wild animals, the most docile milk-producing species that were employed in agriculture produce milk with the best properties for multipurpose processing! Furthermore, cow's milk butterfat was used as model for physical properties to be achieved by chemically modified vegetable fats!

With regard to the foster milk used for human nutrition, the milk of the domesticated species lacks sufficient amounts of oligosaccharides for protection against pathogenic microorganisms in the intestine. Species such as bears, elephants, and the great apes can shed more light on this theme.

Differences in nutrient composition of milk among species mainly show a shift of one source of energy to another or one source of protective mechanism to another. However, it is not yet understood why a great change in fatty acid composition over lactation period, in favor of shorter *de novo* synthesized fatty acids, is observed only in the Perissodactyla and Proboscidae and not in other monogastric mammals, and what the nutritional benefit of such change is to the lactating mother or the suckling young.

Milk of Monotremes and Marsupials

Introduction

Lactation has evolved from an ancient reproductive strategy that appears to have been there long before the evolution of extant mammals. The ability to lactate is a feature found only among mammals and involves a facet of maternal care where mothers secrete nutrient-rich milk, which is delivered to the young by the mammary gland. Evolutionary studies indicate that lactation was established prior to the divergence of extant mammalian lineages. It also seems that lactation arose long before gestation. Secretions of ancestral mammary glands may have had antimicrobial properties that protected either the eggs or the hatchlings and contained organic components that supplemented offspring nutrition. Over the course of evolution, lactation became a highly efficient, effective, and adaptable means of providing maternal care for neonates. The evolution of a placenta in eutherian mammals resulted in more extensive intrauterine development of an embryo, and the ability to lactate after giving birth became a critical part of the reproductive strategy of mammalian species. Following the development of highly nutritious milks, evolution produced diversity in milk composition and function, quantity of milk output, length of lactation period, length of intervals between nursing, and contributions of lactation to offspring nutrition.

Monotreme Reproduction and Lactation Strategy

Monotremes diverged from therians ~231–217 million years ago in the Middle or Late Triassic. Consequently, monotreme milk may be regarded as an ancestral form of milk and may be used to trace the progenitors of the better-characterized marsupial and eutherian milk protein genes to provide insight into the evolution of function of these proteins. Living monotremes are classified into three genera confined to the Australian region: *Ornithorhynchus* (represented only by the duck-billed platypus) and the echidna genera, *Tachyglossys* and *Zoglossus* (two species found in Australia). *Ornithorhynchus* is confined to the Australian subcontinent. Monotreme young are born from small eggs covered by a leathery shell, and the tiny hatchlings are highly altricial. Monotreme young are completely dependent on milk as their source of nutrition, and the period of suckling is prolonged relative to gestation and incubation. A large amount of development of the young occurs during the suckling period.

Some characteristics of monotreme lactation are suggested to be ancestral to extant mammals, with marsupials and eutherians later evolving divergent lactation strategies. Extant monotremes, *Ornithorhynchus anatinus* (duck-billed platypus), and *Tachyglossys aculeatus* and *Zoglossus bruijni* (echidna genera), are the only mammals that begin early developmental stages in an external egg (echidna 14–15 mm; platypus 16.5 mm × 15 mm) covered by a soft leathery shell, which is incubated outside the mother's body.

Eggs are carried by mothers in an external skin flap or pouch where pouch secretions are predicted to keep eggs moist and protected against bacterial infection. The small and altricial hatchlings emerging from the eggs are completely dependent on milk as the sole source of nutrition during the suckling period and undergo a significant amount of development during this stage (**Figure 1**). Thus, monotremes invest only minimally in development in gestation in comparison with development during lactation, exchanging the placenta as the path of nutrition and developmental signals for milk during lactation. Relative to gestation, the lactation periods in echidnas and platypus are extensive and are characterized by intermittent suckling lasting up to 200 days and at least 120 days, respectively. In contrast to the tammar pouch young, which remains attached to the teat for the first 100 days post-partum, monotreme young suck from the areolae, as teats are absent in all monotreme species. In monotremes, glands appear as paired structures consisting of discrete elongated lobules that fan out as oval clusters beneath the skin, where they are surrounded by connective tissue. Ducts connecting to the glands open on specialized skin patches, areolae, with a well-defined structure. Despite monotremes lacking a nipple, monotreme young exhibit true sucking behavior.

Marsupial Reproduction and Lactation Strategy

Marsupials diverged ~193–186 million years ago in the Early Jurassic Period. The reproductive strategy of marsupial differs from that of monotremes; they give birth to an altricial young that emerges from the uterus. Similar to

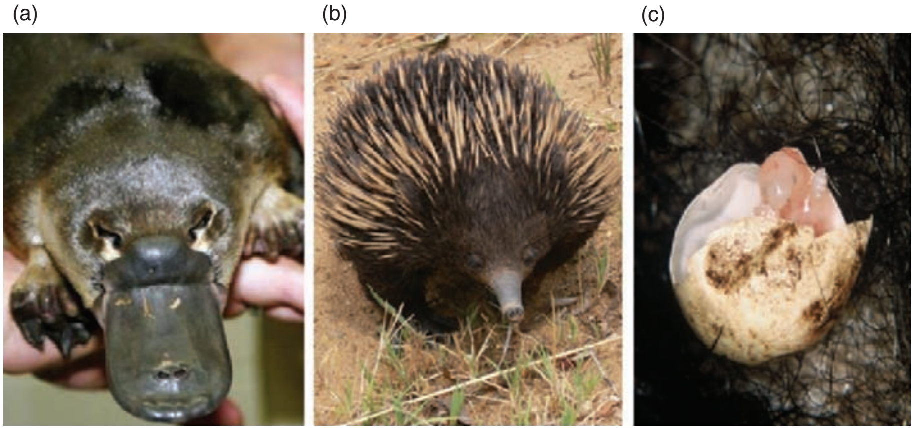

Figure 1 Reproductive strategy of the monotremes. The platypus (a) and echidna (b) lay eggs. Young hatch in a highly altricial state (c) and rely solely on milk as a source of nutrition and for developmental cues.

monotremes, marsupials rely solely on milk as the source of nourishment for the young during a long lactation period (up to 300 days, depending on the species). Much of the work on marsupial lactation has been performed using the tammar wallaby (*Macropus eugenii*) as a model. Many of the features of the tammar lactation cycle are present in other marsupials such as brushtail possums (*Trichosurus vulpecula*), eastern quolls (*Dasyurus viverrinus*), northern bandicoots (*Isoodon macrourus*), potoroos (*Potorous tridactylus*), red-necked wallabies (*Macropus rufogriseus banksianus*), Tasmanian bettongs (*Bettongia gaimardi*), and North American opossums (*Monodelphis domestica*). Like the offsprings of all other marsupials, the tammar wallaby pouch young is born altricial and relies solely on the mother's milk for growth and development during the initial 200 days of its life (**Figure 2**). During this long lactation period, the milk composition changes progressively to meet the developing nutritional requirements of the young.

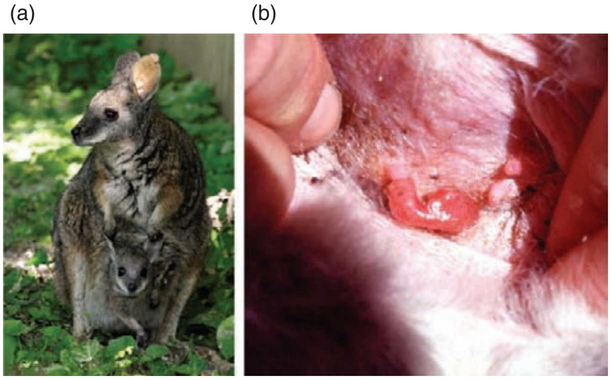

Figure 2 Reproductive strategy of the tammar wallaby. The tammar wallaby (a) gives birth to a highly altricial young (b) which climbs into the pouch, attaches to the teat, and remains there for a further 200 days during the lactation period, where it receives nutrition and developmental signal supplied in the milk.

Lactation in the tammar wallaby is divided into three main phases and was first characterized by suckling stimulus (**Figure 3**). Phase 1 comprises a 26- to 27-day gestation period, followed by birth of the altricial pouch young. The subsequent 100-day period (phase 2A) is characterized by lactogenesis and the secretion of dilute milk. During this phase the young is permanently attached to the teat. During phase 2B the young relinquishes the teat, sucking intermittently and less frequently for an additional 90–100 days. Phase 3 commences at about day 200 when the young begins periodically exiting the pouch, sucking less frequently but more vigorously. At this stage the young begins the consumption of herbage as well as milk.

Composition of Monotreme and Marsupial Milk

The amounts of total solids in both monotreme and marsupial milks (12%) at the time of hatching and birth, respectively, are much lower than that in mature milk (30–55%). Comparative studies have revealed marked differences between species and between mammalian subclasses in the quantity and combination of milk constituents. However, such studies also indicate that different milks exhibit a number of common features, which include lipid globules that consist largely of triacylglycerols, casein phosphoproteins, some whey proteins, and carbohydrates. The most marked difference between these groups is in the progressive changes in milk composition during the lactation period. Eutherians have a longer gestation relative to their lactation period and produce milk of a relatively constant composition after the expression of the initial colostrum, whereas marsupials such as the tammar wallaby have a short gestation and give birth to a highly immature young. This is

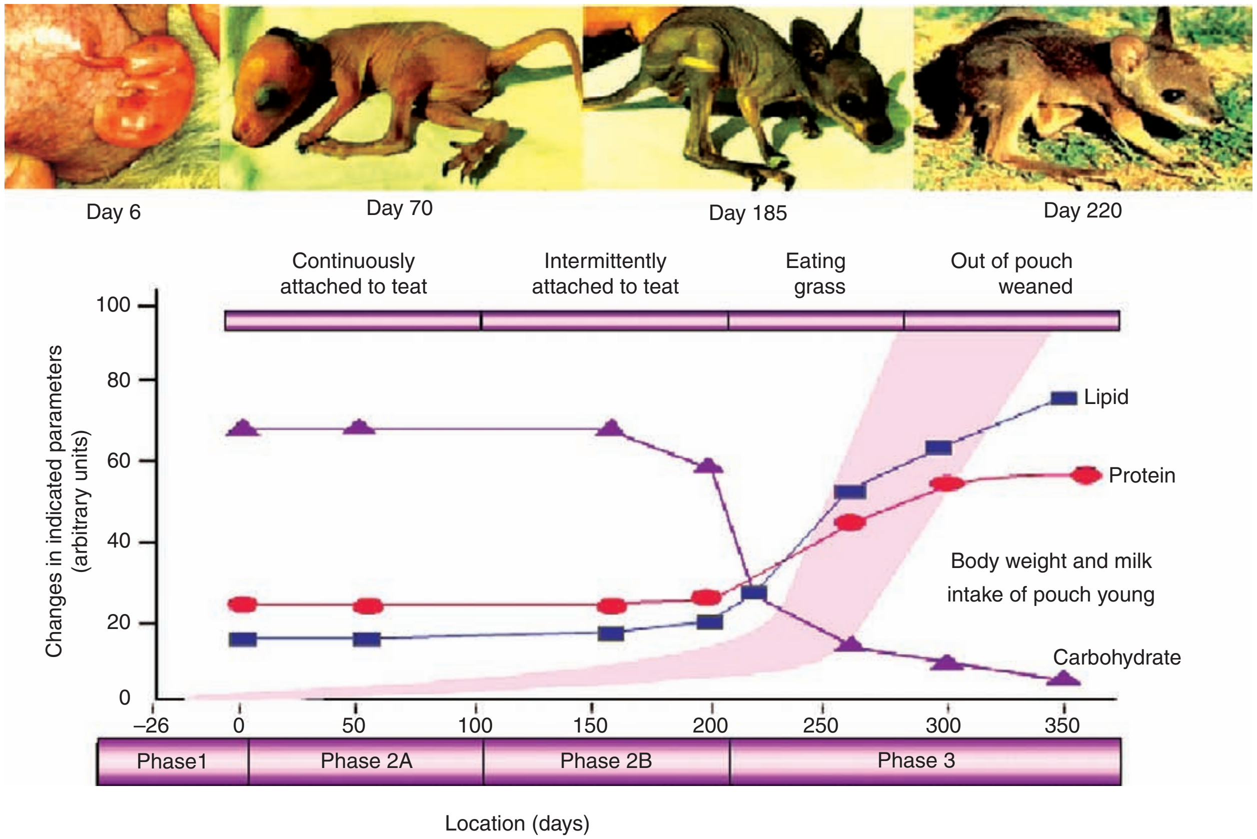

Figure 3 Lactation strategy of the tammar wallaby. The top panel shows the developmental stages of the pouch young throughout lactation. The bottom right panel represents the profile of milk composition – carbohydrate, protein, and lipid – across the long lactation period.

followed by a long lactation during which milk production changes progressively in composition to suit the needs of the developing young. Tammar wallaby milk produced in early lactation (phases 1 and 2) shows an enrichment of complex carbohydrates, which is the nutrient most easily utilized by the undeveloped young, and low concentrations of proteins and lipids. As the young becomes endothermic later in lactation (phase 3), the mother's milk composition changes markedly to become a highly concentrated source of energy. There is a sharp decrease in carbohydrate levels, which also changes to monosaccharides, and an increase in protein and lipid, which together become the major components of the milk (**Figure 3**). This milk is similar in composition to that of eutherian mammals, and thus the transition from marsupial lactation phase 2B to 3 has been described as equivalent to eutherian lactation. For example, milk production increases with a corresponding increase of the young's milk intake and weight gain, which is similar to weight gain in the eutherian neonate. Thus, the milk of phase 3 is suited to assisting maximal growth of the young, whereas the characteristics of phase 2 milk, unique to marsupials, are ideal for maximal physiological development of the young, and limited growth.

Like marsupial milk, echidna milk also changes in composition over the lactation period, but platypus milk remains unchanged. Very little is known about the changes in composition of monotreme milk, which has not been studied as extensively as milk from marsupials such as the tammar wallaby.

Milk Carbohydrate

The main carbohydrate in mammalian milk is generally the disaccharide lactose (Gal(β1-4)Glc), which is synthesized in the lactating mammary gland from UDP-Gal (donor) and Glc (acceptor) by a transgalactosylation catalyzed by the lactose synthase complex comprised of β-1,4galactosyltransferese (β-1,4GalT) and α-lactalbumin (modifer). The modifying action of α-lactalbumin lowers the K_M of β-1,4GalT for glucose 1000-fold and changes β-1,4GalT's acceptor from GlcNAc to Glc.

When lactation commences in phase 2A of the tammar wallaby lactation cycle, carbohydrates are the primary energy source for the tammar young. During the first 5 days of lactation in the tammar the major carbohydrate is lactose, but by about day 6 this disaccharide is replaced by complex oligosaccharides, and this remains so for the remainder of phase 2. It is likely that at birth the young's gut does not express the appropriate enzymes to break down complex oligosaccharides; hence disaccharides are present in the milk immediately post-partum. Presumably, the complex oligosaccharides are utilized as energy source more efficiently than is lactose, without significantly increasing the osmolarity of milk. Oligosaccharides have also been shown to have numerous bioactivities, particularly in the development of the neonate. The presence of complex oligosaccharides in milk at this stage of lactation may therefore also be beneficial to the development of the young. Formation of the complex oligosaccharides occurs owing to the catalytic action of galactosyltransferases, including β-1,3 galactosyltransferase (β-1,3GalT), which uses lactose as an acceptor for galactose and appears to be active in the mammary gland only during phase 2.

At the transition to phase 3, β-1,3GalT activity declines, resulting in the loss of complex oligosaccharides. At this stage of lactation only monosaccharides are secreted into the milk; the lactose synthesized with UDP-galactose by β-1,4GalT and α-lactalbumin complex is hydrolyzed to monosaccharides following the induction of β-galactosidase. In addition, the total carbohydrate concentration decreases, most likely owing to a high UDP-galactose hydrolase activity in phase 3 mammary tissue. UDP-galactose hydrolase cleaves UDP-galactose, the substrate for lactose synthesis. Thus, even though β-1,4GalT activity is vital for the formation of lactose (a simple sugar and building block for oligosaccharides), the composition of the complex carbohydrates is controlled largely by the transient activity of galactosyltransferases such as β-1,3GalT in phase 2 of lactation.

Studies have shown that oligosaccharides very similar to or identical with those found in tammar wallaby milk are present in the milk of all other marsupials so far studied, including the milks of red-necked wallaby and several nonmacropod marsupials such as the eastern quoll, brushtail possum, and the American opossum. The available evidence thus strongly suggests that the presence of high concentrations of a variety of oligosaccharides, and low concentrations of free lactose, in their milk is characteristic of marsupials.

The carbohydrate content of monotreme milk is distinguished from that of both marsupial and placental mammal milks by its high fucose content. It is therefore likely that suckling monotremes, unlike the sucklings of other mammals, utilize fucose as an energy source, or that fucose has an unknown specific biological significance for these animals. The principal neutral carbohydrates of echidna and platypus milks are a trisaccharide, fucosyllactose, and a tetrasaccharide, difucosyllactose, respectively. Studies have also shown that platypus milk contains low concentrations of other oligosaccharides and echidna milk contains sialyllactose, characterized by the unique presence of an *O*-acetyl group at C-4 of its Neu5Ac residue. Monotreme milk also differs from other milks in lactose content. Free lactose is found only in small amounts in both monotreme species. This is most likely due to very low concentration of α-lactalbumin in the milk compared with the concentrations of α-lactalbumin in the milks of other species. The main oligosaccharide (50%) in monotreme milk is 4-*O*-acetyl-α-*N*-acetylneuraminyl-(2-3)-lactose.

There is no evidence for quantitative or qualitative changes in milk carbohydrates in echidna and platypus during the course of the lactation season, except for a small decline in total hexose toward the end of lactation in platypus.

Lipids

Major quantitative and qualitative changes in milk lipids occur during lactation in marsupials. The crude lipid content of the milk is relatively low at the beginning of lactation and increases gradually, but toward late lactation it increases rapidly. The triglyceride fraction of the lipid at early lactation contains a large amount of palmitic acid and relatively little oleic acid, whereas mature milk contains little palmitic and more oleic acid. Very little is known about the lipid content of monotreme milk.

Milk Protein

The protein composition of tammar milk changes considerably during the lactation cycle (**Figure 4**). Protein levels are low during phase 2 of lactation, but increase dramatically in an inverse relationship with carbohydrate during phase 3. Though many of the milk proteins are common to eutherians and marsupials, a number of whey proteins appear to be novel to marsupials. Marsupial milk protein secretion has been studied primarily in the tammar and the possum, which practice similar reproductive patterns. In the tammar, some milk protein genes are induced at parturition and expressed consistently during the entire lactation, whereas some other milk protein genes are asynchronously expressed throughout lactation (**Figure 5**). At parturition there is a coordinated induction of the genes encoding β-casein, α-casein, α-lactalbumin, and β-lactoglobulin (BLG). Early-lactation protein (ELP) gene is induced at parturition and is downregulated during the transition to phase 2B when whey acidic protein (WAP) gene expression is induced. During the transition from phase 2B to 3, there is an increase in total milk protein and there is also a considerable change in protein composition. During this phase the *WAP* gene is downregulated, and late-lactation protein-A (LLP-A),

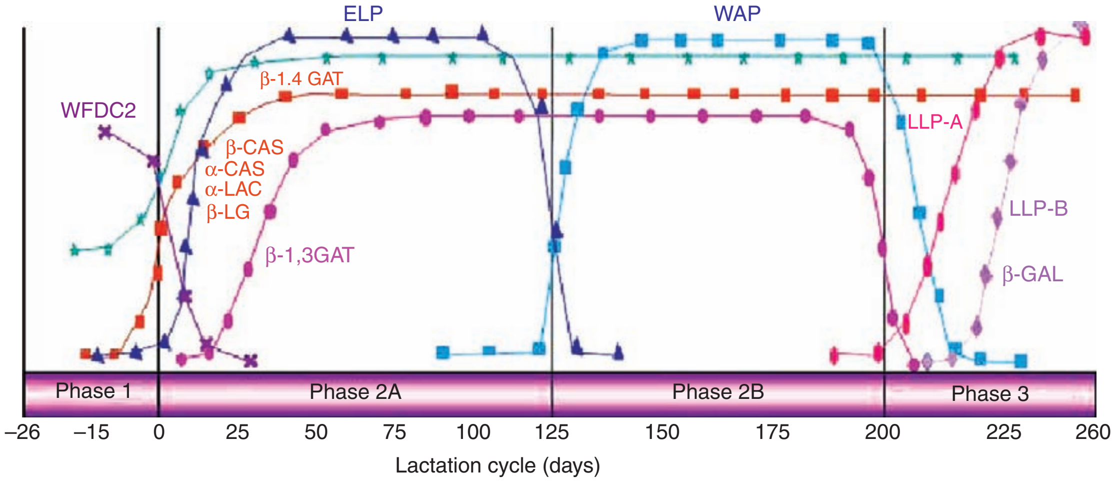

Figure 4 Milk protein gene expression during the lactation cycle. Profile of tammar milk protein composition across the lactation cycle showing changes in secretion of the major milk proteins α-casein (α-CAS), β-casein (β-CAS), α-lactalbumin (α-LAC), and β-lactoglobulin (β-LG), early-lactation protein (ELP), whey acid protein (WAP), late-lactation protein-A (LLP-A), and late-lactation protein-B (LLP-B) corresponding to the major phases of milk secretion.

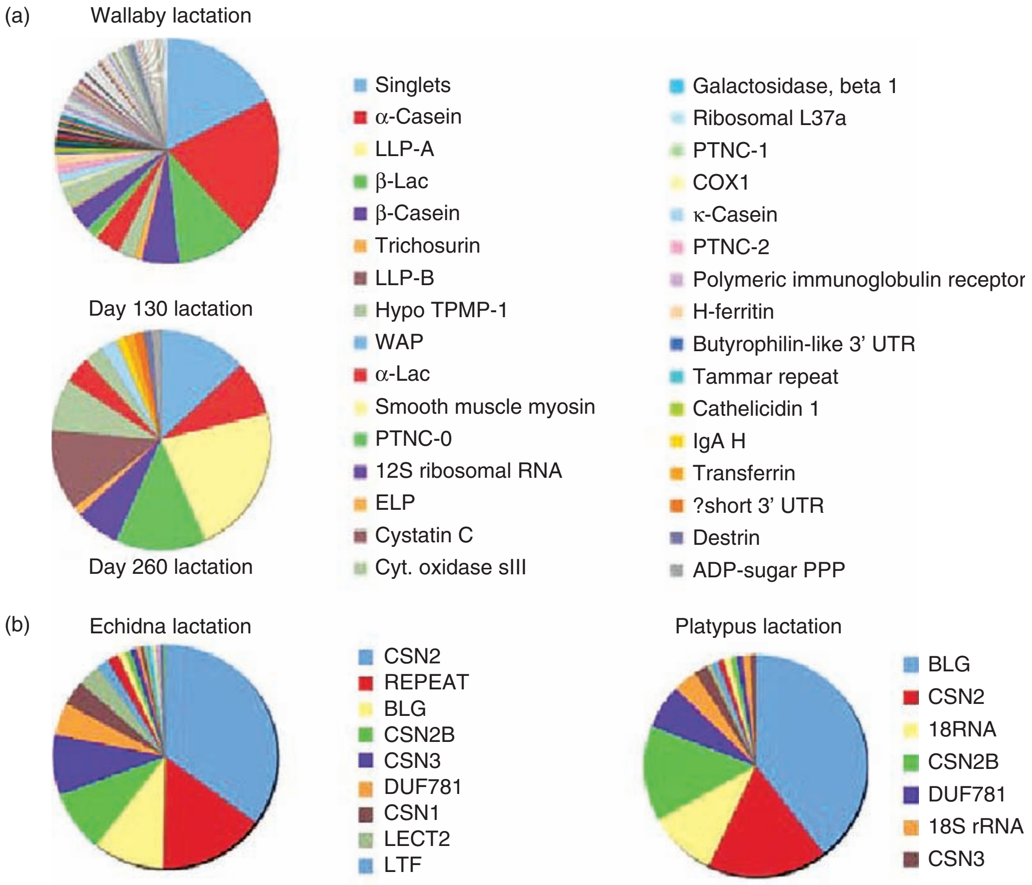

Figure 5 Transcriptome analysis of representative stages within the wallaby, echidna, and platypus lactation cycles. (a) The tammar wallaby mammary gland produces a wide variety of transcripts during lactation. At day 150 lactation (phase 2B) and day 260 lactation (phase 3), the mammary gland shows an abundance of major transcripts relating to the various stages of milk secretion. (b) The echidna and platypus milk cell transcriptomes show that the major milk protein transcripts, BLG, caseins, and lactoferrin, are abundant in the milk.

β-galactosidase, and lactoferrin are upregulated, and late-lactation protein-B (LLP-B) is induced. A similar profile of milk protein gene expression is reported in the possum, with the exception that no β-1,3GalT activity has been identified, and two of the phase 3 whey proteins, LLP and lactoferrin, are expressed transiently for 4–5 days post-partum.

The complete gene expression profile in the tammar wallaby mammary gland during the entire lactation period has been investigated by use of a comprehensive set of cDNA libraries derived from lactating tissues throughout the lactation cycle. A total of 14 837 express sequence tags (ESTs) were produced by cDNA sequencing and analysis. Sequence assembly was used to construct a comprehensive catalog of mammary transcripts representing about 25% of the tammar genome. This analysis enabled the construction of a comprehensive list of 213 secreted milk proteins produced by the tammar mammary gland and reiterated the known changes in milk protein gene expression between the different stages of lactation (**Figure 5(a)**). This analysis also revealed a number of potential new milk proteins including PTMP-1, a predicted 132- amino acid protein, which appears to be highly specific to the tammar, as no similarities could be found in the opossum or other available genome sequences, and PTMP-2-GlyCAM, a protein with no clear similarity to any known proteins except for a predicted glycosylation-dependent cell adhesion motif.

The transcriptome of monotreme milk cells, harvested from the milks of the echidna and platypus, has also been studied recently, revealing a partial set of milk protein genes (**Figure 5(b)**). Analysis of the casein genes from these monotremes revealed the presence of a second β-casein gene, which suggests that a recent duplication of β-casein has occurred in the monotreme lineage. In the monotreme it appears that the most abundant milk protein is BLG, whereas in the wallaby, generally the caseins appear more abundant (depending on the phase). Interestingly, BLG is also the major whey protein in ruminant milk, but its function remains unknown.

Immune-Related Proteins

The immunological significance of milk is a well-studied area in eutherians. Immunoglobulins are usually secreted in high amounts in colostrum of eutherians. These immunoglobulins may be absorbed by the eutherian neonate's gastrointestinal system and may be transferred into their circulation in some species, thus providing passive immunity. This absorption is limited by the time taken for the gastrointestinal system's epithelium to close, which ranges from 24 h in some ungulates to up to 19 days in rodents. Immunoglobulin levels in marsupial milk are much lower than those seen in eutherian milk. However, in marsupials absorption of immunoglobulins, other proteins, and possibly cells in the milk continues throughout the entire lactation period. Consequently, marsupials must rely upon more efficient uptake and different immunoglobulin isotypes to help meet the immunological challenges of the young. Evaluation of the expression of immunoglobulin genes in the tammar mammary gland throughout lactation suggests that there are two periods of increased expression of immunoglobulin genes corresponding to two periods of immune transfer to the young. This has also been observed in the brushtail possum lactation cycle. These periods of immune transfer coincide with the periods of greatest immune challenge for the pouch young, which include the periods following parturition and leaving the pouch. Immunoglobulins and other immune components such as the neonatal Fc alpha receptor (FcRn) and the iron regulatory proteins ferritin and transferrin in the brushtail possum are transferred at this time. Consequently, differential regulation of expression of immune components in the mammary gland may help the marsupial neonate to survive periods of immune stress though still being relatively immunocompromised.

Proteins known to be associated with immunological protection of the pouch young have also been identified across all phases of tammar lactation. A total of 14 proteins, detected by proteomics studies, were identified and were proposed to play a role in host defense, whilst a number of other proteins had proposed secondary roles in immune protection. An important immunological protein, cathelicidin, is expressed in tammar milk from day 0 to 137. Cathelicidins are small peptides (<50 amino acids) that share a conserved precursor peptide sequence, although the mature peptide can vary enormously in sequence, length, and secondary structure. Cathelicidins are important in mucosal defenses in both adults and infants owing to their antimicrobial and immunoregulatory roles and play a role in host defense as effector molecules and as modulators of innate immunity. Antimicrobial peptides, such as cathelicidin, are an evolutionarily old defense system. However, they have more complex actions than just simply their antimicrobial effects, which include immunoregulation and interaction with the adaptive immune system. A total of seven novel tammar cathelicidin peptides have been identified from the tammar mammary gland, reflecting the ability for diverse immune and antimicrobial protection provided by milk.

Few immune-related proteins have been identified in monotreme milk. However, transcript analysis of echidna milk cells by Sharp and Nicholas has suggested that echidna milk contains LECT2, a protein that has previously been shown to be associated with the acute-phase response of the innate immune system, and polymeric immunoglobulin receptor (PIGR), a protein that plays a major role in the transport mechanism of IgA and IgM.

The presence of these proteins suggests that like marsupial and eutherian milk, monotreme milk also plays a role in immune protection of the young.

Egg Proteins

A plausible hypothesis has suggested that mammary secretions originated to provide moisture and nutrients to hatchlings of monotremes, allowing a progressive decline in egg size, which was accompanied by the young hatchlings becoming more altricial. This hypothesis can be extended to include the possibility that ancient mammary secretions may have resembled egg white, enabling hatchlings to emerge from the egg at an earlier stage without compromising on consumption of nutrients or growth factors. Analysis of ESTs within echidna and platypus milk cells shows that ovostatin-2 (OVOS2), a minor protein present in avian egg white, is secreted by these cells into milk and gives support to this hypothesis.

Biological Activity of Milk

Milk not only does provide nutrition to the suckling young, but also has a more comprehensive role in programming and regulating growth and development of the suckling young, and an autocrine impact on the mammary gland so that it functions appropriately during the lactation cycle. Many of the tammar wallaby genes encode secreted proteins that are differentially expressed at specific phases of lactation and have a variety of bioactivities. Many studies have shown that the progressive changes in the milk profile across the long lactation are necessary to meet the nutritional needs of the growing pouch young, making the tammar wallaby a unique model to study the role of these proteins. Indeed, cross-fostering experiments in which younger pouch young at day 60 were fostered onto mothers secreting milk at day 120 of lactation, suggesting that the tammar milk may contain factors that dramatically accelerated growth of the fostered pouch young.

Identification of potential bioactives has been possible in the tammar wallaby by interrogation of the tammar EST database and microarray data to identify cDNAs coding for proteins that contained a signal peptide. This approach identified 75 novel genes that were differentially expressed during different phases of lactation and therefore had the potential to have different bioactive properties. To determine the functional significance of these genes, individual proteins encoded by each cDNA were synthesized *in vitro* and subsequently shown to have activity for immune modulation, inflammatory responses, growth, and differentiation effects. Some of these synthesized proteins showed a capacity to alter the development of mammospheres – a culture model that employs primary mammary cells to generate three-dimensional (3D) structures that functionally and morphologically resemble the secretory unit of the mammary gland – by increasing the size of the mammospheres and the rate of mammosphere formation. This raised the possibility that these milk proteins may contribute to growth and function of the mammary gland during lactation.

Tammar milk has also been observed to affect the gut maturation of the young. The normal stomach is lined with a self-renewing epithelial monolayer that is organized into pit/gland units, and each pit/gland contains a heterogeneous population of cells that originate from the stem cells the cytodifferentiation of which is influenced by factors from the external milieu. In the tammar wallaby, it has been reported that dramatic changes in stomach tissue morphology take place during the suckling period. Changes in fore-stomach morphology during the development of tammar wallaby have been correlated with significant changes in milk composition, raising the possibility that these processes may be regulated by specific milk components. In a recent study, tammar wallaby pouch young at day 120 were cross-fostered to host mothers at day 170 of lactation. In the fore-stomach of the fostered pouch young, the parietal cell population was significantly reduced and the expression of gastric glandular phenotype markers (*ATP4A*, *GKN2*, *GHRL*, and *NDRG2*) downregulated, suggesting downregulation of the gastric phenotype. However, the expression of cardia glandular phenotype genes (*MUC4*, *KRT20*, *CSTB*, *ITLN2*, and *LPLUNC1*) was not affected. There was also an increased apoptosis, but no change in cell proliferation. These data suggest that fore-stomach maturation is driven by milk composition and proceeds via two temporally distinct processes: downregulation of gastric glandular phenotype and initiation of cardia glandular phenotype. In the fostered pouch young, these two processes appear uncoupled, as gastric glandular phenotype is downregulated, but cardia glandular phenotype is not initiated. It remains to be determined what factors regulate these two apparently distinct processes.

Functions of milk proteins such as BLG and WAP have remained obscure; however, the divergent nature of *WAP* gene structure and expression profile across various monotreme, marsupial, and eutherian species suggests that the protein is still evolving. In some species such as marsupials, monotremes, and specific eutherians, WAP is a major whey protein, whereas it is completely absent in others species such as ruminants. In eutherians that express *WAP*, the protein is produced consistently throughout lactation; in contrast, *WAP* is expressed only transiently during the lactation period of the tammar. Its presence in the milk of other marsupials such as the brushtail possum, red kangaroo, and stripe-faced dunnart, which also demonstrate significant changes in milk composition during lactation, suggests that in these species it may be regulated in a similar way as in tammar. Although the amino acid sequences of WAP from the two monotremes, platypus and echidna, have also been reported, the pattern of secretion in these species is yet to be established. The transient expression pattern of *WAP* in the tammar suggests that it may either play a role in development of the mammary gland or influence development in the young.

The WAP proteins identified from all species show moderate sequence similarity at the amino acid level and contain a signal peptide and a varying number of four-disulfide core (4-DSC) domains, which are characteristic of the Kunitz family of protease inhibitors. The Kunitz family has over 150 members that contain from one to three 4-DSC domains. Although a large functional diversity exists between these proteins, typically the 4-DSC domain is associated with protease inhibitor activity. The families of proteins containing these domains are grouped according to tissue specificity and functions, such as serine protease inhibitors, pancreatic trypsin inhibitors, inter-alpha-trypsin inhibitors, elastase inhibitors, chymotrypsin inhibitors, and hepatocyte growth factor activator inhibitors. However, WAP has not been shown to possess any of these properties.

Interestingly, the number of 4-DSC domains differs between eutherian, marsupial, and monotreme WAPs. Eutherian WAP encodes two 4-DSC domains, designated Domain I and Domain II (DI-DII). WAP DI has a characteristic SSSE sequence, which is conserved in most species and is absent in DII. Marsupial WAP encodes an additional 4-DSC domain, designated Domain III (DIII), at the N-terminus of the WAP protein, so that the domain structure has the configuration DIII-DI-DII. Monotreme WAPs also encode the DIII; however, there is limited similarity within the other domains. Echidna WAP has the structure DIII-DII, whereas platypus WAP has the structure DIII-DII-DII (**Figure 6**).

In mice, WAP has been implicated in alveolar development and has been shown to impair the proliferation of mouse epithelial cells and mammary tumor cell lines *in vitro* by inhibiting cell cycle progression. The inhibitory action of WAP on the proliferation of mouse epithelial cells was also demonstrated to be enhanced by the presence of extracellular matrix. This is consistent with studies showing that over-expression of WAP in transgenic mice inhibits development of the mammary gland and secretion of milk. In contrast, in studies at Deakin University laboratory, Geelong,VIC, Australia, using full-length tammar WAP and DIII added to culture media stimulated proliferation of tammar mammary epithelial cells. In addition, WAP increases expression of the cell cycle genes cyclin D1 and CDK-4, stimulates DNA synthesis in primary cultures of mammary epithelial cells, and promotes *in vitro* growth of 3D alveoli-like structures (or mammospheres), which mimic *in vivo* mammary gland development and function. These studies also showed that this stimulation is entirely due to the presence of the third tammar WAP domain (DIII), which is absent in eutherian *WAP* genes. Earlier studies have shown that DNA synthesis in the tammar mammary gland is higher in phase 2 than in phase 3, which is consistent with a potential role of tammar WAP in the development of the mammary gland. As tammar WAP is a major milk protein secreted during the middle third of lactation when the pouch young's diet comprises only milk, it could be speculated that this protein plays a specific role in the development of both the mammary gland and the suckling young at this time. Interestingly, studies in *WAP* knockout mice have demonstrated that the expression of the *WAP* gene is not required for alveolar specification and functional differentiation, and is dispensable as a protease inhibitor to maintain the stability of secretory proteins in milk. This study, however, found that pups failed to thrive in the second half of lactation, suggesting that WAP may be essential for the adequate nourishment of the growing young. From the above-mentioned studies it is clear that marsupial WAP and eutherian WAP have quite different roles in milk; the role of WAP in monotreme milk is yet to be determined. However, WAP is not found in all eutherian milk; it is absent in the milks of cows, sheep, and humans. The role of WAP in milk is therefore species specific, and it appears that this role is dispensable in some species. As a consequence, it has been postulated that the WAP protein is slowly being lost during the process of evolution in eutherians.

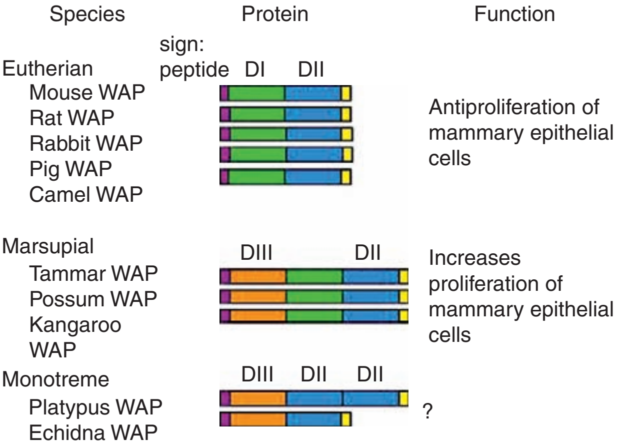

Figure 6 The diverse structure and function of eutherian, marsupial, and monotreme WAP proteins. Eutherian WAP contains two domains, whereas the marsupial and monotreme WAPs contain three domains. The difference in protein domain structure has been shown to account for the difference in WAP function between lineages.

Autocrine Factors in Milk

Milk-borne factors involved in the control of mammary gland function have been reported in a number of species, including the tammar wallaby. There is increasing evidence to suggest that milk plays an important role in regulating mammary epithelial function and survival, and this is particularly evident during involution. For example, apoptosis has been induced preferentially in the sealed teats of lactating mice, whereas the litter suckled successfully on the remaining teats, indicating that cell death is stimulated by an intramammary mechanism sensitive to milk accumulation. A protein known as feedback inhibitor of lactation (FIL) has been identified in the tammar wallaby as well as in a number of domestic species including cows, goats, and rabbits, and is thought to control milk production by responding to the frequency and completeness of milk removal, acting specifically through interaction with the apical surface of the mammary epithelial cell to reduce milk secretion.

Recent studies using small pieces of mammary tissue maintained in culture, known as the explant culture model, have confirmed a role for milk in the process of involution showing that milk directly acts on the mammary tissue during involution. Mammary explants from pregnant tammar wallabies were cultured with lactogenic hormones (insulin, cortisol, and prolactin) to induce milk protein gene expression; subsequent removal of all hormones for 10 days downregulated the expression of the milk protein genes and mimicked involution. Surprisingly, the explants retained the same level of lactogenic response during a subsequent challenge with lactogenic hormones. The maintenance of epithelial cell viability and hormone responsiveness in explants cultured in the absence of hormones is consistent with the idea that accumulation of local factors in the milk is the primary stimulus for apoptosis of mammary epithelial cells in the tammar wallaby mammary gland. This model shows how hormones and mammary gland involution are uncoupled, and provides evidence for the extraordinary capacity for survival and maintenance of hormone responsiveness exhibited by mammary epithelial cells cultured in a chemically defined medium in the absence of exogenous hormones and growth factors.

The authors have recently identified an apoptotic role for another key milk protein, α-lactalbumin, which is proposed to regulate mammary function by causing apoptosis of the gland following milk stasis. We have already discussed the α-lactalbumin protein in relation to lactose synthesis; thus it appears that α-lactalbumin possesses dual functionality in the lactation process. Analysis of function shows that α-lactalbumin has apoptotic effects on a variety of mammary epithelial cells, including tammar wallaby mammary cells grown in cell culture, and acts to initiate mammary gland regression at the end of lactation. The tammar wallaby has an unusual α-lactalbumin expression profile. As previously discussed, the wallaby milk during peak lactation is devoid of lactose, but α-lactalbumin is secreted in wallaby milk at levels similar to those in other mammal milks throughout lactation. Examination of expression levels of the wallaby α-lactalbumin gene also revealed levels similar to those in other mammals such as pigs and mice during peak lactation. The wallaby, therefore, is a species that has uncoupled α-lactalbumin secretion and lactose production. The continued secretion of α-lactalbumin during wallaby lactation is predicted to be required solely for rapid initiation of mammary gland involution at weaning.

Conclusion

Milk production has evolved over the course of evolution. As such, milk has developed as the most efficient, effective, and adaptable medium for nutrient provision that has risen among vertebrates. Milk has played an important role in the worldwide adaptive radiation of mammals. It has conferred a primary advantage on mammals: the ability to reproduce and nourish their young in any environment that supports the health and well-being of the adult. Milks from species such as the marsupial and the monotreme, whose young rely solely on milk at a time when regulated development is paramount, provide useful insight into the function of milk.

Milk of Marine Mammals

The Origin and Evolution of Marine Mammal Lactation

Lactation is a diagnostic mammalian trait, involving the synthesis of a nutrient-rich secretion by specialized mammary glands. Since its initial evolution during the Mesozoic, perhaps more than 200 million years ago (mya), lactation has undergone profound evolutionary divergence among mammalian taxa, resulting in a diversity of lactation patterns characterized by major differences in milk composition, milk yield, suckling patterns, and duration of lactation. In comparison to terrestrial mammals, nearly all species of marine mammals, including seals (**Figure 1**) and whales, produce exceptionally rich milks high in fat and energy. For example, in the order Carnivora, the true seals (family Phocidae) typically produce milks that contain 48–60% fat, while dolphins and whales (order Cetacea) produce milks that typically contain 15–50% fat.

The species included as marine mammals do not form a single phylogenetic group but represent several distinct lineages that made the transition from terrestrial to marine life at different points in time. Given that seals, whales, and manatees are not closely related to each other, one would not expect them, *a priori*, to produce milks similar in composition. Any similarities that do occur represent convergent evolution.

The marine mammals include three major lineages. The dolphins and whales (order Cetacea) derive from the even-toed ungulates (order Artiodactyla). Genetic analysis indicates that the cetaceans are nested within the Artiodactyla, which is therefore sometimes termed the Cetartiodactyla, including cetaceans. The stem group of ancestral cetaceans, the 'Archaeocetes', appears in the fossil record from early to middle Eocene, 52–42 mya. Thus, the milks of cetaceans and other artiodactyls have diverged for at least 52 million years. Subsequently, two major groups of cetaceans, the odontocetes or toothed whales and dolphins, and the mysticetes or baleen whales, diverged about 35 mya. Among living mammals, the odontocetes are much more species-rich (71 species) than the baleen whales (13 species) and typically have longer lactations (**Table 1**). Among mammals, lactation duration typically increases in length with body mass, but the largest mammals of all, the large baleen whales, depart from this trend and have lactation durations of only 5–12 months, as compared to 1–4 years or longer in much smaller odontocetes. All cetaceans give birth in the water to single offspring, which nurse from nipples buried within mammary slits on the posterior abdomen. At least fragmentary data are available on the milk composition of 17 odontocete species and 8 mysticete species (**Table 1**).

A second lineage of marine mammals, the order Sirenia (manatees and dugongs), first appears as early and middle Eocene fossils from 50 mya, or shortly after the appearance of the 'Archaeocetes'. The herbivorous Sirenia are not closely related to either cetaceans or marine taxa of the Carnivora, but are rather nested within a group of African mammals known as the Afrotheria. Among living taxa, the sirenians are most closely related to the Proboscidea (elephants). The placement of the single pair of mammae in the axillary region (armpits) is distinctive. Although there are only four living species of Sirenia (three manatees and the dugong), another much larger species, the *c.* 4–10 tonne Steller's sea cow (*Hydrodamalis gigas*), grazed on algae in the North Pacific until discovered by Europeans in 1741 and then hunted to extinction by 1768. Apparently, milk was never collected from this 'sea cow'. Milk composition has been reported only for the West Indian manatee.

A third lineage of marine mammals evolved within the order Carnivora. The seals, sea lions, and walruses (collectively termed pinnipeds) are represented by three families, Phocidae (true seals), Otariidae (fur seals and sea lions), and Odobenidae (walrus). The pinniped lineage diverged from arctoid carnivores in the late Oligocene (27–25 mya); pinnipeds are most closely related to raccoons (Procyonidae), bears (Ursidae), and weasels (Mustelidae). The phocids appear in the late Oligocene, the walruses (formerly a more diverse group) in the middle Miocene (16–14 mya), and the otariids in the late Miocene (11 mya). The phocids, otariids, and odobenids are currently represented by 18, 16, and 1 species, respectively; the Caribbean monk seal is extinct (**Table 1**). Lactation duration varies greatly among species, from 4 days in the hooded seal to 17 months in Australian sea lions and 24 or more months in the walrus; in general, otariids have longer lactation periods than phocids (**Table 1**). Pinnipeds have 2–6 mammae, primarily abdominal in location and typically inverted. All pinnipeds give birth on land or ice, and as all except the walrus nurse their pups out of the water, they are more accessible for lactation research than other marine mammals. Lactation has been more thoroughly studied in pinnipeds than in any other wild mammal group. At least fragmentary milk composition data

Table 1 Lactation in marine mammals

Family	Common name	Scientific binomial	Milk samples	Age at first major solids	Duration of lactation
Order Carnivora (carnivores, 286 spp.)					
Mustelidae (weasels, otters, 59 spp., 2 marine)					
	Sea otter[a]	*Enhydra lutris*	Yes	1 month	6 months
	Marine otter	*Lontra felina*	No	??	??
Ursidae (bears, 8 spp., 1 marine)					
	Polar bear	*Ursus maritimus*	Yes	3–6 months	18–34 months
Odobenidae (walruses, 1 sp., marine)					
	Walrus	*Odobenus rosmarus*	Yes	5–6 months	12–24 months
Otariidae (fur seals, sea lions, 16 spp., all marine)					
	South American fur seal	*Arctocephalus australis*	Yes	??	12 months
	New Zealand fur seal	*Arctocephalus forsteri*	Yes	??	12 months
	Galapagos fur seal	*Arctocephalus galapagoensis*	Yes	??	11 months
	Antarctic fur seal	*Arctocephalus gazella*	Yes	At weaning	4 months
	Juan Fernandez fur seal	*Arctocephalus philippii*	Yes	??	7 months
	Australian/Cape fur seal	*Arctocephalus pusillus*	Yes	4–7 months	9 months
	Subantarctic fur seal	*Arctocephalus tropicalis*	Yes	??	10 months
	Northern fur seal	*Callorhinus ursinus*	Yes	At weaning	4 months
	Steller sea lion	*Eumetopias jubatus*	Yes	??	4–12 months
	Australian sea lion	*Neophoca cinerea*	Yes	??	17 months
	California sea lion	*Zalophus californianus*	Yes	4–5 months	11 months
	Galapagos sea lion	*Zalophus wollebaeki*	Yes	??	24 months
Phocidae (true seals. 18 spp., all marine or freshwater)					
	Hooded seal	*Cystophora cristata*	Yes	Postweaning	4 days
	Bearded seal	*Erignathus barbatus*	Yes	13–14 days	24 days
	Gray seal	*Halichoerus grypus*	Yes	Postweaning	17 days

(*Continued*)

Table 1 (Continued)

Family	*Common name*	*Scientific binomial*	*Milk samples*	*Age at first major solids*	*Duration of lactation*
	Weddell seal	*Leptonychotes weddellii*	Yes	45 days?	40–50 days
	N. elephant seal	*Mirounga angustirostris*	Yes	Postweaning	26 days
	S. elephant seal	*Mirounga leonina*	Yes	Postweaning	23 days
	Mediterranean monk seal[b]	*Monachus monachus*	No	??	119 days
	Harp seal	*Pagophilus groenlandicus*	Yes	Postweaning	12 days
	Harbor seal	*Phoca vitulina*	Yes	Postweaning	27 days
	Ringed seal	*Pusa hispida*	Yes	??	39 days
Order Cetacea (dolphins and whales, 84 spp., all marine or freshwater)					
Suborder Odontoceti (toothed whales, 71 spp.)					
Delphinidae (dolphins, 34 spp.)					
	Common dolphin	*Delphinus delphis*	Yes	??	16 months
	Long-finned pilot whale	*Globicephala melas*	Yes	6–9 months	24 months?
	Humpback dolphin	*Sousa chinensis*	Yes	??	??
	Spotted dolphin	*Stenella attenuata*	Yes	3–7 months	20 months
	Atlantic spotted dolphin	*Stenella frontalis*	Yes	??	??
	Spinner dolphin	*Stenella longirostris*	Yes	??	11–34 months
	Bottlenose dolphin	*Tursiops truncatus*	Yes	4–11 months	19 months
Iniidae (river dolphins, 3 spp.)					
	Amazon River dolphin	*Inia geoffrensis*	Yes	??	??
	Franciscana dolphin[c]	*Pontoporia blainvillei*	Yes	??	9 months
Monodontidae (beluga, narwhal, 2 spp.)					
	Beluga whale	*Delphinapterus leucas*	Yes	12 months	20–24 months
Phocoenidae (porpoises, 6 spp.)					
	Harbor porpoise	*Phocoena phocoena*	Yes	2–3 months	8–12 months
	Dall's porpoise	*Phocoenoides dalli*	Yes	??	??
Physeteridae (sperm whales, 3 spp.)					
	Pygmy sperm whale	*Kogia breviceps*	Yes	??	??
	Dwarf sperm whale	*Kogia simus*	Yes	??	??
	Great sperm whale	*Physeter macrocephalus*	Yes	12 months	25 months
Ziphiidae (beaked whales, 21 spp.)					
	Bottlenose whale	*Hyperoodon* sp.	Yes	??	??
	Stejneger's beaked whale	*Mesoplodon stejnegeri*	Yes	??	12 months
Suborder Mysticeti (baleen whales, 13 spp.)					
Balaenidae (right whales, 4 spp.)					
	Bowhead whale	*Balaena mysticetus*	Yes	??	9–12 months
Balaenopteridae (rorquals, 7 spp.)					
	Minke whale	*Balaenoptera acutorostrata*	Yes	5–6 months	5–6 months
	Sei whale	*Balaenoptera borealis*	Yes	6–7 months	6–7 months
	Bryde's whale	*Balaenoptera edeni*	Yes	??	??
	Blue whale	*Balaenoptera musculus*	Yes	6–7 months	6–7 months
	Fin whale	*Balaenoptera physalus*	Yes	6–7 months	6–7 months
	Humpback whale	*Megaptera novaeangliae*	Yes	5–6 months	10–11 months
Eschrichtiidae (gray whale, 1 sp.)					
	Gray whale	*Eschrichtius robustus*	Yes	6–7 months	7–8 months
Order Sirenia (manatees, dugongs, 5 spp., all marine or freshwater)					
Trichechidae (manatees, 3 spp.)					
	West Indian manatee	*Trichechus manatus*	Yes	3–5 months	12–24 months

Unless otherwise specified, data from Oftedal OT, Boness DJ, and Tedman RA (1987) The behavior, physiology, and anatomy of lactation in the Pinnipedia. *Current Mammalogy* 1: 175–245; Oftedal OT (1997) Lactation in whales and dolphins: Evidence of divergence between baleen- and toothed-species. *Journal of Mammary Gland Biology and Neoplasia* 2: 205–230.

are available for 12 of 16 otariids, 9 of the 18 phocids, and on the sole odobenid (the walrus) that is, on 63% of the extant pinniped species. By comparison, among the approximately 250 species of non-pinniped carnivores, in only 12 species (5%) have at least 3 samples of mid-lactation milk been assayed (**Table 2**).

The order Carnivora also includes three 'newer' marine mammals, the marine and sea otters and the polar bear (**Table 1**). They arose in the Pleistocene (*c.* 1–3 mya), but remain closely related to other lutrine otters and other bears of the genus *Ursus*, respectively. Milk data are available for sea otters and polar bears.

Factors Affecting the Composition of Marine Mammal Milks

The collection of milk samples from wild mammals requires that animals be captured and restrained (**Figure 2**), or chemically immobilized. Marine mammals often react adversely to chemical immobilization, but whether this affects the composition of collected milk is not known. During the heyday of whaling, milk samples were taken during the processing of carcasses, and samples have been obtained from stranded animals. For such samples, there is always concern that post-mortem or pathological changes may result in abnormal results, especially for labile constituents such as carbohydrates or constituents that may diffuse into or out of damaged mammary glands, such as sodium and potassium. More recently, captive animals, such as bottlenose dolphins, have been trained to present for milk collection. Even in this situation, seawater contamination can occur, leading to elevated levels of water, sodium, and magnesium. Another potential error could arise from incomplete mammary evacuation, which in some terrestrial species can lead to underestimation of milk fat. In seals, milk composition does not change during the course of mammary evacuation, but this has not been examined in otters, bears, cetaceans, or sirenians. Thus, the magnitude of sampling bias in the data in **Tables 2–4** is unknown.

Marine mammal milks change in composition according to lactation stage. In most species of pinnipeds and cetaceans, fat and energy contents rise, and water content falls, from early to mid-lactation (**Figure 3**). In some species, fat and energy contents then remain high to the end of lactation, while in others a modest decline in fat and energy content may occur toward the end of lactation. In polar bears, milk fat content is constant at about 32–36% from 3 to 4 months until weaning, or may decline when bears return onto land from the sea ice.

Other constituents may also change with lactation stage. The protein content of pinniped and cetacean milks may rise somewhat over lactation, but the degree and direction of change vary among species and may even vary with maternal condition. In general, milk composition should be compared across species at similar stages of lactation to avoid confounding effects.

An additional complication occurs in sea lions and fur seals (family Otariidae). After a short (*c.* 1 week) post-parturient period ashore, mothers undertake foraging trips to sea. The pups remain on land or in shallow pools, fasting, until the mothers return. Foraging trip length varies by species, breeding population, and maternal condition, with trips lasting less than a day in some sea lions or as much as 23 days in the sub-antarctic fur seal. During the foraging trip, the rate of milk protein synthesis and overall milk production declines and the composition of secreted milk changes. On return to the breeding colony, the first milk provided to the pup is considerably higher in fat and protein than milk provided on subsequent days ashore. Some authors consider this a case of two separate milks (milk on arrival vs. milk obtained by subsequent suckling), but it is more likely a continuous process whereby secretory processes are up- and down-regulated according to the stage of the foraging/nursing cycle. Nonetheless, this complicates determination of the 'average' milk composition.

The Proximate Composition of Marine Mammal Milks

The summary data in **Tables 2–5** were selected from available data as those that best represent milk composition at the period of maximal milk production or peak lactation. Although milk production has been measured at different lactation stages only in a few pinniped species, peak production can be inferred from the pattern of offspring growth and behavior. Offspring growth can be sustained only if the increased energy needs associated with increasing size are matched by an increase in milk yield, an increase in milk energy/nutrient density, or the ingestion of solid foods. Peak lactation is estimated as the period preceding the onset of substantial food intake by the young (**Table 1**), as determined by observation or examination of stomach contents.

The adaptation to marine life has apparently entailed changes in milk composition, but to discriminate such changes from simple phylogenetic variation due to long periods of separate evolution, milk composition needs to be compared to the closest living relatives of marine mammals. Thus in **Tables 2–4** compositional data are provided for terrestrial carnivores, a subset of the artiodactyls, and elephants as the closest living relatives of marine carnivores, cetaceans, and sirenians, respectively.

Both the polar bear and sea otter, species that have recently diverged from terrestrial counterparts, produce milks that are higher in fat and energy than other

Table 2 Milk composition of terrestrial and marine Carnivora

Unless otherwise specified, data from Oftedal OT and Iverson SJ (1995) Phylogenetic variation in the gross composition of milks. In: Jensen R (ed.) *Handbook of Milk Composition*, pp. 749–789. New York: Academic Press.

Species in bold are considered marine mammals. See **Table 1** for scientific binomials. *N* refers to number of milk samples assayed.

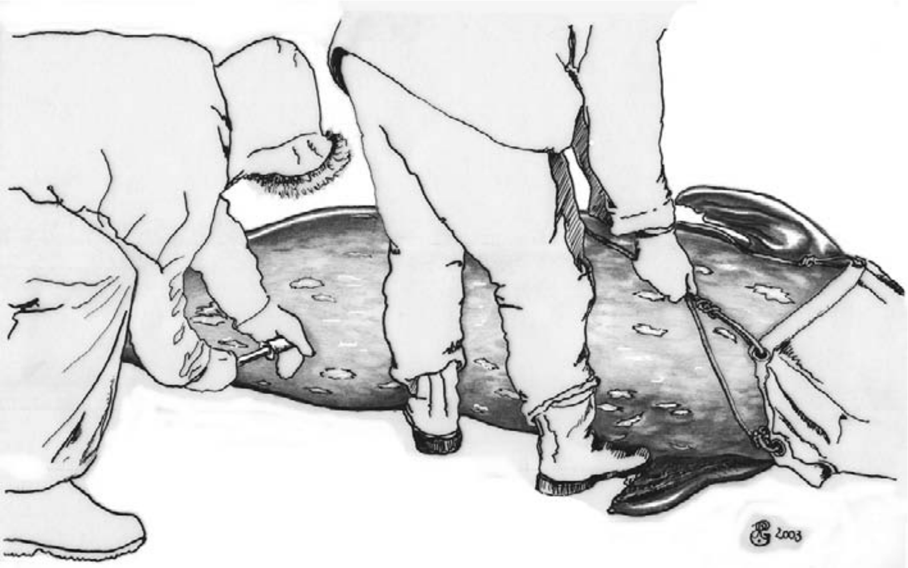

Figure 2 Milk collection from the Weddell seal in Antarctica. Lactating seal (*c.* 450 kg) is manually restrained in a head bag, injected intramuscularly with oxytocin, and milk is collected by pumping a cutoff 60 ml syringe placed over the inverted nipple. Drawing by Regina Eisert.

terrestrial carnivores, except bears (**Table 2**). The high fat and low sugar contents of bear milk are believed to be important to preservation of lean body mass during 'hibernation', when bears are simultaneously lactating and fasting. Bear milk was thus 'preadapted' to a marine lifestyle (see below); such a process is termed exaptation in evolutionary biology. Unfortunately, there are no reliable data on milks of other otters with which to compare sea otters, although mink, which are quite aquatic, do not have high milk fat levels.

Seven of nine otariids (fur seals and sea lions) and eight of nine phocids (true seals) that have been studied produce extremely high-fat (40–60%) and high-energy (19+ MJ kg^{-1}) milks (**Table 2**). No other terrestrial mammals produce milks that come close to these levels, although some shrews, tree shrews, bears, and bats produce milks containing about 30% fat and 12–15 MJ kg^{-1} energy. Even walrus, Australian sea lion, and southern sea lion milks, although not as energy dense as other otariids or phocids, are still high in fat (24–26%) and energy (12 MJ kg^{-1}) compared to terrestrial carnivores. Pinniped milks are less variable in protein content (about 9–12%) and these levels are matched by such terrestrial carnivores as Arctic fox, striped skunk, and various cats (**Table 2**). The reported sugar levels are usually low (0.1–1.2%), although at least one species appears to have more than 2% (**Table 2**).

The milks of the cetaceans differ greatly from those of the terrestrial Artiodactyla to which they are related (**Table 3**). Artiodactyl milks typically contain 4–10% fat and 3–8 MJ kg^{-1} energy, as compared to 10–30% fat and 7–14 MJ kg^{-1} energy in dolphins and toothed whales (Odontoceti), and 30–44% fat and 15–19 MJ kg^{-1} energy in baleen whales (Mysticeti) (**Table 3**). Like the pinnipeds, cetaceans produce milks containing about 8–12% protein (as compared to 3–9% in artiodactyls). Cetacean milks are also low in total sugar (1–2.5%).

Manatee milk is higher in fat, protein, and energy, but lower in sugar, than the milks of elephants, to which it is related (**Table 4**); manatee milk resembles the milks of dolphins and toothed whales in gross composition (**Table 3**).

Thus, all marine mammals produce milks that are higher in fat and energy than the terrestrial taxa to which they are most closely related. It is likely that this is a necessity due to the thermoregulatory challenge of a marine environment. A newborn mammal is not only small but typically has less subcutaneous body fat that can provide insulation against heat loss upon immersion in water. High-fat, high-energy milks allow rapid postnatal fat deposition, generating insulation, and also supply energy that can be used to sustain high metabolic rates in a thermally demanding environment. Polar bears use snow dens to provide a more benign climate for neonates. Many pinnipeds live in cold temperate or polar environments and pups delay water entry until a substantial blubber layer is developed. Some polar cetaceans, such as the large baleen whales, migrate to warm temperate or subtropical waters for parturition and early nursing. The distribution of manatees is restricted by cold water temperatures.

The highest milk fats (48–61%) are found in phocid seals, which have relatively short lactations, and deposit fat rapidly after birth. Phocid seals that pup on unstable floating ice (such as hooded and harp seals) have particularly

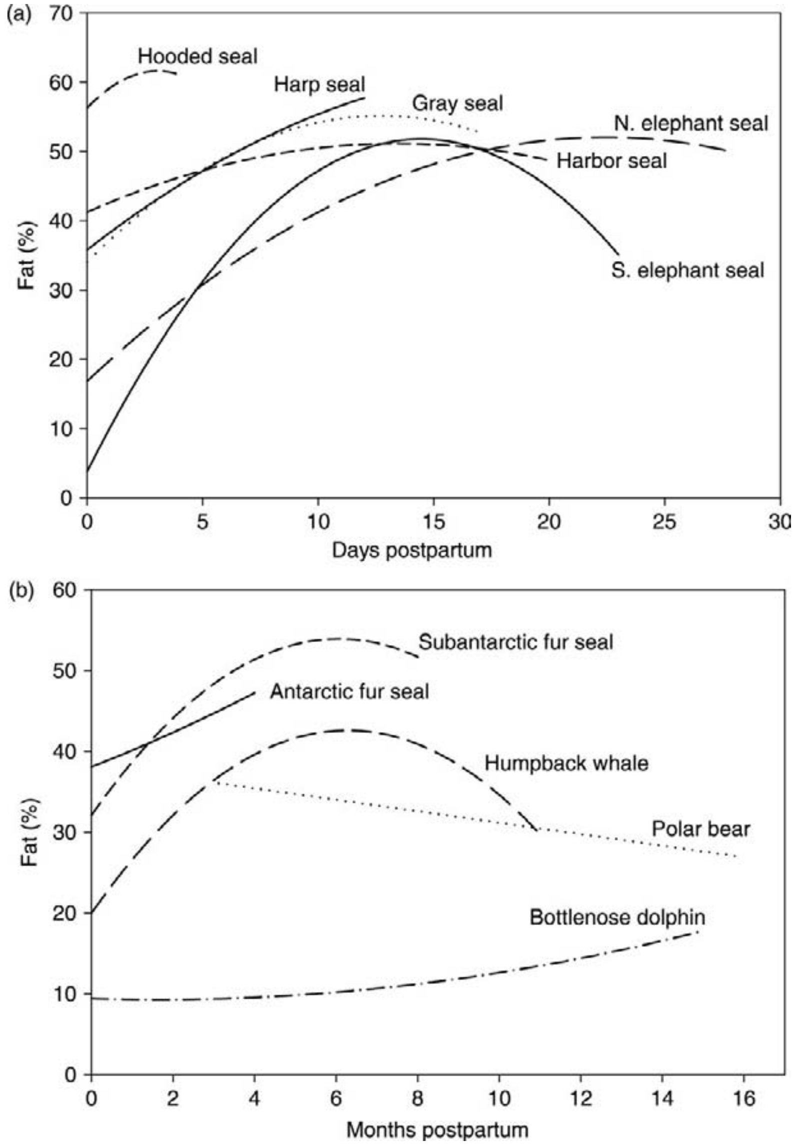

Figure 3 Changes in milk fat composition over the course of lactation in marine mammals. (a) Phocid seals with short lactation periods (<1 month). (b) Other marine mammals with long lactation periods (4–16 months). Data are from references listed for these species in **Tables 2** and **3**, plus Kretzmann MB, Costa DP, and Le Boeuf BJ (1993) Maternal energy investment in elephant seal pups: Evidence for sexual equality? *The American Naturalist* 141: 466–480; Lydersen C and Kovacs KM (1996) Energetics of lactation in harp seals (*Phoca groenlandica*) from the Gulf of St. Lawrence, Canada. *Journal of Comparative Physiology B* 166: 295–304; Mellish JE, Iverson SJ, and Bowen WD (1999) Variation in milk production and lactation performance in grey seals and consequences for pup growth and weaning characteristics. *Physiological and Biochemical Zoology* 72: 677–690.

short and intensive lactations. Hooded seal pups gain 7 kg mass per day, most of which is fat, and are weaned in 4 days, the shortest lactation of any mammal. Hooded seals also produce milk which has the highest fat content (61%) of any mammalian milk. As the mothers of many phocid species fast during lactation, the secretion of high-fat, low-sugar milk may also be important in reducing the glucose demand of the mammary gland, thereby conserving gluconeogenic substrates (especially body proteins).

Most fur seals and sea lions also have high-fat, high-energy milks (**Table 1**). This may be related, in part, to the fact that mothers undertake extended foraging trips to sea during the long lactation period. The pups of otariid seals do not deposit fat as rapidly as phocid pups, partly because when their mothers depart to sea they must use stored energy to cover metabolic costs until she returns. In some species (such as subantarctic and Juan Fernandez fur seals), these maternal foraging trips may be 2–3 weeks in duration, as the mother travels hundreds of kilometers to find suitable prey densities. The high-fat, high-energy milks of otariid seals allow rapid energy transfer during the short period the mother is on land with her pup. Thus,

Unless otherwise specified, data from Oftedal OT and Iverson SJ (1995) Phylogenetic variation in the gross composition of milks. In: Jensen R (ed.) *Handbook of Milk Composition*, pp. 749–789. New York: Academic Press. Marine mammals are indicated in bold.

otariid pups experience a feast–famine–feast pattern throughout lactation; those species with the longest foraging trips tend to produce the highest fat milks. The high fat and energy density of otariid milks may also be important in maximizing milk energy storage in the mammary glands during the prolonged foraging trips. It appears that rates of milk protein synthesis and milk production decline during otariid foraging trips, but recover once suckling is reinitiated upon return to the pup. The amazing fact that otariid mammary glands do not involute during these prolonged periods between suckling may be related to milk composition (see below). In contrast, phocid mammaries begin to involute if not suckled for a day or more.

Both cetaceans and manatees give birth in the water, and the calf accompanies its mother while she forages. High-fat milk is presumably important both for deposition of insulating blubber and for supporting the energetic (and thermoregulatory) costs of living in water. Among the cetaceans, the toothed species (odontocetes) have long lactations and grow slowly, and therefore fat deposition is also slow. As there is no added burden of a concurrent fast by mother or calf, and no need for rapid fat accumulation by calves prior to weaning, it is perhaps to be expected that the fat and energy levels in odontocete milks are not as high as in most pinniped milks. The baleen whales, including the gargantuan blue whale (the largest living vertebrate), have higher milk fat levels than odontocetes, but unlike odontocetes most species eat little if anything during the first 6 months of lactation. During this period, milk production derives mostly from body reserves, and high-fat, low-sugar milks may limit protein catabolism via minimizing mammary glucose demand, as in phocids and polar bears that fast while lactating.

Other Milk Constituents

Most recent research on marine mammals has focused on understanding reproductive energetics and relatively little attention has been paid to milk constituents other than the primary energy sources.

Lipids

Lipids are by far the most abundant organic component of marine mammal milks, and in some cases the lipids exceed water content (**Tables 2** and **3**). As in other mammals, the milk lipids are packaged into membrane-bound milk fat globules, and at least in the Weddell seal these milk fat globules are relatively large. There has been considerable interest in the fatty acid composition of the lipids (**Table 5**), in part because this may provide indirect information on the prey species eaten by lactating females. Most marine mammal milks are high in long-chain polyunsaturated lipids, including such omega-3 fatty acids as 18:3n3, 20:4n3, 20:5n3, 22:5n3, and 22:6n3, as well as such omega-6 fatty acids as 18:2n6 and 20:4n6 (**Table 5**). The differences among species may reflect differences in diet more than species differences in lipid processing, since the fatty acid composition of marine mammal milks typically reflects both the fatty acid composition in the diet and the fatty acid composition of stored lipids (which reflect previously consumed lipid). The extent to which milk or blubber fatty acids are altered by lipogenesis, preferential mobilization, chain elongation, or desaturation is debated, but this is undoubtedly important in some species, particularly those that ingest low-fat diets (such as manatees). Manatee milk appears to lack the long-chain (C20 and longer) polyunsaturated fatty acids characteristic of pinniped and cetacean milks, but does have short-chain saturates such as 8:0, 10:0, 12:0, and 14:0 (not shown in **Table 5**), as might be expected of a herbivore that generates volatile fatty acids via intestinal fermentation.

Proteins

The crude protein in marine mammal milks represents about 8–12% of the milk by mass, which may seem high by comparison to most terrestrial mammals but is actually low relative to total milk energy. The proportion of milk energy provided by protein is lower in odontocetes and mysticetes than in artiodactyls, and lower in otariids and phocids than in terrestrial carnivores (**Figure 4**). The particularly low percentage of energy provided by protein in phocid milks relates to the pattern of post-natal pup growth, which entails high rates of fat deposition rather than high rates of lean mass gain. About 3–9% of the total nitrogen in marine mammal milks is non-protein nitrogen, and thus crude protein somewhat overestimates true protein.

Marine mammal milks contain both caseins and a variety of whey proteins, as do the milks of terrestrial mammals. The relative proportions of caseins:whey proteins range from 30:70 (in the southern elephant seal) to 70:30 (in fin and blue whales); sea otters (35:65) and polar bears (61:39) are intermediate. It is not known if these differences are associated with differences in the formation and retention of curds in the stomach of the young, although gastric retention of milk solids may be important to allow gastric lipolysis of high-fat milks. Gene transcript sequencing has identified αS1, αS2, β, and κ caseins in fur seal mammaries, although the proportions in milk are not known. Genes for the whey proteins β-lactoglobulin 1 and lysozyme C have also been identified in fur seal mammary tissue. Electrophoretic bands with the mobility of β-lactoglobulin have been found in milks of the northern fur seal, Stejneger's beaked whale, and bowhead whale, and two variants of β-lactoglobulin

have been isolated and partially sequenced from bottlenose dolphin milk. Electrophoretic evidence for the presence of serum albumin has been observed in gray and southern elephant seals. However, other whey proteins observed via electrophoresis of marine mammal milks have not been characterized. Activity of the enzyme bile salt-stimulated lipase has been observed in hooded seal milk. The milk fat globule membrane of the Weddell seal contains the proteins butyrophilin and xanthine oxidoreductase.

Of particular interest is the apparent lack of lactose synthase activity in otariid mammary glands. This appears to be due both to mutations causing aberrant splicing during the transcription of the α-lactalbumin gene and to great reduction in the transcription and translation of α-lactalbumin, which is an essential component of the lactose synthase complex. Without α-lactalbumin, the β1,4-galactosyltransferase does not utilize glucose as a receptor for galactose, and thus lactose is not formed. As noted below, otariid milks lack both free lactose and oligosaccharides that incorporate lactose. The failure to produce α-lactalbumin appears to be important in preventing mammary involution during the long foraging trips that lactating otariids may undertake. The milk of Stejneger's beaked whale, which lacks lactose, also lacks α-lactalbumin in amounts detectable by electrophoresis.

Carbohydrates

Marine mammal milks are typically much lower in total sugar content than the milks of related terrestrial taxa (**Tables 1–3**). Most marine mammals, including polar bears, phocid seals, and at least some dolphins and whales, produce milks with low levels of both lactose and other more complex sugars (**Table 6**). These complex sugars are synthesized by the addition of other monosaccharide units to lactose (Gal(β1-4)Glc), such as the trisaccharides isoglobotriose (Gal (α1-3)Gal (β1-4)Glc), 2′fucosyllactose (Fuc(α1-2)Gal(β1-4)Glc), and 3′sialyllactose (Neu5Ac(α2-3)Gal(β1-4)Glc). Of these, isoglobotriose is the predominant sugar in polar bear milk (and in the milk of some other bears), and 2′fucosyllactose is a codominant sugar (with lactose) in at least some phocid seals (hooded seal, harbor seal) and some baleen whales (minke whale).

Most marine mammals with the ability to synthesize lactose also synthesize an array of longer chain oligosaccharides (up to octa- and nonasaccharides) that include lactose (i.e., Gal(β1-4)Glc) at the reducing end as well as varying combinations of galactose, *N*-acetyl galactosamine, *N*-acetyl glucosamine, fucose, and sialic acid (or *N*-acetyl neuraminic acid (Neu5Ac)) (**Table 6**). Thus, 7–10 oligosaccharides have been identified in the milks of polar bears, hooded seals, harbor seals, and minke whales, but not the same oligosaccharides in each species. The biological significance of this array of oligosaccharides is not clear, although by analogy to human milk oligosaccharides, antimicrobial functions in either the mammary gland or the neonatal digestive tract have been hypothesized.

Some marine mammals, including otariids, the walrus, and Stejneger's beaked whale, appear to produce milks devoid of lactose, the primary sugar in the milks of most mammals. In otariids and the walrus, gene mutations and/or changes in transcription rates effectively

Predominant sugar is identified by xx; others by x.

produce milks lacking functional α-lactalbumin, and α-lactalbumin is reported missing from Stejneger's beaked whale. The West Indian manatee also produces milk in which lactose was not detected by paper chromatography or enzymatic methods, although trace levels of lactose were found by high-performance liquid chromatography (HPLC) and very low levels of α-lactalbumin could be detected. It is not known if the low level of sugar in manatee milk (**Table 3**) represents free sugars or covalently bound sugars that were hydrolyzed from glycolipids or glycoproteins during analysis.

Sea lions and fur seals that lack the ability to synthesize lactose produce milks devoid of lactose-containing oligosaccharides. It appears that the primary free sugar in these milks is the monosaccharide inositol (**Table 6**). Whether inositol or other small organic osmolytes replace the osmotic role of lactose in the secretion of the aqueous phase of otariid milks is not known.

Mineral Elements

The milks of marine mammals presumably supply the wide variety of macrominerals, trace elements, and vitamins that growing young require for tissue growth and metabolic function, but these constituents are not well studied. Some of the early work on whale milks collected during whaling operations used what are now outdated methodologies, and as the results may not be reliable they are not included herein. As noted above, contamination of milks with water, sodium, and magnesium from seawater is of concern, and contamination of milk with dirt or fecal material may be hard to avoid when working with land-breeding seals in large colonies.

Among terrestrial mammals, the ratio of calcium to phosphorus (Ca:P) in milk is typically above 1:1, reflecting a greater post-natal requirement for calcium than for phosphorus, primarily due to calcium deposition in growing bone. Ca:P ratios above 1 are also found in the milks of the polar bear, sea otter, some dolphins and whales, and the West Indian manatee (**Table 7**). However, both the

Data are presented on a whole milk basis.

otariids and the phocids produce milks with an inverse Ca:P ratio, that is, more phosphorus than calcium. The functional significance of this is not known. In captivity, seal pups allowed to suckle beyond normal weaning dates may develop pathological bone demineralization.

In terrestrial mammals, milk is higher in potassium than sodium, reflecting the existence of sodium and potassium gradients maintained across the basal membranes of mammary secretory epithelial cells. The same is probably true of marine mammals, although data are limited (**Table 7**). The high sodium values reported for some cetacean and manatee milks are suspect due to the possibility of seawater contamination. Based on data on a handful of species, marine mammal milks are reported to contain about 1000–1700 mg kg^{-1} chloride, 120–200 mg kg^{-1} magnesium, and trace levels of iron (5–36 mg kg^{-1}), copper (2–3 mg kg^{-1}), zinc (1–8 mg kg^{-1}), and selenium (0.4–0.5 mg kg^{-1}).

Vitamin data on marine mammal milks are sparse. The milks of blue and fin whales reportedly contain, per kg fresh milk, the following vitamins: 3100–7800 IU vitamin A, 1.1–1.6 mg total thiamin, 0.2–1.6 mg riboflavin, 7–26 mg niacin, 0.9–1.1 mg vitamin B_6, 3–18 mg pantothenic acid, 12–65 μg biotin, and 8–130 μg vitamin B_{12}. Fairly fresh (<6 h post-mortem) fin whale milk reportedly contains 70 mg l^{-1} ascorbic acid (vitamin C). In harp and hooded seals, vitamin E content of colostrum is high but then falls to stable levels of about 20–50 mg kg^{-1} at mid-lactation; by contrast, vitamin A levels are constant throughout lactation. Similar patterns have been seen in gray seals. Further research is needed on freshly collected and well-preserved marine mammal milks to determine if the above values are representative or include errors due to vitamin losses during collection, storage, and analysis.

Introduction

The primary function of mammalian milk is to nourish the neonate in the most efficient manner possible from the mother's perspective, while providing the neonate with additional benefits from enhanced immune protection, and a source of nonnutrient growth promoters, hormones, and other bioactive components that serve as biochemical messengers within the body. In addition, several components in human milk help to maintain the integrity of mammary tissue, optimizing milk output and composition.

Human milk, a biologically complex fluid containing many hundreds of different constituents, is ideally suited to meet the term infant's nutritional needs during the first 4–6 months of life, provided that the mother is also healthy and well nourished. For this reason, infant formula manufacturers often refer to the gross composition of human milk as the 'gold standard'. However, it is important to remember that, unlike infant formula, the composition of human milk is not uniform. Significant changes in the composition of breast milk occur not only between individual women, but also within a single feed, between feeds, throughout the day, throughout the lactation period, with changing maternal diet, and as a result of other external factors such as exercise or metabolic illness. Implicit in these findings is the understanding that a single description of human milk is somewhat erroneous. Nevertheless, it is important to establish data on the composition of human milk at various key stages of lactation.

Gross Nutrient Composition

There are three stages in human lactation that are clearly identified by changes in specific components in the milk, such as the whey proteins and lactose. These compositional changes appear uniquely to match the changing physiological needs of the infant, and can be defined based on the following time periods: 1–5 days post-partum, colostrum; 5–21 days postpartum, transitional milk; and >21 days post-partum, mature milk. Nutrient information relating to human milk at the predominant stages of lactation is provided in **Table 1**.

Human colostrum differs from mature milk in both the types and amounts of individual components. Colostrum has a much higher protein content and a lower lactose content than mature milk. The specific gravity of colostrum is 1.040 compared with 1.060 for mature milk, and the mean energy content of colostrum is also lower at 67 kcal 100 ml^{-1} compared with mature milk, which supplies 75 kcal 100 ml^{-1} of energy. Although the fat and ash contents of colostrum and mature milk do not differ significantly, variations in specific micronutrients are apparent, with the concentrations of sodium, chloride, and magnesium being higher, and that of potassium and calcium lower, in colostrum.

Component Composition

Human milk contains hundreds of different components; **Table 2** lists some of these grouped according to their physicochemical properties. The water-soluble constituents found in the aqueous phase account for 87% of milk volume, and include some salts, vitamins and trace elements, lactose, oligosaccharides, whey proteins, and non-protein nitrogen (NPN) components. Complementing the aqueous phase is a colloidal dispersion (0.3% of volume) containing casein proteins held in micellar form, which contributes to the white color of milk. Calcium phosphate and some other proteins are also linked to the casein micelles. A further 6% of milk volume is made up of an emulsion containing fat globules, fat globule membranes, triglycerides, and other lipid components, including the fat-soluble vitamins. The remainder consists of cellular components, non-peptide hormones, and other minor fractions.

Proteins

Many of the functional properties of human milk are delivered via the milk proteins. Provision of essential amino acids for growth is the most obvious role of milk proteins. Determining the gross amino acid composition of human milk will accurately describe amino acid

Table 1 Gross nutrient content (g 100 ml^{-1}) of human milk at different stages in lactation

Nutrient	*Colostrum (1–5 days)*	*Transitional milk (5–21 days)*	*Mature milk (21 days+)*
Protein	1.5–1.7	0.9	0.8–0.9

content, and in the past this figure has been used to define the amount of protein available to the infant for growth and development. However, milk proteins also provide the infant with immune protection, increased digestive capacity, and enhanced micronutrient availability, and, as many bioactive components of human milk are of protein origin, implicit in their functionality is a resistance to digestion. Investigation of the nutritive value of human milk protein reveals that although most (95%) milk protein is available, a proportion does not contribute significantly to amino acid nutrition. To determine accurately the amounts of amino acids, and therefore protein, used for nutrition by the breast-fed infant, a correction needs to be made for bioavailability. A comparison of gross and available amino acid composition of mature human milk is made in **Table 3**.

The total protein content of human milk consists of two major groups, caseins and whey proteins, as well as

Table 3 The gross and available amino acid[a] composition of mature human milk (mg 100 g^{-1} protein[b])

Amino acid	*Gross*	*Available*
Aspartic acid	9.2	9.1
Threonine	4.7	4.6
Serine	5.0	4.2
Glutamic acid	18.4	16.8
Proline	8.5	8.4
Glycine	2.3	2.1

some minor components (**Table 1**) and proteins present in the milk fat globule membrane. The ratio of whey proteins to casein changes during the initial stages of lactation, from 90:10 immediately post-partum, to 60:40 in mature milk and 50:50 in late lactation. These ratios directly reflect a decrease in the content of immune proteins (**Table 4**) in line with development of the infant's own immune system.

Casein

Human milk contains two (β and κ) caseins, and is devoid of α-casein, the predominant casein found in bovine milk. The casein pattern differs depending on the stage of lactation, with κ-casein detectable in human milk only from day 3–4 post-partum onward. A unique feature of human milk is the high degree of glycosylation of κ-casein (40–60% glycosylated) and other milk proteins (e.g., immunoglobulins (Igs) and lactoferrin). Glycosylated proteins exhibit anti-infective properties and enhance the absorption of some micronutrients. As part of the normal digestive process, the caseins in human milk release smaller peptides into the gut lumen. These casein fragments are thought to enhance the absorption of calcium by keeping it in solution in the gut lumen. Other casein-derived peptides have been linked to the regulation of intestinal motility and to the growth promotion of beneficial bacteria in the infant's gut.

Whey proteins

α-Lactalbumin, lactoferrin, serum albumin, and secretory IgA (sIgA) are the main whey proteins found in human milk. β-Lactoglobulin, prominent in bovine milk, does not occur in human milk.

The predominant sources of amino acids for nutrition among the whey proteins are α-lactalbumin and serum albumin. The other whey proteins, while contributing to nutrition to some extent, have a primary function in other roles. Lactoferrin, an iron-binding protein, has bacteriostatic properties that may impact on both the infant and the mammary gland. Lysozyme is capable of cleaving proteoglycans in the cell wall of certain bacteria, providing an antibacterial effect. The Igs in human milk are distinct from those found in blood serum, indicating selective synthesis in the mammary gland. sIgA, formed by the linking of two serum IgA molecules by disulfide bonds, is present at very high concentrations in colostrum, but the sIgA content declines rapidly to a much lower level within 14 days of lactation. sIgA protects the infant by blocking the attachment of pathogenic bacteria to the gut epithelium. Other Igs in human milk provide immune protection through activation of the complement system, or by promoting phagocytosis.

Other proteins

In addition to casein and whey proteins, human milk contains other proteins, such as serum proteins, most of which are in the aqueous phase. The milk fat globule membrane proteins surround the lipid droplets, but are a minor fraction quantitatively (1–3% of total protein). However, these minor proteins can contribute in many ways to the health and well-being of the infant, for example, by facilitating transport of certain vitamins and minerals. Milk-borne peptide hormones and enzymes assist in the digestion of other milk components (e.g., bile salt-stimulated lipase (BSSL) and amylase). A detailed list of the hormones, both peptide and non-peptide, and enzymes found in human milk is given in **Table 5**.

Non-protein Nitrogen

Compared with the milk of other mammalian species, human milk is notably different with regard to the NPN fraction. In human milk, the NPN fraction represents a very high percentage (20–25%) of total nitrogen (N). Urea N accounts for almost 50% of the NPN in human milk, with more than 200 compounds, including free amino acids, carnitine, taurine, amino sugars, nucleic acids, nucleotides, and polyamines, making up the remainder. In general, the total NPN of human milk remains constant throughout the lactation period, although there may be some variation in individual NPN components (**Table 4**).

Table 5 Hormones and enzymes found in mature human milk

Hormones			
Peptide		*Non-peptide*	
Growth factors	Epidermal growth factor	Thyroid	Thyroxine
	Insulin		Triiodothyronine
	Insulin-like growth factor 1		
	Nerve growth factor	Adrenal	Cortisol

Enzymes			
Phosphoglucomutase		Lactose synthase	
Fatty acid synthase		Thioesterase	
Galactosyltransferase		Amylase	
Bile salt-stimulated lipase		Proteases	
Lysozyme		Peroxidase	
γ-Glutamyltransferase		Platelet-activating factor acetylhydrolase	
Protease inhibitors		Sulfhydryl oxidase	
Lipoprotein lipase		Glutathione peroxidase	
Alkaline phosphatase		Xanthine oxidase	

Given that the total protein content of human milk is low compared to other species, yet supports adequate growth of the breast-fed infant, the suggestion has been made that the urea found in the NPN fraction of human milk is used by the infant for protein synthesis. This would have major implications for infant formula manufacturers, necessitating a total reevaluation of infants' protein requirements. Isotopic tracer experiments with infants have shown that as much as 40% of labeled urea N was retained within the body. However, this may not directly reflect the incorporation of urea N into body protein, as NH exchanges occurring during transamination may in part explain the appearance of urea ^{15}N in body proteins. This remains an important area for future investigation of infant protein metabolism.

Taurine and glutamine, two predominant free amino acids in human milk, are considered conditionally essential, as the infant appears to have a requirement for these amino acids above what the body can synthesize. Taurine plays an integral part in fat digestion by conjugating with bile acids to form bile salts. Although no direct link has been made between a deficiency in taurine and abnormal development of retinal and brain tissue in infants, the addition of taurine to infant formulae is now routine. Glutamine is involved in the cellular metabolism of enterocytes and in the immune response associated with inflammation and sepsis.

During periods of rapid growth or tissue repair, a dietary source of nucleotides may be beneficial, as *de novo* synthesis of nucleotides can be a limiting factor.

Table 6 Nucleotide content of human milk, and the amounts of specific nucleotides approved for inclusion in infant formulae

Nucleotide	*In human milk (mg 100 ml^{-1})*	*Maximum to be added to infant formula (mg 100 kcal^{-1})*
Adenosine diphosphate (ADP)	69	
Adenosine monophosphate (AMP)	175	1.5
Cytidine diphosphate (CDP)	474	
Cytidine monophosphate (CMP)	461	2.5
Guanosine diphosphate (GDP)	96	
Guanosine monophosphate (GMP)	138	0.5
Inosine monophosphate (IMP)	228	1.0
Uridine diphosphate (UDP)	174	
Uridine monophosphate (UMP)	179	1.75

Adapted from Lawrence and Lawrence (1994); infant formula inclusion rates from Rudloff S and Kunz C (1997) Protein and nonprotein nitrogen components in human milk, bovine milk, and infant formula: Quantitative and qualitative aspects in infant nutrition. *Journal of Pediatric Gastroenterology and Nutrition* 24: 328–344.

The infant is in a state of rapid growth and cellular development, and human milk is rich in nucleotides (**Table 6**). To date, however, no link between nucleotides in human milk and enhanced cellular function in the infant has been made. Despite this lack of direct evidence, some regulatory authorities have approved the inclusion of nucleotides in infant formulae (**Table 6**).

Carbohydrate

Besides water, lactose constitutes the largest component of human milk (**Table 1**); lactose concentration decreases as lactation progresses, in line with the decline in milk volume.

Oligosaccharides constitute the next greatest fraction of carbohydrate in human milk, representing more than 27% of the carbohydrate in colostrum. This gradually decreases to 15–16% of carbohydrate as oligosaccharides in mature human milk. Most oligosaccharides found in human milk contain lactose at the reducing end, and may contain fucose or sialic acid at the non-reducing end. Compared to other mammalian milks, human milk is unique due to its content of complex oligosaccharides. Milk oligosaccharides provide a low osmolar source of calories for the infant, and have been classed as 'soluble' fiber because they appear to remain largely undigested in the infant's gut. Human milk oligosaccharides contain significant quantities of sialic acid, which is essential for brain development, and they are also thought to stimulate the growth of bifidus bacteria and to inhibit the adhesion of pathogenic bacteria to epithelial surfaces. Approximately 130 oligosaccharides have been identified in human milk, some of which are listed in **Table 7**. Glucose and galactose are present in much smaller quantities in human milk, as are other carbohydrates such as monosaccharides, and peptide-bound and protein-bound carbohydrates.

Table 7 Quantities of some carbohydrates found in human milk

carbohydrate oligosaccharid	*Concentration mg 100 ml^{-1}*
Lactose	6800
Oligosaccharides	1200–1300
Lacto-*N*-tetraose	5–15
Lacto-*N*-fucopentaose I	12–17
Lacto-*N*-fucopentaose II	3–10
Lacto-*N*-fucopentaose III	0.1–2
Lacto-*N*-difucohexaose I	1–2
NeuAc(α2–6)lactose	3–5
NeuAc(α2–3)lactose	1–3

Lipids

The lipids in human milk occur in globular form, emulsified in the aqueous phase, and provide the infant with a major proportion (45–55%) of the energy needed to support growth. They also contain bioactive components important to the infant's retinal and neural tissue development.

The triacylglycerols (TGs) account for 98% of total fat, and 90% of this is fatty acids (FAs). Phospholipids (0.8%), cholesterol (0.5%), and other minor lipid components make up the remainder of the fat, which includes fat-soluble vitamins.

In the first few weeks of lactation, the total lipid content increases from around 2 to 3.5–5% (**Table 8**). As the fat content increases, so too does the average size of the milk fat globules, which in turn results in a reduction in the ratio of phospholipids and cholesterol in TGs.

Table 8 Lipid content of human colostrum and milk

Lipid component	*Colostrum*	*Mature milk*
Total lipid (percentage of milk volume)	2	3–5
Phospholipid (percentage of total lipid)	1.1	0.8
Triacylglycerol (percentage of total lipid)	97–98	97–98
Cholesterol (percentage of total lipid)	1.3	0.5

22:5$n-6$	0.4	0.2

The TG composition in human milk is determined by the types and quantities of FAs esterified to the glycerol molecule. Human milk contains eight major FAs in amounts greater than 1% (**Table 9**), and is an excellent source of the essential FAs $C_{18:2n-6}$ and $C_{18:3n-3}$ and their long-chain derivatives $C_{20:4n-6}$ (arachidonic acid) and $C_{22:6n-3}$ (docosahexaenoic acid). The latter FAs, although not classed as essential for adults, are the only FAs utilized by the brain and are important structural components of the membrane systems of all tissues.

Approximately 60% of the $C_{16:0}$ FAs in human milk are situated at the *sn*-2 position on the TG, which is a unique feature of the FAs in human milk. Lipolytic hydrolysis cleaves FAs from the *sn*-1 and *sn*-3 positions, and a $C_{16:0}$ remains as a monoacylglycerol. This facilitates the absorption of $C_{16:0}$ across the infant's gut epithelium, improving overall lipid utilization to around 90–95%.

Lipid digestion and absorption are enhanced further by four enzyme systems. These are, in the order of utilization, the gastric phase with lingual lipase and gastric lipase, and the intestinal phase with pancreatic lipase and BSSL. The gastric phase is important because the milk fat globule would otherwise resist the action of pancreatic lipase and BSSL. Unlike the other lipases, which are endogenous, BSSL is secreted in human milk specifically to assist the infant with milk fat digestion.

Of all the components in human milk, the lipid fraction is the most variable. Changes in fat content occur not only during the first few weeks of lactation (**Table 8**), but also in milk secretions throughout the day, and even within a single feed, with the hindmilk being significantly higher in fat content than the foremilk. Variations also exist in the fat content of milk from individual women, although by far the greatest variation occurs in the types and amounts of FAs.

Micronutrients

Vitamins

Most vitamins found in human milk increase in concentration as lactation shifts from colostrum to a mature secretion (**Table 10**), with the exception of carotenoids (α-carotene, β-carotene, lutein, cryptoxanthin, and lycopene), retinol, and vitamin E, which decrease. Reduction in the concentration of some vitamins may not alter the total amount available to the infant, however, as any reduction may be offset by an increase in the quantity of breast milk consumed.

The milk from healthy, well-nourished women usually contains sufficient quantities of most of the vitamins required by the infant. There are a few exceptions, however, when the amount in milk may not be adequate. Deficiencies in vitamin D, with consequent development of rickets, have been reported in breast-fed infants, directly linked to the mother's diet and the infant's lack of exposure to sunlight. To meet physiological requirements, vitamin K is routinely given to newborn babies because transplacental transfer is limited, and the level in milk is low.

Minerals

In general, the macromineral content of human milk remains stable during the lactation period after an initial decrease in the concentration of chloride, potassium,

Table 10 Micronutrient content of human colostrum and milk

Micronutrient	*Units* l^{-1}	*Colostrum*	*Mature milk*
Water-soluble vitamins			
Ascorbic acid	mg	60	50–100

Zinc	mg	8–12	1–3

[a] Citrate is not classed as a mineral, but is soluble in water and binds some minerals, so is included in this table.

sodium, and sulfur (**Table 10**). Most of the sulfur in human milk is found in the sulfur-containing amino acids methionine and cysteine, with only a small fraction (10%) existing in salt form. The sulfur amino acids predominate in whey proteins, so a reduction in whey protein content during the first few days of lactation is matched by a similar reduction in sulfur content.

Human milk has a higher calcium-to-phosphorus ratio (2:1) than the milk from other mammalian species (e.g., in bovine milk, Ca:P ratio is 1.1:1), although the absolute amounts of calcium and phosphorus are lower. A low phosphorus content suits the infant's limited renal capacity. In addition, the contribution of phosphate to the buffering capacity of human milk is such that a low pH results, promoting the growth of beneficial gut bacteria.

Human milk contains what would initially appear to be an inadequate level of iron, yet breast-fed infants rarely deplete their iron stores until after 4–6 months of age. Maximum utilization of the iron in human milk is achieved with the assistance of lactoferrin, most likely via specific protein receptors in the gut that link with lactoferrin and therefore facilitate iron absorption.

Bioactive Factors

Human milk contains an optimal balance of the nutrients required by the infant and, in addition, it contains an array of bioactive factors. In the first instance, these factors assist in the production and secretion of milk components and provide immune protection of mammary tissue. Once ingested by the infant, however, bioactive factors actively promote growth and development, and afford the infant immune protection until its own defense system has matured. Even the major components in milk may have specific bioactive functions either before being digested or as a result of releasing bioactive components during the digestive process.

The main sites of action for these bioactive factors are mucosal surfaces, although some may enter the circulation and have a systemic effect elsewhere in the body. The various physiological roles of milk components and their derivatives, either within the mammary gland or in the infant, are listed in **Table 11**.

Intact cellular components are found in human milk (**Table 12**), and although their exact role within either the mammary gland or the recipient infant is not clearly defined, there does appear to be a degree of biological activity associated with them. The total count of cells is high in colostrum, with the numbers decreasing as lactation becomes established. More than 90% of the cells in human milk are macrophages and neutrophils, while the remainder are lymphocytes (80% of which are T cells) and epithelial cells.

The primary function of milk leukocytes is thought to be as a means of defense within the mammary gland, and not necessarily to transfer maternal immunocompetence to the infant. Macrophages,however, have been suggested as a potential vehicle for the storage and transport of milk-borne Igs, and may be involved in the formation of lactoperoxidase and other factors that enhance the growth of intestinal epithelium and digestive capacity. The lymphocytes present in human milk are part of the immunological system that synthesizes IgA, and considerable research data are available to support the suggestion that lymphocytes in colostrum and milk provide the infant with immunological benefits.

Table 11 Physiological roles of components in human milk, either within the mammary gland or following ingestion by the infant

Physiological function	*Components in human milk*
Within the mammary gland	
Component synthesis/secretion	α-Lactalbumin, lipoprotein lipase, xanthine oxidase
Immune effect/anti-infection/ anti-inflammatory	Lactoferrin, lysozyme, γ-glutamyltransferase, cytokines
Within the infant	
Nutrition	β- and κ-casein, whey proteins, lactose, fats, minerals, and vitamins
Enhancing nutrient availability[a]	Bile salt-stimulated lipase, milk amylase, lactoferrin (Fe), glutamine (Zn), α-lactalbumin (Ca), casein phosphopeptides (Ca), folate-binding protein
Gut colonization	Bifidus factor peptide, κ-casein oligosaccharides
Gastrointestinal development	Epidermal growth factor, insulin-like growth factor, growth factor-binding proteins, hormones, enzymes, nucleotides, oligosaccharides, amino sugars
Brain development	Docosahexaenoic acid, other long-chain polyunsaturated fatty acids, taurine, carnitine
Immunity	Immunoglobulins, leukocyte-stimulating factors, T lymphocytes, macrophages, immunopeptides
Anti-infective	Lactoferrin, lysozyme, free fatty acids, cell adhesion molecules, cytokines, mucins, glycoproteins, glycopeptides, oligosaccharides
Anti-inflammatory	Vitamins, prostaglandins, growth factors, cytokines (interleukin-10), transforming growth factor-β
Immunomodulating	Interleukins, tumor necrosis factor-α

[a] Nutrient that has increased availability due to a particular component in human milk is given in parentheses.

Table 12 Cellular components (number per ml) in human colostrum and milk

Cell type	*Colostrum*	*Mature milk*

Factors that Influence Milk Volume and Composition

Factors Affecting Milk Volume

In women, the principal determinant of milk volume is infant demand. Comprehensive review of milk volume from exclusively breast-feeding women throughout the world has revealed that milk volume, 6 months into lactation, is incredibly constant, with an average of 800 ml (range 500–1200 ml) of milk transferred from mother to infant each day. The potential for milk production far exceeds this amount, however, given that mothers of twins or triplets can adequately nourish their children with human milk.

The energy density of human milk, in part, influences milk production, as infants consuming lower calorific milk will suckle more to obtain the energy required, in turn stimulating greater milk production. In one study, women with a low body fat content produced as much as 15% more milk as a result of increased infant demand. As soon as the weaning process begins, and human milk is substituted by either supplementary formula or complementary solids, milk production declines, indicating yet again the dominant role the infant plays in controlling milk volume.

Major Factors Affecting Milk Composition

Stage of lactation

Major compositional changes that occur from parturition through to day 21 of lactation have been discussed. The composition of human milk continues to change throughout lactation, however, with a gradual reduction in component content, although some components, for example, lysozyme, may increase.

During weaning, changes in composition can occur depending on the time taken to wean. When weaning is rapid (several days/weeks), lactose and potassium contents decrease, while sodium, chloride, fat, and total protein (specifically the whey proteins) increase. Gradual weaning (over several months) results in an increase in sodium (220% from baseline), iron (172%), and protein (142%), no change in calcium, and a decrease in zinc (58% from plateau). Both rapid and gradual weaning produce a decrease in lactose content.

Prematurity

Relative to normal human milk, the milk of mothers delivering prematurely contains higher concentrations of protein (1.8–2.4 g 100 ml^{-1}), short-, medium-, and long-chain FAs, calcium, phosphorus, sodium, chloride, magnesium, and iron, which is related to the low volume produced. Cellular components are also significantly greater in premature colostrum (total cells 6800 per ml). Levels of the other components in premature milk do not differ markedly from those found in normal human milk.

Changes during a feed and during the day

Changes that occur in composition during a feed relate more to the physicochemical nature of fractions in the milk, rather than a selective change in individual components. In general, most components remain relatively constant throughout a feed. The lipid content increases rapidly toward the end of a feed, however, reflecting a propensity of the mammary gland tissue to retain the lipid globules.

Subjective evidence from breast-feeding women suggests that milk composition changes during the day, especially toward evening, when the infant appears to be less satisfied by milk consumed. An unsettled infant is more likely to be due to insufficient milk volume, however, as lipid content actually increases toward the end of the day (by two- to fivefold). No significant changes occur during the day in other components.

Nationality/age/parity

The composition of milk from women from different geographic, ethnic, and socioeconomic backgrounds is remarkably similar, particularly in reference to the macronutrients. Any differences observed are more likely to be the result of dietary variation, rather than genetic modification of composition.

Milk from teenagers has a significantly lower concentration of lactose and some macrominerals compared to adults, but diet may play an important part in this difference as the diet of teenagers is often suboptimal.

Parity may have a significant effect on milk composition, with primiparous women having higher concentrations of protein and fat, and multiparous women experiencing a reduction in the content of major components in milk with each successive lactation.

Maternal diet

Two of the most significant factors influencing milk composition are the nutritional status of the mother and her ongoing diet. An inadequate nutritional status will adversely affect milk volume and the content of milk minerals such as iron and selenium. Severe malnutrition and diminished nutritional status will cause a decrease in the protein and fat content of milk.

The components most affected by maternal diet are FAs, vitamins, and some macro- and micro-minerals. The FA content of human milk can undergo pronounced changes that directly reflect the FA content of the diet. For example, the $C_{18:2n-6}$ content of milk from vegetarians is high compared to the milk from women consuming an omnivorous diet. Also, a low-fat diet will result in a marked increase in medium-chain FAs as the *de novo* synthesis of FAs in the mammary gland increases.

Exercise

Recent evidence suggests that the lactic acid content of human milk can change following exercise, with a decline in infant acceptance of milk secreted immediately after exercise. Exercise regimens at 100, 75, or 50% of $VO_{2\ \max}$ resulted in increases in the lactic acid content of milk sampled immediately after exercise, although only 100% intensity exercise produced milk with a lactic acid content significantly different from baseline. Thus, breast-feeding women can complete a moderate exercise program without the fear that the infant will reject their milk.

Illness and metabolic disorders

Mastitis

Infection of the mammary tissue, with cellulitis and, more rarely, abscess formation, can alter milk composition to such an extent that the infant's nutrition is compromised. During a bout of mastitis, milk volume and lactose content decrease, while the levels of sodium and chloride increase, giving the milk a much saltier taste. Immune factors such as sIgA, lysozyme, and lactoferrin also increase in milk from mastitic tissue, as part of the mammary gland immune response.

Insulin-dependent diabetes mellitus

The delayed lactogenesis associated with mothers with insulin-dependent diabetes mellitus (IDDM) results in a lower volume of milk being consumed by the infant in the first few days following birth. Initially (<5 days' lactation), the milk from an IDDM mother has a composition different from that of normal milk, with less lactose and fat, and more total nitrogen. Once lactation has been established, however, most of these differences diminish. The FA content of milk from IDDM women continues to differ throughout the lactation, with more C_{10}, C_{12}, and C_{14}, and less C_{20} and C_{22}, FAs.

Drug use

The degree to which a drug taken by the mother will affect the breast-fed infant depends entirely on the class of drug. Detailed information on the transfer of pharmaceutical drugs in human milk is available. Recreational drugs, such as alcohol, caffeine, nicotine, and marijuana, also appear in human milk and can affect both milk volume and composition. Human milk from a mother who smokes not only contains many chemical by-products, including nitrates, nitrites, lead, and cadmium, but is also likely to have lower levels of certain vitamins. Exposure of an infant to drugs (both medical and recreational) in milk can be minimized by advising the mother to take any medication immediately after a breast-feed, and/or just before the infant is due to have a lengthy sleep period.

Human Milk Banking

Human milk is usually collected and stored in milk banks to assist in the nourishment of premature infants. Implicit in this action of 'banking' milk is the need to maintain functional integrity in the milk. Numerous steps in the process can affect the composition of human milk, including the suitability of the donor, and her dietary regimen; the method of milk collection and the type of container chosen to collect the milk; the length of time and temperature at which the milk is stored; and the methods used to thaw, mix, and reheat the milk prior to a feed. The Human Milk Banking Association of North America has compiled a set of guidelines for the establishment and operation of a donor milk bank.

Colostrum

P Marnila and H Korhonen, MTT, Agrifood Research Finland, Jokioinen, Finland

Introduction

Colostrum is the initial mammary secretion after parturition. In the cow, it is secreted for approximately the first 5–7 days after delivery. The biological function of this early milk is to provide the newborn with immune protection against pathogens at its most vulnerable phase of life and to boost its physiological performance, growth, and development. Thus, the composition of colostrum is different from that of mature milk. Colostrum contains plenty of immunologically and physiologically active components. These include immunoglobulins (Igs), leukocytes, lactoferrin (LF), lysozyme (LZM), cytokines and other (casein-derived) immunomodulatory factors, growth factors, hormones, and oligosaccharides. Therefore, the commercial exploitation of colostrum for pharmaceutical and dietary use has attracted a great deal of attention of late.

Composition and Changes during Lactation

Cow's colostrum contains more dry matter, mineral salts, and protein and less lactose than mature milk. Also, the fat content is often, but not always, higher than that of milk (**Table 1**). Moreover, the composition of colostrum varies more between individuals than that of mature milk. The concentration of the elements Ca, Na, Mg, P, and Cl is higher and that of K is lower in colostrum than in milk. The main change from colostrum to normal milk occurs in the first few milkings after parturition and continues at reduced rates for approximately 5 weeks. Thereafter, the fat and protein contents rise gradually, and toward the end of lactation they increase more sharply (see **Table 1**).

The proportion of whey proteins is substantially higher in colostrum than in milk. The foremost protein fraction in colostrum consists of Igs (IgG, IgM, IgA). In the first milking, the total amount of Ig varies between 20 and 200 $\mathrm{g\,l^{-1}}$ and the IgG concentration post-partum ranges from 15 to 180 $\mathrm{g\,l^{-1}}$, the mean being approximately 60 $\mathrm{g\,l^{-1}}$. Thereafter, the IgG concentration falls sharply (**Figure 1**). Cows at their first lactation produce significantly less (total yield about half or less) IgG than cows in later lactations due to both a lower IgG concentration and a smaller volume of colostrum. The levels of both α-lactalbumin and β-lactoglobulin are highest in the first milkings of bovine colostrum and decrease sharply thereafter. The protein composition of human colostrum and milk differs considerably from that of bovine colostrum. Human colostrum does not contain β-lactoglobulin and the major Ig class is IgA. The major casein component of human colostrum is β-casein instead of α_{s1}-casein, which is the predominant casein fraction in bovine colostrum.

The fatty acid composition of human and bovine colostrum is markedly influenced by maternal dietary composition. Changes in nutrition have an effect on the colostral fatty acid profile. Both human and bovine colostra typically contain more polyunsaturated fatty acids than mature milk. In colostrum the proportions of short chain fatty acids (C4-C10) are typically lower than in mature milk (**Table 2**). The fat fraction of bovine colostrum contains significantly higher concentrations of phospholipids, cholesterol, and fat globule membrane material than mature milk.

The concentrations of vitamins vary in bovine and human colostra and milk according to stage of lactation and maternal dietary intake. However, much of the variation in reported values in the literature is due to analytical difficulties rather than variable patterns of secretion. In bovine colostrum, the concentrations of fat-soluble vitamins A, D, and E and carotenoids, as well as those of water-soluble vitamins thiamine, riboflavin, vitamins B_6 and B_{12}, folate, and vitamin C, are higher than in mature milk. The contents of pantothenic acid and biotin are lower in colostrum and that of niacin about the same as in mature milk (see **Table 1**). In human colostrum, the levels of vitamins A and E and carotenoids are higher than those in milk. The content of vitamin K in the colostrum is equal to that in milk. (Most of the water-soluble vitamins (thiamine, riboflavin, vitamin B_6, folate, vitamin C, pantothenic acid, biotin, and niacin) exist at lower concentrations in colostrum than in mature milk, whereas the vitamin B_{12} content is higher in colostrum.

Immune Protection by Colostrum

Passively acquired immunity from colostrum is important for the health of a neonate. Newborn calves and piglets that do not receive colostrum show high mortality and poor weight gain during the first weeks of life. Calves deprived of colostrum or given colostrum of poor quality

suffer severe long scour episodes. Colostrum from the first two milkings is most important since the concentrations of Igs and LF decrease steeply after the first milkings (see **Figure 1**). The gut of a newborn calf is non-selective and open to the transport of a variety of macromolecules from 12 to 36 h matching with the time of the highest IgG content of colostrum. A newborn calf needs about 2–4 l of colostrum (100–200 g Ig) to protect it against scouring.

Most farm animals do not have *in utero* transport of Igs to the fetus and their young are born virtually without protective antibodies. In humans, IgG transport via the placenta is very efficient and therefore the human infant is born with a serum concentration of IgG equaling that of the mother. Mammals can be categorized into species with extensive placental transfer (e.g., human and rabbit), those with no placental transfer but extensive lacteal transport (e.g., pig, horse, cow, sheep, and goat), and those that use both pathways (e.g., dog, mouse, and rat).

The transport of Ig from serum to colostrum is selective, favoring homologous IgG in most species. Specific receptors are involved in the process (see **Figure 2**). This enables the selective concentration of IgG isotypes in colostrum. For information on the absorption of antibodies, *see* **Milk Proteins**: Immunoglobulins.

Colostrum also contains an active complement system that participates in immune defense of the udder. It is not known whether the colostral complement system provides any immunological protection to the newborn. There is some evidence that feeding colostrum or colostral whey concentrate to a calf increases the lytic activities of both antibody-dependent classical and antibody-independent alternative pathways of complement in the serum of the calf.

Colostral Ig and complement proteins are quite resistant to gastric acids but sensitive to trypsin. On the other hand, bovine colostrum contains a trypsin inhibitor that neutralizes trypsin activity and allows absorption of Ig.

Living leukocytes are an integral part of normal bovine and human colostrum and milk. Their concentration is highest in the colostrum and declines gradually in transition to normal milk. The leukocytes defend the breast or udder against pathogens. It has been established that maternal leukocytes cross the neonatal gut and circulate in the newborn calf. This may result in the

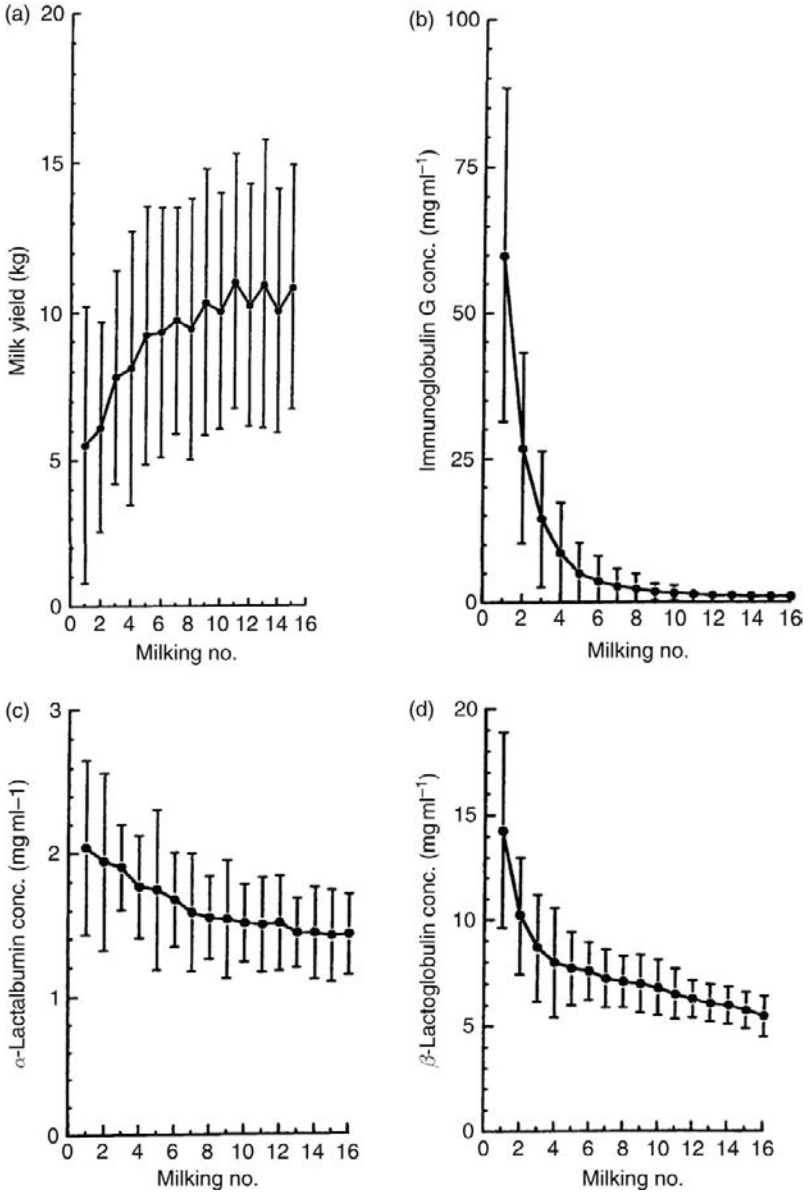

Figure 1 (a) Milk yield and concentrations of (b) immunoglobulin G, (c) α-lactalbumin, and (d) β-lactoglobulin of the first milkings after calving in 60 Holstein-Friesian cows (mean values with SD indicated by vertical bars). Adapted with permission from Levieux D and Ollier A (1999) Bovine immunoglobulin G, β-lactoglobulin, α-lactalbumin and serum albumin in colostrum and milk during the early post partum period. *Journal of Dairy Research* 66: 421–430.

transfer of antigen-specific cellular immunity to the calf. Recent studies have shown that these maternal leukocytes have an important role in the development and maturation of neonatal cellular immunity. However, so far, only little is known about the mechanisms of the immunological interactions of maternal leukocytes with the neonate.

Colostral Ig and lymphocytes represent the mother's specific immune response to antigens encountered in the past. This immunological memory is mediated to the next generation via colostrum. In addition, colostrum also contains components that carry nonspecific antimicrobial and immune-enhancing properties. Such factors are LF, LZM, lactoperoxidase (LPO), and leukocytes (**Table 3**).

Human colostrum is particularly rich in LF, with the concentration ranging from 5 to 10 $g\,l^{-1}$. The concentration decreases in transition to mature milk to about 0.1 $g\,l^{-1}$. In cow's colostrum, the LF concentration varies from 1 to 2 $g\,l^{-1}$, decreasing soon after parturition to a level of about 0.1 $g\,l^{-1}$ in normal milk (see **Table 3**). LF is synthesized in the mammary gland, but also in other exocrine glands. LF and especially its cleavage products have a broad bacteriostatic and bactericidal spectrum; in particular, LF has a synergistic antibacterial effect with

Data from M. Paulsson and H. Lindmark-Månsson (unpublished results).

LZM. LF also regulates immune defense by inhibiting the progressive inflammatory cascade. In the mouse, orally administered bovine milk LF increases the numbers of CD4+ and CD8+ lymphocytes and natural killer (NK) cells and regulates cytokine secretion in gastrointestinal lymphoid tissue. The systemic effects of orally administered LF include increased cell numbers in spleen and lymph nodes, enhanced cell activity of phagocytes and NK cells, and modulation of lymphocyte functions (*see* **Milk Proteins**: Lactoferrin).

Soluble CD14 receptors (sCD14) belong to the family of pattern-recognizing receptors and bind lipopolysaccharides (LPS). It is reported to exist in human colostrum ($20 \pm 9\,\mathrm{mg\,l^{-1}}$ (mean ± SD)) and mature milk (about $14 \pm 6\,\mathrm{mg\,l^{-1}}$ (mean ± SD)) at a remarkably higher concentration than in serum (about $3\,\mathrm{mg\,l^{-1}}$). Quantification of sCD14 in bovine milk has been difficult due to the lack of a specific assay. Nevertheless, it is estimated to be present at slightly lower concentrations than in human milk and the levels are elevated during mastitis or intramammary challenge with LPS. It contributes to the 'education' and maturation of the neonatal immune system for recognizing and responding to microbial components.

LPO is an effective antimicrobial oxidoreductase enzyme that catalyzes the oxidation of thiocyanate and halide ions (mainly chloride, iodide, or fluoride) to corresponding hypohalides to generate highly reactive oxidizing agents having a broad spectrum of antimicrobial effects. Cow's colostrum contains about $30\,\mathrm{mg\,l^{-1}}$ LPO, the same level as in mature milk. In human colostrum, practically all of the peroxidase activity is derived from myeloperoxidase of leukocyte origin, and only a trace amount of it is from LPO. LPO plays an important role in protecting the lactating mammary gland and the intestinal tract of the newborn against pathogenic microbes. Feeding of LPO-supplemented milk to calves reduces the incidence of scouring and improves growth in newborn calves. LPO can also be exploited for preservation of raw milk. In human infants, salivary peroxidase may compensate the paucity of LPO in colostrum.

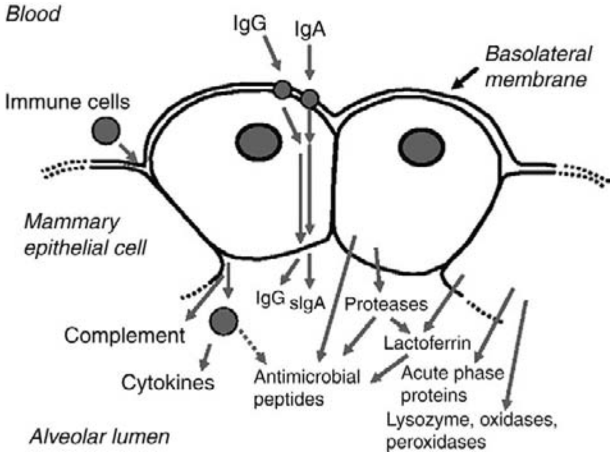

Figure 2 Schematic diagram showing some of the principal known proteinaceous components of the host defense system in milk and colostrum. IgA and IgG, immunoglobulins A and G; sIgA, secretory IgA. Reproduced with permission from Wheeler TT, Hodgkinson AJ, Prosser CG, and Davis SR (2007) Immune components of colostrum and milk – a historical perspective. *Journal of Mammary Gland Biology and Neoplasia* 12(4): 237–247.

LZM is a potent antibacterial component in human colostrum and milk and influences the intestinal bacterial flora of the neonate. Human colostrum contains LZM at about $0.36\,\mathrm{g\,l^{-1}}$; the concentration of LZM decreases to $0.30\,\mathrm{g\,l^{-1}}$ in transition and mature milk. In bovine colostrum, the LZM level ranges from 0.3 to $0.8\,\mathrm{mg\,l^{-1}}$, declining to $0.1\,\mathrm{mg\,l^{-1}}$ in mature milk.

Growth Factors

Colostrum and milk contain many factors that influence cell growth and differentiation. These non-nutrient components contribute to the specific stimulation of jejunal and skeletal muscle development in colostrum-fed neonatal pigs and calves as well as humans. Results from animal studies suggest that feeding of trace amounts of colostral growth factors augments intestinal absorptive capacity as well as protein and fat metabolism and exerts beneficial effects on the endocrine system of neonatal calves. Also, it is suggested that colostral growth factors stimulate brain and heart protein synthesis in colostrum-fed neonatal animals. Furthermore, some non-peptide constituents of colostrum (e.g., glutamine, polyamines, and nucleotides) play an important role in maintaining the gastrointestinal mucosal mass and in modulating the immune system via multiple mechanisms, for example, by modulating the gastrointestinal microflora and

Data compiled from Jensen RG (ed.) (1995) *Handbook of Milk Composition*. San Diego, CA: Academic Press, Inc.; Korhonen H, Pihlanto-Leppälä A, Rantamäki P, and Tupasela T (1998) The functional and biological properties of whey proteins: Prospects for the development of functional foods: A review. *Agricultural and Food Science in Finland* 7: 283–296; Pakkanen R and Aalto J (1997) Growth factors and antimicrobial factors of bovine colostrums: A review. *International Dairy Journal* 7: 285–297; Velona T, Abbiati L, Beretta B, *et al*. (1999) Protein profiles in breast milk from mothers delivering term and preterm babies. *Pediatric Research* 45(5 Pt. 1): 658–663.

influencing the actions of growth factors. In general, the growth factor concentration in colostrum is highest during the first hours after calving and declines substantially thereafter.

In bovine colostrum, the epidermal growth factor (EGF) and betacellulin belong to the EGF family. Members of the EGF family stimulate the proliferation of epithelial and epidermal cells, act as differentiation factors for some cell types, and modulate the synthesis of a number of hormones. EGF inhibits the secretion of gastric acid. In bovine colostrum, the concentration of EGF varies from 4 to 320 $\mu g\,l^{-1}$ and it ranges from 2 to 155 $\mu g\,l^{-1}$ in mature milk. In human colostrum, the total EGF concentration is about 35–330 $\mu g\,l^{-1}$ and ranges from 3 to 60 $\mu g\,l^{-1}$ in milk. Betacellulin is present in bovine colostrum (2.30 $\mu g\,l^{-1}$) and in cheese whey (2.59 $\mu g\,l^{-1}$), suggesting that it plays a role in accelerating the growth and maturation of the calf and/or in mammary gland function. Human EGF is degraded in both gastric and duodenal lumen. Bovine milk is reported to contain peptidase inhibitors that protect human EGF from proteolytic degradation in human gastrointestinal fluids.

Insulin-like growth factors 1 and 2 (IGF-I and IGF-II) are single-chain polypeptides structurally resembling insulin. They are widely distributed and promote cell proliferation and differentiation and have *in vitro* acute anabolic effects on protein and carbohydrate metabolism. In serum and milk, the IGFs are found almost entirely bound to high-affinity binding proteins (IGFBPs). In bovine colostrum, IGFBP-3 is the major binding protein, but IGFBP-2 is also abundant. The IGF peptide is released from binding proteins by acid treatment. Bovine colostrum contains significantly higher concentrations of IGF-I than does human colostrum (32–800 $\mu g\,l^{-1}$ as compared with 17–52 $\mu g\,l^{-1}$), with lower concentrations in mature bovine milk (4–27 $\mu g\,l^{-1}$). In neonatal piglets, parenteral IGF-I administration enhances the thickness of epithelial, submucosal, and smooth muscle layers, promotes gastrointestinal tract growth, and improves the absorption of sodium and glucose. IGF-I in bovine colostrum is an anabolic agent and is at least partly responsible for mediating the growth-promoting activity of the growth hormone (GH), which has been detected in bovine colostrum at a low concentration of 0.17 $\mu g\,l^{-1}$ but is absent from mature milk. Although many proteins are absorbed effectively within the first 24–48 h after birth, only negligible or no absorption of insulin or IGF-I is detected in the blood circulation of calves within the first 24 h after birth. IGF-II is present in bovine colostrum and milk at concentrations of 150–600 and 2–100 $\mu g\,l^{-1}$, respectively. IGF-II has anabolic activity and has been shown to reduce the catabolic state in starved animals.

LF may also participate in regulation of the gut and in bone growth in developing neonates as it stimulates *in vitro* the growth of fibroblasts, intestinal epithelial cells, leukocytes in the gastrointestinal tract-associated lymphoid tissue, and osteoblasts. Receptors for LF are expressed by several cell types, including T and B lymphocytes, platelets, and intestinal epithelial cells.

Transforming growth factor-α (TGF-α) is present in human colostrum and milk at concentrations of 2.2–7.2 $\mu g\,l^{-1}$. Most studies suggest that the major physiological role of TGF-α is to act as a mucosal integrity peptide, maintaining normal epithelial function in the nondamaged mucosa.

The TGF-β family comprises multi-functional growth and differentiation factors acting on most cell types, stimulating the proliferation of connective tissue cells and acting as growth inhibitors of some other cell types such as lymphocytes and epithelial cells. TGF-β1 is detected in bovine colostrum and milk (12–43 and 0.8–4 $\mu g\,l^{-1}$, respectively) but TGF-β2 is the predominant isoform present at high concentrations in bovine colostrum and milk (150–1150 and 13–71 $\mu g\,l^{-1}$, respectively). The physiological function of TGF-β in bovine colostrum and milk is obscure, but the high concentrations suggest that TGF-β in colostrum may be a mediator of mucosal immunity and may contribute to epithelial differentiation of gastrointestinal tract of suckling neonates.

Sialyl oligosaccharides in colostrum and milk prevent adhesion of pathogenic microbes. Sialic acid is probably used in the biosynthesis of neonate brain gangliosides and sialyl glycoproteins. In the cow, the total sialic acid content is 2–4 times higher in colostrum (0.3–0.8 $g\,kg^{-1}$) than in transition and mature milk (0.1–0.2 $g\,kg^{-1}$).

Other growth factors, cytokines, and hormones are also found in human and bovine colostrum, but their physiological significance remains obscure. These are, for example, the vascular endothelial growth factor, fibroblast growth factors, the platelet-derived growth factor, GH and its releasing factor, insulin, granulocyte, macrophage, and granulocyte–macrophage colony-stimulating factors, interleukins 1β, 6, 10, and 18, and tumor necrosis factor-α.

Recent studies suggest that colostral fractions, or individual peptides present in colostrum, might be useful for the regulation/modulation of a wide variety of gastrointestinal functions. It is likely that in the future, additional growth factors will be identified in colostrum and milk. For additional information on these factors and their extraction and bioavailability from colostrum and milk, see the 'Further Reading' section.

Industrial Utilization of Colostrum

Colostrum is normally produced in amounts that exceed the need of the newborn. At present, dairy or food industries do not exploit bovine colostrum commercially on a large scale due to technical and hygienic problems related to collection and processing. In many countries, colostrum must be excluded from bulk milk collection during the first 5 days post-partum. The low clotting temperature of colostrum interferes with pasteurization and the high protein content leads to problems in industrial processes. Furthermore, the high content of antimicrobial components in colostrum may slow down or inhibit fermentation processes. This also affects the antibiotic residue tests based on microbial growth, causing false-positive results.

Bovine colostrum is utilized on a minor industrial scale and in households in many countries, for example, in Scandinavia, in the form of cheese baked in an oven. Also, the casein fraction of renneted colostrum is baked and used as fresh cheese.

Cheese whey-based and colostral whey-based antibody preparations are commercially available in many countries as feed supplements or colostrum substitutes for farm animals. They are prepared mainly for neonate calves and pigs and have shown variable efficacy in the prevention of diarrheal diseases caused by pathogens such as rotaviruses and enterotoxigenic *Escherichia coli* strains. There is increasing interest in the development of so-called immune milk preparations made from colostrum of hyperimmunized cows. Such preparations may target both humans and domestic animals for prevention and treatment of specific gastrointestinal diseases. A few preparations, for example, those against rotavirus and *E. coli*, are already on the market.

The pharmaceutical and biotechnological industries have recently shown interest in bovine colostrum as a source of growth factors and other specific bioactive components. Colostrum-based growth media have been developed for culturing cells. Also, a multitude of health products and foods made from various colostrum fractions, for example, drinks and chewing gums for sportsmen, have been launched on the market. Scientific studies have shown some evidence that orally administered bovine colostral supplements can increase lean body mass and have a small improving effect on exercise performance and/or recovery but the mechanisms still remain elusive. A few studies suggest that orally administered bovine colostral whey preparations could reduce the incidence of upper respiratory tract infections and have beneficial effects on cholesterol level and type 2 diabetes in humans. However, more research is needed to verify these effects. Currently, there is increasing pharmaceutical research under way to examine the potential related to the use of colostrum-derived preparations for a wide range of gastroenterological conditions.

Seasonal Effects on Processing Properties of Cows' Milk

B O'Brien and T P Guinee, Teagasc Moorepark, Fermoy, County Cork, Ireland

Introduction

Milk production may be described in terms of two distinct cow herd management systems; one system is defined by a comparatively even milk production pattern throughout the year, whereas the other system is defined by milk production peaking at a specific time of year (e.g., April–May) and decreasing steadily until end of lactation (e.g., December). The consistent milk production system observed in most European countries is characterized by a relatively consistent calving pattern throughout the year. For example, in Norway, the month with greatest incidence of calving is September with fewer than 14% of the total cow population calving during that month. Alternatively, the seasonal milk production system is characterized by a compact calving pattern where a large proportion of cows calve between January and April, for example, with as many as 60% of total cows calving in the February–March period in Ireland.

Some dairy industries such as that of Ireland and New Zealand are based around the use of pasture as a natural low-cost feed source, which has led to the wide adoption of seasonal calving to maximize pasture utilization. Milk producers continually adjust the date of calving, so that most cows calve in early spring, and are dried off for 8–10 weeks during winter. Though this system maximizes cost efficiency from a grass-based production perspective, the seasonal milk production system creates two constraints for the milk processing industry; that is, an irregular supply of milk for product manufacture during the winter months (when milk production ceases) and an irregular quality of milk during the autumn/winter period when cows have reached an advanced stage of lactation (>250 days). When the national herd is predominately spring-calving and a management strategy of compact calving is applied, the composition of the milk varies as the milk of an individual cow would throughout her lactation. This phenomenon may be less noticeable in countries where a more consistent calving pattern is practiced throughout the year. Although seasonal variation in quality is most evident and extreme in seasonal calving milk production systems, seasonal variation in composition and quality is also notable in milk from consistent milk production systems. Seasonal variation in the processing quality of milk is manifested through stage of lactation and nutritional and physiological effects.

Seasonality of milk may be defined simply as the changes in composition, quality, and suitability for processing into dairy-based products throughout the calendar year. For compact spring-calved herds on pasture-based feeding systems, advance in season coincides with advance in stage of lactation (e.g., typically start of lactation in February to end of lactation in December in the Northern Hemisphere). This is less so in the case of milk produced by herds with a consistent calving pattern over the year, where milk is produced all year round.

The main factors affecting seasonal changes in milk composition and quality are stage of lactation and nutritional status/environment. Lactation changes in milk composition may be defined as those that take place during the period of milk production, between parturition and drying-off, mainly as a result of physiological changes occurring in the mammary gland in healthy cows fed on standard good-quality diets. On the other hand, seasonal changes in milk may be defined as those arising due to lactation and the superimposed effects of other factors such as variations in diet, illness (e.g., subclinical mastitis), environmental factors, and climate.

The aforementioned effects of stage of lactation occur in milk from both calving systems (i.e., compact spring-calving and consistent calving) but are not as evident in the overall milk pool of the latter because of the masking by milk contributed from cows at different stages of lactation. Indeed, the late-lactation effects of individual cow milk may be more extreme in consistent-calved herds than spring-calved herds owing to the herd management/practices applied (e.g., somatic cell count as influenced by hygiene issues associated with the production of milk indoors, and days of lactation of individual cows at drying-off). However, other factors influencing milk composition/quality include, *inter alia*, breed, health status, age of the cow, and the counts and types of somatic cells and bacteria in the milk.

The processing properties of cows' milk may be described as the characteristics that enable it to meet the criteria required for efficient manufacture and production of a quality product. This article describes the effect of season on milk processing properties and its suitability for product manufacture, focusing on three main areas: cheese-making properties, heat stability, and alcohol stability of milk, with particular emphasis on the former.

It is noteworthy that cheese manufacture accounts for a significant portion of total milk produced globally (i.e., ~25%), even though it varies widely with region.

Cheese

Principles of Cheese Manufacture

Cheese is a concentrated protein gel, which occludes fat and moisture. Its manufacture essentially involves gelation of cheesemilk, dehydration of the gel to form a curd, and treatment of the curd (e.g., dry stirring, cheddaring, texturization, salting, molding, pressing). The molded curds may be consumed fresh (shortly after manufacture, e.g., within 1 week) or matured for periods of ~2 weeks to 2 years to form a ripened cheese. The gelation of milk may be induced by:

- selective hydrolysis of the κ-casein by the addition of acid proteinases, referred to generically as rennets (e.g., chymosin, pepsin);
- acidification (e.g., using starter cultures or food-grade acids and/or acidogens), at a temperature of 20–40°C, to a pH value ~4.6; and/or
- a combination of acid and heat (e.g., heating milk at ~pH 5.6 to ~90°C).

Essentially, cheesemaking is a process involving protein (of which casein is the largest component) aggregation and gel formation, and dehydration of the resultant gel. Thus, the degree of casein aggregation is a critical parameter controlling the properties and quality of the final cheese. The most important milk-quality characteristics for cheese manufacture are those that promote:

- aggregation of the casein to form a gel that is sufficiently firm to cut within an acceptable time frame (typically, 30–50 min for rennet-curd cheese; 4–14 h for acid-curd cheeses);
- continued aggregation together with whey expulsion during the remaining cheesemaking operations after gelation;
- a gel structure and rheology that at all stages of manufacture provides (a) a robustness that maximizes the retention of fat and casein in the curd and curd yield and (b) the desired texture in the final cheese, at the point of use (secondary processing or consumption).

These attributes are prerequisite to the formation of a fresh curd with desired composition, structure, texture, and yield. Characteristics of the milk that are generally positively correlated with enhanced rennet coagulation include:

- high values for casein number, intact casein content, contents of total casein, individual (α_{s1}-, β-, and κ-) caseins, calcium-to-casein ratio, and ratios of κ-casein to total casein and to individual caseins (α_{s2}- and β-caseins);
- low values for serum casein, micelle size, and degree of κ-casein glycosylation.

Quality Requirements of Milk for Cheese Manufacture

In an overall context, the quality of milk for cheese may be defined as its characteristics that fulfill the requirements of its users, direct (the cheese manufacturer) and indirect (the cheese user, consumer). The quality requirements of the manufacturer/processor are discussed below.

1. Compositional/nutritional, which indicate the conformity to minimum levels of particular components (e.g., fat, protein, casein, calcium) that make it suitable for cheese manufacture (e.g., enable the milk to form a gel suitable for cutting within a certain time after addition of rennet); to give desired manufacturing efficiency (e.g., percentage recovery of fat and casein; product yield), composition (e.g., levels of protein, calcium, moisture), and sensory characteristics.
2. Intact casein level (an index of the wholeness of the milk casein, the absence of milk protein hydrolysis) reflecting the ability of the milk to form a strong intact gel, capable of occluding protein, fat and moisture during manufacture, maximizing the recovery of milk fat and water to cheese, and imparting the desired texture and functional properties to the final cheese (*see* **Cheese**: Cheese as a Food Ingredient; Cheese Rheology). Native bovine milk contains proteinases from a number of sources, the indigenous milk trypsin-like proteinase (plasmin), lysosomal proteinases of somatic cells, and bacterial proteinases of bacteria (especially psychrotrophic bacteria such as *Pseudomonas* or *Bacillus*). These proteinases hydrolyze caseins, are complex in their regulation, and vary in activity according to factors such as stage of lactation and mastitis status. Hydrolysis of the milk casein, apart from its effects associated with reduction in intact casein level, reduces protein recovery to cheese during the manufacturing process, an effect that reduces the overall manufacturing efficiency.
3. Fat stability, an index of the intactness of the fat globule (with little or no damage to the milk fat globule membrane, or MFGM) and absence of lipolysis of fat triacylglycerols (to products such as di-/mono-acylglycerols and free fatty acids, FFA). Bovine milk contains lipases which hydrolyze the fat into FFA, which cause unpleasant rancid or bitter off-flavors in many dairy products. Milk from cows in late lactation has a higher FFA level than milk from cows in early lactation (0.68 and 0.28 mM 100 g^{-1} fat, respectively). This may be related to the type of feed (pasture or dry

feed indoors) and/or quality of feed, particularly in regions where cows are compact spring-calved and late lactation corresponds with a time of year when good-quality feed is in short supply. Alternatively, the increased milk lipolysis levels may be due to mechanical damage of the fat globule membrane (which encloses the fat) by excessive mixing of air into the relatively small volume of milk, especially during late lactation.

Effect of Milk Composition and Quality on Cheese

Variation in the fat content of the raw milk is generally of little practical significance, as milk for cheese manufacture is easily standardized to a protein-to-fat ratio (PFR) within a defined range (e.g., ~0.85–0.90 for Cheddar cheese), as part of a standard operating procedure, by the appropriate removal of fat *via* mechanical separation (skimming) (e.g., for low-moisture part-skim Mozzarella) or the addition of cream (e.g., for cream cheese). However, where milk is not standardized, seasonal variation in the PFR of milk (**Figure 1**) can have significant effects on cheese composition. Increasing the PFR in the range 0.70–1.15 has been found to significantly increase the level of moisture but reduce the level of moisture-in-non-fat substances (MNFS), fat, fat-in-dry matter (FDM), and salt-in-moisture (S/M).

Similarly, the protein content, or more specifically the casein content, of raw milk has little effect when the protein content of the cheesemilk is standardized to a defined level, for example, by low concentration factor (1–1.5 times) ultrafiltration of the raw milk or by addition of a milk protein supplement. However, protein standardization is not a universal practice, and consequently variation in milk protein level can have significant effects on cheese composition, yield, and quality.

Apart from variations in the levels of gross constituents, seasonal variation can also occur in the functionality or 'quality' of the protein in terms of its ability to form a gel with satisfactory curd firming and syneretic (wheying-off) properties and to produce cheese curd of satisfactory moisture content and texture. Late-lactation milk generally gives poor rennet coagulability (low curd firmness), impaired curd syneresis, high-moisture Cheddar cheese, and lower recovery of milk fat in cheese. These defects coincide with low levels (approximately ≤4.3%, w/w) of milk lactose, low casein number (<72, casein as a percentage of true protein), and increased levels of serum casein (>40 g 100 g^{-1} total protein), non-sedimentable at 30 000 × *g*. In this context, it is noteworthy that low lactose levels in milk generally coincide with high somatic cell count (SCC) and level of plasmin activity and may be indicative of udder infection and increased excretion of blood constituents into the milk. The extent of these cheesemaking defects in late-lactation spring-calved herds is accentuated when both the plane of nutrition of the cow and the milk yield at drying-off are low (e.g., high stocking density on pasture in October and November without dietary supplementation in the Northern Hemisphere, and <6 l of milk per cow per day).

Seasonal Changes in Milk Composition

There are notable changes in the concentrations of fat, protein, casein, and lactose and individual minerals associated with seasonality (**Figures 2** and **3**). These changes in turn affect the rennet gelation characteristics (**Figure 4**) of milk and its cheesemaking properties. The seasonal changes are affected by a number of factors, especially stage of lactation and cow nutrition/environment.

Effect of Stage of Lactation on Milk Composition

The composition of milk changes markedly with stage of lactation. After parturition, yield increases during the first 6 weeks and thereafter declines steadily to the end of lactation. The colostrum produced at parturition has a very high concentration of total solids (i.e., ~25% compared with 13% in mid-lactation). The increase in milk

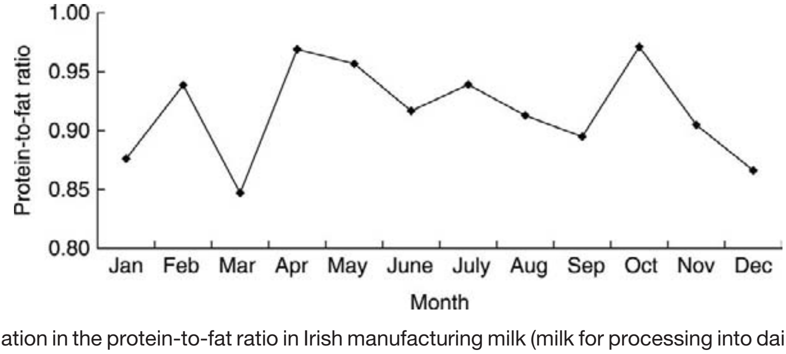

Figure 1 Seasonal variation in the protein-to-fat ratio in Irish manufacturing milk (milk for processing into dairy products rather than for sale as pasteurised drinking milk).

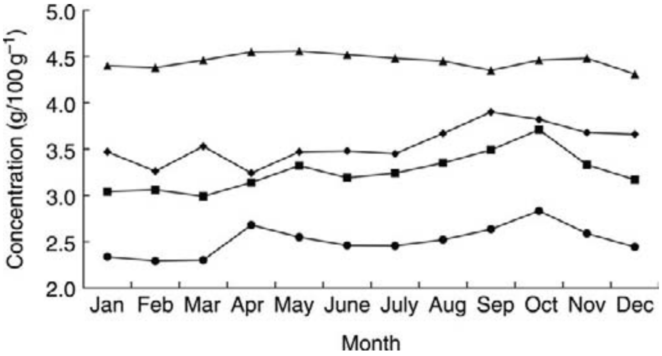

Figure 2 Seasonal variation in the concentration of fat (◆), protein (■), lactose (▲), and casein (•) in Irish manufacturing milk.

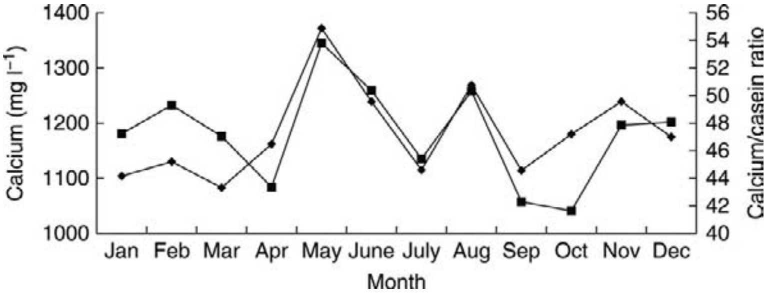

Figure 3 Seasonal variation in the concentration of calcium (◆) and calcium-to-casein ratio (■) in Irish manufacturing milk.

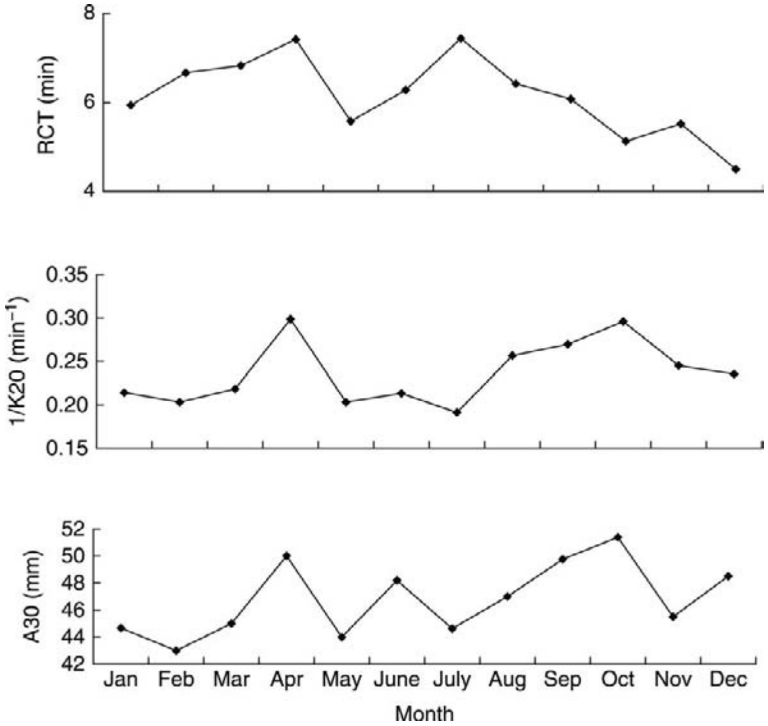

Figure 4 Seasonal variation in rennet coagulation time (RCT), curd-firming rate (1/K20), and curd firmness at 30 min (A30) of Irish manufacturing milk at natural pH (~6.6–6.7) and at 31 °C.

yield to its peak level in early lactation (~6 weeks) is paralleled by reductions in the levels of total solids, protein, casein, and fat and an increase in the concentration of lactose. In contrast, the subsequent steady decrease in milk yield to late lactation (i.e., 285 days) coincides with gradual increases in total solids, fat, protein, and casein and a reduction in lactose level. Lactation effects on gross composition are more pronounced at the beginning (first 6–8 weeks) and end of lactation (increasingly so from 225 days onward). During the latter period, the proportional increases in total protein and fat are similar, but that for casein is less than that of total protein (as reflected by the decrease in casein number). Hence, the casein-to-fat ratio decreases rather dramatically, emphasizing the need for accurate milk standardization for cheese manufacture to maintain optimum composition and cheese yield. Whereas the cheese-yielding potential of acceptable-quality milk increases progressively in the late-lactation period (days 225–285) due to the increase in casein level, the decrease in casein number indicates that for a given protein level, the cheese-yielding capacity is lower compared with that at mid-lactation.

Moreover, the proportions of different caseins and whey proteins change over the course of lactation. α_{s1}-Casein as a percentage of total casein drops rapidly during the first few days of lactation, then increases, and thereafter remains more or less constant throughout the remainder of lactation. In contrast, the proportion of β-casein is low at the initial stages of lactation, then increases to ~200 days and thereafter decreases as the levels of γ-caseins increase. Although no information is available on the effects of the differences in the proportions of individual caseins on cheese yield, it is expected that the dry matter cheese yield per 100 kg of casein- and fat-adjusted milk would decrease slightly toward the end of lactation with the increase in the proportion of γ-caseins and the concomitant reductions in intact casein level and protein recovery from milk to cheese. The proteose peptones, produced on hydrolysis of β-casein to γ-caseins, are soluble in the serum phase and are likely to be only partly, if at all, recovered with the curd during cheese manufacture. The total proteose peptone fraction increases during lactation from ~20 to 50 mg N 100 g^{-1} milk. Moreover, changes in the proportions of different caseins are likely to affect protein interactions (ratio of hydrophobic to electrostatic), gel strength, and the physical properties of the resultant cheeses.

Effect of Cow Nutrition on Milk Composition

One alternative to influence the manufacturing potential of milk is through the nutrition of the cow, but the response may vary depending on the stage of lactation.

Early lactation

In pasture-fed systems, calving date is targeted to commence with the start of the grass herbage-growing season. However, supplementing spring-calved cows on grass silage and concentrates with grazed grass in late February to late April (by allowing cows on pasture for 2–4 h per day) was found to significantly improve the gelation properties of milk, an effect concomitant with numerical increases in protein concentration (e.g., 3.06–3.17%, w/w).

Mid-lactation

Studies have shown that increasing herbage allowance from 16 to 24 kg grass dry matter (DM) in mid-lactation significantly increased both the yields and concentrations of total protein (e.g., from 3.2 to 3.4%, w/w), casein (2.43–2.61%, w/w), and lactose (4.60–4.65%, w/w) but did not significantly affect the concentrations of calcium and phosphorus, rennet gelation properties, and the alcohol stability of the milk. Similarly, the cheesemaking characteristics were not influenced, as reflected by the absence of significant effects of herbage allowance on the gross composition, rheologic characteristics, or cooking properties of the resultant Mozzarella cheese. However, the moisture-adjusted cheese yield increased by ≥0.5 kg 100 kg^{-1} milk, an effect that coincided with the higher level of milk casein (~0.1%, w/w) at the higher herbage rates. The above trends were corroborated by further studies, showing that an increase in stocking density above a standard system (defined as post-grazing grass height of 60 mm) resulted in significant reductions in the concentrations of total protein (e.g., 3.22 vs. 3.40%, w/w), casein (2.48 vs. 2.67%, w/w), and whey proteins, and a deterioration in rennet coagulability. Imposing concentrate supplementation on the standard system increased the levels of total protein (e.g., 3.40 vs. 3.49%, w/w), casein (e.g., 2.67 vs. 2.76%, w/w), and whey protein but generally did not affect processing characteristics, including rennet coagulability and alcohol stability (stable to 76 vs. 79% ethanol). The supplemented diet also resulted in an increase in moisture-adjusted cheese yield of 1.1 kg 100 kg^{-1} milk, an effect that coincided with the higher level of casein (~0.25%, w/w).

Late lactation

Maintenance of a high plane of nutrition has also been found to maintain satisfactory milk processing (composition, N fractions, free fatty acid levels, alcohol stability, rennet coagulability) and Mozzarella cheesemaking characteristics of milk from spring-calved herds into late lactation (278 days in lactation), as reflected by acceptable cheese yield, composition, texture, and cooking properties. Some characteristics of this milk were lactose ≥4.3% (w/w); protein = 3.6% (w/w); casein = 2.8% (w/w); rennet gelation parameters (Formagraph Type 1170; Foss Electric, Denmark): curd firmness A60 = 42.1 mm at 60 min.

Seasonal Changes in Milk Quality

In addition to composition, seasonality also affects the state (quality) of the protein and fat in milk and their suitability for processing into products, including cheese.

Protein Hydrolysis (Proteolysis)

Excessive proteolytic activity is undesirable as it hydrolyzes caseins to water-soluble peptides that are lost to varying degrees in whey and not recovered fully during the manufacture of products such as casein or cheese. Moreover, hydrolysis may alter the functionality (e.g., molecular mass, charge) and interactivity of the remaining (recovered) protein and thus the techno-functionality of the resultant products, such as the ability of the resultant cheese to shred or grate, or the ability of casein to hydrate, form gels, or impart structure/texture to products in which it is used as an ingredient (e.g., gluten substitute in bakery products, imitation cheese, and processed cheese products).

There are three main pathways by which proteolysis occurs: native milk proteinase (plasmin), proteinases of somatic cells, and proteinases of psychrotrophic bacteria.

The native proteinase system of milk comprises plasmin as the active enzyme, its zymogen (plasminogen), and enzyme activators/inhibitors. Whereas plasminogen, plasminogen activator, and plasmin are all very heat stable, the plasmin inhibitor is heat labile. Plasmin and plasminogen in milk fully survive pasteurization at pH 6.8. Plasmin is associated with the casein micelles and readily hydrolyzes α_{s1}-, α_{s2}-, and β-caseins, resulting in an increase in γ-caseins. κ-Casein can also undergo some degree of hydrolysis by plasmin, but reports differ on the extent of hydrolysis, which may be due to environmental conditions or the concentrations of enzyme and substrates used.

High levels of plasmin activity and corresponding proteolysis (e.g., >40 to 50% of total α_{s1}- and β-caseins) as affected by addition of plasmin to milk have generally been found to give longer rennet gelation times and markedly lower gel firmness. The impaired rennet gelation characteristics coincide with a more porous, open-structured gel and less connectivity between the particles and clusters making up the gel matrix.

The lysosomes of somatic cells in milk are a significant source of proteinases (e.g., cathepsins D and B). The level of cathepsin D in milk is correlated significantly with SCC, which is an indicator of the intensity of the cellular immune defense in cows.

Although the refrigerated storage of raw milk is used to prolong shelf life and reduce spoilage by mesophilic bacteria, it favors the growth of psychrotrophic microorganisms, which produce heat-resistant extracellular enzymes such as proteinases and lipases. These proteinases hydrolyze the caseins in milk, to a degree dependent on temperature (2–7 °C) and duration of cold storage. The contribution of this source may be particularly important during autumn and winter when milk volumes are low, resulting in extended storage time on-farm. The caseins are particularly susceptible to hydrolysis at low temperatures because of the solubilization of colloidal calcium phosphate, lower degree of hydrophobic-induced casein interactions, loosening of the micelle structure, and the solubilization and dissociation of all caseins, especially β-casein, into the serum phase.

Effect of stage of lactation on proteolysis

The levels of plasmin and plasminogen of milk have been found to increase significantly with advancing lactation. However, the levels of both are affected by husbandry practices such as nutritional status and milking frequency, udder health, and by the onset of involution. The process of involution involves para-cellular leakage from the blood, assisted by disruption of tight junctions between mammary epithelial cells. It is suggested that there may be a positive correlation between loosening of the mammary tight junctions and plasmin and plasminogen-derived activity in milk. This phenomenon is normally associated with significant reductions in both milk yield and lactose content of milk.

Milk SCC generally increases with stage of lactation, a trend that may be associated with a reduction in the milk yield and/or increased infection where late-lactation milk coincides with a deterioration in environmental conditions of the animal (e.g., wet lying conditions). Infection with pathogens such as *S. aureus*, *S. chromogenes*, *E. coli*, and *S. dysgalactiae* is conducive to the development of mastitis and udder inflammation in the cow. Cellular damage at the site of this infection initiates chemical signals that attract white blood cells to the area of infection. Some of these cells are transferred to milk and, therefore, the SCC of milk increases during mastitis. An increase in SCC of milk is associated with a higher rennet clotting time and decreases in curd firmness, cheese yield, and the percentage fat recovered from milk to cheese. The magnitude of these effects varies with SCC and cheese type. An SCC standard of 400×10^3 cells ml^{-1} for bulk milk is adopted in European milk quality schemes with many milk purchasers now applying bonus payments for milk with $\leq 200 \times 10^3$ cells ml^{-1}, and this has reduced the effects of mastitis and high SCC on product quality.

Modern farm and milk collection practices have resulted in milk being cooled rapidly to <8 °C after milking and a relatively low frequency of milk collection from the farm, for example, every 2 or 3 days. Moreover, cold milk is hauled over long distances and is often cold-stored at the cheese plant for 1–3 days depending on time of year and the manufacturing schedules; hence, milk can be cold-stored for 2–5 days prior to processing, particularly during winter. Psychrotrophic bacteria grow during refrigerated storage of milk and produce proteolytic enzymes, which can have a major effect on the quality of products. Hydrolysis of casein by proteinases from psychrotrophic bacteria is undesirable because of the deterioration in cheesemaking quality of the milk, especially when counts of the psychrotophic bacteria are high (e.g., $>1\,000\ \times 10^3$ cfu ml^{-1}). Adverse effects include increased rennet coagulation time, reduced curd firmness, higher losses of protein in cheese whey, lower cheese yield, higher cheese moisture, and development of off-flavors such as bitterness and rancidity. The extent of these defects is exacerbated by an increase in the temperature of cold storage in the range 2–10 °C, as a consequence of higher levels of bacterial growth and activities of lipases and proteinases, especially during the first 48 h.

Fat Hydrolysis

Inadvertent lipolysis in milk leads to elevated levels of FFAs, which are carried over into the cheese and result in off-flavors (rancid, soapy, bitter) and flavor inconsistency. This is undesirable in all cheeses, even in those where the cheesemaking procedure is designed to promote controlled hydrolysis of the milk fat (triacylglycerols) by the addition of exogenous lipases/esterases and/or lipolytic cultures (e.g., *Penicillium roqueforti* in Blue-type cheese). The addition of the latter enzymes to the cheesemilk for cheeses such as Pecorino and Blue-type promotes the development of the desired flavors (e.g., piccante, peppery, ketone) and sensory properties during maturation (*see* **Cheese**: Blue Mold Cheese; Hard Italian Cheeses).

Most lipolysis in milk is caused by the native lipoprotein lipase (LPL). LPL acts on the milk fat triacylglycerols, with the resultant production of FFAs, which are carried over to the cheese. Lipolysis in milk can be broadly described as induced or spontaneous depending on the means of activation of the LPL. Induced lipolysis is defined as lipolysis promoted by both mechanical damage to and temperature changes of the milk. Mechanical damage to milk involves disruption of the membrane surrounding the fat globule, thus allowing direct contact between fat and LPL. Such damage may be accelerated by subjecting the milk to mechanical processes and/or temperature cycling (cooling/reheating). Physical actions that promote mechanically induced lipolysis include excessive shear/whipping and cavitation, which may be caused by a number of factors such as over-agitation and pumping, air incorporation, and poor design of milk-handling systems; the resultant damage may be accentuated by freezing and thawing of milk. Milk may be particularly vulnerable to these actions when volumes are low, depending on time of year.

Temperature-activated lipolysis is induced by temperature cycling, which can occur at several stages on the farm, during milk collection, and at assembly at the factory. Milk as it leaves the cow is at ~37 °C. The activity of LPL on milk fat is at a maximum at 30 °C and markedly decreases at temperatures >37 °C and <12 °C. However, change in temperature can also promote the development of lipolysis, for example, cooling to 5 °C followed by rewarming to 25–37 °C and recooling.

Alternatively, spontaneous lipolysis is defined as that which develops in the milk of some cows during cold storage without being subjected to any physical or mechanical treatment. Lipolysis in this milk is initiated just by prompt cooling of the milk after removal from the cow. Milk from individual cows differs in its tendency to develop spontaneous rancidity depending on the biochemical factors in milk and several predisposing factors in the animal. The main biochemical factors include the amount of lipase activity, the integrity of the MFGM, and the balance of lipolysis activating and inhibiting factors. The major predisposing factors associated with spontaneous lipolysis in the cow are late stage of lactation, poor-quality feed, and mastitis.

Effect of stage of lactation on lipolysis

A number of studies have reported that milk from cows in late lactation has a higher FFA level than that from cows in early lactation. This may be due to changes in the lipolytic activity of the milk and/or greater damage to the MFGM, especially when milk volumes are relatively small, making the milk more susceptible to agitation, pumping, and freezing (freezing onto the cooling surface of direct expansion milk storage tanks). Moreover, diet also has a significant impact on lipolysis in late lactation, as cows are generally under nutritional stress at this time, resulting in milk with relatively high FFA levels.

Psychrotrophic bacteria produce heat-stable lipases that survive pasteurization and ultra-high temperature (UHT) treatments. Even though the bacterial lipase is not inactivated by pasteurization (unlike indigenous LPL), the psychrotrophic bacteria that produced them are destroyed. This has implications in that the bacterial lipase may be carried through to the manufactured cheese where it contributes to off-flavors (rancidity, soapiness, bitterness) during advanced maturation. However, lipolysis associated with psychrotrophic lipases in cold-stored milk is generally only a problem where bacterial counts are very high ($>1 \times 10^6$ to 1×10^7 cfu ml^{-1}) and not an issue with modern milk production practices, except perhaps where holding times prior to processing are long (eg., > 5days). EU Regulation 853/2004 of 2004 (Annex III, Section IX) specifies a plate count requirement (at 30 °C) of $\leq 100 \times 10^3$ colony forming units (cfu) ml^{-1} for cows' milk, corresponding with the rolling geometric average over a 2-month period, with at least two samples per month.

Heat Stability of Milk

A further important parameter of milk quality is that of heat stability, which represents the susceptibility of the milk proteins to aggregate on heating, especially at high temperatures (e.g., >80 °C), as a consequence of protein-protein interactions and hydrophobic bonding. In contrast with cheese manufacture, where casein aggregation, as promoted by enzymatic treatment and/or acidification, is desirable, heat-induced aggregation of milk during processing is highly undesirable in most situations. Raw milk is generally heated during the processing of most products. However, the type of heat treatment varies depending on the product (e.g., concentration and dehydration processes). If the raw milk is not heat stable, problems can arise during processing, such as coagulation on equipment (e.g., heat exchanger). Many factors affect heat stability such as concentrations of urea and ionic calcium, salt concentration, pH, β-lactoglobulin to κ-casein ratio, ratio of different caseins, and casein hydrolysis. Many of these milk components change in absolute and/or relative contents with season and may be responsible for the seasonal variation in heat stability of milk. Various studies have shown that the heat stability of milk is highest during the summer; minimum heat stability was observed during autumn and winter.

Alcohol Stability of Milk

Milk ethanol stability can be defined as the minimum added aqueous ethanol concentration that gives rise to milk coagulation. Knowledge of ethanol stability is critical for the formation and stability of dairy products such as cream liqueurs or alcoholic beverages, in which casein hydration is central to providing its fat-emulsification role. Various studies have shown seasonal variation in the ethanol stability of milk; lower stability has been observed both in autumn or spring periods and during winter time (e.g., Ireland). The stability of milk proteins to alcohol is influenced by various parameters including ionic strength, concentrations of milk salts, and pH. A high salt balance ratio (expressed as [Ca and Mg] to [inorganic phosphate and citrate]) may be a contributor to reduced ethanol stability of late-lactation milk.

Conclusion

Different products require different processing regimes for manufacture (e.g., aggregation of protein into a gel, enclosing fat and moisture, in the case of cheese, or stability to heat in the case of UHT milk manufacture). In all cases, it is desirable that the components (e.g., casein, fat, minerals) in milk are as close as possible to the native state when leaving the udder of a healthy cow, on a good plane of nutrition, in a period excluding the extremes of early and late lactation. Such milk lends itself to the desired degree of alteration (e.g., controlled limited destabilization of the protein phase) on the application of unit operations (e.g., heat, acidification, and enzymatic treatment) during manufacture to give products with the desired quality. Satisfactory milk processing characteristics are conditional on a number of factors including the breed, health status, age, plane of nutrition, and stage of lactation of the cow; the somatic cell count and bacterial count of the milk; associated enzymatic activities; season of year; and milk production practices.

The optimum 'designer' milk for product manufacture is most naturally and cheaply obtained through 'best farm and cow management practices'. Changes in characteristics particularly influenced by season (e.g., composition, protein hydrolysis, and fat lipolysis) may be minimized by maintaining a consistently adequate diet to the cow throughout lactation and ceasing to milk cows at low yields, while also maintaining clinical and subclinical mastitis at a minimum, ensuring minimum storage time of milk between production and processing, treating milk gently when pumping or agitating, and having a consistent supply of milk throughout the year.

Milk in Human Health and Nutrition

S Patton, La Jolla, CA, USA

Introduction

Milk is by far the best single food available to man. Regular consumption of it is an easy way for one to help ensure the adequacy of her/his nutrition. The nutritive value of milk has been very extensively investigated for over a 100 years in laboratories throughout the world. As a consequence, one can have a great deal of confidence in the reliability of the published information about it. This massive research effort is a reflection of the highly important role milk, both human and bovine milk, plays in man's health and well-being. While a variety of animal species are used by man for their milk, the dairy cow is by far the most important. This arises from her ability to produce large volumes of milk and to support the process using crude plant materials as feed. The cow has been appropriately and colorfully described as 'the foster mother of the human race'. In this article, the major contributions of cow's milk to human nutrition are described.

In order to fully appreciate the many contributions of milk to the nutritional well-being of humans, one must first understand a few fundamental aspects of milk, in particular, how it is made and what its purposes are. Milk is made by female mammals for the nourishment of their young. Mammals are a large group of animals with warm blood and include, among others, man and the species he has domesticated, such as horses, dogs, cats, cattle, sheep, goats, and pigs. Newborn mammals are in urgent need of food. Environmentally available plant material is not suitable for them at that early stage of life. The food supplied to them via their mothers' mammary glands, milk, is a complete food. It is specifically designed to support life in new individuals, and is also an invaluable immune support for the newborn. No other food or supplement is required. As nursing proceeds day after day, it can be seen that the limbs are growing and that the baby animal is getting larger, but most importantly, all the organs, tissues, and bones that the animal was born with are being kept healthy and functional. There is a tendency for people to think of milk as exclusively a growth promoter. One often hears, 'It's for kids.' In addition to being a growth promoter, milk is an excellent maintenance food, not just for kids but for humans at any age. It maintains the body in a healthy, functional condition.

Milk and Evolution

Milk as made by a mammal mother is a complete food for her young. An important question is how did it get that way? The most plausible answer is by evolution. Any mammal mother that produces milk of inadequate nutritional quality will produce young that become sickly and either die young or will be incapable of producing healthy offspring. In this situation, the mother's genes for producing milk are not perpetuated. However, the mother that by virtue of her abundant, nutritious milk rears normal healthy offspring will have her genetic facility for making such milk passed on to the succeeding generations. As a result of such selectivity, one can see that nature is constantly perfecting the nutritive value of milk for each species.

It is possible at this point to raise an objection: while cows may have perfected milk for their calves, it does not necessarily mean that such milk is good for humans. Nonetheless, it appears to be. The public's general experience with cows' milk for hundreds of years is supportive of its value as a human food. There has been no convincing evidence, either short or long term, of a cause-and-effect relationship between milk consumption and toxicity or disease. Of course, some humans may experience allergy to cows' milk, but in the case of infants and children so afflicted, most usually outgrow the situation quickly.

A Historical Perspective

If a country has had extensive favorable long-term experience with a particular food, that is reliable evidence of the food's wholesomeness. People will not continue to consume something that shows obvious evidence of making them sick. On the other hand, there will be a strong continuing demand for foods that make them strong and healthy. The experience with milk and milk products in the United States is instructive in that regard. Having had favorable experience with milk, our European forbearers promptly brought dairy cattle to this country in the early 1600s. From that point on, paralleling development of the human culture itself, milk grew to be a decided success. One might say that man and the dairy industry tended to make each other prosper. This brings up the matter of milk's quality and stability.

Since milk of animals has been used as food by man for many thousands of years and in various areas of the world, one of the earliest observations about it must have concerned its tendency to deteriorate. On even brief storage, it spoiled quickly. In time this led to cooling of milk, which discouraged the growth of spoilage bacteria, and next to pasteurization, which simply kills most of the bacteria and, most importantly, those causing diseases. The application of these two processes together with other quality control and sanitation measures has enabled the dairy industry to make available one of the cleanest, safest, most uniform food products known.

Gross Composition of Milk

Details about the many components in milk are provided elsewhere in this encyclopedia. However, it is helpful to have a general idea of the composition of milk. This is provided in **Table 1**, which also affords a comparison of bovine and human milk. The significantly higher protein and ash, especially calcium, content of cow's milk arises from the much greater need of the calf for protein and calcium to support its rapid increase in bone, tissue, and total mass as compared to the human infant. For this reason, babies who are breastfed generally tend to gain weight less rapidly than those nourished on cow's milk or formulae based on it. However, there is nothing unhealthy about this slower rate of gain.

With specific reference to cow's milk, it is a good source of sodium, potassium, and most other mineral elements. It is an outstanding source of calcium, needed especially to make and maintain strong bones. Supplementation of milk with other sources of iron, copper, manganese, and magnesium is appropriate. The fat and carbohydrate of milk serve mainly as a source of calories (energy) and, in general, are not unlike those components in other foods. The aqueous (skim milk) phase contains significant amounts of all B-vitamins and vitamin C. While in fresh raw milk the content of vitamin C is appreciable (28 mg qt^{-1}), the concentration may be lowered appreciably by exposing milk to heat (pasteurization), light, or air. Thus, milk should not be relied on as source of vitamin C. It is also deficient in iron. These two nutrients are well supplied by fruits and red meat, respectively. Because milk is liquid and not chewable, one might be led to think that it is not much of a food. Milk is better than any other food as a source of nutrients that a human needs. Milk does form solid particles called curd in the human stomach. Milk protein is of very good nutritional quality and contains substantial amounts of essential amino acids.

The sugar of milk is known as lactose. While it is only about one-fifth as sweet as ordinary table sugar (sucrose), the two are equivalent in generating energy in the human body. On hydrolysis in the gut, lactose yields one molecule each of glucose and galactose. Both are absorbed into the circulation and eventually the galactose is converted to another molecule of glucose.

Completeness of Milk as a Food

A classical proposition of human nutrition is the so-called 'balanced' diet. It assumes that steady consumption of no single food or small group of foods will be adequate to supply the many essential nutrients humans require. Thus, it is recommended that different kinds and amounts of foods should be eaten so that all the needs are met. The balanced diet idea was conceived following discoveries of the many vitamins, amino acids, and minerals humans must have to maintain health and vigor. The advice to eat a balanced diet has been with us for over 50 years. Another form of this instruction is that we should regularly, if not at every meal, consume foods from each of the main categories: meats, dairy, fruits, and vegetables. A few single foods consumed exclusively such as meat, milk, or eggs come close to fulfilling all nutrient requirements of humans. In brief, milk by itself is designed to sustain life in the young growing animal. Meat is what animals are composed of. So it is not too surprising that we can digest meat and use the resulting products to replenish ourselves. Eggs contain everything to support the development of a young bird. So again one has a relatively complete food in the egg.

As foods, milk and meat share considerable features in common. Both are animal products containing very high-quality protein, both include a full spectrum of vitamins and minerals required by humans, and both contain a similar (relatively saturated) type of fat.

Table 1 Proximate composition of milk

	Fat (%)	*Protein (%)*	*Carbohydrate[a] (%)*	*Ash (%)*	*Water (%)*
Cow	3.5	3.3	5.0	0.7	87.5
Human	4.4	1.0	6.9	0.2	87.5

[a] Refers to lactose content.

Flavor

It is known that flavor plays a critical role in consumer acceptance of a food. Of course, no nutritional value is delivered if the food is rejected because of its flavor. Normal milk is bland tasting and not unpleasant. Nonetheless, there are a few who object to its faint characteristic flavor, the way it feels in the mouth, or to a perceived aftertaste. This is unfortunate but no different from the varied human response to all other foods. In the case of milk, which has so much good nutritional value to deliver and potentialities for weight control, one can only hope that objectors will keep giving it another try. In the case of some foods, one needs to develop a taste for them.

Another notable aspect of milk flavor is its susceptibility to change. In part, this is because normally it has so little flavor that it makes any kind of a newly developed flavor quite noticeable. In addition, exposure of milk to heat, light, or air may bring about a change in flavor that is objectionable. Aberrations in the cow's metabolism or what she is fed can also produce milk with abnormal flavor. Experimentation has shown that inhaling the odor of onions by a cow can impart their flavor to her milk in less than a minute. It is a minor miracle that the dairy industry has learned so well how to successfully manage the challenging situation that milk presents with regard to flavor. Much of the needed information for this has been derived from state and federally sponsored research programs.

Vitamin D

Milk represents a special situation with respect to vitamin D. With the exception of oily fish, that is, sardines, salmon, tuna, and mackerel, most foods contain little or no vitamin D. There are some other foods such as cereals, margarine, some cheeses, and orange juice that are fortified with this vitamin. However, since the 1930s, it has been required by law in most areas of the country that milk be fortified with vitamin D at a level of 400 IU per quart. This was brought about in order to prevent the bone deforming disease known as rickets (osteomalacia), the most obvious ultimate symptom of which is bowed legs. With high levels of naturally occurring calcium in milk, mandated additions of vitamin D made it the ideal food for supporting bone maintenance and development.

One might wonder if milk is so relatively low in vitamin D, how does the calf manage to develop its substantial bony structure? The answer seems to be that it has a diversity of sources that together provide an adequate supply. These include vitamin D the mother transfers to her fetus before birth and in her milk after birth, that which the newborn synthesizes through its exposure to light, and that consumed in its feed, often vitamin D-fortified. Actually the question is worthy of research. It would be of interest to know if there are other substances in milk that, similar to vitamin D, help to catalyze bone formation.

In more recent years, scientists have come to recognize other beneficial effects of vitamin D on human health, including reduced risks of heart disease, diabetes, and various forms of cancer and strengthening of the immune system. Another reported function of the vitamin is its ability to suppress the development of new fat cells (adipocytes) in the body. This is of particular interest in light of obesity as a growing public health problem. Considering its multiple beneficial effects, some researchers feel that the recommended daily intake of vitamin D should be raised from the current 400 IU to 800 or 1000 IU. They are concerned that worldwide there is insufficiency of vitamin D in many populations. It should be noted that consumption of vitamin D above 2000 units per day can be toxic.

Myths and Facts about Milk

Because milk is such a key food and of great importance in many countries and cultures, it is constantly being evaluated and sometimes criticized, without unequivocal clinical or epidemiological evidence to support the criticism.

Saturated Fat/Cholesterol

The most damaging misinformation about milk in recent years is that regarding saturated fat in the diet. In the early 1950s, Ancel Keys, a researcher at the University of Minnesota, observed that men with heart disease had cholesterol deposits in the walls of their arteries. By inference this quickly came to mean that cholesterol circulating in the blood was depositing in coronary arteries, thickening their walls, thereby choking off the circulation and causing heart attacks. A more refined later version was that deposition of cholesterol weakened the walls of the arteries making them susceptible to injury, which could give rise to clots with the potential to restrict blood flow if not plug the vessel shut. Further studies showed that saturated fats in the diet, that is, primarily those of milk, milk products, and meat, raise circulating cholesterol. So based on these associations, and without it ever having been demonstrated as a cause-and-effect relationship, consumption of milk fat was implicated as a factor in heart disease. This led to the widely disseminated advice, "Avoid milk fat (milk, cream, ice cream, butter, etc.) because it will raise your 'bad' cholesterol, which is associated with heart disease."

This recommendation has been purveyed by major medical groups, agencies of the federal government, and news media for years. One was always reminded in any news article involving diet/heart disease to reduce or eliminate consumption of saturated fats, that is, milk or meat. The great body of evidence, not just a few studies, indicating that saturated fats are not problematic was either overlooked or ignored. At this point, there are at least three major medical/nutritional reviews of the literature that make it very clear that saturated fat in the diet is not a problem in relation to heart disease.

One of the truly misleading tangents of this half a century of advice about diet and heart disease has been the implication that everyone is susceptible to if not suffering from an elevated cholesterol pathology. This is said even though there are studies showing that in older people higher cholesterol is associated with better health. It seems evident that the only people with a truly problematic high blood level of cholesterol are those afflicted with the genetic disorder known as familial hypercholesterolemia, and they make up far less than 1% of the population.

Cancer

Various antimilk groups often resort to the warning, 'Milk causes cancer!' No cause-and-effect relationship has ever been shown between milk consumption and any form of cancer. On the contrary, milk contains a large array of cancer antagonists, including conjugated linoleic acid, butyric acid, vitamins A and D, carotene, sphingomyelin, ether lipids, and whey proteins. In addition, there are impressive studies of thousands of women showing that regular consumption of milk is associated with reduced incidence of breast cancer. The results from one of these studies, showing that the incidence of breast cancer was lowered in proportion to the amount of milk consumed, are presented in **Figure 1**.

Digestion of Lactose

Human milk, like cow's milk, contains lactose (**Table 1**). So all humans start off being able to digest and utilize lactose. However, this capability does not persist in all individuals, nor to the same degree. If milk is discontinued in the diet, such as at weaning, normally the ability to digest lactose is lost, and in time the individual will exhibit what is known as lactose intolerance. However, in the United States and Europe among other areas, milk and milk products continue to be major items in the human diet throughout childhood and the rest of life. Thus, lactose is well utilized by most people in those areas.

When lactose is not digested, it moves along with the food residue to an area of the lower intestine where it is fermented by bacteria with the production of acid and gas (these, when substantial, can cause discomfort). Here again, those opposed to milk consumption imply that many people have a very grave problem in this regard. This clearly is not the case. For those relatively few people who have a real problem digesting lactose, there are a number of simple solutions:

Purchase milk in which the lactose has been hydrolyzed; such milk is available in many supermarkets.
Purchase a lactase enzyme preparation that can be added to milk to digest the lactose.
Avoid quickly downing large glasses of milk and, instead, ingest smaller portions of it over several hours.
Consume some yogurt with (or in) your milk. It contains lactase enzyme naturally.

Because people of certain nationalities and ethnic groups have lactose intolerance, it is assumed that genetics plays an important role in their limitation. However, a total and continuing lack of lactose in their diets may be more important in the development of their intolerance than their genetics. Interestingly, milk was recently introduced into schools for Chinese children without apparent problem. This suggests that lactase enzymatic activity is inducible.

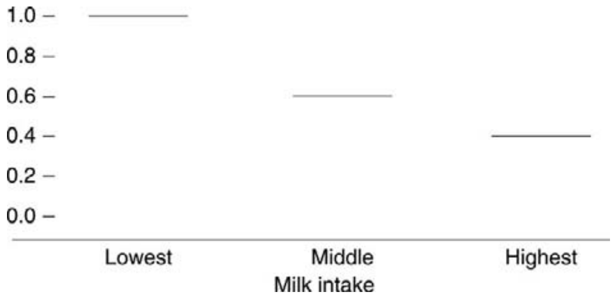

Figure 1 Relative risk of breast cancer as a function of milk consumption. Breast cancer risk is reduced ($p < 0.003$) in relation to milk intake (low = 486, middle = 679, and high = 1060 g of dairy products per day). Data adapted by DE Bauman from Knekt P, Järvinen R, Seppänen R, Pukkala E, and Aromaa A (1996) Intake of dairy products and the risk of breast cancer. *British Journal of Cancer* 73: 687–691.

Of course, what one accomplishes by drinking smaller amounts of milk incrementally is avoidance of burdening the digestive system. This is always a good idea with any food, or as they say, ‘not too much of anything’. On the other hand, in the interest of getting the excellent nutritive value milk offers, it is well worth one’s adopting one or more of the mentioned measures if that is essential for milk to be accommodated comfortably in one’s diet. Due to misunderstandings about the need and the ability to digest lactose, many people have self-diagnosed incorrectly that they have a serious unsolvable problem. The phenomenon and genetics of lactose intolerance have been extensively covered in a number of reviews.

Asthma

There are unsupported claims that milk causes asthma, a complicated disorder of the lungs and respiratory tract. At least one study has shown that milk consumption is not a factor in asthma.

Types of Milk Commercially Available

Due to the growing concern about human health and well-being, milk is now being scrutinized in ways and to degrees that were never considered necessary in the past. Consumers are demanding that variations in the way milk is produced be defined and labeled on the carton. So now we have organic milk, and, in some countries such as the United States, we have milk produced with or without the aid of additional bovine growth hormone (BGH; also called bovine somatotropin (BST)) and milk produced by cows either treated or not treated with antibiotics. Other variables, such as whether the animals were grazing pastures or not, may also come to be considered. While the consumers’ interest in these matters is understandable, they are beyond the scope of this article because they are not currently relevant to the well-established nutritional properties of milk.

Homogenized Whole Milk

In the United States, for the past 70 years or so, there has been one principal marketed form of milk, that is, homogenized whole milk. Its fat content as defined by law is somewhere in the 3.0–3.5% range, which approximates the average fat content of milk as secreted by the cow. It was and still is produced under very strict government regulations and industrial standards. All things considered, it is an extremely uniform product. Normally, in the United States, no matter where one obtains it, restaurant, supermarket, schools, or home delivery, milk will exhibit little or no difference in its highly acceptable odor, flavor, or appearance. There are many factors that have contributed to this success story, but one of the most important has been the informed and demanding legal requirements at local, state, and federal levels for milk production, processing, and distribution.

Raw Milk

In view of humanity’s long and continuing association with raw milk, that is, unaltered milk as withdrawn from the udder of the cow, it deserves special considerations. Until the adoption and mandatory application of pasteurization to milk, the human experience for thousands of years had been with raw milk exclusively. Considering the ability of raw milk to support the growth of bacteria, including pathogens, it is not surprising it came to be recognized as a potential menace to health. The development of pasteurization technology to deal with that problem is perhaps the greatest milestone of progress ever achieved by the dairy industry. The minimal safe heat treatment for the destruction of milk-borne pathogens was established and equipment designed to carry out the necessary heating and cooling process in application to huge volumes of milk. A remarkable feature of pasteurization is that the flavor and appearance of the milk remain essentially unchanged. There are only very minor effects on the nutritive value. Mainly, about half of the vitamin C content is destroyed and slight losses, <10%, of vitamins B_1 and B_{12} occur. It is speculated that pasteurization destroys enzymes, vegetative forms of native bacteria, and other milk components of possible value to human health. In the opinion of health authorities, these minor concerns in no way justify doing away with the process, which they view as having tremendous public health benefits. Industrial production of pasteurized milk commenced in earnest between 1900 and 1920 when most of the laws mandating it were passed by municipalities and states. Generally speaking, we can be very thankful for pasteurization. It is still not uncommon to read notices in the news that lack of pasteurization of milk or milk products led to a communicable disease outbreak.

Despite the huge legal and health momentum supporting pasteurized milk, there are many people in the United States who recognize that a market exists for raw milk. The commercial supply of the product, known as certified raw milk, was initiated in the 1930s. It was permitted only in areas specifying extremely demanding standards of animal health and cleanliness in the circumstances surrounding production and processing of the milk. Under such conditions, it is possible to produce milk with very low bacterial counts.

Raw milk is legally available in many parts of the United States today. The current environmentalist trend in our culture has developed partisans for it. In their opinion, it has not been debased by man and is more natural and therefore better. Controlled human feeding studies comparing raw and pasteurized milks might be worth pursuing. That should be a good way to reveal whether there is a difference in their nutritive value and if so how significant it is.

Introduction

Primate is a member of the mammalian order Primates (prime, first rank), which contains a total of ~431 species of lemurs (100 spp.), lorisids (9 spp.), galagos (19 spp.), tarsiers (9 spp.), monkeys (139 spp. of New World monkeys, Platyrrhini; 135 spp. of Old World monkeys, Cercopithecoidea), and apes (20 spp. in the superfamily Hominoidea). The number of species reported varies depending on the classification criteria used. The superfamily Hominoidea comprises two families: Hylobatidea (13 species in 4 genera of gibbons or lesser apes) and Hominidae (4 genera of Great Apes: *Pongo* (2 species of orangutan), *Gorilla* (2 species), *Pan* (2 species and 3 subspecies of *Pan troglodytes*), and *Homo* (1 extant species, *Homo sapiens*)). A phylogenetic tree of the primates is shown in **Figure 1**, which reflects current understanding of the evolutionary relationships among primates.

It is generally assumed that human milk has evolved as the most appropriate food for nutrition of the human infant. The composition and constituents of human milk are quite different from those of the principal dairy species (cattle, buffalo, sheep, and goat; *see* **Milk**: Bovine Milk; Buffalo Milk; Goat Milk; Introduction; Sheep Milk). The milks most like human milk in macronutrient composition are those of the horse and donkey (*see* **Milk**: Equid Milk), which is rather surprising since *Homo sapiens* is phylogenetically quite distant from *Equus caballus* and *Equus asinus*. In this article, human milk is compared with that of our closest relatives, the Great Apes, and, to a lesser extent, with the milk of primates in general. Unfortunately, the milk of most primates has not been studied at all, and the milk of those species that have been studied has been the subject of relatively few studies; according to Oftedal and Iverson, the milk of only 16 primate species had been studied till 1995 in sufficient detail as to be reliable; since then, the number of species studied has doubled and considerable information is now available on some species. However, in comparison with the milk of the commercial dairying species (cow, buffalo, sheep, and goat), the horse, pig, and human, the milk of nonhuman primates has been studied only superficially. Many reports on primate milk have focused on gross composition, mainly with the objective of improving the nutrition of captive species. However, there is a lack of information on the chemistry of the constituents of primate milks, especially of the proteins.

The composition of milk is significantly affected by the animal's diet. The human diet is quite different from that of the three other Great Apes: the human diet includes a high proportion of animal-derived products (meat, fish, milk, and eggs), whereas diets of the three other genera of Great Apes is mainly or exclusively vegetarian. The human diet was probably vegetarian when the genus *Homo* first evolved, but meat eating has been common for a long time and is considered to have been a major factor in human evolution. Also, most items in the human diet are cooked, which alters digestibility and energy yield, and may affect milk synthesis.

Gross Composition

Mammals differ with respect to the gross composition of their milk, the frequency of neonatal feeding, and the duration of lactation. Differences in the nutrient requirements of young mammals arise from differences in postnatal growth rate, the stage of maturity at birth, body composition at birth, and environmental peculiarities of their natural habitat. Factors that directly affect the lactating female, for example, litter size, lactation load, maternal diet, and nursing schedule, may affect the gross composition of her milk.

The gross composition of the milk of the four Great Apes and several other primate species is shown in **Table 1**. Although only 31 of the 431 primate species are included in this table, a number of general features are apparent: generally, the milk of primates is dilute with a high concentration of lactose and low concentrations of fat and protein. This is true even for callitrichid species, the smallest primates (lion tamarin and pygmy marmoset at ~700 and 100 g body weight, respectively), which would be expected to produce milk with higher levels of fat and protein, but, in fact, produce milk approximately similar to the milk of larger primates, although the milk shows large individual variations, for example, 1–10% fat. There is some evidence that maternal condition affects milk composition in these primates: small marmoset and tamarin mothers with twins or triplets produce milk lower in energy and infants are weaned early (within ~2 months). Nursing style also affects the overall composition of milk: prosimians that carry their young throughout the day produce more dilute milk than those that leave their young unattended for periods. Lorises and bush babies produce relatively rich milk. It has been

suggested that as primates in the wild live in hot humid climates, they require a large intake of water for evaporative cooling, which is supplied by milk during the early period postpartum – hence the provision of dilute milk. The high environmental temperature avoids the need for a high-energy diet, unlike marine mammals and land animals that live in a cold environment.

In human milk, the protein content has a pronounced lactation pattern and is high in early lactation (15 g kg^{-1}) and lower in mature milk (9 g kg^{-1}), whereas in primate milks, in general, the decrease in protein concentration is relatively slight (Rhesus monkey: 24.9 g kg^{-1} in colostrum compared to 23.5 g kg^{-1} in milk). The fat and lactose contents of Rhesus monkey milk do not vary significantly over lactation, but for human milk, fat content increases ($\sim$23 g kg^{-1} in colostrum to $\sim$35 g kg^{-1} in milk), as does lactose ($\sim$41 g kg^{-1} in colostrum to $\sim$68 g kg^{-1} in milk).

Across the primate species, the proportion of gross energy from protein varies considerably (**Table 2**) but correlates negatively with the rate of growth; for example, the percentage of energy from milk protein is lowest in human milk and the time to reach maturity is the longest among primates. In some lemurs and lorises, the proportion of energy from protein is high and reflects the comparatively rapid development of their infants.

Infants of low-ranking Rhesus macaque mothers nurse frequently for short bouts, and their milk is more dilute than that of higher-ranking species. Furthermore, Rhesus mothers who are nursing sons produce milk with higher gross energy than those rearing daughters, although the milk yield of the former is lower and, overall, the available energy is equal whether the offspring is female or male.

It has been suggested that the unique pattern of human brain growth is due to the unique composition of human milk. Using an encephalization quotient (EQ) (brain size divided by that expected for an animal of the same body size), humans are twice as encephalized as chimpanzees. At birth, the human neonate has an EQ similar to that of other primates (the brain is $\sim$12% of body weight at birth), but the critical period of rapid brain growth is longer in humans than in other primates. Rapid postnatal brain growth slows down at about 2 months in Rhesus infants, at 6 months in chimpanzees, but continues for up to 12 months in human infants.

The pH of mature baboon milk is 7.17 and its specific gravity is 1.027, which are comparable to the values for human milk, 6.9–7.0 and 1.031, respectively.

Data from various sources.

Saccharides

Lactose, a reducing disaccharide composed of galactose and glucose linked by a β1-4-glycosidic bond, is unique to milk. It is the principal sugar in the milk of most species, exceptions being a few species of seal, which lack lactose. The concentration of lactose, which serves as a ready source of energy, in primate milk ranges from ~5% for galago to >10% for the African green monkey (vervet; the highest concentration reported); the value for all the Great Apes is ~7%. The milk of gorilla also contains relatively high concentrations of glucose, galactose, and fucose.

The milk of all species examined contains oligosaccharides (OSs), the concentration of which is particularly high in the milk of humans, bears, elephants, and marsupials (*see* **Lactose and Oligosaccharides**: Indigenous Oligosaccharides in Milk). The OSs serve mainly nonnutritional roles, for example, antibacterial or bifidogenic. Human, gorilla, and macaque monkey milk contain approximately 15, 7, and 0.1 g kg^{-1} OSs, respectively, and, in the case of human milk, OSs are the third largest solid constituent. The OS-to-lactose ratio in chimpanzee milk, bonobo milk, gorilla colostrum, gorilla milk, orangutan colostrum, and siamang (a lesser ape) milk is 1:4, 1:5,

Table 2 Percentage of calories from protein in the milk of some primate genera

Adapted from Power ML, Oftedal OT, and Tardif SD (2002) Does the milk of callitrichid monkeys differ from that of larger antropoids? *American Journal of Primatology* 56: 117–127.

1:20, 1:7, 1:0.8, and 1:3, respectively. The ratio in human milk, at peak lactation, is 1:2.7.

Human milk contains over 100 different OSs, the core units of which are shown in **Table 3**. The types of OSs in the milk of nonhuman apes are different from those in human milk – OSs containing Gal(β1-4)GlcNAc (Type II) units are found exclusively in the milk of the gorilla, siamang, and brown capuchin monkey and predominantly in the milk of the chimpanzee, bonobo, and orangutan, whereas Gal(β1-3)GlcNAc (Type I) units are found only in human milk. It has been reported that Type I, and not Type II, OSs promote the growth of a beneficial bifidus flora in the infant intestinal tract. The milk of Great Apes and human milk contain fucosylated OSs, whereas siamang milk does not. **Table 3** lists the principal OSs that have been identified in the milks of some primates.

Lipids

The fat content of primate milk is reported to vary from $\sim$10 to $\sim$40 $g\ kg^{-1}$ (**Table 1**); exceptions are species of Lorisidae, the milk of which is reported to contain $\sim$70 $g\ kg^{-1}$ fat. The milk of all the Great Apes contains 30–40 $g\ kg^{-1}$ fat. The relatively low concentration of fat in the milk of primates probably reflects the need for low dietary calories.

Species-specific physiological mechanisms and maternal diet determine the concentration of fatty acids (FAs) in milk. The FA profile of the milk fat of a number of primate species has been reported; it is probably the most extensively studied feature of primate milks and the results are summarized in **Table 4**. Notable features are the relatively high concentrations of the middle-chain acids, $C_{8:0}$ and $C_{10:0}$; the very high concentrations of polyunsaturated fatty acids (PUFAs), especially $C_{18:2}$; and the substantial concentrations of C_{20} and C_{22}. In Cebidae and Cercopithecidae monkeys, the levels of $C_{8:0}$ and $C_{10:0}$ are much higher than those in the gorilla: these FAs are synthesized in the mammary gland and are not diet related (hence values for captive and wild species are similar). The milk fat of lemur (three species) contains exceptionally high concentrations of $C_{12:0}$ and $C_{14:0}$, in some cases up to 50% of the total FAs. There are large, in some cases very large, interspecies and interstudy differences in FA concentrations, which may reflect differences in diet and whether the animals were wild or captive, as well as representative sampling and the use of unreliable analytical methods. The high levels of PUFAs probably reflect the plant-based diet of most of the primate species and have implications for the nutrition of captive primates.

FA synthesis in the mammary gland varies across mammals, and the distribution of FAs over three possible stereospecific positions may be important in neonatal nutrition. $C_{8:0}$, $C_{18:0}$, and $C_{18:0}$ are esterified mainly at the *sn*-1 and *sn*-3 positions of glycerol in the triglycerides in the milk fat of four species of monkey (macaque (2), Rhesus, and mangabey), whereas $C_{12:0}$, $C_{14:0}$, $C_{16:0}$, and $C_{16:1}$ are concentrated at the *sn*-2 position. In a somewhat similar study by Myher and collaborators, the unhydrolyzed lipids of eight prosimian primates were studied by gas chromatography (GC). Triglycerides represented 88–95% of the lipids; free fatty acids (FFAs), 0.5–10%; and diglycerides (DGs), 5–10%; monoglycerides were absent (the high levels of FFAs and DGs may suggest lipolysis in some samples, perhaps as a consequence of damage to the milk fat globule membrane (MFGM)). The acyl carbon number of the TGs was mainly in the range C40–C49, and of the FFAs was $C_{8:0}$–$C_{18:0}$. Considerable information on the structure of the lipids in the milk fat is available.

A noteworthy feature in **Table 4** is the relative proportions of $n-6$ to $n-3$ fatty acids. In the wild primate

Data from various sources.

species studied, this ratio is very low, whereas in captive species and human milk, it is high. Today, the Western human diet is generally deficient in $n-3$ acids, with an $n-6$-to-$n-3$ ratio in the range 7.5:1–17:1. Such diets have been shown to promote many cardiovascular and autoimmune diseases. Compared to captive species, the diet of wild primates contains ~5 times more PUFAs, of which ~4% are $n-3$ acids, resulting in a favorably low $n-6$ to $n-3$ ratio.

The fat in milk exists as a water-in-oil emulsion, stabilized by a special emulsifier referred to as the MFGM. In bovine milk, the diameter of the fat globules is in the range 0.1–20 μm (mean 3–4 μm) (*see* **Milk Lipids**: Fat Globules in Milk); we have found no information on the size of fat globules in primate milk. The MFGM is a very complex structure comprised principally of phospholipids and specific proteins; the inner layer of phospholipids and proteins (including xanthine oxidoreductase and butyrophilin, which associate, and are involved in the expression of the fat globules from the mammocytes) is acquired within the mammocyte, and this is surrounded by a trilaminar structure acquired as the globule is expressed from the mammocyte through the apical membrane into the lumen of the alveolus (*see* **Milk Lipids**: Milk Fat Globule Membrane). This structure contains mucoproteins, mucins (MUC 1 and MUC 15), which increase the hydrophilicity of the membrane. In human and equine milk, the mucins form filaments, 0.5–1 μm long, which are lost on mild heating. It has been suggested that the filaments retard the movement of fat globules through the intestine and facilitate the action of lipase, thereby improving digestibility. SDS-PAGE shows that the MFGM of chimpanzee and Rhesus monkey contains high-molecular-weight glycoproteins like human and equine milk fat, but the electron micrographs of these globules have not been reported, and it is not known if the fat globules in these milks have filaments.

Proteins

The protein content of primate milk is generally low (~10 to ~40 g kg^{-1}, with a few exceptions), especially that of the milks of the Great Apes. This low level of protein reflects the slow growth rate of the Great Apes, all of which are born in an immature state, have a long nursing period, grow and mature slowly, and have a relatively long life. Like in all other species, the milk proteins of primates fall into two groups, the caseins and whey proteins (WPs), the ratio of which varies considerably between primate species, ranging from about 30:70 for human milk (the lowest proportion of all mammalian species reported) to 70:30 for some small primates (similar to that for the Bovidae). According to Bounous and collaborators, WPs enhance the humoral immune response in humans and promote longevity. These authors claim that WP-based formulae are nutritionally better for human infants than casein-based formulae (*see* **Dehydrated Dairy Products**: Infant Formulae); this hypothesis warrants further investigation. It should be noted that all WPs have a biological function, whereas the function of the caseins is nutritional.

Table 5 is a summary of the distribution of casein and WPs in the milks of some primate species and includes bovine milk for comparative purposes. Both caseins and WPs are very heterogeneous, but the milk proteins of only a few primates have been analyzed by modern electrophoretic techniques. Urea-polyacrylamide gel electrophoretograms (PAGE) of milks of various species are shown in **Figure 2**; work in this area and the application of 2D electrophoresis to the study of primate milk proteins are warranted.

Bovine milk and the milk of many other ruminants contain four caseins (α_{s1}, α_{s2}, β, and κ) and two principal WPs (α-lactalbumin (α-La) and β-lactoglobulin (β-Lg)) with lesser amounts of blood serum albumin and immunoglobulins (Igs), and perhaps 100 other proteins at very low or trace levels, including about 70 enzymes (*see* **Milk Proteins**: Minor Proteins, Bovine Serum Albumin, Vitamin-Binding Proteins). The milk protein system of other commercially important species is also very heterogeneous and has been studied thoroughly (*see* **Milk**: Buffalo Milk; Camel Milk; Equid Milk; Milks of Other Domesticated Mammals (Pigs, Yaks, Reindeer, etc.); Sheep Milk). However, there are very few studies on the milk protein systems of primates other than humans.

Electrophoresis is the best technique for studying the heterogeneity of protein systems and identifying the constituents. Probably, the first interspecies (40 species, including one sample from *Homo sapiens* and one sample from *Macaca mulatta*) study of milk proteins is that of Sloan and colleagues in 1961, who used zone electrophoresis on paper at pH 8.6; the identification of the protein zones was uncertain, but the Rhesus and human electrophoretograms were generally similar and both appeared to lack β-Lg and α-casein. Subsequently, β-Lg has been identified in the milk of Rhesus monkeys. The casein-to-WP ratio in baboon milk changes from 0.3:1 after parturition to ~1.0:1 after 5 days; the caseins and WPs were shown by electrophoresis on cellulose acetate to be heterogeneous. Cynomolgus monkey (*Macaca fascicularis*) milk contains β- and κ-caseins but apparently no α-casein; the β-casein consists of nine components, which are resolved by SDS-PAGE. The microheterogeneity is probably due to different levels of phosphorylation, as it disappears on treatment with potato acid phosphate. Monkey κ-casein is highly glycosylated (~50% CH_2O); the constituent monosaccharides are galactose, fucose, *N*-acetylgalactosamine, *N*-acetylglucosamine, and *N*-acetylneuraminic acid.

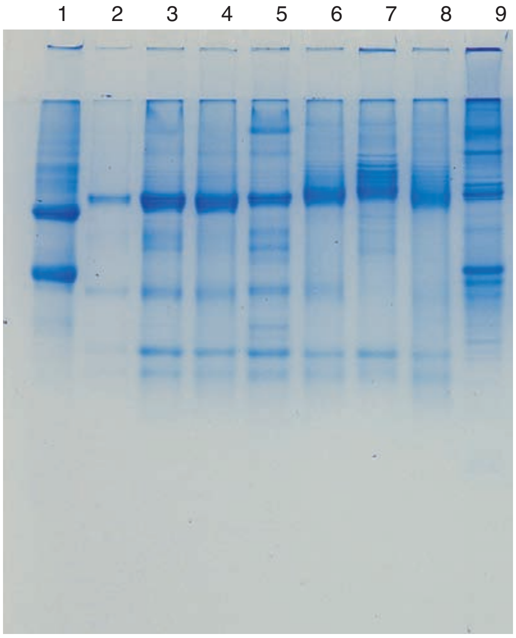

Figure 2 Urea-polyacrylamide gel electrophoretograms of four individual vervet monkey milks, three macaque monkey milks, and a human milk sample. Lane identification: 1, NaCaseinate (bovine); 2–5, Vervet monkeys; 6–8, Macaque monkeys; 9, Human.

Urea-PAGE shows that the milk proteins of Rhesus, and especially vervet monkeys, are very heterogeneous (**Figure 2**, *see* **Milk**: Milks of Non-Dairy Mammals). They appear to contain α-La, β-Lg, and β-casein, but lack α-casein; several other proteins present have not been identified.

Caseins

As far as we are aware, no casein has been isolated from nonhuman primate milk and characterized with respect to amino acid composition and sequence, mass, degree of phosphorylation and/or glycosylation, genetic polymorphism, sensitivity to Ca^{2+}, and so on. Human milk contains β- and κ-casein; although it is generally regarded as being devoid of α_s-casein, there are some reports of its presence. κ-Casein represents only $\sim$12% of bovine casein, but it is critical for many of the physicochemical and technologically important properties of the casein system, and indeed of milk. Apart from a high level of glycosylation reported for the κ-casein of cynomolgus monkey and humans milks, we are not aware of any reports on the properties of other nonhuman primate κ-casein.

Whey proteins

The WPs of primate milk are better characterized than the caseins. SDS-PAGE showed that baboon milk contains α-La, lysozyme, and β-Lg (which is well characterized, see below) and a group of uncharacterized proteins (probably caseins).

α-Lactalbumin

Considering the high concentration of lactose in primate milks, the presence of α-La (which is involved in the biosynthesis of lactose, *see* **Milk Proteins**: α-Lactalbumin) in primate milk is expected. α-La has been isolated from the milk of chimpanzee, baboon, cynomolgus, and Rhesus monkey; the amino acid composition is virtually identical and the sequence of the 20 N-terminal residues is identical to that of human α-La, and they have a good activity in lactose synthesis; baboon α-La has been crystallized.

β-Lactoglobulin

β-Lg, the principal WP in the milk of most species, but which is absent from the milk of humans, guinea pig, rodents, and rabbit, is a very well-characterized protein (*see* **Milk Proteins**: β-Lactoglobulin). β-Lg has been identified in the milk of baboon, cynomolgus, Rhesus, and vervet monkey. The sequence of the 26 N-terminal residues of cynomolgus monkey β-Lg is 54% homologous with bovine β-Lg. Baboon β-Lg occurs as three genetic variants, A, B, and C, with pIs of 5.25, 5.45, and 5.75, respectively. It contains 168 amino acid residues, compared with 162 for the bovine protein; the difference is due to the insertion of eight amino acids between residues 61 and 62 (bovine numbering) and the deletion of residues 109 and 112. It has an apparent mass (by SDS-PAGE) of 20 750 Da (about the same MW as Rhesus β-Lg), compared with 18 281 Da for bovine β-Lg. Baboon β-Lg is more similar to human glycodelin protein (a glycosylated homologue of β-Lg found in the uterus of humans and baboon and thought to have a protective role as the embryo is embedded) than it is to bovine β-LgA.

β-Lg of some species has a free –SH group, whereas those of others do not; some exist as a dimer at neutral pH, others do not (these characteristics are not related) (*see* **Milk Proteins**: β-Lactoglobulin). These properties have not been reported for primate β-Lg.

The homology (%) of baboon β-Lg with the corresponding protein from other species is sheep, 51.3; reindeer, 51.8; pig, 48.7; horse, 55.6; cat, 56.8; and dolphin, 54.9 (*see* **Milk Proteins**: β-Lactoglobulin).

We are not aware of reports of the presence of β-Lg in the milk of the Great Apes. Considering the absence of this protein from human milk, it is expected that it is also absent from the milk of nonhuman apes. Extending the range of primates for which the status of β-Lg is known is desirable.

Immunoglobulins

Mammal neonates acquire immunity either *in utero* or postpartum through the action of maternal Igs; however, the mode of transfer of Igs from mother to offspring is species specific. Ungulates transfer Igs, mainly IgG1, postpartum via colostrum (first colostrum of bovines contains ~10% Ig), whereas humans and other advanced primates and lagomorphs transfer Igs *in utero*; some species, for example, rodents, use both mechanisms. Whether Igs are passed transplacentally or via milk depends on the structure of the placenta, and the transfer process becomes increasingly more elaborate from prosimians to Old World monkeys and the Great Apes. In hominoids, the placenta is hemochorial, and maternal blood comes in direct contact with the placenta trophoblast; Igs (mainly IgG, which is relatively small) reach the fetal bloodstream by direct transfer and provide sufficient passive immunity against pathogens until the neonatal immune system has matured. Colostrum in these primates contains predominately IgA (the primary function of which is protection of the newborn's intestine from bacterial pathogens). The production of IgA, IgM, IgE, cytokines, growth factors, and other immune-related substances is delayed in human infants and presumably in other nonhuman primates. Placentation is more primitive (epitheliochorial) in Strepsirrhini primates and maternal Igs are transferred only via colostrum postpartum.

In Rhesus macaques, serum IgG levels in the neonate have been measured and are comparable to those of the adult. The concentration of IgG in the blood serum of neonatal Japanese macaque is ~70% of that of the adult; the concentrations of IgA and IgM are very low at birth but increase thereafter, presumably as the neonate encounters antigens. Macaque colostrum/early milk contains a substantial amount (mean $2.4\,\mathrm{g\,l^{-1}}$) of IgA (probably sIgA), though the amount is lower than that of human early milk, but it contains very little IgG or IgM.

Lactoferrin

Lactoferrin (Lf) is a nonheme, iron-binding protein with bactericidal and other biological functions (*see* **Milk Proteins**: Lactoferrin). Rhesus monkey milk contains a considerable concentration of Lf, which has been isolated and characterized. We are not aware of reports on Lf in the milk of other nonhuman primates, but it seems reasonable to conclude that it is a general constituent (Lf has been found in the milk of all species investigated, and human milk is a very rich source – about 20% of total N).

Casein micelles

Considering that the milk of all primates for which data are available is white, it seems reasonable to conclude that the caseins of all species exist as micelles capable of scattering light. The casein micelles in human milk are much smaller (~60 nm) and more porous than bovine casein micelles (mean diameter ~150 nm). We are not aware of any work on the casein micelles of other primates; work in this area is warranted.

An important property of milk is its rennet-induced coagulation in the neonatal stomach following the specific and limited proteolysis of κ-casein, a property that delays the discharge of milk from the stomach into the small intestine, thereby improving digestibility. The proteins of human milk form flocs, rather than a gel, on renneting and are more easily digested than bovine milk, which forms a firm gel, by the human baby. Milk proteins of primate species generally have a casein content of $\leq$60% of total protein and form soft clots in the stomach, which should be an important consideration in the selection of a substitute for maternal milk when hand-rearing is necessary. We are not aware of any work on the rennet-induced coagulation of the milk of nonhuman primates.

Neither are we aware of any work on other technologically important properties of the proteins in primate milk, for example, acid-induced coagulation, ethanol-induced coagulation, surface activity, water binding, or rheological properties.

Total amino acids

Human and chimpanzee (*Pan troglodytes*) milks have significantly lower concentrations of total amino acids (protein-bound plus free) than the milks of other primate and nonprimate species, though concentrations are similar between the gorilla (*Gorilla gorilla gorilla*) and lower primates (**Table 6**). The low protein, and hence low total amino acid concentration, is not unique to human milk but occurs across primates generally, but in nonprimates it is observed only in the horse (*Equus caballus*). There is some commonality in the general amino acid patterns of primate and nonprimate species (**Table 6**) despite differences in total amino acid concentrations. In all species studied, total amino acid concentration is much greater in colostrum than that in mature milk, and a decrease of ~75% in total amino acids occurs between colostrum and milk for humans and horses, but the decrease in baboons and Rhesus monkeys is ~34 and 21%, respectively. Glutamate, leucine, and proline comprise 40, 10, and 10%, respectively, of the milks of primate and nonprimate species, and no phylogenetic trend is found across species for these amino acids, except perhaps, leucine, which is high in primate milk. There is some phylogenetic trend between primate and nonprimate species in the concentration of cystine and methionine, as primates have lower methionine and higher cystine levels than nonprimates. Across primate species, humans and Great Apes have lower methionine and higher cystine than lower primates. Total essential amino acids concentration is similar across primate and nonprimate species and represents ~40% of total amino acids in both.

Nonprotein nitrogen and free amino acids

About 3–5% of the total nitrogen in bovine milk is nonprotein nitrogen (NPN; soluble in 12% TCA), comprised

Table 6 Total (g l^{-1})[a], essential amino acids (mg g^{-1} total) and some important amino acids (mg g^{-1} total) in the milk of some primate and nonprimate species

[a] Amino acids in proteins plus free amino acids.

[b] Glutamate plus glutamine.

Modified from Davis TA, Nguyen HV, Garcia-Bravo R, *et al*. (1994) Amino acid composition of human milk is not unique. *The Journal of Nutrition* 454: 1126–1132.

mainly of urea and amino acids, whereas the corresponding value for the milk of human, Rhesus monkey, and baboon is 25, 6–13, and 20%, respectively. Of the Lemuridae species studied, *Eulemur fulvus* has 10.4% and *Eulemur macaco* has 13.9% NPN as percentage of total nitrogen (TN), whereas for one species from the Galagidae family, *Otolemur garnetti*, the NPN is only 2.8% of TN. The free amino acids may be important from a nutritional point of view and, in the case of bovine milk, they also sustain the initial growth of lactic acid bacteria in fermented milk products. The high concentration of free amino acids in human milk is assumed to have a beneficial role in postnatal development, and, across mammals, it is assumed that each species has a characteristic free amino acid pattern. Of the 13 species studied by Sarwar and colleagues, in 1998, the concentration of free amino acids was the highest in the milk of pinnipeds (up to 20 mmol l^{-1}) and lowest in bovine milk. The milk of human, chimpanzee, baboon, and Rhesus monkey contains ~0.6 to ~4 mmol l^{-1} free amino acids (**Table 7**). Glutamic acid is the most abundant free amino acid in the milk of primates and nonprimates. Taurine, which is considered to be important for brain development in the neonate, is the free amino acid present at the highest or second highest concentration in the milk of many species, including human, chimpanzee, baboon, Java monkey, and Rhesus monkey (**Table 7**).

Urea, which represents ~50% of the NPN of bovine milk (~6 mmol l^{-1}), is also present at substantial concentrations in the milk of other species, including primates.

Milk Salts

Bovine milk contains 4 principal (macro) inorganic cations (Ca^{2+}, Mg^{2+}, K^{+}, Na^{+}), 3 macro inorganic anions (PO_4^{3-}, Cl^{-}, SO_4^{2-}), 1 macro organic anion (citrate), and about 20 elements at low or trace (micro) levels (*see* **Milk Salts**: Distribution and Analysis; Interaction with Caseins; Macroelements, Nutritional Significance; Trace Elements, Nutritional Significance). These elements are present as salts in solution or associated with proteins in the colloidal phase. Although quantitatively minor constituents, these inorganic elements play very important physicochemical, technological, and nutritional roles. The concentration of the inorganic elements can be determined by various techniques, and the total concentration can be estimated as the ash remaining after incineration at 550 °C × 5 h. The amount of ash obtained from the milk of most primates is very low, 2–3 g kg^{-1}, which is as would be expected considering the dilute nature of these milks. The concentration of minerals and trace elements in the milk of some primates is shown in **Table 8**. In human milk, as lactation progresses, the concentration of

Data from various resources.

individual minerals changes. Na, K, and Cl decrease, whereas Ca increases initially but decreases again by ~6 months lactation. Magnesium concentration remains fairly constant throughout lactation with a small decrease at 6 months, and P increases slightly over the first 3 months of lactation and subsequently decreases. Fe, Cu, and Zn, which are relatively high in colostrum, decrease significantly as lactation progresses. The pattern described above has been observed also for the minerals of Rhesus monkey milk over the course of lactation. Overall, the levels of iron and copper in Rhesus monkey milk are significantly higher than those in human milk.

Indigenous Enzymes

Milk contains numerous indigenous enzymes, which originate from the blood (leukocytes or serum), mammocyte cytoplasm, and the apical membrane of mammocytes. These enzymes may cause spoilage, have a bactericidal effect, or assist in digestion. About 70 indigenous enzymes have been identified in bovine milk, and the most important of these have been isolated and characterized. The milk of all species probably contains the same range of enzymes as bovine milk, but only a few enzymes have been studied in most species, an exception being human milk in which 30 enzymes have been identified. There are large interspecies differences in the levels of many enzymes in milk. Unfortunately, there are very few studies on the indigenous enzymes in the milk of nonhuman primates. An interesting exception is bile salts-stimulated lipase (BSSL). The principal lipase in the milk of all species studied is lipoprotein lipase (LPL) from blood serum. However, in 1928, E. Freudenberg showed that human milk contains a lipase activated by bile salts, and hence was called BSSL. In 1966, Freudenberg showed that gorilla milk also contains BSSL and that the milk of several other species lacked this enzyme. BSSL is identical to pancreatic carboxyl ester hydrolase (CEL), and was shown to be present in the milk of human, gorilla, squirrel monkey, and African green monkey, but absent from the milk of all other species studied, including other apes and monkeys. Initially, it was thought that the milk of most species lack CEL, but it is now known that it occurs widely in the pancreas and mammary gland, including in the human, gorilla, chimpanzee, orangutan, and macaque. Gene duplication has resulted in the evolution of a pseudogene in most species. The structure and organization of the human and gorilla CEL gene have been studied, and the primary structure of the enzyme determined; they show 97% homology. CEL contributes to the digestion of lipids in human infants, who have limited pancreatic function; presumably, it serves a similar function in other species. Baboon milk contains both lipase and esterase activities, but the enzymes were not separated.

In 1923, Alexander Fleming identified a bactericidal agent in nasal fluid, tears, sputum, saliva, and other body fluids, which lysed bacteria (*Micrococcus lysodeikticus* was used for the assay and hence the name lysozyme, which was shown to be an enzyme). He did not report the presence of lysozyme in milk, but shortly thereafter Bordet and Bordet reported the presence of lysozyme in the milk of several species and that human milk is a particularly rich source; the enzyme has been isolated from the milk of several species. Human and equine milks are exceptionally rich sources, containing 400 and 800 mg l^{-1}, respectively (3000 and 6000 times the level found in bovine milk, or 4 or 3% of the total protein in human or equine milk). Lysozyme represents ~5% of the total N of baboon milk; the enzyme does not survive passage through the gastrointestinal tract (GIT; active lysozyme is not found in the feces of the infant baboon). The enzyme has been purified from baboon milk and characterized. Human milk lysozyme contains 130 amino acid residues, and 129 residues are found in egg white lysozyme, but the two enzymes differ at 14 positions.

Hanke and colleagues compared the lysozyme in the milk of 19 primate species using antibodies raised against human or baboon lysozyme; the milk of all 19 species contained lysozyme (activity not quantified) that was immunologically related to human lysozyme approximately, according to the phylogenetic relationship among primates; human and chimpanzee lysozyme were immunologically indistinguishable.

Vitamins

There appear to have been very few studies on the vitamins in primate milk, which is surprising because many of the studies on these milks have concerned the artificial feeding of primates. The concentrations of most B-vitamins in the milk of captive baboons (*Papio cynocephalus*) throughout lactation are intermediate between those in human and bovine milk (**Table 9**), except for niacin and pyridoxine, which are higher in baboon milk than in human and bovine milk, and folate, which is lower. This was the only study on vitamins in the milk of nonhuman primates, and there seems to have been no reports since.

Conclusions and Prospects

The gross composition of about 30 primate species is known; they contain the same types of constituents as all other mammalian species examined but at different

Table 9 Concentration of water-soluble vitamins (μg l^{-1}) in baboon (*Papio cynocephalus*), human (*Homo sapiens*), and bovine (*Bos taurus*) milk

Vitamin	*Baboon*[a]	*Human*[b]	*Bovine*[c]

concentrations. With a few exceptions, the milk of primates is dilute, with low levels of fat, protein, and inorganic salts, and a high level of lactose. In-depth knowledge of nonhuman primate milk composition is of fundamental importance for selecting formulae for hand-rearing animals in captivity. Furthermore, the formula should reflect the natural proportions of proteins (both casein and WPs), fats, and sugars in maternal milk, and should be appropriate for an individual's digestive capability (i.e., frequency of feeding, amount fed, and gastric clot formation should be similar to the corresponding traits of normal maternal feeding). Detailed information on the constituents, especially the proteins, is lacking for primate milks. The OSs of a few primate species have been studied; though the constituent monosaccharides are common with those of other species, the glycosidic bonds are somewhat different. The FAs in the lipids seem to be common with all other species, but the lipids of many primates contain high levels of $C_{8:0}$ and $C_{10:0}$, and very high levels of PUFAs; there appear to be no unique FAs. Like the milk of other species, primate milks contain caseins and WPs; the principal WPs are those present in the milk of other orders, namely, α-La, β-Lg, Igs, and Lf, and no novel WPs have been reported. Unfortunately, the milk proteins of only a few primate species have been examined by high-resolution electrophoretic techniques; available data indicate that, like human milk, the milk of nonhuman primates contain β- and κ-caseins, but the situation of the α-casein is unclear. Primate milk contains several minor proteins that have not been identified. A thorough proteomic study of primate milks is warranted.

There is essentially no information on the colloidal aspects of primate milks, that is, of the fat globules and casein micelles, and there are no data on the colloidal stability of primate milks. A number of primates, for example, chimpanzee, gorilla, orangutan, baboon, and Rhesus and other macaque monkeys, are readily available in captivity (in primate centers and zoos) or in the wild, and it should be relatively easy to obtain milk samples. An extensive interspecies electrophoretic study of the proteins in primate milk should provide interesting information on the evolution of primates, which have been evolving and undergoing speciation for about 65 million years; the most recent species, *Homo sapiens*, evolved only ~200 000 years ago.

Microbiological Contamination

The following main sources of microbial contamination of milk can be distinguished: (1) interior of the udder, (2) exterior of the teats and the udder, and (3) milking and storage equipment.

The interior of the udder is of minor importance as long as cows are healthy: primary infection of milk is very low. Housing conditions and the exterior of the teats are permanent although highly variable sources of contamination. Also organic residues on the inner surface of the milking equipment including the bulk milk tank contribute to microbiological contamination of fresh milk.

The two main sources of bacteria in raw bulk milk are organisms transported from the environment into the milking machine and mastitis organisms from within the udder. Bacteria deposited in milk handling equipment will multiply and can become a major source of contamination if this equipment is not cleaned and sanitized properly.

Microbiological contamination of these main sources can be minimized by: (1) post- and premilking teat disinfection, (2) premilking cleaning and disinfection of udders, and (3) cleaning and disinfection of equipment.

Post- and Premilking Teat Disinfection

Teat dipping, or better teat disinfection, reduces bacterial numbers on the teat skin and orifice (*see* **Mastitis Pathogens**: Contagious Pathogens; Environmental Pathogens). Postmilking teat disinfection is an effective procedure for reducing the rate of subclinical and clinical mastitis during lactation. While postmilking teat disinfection with an effective germicide reduces intramammary infections caused by contagious mastitis pathogens, it is less effective in controlling mastitis due to environmental pathogens.

Premilking teat disinfection was developed as a potential method to control environmental pathogens by reducing bacterial populations on teat skin before milking. Teat disinfection can be performed by dipping the teats in a dipping solution or by spraying the disinfectant on the teats by a hand spray or by automatic spraying devices.

The disinfectants used for pre- and postmilking disinfection can be based on:

1. Chlorhexidine gluconate solutions.
2. Iodine solutions varying in concentrations from 0.1% to 1% active iodine, in many cases mixed with glycerine or other emollients.
3. Linear dodecyl benzene sulfonic acid.
4. Sodium chlorite and lactic acid.
5. Sodium hypochlorite.

The first two mentioned disinfectants are used in most commercially available products.

Although teat disinfection reduces the number of bacteria, there may be problems with possible residues in the milk.

Premilking Cleaning and Disinfection of Udders

Between milkings, cows' teats may become soiled with feces, mud and bedding materials (e.g. straw, sawdust, wood shavings or sand). If not removed beforehand, this dirt, together with the large number of microorganisms associated with it, may be washed into the milk during milking. A first step in hygienic milking is cow hygiene in stables and outdoors. This influences the effectiveness of cleaning the udder. Differences in teat contamination can be found between housed cows and cows at pasture (see **Table 1**). Contamination of teats is lower when cows are at pasture. When cows are housed, bedding material and feedstuffs can be sources of contamination. Feces and urine are also important sources of microbiological contamination of teats and udders.

Therefore, before milking, udder preparation should take place to remove visible dirt and reduce bacterial contamination of the milk. This udder preparation can be done in different ways:

1. Cleaning with a dry towel (textile or paper).
2. Cleaning with a wet towel (towel put in water with disinfectant between cows).
3. Washing with water, left wet.
4. Washing with water, dried with towel (textile or paper).
5. Washing with water including disinfectant, left wet.
6. Washing with water including disinfectant, dried with towel (textile or paper).

The effect of different methods of udder preparation is shown in **Table 2**.

With the last most intensive way of udder preparation, a maximum reduction of teat contamination of 90% can be reached for total bacterial and spore count. If teats are left wet, the effect may also be negative because more bacteria are found on the teats. In practice the time for drying is very short and not always done effectively. Therefore in many cases a dry cleaning is advised.

During udder preparation not only is cleaning of the teats important, but also the milk letdown that is stimulated by massage of the teats. In the case of automatic milking the premilking udder cleaning and disinfection is done automatically in different ways, depending on the brand of milking system. There are systems with rotating brushes, with possible addition of disinfectant during or after preparation. Also washing of teats in teat cup liners combined with drying with air is possible in some systems. There are systems with separate udder preparation and systems without no separate udder preparation. Although automatic detection of dirt is in theory possible, all current automatic milking systems do not adapt to the dirtiness of the teats.

Cleaning and Disinfection of Equipment

Cleaning of milk handling equipment is accomplished by a combination of chemical, thermal and physical processes. Recommended cleaning and sanitizing practices are a balance between the cleaning temperatures, cleaning chemical concentration, contact time and mechanical action (see **Figure 1**). Any one of these factors can be intensified to make up for lack in another, up to a point.

Although system designs vary considerably, typical features of milking parlor cleaning-in-place (CIP) systems are shown in **Figure 2**. Cleaning solutions are transported from the wash vat through the sanitary parts of the system and back to the wash vat during the process.

A cardinal rule for an efficient and effective CIP system design is to keep pipe lengths and number of fittings to a minimum. This will reduce the installation and

Table 1 Contamination of teats of housed cows and of cows at pasture

Conditions	*Total plate count (log cfu per swab ± SD)*	*Aerobic spore counts (log cfu per swab)*

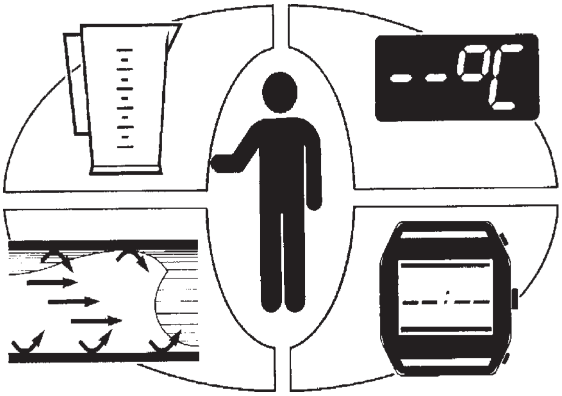

Figure 1 Factors influencing the result of the cleaning process of milking equipment.

operational cost of the CIP system as well as improving both milking and cleaning performance.

Temperature, Time and Concentration of Chemicals

Water Rinses

A water rinse should be performed immediately after milking is completed, to remove most of the residual milk remaining in the system or between chemical washes to remove residual cleaning chemicals. The temperature of these water rinses is usually between 38 °C and 55 °C. The upper limit has been specified in the belief that proteins may be 'baked' on to surfaces at higher temperatures. The lower limit is set above the melting point of milk fat to ensure that fats will be removed and not redeposited. A second benefit of the initial rinse is to warm the equipment so as to reduce the temperature drop during the subsequent cycles. This benefit is marginal, however, when the subsequent cycles are not started within 5 min after the rinse. These rinses should not be recirculated. Water rinses are also recommended after every chemical cycle to remove residues from the milking machine.

Alkaline Detergent

Chlorinated alkaline detergents are used to remove organic soils such as milk fat and proteins. Most detergents have a working temperature range between 43 and 77 °C, but there are also low-temperature formulations available. The cleaning effectiveness of detergents improves as temperature is increased and as water hardness decreases. The detergent concentration must be adjusted to account for these factors.

Acid Rinse

An acid rinse cycle may be performed to remove mineral deposits from water and milk. This may be a cold or warm rinses. The required frequency of acid rinses depends on the quality of the water used for cleaning.

Acidified Boiling Water

The acidified boiling water method is used in some parts of the world. An acid detergent solution is used at a temperature of nearly 100 °C. The wash solution makes

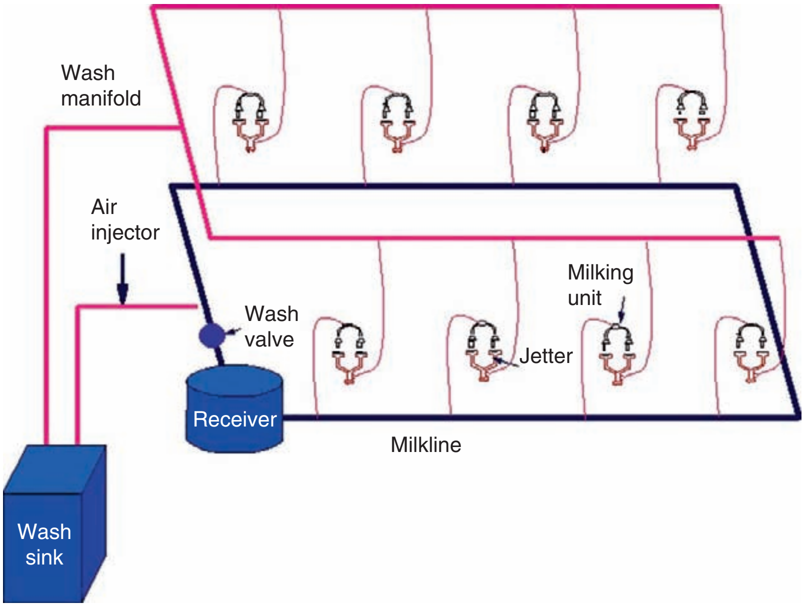

Figure 2 Basic cleaning-in-place (CIP) system for milking parlors.

a single pass through the system and is not recirculated. The objective is to maintain all surfaces at a temperature above 77 °C for at least 2 min. This method replaces the chemical action of alkaline detergents with intensified thermal action. It requires special equipment to achieve elevated water temperatures and milking system components that can withstand these high temperatures.

Chlorine Sanitizers

Chlorine-based sanitizers are circulated immediately before milking to kill bacteria that have survived the cleaning process. This premilking sanitizing step is performed on milking machines that stand idle for several hours between the previous wash cycle and the subsequent milking. A premilking sanitize is not practiced in many areas where a sanitizer is combined with either the detergent or acid rinse cycles and where water rinsing after each chemical treatment cycle is enforced.

The chemical processes described above are used in various combinations around the world. The most common routine in the United States is a combination of: prerinse, alkaline detergent, acid rinse (frequency depending on water hardness), and premilking sanitize. In The Netherlands and many other European countries, the standard cleaning of milking equipment consists of three phases: prerinse, combined alkaline detergent and chlorine sanitizer, followed by a postrinse. A common practice in New Zealand is an acidified boiling-water wash (alternated periodically with alkaline detergent) followed by a cold water rinse. A conventional Nordic procedure is composed of prerinse, alkaline detergent, cold water rinse, acid rinse, and then a pure water rinse immediately before milking.

The choice of which cleaning regime is used depends strongly on the habits and regulations of each country, the relative cost of energy for heating water, chemical cost and availability and effectiveness of the process.

Mechanical Action

Assuring an adequate mechanical cleaning action typically requires very little added cost but relies on the skill of the equipment installer. As milking machines become more complex the task of assuring adequate mechanical cleaning action in all parts of the milking machine becomes increasingly complex.

Milklines must be sloped between 1% and 2% toward the receiver jar to prevent slugging in milklines during milking. All pipelines, hoses and components must also be installed so that they will drain by gravity between cleaning cycles. Drainage is an important aspect of cleaning, because any standing water in the system increases the risk of bacterial growth between milkings and mixing of different cleaning chemicals during cleaning. Different mechanical processes are discussed.

Manual Cleaning

Simple milking machines such as bucket milkers are typically disassembled and cleaned by hand. Even in the most complex machines using circulation cleaning, however, there are still components that must be disassembled and cleaned by hand. The source of the mechanical cleaning action is typically a brush used to remove milk solids deposits. The use of extended contact times (soaking parts in a sink) is also widely practiced for small components.

Flooded Flow

The milk transfer line (from the milk pump to the wash sink) is cleaned in a flooded condition with the milk pump providing the fluid velocity. Milking machines with milkline diameter less than 48 mm have used flooded flow to circulate cleaning solutions through milklines. Flooded flow is also encountered in components such as hoses in milking units in which internal diameters are small. The desired flow velocity for flooded components is about 3 m s^{-1}.

Milk pump capacity is often the limiting factor in CIP systems. The distribution of water flow between units should be as uniform as possible to make the most efficient use of water and air when cleaning milking equipment and to avoid exceeding the capacity of the milk pump. Adding flow restrictors is an effective way of optimizing water flow rates for cleaning and balancing the flow between units. Systems with milk meters or weigh jars require 4.5 to 6 l min^{-1} for effective cleaning.

Steady Air Admission

The amount of water required to fully flood a milking system with very long and/or large diameter milklines is impractical. The power available to achieve adequate flow velocity is also limited with the equipment available as part of the milking machine. Air admission has been used to produce two-phase (air/water) flow and overcome these limitations. Steady air admission is practiced on some small-diameter milklines (<48 mm) to reduce the required water volume and increase flow velocities. Some milking units and milk meters are also designed to introduce steady air admission during cleaning. This steady air admission will improve mechanical cleaning action slightly but makes balancing water flow through units more difficult and increases the vacuum pump capacity required for cleaning.

Cycled Air Admission and Slug Flow

Cycled air admission is commonly practiced on milking machines with milkline diameter of 48 mm or greater. The objective in air-injected flow is to form a 'slug' of cleaning solution and move this slug around the entire pipeline. The slugs may vary from a few centimeters up to several meters in length. The area between the slugs contains a slower-moving liquid film in the bottom of the pipe. The slug velocities developed with air injected two-phase flow can be three to five times higher, and the wall shear stress developed 10 to 20 times higher than those in flooded CIP circuits. The contact time between the slug and pipe wall is significantly reduced, however.

Slug velocities of 7–10 m s^{-1} maximize the wall shear stress developed while minimizing the variation of shear stress along the pipe. The rate of air admission to the milkline should be controlled to achieve these slug velocities. Air admission rates above this maximum will result in reduced slug density and reduced mechanical cleaning action in the milkline.

Spray Cleaning

Bulk tanks and other large vessels are cleaned by covering their inner surfaces with a sprayed sheet of water. The mechanical action and surface temperatures are significantly lower than for circulation cleaning. The chemical concentrations and wash water temperatures are therefore of critical importance for successful cleaning.

Very small herds (fewer than 30 cows) tend have a high degree of manual cleaning and disinfecting. This usually involves hand cleaning of some or all of the milk harvesting and storage equipment. Small to medium herds (30 to 500 cows) commonly use automatic washing equipment. This equipment will automatically mix the chemicals with the appropriate water volume and temperature and circulate these solutions through the milking machine. On large farms (1000 cows or more), an attendant may be present to mix chemical solutions and operate valves for circulation.

Environmental Issues

There are several environmental issues that are beginning to influence cleaning practices in some parts of the world. The discharge of cleaning and disinfecting chemicals into the environment can be an issue, with elements such as phosphorous and chlorine. The uses of enzyme cleaners and ozone sanitizers has been investigated but in general these have not reached the market yet.

The volume of water used for cleaning and discharged into the environment can be an issue in areas with water shortages. The energy used for heating and pumping water also has environmental implications. Various methods to reduce water volume, chemical volume and energy requirements for cleaning through efficient system design and control and through reuse of cleaning solutions have been reported.

Cleaning Assessment Methods

Visual Inspection

Cleaning failures usually result in a visible build-up or residual film on some part of the milk harvesting or storage equipment. Parts that can be controlled are for example: milking claws, milk production meters and the milkline, especially at an end of a line.

Some of these residual films have a characteristic appearance, which can help determine the cause of the cleaning failure. There are two broad categories of residual films: organic films such as fat and protein, and inorganic films such as hard water minerals, iron and silica. Discoloration may also occur due to corrosion and/or pitting of surfaces. Protein films can appear as a brownish slime ('applesauce') when wet. Mineral films usually have a rough porous texture and are invisible when wet. Organic films are generally alkaline soluble whereas inorganic films are generally acid soluble. Protein films are soluble in chlorine. Films can be diagnosed by scrubbing a small area with concentrated acid and/or detergent solutions.

Bulk Milk Cultures

Some form of testing for bacterial contamination is done periodically on all farms to assure compliance with national, state and local requirements.

The most common method used to assess the bacterial quality of raw milk is the standard plate count (SPC) or total bacteria count (TBC). These are broad-spectrum tests that do not identify the types of organisms present. These tests provide an overall measure of milk quality but they have little diagnostic value in determining the source of bacterial contamination.

ATP Measurements

Cleanliness of the equipment can also be tested by ATP measurement. ATP produced by bacteria or organic residues can be determined by using special swabs with reagents. Measuring light emission gives an indication about the hygiene in the equipment.

Influence on Free Fatty Acids

L Wiking, Aarhus University, Tjele, Denmark

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Around 60–70% of the free fatty acid (FFA) concentration in the final pasteurized milk product is produced during milking and milk transfer to the bulk tank. Therefore, increased FFA concentration is one of the most frequent farm-related defects in drinking milk. FFAs are formed by the hydrolysis of triglycerides by the enzyme lipoprotein lipase (LPL). Large concentrations of FFAs result in the appearance of rancid off-flavors in dairy products. The rancid flavor developing from lipolysis in milk is often described as gouty or soapy. The sensory threshold for lipolytic rancidity in milk is not precisely established, but it is estimated to be in the range of 1–1.5 meq per 100 g fat, because the development of rancid flavors is greatly affected by the composition of the FFA. It is mainly the fatty acids with a chain length of 4–12 that contribute to the rancid flavor; for example, the concentration for off-flavor threshold of C_{14} is more than 10 times that for C_4.

Since the milk quality payment globally focuses on criteria such as freezing point and bacteria and somatic cell count, milk producers do not pay much attention to the problems of accumulation of FFAs in the milk. However, in the Netherlands, the farm milk is tested twice a year for the level of FFAs, and if the concentration is above 1.0 meq per 100 g fat, a reduction in payment is executed.

Lipolysis

LPL is the enzyme mainly responsible for lipolysis in raw milk. It originates from the mammary gland, where it is involved in the uptake of blood lipids for milk synthesis. The enzyme is active in lipid–water interfaces. Its optimum temperature is 33 °C and pH optimum is about 8.5. It is a relatively heat-labile enzyme and is mostly inactivated by a high-temperature short-time heat treatment. In milk, LPL is mainly associated with the casein micelles. LPL is brought into contact with the triglycerides when the milk fat globule (MFG) membrane is disrupted and casein coats the formed lipid–water interface. The enzyme is activated by apolipoprotein CII from the blood, which assists LPL to bind onto the fat globule. In spite of the high amount of LPL in milk, lipolysis is limited since milk fat is protected by the membrane and raw milk is normally stored at temperatures far below the optimum temperature of LPL. Furthermore, the products formed by the hydrolysis of triglycerides, the FFAs, inhibit the enzyme, presumably by binding to the enzyme.

The activity of LPL in whole milk is not correlated to the FFA content in raw milk. However, studies have shown that the activity of LPL in the cream fraction is related to the level of lipolysis. Consequently, the formation of FFAs is assumed to be dependent on the susceptibility of MFG to the action of lipases. LPL preferentially hydrolyzes fatty acids in positions sn-1 and sn-3. The fatty acids placed at high frequencies in positions sn-1 and sn-3 are C_4, C_6, C_{18}, and $C_{18:1}$. The development of a rancid flavor in milk is greatly affected by the composition of FFAs. It is mainly the fatty acids with a chain length of 4–12 that contribute to the rancid flavor.

Lipases synthesized by bacteria such as *Pseudomonas* and *Bacillus* species can also be developed in milk. Flavor defects can be detected in milk only when the bacterial counts reach approximately 10^6–10^7 CFU ml^{-1}. Therefore, if milk is properly stored and has an acceptable hygienic quality, microbial lipases are not an important factor for lipolysis until after several days of storage.

The classic differentiation of lipolysis in milk is between spontaneous and induced lipolysis. The factors affecting spontaneous lipolysis include milking frequencies, udder health, and stage of lactation. Induced lipolysis is caused by homogenization, pumping, and temperature fluctuations.

Factors Affecting FFAs in Milking Systems

Air Intake

In milking systems, the milk is mixed with air, especially when air is used as a transport medium for the milk. The stability of the MFG is lowered by mixing with air or any other gas during pumping or agitation of the milk. The contact between an MFG and an air bubble results in rupture of the MFG, since the membrane material and part of the core fat will spread over the air/milk plasma interface and will be released into the milk plasma when air bubbles collapse or coalesce. The total air admission in the cluster should be between 4 and 12 l min^{-1}; however, in automatic milking systems (AMSs), it is often higher. Increasing air intake has great impact on the formation of FFAs, and even if milk and air are mixed only for a short pumping distance, it causes damage.

Pumping

Mechanical treatments of the milk such as pumping and stirring subject MFG to physical stress. Higher flow velocities during pumping in pipes result in a greater friction in the liquid itself and between the liquid and the pipe wall. These relative differences in flow velocity perpendicular to the flow direction are called shear rates. The shear rate depends on the diameter of the pipe and the flow velocity. The presence of air, the temperature of the milk, and the fat content affect the stability of the MFG during mechanical treatments of milk.

The milk temperature is also a very important factor when milk is exposed to mechanical treatments. Several studies have reported that the maximum accumulation of FFAs upon agitation is at a temperature of ∼15 °C and again after ∼30 °C, with low formation of FFAs between 20 and 30 °C. At low temperatures, the milk fat is more resistant to mechanical stress, since large parts of the triglycerides in the MFGs are crystallized, and this stabilizes the globules against coalescence. One minor factor is that the temperature affects the activity of LPL.

The average diameter of MFGs can be affected through the feeding of cows. Diets with high levels of saturated fat supplements result in high milk fat production and in MFGs with large average diameters. These milk types with large MFGs are more susceptible toward coalescence and lipolysis during pumping compared with milk from cows fed a low-fat diet or unsaturated fat supplements. The reason for the lesser stability of large milk globules during pumping is presumably that the surface potential is lower for large globules than it is for smaller globules. Therefore, less energy is needed to coalesce large globules, and at the same time the collision energy is greater for large MFGs.

Figure 1 shows that a cooling system consisting of a plate cooling exchanger placed in the milking parlor close to the milking unit significantly decreased the formation of FFAs in the milk. Moreover, the milk flow in the milking systems was controlled by a variable frequency pump in order to control the cooling more precisely and economically. The figure indicates that the right cooling strategy in a milking system can improve the milk quality regarding lipolysis.

Milking Frequencies

One advantage of AMSs is that the cows are more frequently milked, since they voluntarily attend the robot. Increased milking frequency enhances the milk yield; for example, with thrice-daily milking, the milk output is increased by ∼18% when compared to twice-daily milking. The average milking frequency in AMSs is between 2.4 and 2.6 per day. This implies that a large share of cows attend the milking robot 3 or 4 times per day. **Table 2** shows that one drawback of increasing milking frequency to 3 or 4 times a day is a higher concentration of FFAs in milk. In the studies presented in **Table 1**, the effect differs among studies, which can be ascribed to different analytical methods; however, the trend of an increased concentration of FFAs upon increased milking frequency is clear.

A study in our laboratory demonstrated that the difference in the concentration of FFAs is not present immediately after milking, but only after 24 h of storage,

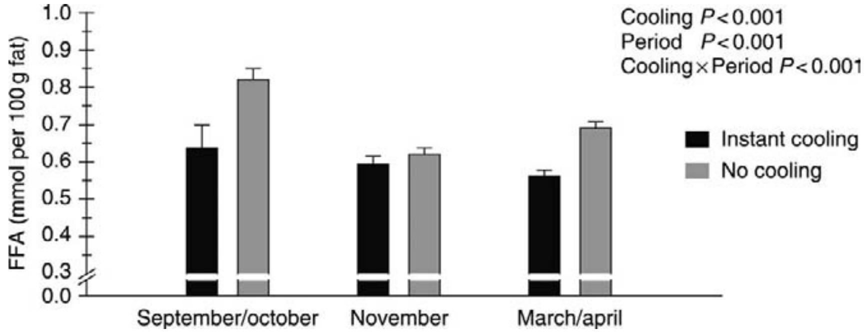

Figure 1 The effect of cooling of milk in the milking parlor compared with no cooling. The milk was cooled down to 4 °C by a plate heat exchanger before being further pumped to the bulk tank. The milk flow in the milking systems was controlled by a variable frequency pump in order to control the cooling more precisely and economically. The samples were collected just before the inlet to the bulk tank by a small separation pump, which was regulated by the main milk pump frequency, so the sample represents milk from the whole milking session of 120 Danish Holsteins cows. The distance between the milking parlor and the bulk tank was only 22 m. Samples were collected during three periods. The concentration of FFAs was analyzed 24 h after milking by using the BDI method. Reproduced with permission from Wiking L and Nielsen JH (2007) Effect of automatic milking systems on milk quality. *Journal of Animal and Feed Sciences* 16(supplement): 108–116.

Table 1 Effect of milking 3 or 4 times a day compared with 2 times a day on FFA concentration in milk

	2×	*3×*	*4×*	*Year of study*
FFA (meq per 100 g fat)	1.14		1.49	2006[a]
	0.72	0.99		1997[b]
	0.42	0.71		2004[c]
	0.33	0.44		1986[c]

[a]Used the autoanalyzer method.
[b]Used the copper soap method.
[c]Used the BDI method for FFA content analysis.

which indicates that the increased concentration of FFAs in milk is caused by a weakness of the MFG membrane. We also observed that the average diameter of MFG was significantly larger in milk obtained by milking 4 times than in milk obtained by milking two times. This could be one of the explanations for the weakness of the MFG membrane.

Cool Storage in the Milk Tank

Cooling

The initial FFA concentration in fresh drawn milk is around 0.15–0.5 mmol per 100 g fat. During cool storage of the milk in the tank, the concentration of FFAs increases. The increase in the concentration of FFAs is largest during the first 24 h after milking. The cooling itself renders plasma proteins to adsorb to the MFG membrane. Hereby, the LPL is brought into contact with the lipids, since it is bound to the caseins. Furthermore, crystallization of the triglycerides will occur, which will result in some structural changes of the MFG membrane. The crystallization range for milk fat is broad due to the large variety of triglycerides. Crystallization begins from the edges moving inward to the core. The membrane mainly consists of phospholipids, which are unsaturated and therefore crystallizing only at very low temperatures. However, volume changes caused by crystallization of the core fat will affect the structure of the membrane. In addition, some proteins and Cu are released from the membrane to the serum phase during cooling. On the whole, the composition and the structure of the MFG membrane are altered when raw milk is subjected to cooling. The relation between the structural changes of the MFG membrane during cooling and the access of LPL is not clearly understood (*see* **Milk Lipids**: Lipolysis and Hydrolytic Rancidity).

Temperature fluctuations in the bulk milk tank are a risk if the milk is not precooled before it enters the tank. Mixing warm fresh milk with cold milk from the previous milking results in a fast temperature increase before cooling starts again. Temperature fluctuations in milk can cause major increases in the concentration of FFAs. In some modern milking systems, the milk is precooled in a plate cooling exchanger or buffer tank, so temperature fluctuations are avoided in the bulk milk tank. This will also reduce energy costs of cooling in the bulk tank.

Stirring

A wrong dimension of the stirring unit in the bulk tank results in inexpedient mechanical treatments of milk, which again leads to churning of the MFGs and thereby susceptibility of fat to lipolysis. Incorporation of air into milk using wrongly dimensioned stirring unit also contributes to the rupture of MFGs. The problem is presumably largest when the milk volume in the tank is low and the stirring unit therefore touches only the milk surface.

FFAs in Milk from Different Milking Systems

High pipeline milking replaced bucket milking in stanchion barns many years ago, but lifting of the milk from the udder to the milkline requires inlet of air in the claw. Milking parlors and carousels (*see* **Milking Parlors**) are normally equipped with milklines mounted below cow level and milk flows directly from the cow into the milkline without air bubbling into the milk. **Table 2**, which is from a large Danish study, shows that milk from automatic milking and high pipeline systems contains greater concentration of FFAs than milk from systems with low lines. Similar observations are made regarding greater concentrations in milk from automatic milking in other West European countries since the introduction of the AMS, and this problem is still not solved. In the following section, the possible factors causing higher level of lipolysis in automatic milking are described.

Automatic Milking Systems

A recent survey of AMSs in Denmark showed that the most frequent faults in AMS herds with large concentrations of FFAs in bulk milk were stirring (79%), pumping (67%), and cooling of milk (58%). The milk flow into the bulk tank in AMSs is different from that in conventional systems due to the continuous flow of milk all day instead of just from two milking sessions. This also means that in some periods, such as after collection and cleaning, the milk volume in the tank is low. In some tanks, the stirring unit and cooling capacity are wrongly dimensioned in relation to a slow inlet of milk, causing churning of MFGs and mixing with air. On the other hand, too fast jacket cooling causes freezing of the milk to the shell of the bulk tank, which damages the MFG membrane. Furthermore, some AMSs have a buffer tank with a capacity to store up to 300 l milk, where the milk is precooled

Table 2 Concentration of FFAs in milk from different milking systems

Milking systems	*Number of herds*	*FFA (meq per 100 g fat)*
Automatic milking	219	0.889
Pipeline in traditional cow houses	1339	0.888
Milking parlor	1618	0.615
Rotary parlor	99	0.585

Reproduced from Danish Dairy Board, 2007.

before it is pumped into the bulk tank. However, during periods with low milking intensity, there is a risk that the milk may be stored in the buffer tank for a long time.

As mentioned earlier, the milking frequency in AMSs is often higher than that in other systems, and this fact contributes to the large concentration of FFAs in the milk. AMSs have greater air intakes than conventional milking systems since the milking units of AMSs are individual quarter milkers with rather long 'short milk tubes', individual shutoff valves, foremilk separators, and different kinds of flow meters, and the milk normally has to be lifted several times before it enters the receiver. Such technical constructions may require different amounts of air for transportation of the milk compared to conventional milking units.

High Pipeline Milking Systems

In high pipeline systems, high air intake from the claw or the pumps is also a main reason for a relatively high accumulation of FFAs in milk. Furthermore, the milk is often lifted in the pipes above cow level, which increases the pressure on the MFGs and thereby increases the degree of damages. A continuous flow of milk in the milkline to the bulk tank instead of a controlled milk flow is also a factor that increases FFA concentration in the milk. The most frequent faults in conventional herds in a Danish study were leakage (71% of the herds) and intake of too much air in the cluster (61%), whereas pumping and stirring faults occurred on 29% of the farms.

Many of the high pipeline milking systems used today are rather old and have leakages into the milk stream. This may also be an explanation for the fact that the average FFA concentration in milk from high pipeline systems is high in surveys comparing milking systems. As a consequence of better animal welfare conditions, the number of stanchion barns with high pipeline systems is decreasing at the expense of free barn systems with milking parlors.

Conclusion

A decrease in the number of farms with high pipeline milking systems will improve milk quality pertaining to FFAs, but the increasing number of AMSs may increase the risk for greater concentrations of FFAs in silo milk. Thus, the margin to the threshold of rancid flavor of milk becomes smaller.

The factors that contribute to elevated FFA concentration are virtually elucidated. Therefore, technical solutions such as correct cooling and gentle mechanical treatment could be implemented in modern milking systems.

Generally, in the future, more attention should be given to the effect on FFAs during development and implementation of new milking technologies.

Effect of Storage and Transport on Milk Quality

C H White, Mississippi State University, Starkville, MS, USA, Randolph Associates, Inc., Birmingham, AL, USA

Introduction

Never has there been a time when the quality and safety of our milk supply have been more critical. Like most perishable foods, the quality of finished dairy products begins with that of the raw milk. The quality of the raw milk received by the processing plant depends on a number of key factors, such as

1. health of the animal;
2. feed consumed;
3. milking conditions and procedures;
4. cleanliness of milking equipment, lines, and bulk tank, and freedom from residual sanitizer;
5. temperature control from bulk tank through to the silo storage tank at the processing plant;
6. cleanliness of tanker, lines, and silo; and
7. good handling practices at all points in the process.

In the United States, the usual way for raw milk to be handled is for the milk to be pumped from the milking parlor to the bulk tank. The product is then cooled rapidly to 7 °C or lower within 2 h of milking. The legal maximum temperature at which milk can be maintained, either raw or pasteurized, is 7 °C. Milk is picked up by a bulk hauler on a daily or every-other-day basis. It is transported mostly in tank trucks with a storage capacity of typically 6200 gallons (can be larger or smaller). The milk can then be taken (1) directly to a dairy processing plant, depending on the type of dairy food being produced at that facility; or (2) to a transfer or pump-over station. The trend in the United States appears to be more toward milk being transported directly to the processing plant. This trend is based on several factors such as a shift toward larger but fewer dairy farms and dairy processing plants, higher transportation costs, and fewer but larger cooperatives. This basic process is outlined in **Figure 1**.

Assuming that milk is taken directly to the dairy processing plant, several quality and safety tests should be run on the milk before unloading it from the tank truck. Other tests are then run on the milk after unloading it, but before it is processed. Raw milk is pumped into refrigerated silo storage tanks, where it is maintained at temperatures that are normally lower than 4 °C. The sizes of these silo tanks typically range from 10 000 to 80 000 gallons or more (tanks of 200 000-gallon capacity are not unknown) for some plants that manufacture dairy products such as cheese. It is important that the haulers start their pickup route each day with a tank truck that has been thoroughly cleaned. The trucks are cleaned after the milk is removed. The trucks are usually cleaned and sanitized at the dairy plant (but not in the receiving area) to which the milk was delivered or at an intermediate wash station. At either place, the truck must be tagged to indicate that this cleaning has indeed occurred. This process is critical to ensure the supply of high-quality raw milk.

Raw Milk Testing

While most dairy processing plants have their own lists of tests to be routinely performed on the raw milk received by them, there are tests that should be done to ensure a safe and high-quality milk supply. A suggested listing of these tests follows and this has been arbitrarily divided into tests to be performed 'prior to unloading' the milk and 'after unloading' the milk. The latter tests are also classified as 'troubleshooting' tests (**Tables 1** and **2**).

With regard to the tests to be run before unloading, the direct microscopic count (DMC) appears to be an old-fashioned laboratory technique; however, it is probably the only economical test currently available to processing plants that can estimate the microbiological quality of milk in the time allowed prior to tanker unloading. To facilitate milk unloading, all testing needs to be completed within 30–45 min. Other technologies are being developed and optimized, but the DMC has an advantage of low cost per sample. Technician error can be minimized by training and attention to detail. The DMC shows living and dead cells, which normally results in higher counts than the standard plate count (SPC) when run on the same sample.

There are several screening tests designed to detect the presence of inhibitory substances, especially antibiotics. No milk should be accepted by a dairy processing plant unless a 'negative' is received. If a 'positive' is obtained, state or federal regulations must be followed, to ensure that contaminated milk does not get into products offered for sale to the consuming public.

While temperature measurement is very simple, decisions as to whether or not to accept the milk on the basis of a temperature reading can sometimes be difficult. This is especially true in times of a reduced supply of milk. One needs to remember that as the temperature of milk increases, even slightly, the generation time of the bacteria present is decreased. The psychrotrophic

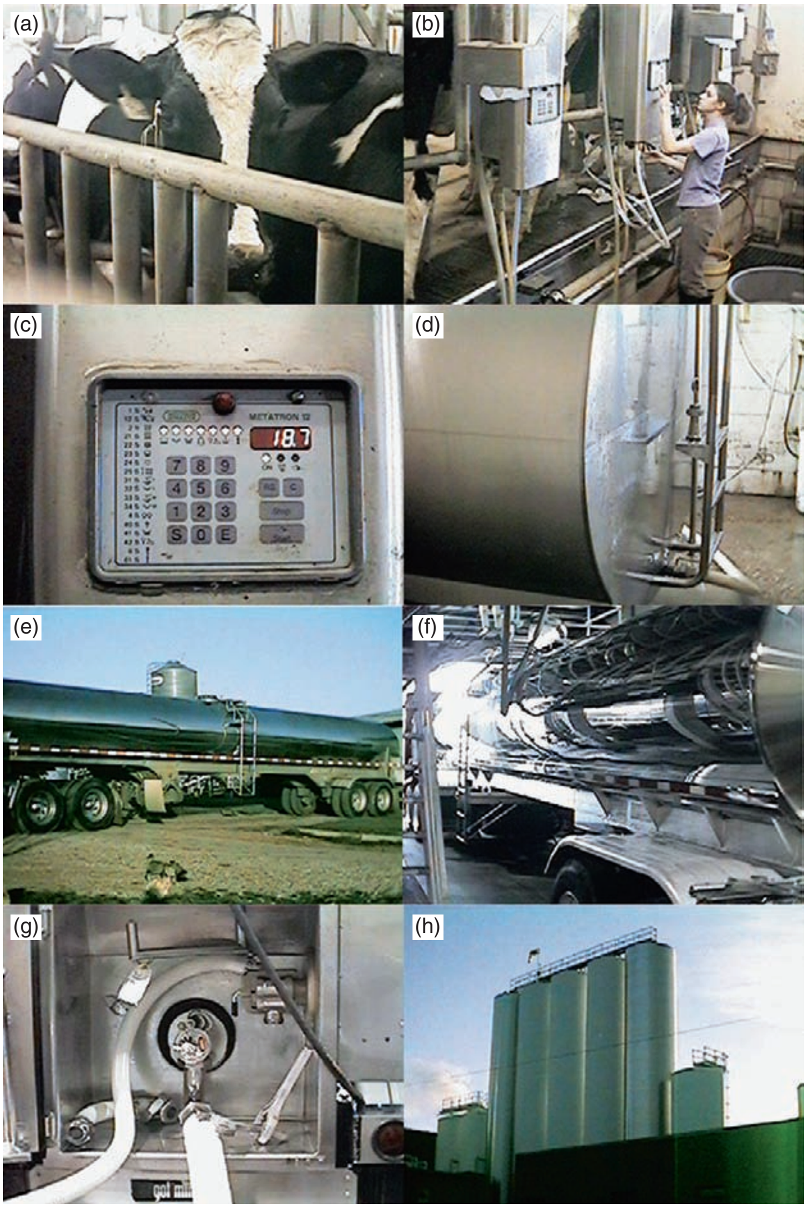

Figure 1 Typical flow of milk from dairy farm to processing plant appearing left to right in rows: (a) cows; (b) milking parlor; (c) milk meter in parlor; (d) bulk tank in milk room of parlor; (e) tank at farm; (f) tank truck at processing plant; (g) off-loading milk at processing plant; and (h) milk storage silos.

Table 1 Tests to be run on all raw milk prior to unloading from the tanker

	Test	*Standard (goal)*
1	Direct microscopic count (DMC)	<100 000 clumps ml^{-1}
2	Presence of inhibitory substance (antibiotic)	None detected with screening test
3	Temperature	Legal = .7 °C; desired = .4 °C
4	Freezing point (cryoscope)	Legal = lower than −0.530 °C
5	Sensory evaluation	No off-odors or off-flavors
6	Sediment test	('2' (1.50-mg equivalent) or '1')
7	Preliminary incubation count (PIC)	<100 000 cfu ml^{-1}

Table 2 Tests to be run on raw milk after unloading at the processing plant (and 'troubleshooting' tests)

	Test	*Standard (goal)*
1	Standard plate count (SPC) (only on 'high' DMC loads)	<100 000 cfu ml^{-1}
2	Direct microscopic somatic cell count (DMSCC)	Legal = <750 000 ml^{-1}
3	Acid degree value (ADV)	<0.90
4	Laboratory pasteurization count (LPC) (troubleshooting only)	<500 cfu ml^{-1}
5	Fat and total solids	NA
6	Coliform	<200 cfu ml^{-1}
7	Presence of aflatoxins	<0.5 ppb
8	HR-3 (test for Gram-positive bacteria)	Insignificant number of Gram-positive bacteria
9	Titratable acidity	>0.17%

bacteria – bacteria that are capable of fairly rapid growth at refrigeration temperatures – increase dramatically as the temperature is increased even from 4 to 7 °C.

Checking the freezing point of the raw milk indicates whether or not water has been added (either deliberately or inadvertently). Typical cryoscope values for tanker milk fall between −0.530 and −0.550 °C. Higher-solids milk yields values closer to the −0.550 °C end of the range. The closer the value gets to 0 °C (the freezing point of water), the more it proves that water has been added to the milk. These values can be calculated on a percentage basis.

Flavors (Taste or Odors) of Raw Milk

Desirable sensory properties are essential for high-quality raw milk. The milk should be checked for off-odors while still in the farm bulk tank. At the processing facility, the receiving room personnel should be the only ones to open the dome lid and carefully check for odors. The tanker should have been cleaned prior to picking up the milk. When the samples are being taken (aseptically) for acceptance testing, a sample can actually be laboratory pasteurized (heated up to 73–75 °C for 15–20 s), then cooled rapidly to 21–32 °C, and tested for the presence of off-flavors. This is especially critical for milk that has a suspicious odor. A 'feed' flavor is normal but should not be too strong or high in intensity. Other flavors that may be encountered occasionally are listed in **Table 3**.

While there are other off-flavors that may rarely be found in raw milk, those described above are probably the ones most commonly seen.

The sediment test can be run at the receiving plant by pouring 470 ml of raw milk through a white disk and checking for the amount of residue, that is, the sediment retained on the disk. This is a measure of the care taken during milking and pumping of the milk from the farm. While the milk is either run through a 'sock' filter as it is being pumped to the silo tank or run through an in-line separator before pasteurization, the presence of sediment in milk is unacceptable and should be avoided.

The SPC is simply a measure of the aerobic bacteria capable of growth on plate count agar at 32 °C. It is not a 'total' count but is a good indication of the 'total' microflora present in the milk sample. The SPC is accepted as an 'official' estimate of the microbial quality of a sample of raw milk. The problem in using it as a screening test for raw tank milk is the fact that the plates must be incubated for 48 h before the results are known; hence, we have the most logical reason for using the DMC. When an unacceptable DMC is obtained, the SPC should be run on that tanker for documentation purposes. In the United States, the legal maximum for individual producer milk is 100 000 cfu ml^{-1}, and for commingled milk it is 300 000 cfu ml^{-1}.

The direct microscopic somatic cell count (DMSCC) is the standard method for estimating the number of somatic cells in raw milk. This count provides a fairly

Table 3 Off-flavors occasionally encountered in raw milk

Flavor	*Cause*
Malty (do not accept)	Bacterial – normally traced to refrigeration problems at farm
Acidic (do not accept)	Bacterial – normally traced to refrigeration problems at farm
Onion (do not accept)	Feed-related
Flat (if definite, do not accept)	Mostly related to water getting into milk
Light-activated (do not accept)	Milk exposed to sunlight (ultraviolet light)
Rancid (do not accept)	Normally excessive pumping with air incorporated into milk; can be bacterial
Sanitizer (do not accept)	Excessive sanitizer in lines, bulk tank (or dipper)
Unclean (do not accept)	Primarily psychrotrophic bacteria

accurate picture of the health of the cows, especially with regard to bovine mastitis.

The acid degree value (ADV) is actually a measure of the free fatty acids present in the raw milk. If rancidity is a problem, incoming loads of raw milk should be screened with the ADV test since butyric acid is the fatty acid commonly associated with rancidity. The range of ADVs and how they should be interpreted are given below:

$$<0.7 = \text{normal milk}$$

$$0.7-1.1 = \text{slightly hydrolyzed}$$

$$1.2-1.4 = \text{definitely hydrolyzed}$$

$$>1.4 = \text{extremely hydrolyzed}$$

The laboratory pasteurization count (LPC) is a good test to run when shelf life problems are occurring and there is a need to know more about the quality of the incoming raw milk. The LPC indicates whether or not there are significant numbers of pasteurization-resistant bacteria present in the raw milk. When the LPC exceeds 500 cfu ml^{-1} or especially 1000 cfu ml^{-1}, there is a definite thermoduric bacterial problem in the raw milk.

The HR-3 test is a color-reaction test designed to estimate the number of Gram-positive bacteria in raw milk. Many Gram-positive bacteria can survive pasteurization. With the increased emphasis on the extended shelf life (ESL) of fluid milk, it becomes critical to know if certain raw milk samples have high numbers of Gram-positive bacteria that can cause shelf life problems when the milk is in the later stages of storage or distribution.

The fat, protein, and total solids content of the raw milk must be accurately measured. This importance is not just from a payment (to the farmer) standpoint, but – in the case of cheese plants – a major factor in calculating the cheese yield. Rapid and accurate measurements are readily available with the laboratory instruments being used. Regular maintenance and calibration make this critical area controllable.

While coliforms are not a legal standard in raw milk, in most states in the United States, they do give valuable information as to the sanitary methods by which the milk was taken from the cow, stored at the farm, and transported to the processing plant. Coliforms are 'indicator' organisms, in that their presence in the milk indicates that conditions are suitable for the presence of enteric pathogens. The legal standard for coliforms in pasteurized milk in the United States is <10 cfu ml^{-1}. A suggested standard in raw milk might be <200 cfu ml^{-1}.

The molds *Aspergillus flavus* and *Aspergillus parasiticus* produce a group of highly toxic secondary metabolites that are referred to as aflatoxins. These molds may grow on wet feed or grains and produce the aflatoxins, which could be consumed by the cow and thereby gain entrance into the milk. Raw milk should be routinely screened for the presence of aflatoxins owing to the inherent danger to humans consuming the milk.

Microbiology of Raw Milk

The microorganisms found in raw milk may come from several sources: the milk as it is excreted from the teat, the environment (water, soil, etc.), milking equipment, milk lines, farm bulk tank, the tank (transfer) truck, lines and pumps at the processing plant, and the raw storage silo tanks at the processing plant. Cows with mastitis can shed high numbers of bacteria and somatic cells. An elevated somatic cell count (SCC) can adversely impact milk quality.

According to the International Commission on Microbiological Specifications for Food (ICMSF; 2000), "The normal flora of the udder includes streptococci, staphylococci, and micrococci (normally >50%) followed by *Corynebacterium* spp., *Escherichia coli*, and others."

The main types of aerobic mesophiles include micrococci, streptococci, and asporogenous Gram-positive rods, such as *Microbacterium*, *Corynebacterium*, and others; spore-formers, *Bacillus* spp.; Gram-negative rods, such as *Pseudomonas*, *Flavobacterium*, and others; and miscellaneous, such as yeasts and molds. In reflecting on the various microorganisms in raw milk, the ones with which we are most concerned are those bacteria that can survive the pasteurization process, that is, the thermodurics, and those bacteria that can grow, although slowly, at refrigeration temperatures, that is, the psychrotrophs.

Psychrotrophs that have been isolated from raw milk include the following genera: *Pseudomonas*, *Acinetobacter*, *Flavobacterium*, *Enterobacter*, *Alcaligenes*, *Achromobacter*, *Klebsiella*, *Aeromonas*, and *Bacillus*. Genera of thermoduric bacteria found in raw milk are *Microbacterium*, *Micrococcus*, *Alcaligenes*, *Bacillus* (spore-former), and *Clostridium* (spore-former). Several genera are both thermoduric and psychrotrophic. These bacteria are *Bacillus*, *Clostridium*, *Microbacterium*, *Micrococcus*, and *Corynebacterium*. In general, the psychrotrophs are Gram-negative bacteria, with the thermodurics tending to stain Gram-positive. The psychrotrophs can be very detrimental to milk quality, especially as related to heat-stable enzymes produced by many of these psychrotrophic bacteria. Many of the proteases produced by common psychrotrophs, such as *Pseudomonas*, are extremely heat-stable and can degrade the milk proteins especially upon prolonged storage of raw milk. Consequently, even though the bacteria may be killed upon pasteurization of the milk, these enzymes can easily survive and cause decreases in shelf life, quality, and yield (of cheese). Researchers have shown that protease from *Pseudomonas fluorescens* P26 retained 71% of its original activity after being heated at 71.4 °C for 60 min. When the enzyme was added to milk, both cottage cheese and Cheddar cheese were made. Significant proteolysis occurred in both products with a definite reduction in quality (especially flavor). It has been demonstrated that psychrotrophic development during milk storage adversely affects cheese yield and quality. Proteinase-producing Gram-negative psychrotrophic bacteria are often isolated from milk. The fact that psychrotrophs are present in raw milk, coupled with the facts that heat-stable enzymes may be produced and liberated in the milk by these psychrotrophs and these enzymes degrade the quality of milk and milk products, demands that raw milk be stored for no longer than necessary. The 72-h maximum time for a US dairy processor to hold milk prior to pasteurizing is justified and should not be violated. If anything, this time should be minimized. The two factors of temperature and time are constantly at work hurting milk quality. Unless the milk has been held at temperatures below 5 °C and comes into the processing plant at 5 °C or lower, its quality is in jeopardy. This is true since the generation times of typical psychrotrophs are only 9–18 h (obviously based on growth temperature). At any rate, the higher the level of psychrotrophs in the raw milk upon arrival at the processing plant, the higher the potential number of bacteria at the pasteurizer. Since high-temperature, short-time (HTST) pasteurization is a percentage kill, the higher the numbers in raw milk, the greater the numbers surviving.

The predominant contaminants of processed dairy products have their origins in the raw milk supply. While recognizing that there are many pathogens that could be linked to raw milk, some specific foodborne illnesses attributed to dairy products are caused by *Salmonella*, *Listeria monocytogenes*, and *Yersinia enterocolitica*. An important issue with *Listeria* and *Yersinia* is that they are both psychrotrophic pathogens. Major outbreaks have been caused by these bacteria, resulting in many illnesses and even deaths. Even though the milk is pasteurized before consumption, the potential for cross-contamination in the dairy processing plant stresses the importance of the raw milk being of high quality, to minimize these occurrences and the high numbers of pathogens. Some pathogens associated with raw milk are as follows:

Gram-Negative Pathogens:

Escherichia coli, Salmonella, Y. enterocolitica, Campylobacter jejuni, Aeromonas hydrophila (another psychrotrophic pathogen), and so on are Gram-negative pathogens.

Gram-Positive Pathogens:

Bacillus cereus, *Bacillus anthracis*, and *Clostridium perfringens* – spore-formers

Staphylococcus aureus, Streptococcus agalactiae, and Streptococcus pyogenes – cocci

Listeria monocytogenes, Mycobacterium tuberculosis, and so on – ‘other’

Rickettsia

Coxiella burnetii

Viruses

Enteroviruses, foot-and-mouth disease (FMD) virus, and so on

Fungi

Molds, such as *A. flavus*

Protozoa

Entamoeba histolytica, Giardia lamblia, and *Toxoplasma gondii*

While many of us have drunk raw milk, one cannot rule out the possibility that human pathogens could be present. The dairy industry compares very favorably with other segments of the total food industry regarding safety to the consumer; nevertheless, the industry must continue to be diligent in eliminating any known threat.

As a means of pinpointing the exact source of contamination of high-count milk from a specific form, an in-line sampling technique to measure the bacterial contamination of milk during milking has been studied. The in-line milk (ILM) sampler could be used in conjunction with appropriate culture media to compare bacterial contamination at the clawpiece (this would represent contamination from mastitic milk or milk at the teat surface), at the end of the milking pipeline, and in the final bulk tank. Improperly cleaned bulk tanks represent the major source of contamination, especially with regard to psychrotrophic bacteria. Studies indicate that the types and numbers of organisms introduced into the milk from milk handling equipment (including the bulk tank) depend largely on the efficiency of cleaning and sanitizing. When psychrotrophs are introduced into the milk, there is evidence that – generally within 2–3 days of the transfer of the milk from transport tankers – the microflora of the milk is dominated by psychrotrophs, whereas the thermoduric microflora does not increase and changes little in composition.

Researchers have found that storage at 4.0̣ 1 °C for 48̣ 2 h caused significant increases in the numbers of lipolytic and proteolytic bacteria ($p < 0.01$). The observed dominance of psychrotrophs after 2 days’ storage indicated their significance in bacterial counts in raw milk, when bulk storage at refrigeration temperature was practiced.

Realizing that psychrotrophs are in almost all raw milk, one must also accept the fact that spore-forming bacteria are present. It was reported that *Bacillus* species account for 95% of the total spore-forming bacteria in milk (*Clostridium*, 5%). This indicated that in the United States, 43% of the *Bacillus* bacteria are *B. licheniformis* and 37% are *B. cereus* (in other countries, *B. cereus* may be predominant). As there is more and more demand for the ultra-heat treatment (UHT) of milk and for ESL products, the presence of spore-forming bacteria takes on added importance. In the future, incoming raw milk should also be tested for an estimation of the numbers of spore-forming bacteria and the numbers of psychrotrophic bacteria. This must be in addition to the DMC – a rough estimation of the total number of bacteria present.

Typical Flow Pattern at the Processing Plant

After milk is pumped from the truck to silo tanks at a processing plant, a recommended practice is to pump the milk through a cloth filter (sock filter) as a way of reducing sediments in the milk. The normal process for 'processing' the milk after refrigerated storage (silo tanks) is as follows:

1. Separation and clarification – The separation process produces three fractions: skim milk, cream, and sediment (separator or clarifier >slime=). Clarification removes suspended particulate matter and adhering microorganisms by centrifugation. In the United States, most fluid milk plants run milk through in-line separators, which do an efficient job of removing sludge. Most of these plants do not have clarifiers.
2. Pasteurization and homogenization – In the United States, most of the milk is pasteurized by the HTST method, with treatments ranging from 73 to 83 °C and with holding times typically ranging from 20 to 30 s.
3. Specific product treatment – This totally depends on the type of product being made, for example, fluid milk products versus cheese.
4. Packaging.
5. Finished product storage.
6. Distribution.

Future Considerations

There is a greater and greater tendency to process milk using membrane processing. This is already being done to some extent in the United States at the farm level. Either reverse osmosis or ultrafiltration is being used to concentrate the milk. There are probably two basic reasons for this:

1. to take advantage of the functionality of the individual milk components in further processing; and
2. to reduce the transportation costs by removing water. With the extremely long-distance shipping of raw milk in some milk distribution markets, any step to reduce these costs must be considered as an advantage.

The use of membrane processing designed specifically for concentrating or fractionating the milk – either at the farm or at the central plant – thus appears to be a logical step for the dairy industry. With that in mind, this places an even bigger need for high-quality raw milk.

One final consideration is spurred by recent terrorist attacks. These events have made the entire food industry reevaluate the way things are done. Bioterrorism has become a word with real meaning, even to the dairy industry. Specifically for raw milk, we need to consider each step to reduce or eliminate any possibility of contamination of our raw milk supply. Examples that must be considered include things like bulk tanks being locked when the dairy farmer is not present and the domes on the tank trucks being locked or sealed when the hauler or driver is not present. The entire process must be carefully scrutinized by all those involved, to ensure a safe milk supply.

The dairy industry is very special, as the entire world depends heavily on dairy products. It is a vital food for infants and children, as well as for adults. We must continually do everything we can to enhance and maintain high quality.

Introduction

Milk fat is composed largely of triacylglycerols (about 98% of the total fat), with minor contributions from phospholipids, cholesterol, free fatty acids, and mono- and diacylglycerols. There are also trace amounts of β-carotene, fat-soluble vitamins (A, D, E, and K), and flavoring compounds. Milk fat melts over a wide temperature range, from −35 to +38 °C, with a substantial proportion of the fat melting between 10 and 20 °C. These melting characteristics, which are due to the complex mixture of triacylglycerols in milk fat, can markedly affect the functional properties of dairy products. The desirable flavor of milk fat is one of its main attributes. The flavor profile is complex, with a large number of volatile compounds contributing to the overall aroma and taste. Two deteriorative reactions, namely oxidation and lipolysis, can occur in milk fat. These reactions produce off-flavors, which can destroy the pleasant, delicate flavor of milk fat.

A lipid can be broadly defined as any molecule of intermediate molecular weight that contains a substantial portion of aliphatic or aromatic hydrocarbon; included in this group are hydrocarbons, phospholipids, sterols, and triacylglycerols.

There is a tendency to use the terms ‘lipid’ and ‘fat’ more or less interchangeably, although a fat is considered to consist largely of triacylglycerols, with minor contributions from other lipid classes, whereas a mixture of lipids can have significant contributions from a number of different lipid classes.

The lipid (fat) fraction of milk is composed mainly of triacylglycerols, with minor contributions from diacylglycerols, monoacylglycerols, free (unesterified) fatty acids, phospholipids, and sterols. Trace amounts of fat-soluble vitamins, β-carotene, and fat-soluble flavoring compounds are also present (**Table 1**). These lipids exist in milk in the form of minute globules (average diameter 3–4 µm) surrounded by a membrane, which maintains the integrity of

Table 1 Main classes of lipids in milk

Lipid class	*Amount (wt%)*

the globule. Although the vast bulk of the lipids are in the core of the globule, some are found in the fat globule membrane, for example, the majority of the phospholipids and small amounts of triacylglycerols and sterols.

Classes of Lipids in Milk Fat

Triacylglycerols

Triacylglycerols are relatively simple molecules consisting of a glycerol backbone to which are esterified three fatty acid molecules (**Figure 1**). They are nonpolar molecules and hence are insoluble in water. Although not highly reactive, triacylglycerols can undergo hydrolytic and oxidative reactions at ambient temperature. They are by far the most important class of compounds in milk fat, from a quantitative viewpoint, accounting for about 98% of the total fat (**Table 1**). As a result, the triacylglycerols have a major influence on the properties of milk fat, such as density and melting profile.

There are many different types of triacylglycerols in milk fat, which vary considerably in molecular weight and degree of unsaturation. This complex mixture is a direct result of the large number and wide variety of constituent fatty acids, which vary in chain length from 4 to 18 carbons.

The distribution of fatty acids at the three positions of the triacylglycerol molecule (positions *sn*-1, *sn*-2, and *sn*-3) (**Figure 1**) is not random. This is because mechanisms involved in the biosynthesis of triacylglycerols in the mammary gland exert some selectivity over the placement of fatty acids. Indeed, one of the distinctive features of milk fat is the almost exclusive esterification of the short-chain fatty acids, butyric and caproic, at position *sn* 3. As a result of this highly specific distribution, the major triacylglycerols consist of two broad structural types: those containing various combinations of three long-chain fatty acids and those containing two long-chain fatty acids and a short-chain fatty acid.

Phospholipids

Phospholipids are a small but important lipid class in milk. They are present in the fat globule membrane (about 60% of the total) and in other membranous material of the skim milk phase (about 40% of the total). Their composition is shown in **Table 2**. The glycerophospholipids constitute about 75% of the total, while the sphingolipids account for most of the remainder.

Glycerophospholipids consist of a glycerol backbone to which are attached two fatty acids at positions *sn*-1 and *sn*-2 and a phosphate group at position *sn*-3. Different side chains are attached to the phosphate group. The major glycerophospholipids are phosphatidylcholine (**Figure 2**) and phosphatidylethanolamine. Two other glycerophospholipids, namely phosphatidylserine and phosphatidylinositol, are present in small amounts.

Table 2 Phospholipid composition of milk

Phospholipid	*Amount (wt%)*
Phosphatidylcholine	34.5
Phosphatidylethanolamine	31.8
Phosphatidylserine	3.1
Phosphatidylinositol	4.7
Lysophospholipids	0.8
Sphingomyelin	25.2
Cerebrosides	Trace
Gangliosides	Trace

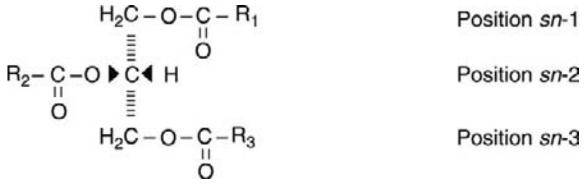

Figure 1 Triacylglycerol: Fischer projection diagram using the stereospecific numbering (*sn*-) convention.

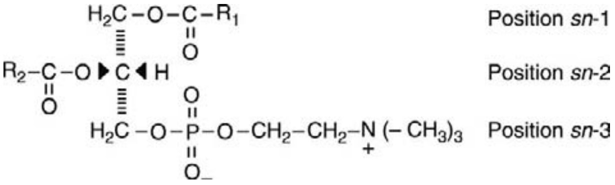

Figure 2 Phosphatidylcholine: Fischer projection diagram using the stereospecific numbering (*sn*-) convention.

The two charged groups in the glycerophospholipids give the molecules a polar part. The remaining part is nonpolar and hence they are amphiphilic and can accumulate at an oil–water interface. This explains their presence in membrane material.

The glycerophospholipids (phosphatidylethanolamine and phosphatidylcholine) have greater proportions of unsaturated fatty acids (47% $C_{18:1}$ and 13% $C_{18:2}$ in the case of phosphatidylethanolamine) than triacylglycerols (25% $C_{18:1}$ and 2% $C_{18:2}$) and hence they are more susceptible to oxidation. This has led to the postulation that fat oxidation in milk may begin with the glycerophospholipids in the fat globule membrane.

Sphingolipids contain a ceramide, which consists of a sphingosine base and a fatty acid. When a phosphorylcholine group is esterified at position 1 of the ceramide, sphingomyelin, which is the major sphingolipid in milk, is formed. Sphingomyelin also exhibits amphiphilic properties.

Trace amounts of glycosphingolipids (cerebrosides and gangliosides) are also present in milk. Cerebrosides consist of a ceramide linked to a sugar group, while the more complex gangliosides contain a ceramide, a number of sugar groups, and sialic acid. These molecules are important biological compounds.

Diacylglycerols, Monoacylglycerols, and Free Fatty Acids

Directly after milking, milk contains only small amounts of di- and monoacylglycerols and free fatty acids (**Table 1**). On storage, however, triacylglycerols in milk fat may be subjected to enzymatic hydrolysis by either milk lipase or bacterial lipases, which can significantly increase the quantities of these compounds. For example, free fatty acids can increase from 0.1% to greater than 1.0%. Such an increase normally leads to a rancid flavor in milk, which is caused by the lipases releasing short-chain fatty acids.

The small proportion of diacylglycerols present in fresh milk are largely *sn*-1,2 diacylglycerols. Since the *sn*-3 position is the last to be acylated during the biosynthesis of triacylglycerols, these diacylglycerols are probably intermediates in this process. They are unlikely to be the products of lipolysis because the lipases preferentially attack the *sn*-1 and *sn*-3 positions of the triacylglycerol molecule, thereby forming a mixture of *sn*-1,2 and *sn*-2,3 diacylglycerols.

The profile of free fatty acids in freshly drawn milk differs somewhat from the profile of the fatty acids esterified to the triacylglycerols (e.g., there appears to be very little free butyric acid), indicating that they also are unlikely to be the products of lipolysis.

Although diacylglycerols have a free hydroxyl group, their physical properties are broadly similar to those of triacylglycerols in that they are only slightly polar and show little surface activity. In contrast, monoacylglycerols can be considered relatively polar molecules. Those containing long-chain fatty acids are amphiphilic, and thus surface active, while those with a short-chain fatty acid are partially soluble in water. Free fatty acids in the undissociated state have properties broadly similar to monoacylglycerols; long-chain free fatty acids are surface active, while short-chain free fatty acids are partially soluble in water. However, at the pH of fresh milk (6.7), free fatty acids are predominantly in the dissociated form, which markedly increases their solubility in water.

Sterols

Although sterols are a minor component of milk fat (0.3%), they are the major part of the unsaponifiable material. Cholesterol is the principal sterol component, accounting for about 95% of the total sterols. Small amounts of other sterols, such as lanosterol and β-sitosterol, are also present. It should be noted that a small proportion of cholesterol exists in the esterified form and that these cholesterol esters are saponifiable.

The basic structure of sterols is a four-membered ring system, termed the cyclopentanophenanthrene ring. Various side chains are attached to this ring system to give different sterols (**Figure 3**). These compounds are very nonpolar but, interestingly, readily associate with phospholipids.

Cholesterol is an important biological compound that appears to play a role in controlling lipid and protein transitions and conformations in membranes. It is also a precursor for a number of hormones. Cholesterol has been implicated in a number of diseases that afflict humans, such as atherosclerosis, cholesterol gallstones, and certain inherited disorders.

An interesting aspect of cholesterol is that, in direct contrast to cows' milk fat and other animal fats, there are

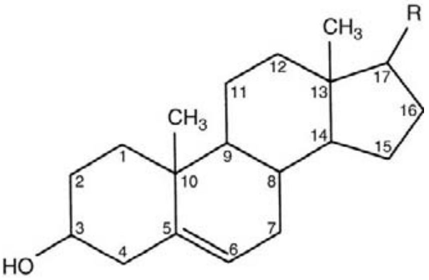

Figure 3 Basic structure of sterols: For cholesterol, $R = -\underset{\substack{| \\ CH_3}}{CH} - CH_2 - CH_2 - CH_2 - CH(-CH_3)_2$.

only trace amounts of cholesterol in vegetable oils. This has important commercial implications, since food products containing only vegetable oils can be labeled as cholesterol-free.

Carotenoids

The principal color component in milk fat is β-carotene, accounting for about 95% of the total carotenoids present. It is a highly unsaturated hydrocarbon, containing a series of conjugated double bonds which absorb at about 450 nm. The concentration of β-carotene in milk fat varies considerably, with levels ranging from 2.5 to 8.5 $\mu g\,g^{-1}$ fat.

The β-carotene content is dependent upon diet and breed of cow. Jersey cows produce milk fat with a higher color than Friesian cows, while cows fed a diet of hay and concentrate tend to produce milk fat with a lower color than pasture-fed cows. This latter finding is not surprising as carotenoid pigments are abundant in green plant material.

Fat-Soluble Vitamins

A significant nutritional aspect of fats and oils is that the vitamins A, D, E, and K are dissolved in the liquid fat or oil phase. Milk fat is considered to be a major source of vitamin A but is a poor source of vitamins D, E, and K.

Vitamin A is considered to exist in two forms: preformed vitamin A (retinol and retinyl esters) and provitamin A (β-carotene). The vitamin A activity of these different compounds varies considerably, ranging from 100% for all-*trans* retinol, 75% for 13-*cis*-retinol, and just 17% for β-carotene. Levels of all-*trans*-retinol in milk fat range from 8 to 14 $\mu g\,g^{-1}$ fat with typical values of about 10 $\mu g\,g^{-1}$ fat. The value for 13-*cis*-retinol is much lower, about 1 $\mu g\,g^{-1}$ fat. The total vitamin A activity can be obtained by summation of the concentrations and activities of all-*trans*-retinol, 13-*cis*-retinol, and β-carotene. This gives an average value for milk fat of approximately 11.5 retinol equivalent per gram of fat or 40 IU g^{-1} fat.

Vitamin D activity is derived from a number of compounds, namely 25-hydroxycholecalciferol (25-hydroxy vitamin D_3), cholecalciferol (vitamin D_3), and ergocalciferol (vitamin D_2), with 25-hydroxycholecalciferol accounting for about 65% of the total activity. The level of vitamin D in milk fat is very low, about 0.01 0.02 $\mu g\,g^{-1}$ fat, which equates to 0.4–0.8 IU g^{-1} fat. There is evidence to suggest that vitamin D levels in cows are affected by the amount of sunlight to which cows are exposed, with greater levels present in summer than during winter months.

A series of compounds termed tocopherols and tocotrienols contribute to vitamin E activity. In milk fat, α-tocopherol accounts for virtually all the vitamin E and is present at a concentration of about 35 $\mu g\,g^{-1}$ fat (the range is 25–50 $\mu g\,g^{-1}$ fat). This is equivalent to approximately 0.05 IU g^{-1} fat. The amount of tocopherol can vary during the dairying season: lush spring pastures result in greater levels than mature summer pastures. It is generally accepted that tocopherols act as antioxidants by reacting with free radicals, thereby protecting unsaturated fatty acids and β-carotene from oxidation.

Vitamin K, which is required for the synthesis of blood-clotting compounds, is present in milk at low concentrations. The amount of phylloquinone (vitamin K_1) is about 0.1–0.2 $\mu g\,g^{-1}$ fat.

Flavor Compounds

The desirable flavor of milk fat is one of its main attributes. The flavor is very complex, with a large number of compounds contributing to the overall aroma and taste. Approximately 120 volatile compounds have been identified in milk fat and, although many are present at concentrations below their individual threshold values, some may interact in a synergistic manner and contribute to the overall flavor profile. Variations in the concentration of individual volatile compounds can also affect the perceived flavor; for example, some aldehydes are thought to contribute buttery flavors at very low concentrations but are the source of oxidized flavors at higher levels.

The main classes of volatile compounds that are considered to contribute to the overall flavor of butter are fatty acids, aldehydes, lactones, and methyl ketones.

Short- and medium-chain fatty acids (C_4–C_{12}), which are present in fresh milk fat at concentrations at or below their flavor threshold values, are thought to act synergistically to provide key flavor components in milk fat. Most of these fatty acids tend to impart unpleasant flavors at higher concentrations and hence lipolysis of triacylglycerols, which releases fatty acids, will inevitably lead to undesirable, rancid flavors.

Aliphatic aldehydes in milk fat originate from the oxidation of unsaturated fatty acids in triacylglycerols. Thus, the concentrations of these aldehydes in high-quality, fresh milk fat are extremely low. However, these aldehydes have very low flavor threshold values, in the range of 0.05–1.0 $\mu g\,g^{-1}$ fat for saturated aliphatic aldehydes and as low as 0.001 $\mu g\,g^{-1}$ fat for unsaturated aldehydes. Thus, slight oxidation of milk fat can increase the concentrations of aldehydes to levels where they can contribute sensorily. Generally, aldehydes are the source of 'oxidized' flavors, but there is evidence that certain aldehydes, at very low concentrations (i.e., at or below their flavor threshold levels), may contribute buttery and deep-fried flavors.

In milk fat, small amounts of 4- and 5-hydroxy acids are esterified in triacylglycerols. These acids act as precursors for a series of four-carbon ring (γ) and five-carbon ring (δ) lactones, which are important flavor components. A proportion of these hydroxy acids rearrange spontaneously at ambient temperature to give a concentration of lactones in the range of 10–30 μg g^{-1} fat in fresh milk fat. Research suggests that three lactones, namely δC_8 lactone, δC_{10} lactone, and γC_{12} lactone, which have flavor threshold values between 1 and 3 μg g^{-1} fat, are present at sufficient concentrations to impart sweet, fruity flavors to fresh milk fat. When milk fat is heated, all hydroxy acids are converted to lactones to give a total concentration of 80–150 μg g^{-1}. Virtually all the lactones exceed their flavor threshold values and contribute to the rich flavor associated with baked goods containing butter.

Milk fat also contains trace amounts of β-keto acids esterified to triacylglycerols. At high temperatures, they are hydrolyzed and decarboxylated to form methyl ketones, which, at low concentrations, are thought to contribute to cooked butter flavors.

In addition to the four classes of compounds discussed above, there are several other volatiles that can contribute to the aroma and taste of milk fat. They include diacetyl (a diketone), phenol and cresol (aromatic alcohols), and skatole.

Physical Properties of Milk Fat

Crystallization and Melting Characteristics

The crystallization and melting characteristics of the triacylglycerols of milk fat have a marked effect on the functional properties of dairy products, particularly the consistency of butter. These characteristics are influenced to a large degree by the fatty acid composition of the triacylglycerols and to a lesser extent by the physical processes of polymorphism and mixed crystal formation.

Triacylglycerols can crystallize in different polymorphic forms, termed α, β', and β. The main difference between the forms is in the packing of the hydrocarbon chains of the triacylglycerols in crystal lattices, which leads to differences in melting points and can also influence the size of crystals.

Triacylglycerols can also form mixed (compound) crystals in which two or more different molecular species of triacylglycerols pack together in the same crystal lattice. The formation of mixed crystals affects the melting characteristics of milk fat: the greater the degree of mixed crystal formation, the more crystalline (solid) fat formed at a given temperature.

These two physical processes are dependent on the thermal history of the fat. The rate at which liquid milk fat is cooled and the temperature to which it is cooled will affect both polymorphism and mixed crystal formation. For example, rapid cooling causes a greater amount of mixed crystal formation than slow cooling.

The fatty acid composition of triacylglycerols influences melting characteristics. Triacylglycerols containing three long-chain saturated fatty acids have closely packed crystal structures and relatively high melting points. The replacement of a long-chain saturated fatty acid in a triacylglycerol molecule with either a *cis*-unsaturated fatty acid or a medium- or short-chain fatty acid gives triacylglycerols that have less closely packed crystal structures and lower melting points. In other words, the melting point of triacylglycerols decreases as the degree of unsaturation of triacylglycerols increases and as their molecular weight decreases.

Milk fat contains a large number of different types of triacylglycerols, which vary considerably in molecular weight and degree of unsaturation. It therefore follows that milk fat will melt over a wide temperature range. This is evident from the melting profile of milk fat, which shows a range from −35 to +38 °C (**Figure 4**). There is a main melting peak at about 17 °C, a smaller broad peak centered at about 7 °C, and a plateau from 22 to 36 °C. It can be seen that a substantial proportion of milk fat melts between 10 and 20 °C. (The area under the differential melting curve is approximately equal to the amount of melted fat.)

As noted earlier, a number of factors, such as the rate of cooling of milk fat and its fatty acid composition, can affect the melting profile. In New Zealand, spring milk fat has greater amounts of triacylglycerols containing unsaturated fatty acids and short-chain fatty acids than summer milk fat. As a consequence, spring milk fat has greater amounts of lower melting triacylglycerols, as can be seen in the melting profiles of the two milk fats (**Figure 4**).

Specific and Latent Heats

The specific heat of completely liquid milk fat (above +40 °C) is about 2.1 kJ kg^{-1} K^{-1}, while completely solid

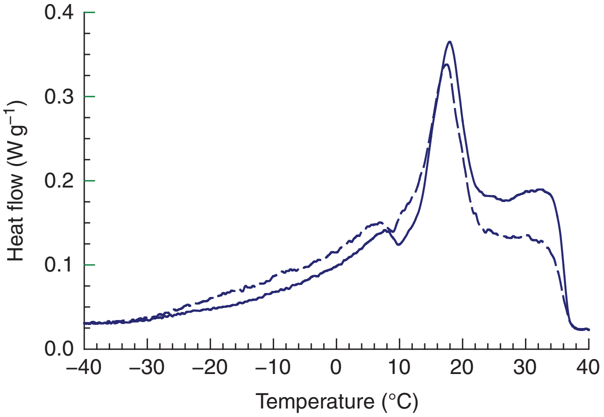

Figure 4 Melting profiles of spring (- - -) and summer (—) milk fat, determined by differential scanning calorimetry. From AKH MacGibbon (personal communication): Seasonal survey of New Zealand milk fat.

milk fat (below $-40\,^\circ\mathrm{C}$) has a value of approximately $1.7\,\mathrm{kJ\,kg^{-1}\,K^{-1}}$. These values vary slightly with temperature, increasing slightly as the temperature is increased.

The latent heat of fusion (solid-to-liquid transition) for milk fat has an average value of about $80\,\mathrm{kJ\,kg^{-1}}$. The latent heat value for milk fat varies according to temperature because higher melting triacylglycerols have greater latent heats of fusion than lower melting triacylglycerols. The values are also dependent on the polymorphic form of the crystals.

Measurements of specific heat made at temperatures within the melting range of milk fat, which will include both sensible and latent heats, are termed apparent specific heats. These values show marked variations through the temperature range because of the different amounts of melting that occur at different temperatures (**Figure 4**). For example, at 0 and 15 °C, milk fat has apparent specific heat values of 3.34 and $5.43\,\mathrm{kJ\,kg^{-1}\,K^{-1}}$, respectively, indicating that a greater amount of melting occurs at 15 °C than at 0 °C.

Other Physical Properties

The refractive index of a fat or oil is influenced by its fatty acid composition; the refractive index increases as the degree of unsaturation increases and as the length of the hydrocarbon chains increases. As a consequence, the refractive index of milk fat varies during the dairying season; in northern European countries, values for refractive index tend to be higher in summer, when there are more unsaturated fatty acids in milk fat, than in winter. Typically, values lie within the range of 1.453 0–1.455 0.

The density of liquid milk fat is $890\,\mathrm{kg\,m^{-3}}$ at 60 °C, with a coefficient of expansion of $0.78\,\mathrm{kg\,m^{-3}\,K^{-1}}$ for the temperature range 40–60 °C. This value is fairly typical for fats and oils; for example, lard has a density of $895\,\mathrm{kg\,m^{-3}}$ at 40 °C, while the value for olive oil is $915\,\mathrm{kg\,m^{-3}}$ at 15 °C.

In a similar manner to other fats and oils, the viscosity of milk fat decreases slightly as the temperature increases, with a viscosity of 31, 22, and 17 cP at 40, 50, and 60 °C, respectively.

Milk fat is a poor conductor of both heat and electricity. It has a thermal conductivity of about $1.7 \times 10^{-4}\,\mathrm{kJ\,m^{-1}\,s^{-1}\,K^{-1}}$ at room temperature and an electrical conductivity of about $10\,\Omega\,\mathrm{cm^{-1}}$.

Deteriorative Reactions of Milk Fat

Triacylglycerols are considered not to be highly reactive. Nevertheless, these compounds can undergo two deteriorative reactions, namely oxidation and lipolysis, which can result in unpleasant flavors in milk fat.

Lipolysis is the hydrolysis of the ester linkage between a fatty acid and the glycerol backbone of a triacylglycerol. The reaction is catalyzed by lipolytic enzymes (lipases), either the indigenous milk lipase or lipases produced by psychrotrophic bacteria. While the indigenous milk lipase is deactivated by pasteurization, bacterial lipases are often heat stable and retain at least some activity after pasteurization. The short- and medium-chain fatty acids released by lipolysis will contribute to undesirable off-flavors once their concentrations increase to levels slightly above their flavor threshold values.

Oxidation is the reaction between oxygen and the unsaturated fatty acids in either triacylglycerols or phospholipids. The reaction, which involves the formation of free radicals, initially produces hydroperoxides. These compounds subsequently break down to form highly flavored carbonyl compounds, such as saturated and unsaturated aldehydes. Even at very low concentrations (i.e., $<1.0\,\mu\mathrm{g\,g^{-1}}$ fat), these aldehydes impart metallic and tallowy flavors to milk fat. The reaction is catalyzed by light and by transition metals such as copper. Antioxidants, such as α-tocopherol, can inhibit the reaction by reacting with the free radicals formed during the reaction. The removal of virtually all air from products containing milk fat will also slow down the reaction.

Introduction

Bovine milk fat contains a large number of fatty acids. However, many of these are found in only extremely small quantities and only 15 or 16 fatty acids are present at concentrations equal to or greater than 1%. The main saturated fatty acids, which account for 62–70% of the total fatty acids, are straight-chain molecules, which vary in length from 4 to 18 carbon atoms. The principal unsaturated fatty acid is oleic acid (about 20% of the total). The acid composition of milk fat is affected by factors such as the diet of the cow and the stage of lactation. As a consequence, the proportions of the fatty acids vary throughout the dairying season, in some instances quite markedly.

The fatty acid composition of bovine milk fat is to a large extent the fatty acid composition of its constituent triacylglycerols because the triacylglycerols make up approximately 98% of milk fat. Small quantities of fatty acids are also esterified to mono- and di-cylglycerols and to phospholipids and there is about 0.1% unesterified or free fatty acids in milk fat. The fatty acids of triacylglycerols account for a large proportion of the molecular weight of the triacylglycerol molecule (85–95%). Furthermore, unsaturated fatty acids contain double bonds, which are reactive sites. Thus, it is not surprising that the fatty acids have a marked effect on the chemical and physical properties of triacylglycerols, and consequently on the properties of milk fat. Fatty acids influence the melting characteristics of milk fat and the rate at which fat oxidation occurs.

Bovine milk fat is regarded as one of the most complex naturally occurring fats and oils because of the large number and wide variety of fatty acids it contains. Using a combination of chromatographic and spectroscopic techniques, research workers have identified approximately 400 fatty acids in milk fat. The common and systematic names of the 16 'major' fatty acids, which constitute about 95% of the fatty acids, are presented in **Table 1**, together with their proportions in milk fat. It should be noted that these proportions are typical values for cows grazed on pasture; the fatty acid composition is affected by factors such as diet and stage of lactation and consequently the proportions of some fatty acids can show marked variations.

There is an empirical classification of these major fatty acids on the basis of the length of the hydrocarbon chain, namely short-chain (C_4–C_6), medium-chain (C_8–C_{14}), and long-chain (C_{16}–C_{18}) fatty acids. The magnitude of the difference in chain length between butyric acid (4:0) and stearic acid (18:0) can be seen in **Figure 1**.

Origins of the Fatty Acids

The fatty acids of bovine milk fat arise from two sources: from *de novo* synthesis in the mammary gland and from the plasma lipids. The types of fatty acids from these two sources are very different (**Figure 2**). The fatty acids synthesized *de novo* are of short- to medium-chain length, from 4:0 to 14:0, and also some 16:0. In contrast, the C_{18} fatty acids and some 16:0 arise from the plasma lipids.

The *de novo* synthesis of fatty acids in the mammary gland utilizes mainly acetate, which is provided by the fermentation of dietary carbohydrates in the rumen. The mechanism essentially involves the carboxylation of acetyl-CoA to malonyl-CoA, which is then used in a stepwise, chain elongation process. This leads to a series of short- and medium-chain length fatty acids that differ by two CH_2 groups, for example, 4:0, 6:0, and 8:0.

The blood lipids come mainly from the diet although they can also include fatty acids released from adipose tissue. This suggests that dietary lipids will have a large effect on the fatty acid composition of milk fat. Indeed, the inclusion of 16:0, 18:0, and 18:1 in the cow's diet increases the proportions of these fatty acids in milk fat. However, changes in the amounts of polyunsaturated fatty acids in the diet of the cow normally affect the levels of only 18:0 and 18:1 in milk fat. This is because polyunsaturated fatty acids are extensively hydrogenated in the rumen by microorganisms. An additional reaction, namely the desaturation of 18:0 to 18:1 by a desaturase in the mammary gland, can also influence the levels of 18:0 and 18:1. The net result is that changes to the diet of the cow normally affect the proportions of 16:0, 18:0, and 18:1 in milk fat but have very little effect on 18:2 or 18:3.

Although the sources of fatty acids in the milk of other species are essentially the same as those for the cow (i.e., *de novo* synthesis and blood lipids), there are some important differences between the fatty acid

Table 1 Major fatty acids of bovine milk fat

			Typical composition[a]	
Fatty acid	*Common name*	*Systematic name*	*wt%*	*Mol%*
4:0	Butyric	Butanoic	3.7	9.6
6:0	Caproic	Hexanoic	2.4	4.7
8:0	Caprylic	Octanoic	1.5	2.3
10:0	Capric	Decanoic	3.2	4.2
12:0	Laurie	Dodecanoic	3.6	4.1
14:0	Myristic	Tetradecanoic	11.1	11.0
14:1	Myristoleic	*cis*-9-Tetradecenoic	0.9	0.9
15:0	—	Pentadecanoic	1.2	1.1
16:0	Palmitic	Hexadecanoic	28.3	25.3
16:1	Palmitoleic	*cis*-9-Hexadecenoic	1.6	1.5
18:0	Stearic	Octadecanoic	11.8	9.5
18:1	Oleic	*cis*-9-Octadecenoic	18.8	15.4
18:1	Vaccenic	*trans*-11-Octadecenoic	4.2	3.4
18:2	Linoleic	*cis*, *cis*-9,12-Octadecadienoic	1.4	1.1
18:2c	Linoleic (conjugated)	*cis*, *trans*-9,11-Octadecadienoic	1.1	0.9
18:3	Linolenic (alpha)	*cis*, *cis*, *cis*-9,12,15-Octadecatrienoic	0.9	0.8

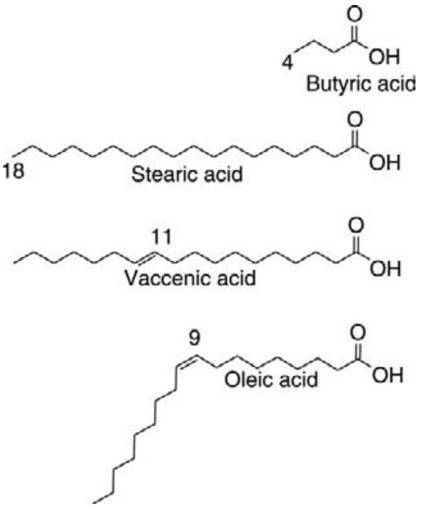

Figure 1 Skeletal structures of some fatty acids

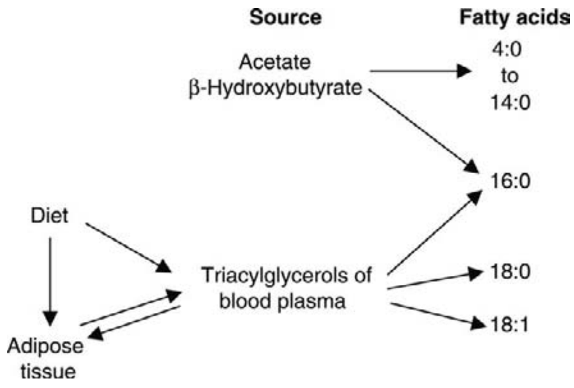

Figure 2 Sources of the fatty acids of milk fat

composition of the milk fat of ruminants and nonruminants. *De novo* synthesis in the mammary gland produces relatively high concentrations of short-chain fatty acids (i.e., 4:0 and 6:0) in ruminants but only small amounts in non-ruminants. Unsaturated dietary lipids are not subjected to biohydrogenation reactions in non-ruminants. Hence, long-chain fatty acids in the milk of non-ruminants are a direct reflection of dietary lipids and consequently the milk fat of non-ruminants often contains appreciable amounts of polyunsaturated fatty acids.

Different Types of Fatty Acids

Saturated Fatty Acids

The major saturated fatty acids are molecules with unbranched hydrocarbon chains containing an even number of carbon atoms; the length of the molecule varies from 4 to 18 carbons. These saturated fatty acids account for approximately 65–70% (w/w) of the total fatty acids. The most important saturated fatty acid from a quantitative viewpoint is 16:0, which accounts for about 25–30% of the total, while two other fatty acids, 14:0 and 18:0, constitute 10–12% each (**Table 1**).

The amounts of the short-chain fatty acids, 4:0 and 6:0, are reasonably high when their proportions are expressed as molar percentages (approximately 9.5 and 4.5%, respectively). Interestingly, these short-chain fatty acids are esterified almost exclusively at position *sn-3* on the glycerol molecule, which means that approximately 42% (3 × 14%) of bovine milk fat triacylglycerols contain a short-chain fatty acid in combination with two other fatty acids.

Two reasons have been postulated to explain the relatively high proportions of short- and medium-chain fatty acids in bovine milk fat. First, these fatty acids are absorbed rapidly as free fatty acids from the intestine into the portal bloodstream and are quickly metabolized in the liver. Hence, they can make a rapid and direct contribution to the energy metabolism of the newborn calf. Second, short-chain fatty acids and, to a lesser extent, medium-chain fatty acids lower the melting point of triacylglycerols and thus their presence helps to keep milk fat liquid at physiological temperatures.

Unsaturated Fatty Acids

The principal monounsaturated fatty acid is oleic acid (*cis*-9-octadecenoic acid), which constitutes 17–25% (w/w) of the total fatty acids. There are also relatively small but significant contributions from other monounsaturated fatty acids, namely 14:1 (about 1.0%), 16:1 (about 1.5%), and vaccenic acid (*trans*-11-octadecenoic acid) (**Table 1**). Vaccenic acid is formed as a result of biohydrogenation in the rumen and its proportion in milk fat is markedly affected by the cow's diet; a mixture of hay and concentrate gives a low level (about 1.5%), whereas pasture results in a high value (about 5.0%).

Because of the biohydrogenation reactions in the rumen, there are only low concentrations of the polyunsaturated fatty acids, linoleic and linolenic, in milk fat. The level of linoleic acid is of interest because it is an essential fatty acid. Despite the low level of linolenic acid (about 1.0–1.5%), the newborn calf appears to be able to build up reserves of this acid. However, there have been concerns that an infant formula made solely from whole milk may not contain sufficient 18:2 to meet the requirements of the human infant. Thus, commercial infant formulae are supplemented with vegetable oils to raise the level of 18:2.

An interesting polyunsaturated fatty acid that is present in relatively small amounts (about 1%) is conjugated linoleic acid. While this acid can exist as a range of isomers of linoleic acid, which possess conjugated double bonds, the principal isomer in milk fat is *cis*-9, *trans*-11-octadecadienoic acid. This fatty acid has been the subject of extensive recent research as it appears to impart a wide range of health benefits. Trials involving animals have shown that conjugated linoleic acid may provide some protection against the development of mammary tumors and may enhance immune functions. In addition, the acid may be able to regulate energy metabolism so that body fat is reduced.

An important difference between *cis* and *trans* unsaturated fatty acids is that the *cis* configuration of the double bond puts a significant 'kink' in the hydrocarbon chain, whereas the *trans* configuration causes only a slight distortion (**Figure 1**). This has a major impact on the packing density of triacylglycerols in crystal lattices. Triacylglycerols containing *cis* unsaturated fatty acids have a lower packing density than triacylglycerols containing either *trans* unsaturated or saturated fatty acids and as a result have lower melting points. Thus, the relative levels of *cis* and *trans* unsaturated fatty acids can exert a considerable influence on the melting characteristics of milk fat.

Minor Fatty Acids

As stated previously, there are a very large number of minor fatty acids, many of which are present at extremely low concentrations (less than 0.02%). As a consequence, most of these fatty acids are of little practical importance.

Among the minor saturated fatty acids are odd-numbered and branched-chain fatty acids. Examples of odd-numbered fatty acids are 13:0 (0.1%) and 17:0 (0.5%). The monomethyl branched-chain fatty acids are quite significant, accounting for about 2.5% of the total fatty acids. Examples are the C_{15} branched-chain acids 13-methyl tetradecanoic acid (the *iso* configuration) and 12-methyl tetradecanoic acid (the *anteiso* configuration), which together make up about 1% of milk fat.

There are only trace amounts of minor unsaturated fatty acids. Among these are approximately 150 positional isomers of monoenoic and dienoic fatty acids; there are, for example, 11 *trans* isomers of 18:1. Trace amounts of hydroxy and keto acids are also found in milk fat.

Variations in Fatty Acid Composition

The fatty acid composition of bovine milk fat is affected by factors such as diet and stage of lactation and as a result the proportions of some fatty acids can vary considerably. For example, values for 16:0 can range from 21 to 36%, while 18:1 can vary from 19 to 31%.

Normal Feeding Regimes

Variations in the normal diet fed to cows throughout the dairying season can lead to relatively small but distinct variations in the proportions of fatty acids in milk fat.

In northern Europe, where the general pattern of dairy husbandry is to house cows in winter, it has been shown that the change from winter feed of hay and concentrate to a diet of fresh grass in spring and summer causes an increase in the proportions of 18:0 and 18:1 and a decrease in the proportions of 14:0 and 16:0.

In contrast, in Australia and New Zealand, where cows are generally grazed on pasture throughout the year, milk fat from cows grazed on mature summer grass contains lower proportions of 18:0 and 18:1 and a greater proportion of 16:0 than milk fat from cows fed lush spring grass.

These observations that 16:0, 18:0, and 18:1 vary as a result of dietary changes are not unexpected when the source of these fatty acids is taken into account.

Lactation

The proportions of fatty acids also show relatively small but distinct variations as lactation progresses. The proportion of 4:0 declines gradually throughout lactation, the fatty acids 6:0 to 14:0 increase from relatively low levels at the beginning of lactation to a maximum 8–12 weeks after calving and decline slowly thereafter, 16:0 shows a slight increase as lactation progresses, and 18:0 and 18:1 decline for the first 4–6 weeks and then increase slightly toward the end of lactation.

Seasonal Effects

The seasonal variation in the fatty acid composition of milk fat is affected by a number of factors such as composition of the diet, plane of nutrition, and stage of lactation. Despite this complexity, studies in different countries have shown a seasonal pattern of fatty acid variation that consistently reoccurs.

In northern Europe, the seasonal variation in fatty acid composition shows the following general trends: 4:0 to 12:0 show no consistent seasonal pattern; 14:0 and 16:0 are lower in summer than in winter; and 18:0 and 18:1 are higher in summer than in winter. The fatty acid composition of samples of winter and summer milk fat from Belgium, which are presented in **Table 2**, shows these trends. The variations in 14:0, 16:0, 18:0, and 18:1 appear to be caused by the change in feeding conditions described above, while the lack of a consistent seasonal pattern in the fatty acids 4:0 to 12:0 may be attributed to the practice of not confining calving to spring.

In New Zealand, where cows calve in spring and are fed on pasture, the seasonal variation shows the following pattern: 4:0 shows a gradual decline throughout the season; 6:0 to 14:0 show a slight increase from low values in early spring to a maximum during early summer and a decline thereafter throughout the rest of the season; 16:0 increases significantly from relatively low values in spring to high values during summer and then decreases in autumn; and both 18:0 and 18:1 show a seasonal trend that is the reverse of that exhibited by 16:0 (**Table 2**). The changes in the proportions of fatty acids of chain length C_4–C_{14} follow the pattern resulting from lactational effects, whereas the seasonal trends in 16:0, 18:0, and 18:1 appear to be the result of dietary effects.

[b]From A. K. H. MacGibbon (personal communication), Fonterra Research Centre seasonal survey.

The differences, described above, in the seasonal variations in the fatty acid composition of milk fats in different countries appear to be a consequence of different dairy husbandry practices.

Fat Supplementation of Diets

For many years, fats and oils have been included in the concentrate mixtures for dairy cows largely because of their high calorific value and their potential to alter the fatty acid composition of milk fat. One of the limitations of this type of supplementation is that a relatively high level of dietary fats/oils impairs digestion and metabolism in the rumen, which in certain instances can lead to a reduction in the overall yield of fat in milk.

Fat supplementation of the cow's diet generally produces two broad trends in the fatty acid composition of milk fat. First, there is a decrease in the amounts of fatty acids that are produced by *de novo* synthesis in the mammary gland (i.e., C_4–C_{16}), which occurs as a consequence of the suppression of rumen metabolism. In one such trial, using soybeans as the fat supplement, there was an overall decrease in these fatty acids from 389 to 313 g day^{-1} (**Table 3**). Second, there is an increase in the amounts of 18:0 and 18:1, but no appreciable increase in the levels of polyunsaturated fatty acids (**Table 3**). The increased levels of 18:0 and 18:1 could be simply from an

Calculated from Banks W, Clapperton JL, and Girdler AK (1990) Effect of dietary unsaturated fatty acids in various forms on the *de novo* synthesis of fatty acids in the bovine mammary gland. *Journal of Dairy Research* 57: 179–185.

increased dietary intake of these acids or indirectly through biohydrogenation in the rumen. Furthermore, increased 18:1 could result from desaturation of 18:0 to 18:1. The absence of any appreciable increase in polyunsaturated fatty acids is a result of ruminal biohydrogenation reactions.

The rumen metabolism and the biohydrogenation reactions can be prevented by treating fat supplements with a mixture of protein and formaldehyde, which largely prevents the release of fat into the rumen. The inclusion of these 'protected fat' supplements in the diet invariably leads to an increase in the yield of milk fat and, if polyunsaturated oils are used as the supplement, a marked increase in polyunsatured fatty acids (**Table 3**).

Milk fat from cows fed a 'protected fat' supplement, which contained a 'high level' of 18:2, has been made into butter. This butter was found to be considerably softer than ordinary butter and was spreadable at domestic refrigerator temperatures. This would indicate that the feeding of 'protected fat' supplements has considerable potential as a technique for dramatically altering the fatty acid composition of milk fat and the rheological properties of butter. However, current trends have seen the blending of milk fat with vegetable oils to achieve changes in the properties.

Introduction

Nutritional quality is an important consideration when making food choices; milk is an excellent source of many essential nutrients and supplies the body with energy, high-quality protein, and a variety of the required vitamins and minerals. In addition, consumers are increasingly aware of the link between diet, health, and disease prevention and a recent National Academy of Sciences report identified research on bioactive food components as a key focus area to enhance human health through nutrition. Traditionally, specific components in fruits and vegetables have been featured for their health-promoting properties; however, recent investigations have established that bioactive components are also present in animal-derived foods, including milk and dairy products. One such bioactive component that has created widespread interest is conjugated linoleic acid (CLA), a group of naturally occurring 18-carbon fatty acids.

CLAs are a mixture of positional and geometric isomers of linoleic acid, and some CLA isomers have been shown to offer benefits in relation to health maintenance and disease prevention. In nature, polyunsaturated fatty acids (PUFAs) typically contain *cis* double bonds that are separated by an interceding carbon (methylene group). Linoleic acid (*cis*-9, *cis*-12 18:2) found in many plant oils is an example (**Figure 1**). In contrast, the double bonds in CLA are adjacent with no interceding methylene group. Furthermore, the geometric orientation of the conjugated double bonds may be *cis–trans, cis–cis, trans–cis*, or *trans–trans* (e.g., the CLA isomer *cis*-9, *trans*-11 18:2) (**Figure 1**). The first recognition of milk fatty acids with a conjugated double bond system dates back to the 1930s when English scientists reported an increase in the spectrophotometric absorption at 230 nm for butter made from summer milk as compared to butter from winter milk. Then, in 1977, PW Parodi identified the *cis*-9, *trans*-11 CLA isomer in milk fat. Subsequent research established that milk fat contains trace amounts of many CLA isomers, but *cis*-9, *trans*-11 CLA is the predominant isomer in milk fat, representing about 75–90% of the total CLA. This is also true for the CLA in ruminant meat fat, and thus, the *cis*-9, *trans*-11 CLA isomer has appropriately been given the common name 'rumenic acid' (RA). Of special interest to nutritionists, ruminant-derived foods are the major dietary source of CLA in human diets, with dairy products and ruminant meats representing over 90% of human intake (**Figure 2**). In the following sections we will discuss the origin of CLA in ruminants and results from biomedical studies demonstrating the potential role of RA as a natural functional food component with anticarcinogenic and antiatherogenic effects.

Origin of RA and Other CLA Isomers

The presence of CLA in dairy products is related to rumen fermentation of dietary PUFAs. The rumen is essentially a large fermentation vat and in dairy cows it has a 50 l volume and contains about 10^{11} bacteria and 10^{6} protozoa per milliliter. Rumen biohydrogenation occurs because dietary PUFAs are toxic to some bacteria. Thus, only a few bacterial species carry out biohydrogenation and most of them have the ability to carry out only some of the steps involved in biohydrogenation.

When dietary lipids enter the rumen, the first major transformation they undergo is hydrolysis of their ester linkages, resulting in free fatty acids. Hydrolysis is catalyzed by enzymes produced by rumen microflora and it results in the liberation of over 85% of esterified fatty acids. Hydrolysis is a prerequisite for the second major rumen transformation, biohydrogenation of unsaturated fatty acids. The predominant dietary PUFAs that are biohydrogenated in the rumen are linoleic (*cis*-9, *cis*-12 18:2) and linolenic (*cis*-9, *cis*-12, *cis*-15 18:3) acids. The first step in the biohydrogenation of linoleic acid is an isomerization of the *cis*-12 double bond to form RA, and this is followed by hydrogenation of the *cis*-9 double bond, producing vaccenic acid (VA; *trans*-11 18:1). The structures of these intermediates are shown in **Figure 1** and the pathway of their formation is presented in **Figure 3**. In contrast to linoleic acid, RA is not an intermediate in the biohydrogenation of linolenic acid; however, VA is an intermediate formed from both dietary fatty acids. The final step in biohydrogenation is a second hydrogenation to produce stearic acid, a saturated fatty acid (**Figure 3**).

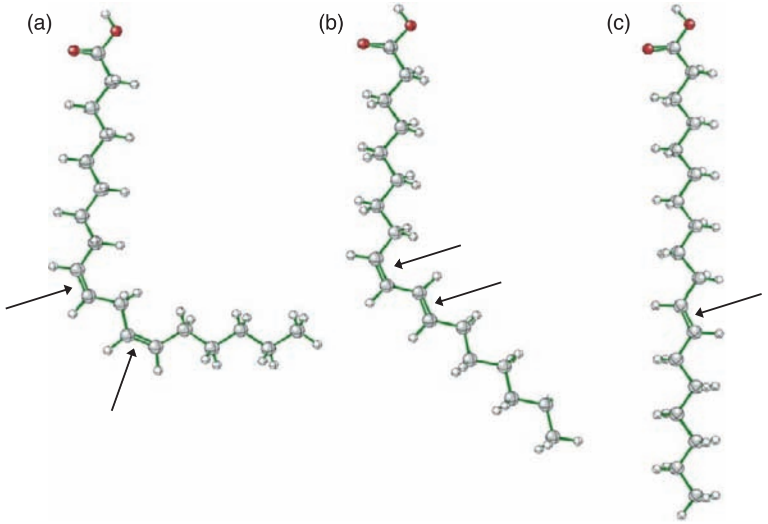

Figure 1 Comparison of the structures of (a) linoleic acid (*cis*-9, *cis*-12 18:2), (b) *cis*-9, *trans*-11 conjugated linoleic acid, and (c) vaccenic acid (*trans*-11 18:1). Double bonds are denoted by arrows. Structures are adapted from Bauman DE and Lock AL (2006) Conjugated linoleic acid: Biosynthesis and nutritional significance. In: Fox PF and McSweeney PLH (eds.) *Advanced Dairy Chemistry, Vol. 2: Lipids*, 3rd edn., pp. 93–136. New York: Springer.

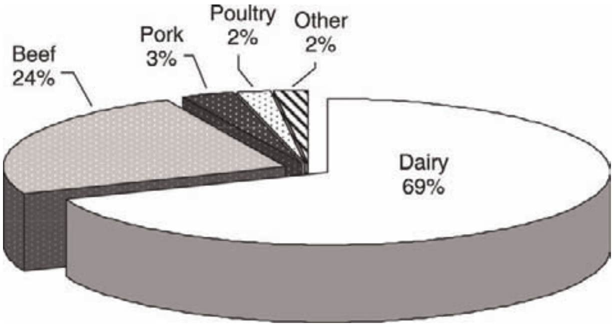

Figure 2 Distribution of conjugated linoleic acid (CLA) sources in the US diet. Based on data from Ritzenthaler KL, McGuire MK, Falen R, Shultz TD, Dasgupta N, and McGuire MA (2001) Estimation of conjugated linoleic acid intake by written dietary assessment methodologies underestimates actual intake evaluated by food duplicate methodology. *Journal of Nutrition* 131: 1548–1554.

Biohydrogenation in the rumen is relatively complete and this represents the basis for ruminant fat having a relatively high content of saturated fatty acids. Nevertheless, small amounts of intermediates can pass from the rumen before they are completely biohydrogenated, and it was assumed initially that this was the primary source of the RA in milk fat. However, *in vitro* rumen fermentation studies revealed that RA was only a transitory product during biohydrogenation, and VA was the major intermediate that accumulated in the rumen. Based on this and additional lines of evidence, it was hypothesized that RA in ruminant fat could originate from endogenous synthesis whereby VA that escaped complete biohydrogenation would be absorbed in the small intestine and converted to RA in the cow's tissues by the enzyme Δ^9-desaturase (**Figure 3**). This was indeed the case, and investigations using several different approaches across a range of diets and management systems have clearly established that endogenous synthesis is the predominant source of RA in ruminant fat.

Endogenous synthesis of RA via Δ^9-desaturase in the mammary gland (milk fat during lactation) and adipose tissue (body fat during growth) is the reason why RA is the predominant CLA isomer in ruminant-derived foods. Synthesis of RA relies heavily on the activity of this enzyme as well as the tissue uptake of its precursor, VA. Studies have consistently shown an enzymatic equilibration between VA and RA, usually in about a 3:1 ratio, providing evidence of the importance of VA in RA synthesis. The second most prevalent CLA isomer in ruminant fat is most often *trans*-7, *cis*-9 CLA (~5–10% of total CLA) and it also arises from endogenous synthesis involving Δ^9-desaturase with the precursor being *trans*-7 18:1 produced in the rumen. There are, however, no analogous desaturases for endogenous synthesis of other CLA isomers. Hence, other individual CLA isomers are produced in the rumen via minor pathways of biohydrogenation, but they are present in milk and meat fat only in trace amounts, with each of these CLA isomers typically representing <1% of total CLA isomers.

Altering the CLA Content of Dairy Products

Diet is the most significant factor affecting the CLA content of milk fat. CLA concentration can be enhanced several-fold by using combinations of feed ingredients that affect the dietary supply of PUFAs and/or affect

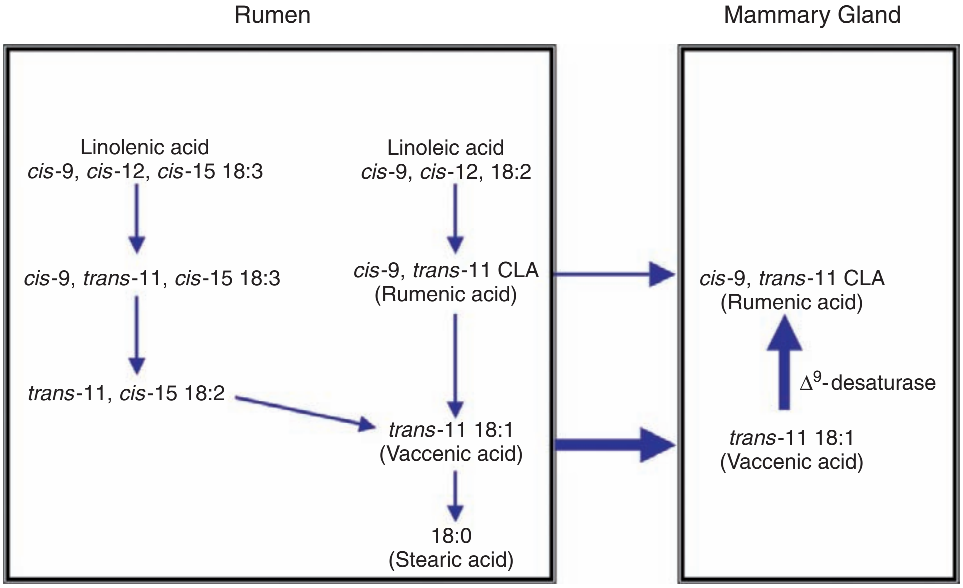

Figure 3 Pathways for ruminal biohydrogenation of linoleic and linolenic acid and the endogenous synthesis of *cis*-9, *trans*-11 conjugated linoleic acid (CLA) in the dairy cow. Adapted from Bauman DE, Lock AL, Corl BA, Ip C, Salter, AM, and Parodi PW (2006) Milk fatty acids and human health: Potential role of conjugated linoleic acid and *trans* fatty acids. In: Sejrsen K, Hvelplund T, and Nielsen MO (eds.) *Ruminant Physiology: Digestion, Metabolism and Impact of Nutrition on Gene Expression, Immunology and Stress*, pp. 523–555. Wageningen, The Netherlands: Wageningen Academic Publishers.

the rumen environment to alter the rate and completeness of biohydrogenation. For example, consumption of lush pasture increases the content of RA in milk fat about two-fold, consistent with this forage source providing linolenic acid for rumen biohydrogenation and the formation of VA. Likewise, feeding total mixed diets that provide seed oils that are high in linoleic acid content (e.g., corn, soybeans, distillers grains) can increase the content of RA in milk fat three-fold or more. Feeding fish oil supplements is also effective in increasing the RA concentration in milk fat, but these have a different mechanism; in this case, the long-chain omega-3 fatty acids in fish oil act to inhibit the final step in rumen biohydrogenation of linoleic and linolenic acids and, as a consequence, the rumen outflow of VA is increased, which can then be used for endogenous synthesis of RA (**Figure 3**).

The RA content of milk fat is also influenced by physiological factors, although to a lesser extent than dietary effects. Individual animal variation is the physiological factor that has the greatest effect, and typically there is about three-fold range among cows. Furthermore, the hierarchy in RA content of milk fat among cows is maintained even when cows are switched between diets that are designed to result in very different average concentrations of RA in milk fat. This genetic variation relates to animal differences in rumen fermentation and/or tissue activity of Δ^9-desaturase, and it provides an opportunity for genetic selection of cows that naturally produce high levels of RA in milk fat. Some studies have also reported that the RA content of milk fat differs according to dairy breed, stage of lactation, and parity, but these effects are minor compared to the effects of individual animal variation and diet.

Functional Food Implications

'Functional foods' is a collective term for any food or food component that provides additional health benefits beyond the traditional nutrient content of the food product. To be considered a functional food, the bioactive component(s) must be consumed as a natural food component rather than taken as a dietary supplement, and the emphasis is on health maintenance and the prevention of chronic diseases as opposed to the pharmaceutical treatment of disease. RA is a bioactive fatty acid, and the functional food role of milk and meat products from ruminant animals relates to these foods being the major source of CLA in human diets and the fact that RA is the predominant CLA isomer in ruminant fat.

The biological effects of CLA were first recognized in the 1980s when M Pariza and colleagues (University of Wisconsin, USA) discovered that partially purified beef extracts could inhibit tumor growth in mice; the anticarcinogenic factors were identified as conjugated 18:2 fatty acids and they coined the term CLA. Subsequent investigations expanded the use of biomedical models, and additional health-related effects were identified for CLA, including anti-obesity, anti-diabetogenic, and anti-atherogenic effects. Although the initial research used mixed isomers of CLA, more recent studies with pure RA and *trans*-10, *cis*-12 CLA, a minor CLA isomer in milk fat, have shown potent bioactivity in biological models, indicating clear differences in biological effects. From a functional food perspective, RA was shown to have anti-carcinogenic and anti-atherogenic effects, while *trans*-10, *cis*-12 CLA has antiobesity and anti-diabetogenic effects as well as anti-carcinogenic effects; however, *trans*-10, *cis*-12 CLA has little potential as a functional food component because only trace quantities of this CLA isomer are naturally present in foods.

There are biomedical models for most types of cancer and many of them have been used to investigate the role of CLA. They have included cell lines, tumor transplant models, and models of *in situ* organ carcinogenesis; in virtually all cases, CLA has been shown to be a potent inhibitor of chemically induced carcinogenesis. In summarizing the overall effects, a report by the National Academy of Sciences on *Carcinogens and Anticarcinogens in Foods* concluded, "conjugated linoleic acid (CLA) is the only fatty acid shown to unequivocally inhibit carcinogenesis in experimental animals".

The anti-carcinogenic effect of RA is particularly impressive in studies of mammary cancer, and a landmark study demonstrated that RA was able to mitigate chemically induced mammary carcinogenesis when provided as either a synthetic supplement or a natural component of the diet, in this case an RA-enriched butter (**Table 1**). A striking observation was that rats fed the RA-enriched butter also had higher levels of RA in their mammary tissue and this was a direct result of the conversion of VA to RA in the tissues via Δ^9-desaturase. As mentioned previously, VA and RA are present roughly in a 3:1 ratio in dairy products, and in humans approximately 20% of the dietary intake of VA is converted to RA. Thus, VA is also an anti-carcinogenic component of dairy products due to its conversion to RA.

Investigations of the anti-atherogenic effects of CLA have also used animal models. When fed an appropriate diet, rabbits, hamsters, and mice develop atherosclerotic lesions in the aorta that exhibit similarities to the early lesions seen in the arteries of humans. Several studies have shown that RA is effective in reducing the development of atherogenic lesions in these animal models, although there are some inconsistencies, especially in studies that supplement with mixed isomers of CLA and those that use lipoprotein-related biomarkers as end points. Furthermore, a recent human clinical investigation reported that an RA supplement produced changes in plasma lipids that are indicative of a reduced risk in cardiovascular disease (CVD).

Studies of the functional food implications have examined the effects of an RA-enriched butter on biomarkers of CVD in the cholesterol-fed Golden Syrian hamster. This animal model is often used in biomedical studies on CVD because its lipoprotein metabolism and low rates endogenous cholesterol synthesis are similar to those humans. The results indicated that hamsters consuming RA-enriched butter had a more favorable plasma lipoprotein profile than hamsters consuming a typical western fat diet, including a reduction in plasma total cholesterol and low-density lipoprotein (LDL)-cholesterol, as well as reductions in the total cholesterol:high-density lipoprotein (HDL)-cholesterol and LDL:HDL ratios (**Figure 4**). The total cholesterol:HDL-cholesterol ratio is considered a particularly effective biomarker for the risk of CVD. While data are limited, several studies provide support that some of the cardioprotective effects of RA-enriched

dairy products reported in animal models will extend to humans.

Consumer acceptability and processing considerations are also important aspects in evaluating the functional food potential of 'CLA-enriched' products. Studies have found no differences in consumer acceptability and shelf life between regular and CLA-enriched dairy products. In addition, the processing of milk has little or no effect on CLA and the end product content is essentially the same as the RA content of the original milk fat. However, it is important to remember that since RA is a fatty acid, the amount in foods will vary according to the product's total fat content. Therefore, dairy products like cheese, ice cream, butter, and whole milk will provide most CLA to the human diet. Current dietary recommendations are to maintain an appropriate fat intake and a healthy balance of saturated and unsaturated fats. By consuming dairy products with an enhanced content of RA and VA, higher levels of these beneficial fatty acids can be obtained while contributing to this balance and not increasing the intake of saturated fat.

Finally, extending the results from biomedical models to implications for RA as a functional food component in humans is challenging and problematic. First, many chronic diseases such as cancer and CVD have long latency periods and lack consensus biomarkers; measuring the potential of a functional food component thus proves difficult and costly in extended studies on humans. Second, the RA and VA content of dairy products is highly variable even when expressed on a fat basis, and there are difficulties in the analysis of these fatty acids in foods; thus, it is problematic to achieve an accurate estimate of intake of RA over the long latency period of these diseases. Overall, the results from biomedical studies with animal models continue to provide exciting evidence of the beneficial health effects of RA, but the functional food role of RA in health maintenance and the prevention of chronic diseases in humans remains to be clearly established.

Triacylglycerols

M W Taylor, Massey University, Palmerston North, New Zealand

Introduction

Bovine milk fat consists of a complex mixture of triacylglycerols, which vary considerably in molecular weight and degree of unsaturation. Despite the complexity, the major triacylglycerols can be broadly categorized into two structural types, those containing combinations of long-chain fatty acids and those containing two long-chain fatty acids and a short-chain fatty acid esterified at position *sn*-3. The latter type is found in significant quantities only in ruminant milk fats. The melting properties of milk fat are determined largely by the fatty acid composition of its constituent triacylglycerols.

The most important class of compounds in bovine milk fat, from a quantitative viewpoint, are by far triacylglycerols, accounting for 98% of the total fat. Triacylglycerols are relatively simple, nonpolar molecules, consisting of a glycerol backbone to which are esterified three fatty acid molecules (**Figure 1**). Although triacylglycerols are not highly reactive, they do undergo two important chemical reactions, namely hydrolysis and oxidation, which cause deterioration in the quality of food (*see* **Milk Lipids**: Lipolysis and Hydrolytic Rancidity; Lipid Oxidation).

The complex nature of triacylglycerols of bovine milk fat is a direct result of the large number and wide variety of fatty acids that make up the triacylglycerols. Although the distribution of the fatty acids on the triacylglycerol molecules is not entirely random, the number of distinct triacylglycerols arising from the combination of a large number of fatty acids is in the order of several hundred. For example, if only the 14 acids that are present at concentrations above 1% are considered and if the position on the triacylglycerol molecule is ignored, then there are a possible 560 compositionally different triacylglycerols (this figure is derived from the equation $N=(n(n+1)\times(n+2)/6)$, where N is the number of triacylglycerols and n is the number of fatty acids). Because of this complexity, the determination of individual triacylglycerols is a very difficult task.

The general composition of milk triacylglycerols, determined by capillary gas chromatography, is presented in **Table 1**. The triacylglycerols show a wide range of molecular weight (from carbon number 28 to 56), which arises from the large difference in the chain length of the constituent fatty acids (from C4 to C18). Interestingly, the range of values for the different carbon numbers is considerable, indicating that there is significant variation in triacylglycerol composition throughout the dairying season.

It should be noted that there are a number of individual triacylglycerols having the same carbon number; for example, C50 could possibly include the triacylglycerols 16:0, 16:0, 18:0; 14:0, 18:0, 18:0; 16:0, 16:0, 18:1; and 14:0, 18:0, 18:1.

Structure of Triacylglycerols

An initial examination of the glycerol molecule may suggest that positions *sn*-1 and *sn*-3 are equivalent (**Figure 2**). However, further examination of configurations A and B shows that when the three-dimensional arrangement of the bonds involving the central carbon is taken into account, the two configurations cannot be superimposed. Thus the carbon atom at position sn-1, in relation to the other groups attached to the central carbon, is different from the carbon atom at position sn-3.

Triacylglycerols are synthesized in the mammary gland by enzymatic reactions that normally involve multi-point attachment, and consequently the spatial arrangement of neighboring groups is critical. This means that it is possible for enzymes to distinguish between positions *sn*-1 and *sn*-3 and the enzymic mechanisms involved in the biosynthesis of triacylglycerols exert some selectivity over the placement of fatty acids at the different positions.

Stereospecific analytical procedures have been developed that have permitted the determination of the positional distribution of fatty acids on the triacylglycerols. Results obtained by several workers have shown that there is a general pattern of stereospecific distribution of fatty acids in the triacylglycerols of bovine milk fat (**Table 2**). For cows fed a normal diet, the fatty acids 4:0 and 6:0 are esterified almost entirely at position *sn*-3. In contrast, 12:0 and 14:0 are esterified preferentially at position *sn*-2 while 16:0 is incorporated preferentially at positions *sn*-1 and *sn*-2. 18:0 is esterified preferentially at position *sn*-1 and 18:1 shows a preference for positions *sn*-1 and *sn*-3. This overall pattern of fatty acid distribution does not change significantly either throughout the dairying season or between countries. This indicates that

in normal milk fats, in which fatty acids vary to some extent as a result of dietary and lactational effects, the overall pattern of positional specificity of fatty acids is relatively constant.

When a cow is placed on a restricted diet, there is a decrease in the fatty acids that are synthesized de novo in the mammary gland (4:0 to 16:0) and an increase in the fatty acids 18:0 and 18:1 as a result of the mobilization of body reserves. The net effect is a marked increase in the proportion of 18:1 at position *sn*-3 from 17.1 to 47.6%, which is accompanied by reductions in the proportions of 4:0 to 16:0 at this position (**Table 2**). Despite these marked changes caused by the restricted diet, the overall pattern of stereospecific distribution of fatty acids is altered only slightly.

Composition of Triacylglycerols

Although milk fat contains a very complex mixture of triacylglycerols, it is possible to fractionate these triacylglycerols into different classes according to their molecular weight and degree of unsaturation using a combination of chromatographic methods. This approach has enabled a detailed analysis of the different classes of triacylglycerols in milk fat.

Milk fats from different countries have been separated in this manner and the proportions of the different fractions are given in **Table 3**. The proportion of saturated triacylglycerols ranges from 33 to 39% and is high relative to other fats and oils. For example, many vegetable oils contain only very small amounts of saturated triacylglycerols, and even palm oil, which contains about 40% 16:0, has only 8–10% saturated triacylglycerols. A further feature of bovine milk fat is the high proportion of low-molecular-weight triacylglycerols (31–44%). These triacylglycerols largely consist of two long-chain fatty acids in combination with a short-chain fatty acid and are found in significant quantities only in ruminant milk fats.

The proportions of corresponding classes (i.e., similar molecular weight and the same degree of unsaturation) in the three milk fats are broadly similar, with saturated and monoene triacylglycerols being the dominant classes. One interesting exception is the lower amount of high-molecular-weight saturated triacylglycerols reported in Canadian milk fat.

Stereospecific analyses of the different triacylglycerol classes have shown that the general pattern of positional distribution of fatty acids of chain length C4–C16 in these classes is similar to that in normal milk fat. However, the pattern of distribution of 18:0 and 18:1 varies according to the molecular weight of the triacylglycerols; these fatty acids tend to be esterified preferentially at positions *sn*-1 and *sn*-3 in triacylglycerols of high molecular weight and concentrated at position *sn*-1 in triacylglycerols of medium and low molecular weight where 4:0 and 6:0 occupy much of the *sn*-3 position. A further interesting point is that the *sn*-3 position in unsaturated triacylglycerols of

[a]Saturated, monoene, diene, and triene triacylglycerols contain zero, one, two, and three carbon–carbon double bonds, respectively. Data from Hawke JC and Taylor MW (1995) Influence of nutritional factors on the yield, composition and physical properties of milk fat. In: Fox PF (ed.) *Advanced Dairy Chemistry, Vol. 2: Lipids*, 2nd edn., pp. 37–88. London: Chapman & Hall.

low molecular weight consists largely of short-chain fatty acids and 18:1. The *sn*-3 position is the last to be acylated during triacylglycerol biosynthesis and it has been postulated that the placement of these fatty acids at this position may well be to keep the fat liquid at physiological temperatures.

In recent times, the use of combinations of chromatographic techniques has been refined further to permit the separation and identification of many of the triacylglycerols in milk fat. Complex mixtures of triacylglycerols are subdivided into much simpler mixtures prior to the separation and identification of individual triacylglycerols.

In one study, milk fat was separated by normal-phase high-performance liquid chromatography and electrospray ionization mass spectrometry (HPLC-ESI-MS) of ammonium ion adducts to enable the identification of over 400 triacylglycerols species in 184 quantified peaks. This exhaustive study included the use of enzymatic *sn*-2 analysis, thin-layer chromatography, and solid-phase extraction (and gas chromatography analysis) to isolate a wide range of fractions for analysis by HPLC-ESI-MS. This allowed their proportion in milk fat, and in many cases the stereoisomeric positions, to be determined. The vast majority of these triacylglycerols were present at very low levels, that is, less than 0.2 mol%. However, a few were present at surprisingly high amounts: for example, in the order of increasing acyl carbon number from quantified peaks 16:0/14:0/4:0 + 18:0/12:0/4:0 (3.4%),16:0/16:0/4:0 + 18:0/12:0/6:0(5.2%), 18:1/16:0/4:0 (4.1%), 18:0/16:0/4:0 (2.9%), 18:1/14:0/16:0 + 16:0/16:1/16:0 (3.1%), 16:0/16:0/16:0 + 18:0/14:1/16:0 (2.4%), 18:1/16:0/18:1 + 18:2/18:0/16:0 (3.7%). These species account for approximately 25% of the milk fat sample analyzed.

These sophisticated separation techniques, in combination with stereospecific analyses, have enabled the major triacylglycerols and many of the minor triacylglycerols in milk fat to be determined. The major triacylglycerols are presented in a somewhat simplistic manner in **Figure 3**. The major high-molecular-weight triacylglycerols comprise combinations of four long-chain fatty acids (14:0, 16:0, 18:0, and 18:1), whereas the major triacylglycerols of medium and low molecular weight contain two of these four long-chain fatty acids and a short-chain fatty acid (either 4:0 or 6:0) esterified at position *sn*-3.

Although these painstaking studies have identified a large number of triacylglycerols in milk fat, the time-consuming nature of these investigations means that it is currently impractical to measure the level of individual triacylglycerols in milk fat on a routine basis.

Crystallization and Melting Behavior of Triacylglycerols

The crystallization and melting characteristics of triacylglycerols of milk fat have a marked effect on the functional properties of dairy products, particularly the consistency of butter. These characteristics are influenced to a large degree by the fatty acid composition of the triacylglycerols and to a lesser extent by the physical processes of polymorphism and mixed crystal formation (see **Milk Lipids:** Rheological Properties and Their Modification).

Triacylglycerols form crystals when they solidify. Generally, triacylglycerols crystallize in layered structures, with glycerol groups and methylene groups in one plane and the axes of the hydrocarbon chains straight and parallel to each other within a layer. The attractive forces acting between molecules are lateral van der Waals' interactions between hydrocarbon chains, van der Waals' interactions of methyl end groups, and polar interactions of ester groups. The melting points of triacylglycerols are determined largely by the packing density of the hydrocarbon chains in the crystal lattice; the greater the packing density, the closer the hydrocarbon chains and the greater the attractive van der Waals' forces, and hence the higher the melting point.

The fatty acid composition of triacylglycerols has a marked effect on their molecular arrangement in the crystal lattice, which in turn affects their packing density. Triacylglycerols consisting of three long, 'straight-chain', saturated fatty acids have a closely packed lattice structure and a high melting point. The replacement of a saturated fatty acid with a 'bent-chain' *cis*-unsaturated fatty acid has a large effect on the molecular arrangement of triacylglycerols in the lattice, which in turn reduces the packing density of hydrocarbon chains and hence lowers the melting point of *cis*-unsaturated triacylglycerols compared to saturated triacylglycerols. In a similar manner, the inclusion of short- and medium-chain fatty acids lowers the melting points of

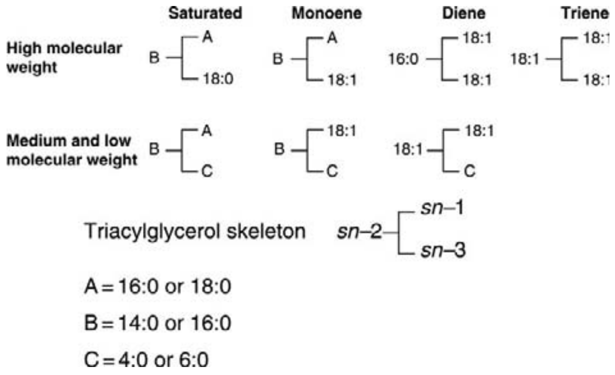

Figure 3 Major triacylglycerols of milk fat.

low-molecular-weight triacylglycerols compared to high-molecular-weight triacylglycerols.

As noted previously, milk fat triacylglycerols vary considerably in both molecular weight and degree of unsaturation and as a result they melt over a wide range of temperature. Indeed, milk fat has a very broad melting range, from −40 to +40 °C. A further consequence of the above trend in melting points is that the higher the proportion of low-molecular-weight and unsaturated triacylglycerols in milk fat, the greater the proportion of low-melting triglycerides and hence the softer the milk fat. New Zealand spring and summer milk fat shows this trend. Spring milk fat contains greater proportions of triacylglycerols containing 4:0 and 18:1 than summer milk fat, which leads to a higher proportion of low-melting triacylglycerols in the former. As a consequence, spring butter is softer than summer butter. Similarly, in Europe, summer butter contains greater proportions of triacylglycerols containing 18:1 than winter butter and consequently is softer.

Introduction

Although polar lipids are only a very small proportion of the lipids in milk, they play an important role due to their mixed hydrophilic and hydrophobic nature. Their dual hydrophilic and hydrophobic structure contributes largely to stabilization of the suspension of milk fat in the aqueous environment of liquid milk, thus allowing the relatively high concentrations of milk fat and protein to coexist in the same solution. This is accomplished by the integral part that polar lipids play in the milk fat globule membrane (MFGM) and, to a lesser extent, the general emulsification properties in the aqueous solution. The major structural features involved are the large nonpolar (hydrophobic) fatty acid chains and the polar (hydrophilic) charged head group residues of the phospholipids.

General Features

Lipids are usually classified on the basis of polarity as neutral lipids or polar lipids. However, an alternative classification often quoted is 'simple lipids' and 'complex lipids' (simple lipids yield only two types of primary products on hydrolysis, while complex lipids yield three or more primary products). Under this second definition, polar lipids are complex lipids while neutral lipids are simple lipids.

Polar lipids can contain a variety of polar groups that contribute to the charged nature of the molecule. Phospholipids contain a charged phosphate group (**Figure 1**), whereas glycolipids contain polar carbohydrate groups, which increase the solubility in water (**Figure 2**). While phospholipids are the major polar lipid components of milk, glycolipids also need to be considered as they have important biological functions, especially in nerve and brain function. In humans, they are involved in a number of disease states such as Tay–Sachs disease, which is characterized by an enzyme deficiency causing the accumulation of a specific ganglioside. Common abbreviations for polar lipids are given in **Table 1**.

Structure

The structures of polar lipids found in milk are shown in **Figures 1** and **2**. Phosphatidic acid has fatty acids at positions *sn*-1 and *sn*-2 and a phosphate group at the *sn*-3 position. The glycerol phospholipids (e.g., phosphatidylcholine and phosphatidylethanolamine) are based on phosphatidic acid with a moiety attached to the phosphate at the *sn*-3 position. Plasmalogens (not shown in the figures) have a similar structure to phosphatidylcholine and phosphatidylethanolamine but with an ether linkage rather than an ester linkage at the *sn*-1 position. Lysophospholipids have only one fatty acid in the glycerophospholipid. These are the products of phospholipases, enzymes that can degrade phospholipids. The sphingophospholipid, sphingomyelin, consists of a ceramide (a fatty acid linked to a sphingosyl base through an amide linkage) and a phosphorylcholine group. Sphingomyelin is usually included as a phospholipid.

The ionic properties of phospholipids are important in their function as emulsifiers. **Table 2** shows the typical ionization constants of glycerophospholipids, illustrating the charge state of the various phospholipids. At the normal pH of milk (pH 6.7), the properties can range from a zwitterion, with no net charge (phosphatidylcholine, phosphatidylethanolamine), to an acid with a net negative charge (phosphatidylserine, phosphatidylinositol).

Glycoceramides (glycosphingolipids) have one or more hexose sugar units attached at the 1-position of the ceramide (**Figure 2**). Gangliosides are complex ceramide polyhexosides, which contain one or more sialic acid groups (*N*-acetylneuraminic acid (NANA)). The specific names of the gangliosides identify their structure (the letter G followed by M, D, T, or Q designates the mono-, di-, tri-, or quatrasialic acid group and the number indicates the carbohydrate sequence that is attached to the ceramide (5−*n*, where *n* is the number of neutral sugar residues)). For example, GM3 is a ganglioside with one NANA unit and two neutral sugar residues (**Figure 2**).

A number of gangliosides have been isolated from bovine milk (GM3, GM2, GM1, GD3, GD2, GD1). The major gangliosides are GD3 (50%) and GM3 (20%) (**Figure 2**).

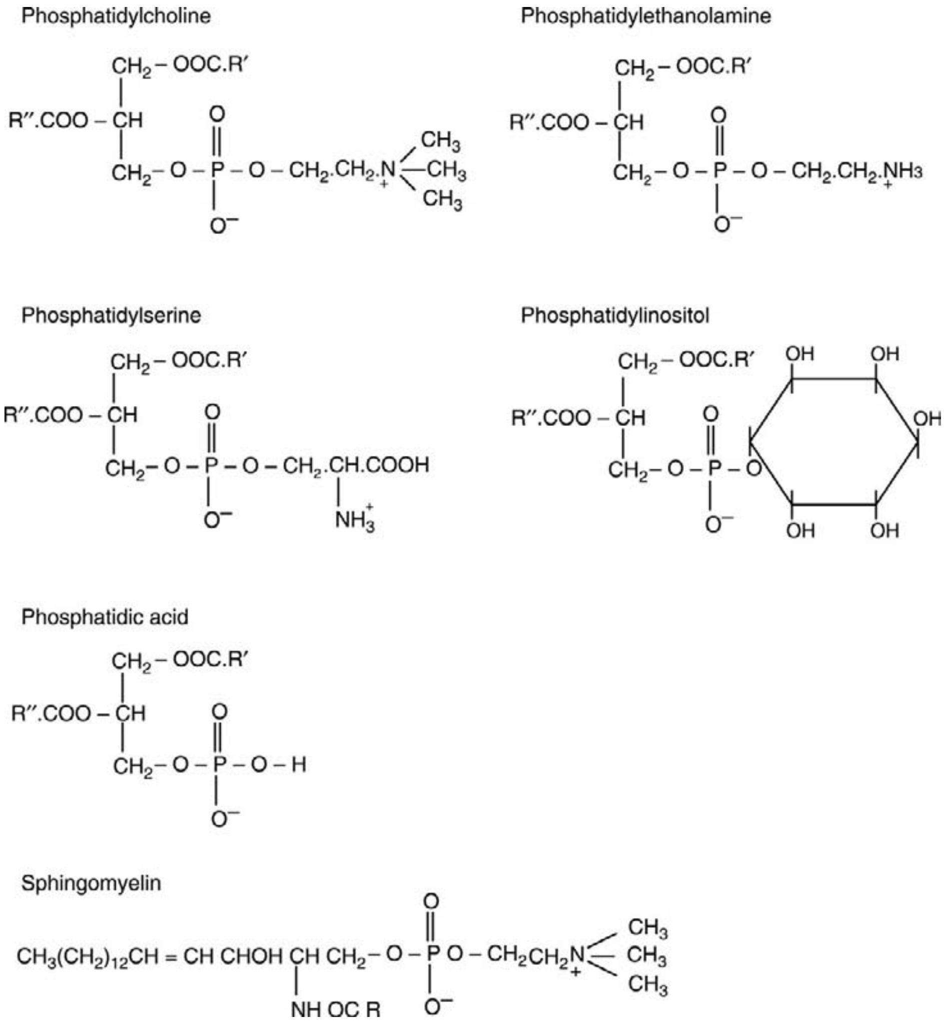

Figure 1 Phospholipid structures. R′ and R″ are fatty acids at *sn*-1 and *sn*-2 positions, respectively.

Source

The MFGM that surrounds the milk fat droplets is derived from the apical plasma membrane of secretory cells in the lactating mammary gland. The MFGM is composed of phospholipids and glycolipids as well as protein, glycoprotein, enzymes, triacylglycerols, and minor components. Estimates of the proportion of phospholipids in the MFGM vary from 15 to 30%.

About 60–65% of the phospholipids in milk are associated with the MFGM. The remaining 35–40% are found in the aqueous phase associated with protein/membrane fragment material in solution rather than still attached to the MFGM.

Polar lipids constitute about 0.5–1% of total milk lipids. This percentage of phospholipids does vary a little with the stage of lactation. Phospholipid levels in milk tend to decline during lactation, although they can increase near the end. While there is a small change in the percentage of phospholipids, the ratio of major phospholipids remains relatively constant, suggesting a constant ratio in the MFGM.

Table 3 shows the percentage of polar lipids in bovine milk. Phosphatidylcholine, phosphatidylethanolamine, and sphingomyelin are the major components and they contribute equally to the total polar lipid content. Phosphatidylserine and phosphatidylinositol are present at lower levels and there are only trace (but important) amounts of ceramides and gangliosides.

As the milk is processed, the phospholipids are partitioned differently from the neutral lipids (**Table 4**). When the whole milk is separated, the phospholipids tightly associated with the MFGM go into the cream with the neutral lipids, while those associated with the protein/membrane fragments in the aqueous phase are retained in the skim milk. Hence, the phospholipids-to-total fat ratio is greater in whole milk than in cream. Furthermore, during buttermaking, a greater proportion of the phospholipids than the

neutral lipids from the cream are retained in the buttermilk, leading to a high ratio of phospholipids to total fat.

Chemical Properties

The positional distribution of fatty acids in the major phospholipids of bovine milk (phosphatidylcholine, phosphatidylethanolamine, and sphingomyelin) is shown in **Table 5**. Unlike triacylglycerols, phospholipids do not have short-chain fatty acids ($C_{14:0}$ being the shortest chain fatty acid that is significant). In glycerophospholipids, the unsaturated fatty acids, especially the polyunsaturated fatty acids, tend to be preferentially esterified at the *sn*-2 position, while the saturated fatty acids are at the *sn*-1 position. There is a range of degree of unsaturation among the specific phospholipids. Phosphatidylethanolamine has a high content of unsaturated fatty acids, especially linoleic acid and even linolenic acid, far higher than that found in the milk fat triacylglycerols. The unsaturated fatty acids are found predominantly at the *sn*-2 position, while the $C_{18:1}$ is fairly evenly distributed and the $C_{18:0}$ and $C_{16:0}$ are at the *sn*-1 position. On the other hand, phosphatidylcholine is more saturated than phosphatidylethanolamine, and the distribution of saturated and unsaturated fatty acids is less distinct between the *sn*-1 and *sn*-2 positions, although the $C_{18:0}$ and the polyunsaturated fatty acids still show the preference described above.

Sphingomyelin has a different structure (**Figure 1**). The major fatty acid moiety is either $C_{16:0}$ or a longer-chain fatty acid ($C_{22:0}$ to $C_{24:0}$), producing an almost completely saturated fatty acid composition. However, the major sphingoid base is sphingosine ($C_{18:1}$), which introduces unsaturation into the molecule.

Analysis

Milk phospholipids can be extracted with slightly polar solvents such as methanol, ethanol, or chloroform.

Phosphate	1.0	1.7	2.6	2.5	3.0
Phosphate (2)					8.0
Carboxylic			5.5		
Ammonium		11.2	11.5		
pH range of neutral charge	3–12	4–9	4		
Type	Zwitterion	Zwitterion	Weakly acidic	Acidic	Acidic

Values determined in 0.1 mol l^{-1} NaCl. Values will be altered for higher ionic strength or in emulsions and membranes.

Table 3 Polar lipid composition of bovine milk

Polar lipid	*Percentage of total polar lipids*[a]
Phosphatidylcholine	34.5
Phosphatidylethanolamine	31.8
Phosphatidylserine	3.1
Phosphatidylinositol	4.7
Sphingomyelin	25.2
Plasmalogens	3.0
Ceramides	Trace
Gangliosides	Trace

[a] Polar lipids account for 0.5–1% of total lipids in milk.
From Patten and Jensen (1976).

Acetone is usually a poor solvent for phospholipids and can be used for precipitation and concentration.

Thin-layer chromatography is a simple and useful technique for the qualitative determination of phospholipid groups. With the use of appropriate stains and standards, the position of most of the specific phospholipids can be determined. More quantitative analysis can be carried out by high-performance liquid chromatography (HPLC) and mass spectroscopy. The fatty acid composition of glycerophospholipids can be determined by fatty acid methyl ester (FAME) analysis, as for triacylglycerols. The fatty acids are hydrolyzed from glycerol, esterified, and then analyzed by gas chromatography. However, the fatty acid of the sphingophospholipid sphingomyelin is more difficult to release due to the attachment by an amide bond and requires extensive acid hydrolysis prior to methylation of the released fatty acid.

Features

Dairy phospholipids are of major importance because they are able to stabilize emulsions and foams, and contribute to the formation of micelles and membranes. Phospholipids also have the potential to be prooxidants, because they contain mono- and polyunsaturated fatty acids and have the ability to attract metal ions. Mono- and polyunsaturated fatty acids and metal ions are known to accelerate lipid oxidation, especially when heat is applied; hence, the phospholipids can be lost

Table 4 Approximate lipid content of different milk products

Product	*Total fat wt%*	*Phospholipids wt%*	*Phospholipids/total fat %*
Whole milk	4	0.035	0.9
Skim milk	0.06	0.015	25
Cream 40%	40	0.21	0.5
Buttermilk	0.6	0.13	22

[b] Fatty acid linked to amide nitrogen of the base.

during processing. However, in dairy products, the situation is complex and it appears that the phospholipids act as both prooxidants and antioxidants, depending on pH and the water content and phospholipid species.

In addition to their importance in cell membranes and cell signaling, specific polar lipids are reputed to have a number of positive health effects related to immune system, heart health, brain health, and cancer. These are related to either the polar lipids themselves or their breakdown products.

Sphingomyelin, gangliosides, phospholipids, and plasmalogen are implicated in different aspects of prevention of cancer. Further research will elucidate whether dairy polar lipids have unique properties related to their fatty acid composition or are simply another source of generic polar lipids.

Fat Globules in Milk

P F Fox, University College, Cork, Ireland

© 2011 Elsevier Ltd. All rights reserved.

Introduction

By definition, lipids (fats and oils) are insoluble in water and, since they are less dense than water, a mixture of water and oil will form two immiscible layers, with the lipid layer on top. If the mixture is subjected to shearing forces, the mass of oil is dispersed into spherical droplets (globules), which, when shearing ceases, coalesce and reform a surface layer. The mutual insolubility of oil and water results in interfacial tension between the phases, which is responsible for the spherical shape of the globules (a sphere has the smallest surface area-to-volume ratio of all geometrical shapes). If the interfacial tension is reduced by adding a surface-active agent (detergent, surfactant, emulsifier), the globules coalesce slowly or not at all, although they still rise to the surface (cream) due to the difference in density between the fat and aqueous phases. This system is an oil-in-water (o/w) emulsion, that is, a continuous water phase in which is dispersed a discontinuous oil phase; although these two phases are immiscible, they are made compatible by a small volume of a third phase, an emulsifier. Milk and cream are examples of an o/w emulsion. In butter, the continuous phase is oil in which are dispersed droplets of water, some intact fat globules, fat crystals, air bubbles, and some protein; thus, butter is a water-in-oil (w/o) emulsion.

In 1674, Anton van Leeuwenhoek reported that the fat in milk exists as microscopic globules, that is, as an o/w emulsion. Since then, the properties of milk fat globules have been studied extensively and have been found to have a marked influence on many properties of milk, for example, color, mouthfeel, and viscosity. The globules in bovine milk range in diameter from 0.1 to 20 μm, with a mean of 3–4 μm (the range and mean vary with the species, breed and health of the animal, stage of lactation, etc.). The size and size distribution of fat globules in milk may be determined by light microscopic examination, light scattering, for example, using a Malvern Mastersizer, or electronic counting devices, for example, the Coulter counter. In bovine milk, 75% of all globules have a diameter <1 μm but these represent only a small proportion of the total volume or mass of the fat. The mean fat globule size in milk from Channel Island breeds (Jersey and Guernsey) is larger than the mean fat globule size in milk from other breeds (the fat content of the milk from Channel Island breeds is also higher), and for all breeds, the size decreases by about 25% throughout lactation.

Milk contains 15×10^9 globules ml^{-1}, with a total interfacial area of 1.2–2.5 m^2 g^{-1} fat. This very large interfacial area means that the properties of the interfacial emulsifying layer play a very important role in determining the behavior of the fat globules. Emulsification of the fat in milk is achieved not by shearing but rather by a process in which the triglycerides synthesized within the mammary cells acquire a layer of emulsifier (protein) and become surrounded by the apical membrane of the secretory cell as they are excreted from the cell into the lumen of the alveolus (*see* **Mammary Gland, Milk Biosynthesis and Secretion**: Milk Fat). Thus, the emulsifying layer in the natural milk emulsion is much more complex than the emulsifying layer formed by an artificial emulsifier (*see* **Milk Lipids**: Milk Fat Globule Membrane).

As far as is known, the fat in the milk of all species occurs as globules and the properties of these globules are generally similar for all species, although there are some significant interspecies differences. This article will focus on some properties of the fat globules in bovine milk; some properties of the milk lipids in other dairying species are described briefly in a number of other articles (*see* **Milk**: Buffalo Milk, Equid Milk, Goat Milk, and Sheep Milk).

Stability of the Milk Fat Emulsion

Owing to interfacial tension, lipid emulsions are inherently unstable systems and are susceptible to flocculation, coalescence, deemulsification, and phase inversion. Although interfacial tension is reduced by the use of an emulsifier, the interfacial film may be imperfect. When two globules collide, they may adhere (flocculate), for example, by sharing emulsifier, or they may coalesce due to the Laplace principle, which states that the pressure is greater inside small globules than inside large globules and hence there is a tendency for large fat globules (or gas bubbles) to grow at the expense of smaller ones. Taken to the extreme, this will lead to the formation of a continuous mass of fat. The rate of destabilization is influenced by the fat content, shear rate (motion), liquid-to-solid fat ratio, inclusion of air, and globule size.

Another destabilizing factor arises from the difference in density between the lipid and aqueous phases (0.9 and

1.036 g cm^{-3}, respectively, for milk), which causes the fat globules to float or cream according to the Stokes' equation:

$$V = \frac{2r^2(\rho_1 - \rho_2)g}{9\eta} \quad (1)$$

where V is the rate of creaming, r the radius of fat globules, ρ_1 and ρ_2 are the densities of the continuous and dispersed phases, respectively, g is the acceleration due to gravity, and η the viscosity of the system. If creaming is not accompanied by other changes, it is readily reversible by gentle agitation.

The stability, or instability, of the milk fat emulsion is very significant with respect to many physical and chemical characteristics of milk and dairy products. The stability of the emulsion depends strongly on the integrity of the milk fat globule membrane (MFGM), which is quite fragile and is more or less extensively changed during dairy processing operations (*see* **Milk Lipids:** Milk Fat Globule Membrane).

In the following, some of the principal aspects and problems related to or arising from the stability of the milk fat emulsion are discussed. Some of these relate to the inherent instability of emulsions in general, while others are specifically related to the milk system.

The Creaming Process in Milk

A cream layer may be evident in milk within 20 min of milking. If formed as a result of the rise of individual globules of 4 μm diameter according to Stokes' equation, it would take approximately 50 h for a cream layer to form. The very rapid rate of creaming in milk is caused by the clustering of globules to form approximate spheres, up to 1 mm in diameter. As milk is drawn from the cow, the fat exists as individual globules and the initial rate of rise is proportional to the radius of the individual globules. Cluster formation is promoted by the disparity in the size of the fat globules in milk. Initially, the larger globules rise several times faster than the smaller ones and consequently overtake, collide with, and flocculate with the slower-moving small globules, forming clusters, which rise at an increased rate, collide with and aggregate with more globules, and continue to rise at a rate commensurate with the increased radius. The rate of creaming of clusters only approximates to Stokes' equation, since they are irregular in geometry and contain occluded serum, and therefore the difference between the aqueous and lipid phases is variable.

In 1889, Babcock postulated that creaming of cows' milk results from an agglutination type of reaction, similar to the agglutination of red blood cells; this hypothesis has been confirmed. Creaming is enhanced by adding blood serum or colostrum to milk; the responsible agents are immunoglobulins (Igs, which are present at high levels in colostrum), especially IgM. Because these Igs aggregate and precipitate at temperatures <37 °C and redisperse on warming, they are often referred to as cryoglobulins. When milk is cooled, the cryoglobulins precipitate on to the surface of the fat globules, causing them to agglutinate, probably through a reduction in surface (electrokinetic) potential. The cryoprecipitated globulins may also form a network in which the fat globules are entrapped. The clusters can be dispersed by gentle stirring and are completely dispersed on warming to 37 °C or higher. Creaming is strongly dependent on temperature and does not occur above 37 °C. The fat globules in the milk of buffaloes, sheep, and goats do not exhibit flocculation and these milks cream very slowly. The milk of some cows also exhibits little or no flocculation; apparently, this is a genetic trait, probably related to a deficiency of cryoglobulins.

The rate of creaming and the depth of the cream layer vary considerably. The concentration of cryoglobulins might be expected to influence the rate of creaming and although colostrum (rich in Ig) creams well and late-lactation milk (deficient in Ig) creams poorly, there is no correlation in mid-lactation milks between Ig concentration and the rate of creaming. An uncharacterized lipoprotein appears to act synergistically with cryoglobulin in promoting clustering. The rate of creaming is increased by increasing the ionic strength and is retarded by acidification. High-fat milk, which also tends to have a higher proportion of larger fat globules, creams quickly, probably because the probability of collisions between globules is greater and because large globules tend to form larger aggregates. The depth of the cream layer in high-fat milks is also greater than might be expected, owing to the greater dead space in the interstices of aggregates formed from large globules.

The rate of creaming and the depth of the cream layer are markedly influenced by processing operations. Creaming is faster and more complete at low temperatures, due to the temperature-dependent precipitation of the cryoglobulins. Gentle agitation during the initial stages of creaming promotes cluster formation and creaming, possibly because of an increased probability of collisions, provided that the globules adhere when they collide. It would be expected that stirring cold milk would lead to the deposition of all the cryoglobulin on to the fat globule surfaces and that rapid creaming, without a time lag, would occur when stirring ceased. However, milk treated in this way does not cream at all or creams only slightly after a prolonged lag period. If cold, creamed milk is agitated gently, the clusters are dispersed and do not reform unless the milk is rewarmed to 40 °C and then recooled, that is, the whole cycle is repeated. Vigorous agitation is detrimental to creaming due to denaturation of the cryoglobulins and/or alteration to the fat globule surface. If milk is separated at ≥40 °C, the cryoglobulins are present predominantly in the serum, while they are in the cream produced at a lower temperature. Agglutination and creaming are impaired or prevented by heating (e.g., 70 °C for 30 min or 77 °C for 20 s) owing to denaturation of the cryoglobulins; addition of Igs to heated milk restores creaming (except after very severe heat treatment, e.g., 2 min at 95 °C or equivalent). Homogenization prevents creaming due to the reduction of fat globule size, possibly due to the denaturation of Ig and due to the increased density of the fat globules owing to the newly attached casein membrane. Two types of Ig appear to be involved in agglutination, of which one is denatured by heating and the other by homogenization. A blend of unhomogenized cream and homogenized skim milk does not cream well.

Influence of Processing Operations on the Fat Globule Membrane

The MFGM is relatively fragile and susceptible to damage during any of several processing operations; consequently, emulsion stability is reduced by dislodging interfacial material by agitation, homogenization, heat treatment, concentration, drying, or freezing. Rearrangement and/or loss of the membrane increases the susceptibility of the fat to hydrolytic rancidity, light-activated flavors, and oiling-off of the fat, but reduces susceptibility to metal-catalyzed oxidation. The influence of the principal dairy processing operations on the MFGM and concomitant defects are discussed below.

Milk Supply: Hydrolytic Rancidity

The production of milk on the farm and transportation to the processing plant can potentially cause major damage to the MFGM. The membrane may be damaged at several stages of the milking operation: foaming due to air sucked in at teat cups, agitation due to vertical sections (risers) in milk pipelines, constrictions and/or expansion in pipelines, pumps (especially if operating below capacity), surface coolers, agitators in the bulk tank, and freezing of milk on the walls of bulk tanks. While some oiling-off and perhaps other physical damage to the milk fat emulsion may accrue from such damage, by far the most serious consequence is the development of hydrolytic rancidity caused by lipoprotein lipase (*see* **Enzymes Indigenous to Milk**: Lipases and Esterases and **Milk Lipids**: Lipolysis and Hydrolytic Rancidity).

Mechanical Separation of Milk

Until 1878, gravity creaming was the only means by which the fat in milk could be recovered for the manufacture of butter or for other purposes. Gravity creaming is relatively efficient, especially in the cold (a fat content of 0.1% in the skim milk phase may be obtained). Milk for the manufacture of Grana Padano and Parmigiano Reggiano cheeses is still partially skimmed by gravity creaming. Incidentally, up to 90% of the bacteria in milk are occluded in the cream layer and are removed from the cheese milk. However, gravity creaming is slow and inconvenient for industrial-scale operations. The centrifugal milk separator, which was developed by Gustav de Laval in Sweden in 1878, permitted the rapid and continuous separation of the fat from milk and revolutionized dairy technology – it was the principal factor responsible for the industrialization of milk processing.

In centrifugal separation, *g* in Stokes' equation is replaced by centrifugal force, $\omega^2 R$, where ω is the speed of angular rotation in rad s^{-1} (2π rad = 360°) and *R* is the distance (cm) of the particle from the axis of rotation. Hence,

$$V = \frac{2r^2(\rho_1 - \rho_2)\omega^2 R}{9\eta} \qquad (2)$$

Thus, the rate of separation is influenced by the radius of the fat globules, the radius and speed of the separator, the difference in the density of the continuous and dispersed phases, and the viscosity of the milk; temperature influences r, $(\rho_1 - \rho_2)$, and η (*see* **Plant and Equipment**: Centrifuges and Separators: Applications in the Dairy Industry; Centrifuges and Separators: Types and Design).

Fat globules <2 μm in diameter are not completely removed by cream separators and since the average size of fat globules decreases with advancing lactation, the efficiency of separation decreases concomitantly. The fat content of cream is regulated by manipulating the ratio of cream to skim milk streams from the separator, which regulates back-pressure. With any particular separator operating under more or less fixed conditions, temperature is the most important variable affecting the efficiency of separation; η decreases with increasing temperature, while r, ρ_1, and ρ_2 change with temperature due to the temperature-dependent cubical expansion. The efficiency of separation increases with temperature, especially in the range 20–40 °C. In the past, separation was usually performed at 40 °C, but modern separators are very efficient, even at low temperatures.

Since the cryoglobulins are entirely in the serum phase at temperatures above 37 °C, cream prepared at such temperatures has poor natural creaming properties and the skim milk foams copiously due to the cryoglobulins. Following separation at low temperatures, most of the cryoglobulins are in the cream phase. Assuming that the cryoglobulins are not denatured and are associated mainly with the fat globules, the viscosity of cream produced by low-temperature separation is much higher than that produced at higher temperatures.

Homogenization

Homogenization is widely practiced in the manufacture of liquid milk and milk products (*see* **Homogenization of Milk**: Principles and Mechanism of Homogenization, Effects and Assessment of Efficiency: Value Homogenizers). The process involves forcing milk through a small orifice at high pressure (13–20 MPa), usually at about 40 °C (at this temperature, the fat is liquid; homogenization is less effective at a lower temperature when the fat is partially solid). The principal effect of homogenization is to reduce the average diameter of the fat globules to <1 μm (the vast majority of the globules in homogenized milk are <2 μm). Size reduction is achieved through the combined action of shearing, impingement, distension, and cavitation. Following a single passage of milk through a homogenizer, the small fat globules occur in clumps, causing an increase in viscosity; a second-stage homogenization at a lower pressure (e.g., 3.5 MPa) disperses the clumps and reduces the viscosity. Clumping arises from incomplete coverage of the greatly increased emulsion interfacial area during the short passage time through the homogenizer valve, resulting in the sharing of casein micelles by neighboring globules.

By reducing the average diameter of the fat globules, homogenization causes a concomitant increase (four- to sixfold) in the fat–plasma interface. There is insufficient natural membrane to coat the newly formed surface completely or insufficient time for complete coverage to occur, and consequently the globules in homogenized milk are coated by a membrane that consists mostly of casein, with some whey proteins. The membrane of homogenized milk contains 2.3 g protein per 100 g fat (10 mg protein per m^2), which is considerably higher than the level of protein in the natural membrane (0.5–0.8 g per 100 g fat), and is estimated to be 15 nm thick. The casein content in the serum phase of homogenized milk is reduced by about 6–8%.

Homogenization causes several major changes in the properties of milk:

1. Homogenized milk does not cream naturally and the fat is recovered only poorly by mechanical separation. This is due in part to the smaller average size of the fat globules, but failure of the globules in homogenized milk to aggregate is mainly due to the agitation-induced denaturation of some Igs.
2. Homogenized milk is very susceptible to hydrolytic rancidity because the artificial membrane does not isolate the fat from the lipase, which is associated mainly with the casein micelle; consequently, homogenized milk must be pasteurized prior to or immediately after homogenization.
3. Homogenized milk is more susceptible to sunlight-oxidized flavor, which is due to the production of methional from methionine, but is less susceptible to metal-catalyzed lipid oxidation, presumably because the phospholipids, which are very susceptible to oxidation (they are rich in polyunsaturated fatty acids) and are located largely in the natural membrane (which contains prooxidants, e.g., xanthine oxidoreductase and metals), are distributed more uniformly after homogenization and, therefore, are less likely to propagate lipid oxidation.
4. Homogenized milk is whiter due to finer dispersion of the fat (and thus greater light scattering) and its flavor is more bland.
5. The heat stability of whole milk is reduced by homogenization, as is the strength (curd tension) of rennet-induced gels. Viscosity is increased for unknown reasons, probably independent of changes in globule size.
6. Homogenized milk has improved foaming characteristics, perhaps due to the release of foam-promoting proteins from the natural membrane or due to the reduction in fat globule size – small globules are less likely to damage foam lamellae. Homogenization reduces surface tension, possibly due to the inclusion of very surface-active proteins in the artificial membrane and due to the changes in the fat globule surface.
7. Homogenized milk drains cleanly from the sides of a glass bottle or drinking glass, probably due to the disruption of large protein and lipoprotein complexes.

The efficiency of homogenization may be assessed by microscopic examination or, more effectively, by a particle sizer, for example, Malvern Mastersizer.

Recently, high-pressure homogenizers have been developed, capable of reaching operating pressures of up to 300 MPa. High-pressure homogenizers are more effective than conventional valve homogenizers. The average diameter of the fat globules is about the same in both cases but high-pressure homogenizers give a narrower size distribution.

Heating

Normal high-temperature, short-time (HTST) pasteurization causes very little change in the fat globule membrane or in the characteristics of milk fat dependent on the membrane. However, excessively high pasteurization temperatures denature the cryoglobulins, and aggregation of the fat globules and creaming are impaired or prevented. Severe treatments, for example, 80 °C for 15 min, remove lipid and protein material from the membrane; the fat globules are partially denuded and may coalesce, forming large clumps of nonglobular (free) fat and resulting in defects such as 'cream plug' in milk or cream.

Processes such as thermal concentration also damage the MFGM with the formation of free fat, especially since many of these treatments also involve vigorous agitation in high-velocity heating systems. Dehydration, especially roller-drying, causes extensive damage to the MFGM, resulting in the formation of free fat. Since milk for concentrated and dehydrated milk products is normally homogenized, damage to the natural membrane is of little significance. Freezing milk, and especially cream, causes extensive damage to the MFGM due to physicochemical changes to the lipoprotein complexes and physical damage by the ice crystals. On thawing, much of the fat is released as nonglobular (free) fat.

Introduction

Membrane material surrounding the lipid globules of milk is called the milk lipid or milk fat globule membrane (MFGM). This membrane originates from material associated with the fat droplets within milk-secreting cells, and from material acquired during the process of secretion of fat globules from the cell (*see* **Mammary Gland, Milk Biosynthesis and Secretion**: Secretion of Milk Constituents). Herein we summarize current information on the composition and structure of the MFGM. The MFGM of bovine milk is discussed most extensively because research has focused primarily on the membrane from this species.

Origin of MFGM

Materials that constitute the MFGM originate from different sites within the milk-secreting cell. Fat globules are assembled in, or close to, the endoplasmic reticulum (ER), wherein the synthesis of the triacylglycerol core lipid is completed by the transfer of fatty acyl chains to diacylglycerols by ER-bound terminal transferases. During or following synthesis, the nascent microlipid droplets are coated with surface material composed primarily of proteins and polar lipids derived from the ER and cytoplasm. Adipophilin (ADPH), a constituent of the MFGM, is a component of this initial coat, and the phospholipids are presumed to form a monolayer in direct contact with the underlying core of neutral lipids. These nascent droplets are then transported from their sites of origin to the apical cytoplasm, during which time they may fuse together to form larger droplets and interact with membranes associated with the Golgi complex, mitochondria, secretory vesicles, and other organelles. Lipid is finally secreted from the cell apex as each droplet is progressively enveloped with the plasma membrane, until the membrane pinches off behind the droplet, expelling it into the alveolar lumen. During this process, a 10–20 nm-thick layer of protein largely derived from the cytoplasmic face of the apical plasma membrane and the surface of the droplet forms between the outer membrane bilayer and the core lipid. Thus, milk lipid droplets are coated with a multilayered envelope comprising a monolayer of protein and lipid acquired from the cytoplasm, ER, and possibly other intracellular membranes, an interstitial layer or protein coat, and an outer bilayer with an associated glycocalyx (**Figure 1**). The origin and secretion of milk fat globules are discussed in detail elsewhere (*see* **Mammary Gland, Milk Biosynthesis and Secretion**: Secretion of Milk Constituents).

Isolation of MFGM

The amount of MFGM in milk can vary considerably, depending upon both the fat content of the milk and the size distribution of the milk fat globules. Bovine milk fat globules range in diameter from under 1 μm to well over 10 μm. While very small globules contain only a small amount of the total milk fat, they contribute a large proportion to the total surface area of the membrane.

Several factors influence the composition and properties of the MFGM material isolated from milk. Following secretion, areas of the initial membrane condense to form islands or lenses on the droplet surface and some of the MFGM vesiculates and is lost to the skim milk phase, either within the mammary gland or following removal of milk from the animal. Estimates of the extent of this loss vary considerably. What factors cause it and whether it is progressive are unknown. Possible causes include aging of the milk post secretion and methods of handling the raw milk and separated cream. In the milk of many species, some globules have cytosolic material, including membranes, entrained between the globule core and the surrounding outer membrane. These inclusions are called ‘crescents’ because of their two-dimensional appearance in electron micrographs (**Figure 2**). Application of most methods for isolation of the MFGM will lead to the inclusion of membrane material from these crescents and therefore affect the composition of the final membrane preparations. However, in cows’ milk, only a small number of globules have crescents, compared to some other species.

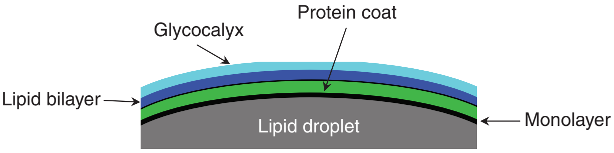

Figure 1 Structure of the milk fat globule membrane. Schematic diagram of the four layers of membrane discussed in the text: monolayer (black); protein coat (green); lipid bilayer (dark blue); and glycocalyx (light blue).

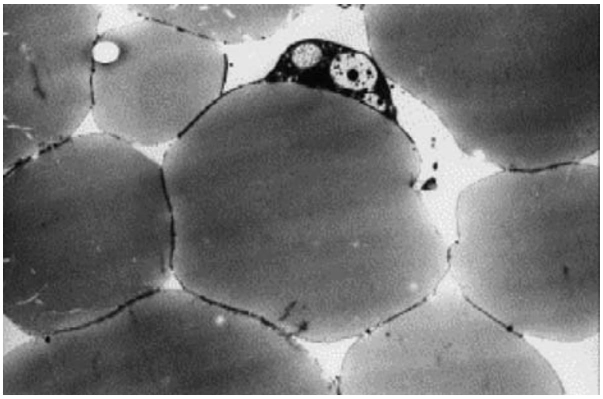

Figure 2 Electron micrograph of fat globules from cows' milk. One of the globules has a cytoplasmic crescent that contains three secretory vesicles as well as densely stained cytosolic material. These globules were fixed simultaneously with glutaraldehyde and osmium tetroxide.

Many different methods have been used to isolate MFGM. The most common approach is to float fat globules centrifugally to the surface, recover the cream layer, and then disperse the cream in water or buffer and refloat to remove entrained skim milk constituents. The membrane can be released from aqueous dispersions of globules by physical methods such as agitation (churning), freezing and thawing, and exposure to ultrasound. Chemical methods include the addition of mild detergents or the dispersion of globules in polar aprotic solvents. Following release of membrane material from the globules, the membrane is usually collected by centrifugal sedimentation.

The isolation method used influences the composition of the resultant MFGM. Washing cream extensively may remove extrinsic proteins from the globule surfaces. Conversely, poorly washed globules, especially if just distilled water is used, will yield membranes contaminated heavily with casein micelles. One gentle method that combines washing and globule recovery in one step is to increase the density of milk with sucrose, place the density-modified milk under buffer, and then centrifuge to hasten flotation of the globules through the buffer layer. However, it is possible that cells, cell fragments, and membranous material in skim milk may be entrained with the globules during centrifugal flotation, in which case particulate material from cells and cell fragments will be present in the isolated MFGM. During the globule washing and membrane collection steps, large proportions of some peripheral proteins originally associated with the globules are lost into the aqueous medium (hereafter referred to as MFGM supernatant).

Gross Composition

At least 95% of the total lipids in milk from cows are present in the globule fraction collected by centrifugal separation, and 95% or more of the lipids in these globules are triacylglycerols. What percentage of the total mass of fat globules is accounted for by MFGM material has not been established with certainty. From available data, membrane-associated materials can comprise from about 2 to 6% of the globule mass. Available information on the gross composition of MFGM is presented in **Table 1**. Proteins and lipids together account for over 90% of the membrane dry weight. Relative proportions of proteins and lipids measured have varied widely in different studies. Neutral lipids, especially triacylglycerols, are the most variable component (**Table 1**), presumably because of differences in the methods used to physically strip the membrane from the core lipid. The phospholipid content of MFGM is less variable, averaging about 0.25 mg mg^{-1} protein. The glycosphingolipid content of MFGM is about 13 µg mg^{-1} protein. RNA has been identified in cow MFGM preparations, about half of which can be removed by extraction with high-salt buffers. Whether

Table 1 Gross composition of milk fat globule membranes

Constituent group	*Amount*
Proteins	25–60% by weight
Total lipids	0.5–1.1 mg mg^{-1} protein
Neutral lipids	0.25–0.88 mg mg^{-1} protein
Phospholipids	0.13–0.34 mg mg^{-1} protein
Glycosphingolipids	13 µg mg^{-1} protein
Hexoses	108 µg mg^{-1} protein
Hexosamines	66 µg mg^{-1} protein
Sialic acids	20 µg mg^{-1} protein
RNA	20 µg mg^{-1} protein
Glycosaminoglycans	0.1 µg mg^{-1} protein

Data compiled from Keenan TW, Mather IH, and Dylewski DP (1988) Physical equilibria: Lipid phase. In: Wong NP, Jenness R, Keeney M, and Marth EH (eds.) *Fundamentals of Dairy Chemistry*, 3rd edn., pp. 511–582. New York: Van Nostrand Reinhold; and Keenan TW and Mather IH (2006) Intracellular origin of milk fat globules and nature of the milk fat globule membrane. In: Fox PF and McSweeney PLH (eds.) *Advanced Dairy Chemistry, Vol. 2: Lipids*, 3rd edn., pp. 137–165. New York: Springer Science and Business Media Inc.

this RNA is a constituent of the primary MFGM or is present in contaminating cytoplasmic crescents is unknown. DNA has not been reported in cow MFGM. Hexoses, hexosamines, and sialic acids are found in the MFGM at about 0.2 mg mg^{-1} protein. Probably, most MFGM-associated carbohydrates are linked covalently to proteins and lipids. The glycosaminoglycans, hyaluronic acid, chondroitin sulfate, and heparin sulfate have been found in MFGM preparations.

Lipid Composition

Triacylglycerols are the most abundant lipids in the MFGM (**Table 2**), but methods used for preparing the membrane have a major influence on the triacylglycerol content. MFGM-associated triacylglycerols contain higher proportions of long-chain saturated fatty acids than do the triacylglycerols of core fat. Triacylglycerols with high melting points may associate selectively with membrane material during globule formation or during processing. When globules are destabilized at elevated temperatures, the MFGM is not enriched in high melting point triacylglycerols. Di- and monoacylglycerols are also found in the MFGM, but whether these are products of lipolysis or are true membrane constituents is not known. Sterols and sterol esters account for 0.3 to over 2% of the total membrane-associated lipids. Cholesterol is the major sterol and is most likely incorporated directly into the MFGM as a constituent of the plasma membrane-derived outer bilayer. Esterified sterols account for 10% or less of the total sterols in the membrane.

Table 2 Lipid composition of milk fat globule membranes

Constituent class	*Percentage of total lipids*
Triacylglycerols	62
Diacylglycerols	9
Monacylglycerols	0–0.5
Sterols	0.2–2.0
Sterol esters	0.1–0.3
Hydrocarbons	1.2
Unesterifiedfatty acids	0.6–6.0
Phospholipids[a]	26–31
Sphingomyelin	22
Phosphatidylcholine	36
Phosphatidylethanolamine	27
Phosphatidylinositol	11
Phosphatidylserine	4
Lysophosphatidylcholine	2

Data compiled from Patton S and Keenan TW (1975) Milk-fat globule membrane. *Biochimica et Biophysica Acta* 415: 273–309; Keenan TW, Mather IH, and Dylewski DP (1988) Physical equilibria: Lipid phase. In: Wong NP, Jenness R, Keeney M, and Marth EH (eds.) *Fundamentals of Dairy Chemistry*, 3rd edn., pp. 511–582. New York: Van Nostrand Reinhold; and Keenan TW and Mather IH (2006) Intracellular origin of milk fat globules and nature of the milk fat globule membrane. In: Fox PF and McSweeney PLH (eds.) *Advanced Dairy Chemistry, Vol. 2: Lipids*, 3rd edn., pp. 137–165. New York: Springer Science and Business Media Inc.

Milk phospholipids are distributed in an approximately 60:40 ratio between the MFGM and skim milk membrane fractions. The five major phospholipids of MFGM are sphingomyelin, phosphatidylcholine, phosphatidylethanolamine, phosphatidylinositol, and phosphatidylserine (**Table 2**). Lyso derivatives of phosphatidylcholine and phosphatidylethanolamine have also been found in the MFGM, but are minor constituents in samples handled in ways that minimize lipolytic degradation. Alkyl and alkenyl ethers have been identified as constituents of the choline and ethanolamine phosphoglyceride fractions from cows' whole milk but what proportions of the various phosphoglyceride classes of MFGM are alkyl or alkenyl ethers has not been determined (*see* **Milk Lipids**: Phospholipids).

Glycosphingolipids, although minor constituents of the MFGM (**Table 1**), have been investigated extensively. Interest in milk glycolipids was stimulated by the recognition that glycosphingolipids and some of their degradation products function in a number of biological phenomena, such as cell–cell interaction, differentiation, and transmembrane signaling, and as receptors. MFGM contains two major neutral glycosphingolipids, glucosyl and lactosyl ceramides, in nearly equimolar proportions. Neutral glycosphingolipids with more complex oligosaccharide structures have not been reported. Nine different gangliosides, including mono-, di-, and tri-sialogangliosides, have been identified. The membrane-associated glycosphingolipids and sphingomyelin contain primarily long-chain fatty acids, especially palmitate (16:0), stearate (18:0), behenate (22:0), tricosanoate (23:0), and tetracosaenoate (24:1).

Protein Composition

Proteins account for 25–60% of the mass of membrane material recovered from milk fat globules (**Table 1**). Variation in the amount of protein in the MFGM almost certainly is due to differences in sample history and MFGM preparative techniques. The membrane-associated proteins have been studied extensively over the past 40 years, especially with respect to the primary sequences derived from the corresponding cDNAs, glycosylation profiles, and in some cases, the three-dimensional structures obtained by X-ray crystallography.

Upon one-dimensional separation by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE), MFGM is resolved into 7–8 major bands of protein (**Figure 3**). In addition, many minor

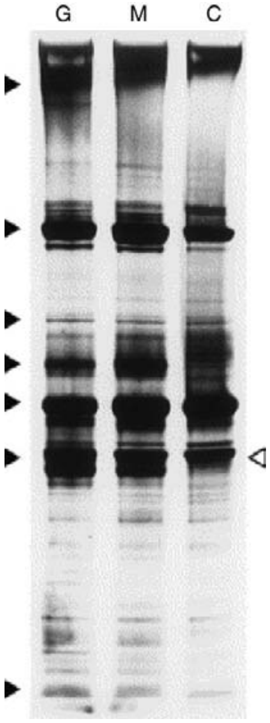

Figure 3 SDS-polyacrylamide gel electrophoretic separation of polypeptides of washed milk fat globules (G), milk fat globule membranes (M), and the Triton X-100- and 1.5 mol l^{-1} NaCl-insoluble milk fat globule membrane coat (C). Arrowheads from top to bottom along the left lane denote the positions of MUC-1, XDH/XO, MUC-15, CD36, BTN, PAS 6/7 combined with ADPH, and FABP. The open arrowhead along the right lane denotes ADPH after the quantitative removal of PAS 6/7 with detergent/high-salt mixtures. Separation was in a commercially prepared 4–12% NuPage electrophoretic gel (Novex, San Diego, CA) run with MOPS buffer. The gel was stained with silver.

polypeptides can be identified, especially when SDS-PAGE gels are overloaded with sample. More recent proteomic techniques have revealed well over 100 MFGM-associated proteins (see **Table 3** for a partial list). Historically, major MFGM proteins were designated according to their relative mobilities during SDS-PAGE and whether they stained with the periodic acid/Schiff (PAS) reagent used for the detection of glycosylated proteins. This led to confusion, because different numbering systems were used by different investigators. The current nomenclature for MFGM proteins recommended by the Milk Protein Nomenclature Committee of the American Dairy Science Association has been used and limited database information is included for the bovine proteins. Extensive information for many species, including cow, is now readily available by accessing the respective genome databases.

The major proteins of MFGM, in the order of increasing mobility upon SDS-PAGE separation, are the mucin MUC-1, the redox enzyme xanthine dehydrogenase/oxidase (XDH/XO), the mucin MUC-15 (previously called PAS III), cluster of differentiation 36 (CD36), butyrophilin 1A1 (BTN), an overlapping group of bands comprising ADPH and glycosylated variants of PAS 6/7, and in a separate band of much higher mobility, fatty acid-binding protein (FABP). Of these major proteins, six (XDH/XO, CD36, BTN, ADPH, PAS 6/7, and FABP) are stained readily with Coomassie blue. The mucins MUC-1 and MUC-15 are not stained with Coomassie blue but can be detected either with the PAS reagent or by silver staining.

Table 3 Enzymes and other selected constituents reported in bovine milk fat globule membranes

Enzyme/enzymic activity	*Enzyme commission number*
Retinal short-chain dehydrogenase/reductase	1.1.-.-
Alcohol dehydrogenase (NADP$^+$)	1.1.1.2
Glycerol-3-phosphate dehydrogenase (NAD$^+$), cytoplasmic	1.1.1.8
Malate dehydrogenase, cytoplasmic	1.1.1.37
Isocitrate dehydrogenase, cytoplasmic	1.1.1.42
Sterol-4-α-carboxylate 3-dehydrogenase, decarboxylating	1.1.1.170
Xanthine dehydrogenase/oxidase	1.2.3.1
Lipoamide dehydrogenase (diaphorase)	1.8.1.4
Cytochrome b_5 reductase	1.6.2.2
NADPH/cytochrome *c* reductase	1.6.99.1
NADH/cytochrome *c* reductase	1.6.99.3
Catalase	1.11.1.6
Lactoperoxidase	1.11.1.7
Fatty acid synthase	2.3.1.85
γ-Glutamyl transpeptidase	2.3.2.2
Galactosyl transferase(s)	2.4.1.-
Pyridoxal kinase	2.7.1.35
Patatin-like phospholipase domain-containing protein 2	3.1.1.3
Cholinesterase	3.1.1.7 (or 8?)
6-Phosphogluconlactonase	3.1.1.31

Uromodulin	-

Adapted from Mather IH (2000) A review and proposed nomenclature for major proteins of the milk-fat globule membrane. *Journal of Dairy Science* 83: 203–247; Reinhardt TA and Lippolis JD (2006) Bovine milk fat globule proteome. *Journal of Dairy Research* 73: 406–416, Fong BY, Norris CS, and MacGibbon AKH (2007) Protein and lipid composition of bovine milk-fat globule membrane. *International Dairy Journal* 17: 275–288, and other sources.

The supernatant fraction recovered after disruption of the globules and centrifugal removal of the MFGM contains 20% or more of the protein originally associated with the fat globules. Major constituents in this supernatant fraction include MUC-1, XDH/XO, PAS 6/7, and FABP (*see* **Milk Lipids**: Buttermilk and Milk Fat Globule Membrane Fractions).

MUC-1

MUC-1 is a heavily glycosylated mucin found in the MFGMs of many ruminant, rodent, and primate species. MUC-1 mucins have single type 1 membrane anchors, short cytoplasmic tails, and extensively glycosylated exoplasmic domains with a variable number of tandem repeats (VNTRs) in the peptide sequences. Ruminant (cow, sheep, goat) and human MUC-1 mucins display allelic polymorphism. Each allele encodes a 20 amino acid tandem repeat sequence of specific length. Alleles are expressed in a codominant manner such that each gives rise to equal quantities of protein. At least nine alleles have been identified in bovine MUC-1 with molecular weights for the predicted polypeptide backbones ranging from 50 400 to 78 700 Da.

MUC-1 is found in both the cream and skim fractions of cows' milk, at an estimated total level of up to 40 mg l^{-1}. When cream is treated to release MFGM, some MUC-1 is found in the MFGM supernatant. In milk stored in a bulk tank, an appreciable amount of MUC-1 is recovered in skim milk. Soluble forms of human MUC-1, lacking the membrane anchor, have been described; they arise either from alternatively spliced mRNA variants or from proteolytic processing. In some cultured cells, proteolytic cleavage in the exoplasmic domain close to the membrane anchor gives rise to a heterodimer in which the exoplasmic domain is bound noncovalently to the membrane-anchored C-terminal fragment. This could explain why some of the membrane-associated MUC-1 is shed into the milk serum upon cooling and agitation, if such proteolytic cleavage occurs in the MFGM.

The biological functions of MUC-1 are not known with certainty. MUC-1 is expressed on the apical plasma membrane and is incorporated into the MFGM upon budding and release of fat droplets from the cells. The exoplasmic domain of MUC-1 appears to be present in filament-like structures extending 0.5–1.0 μm above the MFGM bilayer, well beyond the estimated 10 nm confines of the glycocalyx. Thus, MUC-1 on the cell surface may protect against physical damage and invasive microorganisms. MUC-1 may also have an immunoprotective role in the suckling neonate by binding and sequestering microorganisms in the gut lumen. Notably, *Muc1* null mice are more susceptible to gastritis and infections by *Helicobacter pylori* than wild-type animals.

The consensus structure of MUC-1 (ruminants and primates) has an N-terminal cleavable signal sequence, a repetitive domain, an SEA (sea urchin sperm protein, enterokinase, and agrin) module, a single transmembrane anchor, and a short cytoplasmic tail (**Figure 4**). In humans, the VNTR is repeated 21–125 times in at least 30 alleles. The deduced amino acid sequence of cow MUC-1 included a tandem repeat region with 11 partially conserved repeats of 20 amino acids each (EMBL: AJ400824). The mature secreted protein was deduced to have 558 amino acid residues and an average mass of 55 688 Da.

Cow MUC-1 contains about 60% carbohydrate by weight, and fucose, galactose, mannose, *N*-acetylglucosamine, *N*-acetylgalactosamine, and sialic acid(s) have been identified. From the abundance of each carbohydrate, it is most likely that the predominant glycans comprise the sialyl T antigen (Neu5Ac(α2-3)-Gal(β1-3)-GalNAcα1) linked through O-glycosidic bonds to serine and threonine residues within the repetitive domain and flanking regions. Five asparagine residues in the exoplasmic domain are within the sequon NXS/T, which specifies N-linked glycosylation. That one or more of these sites are most likely glycosylated is indicated by the presence of *N*-acetylglucosamine, mannose, and fucose in purified preparations and sensitivity to digestion with the enzyme protein: *N*-glycosidase.

XDH/XO

XDH/XO is an abundant protein of milk fat globules, comprising about 20% of the globule-associated protein and is concentrated in the protein coat (**Figure 1**), between the outer membrane bilayer and lipid droplet surface. Upon destabilization of washed cream, about half of the globule-associated XDH/XO is released into the MFGM supernatant. Of that remaining associated with MFGM, a little over half can be removed from the membrane by washing with buffers containing either nonionic detergents or high concentrations of salt.

XDH/XO is a complex iron–sulfur- and molybdenum-containing redox protein and the only major component with enzymic activity in bovine MFGM (EMBL: X83508). The enzymatically active form of the enzyme is a homodimer of 293 600 Da, which may be identified by SDS-PAGE as a monomer of approximately 150 000 Da. The three-dimensional structure of the bovine milk enzyme has been determined by X-ray crystallography and the mechanism of enzyme action characterized in detail. Mammalian XDH/XO exists as both a dehydrogenase and an oxidase. The dehydrogenase form utilizes NAD^+ preferentially as an acceptor of reducing equivalents, but can also use molecular oxygen in the absence of NAD^+. The oxidase form transfers reducing equivalents to molecular oxygen, forming hydrogen peroxide and superoxide radical. Under hypoxic conditions, the enzyme can also reduce inorganic nitrite leading to the formation of nitric oxide. XDH/XO is expressed predominantly as a dehydrogenase in tissues and can be converted to the oxidase form by oxidation of cysteine residues or by limited

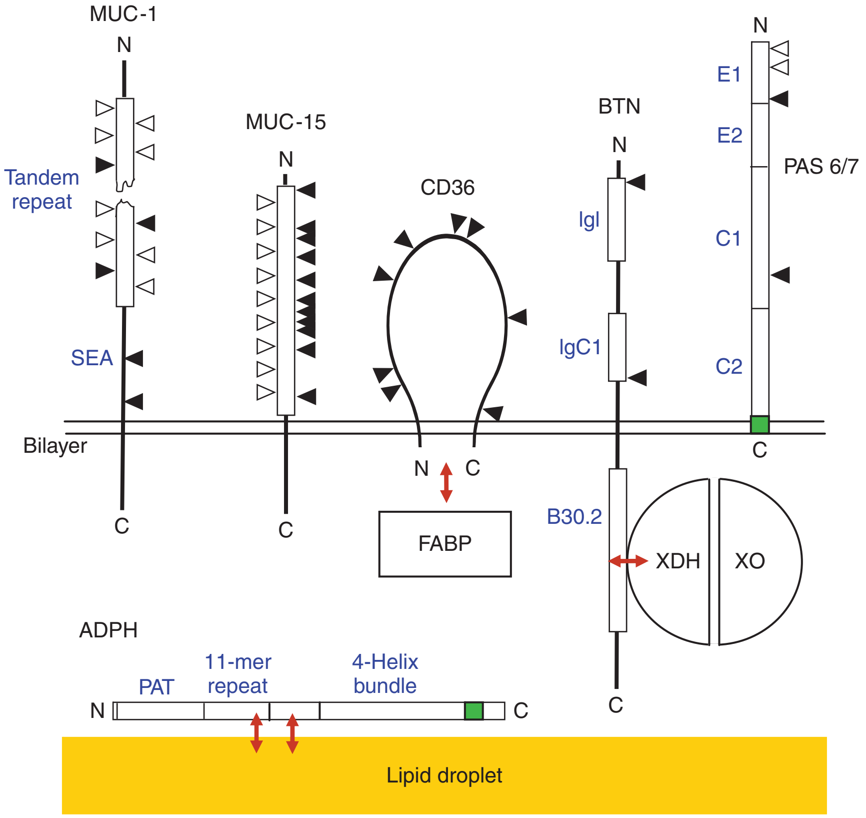

Figure 4 Topology of the major bovine milk fat globule membrane proteins. Shown are the orientations of MUC-1, MUC-15, CD36, BTN, and PAS 6/7 in the lipid bilayer and the locations of XDH/XO, FABP, and ADPH between the bilayer and the lipid droplet surface (yellow band). Confirmed interactions between proteins are indicated by double-headed red arrows, specific protein domains by blue lettering, the amphipathic helix in PAS 6/7 and hydrophobic cleft in ADPH by green boxes, N-linked glycans by black arrowheads, and O-linked glycans by open arrowheads.

proteolysis. XDH/XO of freshly collected milk has been estimated to be 50–70% in the oxidase form, and it is rapidly and completely converted to the oxidase form on storage.

XDH/XO may have multiple functions depending on the physiological context. In many organisms, XDH/XO plays a key role in the terminal steps of purine metabolism, catalyzing the oxidation of hypoxanthine and xanthine to xanthine and uric acid, respectively. In mammals, XDH/XO may also play a key role in milk lipid secretion because ablation of the *Xdh* gene in mice disrupts the regulated secretion of lipid droplets in heterozygous animals (lactation in *Xdh* null mice cannot be analyzed because the mice do not survive to sexual maturity). XDH/XO may function in concert with BTN by forming a protein complex, which is required for the formation of the MFGM (*see* **Mammary Gland, Milk Biosynthesis and Secretion**: Secretion of Milk Constituents). The enzyme may also serve as a signaling molecule through the generation of reactive oxygen and nitrogen species that function as second messengers and activate downstream targets. In yet a further role, the production of reactive oxygen and nitrogen species may protect the mammary gland and the neonatal gut from bacterial infections. Both superoxide radical and nitric oxide are bacteriocidal and together form peroxynitrite, a highly effective antimicrobial agent.

XDH/XOs are not known to be glycosylated or phosphorylated. However, the bovine enzyme may be acylated with long-chain fatty acids (*see* **Enzymes Indigenous to Milk**: Xanthine Oxidoreductase).

MUC-15

MUC-15 (previously called PAS III) is a mucin with a membrane anchor that is found both associated with the membrane and in the MFGM supernatant. Upon separation by SDS-PAGE, MUC-15 migrates as a diffuse PAS-positive band with an apparent molecular weight of 95 000 to over 100 000 Da. The protein comprises 330 amino acids, including a cleavable N-terminal leader sequence of 23 residues (EMBL: AJ417816), and is inserted into membranes as a type 1 glycoprotein with an extensive exoplasmic domain (**Figure 4**). A splice variant that is secreted because it lacks the membrane anchor has also been described. The exoplasmic domain is heavily glycosylated with both O- and N-linked glycans, and carbohydrates constitute 65% of the total molecular weight. The majority of the O-linked glycans are based on core 1-type structures with smaller amounts of more complex oligosaccharides possibly containing poly-*N*-acetyllactosamine. N-linked glycans are principally of the hybrid type. A human homologue with 67% similarity and similar topological features has been characterized from a cloned cDNA and equivalent mucins recently identified in sheep, goat, pig, and buffalo milk. MUC-15 is widely expressed in many tissues on the surface of epithelial cells, as well as hematopoietic and immune cells. In the mammary gland, MUC-15 is concentrated on the apical surfaces of epithelial cells in pre-lactating and lactating glands, making it a useful marker for ductal and secretory epithelia.

CD36

CD36 is an integral protein of the MFGM with an apparent molecular weight of 77 000 Da on SDS gels. Most of it remains associated with the MFGM upon destabilization of cream. CD36 has been implicated in diverse functions such as a receptor for collagen and thrombospondin, as a scavenger receptor for apoptotic cells, and a transporter of long-chain fatty acids. However, what specific functional roles are served by CD36 on the apical plasma membrane of mammary epithelial cells and the MFGM remain unclear.

CD36 appears to be synthesized with an uncleaved hydrophobic N-terminal signal sequence that is hydrophobic and serves as a membrane anchor. Near the C-terminus is another hydrophobic sequence that presumably serves as a stop transfer signal (EMBL: X91503). As a consequence, short sequences in both the N- and C-terminal regions of CD36 are on the cytosolic face of the plasma membrane, and there is a large exoplasmic heavily glycosylated domain (**Figure 4**).

In human CD36, two cysteine residues near the N-terminus and two other cysteine residues near the C-terminus are acylated with palmitate. It is not known if cow MFGM CD36 is palmitoylated, but these particular cysteine residues are conserved in all characterized mammalian CD36 proteins. Excluding sialic acids, carbohydrate accounts for about 24% of the weight of CD36 from cow MFGM. Most of the glycans of CD36 are N-linked and comprise high-mannose-, hybrid-, and complex-type chains. Interestingly, both human and mouse CD36 contain rare O-linked α-2,8-linked polysialic acid glycans, which appear to be specific to CD36 expressed in the mammary gland (e.g., CD36 from platelets is not polysialylated). Such highly charged anionic residues may play a protective role in milk and in the gut of the suckling neonate by binding to and sequestering pathogenic microorganisms.

BTN

BTN migrates during SDS-PAGE with an apparent molecular weight of about 66 000 Da. It is the most abundant integral membrane protein in bovine MFGM and together with XDH/XO comprises over 50% by weight of the globule-associated protein. Upon destabilization of fat globules, most of the BTN remains associated with the membrane. BTN resists extraction from MFGM with solutions of high ionic strength, chaotropic agents, and with a variety of detergents, but is solubilized by the addition of thiol-reducing agents. BTN thus behaves as an integral membrane protein and its association with the membrane is probably stabilized by intramolecular disulfide bonds and by disulfide bonding with other MFGM proteins.

Bovine BTN is synthesized as a polypeptide of 526 amino acids that includes an N-terminal 26-residue signal peptide, which is cleaved *in vivo*, leaving a protein with a calculated molecular weight of 56 460 Da (EMBL: M35551). BTN is a member of a subfamily of BTN-like proteins in the immunoglobulin (Ig) superfamily, a large group of adhesive proteins, receptors, and constituents of the immune system. Canonically, the BTNs comprise type 1 membrane glycoproteins with two or more Ig folds in the exoplasmic domains, single transmembrane anchors, and cytoplasmic regions, which are dominated by the B30.2 or PRY/SPRY domain. The latter domain is predicted to comprise two antiparallel β-strands folded into a β-sandwich and is assumed to function as an interactive binding domain in many proteins. BTN has two exoplasmic Ig folds, one of the intermediate type (IgI) and one of the constant C1 type (IgC1), and a B30.2/PRY/SPRY domain, which binds tightly to XDH/XO in a pH- and salt-sensitive manner (**Figure 4**).

BTN may function in the secretion of milk lipid because its expression on the apical plasma membrane is highly upregulated during lactation and the secretion of milk lipid droplets is compromised in BTN knockout mice. In several current models for milk fat secretion, interactions between BTN and XDH/XO are postulated to form a linker protein complex, which is necessary for the budding and release of lipid globules from the apical surface and formation of the MFGM (*see* **Mammary Gland, Milk Biosynthesis and Secretion**: Secretion of Milk Constituents). BTN may also function in the immune system as a coinhibitor of T-cell activation via interactions between the exoplasmic Ig folds and a presumptive receptor on the T-cell surface.

Bovine BTN is glycosylated at two sites in the exoplasmic domain (**Figure 4**). The glycans linked to BTN have been structurally characterized and comprise bi-, tri-, and tetra-antennary sugar chains. No O-linked glycans have been identified. There is evidence that BTN is acylated with medium- and long-chain fatty acids. BTN contains several potential phosphorylation sites, and it is phosphorylated upon incubation of isolated MFGM with ATP. However, whether BTN is phosphorylated *in vivo* remains unclear.

ADPH

ADPH is a major constituent of the insoluble material remaining after MFGM is extracted with salts, chaotropic agents, and nonionic detergents. ADPH was overlooked for a long time as a constituent of MFGM because its position on gels after SDS-PAGE separations overlaps with that of the PAS 6/7 glycoprotein, and because it is not readily solubilized using conventional methods of sample preparation for electrophoresis.

Originally, ADPH was identified as one of the earliest proteins expressed in cells undergoing adipogenic differentiation and it was named adipose differentiation-related protein (ADRP). Subsequently, ADPH was found in association with storage lipid droplets in a wide variety of cultured cell types, and through sequence comparisons with other proteins it was recognized as a member of a family of lipid droplet-associated proteins, called the PAT family (after three constituent members: perilipin/adipophilin/TIP-47). Structurally, PAT family proteins are characterized by an N-terminal PAT domain, which is the most conserved region across family members, an overlapping 11-mer repeat region, which is predicted to fold into a series of amphipathic helices, followed by a predicted four-helix bundle of amphipathic helices (**Figure 4**; see EMBL: AJ011680 for the bovine sequence). A highly conserved region of 14 amino acids toward the C- terminus forms a hydrophobic cleft, which was identified in the crystal structure of TIP-47, and is assumed to form a similar structure in other family members, including ADPH.

ADPH associates with the surface of lipid droplets during the early stage of their formation in regions of the cytoplasm close to the ER and may play a role in facilitating the transport of triacylglycerols and fatty acids between the ER and forming droplets. It plays a major role in regulating lipid droplet turnover, by sterically blocking the action of lipases on the cell surface. As discussed elsewhere (*see* **Mammary Gland, Milk Biosynthesis and Secretion**: Secretion of Milk Constituents), ADPH may also function in the secretion of lipid droplets at the apical surface, either by forming a protein complex with XDH/XO and BTN, or by direct insertion of the hydrophobic cleft in the C-terminus of ADPH into the phospholipid bilayer of the apical plasma membrane.

Little is known about post-translational modifications of ADPH. It does not have an N-terminal signal peptide, and is either expressed as an unstable protein in the cytoplasm in the absence of lipid droplets, or stably associated with the surface of lipid droplets in their presence. ADPH does not appear to be glycosylated. There is evidence that ADPH may be acylated with long-chain fatty acids.

PAS 6/7

PAS 6/7 appears as a doublet in SDS-polyacrylamide gel profiles of MFGM in the approximate molecular weight range of 48 000–54 000 Da (**Figure 3**). It consists of a single polypeptide chain that is differentially glycosylated, leading to its resolution as a doublet during SDS-PAGE. PAS 6/7 is an extrinsic protein of MFGM and can be displaced from intact globules or membrane preparations by extraction with buffers containing high concentrations of salt or with chaotropic agents. Because of its peripheral nature, PAS 6/7 is a major protein constituent of the MFGM supernatant fraction. The N-terminal region of PAS 6/7 contains two epidermal growth factor (EGF)-like domains, followed by repeat domains that are similar to the C1 and C2 domains of blood clotting factors V and VIII (EMBL: X91895) (**Figure 4**). PAS 6/7 is most probably bound to anionic phospholipids in the MFGM via a C-terminal amphipathic α-helix.

One major modification of PAS 6/7 is the addition of both N- and O-linked glycans. Removal of N-linked glycans converts both PAS 6/7 isoforms to a protein of about 50 000 Da. The higher molecular weight isoform, PAS 6, was found to be N-glycosylated on two residues and O-glycosylated on one residue, and the PAS 7 form was found to be N-glycosylated on one residue and O-glycosylated on one residue. During development, the glycosylation patterns of PAS 6/7 change appreciably, especially in the early stages of lactation. Other post-translational modifications of PAS 6/7 have not been reported.

The name lactadherin has been assigned to the human form of PAS 6/7 to reflect the protein's presence in milk and its adhesive properties. The glycans associated with lactadherin may bind rotaviruses, potentially protecting the neonatal gut from infection. In addition, PAS 6/7 contains the integrin-binding motif 'RGD' in the second EGF-like domain. This property, and its widespread distribution in cells and tissues, suggests a role for PAS 6/7 in adhesion between cells. In this capacity, PAS 6/7 and its human (lactadherin) and mouse (MFG-E8) homologues play a major role in the process of programmed cell death (apoptosis) by linking phagocytic cells (through the integrin-binding domain) to phosphatidylserine displayed on the surface of apoptotic cells (through the C-terminal lipid-binding amphipathic α-helix). Expression of PAS 6/7 is upregulated in late lactation and thus is presumed to play a major role in the apoptosis of mammary epithelial cells during involution.

FABP

FABP has been identified as an approximately 13 000 Da constituent of MFGM and is recovered in both the membrane and MFGM supernatant fraction. A fraction enriched in FABP protein from lactating bovine mammary gland was originally shown to inhibit the growth of tumor cell lines and the protein was called mammary-derived growth inhibitor (MDGI). However, subsequent work showed that the tissue form of MDGI was a mixture of heart and adipose FABP. By proteomic analysis it has been recently confirmed that MFGM contains the heart form, and adipose FABP is presumed to be associated with tissue adipocytes.

FABP in MFGM occurs in at least two major and one minor isoelectric forms, suggesting the possibility of post-translational modifications. The protein is phosphorylated upon incubation of MFGM with ATP, and there is evidence that insulin stimulates phosphorylation of FABP in rat mammary cells. There is no evidence that FABP in MFGM is glycosylated. Other post-translational modifications of FABP have not been reported.

What roles, if any, FABP may play in milk fat globule formation or secretion is unclear. Within mammary epithelial cells, FABP may serve to transport fatty acids in the cytoplasm and it is bound to the integral fatty acid transporter CD36 in isolated MFGM preparations (**Figure 4**).

Enzymes and Other Constituent Proteins

Of the above major proteins, only XDH/XO is known to be an enzyme. Historically, the more-minor proteins of the MFGM were identified by enzyme assay and in some cases linked to specific electrophoretic bands of protein on SDS gels. During the last decade, more comprehensive proteomic approaches and two-dimensional electrophoretic separations have revealed many minor components (**Table 3**).

Close to 80% of the enzymic activities found in bovine MFGM are members of the hydrolase class, including a large number of ras-related GTP-binding proteins. Oxidoreductases are next in abundance, followed by transferases. The only lyases reported are the cytoplasmic enzymes aldolase and carbonic anhydrase. Cytoplasmic proteins constituted 24% of all the proteins identified in a recent proteomic analysis. Many of these soluble proteins may be incorporated into the secreted globules in cytoplasmic crescents.

Several enzymes with high specific activities in MFGM, such as cation-stimulated ATPase, phosphodiesterase I, and 5′-nucleotidase, are enriched in plasma membranes. XDH/XO, which is a soluble cytoplasmic protein, clearly is an abundant enzyme of the MFGM and most probably associates with the membrane by binding to the B30.2 domain of BTN (**Figure 4**). Other enzymic activities detected in the MFGM are associated with intracellular membranes such as the Golgi apparatus (glycosyltransferases), ER (glucose-6-phosphatase), and lysosomes (acid phosphatase, glycosidases). Ras-related GTPases are numerous in bovine MFGM. Why this is the case is unclear because they are typically localized to specific membrane compartments and the cytoskeleton and play diverse roles in the vesicular trafficking of membranes throughout cells. Many of these minor proteins (and the above organelle-associated enzymes) may bind to lipid droplets during their transit to the apical surface and during formation of the MFGM. Proteins that function in the trafficking of membranes and proteins in cells constituted the largest class of identified components (23%) in a recent proteomic analysis of bovine MFGM. Besides the GTPases and cytoskeletal elements, such trafficking proteins include those involved in the machinery of vesicle membrane fusion such as SNAREs and annexins. More detailed functional analysis of these proteins, especially the rabs, rhos, and SNAREs, may reveal the molecular details of lipid droplet trafficking and secretion. Industrial studies of MFGM-associated enzymes have focused on their use as markers of membrane damage and examination of their involvement in degradative events that alter processing characteristics, flavor, or the texture of milk products. Thermal inactivation of alkaline phosphatase is widely used to monitor adequate pasteurization.

Molecular Organization

The current view of the MFGM is that it initially comprises a true bilayer membrane that has a dense, proteinaceous coat of 10–20 nm thickness oriented on the inner membrane face, plus an innermost layer, which existed on the surface of droplets before secretion (**Figure 1**). Following secretion, the membrane undergoes some structural changes such that the membrane condenses into areas akin to islands and continents on the globule surface. Molecular mechanisms underlying these changes are unknown.

Early biochemical and morphological studies showed that there is a distinct asymmetric orientation of the glycans, enzyme active sites, and proteins of the MFGM, and this has been confirmed by molecular biological approaches (**Figure 4**). With respect to proteins, it is now firmly established that PAS 6/7 is an externally disposed, extrinsic MFGM constituent and that XDH/XO is an internal constituent of the protein coat. MUC-1, MUC-15B, and BTN are type 1 transmembrane proteins with externally oriented N-termini. CD36 also is a transmembrane protein but with short internally disposed N and C-termini and a large exoplasmic heavily glycosylated loop. Interactions have been confirmed or inferred between the B30.2 domain of BTN and XDH/XO, FABP and CD36, and the lipid droplet surface and ADPH. As discussed above, several models describing how XDH/XO, BTN, and ADPH may interact with each other during the milk lipid globule budding process have been proposed. Phospholipids are asymmetrically arranged with respect to the plane of the lipid bilayer in many cellular membranes, with phosphatidylcholine and sphingomyelin in the outer leaflet and phosphatidylserine, phosphatidylethanolamine, and phosphatidylinositol in the inner leaflet. However, as yet this disposition has not been confirmed for the phospholipids of bovine MFGM.

Perspectives

There has been a substantial increase in the knowledge of the MFGM and of its protein constituents in recent years. However, we still have little specific information on the cellular mechanisms involved in the formation of the MFGM, and on what roles the constituents of this membrane play in globule secretion, in nurturing of the neonates, and in affecting processing parameters.

Buttermilk and Milk Fat Globule Membrane Fractions

R Zanabria Eyzaguirre and M Corredig, University of Guelph, Guelph, ON, Canada

Introduction

During butter manufacture, milk fat globules are destabilized, and an aqueous by-product, buttermilk, containing milk-derived components as well as the milk fat globule membrane (MFGM) is produced. Buttermilk has received increased interest, as food science and nutrition research turns to develop products with not only increased nutritional value but also health-promoting properties. This by-product of butter-making can be a source of highly valuable functional ingredients, from both the technological and nutritional prospectives. Unfortunately, buttermilk is often subjected to extensive processing not necessarily aimed at preserving the quality of its components. The lack of consistency between buttermilk sources is perhaps the reason why the research strategies aimed at determining the benefits associated with its use as an ingredient or the benefits of fractionation of its components have not always been successful.

The MFGM is complex in composition as well as in its supramolecular structure. To date, the nature and functional properties of many of its components are at least partially understood. Buttermilk can be employed to isolate MFGM material and to prepare valuable ingredients; however, processes have to be designed to produce products with consistent composition and functionality. MFGM components are, in fact, very sensitive to environmental, processing, and storage changes, and it is not yet clear which processing conditions need to be controlled to best preserve their functional properties. In addition, more research has to be conducted to determine the benefits associated with the use and consumption of ingredients prepared from buttermilk.

Buttermilk and MFGM Composition

As a result of cream churning during butter manufacture, the aqueous phase is released and recovered as a by-product, commonly named buttermilk. While the original material (cream) is composed mainly of milk-derived proteins (caseins, whey proteins, etc.) and fat globules polydisperse in size, buttermilk contains skim milk proteins and is also rich in proteins and phospholipids derived from the original MFGM. As a consequence, buttermilk can contain up to 7 times more phospholipids than whole milk.

In raw milk, fat globule sizes vary from about 0.2 to 20 μm in diameter. The size distribution depends on a large number of factors including the breed of cow and the stage of lactation. While the majority of the fat globules are less than 1 μm in diameter, most of the triglycerides are transported by a relatively small number of large oil droplets in the milk. On the other hand, small fat globules contain relatively less triacylglycerides and relatively more phospholipids, glycoproteins, and enzymes as they contain more membrane material per unit fat than large globules.

The milk fat globules are enveloped by the MFGM, which protects them from coalescence and enzymatic degradation by lipases. This membrane originates from the mammary cell, and is composed, in native fat globules, of (1) an inner polar lipid monolayer surrounding the lipid core of the fat droplet, (2) a proteinaceous coat (appearing electrodense in microscopic images), (3) a bilayer membrane of polar lipids and proteins, and (4) an externally oriented glycocalyx. The MFGM is not homogeneous, and the various components are differentially distributed throughout the membrane. While several membrane proteins are located on the outer or inner face, the carbohydrate groups of the glycoproteins and gangliosides are exposed mainly on the globule surface. The lipids are also asymmetrically arranged: the choline-containing phospholipids, phosphatidylcholine (35%) and sphingomyelin (25%), and the glycolipids are located mainly on the outer layer, whereas phosphatidylethanolamine (30%), phosphatidylserine (3%), and phosphatidylinositol (5%) are concentrated mostly on the inner surface. In addition to the different distributions of the components, the amount and composition of MFGM can vary considerably depending on the fat content, fat globule size, and processing applied during and after milk extraction (e.g., agitation, heating, cooling, homogenization, evaporation, spray-drying).

In addition to sweet or commercial buttermilk produced during the manufacture of sweet cream (uncultured) butter, other sources of MFGM include cultured or sour buttermilk and whey buttermilk. These two refer to the products obtained from churning cultured cream and whey cream, respectively, and they both represent potential ingredients for the food industry. While the composition of regular buttermilk and cultured buttermilk is very similar to that of skim milk, the composition of whey buttermilk is closer to that of whey, but with a higher fat content, as a result of the presence of MFGM material.

It has been reported that the processing functionalities of whey buttermilk and regular or cultured buttermilk are different because of their different compositions. For example, whey buttermilk has higher emulsifying properties but lower foaming capacity than regular or cultured buttermilk, as well as different pH stability.

Compared to raw whole milk, the distribution of polar lipids in different dairy products clearly shows that buttermilk and butter serum are among the best sources for the isolation of MFGM material. The polar/neutral lipid ratio, on a dry matter basis, in skim milk, cream, butter, acid whey buttermilk, buttermilk, and butter serum (the aqueous portion obtained from melted butter) is 1.2, 1.7, 0.7, 8.0, 8.8, and 50.1 times that in raw milk, respectively.

In addition to proteins derived from skim milk (caseins, whey proteins), proteins derived from MFGM are also present in buttermilk. A recent study on the MFGM proteome identified up to 120 proteins, of which 71% are membrane-associated proteins, 24% are cytoplasmic, and 5% are secreted. Moreover, from the identified proteins, it was found that almost 50% of the proteins are associated with membrane protein trafficking and cell signaling, with the remainder having different functions including immune response (4%), transport and fat metabolism (20%), and protein synthesis/folding (7%). The functions of some proteins (21%) are not yet known. An important finding of this report was the identification of a large number of proteins, constituting part of the apical membrane of the mammary secretory cells, that are associated with cell signaling and infection detection (CD14, Toll-like receptors 2 and 4).

Moreover, as a result of progress in cloning and proteomics, most of the major proteins present in the MFGM have been sequenced. Proteins account for 25–60% of the mass of the membrane material and this percentage varies according to the method of isolation and sample history. Major proteins include MUC1 and MUC15 (mucins), the redox enzyme xanthine dehydrogenase/oxidase (XDH/XO), glycoproteins PAS III and PAS 6/7, cluster of differentiation 36 (CD36) and butyrophilin (two integral proteins), fatty acid-binding protein, and adipophilin, a lipid-binding protein. Other minor proteinaceous components, such as the proteose peptone fraction (PP3), have also been associated with the MFGM, although it is not clear whether they form part of the membrane or are a result of processing or the isolation procedure. All these proteins are recovered in buttermilk fractions.

Changes Occurring to MFGM during Processing and Storage

The supramolecular structure of the MFGM changes from the moment the fat globule leaves the mammary secretory cell. Depending on the type and extent of the processing treatment, various physicochemical changes may occur. Post-harvest changes (not physiological, i.e., due to diet, breed, or stage of lactation) can be chemical, enzymatic, or physical (i.e., due to mechanical stress). Handling during and after harvesting of milk, agitation, changes in temperature, and processing treatment such as heating, homogenization, and concentration all affect the supramolecular structure as well as the composition of the MFGM. Most work so far has failed to quantify these changes as the different purification procedures are themselves a source of the variation. However, there seems to be general agreement that homogenization under standard conditions results in very little loss of MFGM. Studies have in fact demonstrated that homogenization does not change the distribution of individual phospholipids in globules, although it alters the morphology of the membrane. In fact, because of changes in the size of the fat globules, the MFGM cannot completely cover the newly formed globules; hence, a significant amount of skim milk-derived proteins needs to adsorb to stabilize the interface.

Several methods have been used in attempts to quantify the changes occurring to the milk fat globule and its membrane during processing. These methods include the determination of free fat or free fatty acids by titration, or the changes in ζ-potential of the fat globules. Dairy processing greatly affects the properties and composition of the MFGM. Some of these changes are summarized in **Table 1**. Heating and physical agitation or homogenization, at temperatures as low as 65 °C, can cause changes in the MFGM by increasing the binding of serum proteins. Furthermore, heating at 80 °C results in a total loss of the PAS 6 protein and partial loss of PAS 7, and may result in a loss of phospholipids. Studies on heated washed creams at higher temperatures show the formation of high-molecular-weight complexes between XO and butyrophilin. The temperature at which XO and butyrophilin aggregate is lower than the denaturation temperatures reported for β-lactoglobulin and α-lactalbumin.

Table 1 Fat globule size distribution parameters in raw and homogenized cow milk

Parameters	*Raw milk*	*Homogenized milk*
Volume-surface average diameter (μm)	2.5–4.6	0.13–1.7
Volume average diameter (μm)	2.9–5.9	0.3–2.8
Surface area per 1 g of fat (m^2)	1.4–2.9	4–50
Surface area per 1 ml of milk (m^2)	0.06–0.12	0.13–1.75
Mean free distance between fat globules (μm)	6–25	1–8

Data compiled from Michalski *et al*. (2002), Mulder and Walstra (1974), Rüegg and Blanc (1981), and Walstra (1969).

In addition, a major role is played by the MFGM during heat treatment, causing the release of volatile sulfur compounds including hydrogen sulfide, carbon disulfide, dimethyl sulfide, and methanethiol. Although exposition of sulfhydryl groups of whey proteins by denaturation is considered to be the principal mechanism involved in milk flavor development, it has been suggested that the serine and methionine residues present in the protein fraction of MFGM also have a major effect.

Moreover, mechanical agitation is an important factor affecting the changes in the composition of the MFGM; in a study comparing ultra-high temperature heating of whole milk by direct steam injection or by indirect heating, with or without homogenization, it was demonstrated that agitation has a greater effect than temperature on the changes in the size of the fat globules.

Therefore, damage to the milk fat globule and its membrane can greatly affect the future quality of the derived products, as there will be higher susceptibility to oxidation, coalescence, changes in biological functionality, and interactions with other proteins. Hence, the processing steps to which the raw material and/or the by-products are subjected are a fundamental key to the quality of the isolated products. All these steps may affect the processing and biological functionality of the MFGM material.

Isolation of MFGM

The separation and isolation of MFGM from cream, buttermilk, and whole milk has been studied widely, and the laboratory methodologies typically involve four major steps: (1) separation of fat globules from whole milk by centrifugation; (2) washing of the fat globules to remove undesired components including caseins and whey proteins; (3) disruption of the fat globules and release of the membrane material; and (4) recovery of the membrane fractions. As previously mentioned, the processing history of the material used for the isolation will profoundly affect the final results.

Disruption of the fat globules can be carried out using a number of processes, including freezing and thawing, agitation or churning, or treatment with detergents or bile salts such as deoxycholate. In the native state, the surface of the MFGM is not homogeneous; therefore, various washes and changes in the environmental conditions as well as mechanical agitation will affect the distribution of the various components. After disruption of the fat globules, the MFGM can be collected by centrifugal sedimentation (at high centrifugal forces, i.e., 100 000 *g*). Subfractions of MFGM can also be produced analytically using gradient centrifugation.

For commercial-scale isolation of MFGM material, products containing a high content of polar lipids, such as buttermilk or butter serum, provide a promising basis for further purification. Because of the absence of casein micelles, whey buttermilk seems to be a potential source for the isolation of MFGM fractions as well. However, the presence of neutral lipids is problematic, as polar lipids in dairy products are present mainly as MFGM fragments of lipoprotein particles and the neutral lipids are intimately associated with them. The separation of a polar lipid fraction of high purity is therefore challenging, especially without the use of solvents. Supercritical fluid extraction has been suggested recently as a means to separate the polar lipids from the neutral lipids in MFGM-rich isolates. Membrane filtration may also be a means to separate certain phospholipids, as their transmission in the permeate fraction has been reported. Renneting of heat-treated buttermilk has also been suggested as a way to fractionate milk phospholipids, as fat and phospholipids were recovered in the serum phase, while skim milk-derived proteins were collected in the curd.

The most significant challenge in obtaining a buttermilk-derived ingredient rich in MFGM is the separation of the caseins. In buttermilk, caseins are present in micellar form. Casein micelles, being colloidally similar in size to the MFGM fragments, are difficult to separate from the MFGM using size-based separations such as membrane filtration. With the addition of sodium citrate (i.e. 2%, w /v) to buttermilk, it is possible to disrupt the casein micelle structure; hence, MFGM fractions can be recovered by high-speed centrifugation or membrane filtration. With microfiltration, it is possible to obtain an MFGM concentrate containing approximately 60% (w/w) protein and 35% (w/w) lipid. However, membrane filtration can cause losses of the MFGM phospholipids, especially during the diafiltration steps, and further research is required on the optimization of the filtration conditions and impact of the source and processing history of the initial material. In addition, proteolysis has also been proposed as a means to disrupt the casein micelles and obtain an MFGM extract from buttermilk.

The Potential of Buttermilk and MFGM Fractions as Technological and/or Nutritional Value-Added Ingredients

There have been several studies on the nutritional and technological functionality of buttermilk and MFGM isolates. However, in the area of health effects, data are sometimes contradictory; the information needs to be evaluated carefully, as the method of isolation of the different components and the origin of the raw material greatly affect the properties of the final products. **Table 2** presents a summary of these properties.

Table 2 Technological and nutritional properties of buttermilk and MFGM fractions

Product/component	*Properties/function*
Technological value[a]	
Buttermilk	Emulsifying agent Flavor and texture improver in bakery products Protects against lipid peroxidation Reduces viscosity and prevents crystallization Improves cheese yield, moisture retention, flavor development and mouthfeel, body and meltability
MFGM	Emulsifying agent Production of liposomes
Nutritional value[b]	
Breast cancer type 1 or 2 susceptibility proteins (BRCA1, BRCA2)	Anticarcinogenic activities
Fatty acid-binding protein	Cell growth inhibition Anticancer factor
Sphingolipids and metabolites	Anticholesterolemic Neonatal gut maturation Suppression of gastrointestinal pathogens
Xanthine oxidase	Bactericidal agent
Butyrophilin	Suppression of multiple sclerosis
Phospholipids	Colon cancer inhibition Protects the human gastrointestinal tract against toxic attack Reduction of necrotizing enterocolitis Antidepressant Anticholesterolemic Anti-Alzheimer
MFGM hydrolysates	Antimicrobial activity against pathogens
Mucins and glycoproteins	Inhibition of *Helicobacter pylori* Protective effect against rotavirus infections

[a]Data compiled from Kanno *et al*. (1991), Corredig *et al*. (1998), Roesch *et al*. (2004), Mistry *et al*. (1996), and Thompson *et al*. (2006).
[b]Data compiled from Spitsberg (2005), Clare *et al*. (2008), Hirmo *et al*. (1998), Hancock *et al*. (2002), and Dewettinck *et al*. (2008).

Technological Value

It has been reported that buttermilk can be used as an ingredient because of its good emulsifying properties and the positive impact on flavor and texture. Buttermilk is used in baking and dairy industries and in the preparation of dry mixes, sauces, chips, and chocolate products. In the baking industry, buttermilk is used to improve the flavor and texture of bakery products. The addition of buttermilk powder to flour for bread-making leads to a greater loaf volume, increases water absorption capacity of the flour, and improves softening and development time of the bread dough. In addition, several isolates of buttermilk and MFGM, such as polar lipids, are used to ameliorate fat dispersion and staling in baked goods, as additives to chocolate to reduce viscosity and prevent crystallization, as wetting enhancers to improve the wetting properties of instant products, and as stabilizers of margarine to prevent spattering and browning.

Because of the amphiphilic nature of the MFGM, isolated MFGM has been referred to as a functional ingredient in emulsions. However, the MFGM isolates from industrial buttermilk show inferior emulsifying properties compared to whole buttermilk because of the contribution of the skim milk-derived components in the latter. Differences in the functional properties of various buttermilk samples are attributable to differences in the composition of the samples and differences in the ratio of MFGM components to skim milk proteins, or of proteins to phospholipids. Because whey buttermilk has a different composition, it exhibits higher emulsifying properties and lower foaming ability, possibly due to its higher ratio of phospholipids to proteins compared with commercial sweet or sour buttermilk samples. Also, when looking at a purified phospholipid fraction from buttermilk, studies show that liposomes produced from MFGM fractions by a microfluidization technique have different structural composition and properties than those prepared from soy- or egg-derived phospholipids. It has also been suggested that buttermilk may help stabilize food products against lipid peroxidation. Concentrations in the range of 0.1–0.2% were proven to be effective in delaying the propagation stage of lipid oxidation, although no significant differences from the control were noted during the onset of the reaction.

In the dairy industry, the addition of sweet buttermilk has been shown to improve cheese yield during pizza cheese-making. The cheese made with added buttermilk also showed a reduced amount of free oil. High levels of buttermilk, however, adversely affected the quality of pizza cheese. The potential use of MFGM fractions or ultrafiltered buttermilk retentate to change the structure and properties of various dairy products has also been studied. MFGM fractions prepared from pasteurized cream were retained better in the cheese curds than MFGM prepared from raw cream. When buttermilk ultrafiltrate or condensed buttermilk is used in cheese, usually levels of substitutions higher than 10% result in changes in the structure and quality of the cheese curds, including an increase in moisture retention. The heating process that the cream undergoes before butter-making promotes significant whey protein denaturation and therefore poor rennet coagulation properties of buttermilk are seen. The presence of whey protein aggregates is also the reason for the increase in cheese yield and moisture retention. An enhancement of flavor development and mouthfeel, body, and meltability has also been reported after the addition of buttermilk to reduced-fat cheese. Buttermilk is also used as a heat stability enhancer in dairy products, which results from its low calcium and β-lactoglobulin content and a high non-micellar casein concentration. Applications include improving the heat stability of reconstituted concentrated milk and whey powder (when added to milk before evaporation and drying). These observed effects widen the range of possible applications of buttermilk-based ingredients in dairy products.

In conclusion, the technological functionality of buttermilk can be attributed not only to the skim milk proteins, but also to the presence of MFGM fractions. However, studies on the functionality of the MFGM are still needed, as inconsistent results are often obtained, most likely because of the different treatments applied to and the variability of the sources of commercial buttermilk. Additional factors influencing the technological properties include the dairy source, the methods of MFGM isolation, and the temperature history of the product.

Nutritional Value

Although there is evidence of the nutritional functionality of the various components of the MFGM and buttermilk, the potential of the MFGM as a whole, as an ingredient beneficial to health, has not been elucidated. Controversy exists on the effect of MFGM components on health and disease. While some investigators have suggested that MFGM fractions have beneficial properties such as inhibiting the growth of cancer cells, lowering cholesterol adsorption, inhibiting pathogen adhesion to intestinal cells, or even antimicrobial properties, other researchers have reported adverse effects of buttermilk consumption in relation to certain human pathologies including coronary heart disease and autism. Notwithstanding, published epidemiological results on the latter area are contradictory and hence should be taken with caution.

On the positive effect of MFGM on health, glycosphingolipids stand out. These minor constituents of MFGM and their catabolites are involved in various biological functions such as cell–cell interactions, differentiation, proliferation, immune recognition, and transmembrane signaling, and also function as receptors for certain hormones. One study reported the marked intracolonic efficacy of MFGM in inhibiting intestinal β-glucuronidase in mice, suggesting its potential role in the treatment or prevention of colon cancer.

MFGM is rich in glycosylated proteins, and most of them are still not well understood. Their bioactivity, especially as physiological regulators, is a major area of current investigations. Milk glycoproteins derived from the MFGM have been linked to inhibition of pathogen adhesion in the gut. Sialic acid residues seem to be the principal cause for this bioactivity, because they confer a strong negative charge on epithelial cell surfaces, which translates into the prevention of wall to wall adherence and attachment of bacteria and pathogens to the gastrointestinal mucosa. It is known that the first stage of bacterial colonization is attachment and many pathogens use carbohydrate-binding proteins to attach to cells and begin the infection process; hence, mucins and other mucin-like proteins present in buttermilk and MFGM isolates may exert a positive effect on the prevention of infections. The inhibition of binding of enterotoxigenic *Escherichia coli* to the intestinal epithelial cells and guinea pig erythrocyte membrane, as well as the interference by mucin of the binding of *E. coli* to buccal mucosa, has been shown.

MFGM isolates were also proven effective in the inhibition of *Helicobacter pylori* infection in a BALB/cA mouse model and in the inhibition of hemagglutination and adhesion of *H. pylori* in cell monolayers. In this study, MFGM isolates were obtained directly from bovine buttermilk using ultrafiltration and diafiltration. Both defatted and non-defatted fractions caused similar effects, suggesting that the bioactivity was a result of the proteinaceous components of the MFGM. A similar effect has been suggested for rotavirus infections, which has been attributed to the glycoproteins PAS 6 and PAS 7.

Evidence is also accumulating on the positive effect of consumption of polar lipids and their human health-promoting properties. Phospholipids represent the most abundant species of polar lipids in the MFGM, and are known to affect beneficially diverse cell functions including absorption of nutrients, molecular transport, growth and development, stress response, regulation of the nervous system, and cancer development. In addition to their protective gastrointestinal functions, several antimicrobial functional properties of MFGM fractions have been proposed. Fractions of either raw or protease-digested MFGM were tested against several pathogens including *E. coli* O157:H7, *Listeria monocytogenes*, *Salmonella enterica Typhimurium*, and *Bacillus cereus*, and their effects were compared to treatments with XO alone. It was found that these MFGM hydrolysates have variable antibacterial activity against all of the above bacteria, and that the effect was not necessarily attributable to enzymatic activity of XO. Similar results were obtained after testing different triglycerides and membrane lipids; it was concluded that milk fat sphingolipids and triglycerides, particularly those containing C10:0 and C12:0 fatty acids, may protect against food-borne gastroenteritis.

Finally, considering the many similarities between the components of the MFGM and that of intestinal cells, it has been suggested that two types of lipid-binding activity can be found: (1) that involving the nonpolar lipids, in which the concentration of lipids can affect the affinity of lactic acid bacteria, and (2) that involving the polar lipids, with which, regardless of composition, each strain of lactic bacteria shows specific binding activity. It has been suggested that there may be different degrees of lactic acid bacteria binding depending on the processing history and nature of the MFGM isolation method.

Conclusion

Buttermilk, the by-product of butter manufacture, is a complex mixture of components with important value not only technologically but also nutritionally. Isolates rich in MFGM can be obtained from buttermilk, but there are still important questions related to understanding the biological functions of the MFGM and its components. Its effect on human health is still under investigation. The question of whether MFGM plays a role in interactions between fat globules and in intestinal cells still remains unanswered. In addition, its nutritional significance in the light of its protective effect on the gastrointestinal tract is still unclear. However, it is also very important to note that the properties and composition of buttermilk and MFGM isolates are very sensitive to processing treatments and milk handling procedures; therefore, research is needed to understand if and when during processing biological functionality is lost, so that technologies and processes can be designed to scale up the production and isolation methods to optimize biological functionality.

Fatty Acid Analysis

General Remarks

The fatty acid composition yields information about the relative proportions of the principal fatty acids in a product, giving clues about its origin and properties, and about the classes of fatty acids present (e.g., saturated fatty acids, or ω-3 fatty acids, for nutrition information panels). Fatty acids may also be determined individually in a product (e.g., linoleic acid in infant formulae).

Although the analytical procedures are mostly straightforward, care is needed if valid results are to be obtained. Milk fat contains a wide range of fatty acids, with relative molecular masses ranging from 88.1 for butyric acid (C4:0) to 340.6 for docosanoic acid (C22:0), esterified in triacylglycerols of widely varying melting points. This is a wider range than most common fats and oils and is the reason that milk fat analysis requires extra care. Fatty acid composition results are only as good as the lipid sample, and it is critical that the analyst obtains a sample that is truly representative of the product. The sample must be melted fully and thoroughly mixed before the test portion is removed.

For most purposes, an alkaline digestion method is recommended (Roese-Gottlieb or Mojonnier). Samples containing a significant proportion of phospholipids should be mixed with a sodium chloride solution prior to extraction. For total extraction of lipids from foods and plant and animal tissues, a chloroform/methanol mixture (2:1) can be used (Soxhlet, Folch, or Bligh and Dyer methods). Accelerated solvent extraction is also suitable, provided appropriate extraction conditions (solvent and temperature) are employed. The International Dairy Federation (ISO/IDF) has specified methods for the extraction of milk lipids from a range of dairy products. Acid digestion methods (Schmid-Bondzynski-Ratzlaff (SBR) or Gerber) are not suitable.

Methods

Gas chromatography (GC) of methyl esters is the usual method for determining the fatty acid composition. Fatty acid methyl esters (FAMEs) are formed by direct transesterification of the fat. If it is desirable to reduce the volatility of the short-chain fatty acids, then isopropyl esters or butyl esters can be used. Temperature programming of the gas chromatograph is required to achieve optimal separation of milk fat esters. Detection is by means of the flame ionization detector (FID), which is inexpensive, reliable, sensitive to hydrocarbons, and has a wide linear dynamic range. Gas chromatography–mass spectrometry (GC–MS) is also popular for the increased degree of certainty around identification of the fatty acids.

High-performance liquid chromatography (HPLC) has not been the method of choice, as capillary GC provides superior separation in a much shorter run-time. However, the availability of ultra-performance liquid chromatography (UPLC) and ultra-fast liquid chromatography (UFLC) instruments combined with new column technologies and highly sensitive tandem mass spectrometry detectors now makes liquid chromatography a viable alternative to GC.

Gas Chromatographic Analysis of Fatty Acids

International Organization for Standardization (ISO) and IDF have jointly published standard methods for the preparation of milk fat FAMEs, and determination of the composition by GC-FID. A method for the determination of specified ω-3 and ω-6 fatty acids has also been published. The other commonly used method in the food industry is the Association of Official Analytical Chemists International (AOAC) method 996.06, which determines total fat and saturated and unsaturated fatty acids in foods. Compared to the IDF methods, the AOAC method uses a different methylation reagent and a more polar column that is also significantly longer (100 m).

For preparation of the methyl ester derivatives, alkaline methylation is usually used (sodium methoxide or potassium hydroxide in methanol) and is suitable for trans esterification. Where free fatty acids or sphingomyelin-based fatty acids are to be detected, an acid catalyst (a methanol solution of boron trifluoride, sulfuric acid, or hydrochloric acid) is required. Boron trifluoride is known to generate artifacts, and under extended heating also leads to the degradation of conjugated linoleic acid (CLA) and the loss of butyric acid. Other reagents proposed include boron trichloride in methanol, tetramethylammonium hydroxide (TMAH), and acetyl chloride in methanol. All of the catalysts require neutralization after a certain time (6 min is often recommended) to prevent degradation of the esters formed.

Capillary GC columns give excellent separation of FAMEs, and there is no reason to use packed columns. On polyethylene glycol (PEG)-based phases such as WAX-type columns, fatty acids separate in the order of chain length and degree of unsaturation, with very little overlapping of peaks (**Figure 1**). More polar specialist phases based on cyanosilicones have been developed to provide optimal separation of the *cis* and *trans* isomers, and are used when determining *trans* fatty acids in milk fat, albeit with more overlaps of the different chain lengths. Free fatty acids can be separated underivatized on free fatty acid phase (FFAP) type columns, in which the PEG has been modified with nitroterephthalic acid to achieve greater polarity; however, this requires higher instrument temperatures for elution than for FAMEs.

On-column injection is preferred over split injection because the volatile short-chain esters can be lost disproportionately if split injection is used. In either case, an auto-injector is recommended to maximize the repeatability of injection.

FAME separations are usually predictable, and the major fatty acids can be identified easily by comparison of peak retention times with a standard chromatogram. In case of retention time shifts, relative retention times can be compared, as they change much less than the actual retention time. In cases of doubt, the FAME solution can be spiked with an appropriate concentration of standard FAME. Alternatively, the sample can be submitted for GC–MS, although it can be difficult to categorically distinguish two or more co-eluting fatty acids. More sophisticated techniques are required for charting the positions of double bonds (see section ‘Stereospecific analysis’).

Fatty acids are quantified using response factors to account for the differing response of short- and long-chain fatty acids in the FID. Most of the standard methods use empirical response factors based on a solution of injected FAME standards, although a strong case has been put for the validity of theoretical response factors, provided the detector has been optimized properly. Fatty acid profile results are often reported as mass percent of total fatty acids (normalization). When only selected fatty acids are to be determined, a known amount of internal standard is added prior to derivatization, and the fatty acids are quantified relative to the internal standard and reported on a product basis.

Evaluation of Results

While the composition of milk fat varies with species, diet, and lactation stage, certain features are typical. Butyric acid (C4:0) and CLA are present in the milk of cows, sheep, buffalo, and goats, and their absence means the fat is not that of a ruminant. Palmitic acid (C16:0) is almost always the most abundant, except in soft-fraction milk fats, where oleic acid (C18:1*cis*) predominates. A reasonable estimate of the identities of two fats mixed together can often be made, but may be impossible if the fats are similar in composition or there is only a small amount of one in the other. In these cases, analysis of the triacylglycerols is required (see next section).

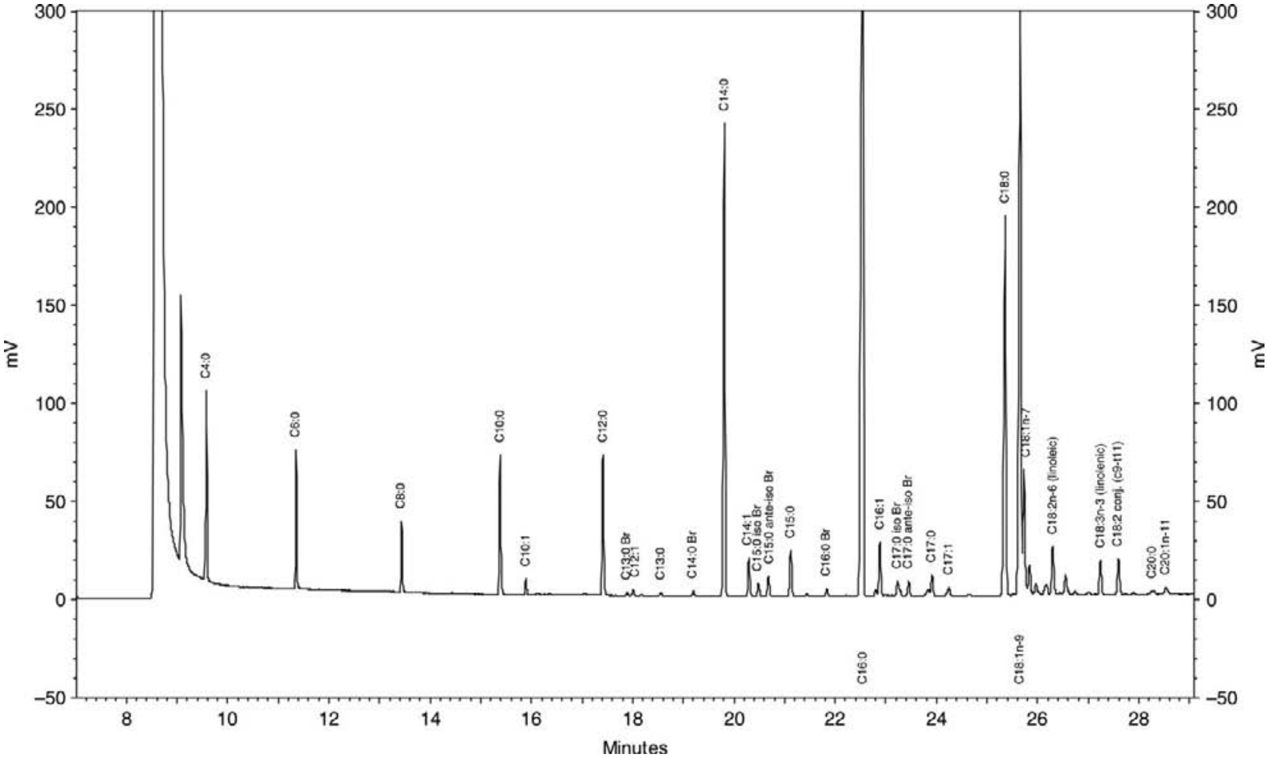

Figure 1 Bovine milk fat fatty acid methyl esters on an FFAP column, which is a modified PEG column.

Triacylglycerol Analysis

The properties of fats rely not only on the fatty acid constituents, but also on the way the fatty acids are arranged on the glycerol backbone. This produces triacylglycerols with a wide range of molecular weights and the accompanying wide range of physical properties (e.g., melting point). For the identification of fats and the overall properties of the fat, the analysis of the intact fats is very important.

The individual triacylglycerols can be categorized by their acyl carbon number (ACN or CN), which is the sum of the carbons of the three fatty acid constituents. For example, the triacylglycerols 16:0/16:0/16:0 and 18:0/16:0/14:0 both have ACN = 48.

Gas Chromatography

The analysis of triacylglycerols by GC requires high temperatures to volatilize the sample due to the approximately 3 times higher molecular weight compared to the individual fatty acids (350–400 °C for elution of milk fat) and is best carried out with on-column injection to avoid sample discrimination. Using short non-polar capillary columns, the triacylglycerols of milk fat can be separated simply by ACN (with no contribution from the different degrees of saturation). This provides a very simple trace (milk fat also has odd-numbered ACN, from the odd-numbered fatty acids) with which to compare the basic triacylglycerol composition of different milk fats, and especially for distinguishing samples of milk fat from other oils (**Figure 2**). Indeed this is the basis of an IDF method for the testing of adulteration of milk fat with other oils and fats (IDF 202:2010). The lack of influence of the degree of unsaturation becomes an advantage in this case as partially hydrogenated oils show the same peaks as their natural oil feedstocks (same ACNs), making determination and identity of the adulterant much simpler. Thus, the degree of hydrogenation of the adulterant is not a complicating issue. The basis of this method is the detection of samples that are outside the expected range for milk fat utilizing those peaks that differ most between the oil and milk fat. Note that in this method, the odd-numbered ACN peaks, if separated, are combined with their nearest lower even-numbered ACN peaks.

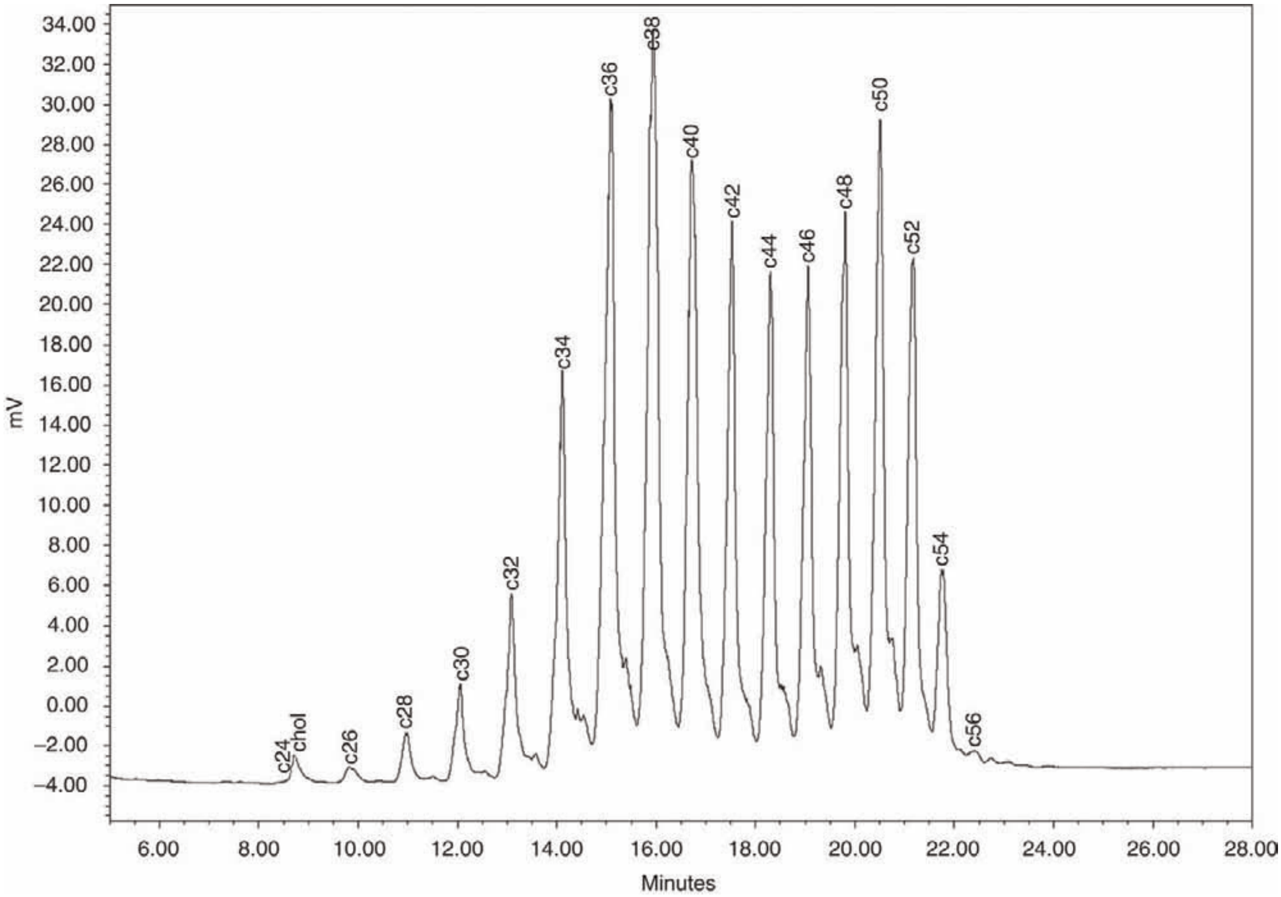

Figure 2 High-temperature gas chromatography of milk fat triacylglycerols, separated by acyl carbon numbers (ACNs) (van der Does and MacGibbon, personal communication). The small ACN 24 peak elutes just before the cholesterol peak.

With more polar columns, the single ACN peak splits due to the triacylglycerols with different numbers of double bonds having different interactions with the column and thereby eluting slightly differently. Realistically, because of the complexity of the triacylglycerols in milk fat, it is only when very polar columns are used that the separation becomes significant enough to show separate quantifiable peaks.

High-Performance Liquid Chromatography

Separation by reversed-phase HPLC (RP-HPLC) has been used in a similar manner to the very polar GC columns. The separation that occurs during RP-HPLC of triacylglycerols is based on both the chain length and the number of double bonds. A common expression that describes the influence of the two factors is

$$\mathrm{PN} = \mathrm{ACN} - (a' \times \mathrm{DB})$$

where PN is the partition number, ACN is the acyl carbon number, DB is the sum of the double bonds, and a' is the affinity factor of the double bond interaction. The affinity factor is often about 2, though it depends on the column and the solvent system. The double bond separation is reflected within each ACN group, so the trace shows a periodicity which greatly enhances identification. The elution order in RP-HPLC shows increasing ACN and decreasing number of double bonds, so for the same ACN, the species with the greatest number of double bonds elutes first. One study showed that this system could easily identify 61 different groups of triacylglycerols. In that case, a C18 column was used with a solvent system of acetonitrile and dichloromethane. However, even with that separation, there can be about 10 different triacylglycerols under the same peak, so the separation is by no means a complete separation of individual triacylglycerols (**Figure 3**).

Some work has been carried out on normal-phase HPLC, and in this case the elution order is decreasing ACN and increasing number of double bonds. This uses a silica column and a solvent system of hexane and hexane/methyl-*tert*-butyl ether/acetic acid. This method is complementary and in some cases shows better separation based on chain length within the ACN, but not as much by double bonds. It has been used for stereospecific determinations.

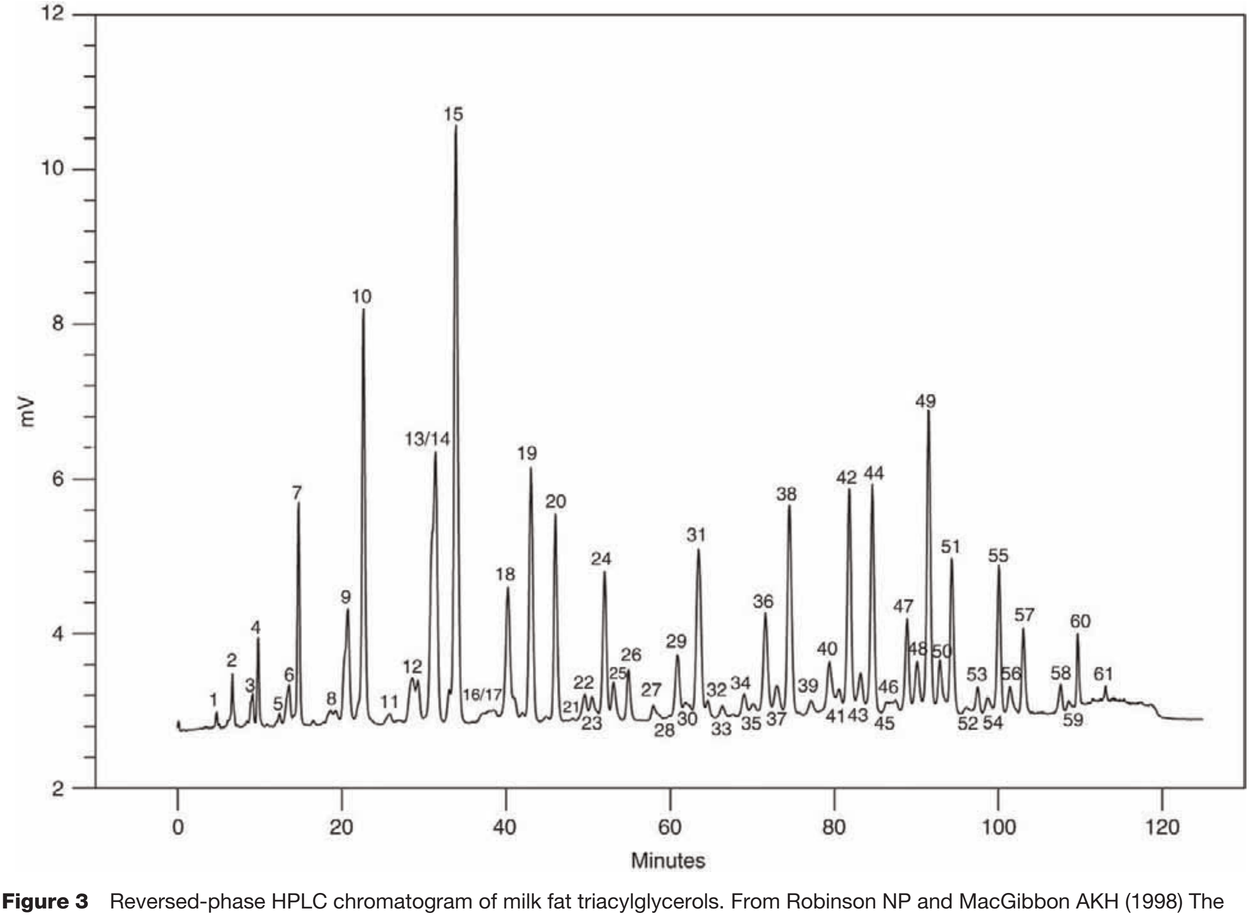

Figure 3 Reversed-phase HPLC chromatogram of milk fat triacylglycerols. From Robinson NP and MacGibbon AKH (1998) The composition of New Zealand milk fat triacylglycerols by reverse-phase high-performance liquid chromatography. *Journal of the American Oil Chemists' Society* 75: 993–999.

While HPLC allows great flexibility in separation conditions, for lipids it does have one disadvantage and that is in quantitation. Unlike the extremely linear response of the FID detector of GC, the HPLC detectors for lipids are less precise. For fats, the general UV response, refractive index, and more recently evaporative light scattering detection (ELSD) have been the means of observing the elution of lipids from the column. Particularly the ELSD can be very reliable; however, it does require calibration to ensure quantitation.

Mass Spectroscopy

The identification of triacylglycerols has been greatly enhanced by mass spectroscopy. This allows identification based on the molecular mass and can easily distinguish species on the basis of the number of double bonds (a decrease in mass of 2, compared to the saturated species for each double bond). The first mass spectral analyses were carried out using electron impact (EI) ionization; however, the introduction of electrospray ionization (ESI) to the analysis of lipids has rapidly increased the use of mass spectrometry in the area. ESI is a soft ionization technique that can result in little fragmentation, enabling the molecular ion to be observed, which is critical for the identification of the triacylglycerol molecule. The ions are usually $[\mathrm{M+NH_4}]^+$ or MH^+, although lithium ions have also been used. Further fragmentation of a particular molecular ion enables the identity of the fatty acid constituents to be determined (MS-MS). The ability to combine HPLC separation and MS has made this method extremely useful, although quantitation requires extra care as the response of the fatty acids differs. However, while the identity of the fatty acids may be determined, the position on the glycerol backbone is not so easily determined.

Stereospecific Analysis of Triacylglycerols

The position of the fatty acids on the glycerol backbone has an influence on the physical properties of the triacylglycerols (e.g., crystallization and melting point) as well as the nutritional properties (**Figure 4**). In digestion, pancreatic lipase attacks the *sn*-1 and *sn*-3 positions releasing the fatty acids while the fatty acid at the *sn*-2 position remains as a monoacylglycerol. Thus, depending on the position of the fatty acid, there are different impacts on absorption and subsequent metabolism (*sn*-2 fatty acid being largely retained in subsequent synthesis of the phospholipids and triacylglycerols). For example, in human milk, the palmitic acid tends to be bound at the *sn*-2 position and is absorbed by the infant as the more soluble monoacylglycerol, rather than the less soluble free palmitic acid, which would occur if it was on the other positions.

Triacylglycerol skeleton
A
B
C
sn-1
sn-2
sn-3

Figure 4 Fatty acid distribution on triacylglycerol.

Milk fat is unusually complex both in the number of fatty acids and in the stereochemistry of those fatty acids. Many oils exhibit regiospecificity (i.e., differences between *sn*-2 and *sn*-1,3); however, milk fat shows stereospecificity (i.e., differences between *sn*-1, *sn*-2, and *sn*-3) and so the full determination is more difficult. The specificity of *sn*-3 for C4:0 is an example of this difference between the *sn*-1 and *sn*-3 positions of milk fat.

Regiospecific Analysis

For regiospecific analysis, the traditional use of porcine pancreatic 1,3 lipase has proved effective and has been used in many studies. The 2-monoacylglycerol produced is separated and the fatty acid content is measured and the 1,3 mixture is determined from the original fatty acid content and the *sn*-2 fatty acid content.

$$sn\text{-}1 \text{ and } sn\text{-}3 = \frac{((3 \times \text{total}) - sn\text{-}2)}{2}$$

The other two positions cannot be differentiated and so have to be calculated as having the same fatty acid composition. This information is useful in digestive models and for some oils where the *sn*-1 and *sn*-3 compositions are similar.

In electrospray mass spectrometry, it has been observed that under certain conditions the response to further fragmentation of the molecular ion is regiospecific and that the different responses can be used to identify the *sn*-2 from the *sn*-1,3 position fatty acids. This is a huge advantage as it determines the regiospecificity for the single triacylglycerol molecular ion, rather than the bulk properties of the whole mixture.

Stereospecific Analysis

There is no lipase specific for only the 1 or 3 position and so stereospecific analysis requires a multi-step approach. Grignard reagent (EtMgBr) is used to produce 1,2 and 2,3 diacylglycerols. These are then reacted to form phospholipid-like molecules (with the phosphorus moiety at the *sn*-3 and *sn*-1 positions, respectively). Snake venom *sn*-2-specific phosphatase A2 reacts only with molecules that have the phosphorus moiety at the *sn*-3 position, hydrolyzing the *sn*-2 position fatty acid to produce only the lysophosphatide-like molecule with the remaining fatty acid retained at the *sn*-1 position. Also in the mixture are the free fatty acid from the *sn*-2 position, and the unreacted molecule with the fatty acids at the *sn*-2 and *sn*-3 positions and the phosphorus moiety at the *sn*-1 position. The molecules are separated and the fatty acids determined on a molar basis for the first two species; the last containing two fatty acids and so is not unique. The *sn*-3 fatty acids are determined by subtraction:

$$sn\text{-}3 = (3 \times \text{total}) - sn\text{-}1 - sn\text{-}2$$

Originally, Brockerhoff used phenyldichlorophosphate to form the phospholipid-like molecule; however, although the overall method has stayed remarkably similar, it is straightforward to form the phosphatidylcholines, a more natural substrate.

More recently, researchers have used chiral chromatography to determine the stereochemistry. An example is the use of a chiral derivatizing agent to form diacyl-*sn*-glycerol urethane derivatives from the diacylglycerols. These are separated and analyzed. The separation depends on the differentiation not being masked by wide variation in the fatty acid components and so has not yet been generally used for milk fat.

Rheological Properties and Their Modification

A J Wright and A G Marangoni, University of Guelph, Guelph, ON, Canada

R W Hartel, University of Wisconsin-Madison, Madison, WI, USA

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Milk fat exhibits unique rheological properties and is largely responsible for the consistency and textural attributes of butter. Milk fat and butter consistency are related to their complex composition and their viscoelastic nature. Strategies for modifying the rheological properties of milk fat are reviewed, including modifications based on compositional and processing factors. The composition of milk fat can be modified by methods such as blending, feed modification, fractionation, and interesterification. Processing factors that influence butter rheology include the type of process (batch vs. continuous churning), cream aging conditions, seeding, plasticizing (post-working), and storage conditions.

Rheological Properties of Milk Lipids

Composition and Melting Behavior

The rheological properties of milk lipids, including butter hardness and spreadability, are directly related to their complex composition. Milk fat contains dozens of different fatty acids, including very short-chain saturated, medium- and long-chain saturated, and long-chain polyunsaturated fatty acids. It also contains a considerable amount of *trans* isomers. The complex variety of fatty acids results in potentially thousands of different triacylglycerol species, each with its own melting point. The overall dropping point of milk fat is approximately 34 °C. However, because of its compositional complexity, milk fat actually has a very wide melting range, between −40 and 40 °C. This results in a fairly wide range of plasticity where both solid and liquid fat are present. **Figure 1** shows the solid fat content of milk fat as a function of temperature.

Saturated fatty acids have higher melting points than unsaturated fatty acids because their chains can pack in a more dense and ordered fashion in the solid state. Long-chain saturated triacylglycerols ($C > 42$) provide significant structural stability to milk fat. Similarly, the melting point of a *trans* fatty acid is higher than the corresponding *cis* isomer. The high proportion of short-chain saturates in milk fat is significant because these confer similar softening properties as the unsaturated fatty acids. The stereospecific distribution of the fatty acids within the triacylglycerols also influences the melting behavior.

Spreadability

Butter has notoriously poor spreadability at refrigeration temperature, and poor structural stability, including oil and moisture migration, at room temperature. Generally, a fat containing 20–40% solids exhibits good plasticity; thus, there is a limited temperature range over which desirable spreadability is achieved. **Figure 1** demonstrates the problem of poor spreadability typically encountered at refrigeration temperatures (5–10 °C). Within this range, the solid fat content is very high. **Figure 2** shows the effect of solid fat content on milk fat hardness where hardness is the force constant, a measure of the solid-like character of the material.

Spreadability is a term commonly used to describe butter texture and refers to how easily the fat can be spread on bread. Because spreadability is inversely related to hardness, some instrumental measure of hardness is often taken as an indicator of spreadability. Typically, hardness is determined by measuring the depth to which a cone placed on the surface of a butter sample will penetrate the sample in a given period of time. **Figure 3** shows the correlation between yield stress determined by cone penetrometry and spreadability evaluated by a sensory panel.

Seasonal Variability

Differences in texture between butters can be attributed to differences in composition. Winter butter is markedly harder than summer butter and often exhibits poor spreadability. This is partly related to compositional differences of individual fatty acids. For example, winter butter typically has a higher palmitic acid content and a lower oleic acid content than summer butter. Because the texture of milk fat is intimately linked to the overall degree of unsaturation, differences observed between summer and winter butter are most frequently attributed to differences in iodine value. Winter butter has a lower iodine value, about 30, than summer butter, which is typically 36. This seasonal variation is related to the fact that the polyunsaturated content of fresh green fodder consumed by ruminants during summer is higher

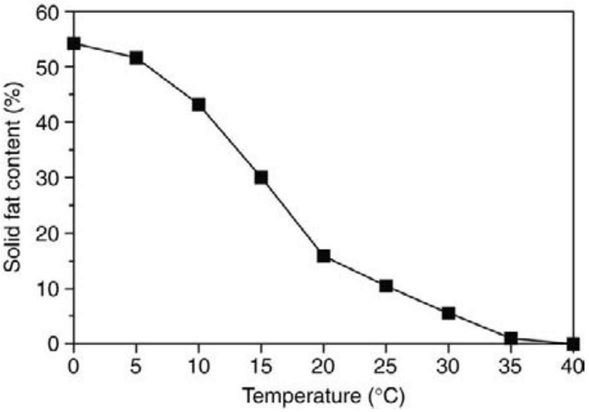

Figure 1 Solid fat content (%) vs. temperature (°C) for milk fat.

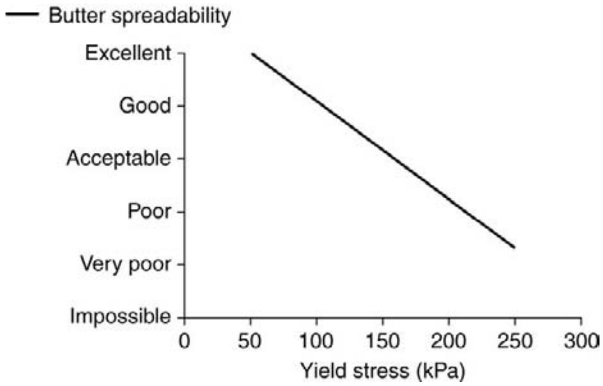

Figure 3 Butter spreadability determined by sensory panel vs. yield stress (kPa) determined by cone penetrometry.

than that of winter feed, which has undergone oxidation during storage. Seasonal variations have been related to specific triacylglycerol fractions present in the fat. Regional variations in butter firmness also exist and the stage of lactation can affect the textural attributes of butter.

Viscoelastic Nature of Butter

The fat crystals in milk fat and butter form three-dimensional networks and are closely associated with the continuous oil phase. As a result, these materials exhibit complex rheological behavior. Milk fat and butter display non-Newtonian plastic behavior and flow when the yield value is exceeded. Butter behaves as a pseudoplastic fluid because it exhibits shear-thinning. The typical flow behavior of semisolid milk fat is shown in **Figure 4**.

While the ratio of solid to liquid fat is the most important factor in determining butter consistency, the theories of viscoelasticity are useful in explaining the complex behavior. Over its melting range (between −40 and 40 °C), milk fat exhibits both solid- and liquid-like characteristics and behaves as a viscoelastic material. Four mechanical models used to describe the viscoelastic behavior of butter include Diener and Heldman's viscous Maxwell–Bingham model, the modified Bingham Body proposed by Elliott and Ganz, Tanaka's viscoplastic model, and the generalized yield-Maxwell model described by Awadhwal and Singh. **Figure 5** shows the frequency dependence of the storage and loss moduli of milk fat at low frequencies. Also, the low value of the loss tangent ($\tan\delta$), approximately 0.15, demonstrates the solid-like nature of milk fat at 5 °C.

The relationship between the storage modulus determined by small deformation oscillatory rheometry and hardness index determined by cone penetrometry for milk fat–canola oil blends is shown in **Figure 6**. Viscoelastic principles and testing are being used increasingly to characterize milk fat consistency and to explain the rheological properties of butter.

Modification of Rheological Properties

Composition-Related Modifications

Blending and modification of feed unsaturation

Because poor butter texture has been associated with low iodine values, some attempts to improve its consistency have focused on increasing the iodine value of butter. Two ways by which this has been accomplished include blending with unsaturated oils and modifying feed to include more polyunsaturates. Blending milk fat with vegetable oils serves to increase the overall level of unsaturation and reduces the melting point. **Figure 7** shows the decrease in melting point and hardness index when canola oil is blended with milk fat.

Blending with vegetable oil improves cold temperature spreadability, but can have deleterious effects on stability at higher temperatures. Also, strict legal definitions of butter in some countries prohibit blending with non-dairy oils. Milk fat has also been blended with tripalmitin and used as an alternative to hard milk fat fractions in applications including edible films with moisture barrier properties.

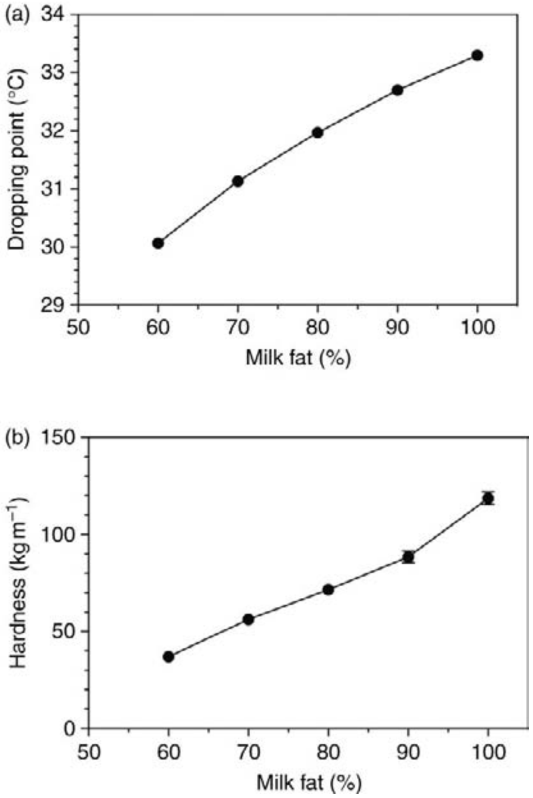

Figure 7 Melting point (°C) (a) and hardness (kg m^{-1}) (b) of milk fat–canola oil blends.

The iodine value of butter can be increased by changing the composition of animal feed to include more unsaturated triacylglycerols. Highly unsaturated vegetable oils can be encapsulated and included in a cow's diet. When the oils are encapsulated in formaldehyde-treated casein or consumed in the form of calcium salts, hydrogenation in the rumen is prevented. As a consequence, the fatty acyl chains are incorporated unaltered into the newly synthesized triacylglycerols. Modification of butter composition through animal feed, including for the purposes of improving texture, is a very active area of research. Similarly, butter texture can be manipulated for the production and sale of reduced-fat spreads by decreasing the typical 80% milk fat to 40% or less using non-fat milk water and including gelatin.

Fractionation

Fractionation can be used to modify the rheology of milk fat and can be accomplished by crystallizing the melted fat at a specific temperature and separating the crystals from the liquid oil by filtration or centrifugation. Crystallization in the presence of a solvent improves the separation of the crystalline mass from the oil; however, dry crystallization is preferred in food applications. Fractionation yields fractions of triacylglycerols that are chemically and physically distinct. Certain triacylglycerol fractions have been associated with butter hardness, as have individual triacylglycerols and fatty acids. Milk fat triacylglycerol fractions are typically distinguished from each other on the basis of their melting behavior. Accordingly, there are three main fractions of triacylglycerols: the low-melting, middle-melting, and high-melting fractions (LMF, MMF, and HMF, respectively). These fractions correspond to the three peaks observed for milk fat by differential scanning calorimetry. LMF is liquid at room temperature, owing to its higher content of long-chain unsaturated and short-chain saturated fatty acids. On the other hand, HMF is enriched in long-chain saturated acids and has a much lower content of long-chain unsaturated and short-chain saturated fatty acids.

Butter spreadability has been improved by fractionating milk fat and then recombining the fractions in different proportions. The addition of LMF to butter reduces its hardness by increasing the level of oleic acid and short-chain fatty acids. Alternatively, the addition of HMF leads to a firmer texture and reduced oiling-off and moisture migration at higher temperatures. In some regions, HMF and LMF butter are combined, achieving a very functional plastic spread. The milk fat fractions themselves have unique rheological properties. Because of its very solid nature and unique fatty acid composition, HMF has been used in puff pastries and as a partial cocoa butter substitute in confectionary products. Fractionation offers the possibility of improved butter texture and functionality, although the high costs associated are prohibitive on the largest scales.

Interesterification

Interesterification serves to change the behavior of milk fat by rearranging the fatty acids within and among the triacylglycerols. Both chemical and enzymatic interesterification with lipases cause randomization of the fatty acid distribution in the triacylglycerols. Both can improve the cold spreadability of butter, although the enzyme-catalyzed process is much more costly. **Figure 8** shows the changes in the melting profile of milk fat upon interesterification. The solid fat content at refrigeration temperatures is reduced, particularly in the enzymatically interesterified milk fat.

Milk fat interesterification causes a relative decrease in the C_{32}–C_{42} triacylglyerols and a relative increase in those triacylglycerols in the range of C_{44}–C_{54}. Further success has come from blending milk fat with canola oil and interesterifying the blends. **Figure 9** shows that interesterification of milk fat–canola oil blends leads to significant reductions in hardness. Unfortunately, the classic problem with interesterification of milk fat is a decrease in butter flavor intensity and the production of off-flavors.

Hydrogenation is used to alter the physical properties of fats by increasing their degree of saturation. Because this results in an overall increase in the firmness of the fat

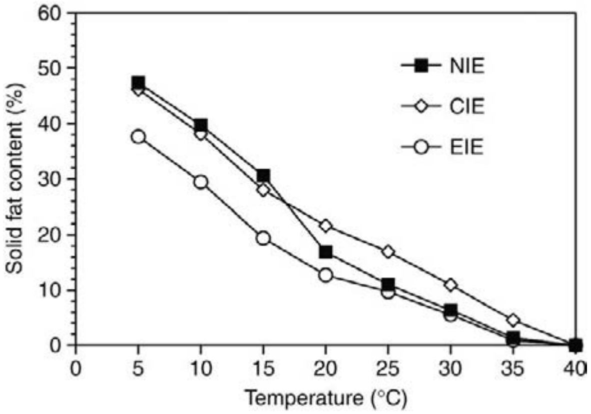

Figure 8 Solid fat content (%) vs. temperature (°C) of non-interesterified (NIE), chemically interesterified (CIE), and enzymatically interesterified (EIE) milk fat.

and does not lead to improved cold temperature spreadability, it is rarely applied to milk fat.

Surfactants in butter and alterations in the moisture and air contents

The techniques discussed for modifying butter texture thus far have focused specifically on milk lipids. The rheological properties of butter can also be altered by adjusting the non-triacylglycerol components. Surfactants have been added in order to improve butter spreadability, although, depending on the surfactant, this can result in deleterious effects. Also, the effectiveness of this approach is debatable because surfactant effects seem to be overcome during the normal setting period of butter. Butter consistency can be modified by adjusting moisture content, although this can affect stability at higher temperatures. In addition, an increased water content increases the potential for microbial spoilage and raises concerns about legal standards of identity. Increasing the air content of butter also serves to reduce its hardness. Whipped butter, in which air or nitrogen is incorporated, can offer improved spreadability, although a loss of butter aroma can occur and, if proper processing conditions are not met, there can be issues with crumbly texture. Butter can be treated under reduced pressure in a vaculator. The result is a decrease in air content and butter that, interestingly, is harder, but reported to have improved organoleptic properties and a glossy appearance. This contradiction is explained by the fact that under pressure, oil, which is originally adsorbed onto air bubbles, becomes free and alters the flow properties of the butter.

Process-Related Modifications

Batch versus continuous buttermaking

The type of manufacturing process and processing parameters influence butter texture. The replacement of many batch buttermaking facilities with continuous operations saw a pronounced change in butter texture. The continuous Gold'n Flow process produces firmer butter than historical batch churning. **Figure 10** shows the higher shear stress failure associated with continuously produced butter over that which is batch churned.

The more rapid cooling rate employed in the continuous process is largely responsible for the differences observed in slowly and rapidly cooled butters. Slow cooling of milk fat typically results in reduced hardness. **Figure 11** shows the higher penetration depth found over time for slowly cooled milk fat compared to that which was rapidly cooled.

The effect of cooling rate has been explained on the basis of mixed crystal formation, differences in crystal structures, and polymorphism. The increased solid fat content associated with a fast cooling rate in milk fat accounts for some of the increased hardness. Milk fat contains a number of similar triacylglycerols, which compete for positions in the growing crystal lattice during crystallization and, upon rapid cooling, tend to form mixed crystals. During slow cooling, there is time for the most compatible triacylglycerols to become incorporated into the growing crystal. However, at a high cooling rate, some of the less compatible triacylglycerols are incorporated. Cooling rate also affects crystal size and homogeneity. **Figure 12** shows that rapid cooling of milk fat results in the formation of many, small crystals, while relatively larger crystals form under slower cooling conditions.

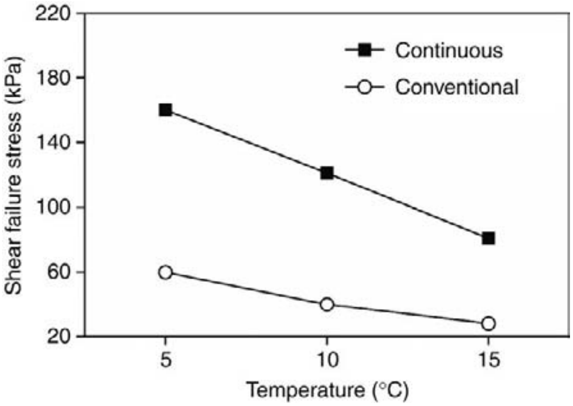

Figure 10 Shear stress failure (kPa) as a function of temperature (°C) for butters made by the conventional (batch churn) and continuous (Gold'n Flow) processes.

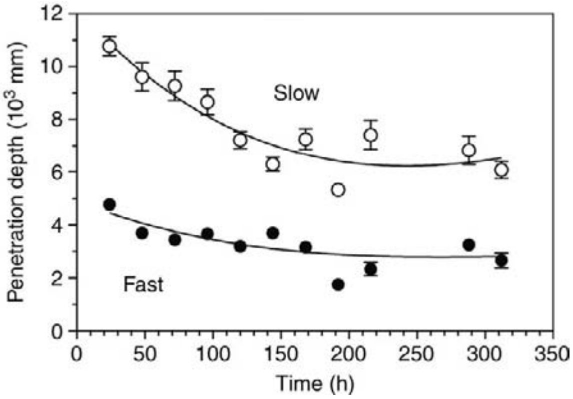

Figure 11 Penetration depth (10^3 mm) vs. time for slow (0.1 °C min^{-1}) and rapidly (5 °C min^{-1}) cooled milk fat at 5 °C.

It is postulated that rapidly cooled milk fat is firmer because the higher crystal surface area allows for more liquid oil to be tightly held by surface forces. Milk fat crystallization and the resulting microstructure are highly dependent on the degree of supercooling. Crystallization at higher temperatures results in a more spherulitic crystal microstructure, whereas at lower temperatures a more fine granular microstructure is observed. Slow cooling allows for more crystallization at the higher temperatures and can change the microstructure of the fat accordingly. Some attempts have also been made to explain the effects

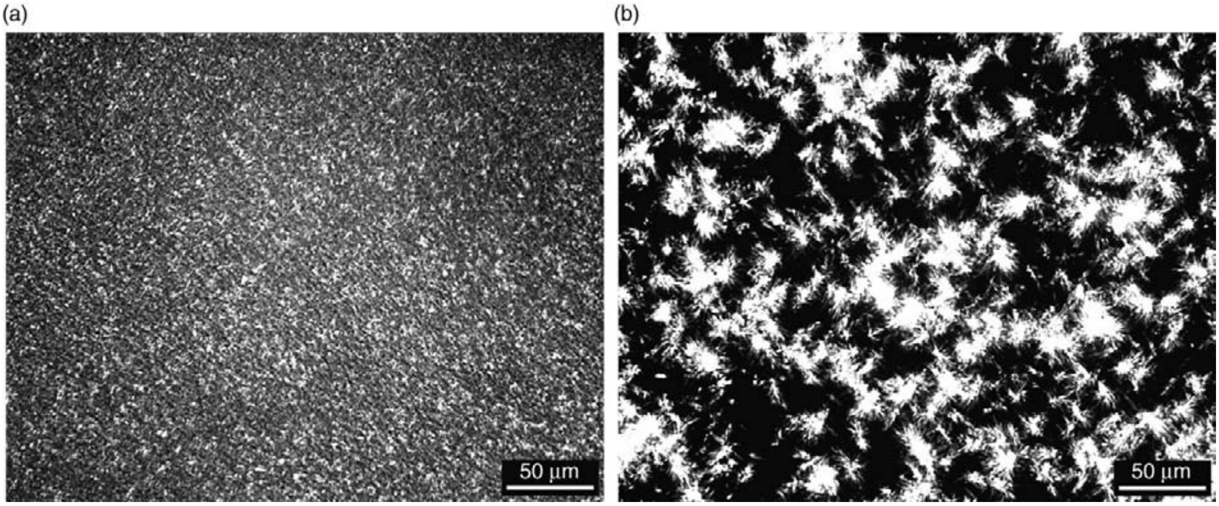

Figure 12 Polarized light micrographs of slow (0.1 °C min^{-1}) (a) and rapidly (5 °C min^{-1}) (b) cooled milk fat at 5 °C.

of cooling rate on polymorphism since polymorphism is affected by temperature conditions and is known to affect the macroscopic properties of several fats.

Cream aging, mechanical agitation, and seeding

The manufacture of continuously made butter typically involves aging the cream at a chilling temperature before manufacture. Prechilling leads to larger fat crystals and more free liquid fat, resulting in a high-quality butter. Cream ripening or tempering, as it is sometimes referred to, has been used industrially for decades and generally involves a cold–warm–cold treatment of the pasteurized cream. The ALNARP process for obtaining softer butter is one example of a commercially used ripening process.

Other processing parameters that can be controlled to improve the texture of butter include mechanical agitation of the cream and seeding with fat crystals early in the buttermaking process. Increased mechanical agitation promotes secondary nucleation and ultimately leads to more discrete fat crystals and a less firm fat at any given solid fat content. Seeding, or recycling, involves adding milk fat crystals to the cream during churning to seed the growth of larger, desirable crystals. While this can produce a softer fat, it unfortunately negatively affects the appearance of the product.

Plasticizing treatments

Commercial buttermaking operations include a mechanical treatment or plasticizing step after manufacture. This serves to soften the product. After mechanical working, butter exhibits thixotropic behavior in which there is a gradual recovery in its firmness. **Figure 13** shows the thixotropic hardening of butter after working.

Storage conditions

The storage temperature and the length of time for which butter is stored affect its firmness. At higher temperatures, the decrease in the amount of solid fat present results in a decrease in hardness. A phenomenon called setting, which is closely related to thixotropy, occurs especially in conventional butter after manufacture, even when stored at a constant temperature. Setting refers to the increase in the hardness of the butter over time and is thought to take place because of continued crystallization of some triacylglycerol species. Also, recrystallization of triacylglycerols, which melt because of heat introduced during working, occurs. The rate of change in hardness due to setting is most significant during the early time periods after manufacture.

Milk lipid rheology has been dominated by a desire to improve the cold spreadability of butter. Empirical tests can be used to measure butter consistency and often correlate well with sensory evaluated parameters like spreadability. However, milk fat and butter are complex systems. An understanding of the relationships between structure and rheological properties will help in achieving desired behaviors and textural attributes.

Introduction

Lipid is the collective term for a diverse range of molecules which have in common the characteristic that they are insoluble in water but soluble in organic solvents, such as ether or chloroform. This range of molecules includes triglycerides (also known as triacylglycerols), other glycerides, phospholipids, sterols, fatty acids, fat-soluble vitamins, all of which have nutritional significance. The overwhelming majority of lipid molecules in milk (approximately 98%) are triglycerides, with small amounts of sterols and phospholipids as the next most important categories.

Lipids typically contribute approximately 40% of total energy in Western diets. This level has fallen slightly in recent decades in many countries due to the availability and promotion of low-fat and reduced-fat foods. Milk and milk products typically contribute about 20% of daily fat intake in Western countries, that is, approximately 8–10% of total energy intake.

Lipids are significant in the diet in a wide variety of ways. They contribute to the palatability of foods by influencing taste, texture, and mouthfeel. They provide a concentrated source of food energy ($9\,\mathrm{kcal\,g^{-1}}$ or $38\,\mathrm{kJ\,g^{-1}}$). Lipids, when deposited as body fat, help protect vital body organs and provide a store of energy for long-term exertion. Food lipids are a source of fat-soluble vitamins (A, D, E, K) and essential fatty acids (linoleic acid and α-linolenic acid).

Considerable research effort over many decades has focused on the health effects of food (including milk) lipids. Dietary lipid intakes have been related to the so-called 'diseases of affluence', such as coronary heart disease (CHD), stroke, and certain cancers. However, in discussing the putative role of dietary lipids, it is important to note the multifactorial etiology of these diseases, that is, there are other risk factors, such as cigarette smoking, hypertension, genetic factors, obesity, diabetes, and exercise level. Indeed, many other dietary factors apart from lipid intake are known to influence chronic disease risk, for example, the protective effects of high intakes of fruit and vegetables are well recognized. Thus, when discussing the health effects of milk lipids in isolation, it is important to emphasize that no food or food constituent, such as fat, should be considered healthy or unhealthy *per se*. All foods and food constituents are to be considered in the context of overall dietary intake, that is, one can discuss healthy/unhealthy diets but not individual foods or food constituents.

Metabolism of Lipids

Digestion

Lipids are a heterogeneous group of molecules which are soluble in nonpolar solvents. Digestion of lipids must take place in the intestinal tract which is an aqueous polar environment and subsequent lipid transport in the blood is also in an aqueous environment. However, as described below, the body has devised means for overcoming this problem.

Digestion of fat is initiated by the action of lingual lipase which is secreted in the mouth. However, the major site of fat digestion is the duodenum. The churning action of the stomach creates a crude oil-in-water emulsion of the fat prior to its entry into the duodenum. In the duodenum, the emulsification of fat is enhanced by the action of bile salts and phospholipids which are released from the gall bladder.

Pancreatic juice supplies lipase which catalyzes the hydrolysis of triglycerides to fatty acids. Fatty acids are cleaved from positions 1 and 3 of the triglycerides, resulting in 2-monoglycerides. Pancreatic lipase has a poor ability to cleave the fatty acid from position 2. However, a process known as acyl migration may occur and the fatty acid may move to position 1 and subsequently be cleaved by lipase. Additionally, the 2-monoglycerides can be absorbed directly without further hydrolysis.

Bile acids play a key role in facilitating the action of pancreatic lipase on triglycerides. The bile acid molecules have both hydrophobic and hydrophilic regions. The former region interacts with the oil surface of the fat droplets while the latter region interacts with the aqueous phase in the duodenum. The association of the bile acids with the oil droplets also results in a negative charge on the surface of the droplets. This negative charge causes pancreatic co-lipase to be attracted to the surface of the oil droplets. Thus, a complex of bile acids, pancreatic lipase, and co-lipase act at the oil–water interface to release fatty acids from the triglyceride molecules. A pancreatic cholesteryl hydrolase releases free fatty acids from any cholesteryl esters present in the duodenum. Phospholipase A cleaves fatty acids from phospholipids to form lysophospholipids.

It has been shown that short-chain fatty acids, for example, butyric acid which is commonly found in position 3 of milk fat triglycerides, are released more rapidly from triglycerides by lipase action than longer-chain fatty acids. However, due to the relatively long time that fat resides in the duodenum, breakdown of triglycerides to fatty acids is virtually complete.

However, malabsorption of fat and the appearance of significant amounts of fat in the feces (steatorrhea) may occur in diseased states if insufficient pancreatic lipase, colipase, and bile salts are secreted into the duodenum or if the intestinal mucosal cells become diseased due to severe bacterial infection or conditions such as coeliac disease.

Absorption and Transport of Fats in the Body

Fatty acids with fewer than 12 carbons are generally absorbed directly across the intestinal wall into the bloodstream where they are bound to plasma albumin and transported to the liver.

Long-chain fatty acids, monoglycerides, cholesterol, and lysophospholipids form micelles in the gut with bile acids. These are then absorbed by the enterocytes that line the gut. In the enterocytes, the lipid digestion products are reassembled into triglycerides, cholesterol esters, and phospholipids. These molecules are immiscible or poorly miscible with water. This is a major issue as these molecules must be transported by the blood (an aqueous environment) throughout the body. This problem is overcome by the association of absorbed lipid molecules with proteins to form lipoproteins. The proteins perform a dual role. Because of their amphiphilic nature, the proteins facilitate transport of lipids in the bloodstream. Second, the proteins (mainly a protein called apolipoprotein B-48, which is present in chylomicrons) allow the lipoprotein particles to be recognized by receptors on cell surfaces throughout the body, thus facilitating the controlled uptake of lipoprotein particles from the bloodstream. Chylomicrons are the lipoprotein particles that are assembled in the enterocytes following digestion and absorption of dietary fat from the gut. The chylomicrons enter the lymphatic system and subsequently the blood following their release from the enterocytes.

The blood enzyme, lipoprotein lipase, is involved in releasing free fatty acids from triglycerides in the chylomicrons. These fatty acids are taken up by tissues (e.g., for storage as triglycerides in adipose tissue or metabolism in muscle tissue) and the remainder of the chylomicron particles (remnants) may pass to the liver.

Triglycerides and cholesterol may also be synthesized directly in the liver rather than derived from the diet. The triglycerides synthesized in this manner are transported mainly in the bloodstream in lipoprotein particles called very low density lipoproteins (VLDL). Cholesterol is transported primarily in either low-density lipoproteins (LDL) or high-density lipoproteins (HDL). Thus, all lipoproteins contain proteins, triglycerides, phospholipids, cholesteryl esters, and cholesterol in varying amounts which account for the differences in their density.

Lipids and Obesity

A considerable body of evidence worldwide indicates that obesity is associated with increased risk of morbidity and mortality from chronic diseases such as CHD and certain cancers. Dietary guidelines worldwide advise individuals to maintain desirable body weight by controlling food intake and by undergoing regular aerobic exercise. It is also recognized that fat distribution in the body is important in predicting risk for chronic diseases. Central obesity, involving fat deposition around the waist and upper body, is a significant risk factor for CHD. Lower body obesity, involving fat deposition around the hips and thighs, is a much lower risk factor.

As noted earlier, the energy value (known as the Atwater factor) for triglycerides is about 9 kcal g^{-1} (38 kJ g^{-1}). This compares with approximately 4 kcal g^{-1} (17 kJ g^{-1}) for both carbohydrates and proteins. Thus, the more fat in the diet, the more energy-dense it is. This energy density, however, makes fat a more attractive energy store in the body.

The degree of digestibility of a fat influences the metabolizable energy available to the body. Most fats, including milk fat, are digested almost completely by healthy individuals. However, long-chain (over 18 carbons) saturated fatty acids are slightly less well digested and absorbed than shorter-chain fatty acids. On the other hand, medium- and short-chain fatty acids have lower metabolizable energy values as they undergo different pathways of metabolism from longer-chain fatty acids. These short- and medium-chain fatty acids are absorbed primarily into the portal blood and metabolized in the liver rather than stored in adipose tissue. Milk fat from ruminant animals contains significant amounts of short-chain fatty acids; about one-third of milk fat triglycerides contain a butyric acid residue.

A number of studies have addressed the issue of whether dairy consumption is inversely associated with reduced risk of the metabolic syndrome (obesity, high blood pressure, abnormal blood lipids). Pereira and colleagues reported a 70% decrease in risk of the metabolic syndrome over a 10-year period in individuals with higher levels of dairy product intakes.

Lipids and Coronary Heart Disease

CHD is the major cause of mortality in Western societies. CHD involves the inability of the coronary arteries to supply sufficient blood, and hence oxygen, to the heart muscle, a portion of which may then die. A heart attack (infarction) is a sudden event involving blockage (thrombosis) of a coronary artery by a blood clot. If significant atherosclerosis is present, that is, an accumulation of plaque deposit in the artery lining resulting in a narrowing of the arteries, the formation of a blood clot is likely to be more serious and often fatal.

The 'lipid hypothesis', that is, that the etiology of CHD is influenced by dietary fat intake, has been researched extensively for many decades. This hypothesis is that dietary fat, in particular saturated fat, results in an elevation of the blood cholesterol level, which over time results in atherosclerosis. Eventually, a coronary artery thrombosis may occur, resulting in a heart attack.

It is thought that atherosclerosis is initiated by damage to a blood vessel wall. This damage may result from factors such as the action of lipid free radicals, reactive oxygen species, infective agents, mechanical stress due to hypertension, and autoimmune reactions. Smooth muscle cells and immune system cells known as macrophages have been shown to accumulate at the site of blood vessel damage. Lipids, principally cholesteryl esters, begin to accumulate at the point of damage as a form of plaque. This atherosclerotic plaque tends to accumulate macrophages which become engorged with lipids, principally from low density lipoprotein (LDL). These lipid-engorged macrophages are known as 'foam cells'.

The ability of dietary fat intake to modulate blood lipid levels has been recognized for nearly a century. Landmark studies were conducted in the 1960s by two independent research groups led by Ancel Keys and Mark Hegsted which systematically evaluated the effects of different types of dietary lipids on blood lipid levels in human subjects maintained under strictly controlled metabolic ward conditions. The human subjects were fed a wide range of fats and oils of varying fatty acid composition. These studies led to the development of equations that predicted the changes that would occur in blood cholesterol level following changes in the intake of dietary saturated fatty acids (SFAs), polyunsaturated fatty acids (PUFAs), and cholesterol. Keys and Hegsted independently showed that SFAs were approximately twice as effective in raising blood cholesterol level as PUFAs. Dietary cholesterol intake had a relatively minor influence on blood cholesterol level.

These early investigators studied the effects of dietary fat on total blood cholesterol and did not discriminate between different lipoprotein fractions. It is now recognized that dietary parameters influence the levels of different lipoprotein fractions in different ways. Furthermore, it has been demonstrated clearly that the levels of different lipoprotein fractions are related to the risk of CHD in different ways. Elevated levels of LDL have been shown to be a major risk factor for CHD. Likewise, low levels of HDL are a risk factor for CHD.

Research findings indicate that dietary intake of different SFAs influences blood cholesterol level to different degrees. Short- and medium-chain fatty acids (4:0 to 10:0), which are found in ruminant milk fat, have little or no effect on blood cholesterol level; furthermore, stearic acid (18:0) has little effect on blood cholesterol. Thus, only lauric (12:0), myristic (14:0), and palmitic (16:0) acids have a significant effect on blood cholesterol and, in particular, LDL cholesterol level.

Monounsaturated fatty acids (MUFAs), in particular oleic acid (18:1), have been evaluated for their ability to influence blood cholesterol level. Data indicate that MUFAs, when substituted for SFAs, tend to reduce total blood cholesterol level and, in particular, again, LDL cholesterol. PUFAs of the *n*–6 family (linoleic, 18:2, being the most important in the diet) have been shown to reduce blood cholesterol level. On the other hand, PUFAs of the *n*–3 family (primarily α-linolenic, 18:3, from plant oils and eicosapentaenoic, 20:5, and docosahexaenoic, 22:6, from fish oils) tend to lower blood triglyceride level to a greater extent than the cholesterol level.

Many of the studies on the effects of fatty acids on blood cholesterol have been highly controlled experiments. Prudence is required in extrapolating the results of these studies to free-living populations where people eat a wide variety of fats as part of a mixed diet. Milk fat is hypercholesterolemic when evaluated in controlled experiments. However, epidemiological studies on free-living populations tend to indicate that intake of milk and milk products does not increase blood cholesterol level significantly. Indeed, studies of the Masai tribe in east Africa indicate that they have very low blood cholesterol levels on a traditional diet rich in milk (primarily fermented) and other animal products. It has been suggested that the Masai may have low blood cholesterol levels due to their low caloric intake and, perhaps, an inherited ability to regulate blood cholesterol level at a low value. Other researchers have suggested that milk contains an unknown cholesterol-lowering factor which counteracts the theoretical hypercholesterolemic effect of milk SFA. However, evidence for such a factor is scant.

Further work has investigated the possibility that cultured and culture-containing milk products may be hypocholesterolemic. There is some evidence that increased gut colonization by lactobacilli, whether by ingestion of culture-containing products or by manipulation of gut pH to favor lactobacilli, may modify cholesterol metabolism. However, the evidence, at best, suggests that lactobacilli are responsible for only small reductions in blood cholesterol.

Conjugated Linolenic Acid (CLA) in Milk Fat

Extensive hydrogenation of ingested PUFAs occurs in the rumen of ruminants, catalyzed by the diverse microflora present. A further effect observed in the rumen is the possible disruption of the original methylene-interrupted (unconjugated) sequence of *cis* double bonds. *Cis–trans* isomerization may occur and double bonds may migrate along the fatty acid chain. A *cis–trans* conjugated double bond sequence may evolve:

$$\mathrm{CH_3-(CH_2)_4-CH\underset{\mathit{cis}}{=}CH-CH_2-CH\underset{\mathit{cis}}{=}CH-(CH_2)_7}$$

$$\mathrm{COOH}(9\text{-}\mathit{cis},12\text{-}\mathit{cis}\text{-}18{:}2,\ \text{linolenic acid})$$

is converted to

$$\mathrm{CH_3-(CH_2)_5-CH\underset{\mathit{trans}}{=}CH-\ CH\underset{\mathit{cis}}{=}CH-(CH_2)_7COOH}$$

$$(9\text{-}\mathit{cis},11\text{-}\mathit{trans}\ 18{:}2,\ \text{conjugated linolenic acid, CLA})$$

9-*cis*,11-*trans*-CLA is the principal isomer found (about 90% of total CLA) in biological systems but other isomers of CLA have also been identified. Milk fat and dairy products have very high concentrations of CLA, which vary with season and stage of lactation. Cheese is the best dietary source of CLA, with reported levels of 0.6 mg g^{-1} fat in blue cheese, 1.9 mg g^{-1} fat in Parmesan, and up to 8.8 mg g^{-1} fat in processed cheeses containing whey protein concentrate. CLA is also found in meat from ruminant animals.

Over the last two decades, there has been significant research effort on the potential health effects of CLA ingestion. Data indicate that CLA is anticarcinogenic in animal models. It has been suggested that it may be partly responsible for the reduced risk of breast cancer that has been reported in women with high milk consumption. The mechanism by which CLA may exert an anticarcinogenic effect is unclear. It may act as an antioxidant, it may influence eicosanoid metabolism, and it may inhibit biosynthesis of proteins and/or polynucleotides that may be involved in the cancer process.

It has been clearly shown that dietary CLA is incorporated into body tissues, such as adipose tissue, human milk, and blood cells. For example, one study has shown that the consumption of 112 g Cheddar cheese per day for 4 weeks significantly increased the level of CLA in blood.

Lipids in Infant Nutrition

There is universal agreement that human milk is the most appropriate food for healthy human babies born at full term. However, as many mothers do not wish or are unable to breast feed, a need has arisen for infant formulae, most of which are based on cow's milk. The formulae try to mimic the composition of human milk to the greatest degree possible, although it is impossible to fully achieve this objective. The concentrations of proteins and salts (sodium) in cow's milk are too high for infants. The fatty acid composition of cow's milk fat also differs very significantly from human milk fat. Furthermore, human milk fat tends to contain slightly more cholesterol than cow's milk fat.

The level of short-chain fatty acids (4:0, 6:0, 8:0, and 10:0) is much higher and the level of long-chain saturated acids (14:0, 16:0, and 18:0) is significantly higher in cow's milk than in human milk fat. Conversely, the content of MUFAs (primarily 18:1 but also 16:1) is significantly higher in human milk fat. Furthermore, the level of PUFAs in human milk fat is considerably higher than in ruminant milk fat; the long-chain *n*–3 PUFAs, which are present at trace levels in cow's milk fat, are present at quite high levels in human milk fat.

Newborn human babies have a significant need for lipids for membrane synthesis, particularly in the brain and nervous system. High levels of arachidonic (20:4, *n*–6) and docosahexaenoic (22:6, *n*–3) are present in membrane lipids of the brain and nervous system. The levels of their respective precursors, linoleic (18:2, *n*–6) and α-linolenic (18:3, *n*–3), are much lower.

The optimum ratios of *n*–3 to *n*–6 fatty acids and of precursors (18:2 and 18:3) to products (20:4 and 22:6) in infant formulae have not yet been definitively elucidated. However, it has been suggested that long-chain *n*–3 fatty acids and long-chain *n*–6 fatty acids should provide 0.25–0.5% and 0.35–0.7% of energy, respectively. Furthermore, the need for *n*–6 linoleic and *n*–3 α-linolenic acids has been estimated to be 5–6 and 1% of energy, respectively. In the past, higher levels of linoleic acid have been used but there is now increasing recognition of the importance of *n*–3 fatty acids.

Conclusions

Milk lipids play a positive role in the diet as a source of energy, fat-soluble vitamins, and essential fatty acids. Milk lipids also contribute to the palatability of the diet. Concerns have been expressed regarding the hypercholesterolemic effect of dietary SFAs. Milk lipids from ruminant animals are rich in short-chain fatty acids which do not exert a hypercholesterolemic effect. Of the longer-chain fatty acids in milk fat, only 12:0, 14:0, and 16:0 exert a significant hypercholesterolemic effect in controlled feeding trials with human subjects. However, the evidence that milk intake in free-living populations is hypercholesterolemic is poor. There is some evidence that CLA present in milk fat may exert beneficial health effects. While a reduction in lipid intake, including milk lipids, may be beneficial for obese and overweight individuals, it is important to place a reduction of dietary fat intake for the general population in the context of the need to alter other practices such as smoking and exercise, and control of blood pressure. An optimum diet should emphasize moderation and variety. Milk and milk lipids can certainly play their part in such a diet.

Lipid Oxidation

N M O'Brien and T P O'Connor, University College, Cork, Ireland

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Edible fats containing unsaturated molecules are susceptible to attack by molecular oxygen. This process is referred to as lipid oxidation and can give rise to undesirable volatile flavor compounds, potentially toxic oxidation products, and a general deterioration in the quality of the fat. Fat oxidation is influenced by a range of parameters including light exposure, temperature, presence of pro-oxidant metals, presence of antioxidant compounds, and the degree of unsaturation of the fat. The volatile flavor products of lipid oxidation include aldehydes, ketones, alcohols, esters, lactones, and hydrocarbons, of which the unsaturated aldehydes and ketones are primarily responsible for undesirable oxidized (rancid) flavors.

Lipid oxidation is a chain reaction involving initiation, propagation, and termination stages. Oxidation of unsaturated fatty acids results in the formation of odorless, tasteless intermediate products known as fatty acid hydroperoxides. These compounds are unstable and can degrade via a variety of pathways, ultimately yielding volatile flavor products. Inhibiting the progress of lipid oxidation in foods, including milk and milk products, is a key factor in maintaining quality and extending shelf life.

Milk is a complex biological matrix which contains many factors that can exert antioxidant and/or pro-oxidant effects. Subsequent processing and storage of milk may also exert a profound influence on the progress of lipid oxidation.

Mechanism of Lipid Oxidation

The fundamental principles of lipid oxidation were elucidated in the 1940s and are widely accepted. Oxidation of unsaturated edible fats (RH) is a free-radical process that involves initiation, propagation, and termination steps. These can be outlined as follows:

Initiation

$$\underset{\text{(fatty acid, free or esterified)}}{\mathrm{RH}} \rightarrow \underset{\text{(alkyl radical)}}{\mathrm{R^\bullet + H^\bullet}}$$

Propagation

$$\mathrm{R^\bullet + O_2} \rightarrow \underset{\text{(peroxy radical)}}{\mathrm{ROO^\bullet}}$$

$$\mathrm{ROO^\bullet + RH} \rightarrow \underset{\text{(hydroperoxide)}}{\mathrm{ROOH}} + \mathrm{R^\bullet}$$

$$\mathrm{ROOH} \rightarrow \underset{\text{(alkoxy radical)}}{\mathrm{RO^\bullet}} + \underset{\text{(hydroxy radical)}}{\mathrm{^\bullet OH}}$$

$$\mathrm{RO^\bullet + RH \rightarrow ROH + R^\bullet}$$

$$\mathrm{^\bullet OH + RH \rightarrow H_2O + R^\bullet}$$

$$\mathrm{RO^\bullet + ROOH \rightarrow ROH + ROO^\bullet}$$

$$\mathrm{ROOH} \rightarrow \text{Nonradical end products, for example, aldehydes}$$

Termination

$$\mathrm{R^\bullet + R^\bullet \rightarrow RR}$$

$$\mathrm{RO^\bullet + RO^\bullet \rightarrow ROOR}$$

$$\mathrm{RO^\bullet + R^\bullet \rightarrow ROR}$$

$$\mathrm{ROO^\bullet + R^\bullet \rightarrow ROOR}$$

$$\mathrm{ROO^\bullet + ROO^\bullet \rightarrow ROOR + O_2}$$

The initiation reaction generally involves removal of a hydrogen atom from the methylene (CH_2) group adjacent to a double bond in an unsaturated fat molecule. This generates the fatty acid radical (alkyl radical, $R^\bullet$). The formation of $R^\bullet$ from RH is influenced by light exposure, metal catalysts, heat, active oxygen species, and other factors. However, full understanding of the detailed mechanism of formation is not known.

The alkyl radical ($R^\bullet$) is extremely reactive and can combine with molecular oxygen to produce a peroxy radical ($ROO^\bullet$) which can combine with another unsaturated fatty acid molecule (RH) and generate the corresponding hydroperoxide (ROOH) and a new alkyl radical. Hydroperoxides are unstable and degrade to produce volatile, nonradical end products, many of which result in off-flavors. Alternatively, the hydroperoxides can degrade to produce an alkoxy radical ($RO^\bullet$) and a hydroxy radical ($^\bullet OH$), both of which are extremely reactive and can propagate the chain reaction by reacting with further RH molecules. The decomposition of hydroperoxides is commonly catalyzed by pro-oxidant metals, such as copper and iron.

The reaction ultimately terminates if the supply of RH molecules is exhausted, if O_2 becomes limiting, if radicals react with each other to generate nonradical end products as outlined earlier, or if radicals react with antioxidant molecules (see later).

Food lipids typically exhibit a lag phase (induction) during which the rate of lipid oxidation is low. However, as the autocatalytic chain reaction accelerates, hydroperoxides rapidly accumulate and reach a maximum, following which hydroperoxide decomposition reactions and the generation of volatile off-flavored (rancid) compounds become more important. The longer the induction period, the more stable the food to oxidation.

Oxidation Products and Off-Flavors in Milk

Milk is characterized as having a pleasing, slightly sweet taste with no unpleasant aftertaste. However, its bland taste makes it susceptible to a variety of flavor defects. Since milk fat contains many minor unsaturated fatty acids as well as major ones, very many carbonyl products may be produced during the autooxidation of milk fat. Thus, the overall flavor produced by autooxidation is the combination of many flavors imparted by individual volatile compounds present at minute concentrations. However, compounds such as *n*-hexanal, 2-octenal, 2-nonenal, 2,4-heptadienal, and 2,4-nonadienal have been reported in many studies as key compounds contributing to the oxidized off-flavor of milk fat. 2, 4-Decadienal and 1-octen-3-one have been reported also.

Flavor threshold values for carbonyl compounds are influenced by many factors, including the number of carbon atoms, number and location of unsaturated double bonds, isomeric form, and the nature of the food; carbonyl compounds have up to 100 times greater flavor potency in an aqueous medium (e.g., milk) than in oil (e.g., butteroil). Hence, off-flavors tend to be more noticeable at lower concentrations of carbonyl compounds in liquid milk than in butter.

Spontaneous Oxidation in Milk

Some samples of raw milk are more susceptible to oxidation than others. Milk which oxidizes spontaneously (spontaneous milk) is capable of developing oxidized flavor within 48 h of milking without the presence of contaminating iron or copper. Approximately 12–20% of raw milk samples exhibit this behavior. Susceptible milk does not oxidize spontaneously but develops oxidized flavors following contamination with iron or copper. Use of non-corrodible dairy equipment reduces the probability of oxidation in this category of milk samples.

Non-susceptible milk does not oxidize even in the presence of iron or copper.

Some cows consistently produce spontaneous milk, others occasionally, and others not at all. The phenomenon is influenced by heredity, stage of lactation, and feeding practices. Some research has suggested that the enzyme, xanthine oxidase, which is a major component of the milk fat globule membrane (MFGM), is involved in spontaneous oxidation. However, the research on this issue is equivocal. Other research suggests that the susceptibility of milk to spontaneous oxidation is related to its relative content and distribution of pro-oxidants and antioxidants. In general, milk from pasture-fed cows is less susceptible to oxidation than from ration-fed cows due to higher content of antioxidant tocopherols.

Factors Affecting Oxidation of Lipids in Milk and Milk Products

The rate and extent of lipid oxidation in milk and milk products is influenced by a range of parameters including oxygen, light, endogenous and exogenous metals, antioxidants such as ascorbic acid, tocopherols, carotenoids, thiols, proteins, and enzymes, MFGM, and storage temperature.

Oxygen

Oxygen is a requirement for oxidative deterioration of lipids. Oxygen has greater solubility in nonpolar than in polar solvents and, hence, is more soluble in liquid milk fat than in whole raw milk. A substantial percentage of the total oxygen in whole milk is present in the fat phase. Oxygen is excluded from the solid fat phase as it crystallizes. However, as the temperature of butter is reduced, oxygen excluded from the crystallized fat phase partitions into and saturates the liquid fat and aqueous phases of the butter. Thus, oxygen is available to react with the more unsaturated fat in the liquid phase and with phospholipids and pro-oxidants in the MFGM fragments. The maximum rate of hydroperoxide production in irradiated butter occurs at −20 °C, which may reflect an increased rate of chain terminations at higher temperatures and reduced propagation reactions at lower temperatures.

Removal of oxygen from liquid milk or its replacement by an inert gas, such as nitrogen, reduces the development of oxidized flavors. Similarly, the oxidative stability of whole milk powder can be enhanced by vacuum treatment or replacement of oxygen with an inert gas. Oxidized flavor is of minor importance in fermented dairy products such as cheese or yogurt. Several factors may be involved, such as depletion of the oxygen level by starter bacteria, the acidic pH of such products, or the formation of antioxidants by microorganisms.

Light

A considerable body of research data indicates that light is a very effective promoter of off-flavor development in milk and milk products. The extent of oxidation-induced off-flavor development is a function of the light wavelength, intensity, and duration of exposure. Light has been shown to penetrate milk to an appreciable depth.

Potential oxidation-induced off-flavors in butter may be reduced by light-barrier packaging, such as aluminum foil. Direct exposure to light is the principal factor affecting photooxidation of butter; temperature and duration of storage exert little effect on butter with subsensory levels of light-induced oxidation.

Metals

A wide variety of metal ions, including the pro-oxidant transition metal ions of copper and iron, are found in milk and milk products. Awareness of the role of metal ions in the oxidation of milk fat has existed for nearly a century. It has long been recognized that copper and iron are the principal metals involved. Both these metal ions occur naturally in milk but may also be present as contaminants. Copper has been reported at levels of 20–400 $\mu g\,l^{-1}$ and iron at levels of 100–900 $\mu g\,l^{-1}$.

These ions function as pro-oxidants primarily by decomposing hydroperoxides to generate new reaction chains. Either the oxidized or reduced metal ion can decompose hydroperoxides to allow the following catalytic cycle to occur:

$$M^{n+} + ROOH \rightarrow M^{(n+1)+} + OH^- + RO^\bullet$$
$$M^{(n+1)} + ROOH \rightarrow M^{n+} + H^+ + ROO^\bullet$$

Thus, small quantities of metal ions can generate large numbers of reaction chains by cycling between the oxidized and reduced forms. The standard reduction potentials for iron and copper suggest that iron is a much stronger oxidizing agent than copper. However, copper in milk is more pro-oxidant than iron. This anomaly probably reflects differences between the interactions of the two metals with other milk constituents such as ascorbic acid, thiol groups, and serine phosphate residues which could modulate their pro-oxidant effects.

The endogenous copper in milk is derived via the bloodstream from the cow's feed. It has been reported that 10–35% of the indigenous copper and 20–47% of the indigenous iron in milk are associated with the MFGM. However, only 2–3% of added (exogenous) copper and virtually no added iron become associated with the MFGM. While indigenous copper and iron in milk are complexed with proteins and are nondialyzable at the normal pH of milk, added copper and iron are dialyzable to some extent. This suggests that added metals interact less with milk proteins than indigenous metals. It appears that the juxtaposition of a copper–protein complex with the phospholipids of the MFGM is an important factor in the development of oxidized flavor in liquid milk.

Antioxidants

Addition of antioxidant compounds is widely used in food products to inhibit the progress of lipid oxidation. However, addition of antioxidants to dairy products is prohibited in most countries. Thus, antioxidant effects in milk rely primarily on endogenous compounds.

Tocopherols

Tocopherols are effective antioxidants in lipid systems. While they may exert a pro-oxidant effect at high concentrations, this is unlikely to occur in milk which contains approximately 20 μg of α-tocopherol per gram of fat. The principal factor influencing the tocopherol content of milk is the feed of the cow which, in turn, is influenced by season. Summer milk produced on green pasture feed typically has a higher α-tocopherol content than winter milk produced on dry-lot feeding. Many studies have demonstrated the feasibility of increasing the α-tocopherol content of milk by supplementation of the feed with consequent increased resistance of the milk to spontaneous and copper-induced oxidation. However, only about 2% of ingested α-tocopherol is actually transferred to the milk and consequently the economics of direct supplementation of feed are unfavorable.

A significant correlation exists between the α-tocopherol content of milk fat and its oxidative stability. Tocopherol concentrations are at least threefold higher in lipids of the MFGM than in the core of the fat globule. Tocopherol concentration in the MFGM lipids shows a closer correlation with oxidative stability than the tocopherol content of butteroil. During storage of cream containing added ascorbic acid and copper, total destruction of tocopherols in the MFGM was observed compared to 30% destruction in the butteroil due to the proximity of the tocopherols in the MFGM to pro-oxidants and highly oxidizable phospholipids. Tocopherols have been reported to act as free-radical scavengers but have also been shown to quench active oxygen species such as singlet oxygen ($^1O_2$). Each tocopherol molecule can typically deactivate about 120 molecules of singlet oxygen before it is destroyed.

Ascorbic acid

Ascorbic acid is a very effective scavenger of alkoxy radicals ($RO^\bullet$). However, under certain circumstances it can exert a pro-oxidant effect. Concentrations of ascorbic acid above those typically found in milk (approximately 20 $mg\,l^{-1}$) provide antioxidant protection in milk. However, at the concentrations normally found in milk, ascorbic acid acts as a pro-oxidant. Ascorbic acid has been shown to be crucial to the development of oxidized flavor in cream. Cream washed free of ascorbic acid did not develop oxidized flavor over 3 days despite being contaminated with copper. It has been proposed that ascorbic acid reduces Cu^{2+} to Cu^{1+}, which in turn reduces molecular oxygen to hydrogen peroxide, which oxidizes lipids in the MFGM. Further work has shown that added copper did not promote oxidation in milk or butter depleted of ascorbic acid and that oxidation in ascorbic acid-free milk could be initiated by addition of ascorbic acid.

Carotenoids

The importance of singlet oxygen ($^1O_2$) as an initiator of oxidation has increased interest in prevention of singlet oxygen reactions by quenching to ground-state oxygen ($^3O_2$). Food constituents such as carotenoids and tocopherols have been reported to exert this effect. Quenchers must either have the ability to accept energy from the $^1O_2$ molecule (energy-transfer quenching) or have the ability to donate electrons to $^1O_2$ (charge-transfer quenching). Quenching of $^1O_2$ by carotenoids is an example of energy-transfer quenching whereas tocopherols, amines, and phenols have been shown to exert a charge-transfer quenching mechanism. β-Carotene is one of the most potent quenchers of $^1O_2$, with one molecule estimated to quench 250–1000 molecules of $^1O_2$. The rate of quenching is influenced by the number of conjugated double bonds present. Carotenoids with nine or more conjugated double bonds are efficient quenchers, whereas those with seven or less are not capable of accepting energy from $^1O_2$.

Thiols

Mild heat transfer (e.g., pasteurization) of milk increases its susceptibility to spontaneous, copper-induced, and photo-induced oxidation, probably due to the migration of copper to the cream phase of milk. However, many researchers have reported an inhibitory effect of high-heat treatment on the oxidative deterioration of milk and milk products. This effect has been associated with the activation of thiol groups primarily in the MFGM and the serum protein β-lactoglobulin. Thiol groups resulting from the heat treatment of milk exert an antioxidant effect probably as univalent reducing agents, peroxide decomposers, or metal ligands.

Proteins and enzymes

Caseins have been shown to possess significant antioxidant activity which may be related, in part, to their hydrophobic nature and orientation of potential antioxidant side chains of constituent amino acids at the lipid interface. Homogenized milk has been reported to be less susceptible to oxidation when milk fat droplets are resurfaced with casein. Caseins can also bind pro-oxidant metals to phosphoseryl residues. The major whey proteins have considerably less antioxidant properties than the caseins. Superoxide dismutase (SOD) has been detected in and isolated from milk but, apparently, it is present at insufficient levels to provide substantial antioxidant protection.

Milk Fat Globule Membrane

Milk fat exists primarily in globules surrounded by a complex membrane consisting of a mixture of unsaturated phospholipids, proteins, glycoproteins, and other minor constituents. The MFGM is a focal point for the oxidation of milk lipids due to the proximity of unsaturated phospholipids to various pro-oxidants in the lipoprotein matrix. Once oxidation is initiated in the MFGM, diffusion of the propagating chain reaction radicals into the more saturated fat globule core from the fat–plasma interface results in generalized oxidation of milk fat triglycerides. It has also been proposed that xanthine oxidase, a metalloprotein abundant in the MFGM, may also be partially responsible for the susceptibility of the membrane to lipid oxidation.

Cholesterol Oxidation

Cholesterol is an unsaturated alcohol and is susceptible to oxidation, with more than 60 known cholesterol oxidation products (COPs). The C7 atom of cholesterol is most susceptible to oxidation, giving rise to a series of A- and B-ring oxidation products. The C20 and C25 atoms in the side chain are also susceptible to oxidation. Humans are capable of absorbing COPs from the diet and there is ongoing research and debate regarding the health significance of COPs, particularly in relation to atherosclerosis.

The development of atherosclerotic plaque by the deposition of saturated cholesterol esters in arteries has been studied extensively for many decades. Many studies have shown, however, that cholesterol does not accumulate in the vascular endothelium until lesions occur. It has been proposed that COPs may be a cause of lesion formation, after which pure cholesterol and cholesterol esters accumulate as a secondary process, generating atherosclerosis.

COPs have not been detected in significant amounts in fresh, pasteurized, UHT, condensed, or skimmed milk. COPs have been reported in full-fat milk powders, baby foods, cheeses such as Parmesan, Cheddar, Blue, and Romano, butter and butteroil, and ghee.

While research and debate on the human health significance of COPs in foods continues, it would be prudent to optimize the processing, preservation, storage, and distribution of milk and milk products to minimize the formation of COPs.

Measurement of Lipid Oxidation

As low levels of oxidation can lead to off-flavors in milk and milk products, routine procedures to assess the extent of oxidation should be sensitive, reliable, and simple.

Measurement of hydroperoxides (peroxide value) is a classical method for quantifying lipid oxidation. A variety of procedures exist. One procedure used extensively to study lipid oxidation of milk fat involves the oxidation of ferrous to ferric iron by hydroperoxides in the fat in the presence of ammonium thiocyanate to produce ferric thiocyanate which can be quantified spectrophotometrically. Another commonly used procedure is based on the liberation of iodine from potassium iodide by hydroperoxides. A serious problem with procedures based on the determination of hydroperoxides is that they may not correlate well with the level of off-flavor in the products, particularly when oxidation has been extensive. During the course of lipid oxidation, peroxide values reach a peak and then decline.

Procedures using thiobarbituric acid (TBA) as an analytical reagent have also been used widely to monitor lipid oxidation in milk and milk products. The TBA procedures have been shown to correlate well with the intensity of oxidized flavor in liquid milk.

A variety of other chemical methods such as the anisidine value and the Kreis test may also be used to monitor lipid oxidation in milk fat.

Instrumental methods of detecting oxidized flavor volatiles include headspace analysis, especially using solid-phase microextraction (SPME) and solid-phase dynamic extraction (SPDE), combined with gas chromatography, with or without mass spectrometric detection.

Lipolysis and Hydrolytic Rancidity

H C Deeth, University of Queensland, Brisbane, QLD, Australia

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Lipolysis or hydrolysis of lipids can result in serious defects in milk and milk products and is a constant concern to the dairy industries of most countries. It is caused by the enzyme lipase, which hydrolyzes the triacylglycerols (triglycerides), the major constituents of milk fat. The products of this hydrolysis are free fatty acids (FFAs) and mono- and di-acylglycerols. The FFAs formed from milk fat, particularly the short-chain acids such as butyric, caprylic, and caproic, have strong flavors and can impart unpleasant flavors variously known as rancid, bitter, butyric, unclean, astringent, or 'lipase'. It should be noted that some of these terms are also applied to other flavor defects: rancid flavors can result from the oxidation of fats, bitter flavors from proteolysis, and unclean flavors from the growth of some bacteria. The flavor defect caused by lipolysis is sometimes referred to as 'hydrolytic rancidity', which should not be confused with 'oxidative rancidity', which results from the oxidation of fats.

Not all effects of lipolysis are undesirable. In some cheeses, lipolysis is important for the development of characteristic flavor. For example, lamb, kid, and calf lipases are used in the manufacture of Parmesan and Romano cheese to produce short-chain fatty acids that impart a piquant flavor, while FFAs produced by the lipases of the blue *Penicillium roqueforti* mold make a major contribution to the flavor of blue-vein cheese. Rennet pastes containing lipase also contribute to lipolysis in some cheese varieties. Lipases are also used in the production of various dairy flavorings used to enhance the flavor of some dairy products, chocolate, and other confectionery products. FFAs, particularly those of short chain length, have antimicrobial effects, and it has been suggested that these acids formed by lipolysis of fat in milk may contribute to the protection of the newborn against gut infections.

The other products of lipase action, the mono- and di-acylglycerols, have surface active properties that can affect some products. For example, they can cause milk to exhibit poor steam-foaming properties. Lack of foaming during the preparation of cappuccino coffee is a relatively common phenomenon, which can often be attributed to lipolysis in the milk.

The lipases that cause problems in milk and dairy products are of two main types – milk lipase, which occurs naturally in all raw milk, and bacterial lipases, which are produced by contaminating bacteria. Each of these lipases causes lipolysis under certain conditions and will be discussed separately below.

Another family of lipolytic enzymes that can affect milk and dairy products are the phospholipases. These hydrolyze phospholipids, which constitute a major part of the milk fat globule membrane (MFGM), and cause destabilization of the milk fat globule. The most well-documented defect caused by these enzymes is 'bitty cream', which results from damage to the membrane, causing partial coalescence of fat globules and the production of unsightly specks of fat on the surface of hot beverages. Fortunately, homogenization effectively disperses the specks and masks the defect in milk.

Lipolysis by the Milk Lipase System

The natural milk lipase is a lipoprotein lipase, which means that it is activated by lipoproteins, such as those in blood serum. (This can be easily demonstrated by adding some blood serum to milk and observing the lipolysis that results.) In milk, it appears to operate without the cofactors associated with blood lipoproteins, although there has been a conjecture that similar molecular entities may exist in milk and activate the enzyme. Milk lipase is inactivated by high-temperature short-time (HTST) pasteurization and hence does not cause lipolysis in pasteurized milk or products made from it. It is also inactivated to some extent by high-pressure treatment and pulsed, high-voltage electric field treatment, while high-pressure homogenization does not inactivate milk lipase but appears to activate it.

The fat portion of milk exists as small discrete globules, neatly enveloped in a biological membrane, the MFGM. The membrane facilitates dispersion of the fat in the aqueous phase of milk and also segregates the fat from the natural milk lipase, which exists in the aqueous phase. In fresh normal milk, this membrane is intact and is impermeable to the milk lipase. However, under certain circumstances, the integrity of the membrane can be disrupted, allowing contact between the lipase and its substrate, resulting in lipolysis. This can occur spontaneously in the milk on the farm or it can be induced during handling before pasteurization.

Spontaneous Lipolysis

Milk from some cows can undergo spontaneous lipolysis. It is initiated by cooling the milk to <10 °C soon after secretion from the cow and continues during refrigerated storage. Most of the lipolysis occurs in the first 12 h of storage. The milk from cows in late lactation and from poorly nourished cows is particularly susceptible to this type of lipolysis. In regions where cows are seasonally calved and late lactation corresponds to a time of year when natural feed is in short supply, spontaneous lipolysis can be a serious problem.

Individual cows vary considerably in the susceptibility of their milk to spontaneous lipolysis. In the author's experience, some cows never produce milk that spontaneously lipolyzes, while others (of the same breed and in the same herd) consistently produce such milk.

It is fortunate for the dairy industry that admixing the milk samples from these two types of cow inhibits, partially or completely, the spontaneous lipolysis that would occur in the 'spontaneous' milk alone. This phenomenon has been attributed to the presence of an inhibitor (or inhibitors) in 'normal' milk.

Spontaneous lipolysis has been attributed to a combination of three major factors: an imbalance of lipase 'activators' and lipase 'inhibitors'; susceptibility of the MFGM; and the amount of lipase. Each can affect the amount of lipolysis but the relative amounts of activators and inhibitors appear to be the most important factor. The nature of these components has not been properly determined, but the evidence suggests that both types of substances are present in milk and that spontaneous lipolysis occurs only when the balance shifts toward more of the activators and less of the inhibitors.

A necessary precondition for lipolysis is attachment of some of the lipase from the skim phase of milk to the MFGM. In milk that undergoes a high level of lipolysis, the amount of lipase redistributing to the cream phase from the skim phase can be a significant proportion of the total lipase present. The nature of this attachment is not well understood.

All raw milk contains sufficient lipase to cause lipolysis and produce a rancid off-flavor under favorable circumstances. Therefore, the amount of lipase in the milk is not normally a significant factor. However, where the activator–inhibitor balance and MFGM characteristics are similar, different levels of lipase can determine the final level of lipolysis. Similarly for the susceptibility of the MFGM, if the activator–inhibitor balance and lipase content are similar, the different levels of lipolysis can be attributed to differences in the membrane characteristics. The MFGM can become more permeable in late lactation, which may partially explain the increased susceptibility of late-lactation milk.

Milk from quarters of the udder with mastitis has a higher level of FFAs than milk from healthy quarters of the same cow after a period of storage. This may be due to a higher amount of lipolysis occurring during storage, but it is often due to a higher-than-normal FFA level in the milk as it leaves the cow. These fatty acids result from incomplete incorporation into triacylglycerols in the mammary gland. Their leakage into the milk is the result of disruption of the normal functioning of the mammary cell during mastitic infection; the more severe the mastitis (i.e., the higher the somatic cell count), the higher the FFA level.

Induced Lipolysis

This is usually associated with damage to the MFGM. It can occur through pumping, agitation (mechanical or air), or excessive mixing of air into the milk. In all of these cases, the incorporation of air is essential for disrupting the MFGM. Surface tension forces at the air–milk interface cause damage to the membrane. Hence, pumping induces little lipolysis unless air is simultaneously taken in through faulty seals, joints, and other parts. Similarly, on the farm, lipolysis can be induced in the milk-lines if excessive air is drawn in at the teat cups and surging occurs in the lines, particularly in vertical sections; the milk is particularly susceptible at this time because it is close to body temperature. Milking with automatic milking machines has been reported to lead to higher levels of lipolysis than when using manually operated machines.

The effect of agitation on lipase action can be easily demonstrated by placing some raw milk at about 30 °C in a blender and 'blending' it at high speed for a short time, say 30 s. Such milk will quickly develop a rancid flavor if left at room temperature.

One very effective way of initiating lipolysis is homogenization of raw milk. Lipolysis begins immediately and the milk quickly becomes rancid. This is avoided in practice in dairy processing by pasteurizing the milk either before or immediately after homogenization. Homogenization before batch pasteurization should not be performed at less than 60 °C to avoid excessive lipolysis during the time period between homogenization and pasteurization.

The fat in homogenized milk is an excellent substrate for lipase. Therefore, if raw milk is mixed with homogenized (pasteurized) milk, lipolysis results. This situation can occur in the industry and cause serious flavor problems in drinking milk. One situation where this has been encountered is when some homogenized milk is left over, for example, from a packaging run, and is returned to raw milk storage vessels for processing the following day. Therefore, constant vigilance is needed to ensure that such actions do not occur as their consequences are not immediately obvious to untrained factory personnel.

The result of mixing raw and homogenized milk can be simply illustrated by mixing equal quantities of raw and homogenized milk, leaving the mixture at about 30 °C, and observing the change in flavor over a time period of 2–3 h. This is also the easiest way to produce a typical 'lipase' flavor to demonstrate the defect. Milk with an FFA content up $6\,\mathrm{mmol\,l^{-1}}$ can be produced, and this can be mixed with unlipolyzed pasteurized milk (FFA $\sim 1\,\mathrm{mmol\,l^{-1}}$) to produce milk samples with a range of FFA levels. Most people detect the off-flavor when the FFA reaches $2\,\mathrm{mmol\,l^{-1}}$.

As in the case of spontaneous lipolysis, induced lipolysis usually involves attachment of the lipase to the MFGM. Under certain conditions of mechanical agitation, a substantial proportion of the total lipase activity associated with casein micelles in the skim phase can be transferred to the fat globules in the cream phase. Once attached to the fat globule membrane, the enzyme has enhanced heat stability and hence cream from milk that has been severely mechanically abused may retain some milk lipase activity after HTST pasteurization.

A unique way in which the milk lipase system can be activated is by 'temperature manipulation'. This involves cooling raw milk to a low temperature (≤10 °C), rewarming it to >20 °C, and then again cooling to ≤10 °C. 'Spontaneous' milk is more susceptible to this type of lipolysis induction. A situation where this can occur at the farm is when warm milk direct from the cow is mixed with refrigerated milk from a previous milking and the temperature reaches >20 °C.

Lipolysis by Bacterial Lipases

Lipolysis caused by bacterial lipases has become significant since the widespread introduction of cold storage of milk on farms. This change has caused the levels of lactic acid bacteria to decline and those of psychrotrophic bacteria to increase. During low-temperature storage, the proportion of psychrotrophic bacteria in the milk increases and they become dominant. Many of these produce extracellular lipases that can cause lipolysis. The principal bacteria concerned are pseudomonads, particularly *Pseudomonas fluorescens*. These are common bacteria in soil and water and are ever present in the farm and factory environments. Consequently, they constitute the dominant type of bacterial flora in both raw milk and pasteurized milk after a period of cold storage. They grow at low temperatures but the rate of growth of a particular strain does not correlate with the amount of lipase elaborated. In fact, some studies have shown that the slowest growing strains are the most prolific lipase producers.

One of the most important properties of these microbial lipases is their heat stability. Most retain at least some of their activity after pasteurization and even after ultra-high temperature (UHT) processing. This means that although the bacterial cells may be destroyed by the heat treatments used in dairy processing, their enzymes can remain active in the heat-treated product. Hence, a product may exhibit no defects immediately after manufacture but develop rancid off-flavors during storage. The longer the product is stored and the higher the temperature at which it is held, the greater the risk of lipolysis defects developing if the product contains small amounts of contaminating lipase.

In contrast to the natural milk lipase, most microbial lipases are not prevented from attacking the fat in milk fat globules by the MFGM. The reason for this difference is not completely understood. The practical significance of this is that milk fat globules do not have to be disrupted before these bacterial lipases can act on the fat.

Proper attention to time and temperature of storage of raw milk is required to prevent problems due to heat-stable bacterial lipases. In virtually all cases of such problems, failure to keep the temperature low or limit the time of storage has been identified as the cause. As a general rule, if milk is stored for more than 3 days, there is a risk of products made from it developing lipase-related defects. If during those 3 days the temperature is allowed to rise above 4 °C, the risk is increased.

One situation in which lipase problems have been encountered is when milk (or cream) is transferred between factories; in such situations, the time/temperature rules are often broken. Another situation is when milk is kept for extended periods of time before processing; this can occur over weekends or public holidays, at times of low milk production (and hence less frequent collection), or at times of adverse weather conditions causing transport delays between farm and factory.

Lipolytic Defects in Milk and Dairy Products

All milk products containing fat have the potential to suffer from lipolytic defects. However, it is important to understand the most likely cause(s) of the problem in different products so that procedures can be devised to minimize the risk. Once lipolysis has occurred to such an extent that a flavor defect is detectable, there are no processes available for eliminating the defect from the product.

Pasteurized Milk

Two major lipase-related problems are encountered in milk: rancid flavors and poor foaming capacity. Lipolysis is most commonly due to milk lipase, and may occur on the farm or in the factory before the milk is processed. If it occurs at the farm, it can be either spontaneous or induced. The former occurs most often when a large proportion of the cows are in late lactation and/or when high-quality feed is not available. A common cause of induced lipolysis is excessive air intake at the teat cup cluster. In the factory, it can be induced by excessive pumping (particularly with centrifugal pumps with faulty seals through which air is drawn into the milk causing foaming); homogenization of raw milk, without immediate pasteurization; and mixing of homogenized (pasteurized) milk and raw milk. Lipolysis caused by bacterial lipases is less likely in market milk as the bacterial count required to produce sufficient lipase to present problems in cold-stored milk over a relatively short time, $\geq 10^7\,\mathrm{cfu\,ml^{-1}}$, does not occur in raw milk and usually occurs only at the end of the shelf life of pasteurized milk. The end of the shelf life of pasteurized milk is characterized by off-flavors (bitter, sour, putrid, and oxidized), which tend to mask the rancid flavors that may also be present.

Foaming difficulties are significant in relation to making cappuccino coffee. When milk is foamed for making cappuccino coffee, steam is injected, with air, into the milk to create foam and to heat the milk to $\sim 70\,^{\circ}\mathrm{C}$. The volume of the foam plus milk should be about twice the original volume of the milk, and the foam should be stable for at least 10 min. However, at times, milk exhibits poor steam-foaming capacity and cannot be foamed enough to make acceptable cappuccino coffee. A major reason for the reduced steam-foaming capacity of milk is lipolysis; the greater the extent of lipolysis, the greater the depression of foaming. Milk with an FFA level of $\geq 2\,\mathrm{mmol\,l^{-1}}$ exhibits very poor foaming. The lack of foaming is related to the change in surface tension of the milk, but there is no evidence for a close relationship between surface tension and foaming behavior.

Ultra-High Temperature Milk

The most common cause of a rancid flavor in UHT milk is lipolysis by heat-stable bacterial lipases produced by psychrotrophic bacteria in the raw milk before heat treatment. Only trace quantities of lipase are required to cause an increase in FFA content during storage at room temperature until the use-by date, which can be 12 months after manufacture.

Butter and Anhydrous Milk Fat

Off-flavors in butter and anhydrous milk fat can be caused by lipolysis before or after manufacture. Off-flavors originating before manufacture are mostly due to milk lipase action and result in soapy, bitter, and 'back palate' taste sensations at manufacture. This is characterized by a high FFA content at manufacture. The FFAs present are generally longer in average chain length than those of the parent milk fat because the shorter-chain acids have some water solubility and are lost in the buttermilk and any washing steps during butter manufacture.

By contrast, post-manufacture lipolysis is caused by heat-stable bacterial lipase action and results in characteristically sharp, butyric, and 'front-palate' flavors. This is because all fatty acids are retained in the butter and contribute to the flavor. Gas chromatography of the FFAs can be used to observe their fatty acid profile. This allows the cause of the off-flavor to be determined. This type of lipolysis occurs more readily in butter because of its higher water content; however, it can occur in anhydrous milk fat through the small amount of water present, given that the product may be stored unrefrigerated for long periods of time before use.

Milk Powder

Residual bacterial lipases in milk and whey powders are a major concern. Since they usually act slowly in the product during storage, lipolysis may be detected months after manufacture and when used in the production of other foods such as recombined dairy products and confectionery. This can have serious economic ramifications.

Cheese

FFAs are an integral part of the typical flavor of most cheeses, especially the more highly flavored types. However, for most cheeses, excessive lipolysis results in a flavor defect.

As with butter, cheese can be affected by pre- or post-manufacture lipolysis. If the former occurs, the flavor defect is noted in the fresh cheese, but if the latter occurs, the defect develops during storage. It is unusual for serious problems to occur in cheese as a result of lipolysis in the milk; however, very serious problems can result from post-manufacture lipolysis, largely due to heat-stable bacterial lipases.

In cheese made from pasteurized milk, lipolysis by the native milk lipase does not occur after manufacture. Even when cheese is made from raw milk, the native milk lipase causes little lipolysis, if any, in the cheese.

Additives can be another cause of lipase action in cheese. Some additives, such as pepper, contain lipases that can cause soapy, rancid off-flavors.

Yogurt

Few problems are caused by lipase action in yogurt. This is due to a combination of factors including low pH (outside of the optimal pH range for most lipases of concern), low storage temperature, relatively short shelf life, and high normal flavor level. However, some additives used in yogurts have been known to cause a lipolytic defect through the action of their constituent lipases. For example, the lipase in passion fruit seeds can produce rancid flavors in some tropical fruit yogurts.

Analytical Methods

Free Fatty Acid Measurement

The most widely used measure of the extent of lipolysis in milk and dairy products is FFA content. The most commonly used methods are based on extraction–titration procedures in which the FFAs (and the fat) are extracted from the product and titrated with an alcoholic alkali solution. The extraction can be by a solvent system, such as isopropanol–petroleum ether or ethyl alcohol–diethyl ether, or by a procedure that isolates the fat from the product.

The fatty acids released from milk fat by lipases range from short-chain, water-soluble acids such as butyric acid (C4) to long-chain, water-insoluble acids such as oleic and stearic acid (C18). Extraction procedures seldom quantitatively extract all of these acids, so absolute FFA contents are usually not obtained. Procedures involving solvents extract more than do methods involving isolation of the fat, as the latter extract almost all the long-chain acids but a low proportion of the short-chain acids.

These two extraction methods also lead to different units for the FFA contents. For example, for milk, FFA values from the solvent extraction methods are reported as milliequivalents of acid per liter of milk or millimolar concentrations (mmol l^{-1}), while those from the fat extraction methods are reported as ADV (acid degree value) in milliequivalents of acid per 100 g of fat. An approximate conversion of one to the other can be made only if the fat content of the milk is known. Alternatively, a relationship between the two can be derived empirically.

Accurate procedures for determining the amount of each of the FFAs produced are now available using gas chromatography or high-performance liquid chromatography (HPLC). These methods are not generally used for routine dairy industry testing but they can provide useful information for troubleshooting and research applications. Gas chromatographic headspace analysis of short-chain fatty acids using solid-phase microextraction (SPME) has been shown to be suitable for milk. The electronic nose has been used successfully for detecting lipolysis in cheese.

Lipase Activity

Ideally, the dairy industry should have a simple, rapid, sensitive, and reliable test for low levels of lipase activity in milk and dairy products. If such activity could be measured before storage of products, only products free of activity can be stored for long periods.

Many different lipase assay procedures are available but to date no single method has been universally adopted for this purpose. Assays based on milk fat as substrate are intuitively ideal since it is the lipase action on milk fat during storage which the test is meant to predict. However, such tests are time consuming and/or not very sensitive. Consequently, methods using non-triglyceride substrates such as β-naphthyl, *p*-nitrophenyl, indoxyl, and umbelliferyl esters have been developed. The major advantage of these is that a colored or fluorescent product is formed, and it can be detected readily. These tests meet the criteria of simplicity, speed, and sensitivity, but most tests lack reliability because esterolytic enzymes that do not act on milk fat, as well as true lipases, are detected. Such tests are ideal screening tests and could be used in this way in the dairy industry.

Other available methods are based on the following: measurement of the decrease in turbidity of fat emulsions; enzymatic analysis of the FFAs; immunological detection of the lipase molecule; radiometric analysis of labeled fatty acids released from radioactive substrates; and chromatographic analysis of the lipolysis reaction products. Methods based on triacylglycerol substrates (such as milk fat or triolein) and a sensitive chromatographic analysis (either gas–liquid chromatography (GLC) or HPLC) of the released FFAs (and/or other products) are particularly attractive because they are sensitive and use natural substrates.

Cholesterol: Factors Determining Levels in Blood

S A Aherne, University College Cork, Cork, Ireland

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Cardiovascular disease (CVD) is a broad term that refers to diseases of the blood vessels of the heart (coronary heart disease, CHD); brain (cerebrovascular disease, stroke); and the limbs (peripheral vascular disease). There are generally two main events that can lead to CVD, namely, atherosclerosis and thrombosis. Atherosclerosis refers to the thickening of the arterial wall and the gradual formation of a plaque that leads to narrowing of the arterial lumen through which blood flows, hence restricting blood flow. One of the major risk factors for CVD is a high cholesterol level in the blood. Therefore, it is important to keep the blood cholesterol level within the recommended guidelines ($<5.2\ \mathrm{mmol\,l^{-1}}$ or $200\ \mathrm{mg\,dl^{-1}}$).

Cholesterol is the principal sterol of animal tissues and is present in animal cell membranes as the free sterol and in blood in the form of cholesteryl esters (CEs). Cholesterol is essential for the body as it plays an important role in cell membranes (i.e., structural and fluidity roles) and in cell growth. It is also the precursor of bile salts, steroid hormones, and vitamin D. Cholesterol is produced in the liver (endogenously sourced) but can also be obtained from the diet (exogenous source). To facilitate intestinal absorption, dietary cholesterol is incorporated into mixed micelles in the gut, whereas biliary cholesterol is solubilized into micelles and phospholipid vesicles that then dissolve into the mixed micelles. Therefore, a mixture of endogenous and exogenous cholesterol is absorbed from the intestinal lumen. Free (unesterified) cholesterol is transferred to the mixed micelles, and once these particles are taken up by intestinal cells (enterocytes), cholesterol is re-esterified into CEs.

Before discussing the factors that influence blood cholesterol level, it is important to understand cholesterol transport and metabolism as well as the various components involved in altering blood cholesterol concentration.

The Importance of Lipoproteins

Cholesterol and phospholipids combine with protein carriers (apolipoproteins) to form lipoproteins. Regardless of the source, that is, endogenous or exogenous, cholesterol is transported around the body by lipoproteins in two forms: (1) free form, which is present largely in the hydrophilic outer layer of lipoproteins, and (2) esterified as CEs, which mainly reside in the lipoprotein hydrophobic core. Lipoproteins not only carry free cholesterol, but also CEs and triacylglycerol (TAG) molecules through the enterohepatic (intestine–liver) and hepato-peripheral (liver–body) cycles of cholesterol transport. TAGs are esters of fatty acids with glycerol and are often termed ‘dietary fat’. Therefore, lipoproteins have a core of neutral lipids (TAGs and CEs) surrounded by a single surface layer of polar lipids (phospholipids and free cholesterol) (**Table 1**). Apolipoproteins extend over the surface of lipoproteins.

The negative imbalance between atherogenic and atheroprotective lipoproteins is a strong modifiable risk factor for CVD. Consequently the levels, functions, and metabolism of lipoproteins and apolipoproteins have influential roles on cholesterol levels in the body. Five types of lipoproteins are involved in the transport of cholesterol, and each type has a specific function (**Table 2**). They are chylomicrons (CMs), very low-density lipoproteins (VLDLs), intermediary-density lipoproteins (IDLs), low-density lipoproteins (LDLs), and high-density lipoproteins (HDLs). The general composition of the five lipoproteins is presented in **Table 3**. There are also five major classes of apolipoproteins (apoA–apoE), and as research progresses, subgroups of these apolipoproteins are being discovered, such as apoA-I and apoA-II. Apolipoproteins play important roles in determining the functions of the different lipoproteins (**Table 4**). They have a role in stability and also provide specificity on the lipoprotein molecules, which enables the lipoproteins to be recognized by and interact with specific cell surface receptors in different body tissues and organs. This, in turn, leads to the uptake of lipoproteins from the blood and the regulation of their metabolism. Some apolipoproteins are also involved in the functioning of lipoprotein enzymes such as lipoprotein lipase (LPL).

Chylomicrons (CMs)

When ‘packages’ of cholesterol, phospholipids, TAGs, and specific apolipoproteins leave the enterocytes, they are called chylomicrons (CMs). These lipoproteins are composed primarily of TAGs and transport dietary fat into the circulation (**Table 2**). The TAGs present in the core of CMs are stabilized by a coat of phospholipids and apolipoproteins (apoA and apoB-48). ApoB-48 in CMs is unique to enterocytes and identifies lipoproteins carrying dietary lipids. CMs are transported by the lymph system through

Table 1 Properties of lipoprotein particles

Lipoprotein	*Particle core*	*Particle surface*
Chylomicrons	TAG >> CE	PL > CH >> apoLP
Very low-density lipoproteins	TAG > CE	PL ~ CH >> apoLP
Low-density lipoproteins	CE > TAG	PL ~ CH >> apoLP
High-density lipoproteins	CE > TAG	PL > CH > apoLP

apoLP, apolipoprotein; CE, cholesteryl ester; CH, cholesterol; PL, phospholipid; TAG, triglyceride.

Table 2 Functions of lipoproteins

Lipoprotein	*Function*
CM	Transport exogenously sourced lipids from intestinal cells to the liver and peripheral tissues
$\mathrm{VLDL}_{\mathrm{INT}}$	Carry exogenously sourced lipids
$\mathrm{VLDL}_{\mathrm{LIVER}}$	Transport endogenously sourced lipids from the liver to the peripheral tissues
IDL	Breakdown product of VLDL-cholesterol
LDL	Carry cholesterol molecules to peripheral tissues and the liver
HDL	Remove cholesterol from tissues and transports cholesterol (CE) to the liver (reverse cholesterol transport) and other lipoproteins

CM, chylomicron; HDL, high-density lipoprotein; IDL, intermediary-density lipoproteins; INT intestinal sourced; LDL, low-density lipoprotein; LIVER, liver sourced; VLDL, very low-density lipoprotein.

the thoracic duct, thus entering the jugular vein where these particles join the blood circulation. As CMs enter the bloodstream, they acquire apo-C and apo-E from HDL, which are then released into the blood and taken up by liver cells (hepatocytes). The first port of call for CMs is adipose tissue because CMs are recognized by their surface apoB-48. In adipose tissue, CMs are depleted of some TAGs by LPL. Therefore, the remnant particles, that is, the remaining CMs, contain less TAGs and more cholesterol. These remnants are taken up by apo-E receptors in the liver cells where cholesterol is used for bile salt formation, lipoprotein synthesis, and/or CE synthesis.

Very Low-Density Lipoproteins (VLDLs)

There are two types of VLDL, namely, those made in the small intestine ($\mathrm{VLDL}_{\mathrm{INT}}$) and others that are produced in the liver ($\mathrm{VLDL}_{\mathrm{LIVER}}$). $\mathrm{VLDL}_{\mathrm{INT}}$ carry exogenously sourced lipids, whereas $\mathrm{VLDL}_{\mathrm{LIVER}}$ transport mostly TAGs that have been synthesized in the liver. $\mathrm{VLDL}_{\mathrm{INT}}$

Table 4 Functions of apolipoproteins

Apolipoprotein	*Function*
apoA-I	Structural protein for HDL; activates lecithin-cholesterol acetyl transferase (LCAT)
apoA-II	Structural protein for HDL
apoA-IV	Activates lipoprotein lipase and LCAT
apoB-48	Formation of chylomicrons and VLDL_{INT}
apoB-100	Structural protein for VLDL, IDL, and LDL. Needed for assembly and secretion of VLDL
apoC-I	Activates LCAT
apoC-II	Involved with LDL activation and activity; activates lipoprotein lipase
apoC-III	Blocks apoE clearance of TAG-enriched lipoproteins and inhibits TG breakdown by lipoprotein lipase; inhibits lipoprotein lipase
apoD	Involved with CETP
apoE-2	Reduced affinity for LDL receptor
apoE-4	Enhanced affinity for LDL receptor

Collated from Kritchevsky D (2006) Cholesterol and other dietary sterols. In: Shils M, Shike M, Ross AC, Caballero B, and Cousins R (eds.) *Modern Nutrition in Health and Disease*, pp. 123–135. Philadelphia, USA: Lippincoot Williams and Wilkins; Link J, Rohatgi A, and de Lemos JA (2007) HDL cholesterol: Physiology, pathophysiology, and management. *Current Problems in Cardiology* 32: 268–314.

and CMs transport TAGs from the gut through lymph and blood to the liver, adipose tissue, and muscles. Apolipoproteins of VLDL_{INT} are different from those of $\text{VLDL}_{\text{LIVER}}$. Like CMs, VLDL_{INT} contain apoB-48, whereas $\text{VLDL}_{\text{LIVER}}$ possess apoB-100. $\text{VLDL}_{\text{LIVER}}$ secreted into the hepato-peripheral circulation have a core of CEs and TAGs with apoB-100, apo-C, and apo-E on their surfaces. VLDLs are degraded in a similar manner to CMs. VLDL remnants are normally called IDLs, and further degradation of these particles yields LDLs.

Low-Density Lipoproteins (LDLs)

LDLs are the primary carriers of cholesterol in blood because their main role is to deliver cholesterol to both peripheral and liver cells. Atherosclerosis develops when oxidized LDL-cholesterol is taken up by macrophages and deposited in atheromatous plaques that develop into atherosclerotic lesions. LDLs have apoB-100 as their sole protein constituent, which interacts with LDL receptors on target cell surfaces. The LDL-receptor complex is then taken up into the cell where LDLs are degraded and cholesterol is released. This, in turn, regulates the amount of cholesterol produced by the cell. Cholesterol taken up by peripheral cells redistributes to various cell membranes and also becomes involved in metabolic reactions. LDLs have CEs in the core and free cholesterol with phospholipids on the surface (**Table 1**).

High-Density Lipoproteins (HDLs)

A reduced level of HDLs in the blood has been associated with an increased risk of CHD and is as significant a risk factor as elevated blood levels of LDLs. HDL originates from the intestine (HDL_{INT}) and liver ($\text{HDL}_{\text{LIVER}}$), and each source provides different apolipoproteins that determine some of their functions. HDL particles have a core of CEs and TAGs with a surface composed of phospholipids, free cholesterol, and the apolipoproteins apoA-I and apoA-II. The main role of HDL is to carry cholesterol from peripheral cells to the liver, where it is degraded or repackaged. This process is known as reverse cholesterol transport. Cholesterol taken up by HDL is esterified by the enzyme lecithin cholesterol acyl transferase (LCAT), and the esterified cholesterol then moves to the core of HDL. LCAT, primarily activated by apoA-I, is secreted by the liver and has a high affinity for HDL. LCAT has two functions: (1) it converts cholesterol to its esterified form, which then migrates from the lipoprotein surface layer into the hydrophobic core, and subsequently (2) more cholesterol can attach to the HDL surface layer because surface cholesterol is esterified and moved to the core by LCAT. The migration from the surface to the core prevents re-uptake of cholesterol by the cells. HDLs then travel to the liver where CE transfer protein (CETP) is involved in exchanging the HDL core CEs for TAGs, thereby completing the process of reverse cholesterol transport. HDL-cholesterol is then broken down by the liver and eliminated as bile or converted into cholesterol-containing steroids. Therefore, efficient reverse cholesterol transport by HDL protects against the development of atherosclerosis.

Lipid Transfer Proteins

Exchange of core lipids from lipoprotein particles is mediated by lipid transfer proteins that are synthesized in the liver. They exchange lipids (TAGs, CEs, phospholipids) from one lipoprotein particle to another. For example, as mentioned earlier, CETP functions in the transfer of CEs and TAGs between lipoprotein subfractions, mostly VLDL, LDL, and HDL-cholesterol. This exchange results in the transfer of CEs from HDL to

VLDL and LDL, and TAGs from VLDL to HDL. In addition, $\mathrm{VLDL}_{\mathrm{INT}}$ and CMs exchange components with HDL particles during lymphatic transport and blood circulation. Apo-C and apo-E are transferred from HDL to VLDL and/or CMs, which is essential for the metabolism of CM particles. In turn, VLDL and CMs transfer phospholipids to HDL.

Factors that Affect Cholesterol Level

Several factors can influence the levels of lipoproteins, apolipoproteins, and hence cholesterol in the blood (**Table 5**). The effects on apolipoproteins are far more complex and unclear. Some determinants are modifiable, such as diet, smoking, body weight, and physical activity, whereas others are non-modifiable, including age and genetics. The amounts and proportions of lipoproteins in the blood respond to the influx of digestion products after the consumption of a meal. Several major dietary determinants of blood cholesterol levels have been identified, including dietary fat, cholesterol, fiber, protein, and alcohol consumption.

Dietary Fat and Fatty Acids

Dietary fats and cholesterol are the most important food components that alter blood lipoproteins. The main dietary approach for lowering LDL-cholesterol level and improving the LDL:HDL ratio is to replace cholesterol-raising fats by carbohydrate and/or unsaturated fatty acids. Recently, there has been a shift toward assessing the apoA-I/apoB ratio, which is also a reliable indicator of CHD risk.

Dietary cholesterol

There is considerable debate as to whether dietary cholesterol affects blood lipoprotein and/or cholesterol levels. Responses appear to vary considerably in individuals within and between studies. People can be either sensitive or resistant to cholesterol intake in the diet. Within the range of cholesterol intakes normally consumed, altering dietary cholesterol content seems to result in little change to circulating cholesterol level. Only when a high proportion of dietary fats are saturated (>15% of dietary energy) and cholesterol intake exceeds 300 mg per day is dietary cholesterol an important determinant of blood total- and LDL-cholesterol. An increase of 100 mg dietary cholesterol per day results in a 2–3 mg dl^{-1} increase in total cholesterol, of which approximately 70% is in the LDL fraction.

Saturated fatty acids (SFAs) and trans fatty acids

Individual SFAs have different effects on cholesterol level. High intakes of the SFAs myristic acid (14:0), palmitic acid (16:0), or lauric (12:0) acid elevate total- and

LDL-cholesterol by suppressing LDL-receptor clearance of LDL by reducing LDL-receptor expression. This effect is thought to occur from a shift in the regulatory pool of liver cholesterol from the CE form to free cholesterol. Stearic acid (18:0) has not been shown to raise blood cholesterol, possibly due to the fact that it is converted rapidly to the monounsaturated fatty acid (MUFA), oleic acid. Trans fats are geometric isomers of cis-unsaturated fatty acids. They are more atherogenic than SFAs because trans fats not only raise LDL-cholesterol level, but also lower HDL-cholesterol level.

Mono- (MUFA) and Poly-unsaturated fatty acids (PUFA)

When dietary SFAs are substituted by cis-MUFA or n-6 PUFA, blood total- and LDL-cholesterol are lowered; however, epidemiological studies report conflicting data in relation to n-6 PUFA and thus fail to confirm a cardio-protective effect. PUFA are more effective than MUFA in relation to improving blood lipid profiles. Intakes of n-3 PUFA such as eicosapentaenoic acid (EPA) and docosahexenoic acid (DHA) lead to a reduction in blood VLDL level, but not LDL, which may be due to a reduction in the rate of synthesis of apoB. It has also been shown that LPL activity increases when 3 g n-3 PUFA is consumed on a daily basis for 6 weeks, thus resulting in an increase in CM clearance.

Plant sterols

Plant sterols function as structural components in plants by maintaining cell membrane structure and function, which is similar to the biological function of cholesterol in humans. A meta-analysis of 41 studies has shown that ingestion of 0.8–4.0 g plant sterols per day results in 10–15% reduction in LDL-cholesterol levels with the beneficial effect leveling out with higher doses (>2.5–3 g per day). Current recommendations are the daily consumption of 2–2.5 g per day in order to reduce blood cholesterol level. The exact mechanism by which plant sterols reduce serum cholesterol is not fully clear but it is generally accepted that there are three possible mechanisms: (1) competition between cholesterol and plant sterols for micellar solubilization, meaning that less cholesterol is absorbed through the intestinal wall; (2) co-precipitation of plant sterols with intestinal cholesterol, which results in the formation of insoluble particles that are then excreted *via* the feces; and/or (3) inhibition of cholesterol uptake due to competition at the absorptive site, that is, the brush border membrane.

Carbohydrates, Fiber, and Protein

A high carbohydrate diet is generally associated with an increase in VLDLs as a result of increased hepatic synthesis of TAGs. Soluble forms of dietary fiber (10–25 g per day), such as pectins and gums found in legumes and fruits, have been shown to reduce total- and LDL-cholesterol levels in the blood; however, the effect is not as significant as altering the nature of fat in the diet. Fiber may have at least three cholesterol-lowering mechanisms: (1) fiber may act as a bile acid sequestering agent; (2) fiber may reduce the rate of insulin rise by slowing carbohydrate absorption, thus slowing cholesterol synthesis; and/or (3) fiber may produce short-chain fatty acids that are absorbed by the portal circulation and inhibit cholesterol synthesis. Consumption of animal versus plant protein increases circulating cholesterol level.

Body Weight

There is a dose-dependent increase in cholesterol level with increasing body mass index (BMI), and there is also a strong link between increased BMI and low blood HDL. Obesity affects blood lipid and lipoprotein levels, which tends to cause elevated VLDL- and LDL-cholesterol concentrations in the blood as well as reduced HDL. Studies have shown that both cholesterol and TAG levels fall during weight loss. For instance, a meta-analysis of more than 70 studies observed that for every 4.5 kg of sustained weight loss, blood HDL increased by 2 mg dl^{-1}. VLDL levels tend to be low in lean individuals and those who are physically active.

Physical Activity

Lower blood TAG concentrations have been reported following regular physical activity. CM and VLDL-cholesterol have been shown to decrease after aerobic exercise, whereas LDL-cholesterol level remains unchanged. On the other hand, prolonged regular activity (>6 months) has been reported to lower LDL-cholesterol. Regular physical activity for longer than 12 weeks is more likely to increase HDL-cholesterol level in a dose-dependent manner. The mechanism(s) by which physical activity increases HDL is not fully understood. Exercise can increase apoA-I levels, whereas apoB changes usually correspond with LDL-cholesterol changes.

Alcohol and Smoking

An excessive intake of alcohol increases VLDL- and LDL-cholesterol levels in the blood. Although moderate consumption of certain alcoholic drinks, such as wine, has been shown to lower LDL-cholesterol and raise HDL-cholesterol levels, because of other health risks the benefit is not sufficient to recommend drinking alcohol. Smoking is one of the major risk factors of CHD, and suggested mechanisms include damage to the arterial wall, altered coagulation, and changes in lipid profile, especially LDL- and HDL-cholesterol levels. Smoking-induced HDL reduction is suggested to result from increases in CETP, decreases in LCAT activity, and apoA-I synthesis. Cessation of smoking has been shown to increase HDL levels, but with no changes in TAG and LDL levels.

Age and the Menopause

After 50, age becomes a predominant risk factor for CHD. A meta-analysis of 61 prospective observational studies characterized the age-specific associations of total cholesterol changes with CHD risk and mortality. As people age, there is a progressive increase in total- and LDL-cholesterol levels. Age has been reported to be an important independent predictor of LDL- and total-cholesterol in men, and total-cholesterol in women. It has been recommended that as an individual gets older, dietary intake should be adjusted for a more sedentary lifestyle in order to maintain a healthy blood lipid profile. Reducing calorie intake by about 20% in a nutritionally balanced diet over periods of 2–15 years has been shown to lower blood pressure as well as blood cholesterol and TAG levels.

HDL cholesterol tends to be higher in women than in men throughout their pre-menopausal state because estrogen elevates hepatic expression of LDL receptors and reduces abdominal LPL activity. However, post-menopausal women develop an unfavorable lipid profile and elevated total- and LDL-cholesterol levels in the blood due to the reduction in endogenous estrogen production

Genetics

Genetic variation of apolipoproteins and lipoproteins has significant effects on lipid and cholesterol metabolism, and as a result, CHD risk. For instance, individuals with the apoA-IV and apoE-2 genotypes have lower cholesterol levels and are less responsive (resistant responders) to dietary cholesterol. On the other hand, individuals with apoE-4 have higher levels of total-cholesterol, LDL-cholesterol, and TAG. They also show a noticeable blood cholesterol response to both dietary fatty acids and dietary cholesterol changes (sensitive responders).

There are several genetic disorders of lipid metabolism (**Table 6**), which are usually characterized by alterations in one or more lipoproteins. For instance, familial hypercholesterolemia is characterized by a marked rise in total- and LDL-cholesterol. Other disorders include familial combined hyperlipidemia, remnant hyperlipoproteinemia, familial hypertriglyceridemia, and common hypercholesterolemia. The disease sitosterolemia is a rare disorder associated with increased absorption of cholesterol and plant sterols from the intestine. Three major classes of LDL metabolism defects have been identified: (1) defects in apoB-100, (2) defects in the LDL receptor, and (3) defects in a binding protein that enables internalization of the LDL–LDL receptor complex. There are also three forms of abnormal HDL metabolism, namely, hyperlipidemia, dyslipidemia, and hypoalphalipoproteinemia. Additionally, there are other genetic contributors to abnormal HDL levels, such as mutations in LCAT, CETP, and HDL-associated apolipoproteins.

Table 6 Genetic conditions leading to abnormal cholesterol levels

Disorder	*Genetic defect*
Total- and LDL-cholesterol levels	
Familial hypercholesterolemia	Mutation in LDL receptor gene.
Familial defective apoB	Multiple mutations occurring in the ligand binding areas of apoB result in reduced binding to the LDL receptor.
Autosomal recessive hypercholesterolemia	Absence of the phosphotyrosine-binding domain protein leads to defective internalization of LDL bound to the LDL receptor.
Abetalipoproteinemia	Unable to produce a circulating form of apoB and as a result no CM, VLDL, or LDL appear in plasma. Fat and vitamin E malabsorption occurs.
Hypobetalipoproteinemia	Defect in the apoB gene.
HDL cholesterol levels	
CETP deficiency	Mutations in the CETP gene result in defective cholesterol transport.
Lipase polymorphisms	Reduces rate of conversion of VLDL to IDL and IDL to LDL.
LCAT deficiency	Absence of or reduced LCAT activity.
ApoA-I deficiency	Mutations in the apoA-I gene resulting in reduced levels of apoA-I.
Sitosterolemia	Also termed phytosterolemia. Caused by mutations in two genes encoding adjoining transporters namely ABCG5 and ABCG8, which result in excessive absorption of plant sterols and abnormal sterol metabolism.

Conclusion

As can be seen, a wide range of factors can influence cholesterol level in the blood, either directly or indirectly *via* alteration of lipoprotein and/or apolipoprotein levels and metabolism. Certain factors are modifiable, such as diet, smoking cessation, alcohol consumption, and physical activity. On the other hand, non-modifiable risk factors also exist, such as age and genetics. Hence, a multidisciplinary approach is needed to successfully achieve and maintain a healthy blood lipid profile.

Introduction

Cholesterol is a waxy, fat-like substance found in the cells of humans and animals. It is a key constituent of cell membranes and a precursor of bile acids, steroid hormones, and also vitamin D. It is located mainly in plasma membranes, lipoproteins, and fat deposits. The highest amounts of cholesterol are found in the brain, bone marrow, kidney, and liver. Cholesterol is a natural component of many food products, especially animal foods, but the amount varies widely from food to food. It is present in the milk of all mammals at modest concentrations, for example, 1 g of bovine milk fat generally contains about 2.6–3 mg cholesterol. During the commercial processing of milk, the cholesterol is carried over with the bulk fat to the product (**Table 1**). Plants, fruits, seeds, and leaf lipids, in addition to phytosterols, also contain cholesterol in very small quantities.

In the 1950s, an increased serum cholesterol concentration was related to the incidence of coronary heart disease and was therefore assessed to be an important risk factor. Therefore, cholesterol and saturated fats in foods came into focus as risk factors in medical research, now known as the 'diet–heart hypothesis'. The importance attached to dietary cholesterol as a possible risk factor in human hypercholesterolemia has led to certain foods being regarded as unhealthy. A restriction of the everyday intake of dietary cholesterol to 300 mg was suggested and the concentration of total cholesterol in serum was not to exceed 5.2 mmol l^{-1} (200 mg dl^{-1}).

Processes for the Removal of Cholesterol from Food

Fear of coronary heart diseases and the persuasive intervention of physicians led consumers to prefer low-cholesterol and cholesterol-reduced foods. As a natural consequence of this consumer preference, legislators such as the US Food and Drug Administration developed labeling guidelines for these products (per serving): cholesterol free, <2 mg cholesterol; low cholesterol, 20 mg or less cholesterol; and reduced cholesterol, >25% less cholesterol than a reference product. Many biological, physical, and chemical methods have become available for the development of cholesterol-reduced products.

Biological Processes

Microorganisms

In nature, there are a number of cholesterol-degrading bacterial species. *Nocardia*, *Rhodococcus*, and *Eubacterium* have been isolated from butter, bacon, pork fat, chicken fat, and soil. Of the approximately 120 bacterial strains isolated from these foods, as well as from cheese, beef fat, beef liver, and egg yolk, 19 isolates had cholesterol-degrading ability. The highest cholesterol-degrading ability was found in the isolate C-5 belonging to the genus *Kurthia*, where cholesterol was completely degraded via 4-cholesten-3-one into other compounds. A suspension culture of *Nocardia labegensis* appears to have potential for the biological degradation of sterols in animal and vegetable fats. Microcapsules containing cholesterol-degrading microorganisms may also be used to reduce the cholesterol levels in liquid foods. In experiments with humans, serum cholesterol concentrations can be lowered by oral administration of a coprostanol-producing microorganism.

Of the 99 strains of lactobacilli and 33 of enterococci, 10 were checked for their ability to reduce cholesterol in broth and cream. In broth, the cholesterol reduction was between 12 and 48% and in cream between 20 and 60%. For buttermaking, *Lactobacillus maltaromicus* AC3-16 and *Lactobacillus casei* ssp. *casei* AB16-65 were selected. The cholesterol reduction was dependent on the pH value but was not particularly successful. Processing with the first strain resulted in a cholesterol reduction of 0.1% at pH 4.46 and a reduction of 19.4% at pH 3.87. With the second strain, the results were 4.1% at pH 4.60 and 25.4% at pH 3.96.

The use of bacteria to lower cholesterol levels in foods raises some important issues. First, there is the question of bacterial inoculation of the food, which may be of great concern to the consumer. Second, some of the species used may be pathogenic; in fact, *Rhodococcus equi* has been

Table 1 Cholesterol content of milk and dairy products

Food	*Fat (g per 100 g)*	*Cholesterol (mg per 100 g)*

Parmesan	25.6	77
Quark, cream	15.6	52
Butter	82.3	241

Reproduced from SwissFIR – The official Swiss food information portal, http://www.swissfir.ethz.ch/, viewed on 17 November 2008.

identified as an important pathogen. Finally, there are the potentially harmful effects of the by-products produced after bioconversion of cholesterol. When cholesterol is reduced to coprostanol, for example, by cholesterol reductase from *Eubacterium*, this does not seem to be a problem as it is absorbed poorly or not at all. *Rhodococcus* strains catalyze the conversion of cholesterol to cholest-4-en-3-one, whose formation and disappearance differ depending on the strain used. In this case, the problem is more serious since oxidized cholesterol products are considered toxic and a potential health risk.

Enzymes

Various enzymes produced by different bacteria, principally cholesterol oxidase(s) and reductase(s), modify cholesterol. *Rhodococcus erythropolis* and *Streptomyces* spp. have cholesterol oxidase activity. These enzymes were shown to be of the intrinsic (membrane-bound) type. Extracellular enzymes have also been described in the broth filtrates of *Streptomyces violascens*, *Brevibacterium sterolicum*, *Streptoverticillium cholesterolicum*, and *Rhodococcus equi*. One strain of *Rhodococcus equi*, isolated from butter, produced more extracellular cholesterol oxidase than two other strains, isolated from butter and bacon. Cholesterol oxidase modifies cholesterol to cholest-5-en-3-one and then to the final product cholest-4-en-3-one. Other oxidized cholesterol products such as 7-keto- and 7-β-hydroxycholesterol could not be detected in milk incubated with *Pseudomonas fluorescens* cholesterol oxidase.

Physical Processes

Distillation and crystallization methods

Cholesterol is soluble in steam. Thus, steam-stripping technology can be used to remove large quantities from fat. This technique allows a reduction of up to 95% of cholesterol from anhydrous butterfat and fish oils. The procedure is quite simple. The fat is first deaerated, mixed with steam, heated, and then flash vaporized with subsequent removal of cholesterol by thin-film stripping in a counter-current of steam. The product is then cooled and stored in the absence of oxygen. The process consumes large amounts of energy, entails significant operating costs, and can lead to polymerization and oxidation of various components.

Short-path distillation and crystallization are processes that are used to fractionate fat. The first process consists of evaporation of fat into a substantially gas-free space. In the latter procedure, the fat is liquefied and is then cooled to specific crystallization temperatures. To crystallize different components that are subsequently separated from the liquid phase, diverse temperatures can be applied. Milk fat, a mixture of different triglycerides with varying physical properties, can be separated into fractions of different chemical composition and also different cholesterol levels.

Supercritical fluid extraction

Supercritical fluid extraction has been used for a long time in the food industry. It has been applied to delipidation of protein, deoiling of lecithin, isolation of important oils, fractionation of butterfat, decaffeination of coffee, oil extraction from oilseeds, removal of bitter aroma compounds from hops, extraction of spices, and removal of cholesterol from different foods. In this process, a product is treated with a gas, for example, carbon dioxide, of high density, low viscosity, and reduced surface tension under high pressure and at high temperatures. Carbon dioxide is used in the processing of natural products intended for human consumption because it has many advantages – it is easily removable, nontoxic, nonflammable, noncorrosive, nonoxidizing, and inexpensive; it is available in large quantities of high purity; and it has a relatively low critical temperature (+31 °C). Supercritical fluid extraction has the great advantage of low energy cost, high yield, superior quality (since a lower extraction temperature range is used), absence of potentially explosive or toxic solvents, and absence of toxic by-products. In general, no chemical solvent is left in the food with this technique. However, a substantial capital investment is required for the installation of the necessary equipment.

Chemical Processes

Solid–liquid extraction

Cholesterol can also be removed from liquid foods by selective solid-phase extraction using adsorbents such as activated charcoal, coated porous glass, ceramics, and plastics. Silica gel may also be used as an adsorbent. In addition, organic solvents or mixtures can be applied to remove cholesterol, but it should be noted that these solvents are mostly toxic and should not be used in foods. Other disadvantages of a process using an organic solvent are the extraction of other lipid-soluble components, denaturation of proteins, removal of flavor and nutritional components, relative nonselectivity as well as high costs.

Complex formation

β-Cyclodextrin, a cyclic oligosaccharide consisting of seven glucose units joined as α-$(1 \rightarrow 4)$ isomers, is nontoxic, edible, nonhygroscopic, chemically stable, and easily separable. It has a cavity at the center of the molecular arrangement and can thus form a stable insoluble inclusion complex with cholesterol. The effectiveness of cholesterol adsorption is dependent on the adsorbent concentration, stirring time, speed, temperature, and centrifugation conditions. Starch-containing products also seem to form stable complexes. All of these complexes are stable in aqueous solutions, which allow removal of cholesterol from the lipid phase. Incidentally, β-cyclodextrin can be fermented by human colonic flora. The safety aspect of residual β-cyclodextrin from egg was studied in rats in a subchronic toxicity study and indicated no toxicity. Extracted β-cyclodextrin can be recovered by heating or by the addition of increasing amounts of sodium chloride, but the recovery of β-cyclodextrin from dairy products is ineffective since considerable amounts are needed for removal of cholesterol, which leads to high costs. To overcome these problems, β-cyclodextrin can be cross-linked with adipic acid or immobilized on a solid support. A maximal level of β-cyclodextrin of 5 $\mathrm{mg\,kg^{-1}}$ per day in foods is recommended by the Joint FAO/WHO Expert Committee on Food Additives (JECFA). β-Cyclodextrin is 'generally recognized as safe' (GRAS) in the United States and a 'natural product' in Japan.

It is also possible to minimize the level of cholesterol in animal fat with an aqueous solution of bile salts and one or several glyceryl esters or with cyclic anhydrides such as succinic anhydride. The cholesterol-containing aqueous phase is then separated or the final product of the reaction with cyclic anhydrides is extracted with aqueous alkali. In another method, animal fat is brought into contact with phospholipid or anionic polysaccharides. The formed sterol-reduced fat is then removed from the aqueous mixture. Saponins such as quillaja powder (a commercial preparation of saponins from the bark of *Quillaja saponaria*), which are accepted for food processing and have received the GRAS list status in the United States, and also polymer-supported saponins such as digitonin (consisting of the aglycone digitogenin linked to a pentasaccharide) or tomatine (composed of a polycyclic steroidal secondary amine, tomatidine, and a tetrasaccharide) form insoluble cholesterol complexes, which can be removed by filtration or centrifugation. The polymers may be regenerated by benzene extraction, which restores the original cholesterol-binding capacity.

Use of the above Processes to Remove Cholesterol from Milk and Dairy Products

The processes described in world patents and the scientific literature relate mainly to the removal of cholesterol from fat of animal origin, especially from milk, egg yolk, and meat. The worldwide attempts to produce low-cholesterol products have generated many patents, indicating that this is of great economic interest. The preferred methods are complex formation with β-cyclodextrin, distillation, and extraction with supercritical carbon dioxide.

Milk

In milk treated with cholesterol oxidase, the cholesterol concentration was reduced by 50% within 10 h at 3 or 7 °C and by 78% within 3 h at 37 °C.

Cholesterol has been removed from milk and dairy products by a β-cyclodextrin-based process. Homogenized milk was treated with β-cyclodextrin to determine the optimum combination of five different factors (**Table 2**). Removal of cholesterol is mostly affected by factors such as β-cyclodextrin concentration, mixing temperature, mixing time, centrifugal forces, and centrifugation time. In various investigations, more than 90% of cholesterol was removed with cross-linked β-cyclodextrin.

Removal of cholesterol from homogenized milk by treatment with saponins is another option. This process was studied using response surface methodology. Using the optimum reaction time (30 min) and the optimum amounts of Celite (0.95%) and saponin (1.5%), the predicted removal of cholesterol by this method was estimated to be 73.4% compared to the experimental value of 73.7%. The use of β-cyclodextrin immobilized on glass beads led to a cholesterol reduction of only 41% in milk.

Milk Fat and Cream

Biological processes

The cholesterol content of anhydrous milk fat, incubated at 28 °C for 12 h with *Nocardia*, was reduced by 86–89%; in contrast, only 7% of the cholesterol was removed after incubation of cream with an extract of *Rhodococcus equi* for a period of 15 h.

Physical processes

After short-path distillation, the solid fraction contains cholesterol at a concentration of 0.2 $\mathrm{mg\,g^{-1}}$ fat compared

Table 2 Effect of various conditions on the removal of cholesterol from milk using β-cyclodextrin

β-Cyclodextrin		*Mixing temperature*		*Mixing time*		*Centrifugal force*		*Centrifugation time*	
(%)	*Cholesterol removed (%)*	*(°C)*	*Cholesterol removed (%)*	*(min)*	*Cholesterol removed (%)*	*(g)*	*Cholesterol removed (%)*	*(min)*	*Cholesterol removed (%)*
0.5	92.2^{a}	4	93.7^{a}	5	93.2^{a}	55	86.7^{a}	5	81.9^{a}
1.0	94.0^{a}	10	$94.6^{a,b}$	10	93.9^{a}	111	94.9^{b}	10	94.6^{a}
1.5	95.3^{a}	15	93.0^{a}	15	92.1^{a}	166	95.9^{b}	15	94.1^{a}
2.0	88.6^{b}	20	93.5^{a}	20	92.5^{a}	222	$91.5^{a,b}$	20	92.9^{a}
		25	95.2^{b}	25	90.3^{b}	178	87.3^{a}	25	88.3^{b}

Except where parameters were varied as above, experimental variables were β-cyclodextrin added, 1%; mixing speed, 800 rpm; mixing temperature, 10 °C; mixing time, 10 min; centrifugal force, 111 *g*; and centrifugation time, 10 min.
Means within a column with different superscript letters differ ($p < 0.05$).

to 2.6 mg g^{-1} fat in native milk fat or 16.6 mg g^{-1} fat in the liquid fraction. After melt crystallization, the concentration of cholesterol in the liquid fraction (3.8 mg g^{-1} fat) was nearly twice as high as in the solid fraction (2.0 mg g^{-1} fat). This may be due to the higher affinity of cholesterol for the triglycerides of the liquid fraction or due to the purifying effect of crystallization.

Using increased pressure and different quantities of carbon dioxide, fractions were obtained in which the cholesterol content was reduced by up to 90%. At a pressure of 20 MPa at 80 °C, the cholesterol content in the liquid extract was 5.5 mg g^{-1}, in the solid extract 2.3 mg g^{-1}, and in the original fat 2.6 mg g^{-1}. When different pressure conditions were applied at 12, 15, and 20 MPa at 48 °C, the cholesterol was concentrated in the first of three extracts. Fractions in which the cholesterol content was reduced by up to 90% using increasing pressure and different quantities of carbon dioxide were obtained. In anhydrous milk fat, the selectivity is too low for direct extraction of cholesterol. By using an adsorbent, selective removal of the cholesterol can be achieved at 40 MPa, 70 °C, and a flow rate of 12.0 g min^{-1} using a multi-separation process. The use of silica gel with a particle size of 5–40 μm removes more cholesterol (97%) than silica gel with a particle size of 1–3 mm (18.2%) or calcium carbonate with a particle size of 50–100 μm (9.8%). Anhydrous milk fat was fractionated using supercritical carbon dioxide at a pressure of 32 MPa and a temperature of 52 °C in different fractions. By using an adsorption column with silica gel (particle size 15–45 μm) that was flushed with pure CO_2, removal of over 99% of cholesterol was achieved. In ewes' milk cream, extraction of cholesterol was effective at a plateau of 15 MPa with an extraction rate of 30% (40 °C) and 40% (50 °C).

Chemical processes

Application of the following reaction conditions to animal fats is recommended: refluxing at 130–140 °C with a mixture of cholesterol and succinic anhydride (1:3); incorporating 5% (by weight) acetic acid in the reaction mixture; and extraction of cholesteryl hemisuccinate with 5% aqueous sodium carbonate. A cholesterol reduction of 35–45% could be achieved and a reduction of 60–70% resulted if succinic anhydride was added to the reaction mixture in small amounts throughout the course of the reaction.

The optimum conditions for removal of cholesterol from cream were established by the use of response surface methods. β-Cyclodextrin concentration, stirring speed, and time were important factors. Although the reduction of cholesterol level varied, under optimal conditions 94% of the cholesterol in cream could be removed. Removal of cholesterol from cream of nearly the same level (92.7%) was attained with β-cyclodextrin cross-linked with adipic acid under the following optimal conditions: 10% of β-cyclodextrin mixed for 30 min at 1400 rpm at 40 °C (**Table 3**). When the cross-linked β-cyclodextrin was used up to 7 times, a removal of cholesterol of 89.4–91.5% resulted.

Butter and Butter Oil

Physical processes

The cholesterol content of supercritical carbon dioxide-extracted butter was reduced to less than one-quarter of the original concentration by passing the extract through a silica gel column. Fractions of butter oil obtained at a pressure of 17.2 and 20.7 MPa at 40 °C had lower cholesterol levels (1.07 and 1.76 mg g^{-1}, respectively) than those obtained at 10.3 and 13.8 MPa at 40 °C (2.96 and 2.78 mg g^{-1}, respectively).

It is also possible to simultaneously remove cholesterol and fractionate butter oil by extraction with supercritical carbon dioxide followed by adsorption on alumina, achieving a cholesterol removal efficiency of 96%. Supercritical extraction of butter oil can also be realized

Table 3 Effect of various conditions on removal of cholesterol from cream using cross-linked β-cyclodextrin

β-Cyclodextrin		*Mixing temperature*		*Mixing times*		*Mixing speed*	
(%)	*Cholesterol removed (%)*	*(°C)*	*Cholesterol removed (%)*	*(min)*	*Cholesterol removed (%)*	*(rpm)*	*Cholesterol removed (%)*
1	81.7^{a}	40	91.0^{a}	10	84.3^{a}	800	85.3^{a}
5	85.3^{b}	45	90.6^{a}	20	85.1^{a}	1000	87.5^{b}
10	90.7^{c}	50	88.7^{b}	30	91.2^{b}	1200	90.9^{c}
15	90.5^{c}	55	81.3^{c}	40	91.0^{b}	1400	92.7^{d}
20	90.0^{c}	60	85.0^{c}	50	90.6^{b}	1600	88.8^{b}

Except where parameters were varied as above, Other experimental variables were cross-linked β-cyclodextrin, 10%; mixing temperature, 40°C; mixing times, 30 min; mixing speed, 1400 rpm.

Means within a column with the same superscript letter are not significantly different ($p > 0.05$).

using ethane as solvent and adsorption on alumina. The advantage of ethane is that it has a lower critical pressure than CO_2. The higher cost of ethane is compensated for by the lower consumption of ethane. Using the combined extraction/adsorption process at 40 °C and 17.2 MPa, the level of cholesterol in butter oil was reduced to 3% of that in the original oil.

Chemical processes

Cholesterol can be extracted from butter oil using a mixture of ethanol and propane or a cyclic anhydride. After mixing and feeding the extraction column, a mixture of ethanol and water was used as an extractant in a counter-current procedure at 30 °C and 1 MPa, resulting in the removal of about 90–95% of cholesterol. Multiple extractions with β-cyclodextrin allow the removal of up to 80% of the sterols from anhydrous butter. However, in cholesterol-reduced butter made from β-cyclodextrin-treated cream, the cholesterol concentration was reduced by 90%. The scores for hardness, elasticity, cohesiveness, and the color measurement value '*L*' were significantly increased and the color measurement value '*a*' decreased compared to control butter, whereas other parameters remained unchanged. The removal of cholesterol from butter oil using a combination of saponins and Celite was dependent on pH (75 and 56% at pH 4.5 and 7.0, respectively), the concentration of saponin solution (25 and 75% with 0.04 and 0.40 g ml^{-1}, respectively), the amount of Celite (75 and 54% with 250 and 50 mg g^{-1} butter oil, respectively), the temperature (83, 76, and 60% at 45, 55, and 65 °C, respectively), and the level of agitation (75% with low and median and 35% with high agitation), but not on the time of interaction (75% at 30 and 60 min). After repeated extractions with an aqueous solution of bile salts, the cholesterol content of anhydrous milk fat can be reduced by up to 97%.

Cheese

Cholesterol-reduced Cheddar, Camembert, and Blue cheeses were manufactured from milk treated with β-cyclodextrin or cross-linked β-cyclodextrin. In these cheeses, the cholesterol concentration was reduced by more than 90% compared to control cheeses. Cholesterol-reduced and control cheeses did not differ significantly in most of the examined parameters: short-chain free fatty acids, free fatty acids, and rheological and sensorial properties. Experiments to produce Mozzarella cheese from cholesterol-reduced milk fat showed a cholesterol reduction of 64%, and the cheese was found to be superior to the control with respect to appearance and flavor, but not to texture.

Removal of Cholesterol and Dairy Applications

The aim of removing cholesterol is to provide highly functional components, which can then be used as ingredients in foods or to produce reformulated products that have unchanged chemical composition, apart from the level of cholesterol. It is evident, however, that some functional properties of these components are changed and the different procedures used clearly have some effect on emulsion stability, foam-stabilizing ability, interfacial behavior, gelling characteristics, and other functional properties. The same is true for other low-fat, low-cholesterol components, which have many potential applications in new products. A butter oil with reduced cholesterol manufactured by removing the cholesterol using a steam-stripping process was recombined with skim milk, sweet buttermilk, and a butter-derived aqueous phase to manufacture 20% milk fat creams. These reformulated creams were quite similar to an oil-in-water emulsion typical of a natural homogenized cream; however, in terms of stability behavior, the incorporation of cholesterol-reduced butter oil into skim milk did not provide an acceptable result. In a processing plant with a capacity of 240 or 800 tonnes yr^{-1}, the fractionation of anhydrous milk fat by supercritical carbon dioxide was calculated to increase costs by US$ 0.75 or 0.34 per kg of product, respectively (results from 1993).

In 1990, according to taste panel evaluations and a preliminary market study, American consumers accepted low-fat milk containing cholesterol-reduced milk fat and a butter made from low-cholesterol milk fat. Nevertheless, conventional butter was significantly preferred by the panel. In a study with 33 healthy postmenopausal women and 10 students, butter, margarine, a dairy spread made from cholesterol-reduced milk fat, and a spread made from cholesterol-reduced lard mixed with vegetable oils were tested. Butter was preferred to the two spreads and margarine, and the flavor of the spreads was thought to be more similar to margarine than to butter.

Cholesterol-Reduced Food on the Market

The extensive published literature and numerous patents show that removal of cholesterol from food is economically and technically possible. While all foods of animal origin contain cholesterol and some contain relatively high concentrations, the focus has been on trying to reduce the level of cholesterol in milk fat and eggs. In the early 1990s, Corman and Entremont used β-cyclodextrin while Hoche employed a steam extraction process to produce cholesterol-reduced milk fat products. In the United States, the Omega Source Corporation modified a cholesterol-stripping technique for an industrial pilot plant, and in 1992 the NutraSweet Company developed a low-fat, low-cholesterol egg yolk ingredient (Eggcellent$^{\mathrm{TM}}$) using supercritical carbon dioxide technology. At about the same time, the American company Michael Foods introduced a low-cholesterol egg product to the American market, but with rather limited success. In 2008, Corman SA (Goé, Belgium) and Uelzena eG (Uelzen, Germany, acquired Hoche (Neunkirchen-Speikern) in 1998) produced cholesterol-reduced butter and butterfat on a commercial scale.

In western Europe also, the consumer response to low-cholesterol milk fat products was poor. When people are concerned about cholesterol, they prefer to eat low-fat products in general.

Removal of Cholesterol from Dairy Products – Scientifically Justified or Not?

During the last 10 years, the scientific interest in the topic 'Removal of cholesterol from dairy products' has faded more and more. Since then, removal of cholesterol from foods of animal origin is no longer justified for different reasons:

- The diet–heart hypothesis has never been proven.
- Cholesterol is not an essential food ingredient.
- Cholesterol intake from foods is 100–400 mg day^{-1}. In general, a limit value of 300 mg cholesterol per day per person is recommended. However, no persuasive arguments exist for this recommendation.
- With increasing dietary intake, the human body absorbs less cholesterol, because a homeostatic control mechanism exists.
- The human body itself synthesizes an enormous amount of cholesterol. One gram of cholesterol, from enterohepatic circulation across the blood, is eliminated per day in the bowel.
- Reduction of dietary cholesterol has practically no or only a small effect on the concentration of total serum cholesterol. According to a recent meta-analysis, a reduction of 100 mg of dietary cholesterol per day lowers the total serum cholesterol concentration by about 0.056 $\mathrm{mmol\,l}^{-1}$ ($=2.2\ \mathrm{mg\,dl}^{-1}$).

In a well-balanced diet, removal of cholesterol from animal-derived food is not scientifically justified, because dietary cholesterol has only a small effect on serum cholesterol levels and the human body itself synthesizes more cholesterol than it consumes. Therefore, further research on removal of cholesterol from food of animal origin is not necessary.

Introduction

Milk contains certainly more than 100 different proteins, usually classified into three nitrogen fractions: caseins (α_{s1}-, α_{s2}-, β-, and κ-casein), which are the most abundant (78%); serum or whey proteins (17%), which include α-lactalbumin, β-lactoglobulin, blood serum albumin (BSA), and immunoglobulins (Ig); and the nonprotein nitrogen (NPN) fraction (5%). Milk proteins also include milk fat globule membrane proteins and a large variety of enzymes (about 60) and hormones. In addition, the caseins and whey proteins are present as at least 28 identified genetic variants. Caseins also possess different degrees of glycosylation (κ-casein) and phosphorylation. They may also be partly hydrolyzed at milking, with the formation of breakdown products.

In this article, only the methods used routinely by the dairy industry or by research laboratories for quantitative and qualitative analysis of the proteins in raw milk are presented. For the particular aspects of milk protein analysis, such as amino acid analysis, sequencing, secondary and tertiary structure and proteolysis of dairy products, readers should refer to the relevant articles.

Among the methods currently used for milk protein analysis, we can distinguish two groups. The first group of methods is based essentially on the measurement of chemical or structural characteristics of the proteins, such as nitrogen, free NH_3^+ groups (terminal or basic amino acids), CO–NH peptide bonds, and aromatic amino acids (**Figure 1**). These methods are particularly suitable for the accurate determination of total proteins and the major nitrogen fractions in milk. They are used routinely for several purposes: animal breeding and feeding, milk payment, and control of the raw material before processing.

The second group of methods is based on physical and biological properties of the proteins, such as pH and salt solubility, electric charge at various pH values, molecular mass, hydrophobicity, secondary and tertiary structure, and antigenicity. These methods are used for the separation, identification, and possible quantification of individual proteins in research and for regulatory purposes.

General Criteria for Analytical Methods

When assessing the performance of methods of analysis, technical and economic criteria, and accuracy are taken into consideration. Accuracy represents the ability of a method to estimate the true value of an analyte with a known degree of uncertainty. It includes precision, trueness, limit of detection, and sensitivity, which have mathematical expressions, as well as specificity.

1. Precision corresponds to the random errors of a measurement. It is expressed as repeatability when measuring conditions are identical, and as reproducibility when measurements are made by different laboratories. Its mathematical expressions are the repeatability and the reproducibility standard deviation (s_r and s_R) or relative standard deviation (RSD_r and RSD_R). The maximum differences ($p = 0.95$) between two determinations performed under repeatability or reproducibility conditions are given by the repeatability and reproducibility limits (r or R).
2. Trueness is the systematic differences, or error, between the measured value (x) and the true or reference value (y). It is expressed as the residual standard deviation ($s_{y,x}$) of the regression equation, $y = bx + a$, and when the instrument is calibrated, by the mean bias (d_{x-y}) and the standard deviation (s_{x-y}) of the difference $x - y$ or by the standard error of prediction (SEP), which is equal to s_{x-y} when $y = x$.
3. Sensitivity is the ratio of the signal increase of the method corresponding to a unit increase in the analyte concentration.
4. The limit of detection is the lowest concentration that can be measured with a known degree of uncertainty.

Definition of Milk Proteins

Total proteins, caseins, whey proteins, and NPN, are complex chemical entities that can be defined only by their methods of analysis. These methods, which are based on the fractionation of proteins by the Aschaffenburg–Rowland method and then the measurement of nitrogen content by the Kjeldahl method, belong to type I or the defining methods of the Codex classification. Casein N corresponds to the N fraction that is insoluble in an acetic acid–acetate buffer at a pH of approximately 4.6; NPN corresponds to the fraction soluble in 12% trichloroacetic acid (TCA), and whey proteins N corresponds to the difference between non-casein N and NPN. The protein content is determined by multiplying N concentration by the conversion factor 6.38, which has been internationally accepted to give the true value for milk proteins. For applications, these definitions have two important consequences:

1. Because milk contains a significant and variable (3–8%) NPN fraction, it is advisable to distinguish between crude or total protein (total N × 6.38) and true protein ((total N − NPN) × 6.38).
2. The conversion factor 6.38 was established a century ago on the basis of the N content (15.6%) of purified acid-precipitated casein. Now, if we consider the primary structure of individual milk proteins, the best estimate for cow's milk total proteins would be 6.35 rather than 6.38, and would vary between 6.00 and 6.37 for individual proteins. When applying the Aschaffenburg–Rowland procedure, the correct coefficient for caseins, serum protein, and NPN would be 6.36, 6.28, and 3.60, respectively.

Analysis of Total Proteins

Three standardized methods are used routinely for quantitative analysis: nitrogen determination by the Kjeldahl or Dumas method, infrared spectroscopy, and the dye-binding method.

Nitrogen Determination

Kjeldahl method

The principle is to convert quantitatively all the organic (and inorganic) nitrogen into ammonium sulfate by digestion at 400–420 °C in a mixture of K_2SO_4/H_2SO_4 with a catalyst, and subsequently to estimate the nitrogen concentration by distilling the ammonium sulfate in the presence of NaOH and titrating the ammonia with standard acid.

To ensure accurate determination, two accuracy checks must be performed periodically:

- recovery ($\geq$98%) of a hard-to-digest compound, such as tryptophan or lysine-HCl, to check the digestion efficiency
- recovery ($\leq$99%) of a pure ammonium salt (sulfate or oxalate) standard to detect nitrogen loss

In addition, it should be kept in mind that milk compounds, particularly fat, consume acid during digestion. Consequently, with high-fat milk, the K_2SO_4 will become concentrated in the H_2SO_4 and will increase the boiling temperature, leading to nitrogen loss by pyrolytic decomposition of ammonia. Usually, crystallization of the mixture at the end of digestion indicates an excess of acid consumption and volatilization.

The Dumas and related methods

Instead of converting nitrogen into a titratable chemical compound, it is converted into gas after combustion at a high temperature (>1000 °C) in a furnace. After removing all interfering gases, the nitrogen is measured by thermal conductivity.

Instruments for this method should be calibrated with a pure compound with a constant nitrogen content (e.g., aspartic acid) or preferably against the Kjeldahl method. For ultra-high temperature (UHT) milk and fluid milk, repeatability and reproducibility limits are 0.015–0.080% and 0.041–0.093%, respectively.

Infrared Spectroscopy

Both the mid-infrared (MIR), from 2.5 to 25.0 μm (4000–400 cm^{-1}), and the near-infrared (NIR), from 0.7 to 2.5 μm (14 825–4000 cm^{-1}), regions are used to analyze milk. The fundamental vibrations of the molecules, which interact with infrared energy, occur mainly in the MIR, whereas absorption in NIR corresponds to harmonic (overtone) and combination frequencies of the fundamental vibrations. Compared with MIR, NIR absorption bands are broader and their intensities are weaker. For MIR analysis of milk, the strong absorption of water and a variable and significant light-scattering effect of the milk fat globules must be taken into consideration. To eliminate in part the influence of these two factors, a spectral subtraction of water is needed, and the instruments should have built-in homogenizers to reduce light scattering. In addition, a short-path length cuvette (37 μm) is used.

Mid-infrared analysis

An infrared spectrum of milk versus that of water shows several absorption bands that are specific to milk components (**Figure 2**). At 6.46 μm (1550 cm^{-1}), there is a peak corresponding to absorption of the amide II peptide bond; 30% of the peak originates from the C–N stretching vibration and 50% originates from the N–H bending deformation (**Figure 3**). In conventional filter instruments, fat, proteins, and lactose measurements are made at their specific wavelengths by reference to close-second reference wavelengths, corresponding to minimal

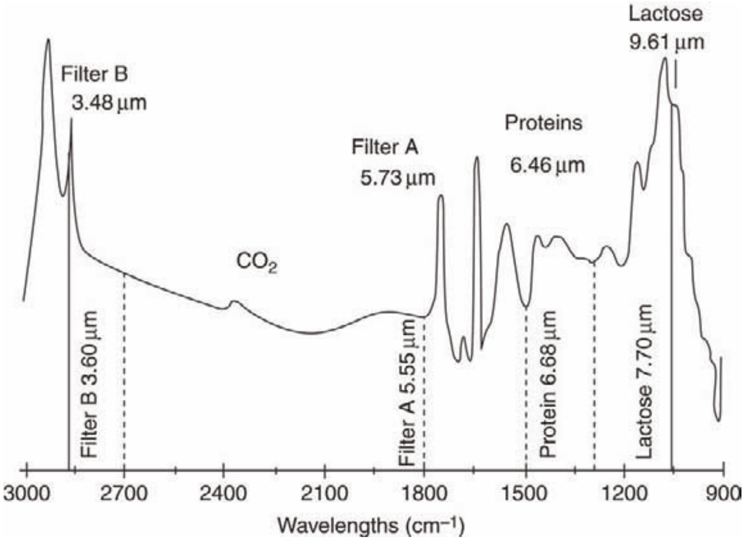

Figure 2 Mid-infrared spectrum obtained in the transmittance mode on a homogenized milk sample compared with water.

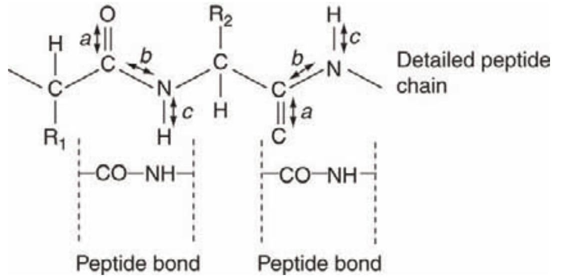

Figure 3 Mid-infrared absorption bands of the peptide bond. *a*, amide I (C=O stretch); *b*, amide II (C–N stretch); *c*, amide II (N–H bending); arrows, direction of the light-induced dipole; R_1, R_2, amino acid side chains.

absorbance. Even though proteins are the main absorbing components at 6.46 μm (1550 cm^{-1}), fat, lactose, phosphate, and organic acids with a free carboxylic group (COO^-) may interfere, provided their concentrations are naturally variable in milk and not highly correlated to the protein concentration. To eliminate fat and lactose interferences, intercorrection factors are calculated at each measuring wavelength during the calibration step, in order to obtain the corrected values for fat, protein, and lactose. In addition, with corrections automatically applied in modern milk analyzers, the variability of NPN (**Figure 4**(**a**)) and citric acid (**Figure 4**(**b**)) concentrations can explain most of the differences between infrared and Kjeldahl methods.

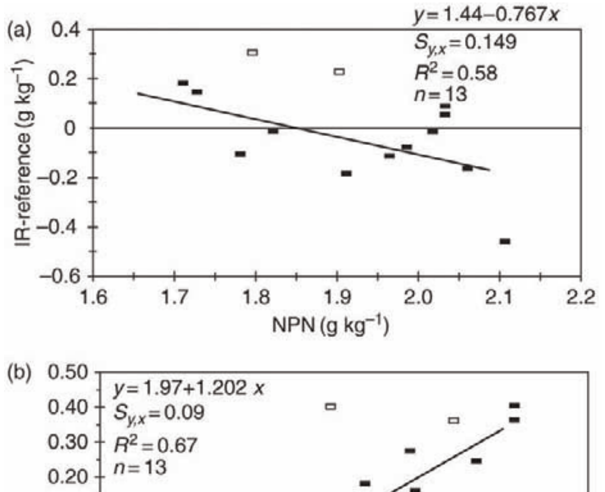

Figure 4 Influence of milk composition (medium molecular mass of fatty acids, non-protein nitrogen (NPN) concentration, citrate concentration) on the differences observed, on the determination of (a) total nitrogen and (b) protein content, between infrared (IR) filter instruments and the reference methods.

With Fourier transform infrared (FT-IR) spectroscopy, which provides the whole infrared spectrum in a few seconds, it is theoretically possible to include in the calibration all the known and unknown factors that may interfere in the measurement.

Near-infrared analysis

Although there are specific absorption bands of the polypetidic chains at about 1525 nm (first harmonic N–H stretching vibration) and 1600 nm (first harmonic-free N–H stretch/amide II combination), two wavebands near 2050 nm (N–H stretch/amide II combination) and 2180 nm (amide A/amide III or first harmonic amide I/amide III combination) are essentially used for milk analysis.

Except for the Infra Alyzer 400 Dairy (Brann and Luebbe, Delaware), which has a built-in homogenizer and a temperature-controlled sample cell, no NIR instrument has been specifically dedicated to the analysis of milk. Milk can be analyzed either in the transmittance or in the reflectance mode, and wavelength discrimination is obtained either with filters (Infra Alyzer) or with a grating (NIR system).

One of the most interesting features of NIR spectroscopy is the possibility of connecting a fiber-optic probe, to make an *in situ* measurement.

Calibration of NIR instruments follows similar principles to the calibration of MIR concerning the selection of milk samples. Multilinear regression, and more often partial least squares (PLS), or even neural networks are used. Often, preliminary treatment of the data, such as derivations, is necessary.

Because of the excellent performance of MIR milk analyzers, very few study results on the performance of NIR instruments for milk protein analysis are available. The repeatability standard deviation is about 0.2 g kg^{-1}, and the accuracy standard deviation is in the range of 0.3–0.8 g kg^{-1}.

Dye-Binding Methods

Dye-binding methods are based on the quantitative reaction between ionized groups of proteins and acid. The amido black method, which uses CI acid black I, is used routinely in different countries. In an acid buffer solution (pH 2.4), the positive charges on the terminal amino groups and the basic amino acid residues of proteins bind in a stoichiometric interaction with the negative sulfonic group of the dye, which must be in excess, to form an insoluble complex. In addition, hydrophobic interactions occur between free and bound dye. After centrifugation, the supernatant is measured spectrophotometrically at about 530 nm. As the quantity of dye bound per unit weight of protein varies with the different proteins, the trueness of the method is influenced by the proportions of the different proteins. Whey proteins bind approximately 27% more dye than caseins, and the NPN fraction does not bind dye.

Analysis of Major Nitrogen Fractions

The Aschaffenburg–Rowland procedure has recently been modified and standardized to measure directly caseins or true proteins with a single Kjeldahl determination instead of two determinations. Acid precipitation is made directly in the Kjeldahl flask, and the precipitated proteins are removed by filtration and analyzed. Caseins (or *para*-caseins) and whey proteins in milk can also be measured by infrared and the dye-binding methods. Because of dilution and the formation of free carboxylic groups with classical acid precipitation, the analysis of caseins by infrared is performed after separation of caseins by rennet coagulation or by precipitation with phosphoric acid, which does not have ionizable carboxylic groups. After calibration, the whey proteins are measured directly in the filtrate, and *para*-caseins or caseins are obtained by the difference between the total proteins in the milk and those in the whey. Attempts have also been made to measure the caseins in milk directly after appropriate calibration of the instrument. With the dye-binding method, only rennet coagulation is used.

Analytical Performances

Precision is a criterion common to all methods of analysis. **Table 1** gives the repeatability and reproducibility values obtained through international inter-laboratory studies for the reference methods. For the infrared and dye-binding methods, the repeatability limits are usually lower than 0.03 g 100 g^{-1} of protein; no reproducibility standard value can be given because the inter-laboratory variability is highly dependent on the procedure used to calibrate the instruments. Lower *R* values are expected when instruments are calibrated using common reference materials, as compared with calibrations made locally with the Kjeldahl method.

Trueness concerns only indirect methods of analysis, such as infrared and dye-binding. **Table 2** gives examples of trueness values obtained. Dairy laboratories nowadays

Table 1 Precision (International Dairy Federation standards) of reference methods for the determination of nitrogen (N) fractions in milk

N fraction	*Repeatability, r (g 100 g^{-1})*	*Reproducibility, R (g 100 g^{-1})*
Total N	0.0060	0.0077
True protein N (direct)	0.0038	0.0092
Casein N: direct	0.0064	0.0096
Casein N: indirect	0.0068	0.0113
Soluble N	0.0043	0.0072
Nonprotein nitrogen	0.0025	0.0052

Table 2 Examples of trueness values ($S_{y,x}$ or S_{y-x}) of infrared milk analyzers for the analysis of crude proteins, true proteins, and caseins of herd or individual cow's or goat's milk samples

				S_{x-y} (g kg^{-1})		
Instrument	*Analysis*	*Milk*	*n*	*Crude proteins*	*True proteins*	*Caseins*

MIR (F), mid-infrared; FT-IR, Fourier transform infrared; NIR (F), near-infrared.

Table 3 Influence of season on the exactness of measurement of crude and true protein of 163 bulk milks, with filter (Milko Scan 605) and Fourier transform-infrared (Nicolet 740) milk analyzers using single or multiple calibrations

		Milko scan 605		*Nicolet 740*	
Calibration		d_{x-y}	s_{x-y}	d_{x-y}	s_{x-y}
Single	Crude protein	−0.48	1.19	+0.10	0.53
	True protein	+0.35	1.21	+0.16	0.44
Multiple	Crude protein	0.00	0.48	0.00	0.46

use fully- or semi-automated dedicated instruments that can analyze up to 400 samples per hour. Repeatability standard deviation is always lower than $0.10\,\mathrm{g\,kg^{-1}}$. However, despite the fact that the entire spectral information is available, similar performances were obtained with filter and FT-IR instruments on a relatively homogeneous population of milk samples, or when calibrations were adjusted regularly to take into account seasonal variations in milk composition (**Table 3**). On the other hand, when a single calibration is used throughout the year, far better estimates for both crude protein and true protein are obtained with FT-IR than with a filter instrument (**Table 3**).

One of the most difficult aspects of analyzing milk proteins by infrared or amido black concerns calibration.

Analysis of Individual Proteins

Three techniques – electrophoresis, liquid chromatography, and immunochemistry – are well adapted for the identification of individual milk proteins. Nowadays, they also remain practically the only methods available for quantitative measurement of the individual proteins, even though none is entirely satisfactory and they are more appropriate for giving relative rather than absolute concentrations. Immunochemistry is particularly suitable for the detection and quantification of proteins at low concentration. The preparation of pure proteins that serve as references for identification and quantification is critical, because their secondary and tertiary structures may be modified and influence the measurement. Improvements in the chromatographic and electrophoretic protocols tend to achieve casein and whey protein separation simultaneously from skim milk. However, when this is not possible, the caseins and whey proteins can be separated preliminarily by precipitation of the caseins at pH 4.6 or by rennet action, ultrafiltration, or ultracentrifugation. For simplicity, examples of electrophoretic and chromatographic separation are limited to bovine milk.

Electrophoresis

Proteins can be separated using a vertical or horizontal slab gel system or within a capillary by various electrokinetic techniques, using the differences in one or a combination of the following: electric charge, isoelectric point, hydrophobicity, and mass ratio.

In slab gel electrophoresis, after migration, the proteins appear as more or less well-separated bands after being fixed by acid or alcohol precipitation and stained. The analytical performance of the quantitative measurements made by densitometry is greatly influenced by resolution between the bands, by the variability in the dye-binding capacity from one protein to another and from one run to another, and by the linearity and sensitivity of the dye, which increase dramatically in the following order: amido black < Coomassie blue < silver stains. The regression coefficient must be determined for each set of analytical conditions. The availability of ultrathin precast minigels with automated electrophoretic equipment, allowing shorter run times, has greatly improved the sensitivity, resolution, and speed of slab gel electrophoretic methods for milk proteins. In capillary electrophoresis, the eluting species pass in front of the spectrophotometer, and the intensity of absorption is registered immediately in return for correction of the velocity.

Polyacrylamide gel electrophoresis

In polyacrylamide gel electrophoresis (PAGE), proteins migrate mainly according to their charge-to-mass ratio. Alkaline conditions, where the proteins are negatively charged, are the most popular protocols for milk proteins. Caseins are better separated in the presence of urea, which dissociates intermolecular aggregates, and in the presence of a reducing agent (dithiothreitol (DTT)), which disrupts the disulfide bonds of α_{s2}- and κ-casein. In addition, the use of polyacrylamide in a gradient from 8 to 12.5% improves the simultaneous analysis of caseins and whey proteins, including some genetic variants and with different degrees of phosphorylation. However, γ_1- and γ_3-casein are not well resolved from κ-casein. The elution order in terms of increasing mobility is BSA, κ-casein and γ-casein, β-casein, β-lactoglobulin, α_{s2}-casein (two bands), α_{s1}-casein, and α-lactalbumin. Whey proteins appear as more diffused bands than the caseins, which affects their quantification.

Sodium dodecyl sulfate–polyacrylamide gel electrophoresis

Proteins are able to bind the anionic detergent sodium dodecyl sulfate (SDS) through hydrophobic interaction in the theoretical ratio $1.4\,\mathrm{g\,SDS\,g^{-1}}$ protein. Under these conditions, the charge-to-mass ratio is constant for each protein, which migrates according to its decreasing mass due to the sieving effect of the gel. However, the binding capacity of milk proteins differs noticeably from the theoretical value for each protein, which means that the molecular mass with reference to the protein standard of known molecular mass cannot be determined. Nevertheless, this method, together with a polyacrylamide gradient, has been used successfully to quantify in a single gel the main proteins in milk (**Figure 5**). Due to the shape of the bands and the somewhat poor resolution, quantification is more variable than for urea PAGE. Genetic variants are not resolved.

Isoelectrofocusing polyacrylamide gel electrophoresis

Separating proteins according to their isoelectric point appears to be the best method for identifying most of the non-silent genetic variants of the caseins (especially β-casein) and whey proteins. It is used routinely for the phenotyping of milks. The proteins migrate in a gel containing ampholytes until they meet the zone of the gel corresponding to their isoelectric pH, at which they precipitate. In combination with urea and a reducing agent, caseins are separated in the decreasing order of their isoelectric pH: γ-casein, κ-casein (A, B, C), α_{s2}-casein (A, D), β-casein (A^1, A^2, A^3, B, C), α_{s1}-casein (A, B, C). Whey proteins are separated without urea in the following order: α-lactalbumin B, β-lactoglobulin (A, B). This protocol allows the analysis of caseins and whey proteins together but with no differentiation of α-lactalbumin B

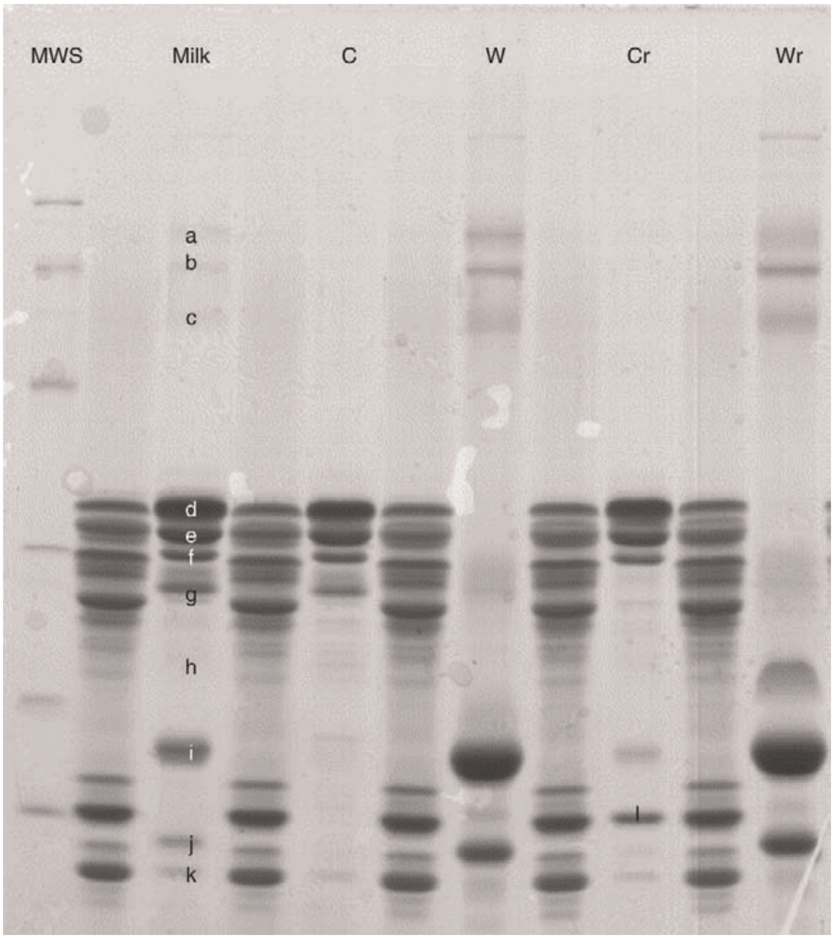

Figure 5 Bovine milk protein analysis by sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS–PAGE). MWS, molecular weight standard; C, caseins precipitated at pH 4.6; W, whey proteins soluble at pH 4.6; Cr, *para*-casein precipitated by rennet hydrolysis; Wr, whey proteins soluble after rennet hydrolysis; a, lactoferrin; b, serum albumin; c, immunoglobulin G; d, α_{s2}-casein; e, α_{s1}-casein; f, β-casein; g, κ-casein; h, γ_1-casein; i, β-lactoglobulin; j, α-lactalbumin; k, ($\gamma_2 + \gamma_3$)-casein; l, *para*-κ-casein.

and β-lactoglobulin A. Isoelectrofocusing (IEF) remains above all a qualitative method.

Two-dimensional electrophoresis

Using a combination of IEF (gel rod, first dimension) and PAGE (slab gel, second dimension), with or without SDS or urea, this high-resolution technique has been applied successfully to identify genetic polymorphism and to study specific protein fractions in complex mixtures. Due to the shape of the spots, a sophisticated image analyzer is needed for quantitation.

Capillary electrophoresis

In capillary electrophoresis (CE), elution is performed in a capillary instead of a slab gel. Resolution results from the combined effects of the presence and nature of a coating on the capillary and the characteristics of the eluting buffer (pH, ionic strength, modifiers), which determine the importance of the endoelectroosmotic flow and electrophoretic mobility of the molecule. Currently, the most competitive simultaneous separation of milk proteins is obtained with a hydrophilically coated capillary, an acidic citrate-eluting buffer containing urea, a reducing agent DTT, a polymeric additive methyl-2-hydroxyethyl cellulose (MHEC), and a sample buffer including Tris, DTT, 3-morpholinopropanesulfonic acid (MOPS) and urea at pH 8. Within 60 min, the proteins elute in the following order: α-lactalbumin, β-lactoglobulin, α_{s2}-casein (A, D), α_{s1}-casein (B, C), κ-casein, β-casein (A^1, A^2, A^3, B, C). The A and B variants of β-lactoglobulin and of κ-casein cannot be separated except when using highly dedicated protocols. Advantages of CE over slab gel electrophoretic methods include higher sensibility in terms of detection (fluorimetry, mass spectrometry), possible separation of uncharged silent variants or oppositely charged molecules (*para*-κ), greater automation, and smaller quantity of the sample. However, good reproducibility depends markedly on the sophistication of sample preparation and capillary cleaning protocol between injections.

Column Liquid Chromatography

Ion exchange and reverse-phase chromatography have been used extensively for the analytical separation of milk proteins. These techniques are complementary to gel filtration and hydrophobic interaction chromatography, which are particularly suitable for preparative analysis.

Ion-exchange chromatography

Separation of proteins by ion-exchange chromatography (IEC) is obtained because of their capacity to bind to a resin exchanger and to be separated with an NaCl gradient buffer. Milk proteins cannot be satisfactorily analyzed simultaneously. The Mono Q and TSK-DEAE-5PW anion exchange columns have been reported to separate the four caseins, and some of their genetic variants, and also according to their degree of phosphorylation. Separation of whey proteins (α-lactalbumin, serum albumin, β-lactoglobulin A and B) is performed on a Mono Q column. The cation exchange Mono S column is used mainly to separate minor proteins in milk or for some particular separation, such as β-casein A^1, A^2, and B variants.

Reverse-phase chromatography

This technique is based upon hydrophobic interaction between a stationary phase made of C_{18} (or C_8 or C_4)-bonded silica or polystyrene–divinylbenzene and the proteins in an aqueous solution of low ionic strength. Elution is obtained by increasing the hydrophobicity of the 0.01% trifluoroacetic acid (TFA) in the water mobile phase by increasing its content in acetonitrile. Until recently, an excellent separation of caseins could be obtained only in the absence of whey proteins. The caseins, dispersed in a citrate buffer containing urea and DTT, are separated in the following order: glycosylated κ-casein, κ-casein (A, B), α_{s2}-casein A, α_{s1}-casein (A, B + C, D), β-casein (C + A^1, A^2, A^3). With a recent modification of the sample buffer where urea was replaced by guanidine hydrochloride, simultaneous separation and quantification of caseins and whey proteins, including most of their genetic variants, were obtained. The latest developments include the use of two-dimensional (2D) chromatography, mass or derivative UV spectra, or dynamic surface tension detection.

Immunochemistry

In spite of their interesting features, such as high specificity and sensitivity, the performance of immunological methods is usually considered to be inadequate technically, commercially, and analytically, as compared with other techniques, for routine use for the quantitative analysis of milk proteins. For instance, their reproducibility ranges between 2 and 10% and, despite their theoretical specificity, their exactness is sometimes questionable. It has been shown, for example, for the measurement of immunoglobulin G, that systematic biases exist between methods, and that most discrepancies may occur with respect to the origin of antigens and antibodies used to construct the standard curves and to make measurements. On the other hand, these techniques are considered to be quite suitable for the analysis of individual proteins, either in the field of research or for clinical and regulatory purposes.

Practically all kinds of immunological technique, using either mono- or polyclonal antibodies, were developed to measure the proteins in milk (**Table 4**). Because milk is an extremely complex biological fluid, the development

Table 4 Examples of immunological methods used for quantitative measurement of proteins in milk

Performance					
Method	*Antibody*	*Proteins*	*Working range or limit of detection*	*Between-assay reproducibility (%)*	*Other applications*
MENI	pAb	α_s-Casein	4.0–34.3 g l^{-1}	1.9–3.4	
		κ-Casein	1.3–3.4 g l^{-1}	1.9–3.4	Whey curd
		β-Lg, α-La	0.6–2.0 g l^{-1}	2–5	
		IgG	>8 µg l^{-1}	2.3–10.0	
Competitive ELISA	mAb	β-Lg	0.03–2.0 ng ml^{-1}	<11	Heat treatment (semi-qualitative) cow in goat (0.03%)
Sandwich ELISA	pAb	β-Lg	>0.02 µg l^{-1}		Cow in human
Inhibition ELISA	mAb	α-La	10–500 ng ml^{-1}	11	Heat treatment
Competitive ELISA	pAb	α-La	20–1600 ng ml^{-1}	2.6–6.4	Heat treatment
RID	pAb	IgG_1	0.2–4 mg ml^{-1}	5.1	Semi-automated detection of abnormal milks
Sandwich ELISA	mAb	Plasmin Plasminogen	2–100 ng ml^{-1}	13	

MENI, microparticle-enhanced nephelometric immunoassay; ELISA, enzyme-linked immunosorbent assay; RID, radical immunodiffusion; pAb, polyclonal antibody; mAb, monoclonal antibody; β-Lg, β-lactoglobulin; α-La, α-lactalbumin; IgG, immunoglobulin G.

of accurate and easy-to-perform immunoassays has always been difficult.

Caseins

Because of their micellar structure, which interferes with the antigen–antibody reaction, and their great susceptibility to hydrolysis by indigenous proteases such as plasmin or cathepsin D, accurate and straight-forward quantitative measurement of caseins in milk is difficult to achieve. Microparticle-enhanced nephelometric immunoassay (MENI) has been applied to a large number of samples (1300 herd milks) for the measurement of α_{s1}-, β-, and κ-caseins. This technique has the advantage that no sample pre-treatment is required. However, it has several drawbacks, such as under-estimation of results, a high limit of detection (1 µg ml^{-1}), and interference of medium turbidity. More recently, an immunosensor allowing the simultaneous quantification of α_{s1}-, β-, and κ-caseins in milk has been developed. This assay consists of a two-step sandwich strategy, with two monoclonal antibodies directed against the N- and C-terminal extremities of each of the caseins, respectively. This strategy permits only intact caseins to be quantified, and not their degradation products. The technique is fast (10 min $sample^{-1}$), automated, and has been applied successfully to raw and drinking milks and cheeses.

Besides this method, very few other techniques have been developed. Rocket immunoelectrophoresis with a monospecific polyclonal antibody was used to quantify human β-casein but hydrolyzed β-casein was also recognized. A specific monoclonal antibody was produced and used to detect by radioimmunoassay as little as 0.3×10^{-4} mmol ml^{-1} of κ-casein in solution, but this method was not applied to milk.

Because of the significant differences in amino acid sequences, caseins (often β-casein) are excellent markers for the development of immunoassays (enzyme-linked immunoassay (ELISA) or immunoblotting) that allow the detection of usually below 1% of a milk added fraudulently to the milk of a different species, particularly cow's milk in goat's or ewe's milk.

Whey and minor proteins

In contrast to caseins, whey proteins have good antigenic properties, and are not usually hydrolyzed in raw milk. However, during heat treatment, they are susceptible to conformational modifications and to binding to other proteins, and therefore to antigen–antibody reaction changes.

In fact, advantage has been taken of this property to produce antibodies able to detect, for instance, native or denatured α-lactalbumin or β-lactoglobulin, and to develop immunoassays for the control of the intensity of the heat treatment of milk.

Since milk proteins are major food allergens, immunoassays allowing the detection of traces of these proteins in complex food matrices have seen important developments in recent years. Most of the commercially available kits correspond to ELISA-type techniques using monoclonal or, more usually, polyclonal antibodies as ligand. They allow a quick quantification of milk proteins in the milligram-per-kilogram range. Extraction of the proteins prior to detection may be required in processed food.

In relation to the presence of psychrotrophic bacteria in milk, particularly of *Pseudomonas* spp., which can produce heat-resistant proteinases responsible for the gelation of UHT milk, qualitative ELISA and MENI were developed to measure the caseinomacropeptide released from the hydrolysis of κ-casein.

Milk hormones, such as prolactin and somatotrophin, which can be present in milk, can also be measured by immunoassays (radioimmunoassay and sandwich ELISA).

Future Trends

Recently, progress has been made in the differential quantification of casein and whey proteins using infrared spectroscopy, and it is probable that separation of these fractions from other milk proteins will no longer be necessary for quantification. Therefore, it can be stated that infrared techniques will find growing applications in the dairy industry.

Immunological techniques will certainly be used more frequently in the near future, especially for applications where their sensitivity and specificity make them unavoidable (minor components, enzymes, hormones). Biosensors have been developed recently for the analysis of dairy products. They are defined as analytical tools or systems consisting of an immobilized biological material in intimate contact with a suitable transducer device that will convert the biochemical signal into a quantifiable electrical signal. Thus, they retain the specificity of biomolecules with the possibility of quantitative or qualitative detection of the biomolecule–analyte interaction by an appropriate, sensitive transducer. They are fast, reliable, sensitive, and sometimes automated. Some consist of electrodes that can make *in situ* measurements.

Finally, liquid chromatography is a powerful tool, especially when coupled with mass spectrometry, which allows the molecular mass of the molecules separated on the column to be determined. With this technique it has been possible to make major advances in the identification of proteins (including some genetic and post-translational variants) in milk and dairy products, interaction between them, and the effects of treatment (heat, photooxidation, etc.), and in understanding complex biochemical pathways such as proteolysis during cheese ripening. Capillary electrophoresis is now competing with liquid chromatography. It is now routinely used for the quantification of proteins (whey proteins in particular) in dairy products. But the challenge remains for both LC and CE to better recover proteins and to be able to quantify the modifications induced by milk treatments, heat in particular.

Introduction

Milk from approximately 150 of the estimated 4000 mammalian species has been analyzed with different degrees of detail and in all cases this secretion has been shown to contain a protein component that varies from 1% in human to >20% in rabbit milk. Berzelius in 1814 described the first method for the separation of casein, the major protein component of cow's milk. With the development of more sophisticated analytical techniques over the years, more than 200 types of protein have been characterized in bovine milk. The proteins in cow's milk are the most widely studied in terms of their isolation, characterization, structural properties, functions, and biosynthetic pathways. Hence, unless otherwise stated, the term 'milk proteins' in this article refers to the bovine species.

Milk protein is a very heterogeneous group of molecules, and for ease of description, could be classified into five main categories: caseins, whey proteins, milk fat globule membrane proteins, enzymes, and other miscellaneous minor proteins. Along with several factors that contribute to the heterogeneity of milk proteins, this article will focus on methods used for isolation, molecular structure, degree of post-translational modification, self-association and association between different types of protein, differences in the amounts and relative proportions of individual proteins, origin of the proteins, diversity of functions, and the presence of homologues across species. The heterogeneity of milk proteins is further complicated by the presence of genetic variants that have been identified in several species apart from the bovine. With the developments in molecular biology and the improvements in cloning techniques, it is possible to increase further the heterogeneity of milk proteins by site-directed mutagenesis, controlling the levels of expression of proteins indigenous to milk and of novel proteins that are foreign to the mammary gland.

The heterogeneity of milk proteins has contributed to difficulties associated with their fractionation and isolation, and as we acquire more information about the macromolecules involved, these problems are being overcome. For more than 50 years, it was thought that the casein fraction prepared by Hammarsten in 1883 was a pure protein. The application of moving boundary electrophoresis by Mellander in 1939 demonstrated the heterogeneity of the casein fraction with three electrophoretic components denoted as α-, β-, and γ-. Present-day knowledge confirms that each of the three components represents more than one protein. The primary structure and gene sequence of the four caseins (α_{s1}-, α_{s2}-, β-, and κ-) and three of the whey proteins (β-lactoglobulin, α-lactalbumin, and bovine serum albumin) are now established. The fractionation and isolation of protein components depend on the intrinsic physicochemical properties of the individual proteins. Because some of the proteins tend to self-associate or associate with other proteins, a denaturing reaction is required prior to fractionation. Techniques of ultracentrifugation, size-exclusion chromatography, ultrafiltration, and sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) could be adapted for the separation of certain proteins on the basis of molecular mass differences. Variability in net electrical charges; sensitivity to ions, for example, calcium; and solubility in the presence of denaturing agents, for example, urea could be exploited for the isolation of some proteins by precipitation with different concentrations of salt (ammonium sulfate, calcium chloride) and solutions of alcohol under different pH and temperature conditions. Based on the charge and ionic strength properties of the proteins, several chromatographic and electrophoretic procedures have been developed for their fractionation and isolation. The most appropriate procedures for the isolation of milk proteins will depend on the level of purity and the amount (analytical, preparative, industrial) of protein required.

For a better appreciation of this article, some familiarity with the nomenclature used for the milk protein system, as proposed by a committee of the American Dairy Science Association is recommended.

Classification and Nomenclature of Milk Proteins

When raw skim milk is adjusted to pH 4.6, a precipitate containing approximately 80% of the protein of cow's milk is formed. This precipitation procedure has been used as the basis for the classification of milk proteins into two main groups, with casein in the precipitate and whey protein (non-casein protein) in the supernatant. **Table 1** gives a summary of some of the characteristics of the four types of caseins and the four major proteins in the whey protein fraction. The primary structure (amino acid sequence) and the gene sequence of the four caseins,

[a] Molecular mass are for the genetic variants in bold.

ranging in molecular mass from 19 038 for κ-casein to 25 388 for α_{s2}-casein, have been established. Among the major whey proteins, α-lactalbumin is the smallest (MW 14 175 Da) and the immunoglobulins are the largest (MW 143 000–1 030 000 Da). The complete amino acid sequence of β-lactoglobulin, α-lactalbumin, and serum albumin, with molecular masses of 18 277, 14 175, and 66 267 Da, respectively, are also known. Unlike β-lactoglobulin and α-lactalbumin, serum albumin and some of the immunoglobulins are not synthesized in the mammary gland. The immunoglobulins are extremely heterogeneous and their identity is based on immunochemical properties. Five classes of immunoglobulins (IgG, IgA, IgM, IgE, and IgD) have been identified in bovine milk. Their basic structure is similar to other immunoglobulins in having two heavy and two light polypeptide chains covalently linked by disulfide bonds. The molecular mass varies from 50 000 to 70 000 Da for the heavy chains depending on the type and about 25 000 Da for the light chains. In addition to differences in the organizational structure, there are also differences in amino acid sequences and carbohydrate groups present in the immunoglobulin molecules. More than 60 enzymes have been identified in milk and, as a group, they account for less than 1% of the total milk protein. Enzymes are heterogeneously distributed in milk, for example, catalase, lactoperoxidase, ribonuclease, and glucosaminidase are found mainly in the whey fraction while proteinases and lipase are associated with the casein micelles, and xanthine oxidase is found in the milk fat globule membrane. The fat globules of milk are stabilized by a complex membrane consisting of proteins and phospholipids; these proteins are designated as milk fat globule membrane proteins. The major proteins of the milk fat globule membrane were reviewed recently. Proteins that do not fall into the classification of caseins, major whey proteins, enzymes, and milk fat globule membrane proteins are categorized as miscellaneous minor proteins and include transferrin, lactoferrin, ceruloplasmin, lactollin, glycoprotein-a, kininogen, M-1 glycoprotein, epidermal growth factor, glycolactin, angiogenin, etc. A wide range of biological functions have been assigned to those minor proteins present at concentrations in the mg kg^{-1} range.

Heterogeneity of Milk Proteins

In addition to the high degree of heterogeneity that exists between the five different classes of milk proteins, there is also heterogeneity among proteins within each class. This is to be expected when one considers that milk proteins range from 10 000 to >1 000 000 Da in molecular mass and have different amino acid compositions and sequences that ultimately determine the structures and physicochemical properties of the molecules. The degree of post-translational modification (proteolysis, phosphorylation, glycosylation, formation of disulfide bridges) and the existence of genetic variants contribute further to the observed heterogeneity.

Caseins

Bovine milk contains four types of caseins denoted as α_{s1}-casein, α_{s2}-casein, β-casein, and κ-casein, each of which is the product of specific genes. However, PAGE of a whole casein preparation could resolve in excess of 20 protein bands. Several of the electrophoretic bands represent post-translational products of one of the four caseins (see below).

The caseins, which are synthesized in the mammary gland, are proteins containing ester-bound phosphate and due to their relatively high content of proline (see **Table 1**), they tend to have very little secondary structure. The primary structure of α_{s1}-casein, containing 199 amino acid residues, is shown in **Figure 1**. It has no cysteine residue and eight phosphates attached to serines. A minor

Figure 1 Primary structure of bovine α_{s1}-casein B. Reproduced from Mercier JC, Grosclaude F, and Ribadeau-Dumas B (1971) Structure Primaire de la caséine α_{s1}-bovine. *European Journal of Biochemistry* 23: 41–51.

α_{s1}-casein with a faster electrophoretic mobility, denoted earlier as α_{s0}-casein, has been characterized and is slightly different from the former by having nine phosphorylated serines and hence contains one extra negative charge at alkaline pH. There are three hydrophobic regions, residues 1–44, 90–113, and 132–199. The sequence of residues 41–80 is very polar due to the presence of seven seryl phosphates, eight glutamates, and three aspartates.

As shown in **Figure 2**, α_{s2}-casein contains 207 amino acids. It has 10 prolines, more phosphoserines (see **Table 1**) and more lysines than the other caseins, and two cysteines at positions 36 and 40. Several forms of

Figure 2 Primary structure of bovine α_{s2}-casein A. Reproduced from Brignon G, Ribadeau-Dumas B, Mercier JC, Pelissier JP, and Das BC (1977) Complete amino acid sequence of α_{s2}-casein. *FEBS Letters* 76: 274–279.

α_{s2}-casein are discernable by PAGE due to different degrees of phosphorylation, which range from 10 to 13 phosphate groups. These forms have been identified as α_{s2}-, α_{s3}-, α_{s4}-, α_{s5}-, and α_{s6}-casein (α_{s5}- is a dimer of α_{s3}- and α_{s4}-). The 13 phosphates (12 on serine, 1 on threonine) are located in three regions of the molecule: residues 7–31, 55–66, and 129–143. Among the caseins, α_{s2}-casein is the least hydrophobic with regions of hydrophobicity located at residues 90–120 and 160–207.

The sequence of the 209 amino acids in β-casein is shown in **Figure 3**. It is the most hydrophobic casein, it has no cysteine, and it has a high proportion of proline (35 residues), which has a profound effect on its structure. At milk pH, the N-terminal 21-residue segment is highly negatively charged while the rest of the molecule, which is very hydrophobic, has no net charge. The amphipathic nature of β-casein is the reason why it forms micellar aggregates in solution. Human β-casein has been shown to consist of six proteins with an identical amino acid sequence, but with 0–5 phosphate groups attached to serine residues. The γ-caseins, which have been known for a long time, are actually the hydrolytic products of β-casein, produced by the action of plasmin. γ-Caseins, corresponding to residues 29–209, 106–209, and 108–209 of β-casein, are present in the precipitate formed on isoelectric precipitation of whole casein at pH 4.6. Other fragments of β-casein (residues 1–28, 1–105, and 1–107) are found in the whey and they constitute part of a fraction formerly known as 'proteose peptone'.

κ-Casein is the only protein of the casein family that is glycosylated. The different degrees of glycosylation, as revealed by up to seven bands during PAGE, are related to the number of negative charges on the *N*-acetylneuraminic acid residues. The primary structure of the carbohydrate-free portion of the 169 amino acid-containing protein is shown in **Figure 4**. κ-Casein is the target for chymosin and it is the most extensively studied milk protein. It stabilizes casein micelles against precipitation by calcium and loses this protective role when the Phe_{105}–Met_{106} bond is cleaved by enzymes to form two peptides: para-κ-casein (residues 1–105), which is the hydrophobic portion and precipitates with the casein micelles, and caseinomacropeptide (residues 106–169), which remains in solution due to its high polarity and high content of negative charges. The glycosyl moieties bind to the caseinomacropeptide by O-glycosidic linkages with threonine at position 131, 133, 135, or 142. The two cysteine residues of κ-casein are located at positions 11 and 88, and the serine residue at position 149, and sometimes at position 127, is phosphorylated. The amphipathic character of κ-casein encourages it to from micelles in solution. Unlike other caseins, κ-casein does not bind calcium extensively and is not sensitive to precipitation by Ca^{2+}.

Figure 4 Primary structure of bovine κ-casein B. Reproduced from Mercier JC, Brignon G, and Ribadeau-Dumas B (1973) Structure de la caséine κ B bovine: séquence complete. *European Journal of Biochemistry* 35: 222–235.

Heterogeneity of the caseins also arises from their interactions with one another and with other proteins and small ions. With the calcium phosphate present in milk, the caseins exist as micelles.

Whey Proteins

The whey protein fraction, which accounts for approximately 20% of total protein in bovine milk, comprises the non-casein proteins that remain soluble when caseins have been isoelectrically precipitated at pH 4.6. Whey proteins are even a more heterogeneous group of compounds than the caseins and share few common characteristics, other than being soluble under conditions that render the caseins insoluble. Unlike the caseins, which lack secondary structures, the whey proteins have more organized secondary and tertiary structures and most are globular proteins. Four major proteins, denoted as β-lactoglobulin, α-lactalbumin, serum albumin, and immunoglobulins, as shown in **Table 1**, account for >95% of the non-casein proteins. Both β-lactoglobulin and α-lactalbumin are synthesized in the mammary gland whereas serum albumin is transported to the mammary gland via the blood serum.

More than half of the whey protein is β-lactoglobulin; its primary structure of 162 amino acids is shown in **Figure 5**. It has five cysteine residues, capable of forming disulfide bonds between residues 66 and 160, 119 and 121, or 106 and 119. At pH 3 to 7, it self-associates to form dimers. α-Lactalbumin is the smallest of the major whey proteins, with a molecular mass of 14 175 Da. It plays a very important role in the biosynthesis of lactose by being the modifier in the lactose synthetase complex. The sequence of the 123 amino acids in α-lactalbumin is shown in **Figure 6**. All the eight cysteine residues in α-lactalbumin are connected by disulfide bridges between positions 6 and 120, 28 and 111, 61 and 77, and 73 and 91. Several studies indicate that α-lactalbumin binds calcium, phospholipids, and membranes. Minor forms of α-lactalbumin have been shown to contain a carbohydrate moiety consisting of mannose, galactose, fucose, *N*-acetylglucosamine, *N*-acetylgalactosamine, and *N*-acetylneuraminic acid.

Milk serum albumin is physically and immunologically identical to blood plasma albumin. The sequence of the 582 amino acids in serum albumin is shown in **Figure 7**. All of the 35 cysteine residues (except Cys_{34}) form intra-chain disulfide bonds. The molecule is considered to have three major domains, each consisting of two large double loops and a small double loop, and assumes an ellipsoidal shape. The N-terminal region is more compact than the C-terminal region. There are different domains, varying in hydrophobicity, net charge, and ligand-binding sites. Isoelectric focusing patterns of serum albumin show evidence of considerable microheterogeneity of the protein.

The largest (MW >1 000 000 Da) and most heterogeneous of the major whey proteins belong to a group collectively known as the immunoglobulins, which have been classified as IgG, IgA, IgM, IgE, and IgD. They all exist either as monomers or as polymers of a basic unit made up of two light and two heavy chains, each containing about 200 and 450–600 amino acid residues,

Figure 6 Primary structure of α-lactalbumin B. Reproduced with permission from Brew K, Castellino FJ, Vanaman TC, and Hill RL (1970) The complete amino acid sequence of α-lactalbumin. *Journal of Biological Chemistry* 245: 4570–4582.

respectively. The various classes of immunoglobulins found in milk are similar to immunoglobulins from other sources in terms of structure and functions. The N-terminal half (residues 1–115) of the light chain is known as the variable region because of its highly variable amino acid sequence. The C-terminal half is known as the constant region because the sequence of amino acids is not as variable. The heavy chains also contain a variable segment (residues 1–115) and a constant region (residues 310–500). The variable regions of the light and heavy chains are responsible for antigen binding, whereas functions of complement fixation, membrane transport, catabolism, and mediation of immediate-type hypersensitivity have been attributed to the constant region of the heavy chains.

Enzymes in Milk

While a large number of enzymes have been isolated from milk, only a relatively small number have been characterized in detail. It is not known whether some of the enzymes found in milk are truly indigenous or may have been introduced due to microbial contamination. The first reported enzyme in milk was lactoperoxidase

and to date over 60 enzymes have been reported as being indigenous to milk. In certain instances, the use of the prefix ‘lacto’ is confusing because it implies that these enzymes occur only in milk, for example, lactoperoxidase refers to a specific enzyme irrespective of its source. Nomenclature of the enzymes in milk does not pose any problems because the standard nomenclature and classification numbers are assigned. Milk enzymes are associated with different milk components, for example, catalase and ribonuclease are found in the whey protein fraction, proteinases are associated with the casein micelles, and xanthine oxidase is a major component of the fat globule membrane. Many enzymes, for example, catalase, are present predominantly in one component of milk, but are not confined exclusively to that component. This may be due to redistribution of the enzymes in the milk system. α-Lactalbumin, a major whey protein, may be classified as an enzyme because of its involvement in lactose synthesis.

Milk Fat Globule Membrane Proteins

A large number of proteins are present in milk at relatively low concentrations and are not isolated with either the casein or whey protein fractions but belong to a separate group known as milk fat globule membrane proteins. These proteins were traditionally classified on the basis of their relative mobility on SDS-PAGE. The protein bands were numbered consecutively from the point of sample application in order of increasing mobility. Confusion arose with regard to the naming of a specific protein because of inconsistencies in the use of the numbering system and different electrophoretic procedures used by various researchers. It has been recommended that the practice of identifying the milk fat globule membrane proteins by number be abandoned and be replaced by specific names as they are characterized by molecular cloning and sequencing techniques. For example, the term ‘butyrophilin’ is used to denote a protein that has been known under the following names: band IV/glycoprotein E, component IV, component V/glycoprotein 6, component 12/IV, Band 4/I, and CB5/PAS 5.

Minor Miscellaneous Proteins

A group of biologically significant milk proteins that do not belong to the above four groups of proteins are classified separately in this category. Two iron-binding proteins, transferrin and lactoferrin (formerly known as ‘red protein’), have been identified in milk. Lactoferrin is a nonheme glycoprotein consisting of a single polypeptide chain of 690 amino acid residues with a molecular mass of about 80 000 Da. Ceruloplasmin is a copper-binding protein that has been detected in milk, colostrum, and blood serum. Also present in milk are several proteins that bind other nutrients and components, such as folate, vitamin B_{12}, corticosteroids, and immunoglobulins. β_2-Microglobulin, also known as lactollin, is part of the histocompatibility complex. The 98 amino acids of β_2-microglobulin with a molecular mass of 11 636 Da have been sequenced. With the development of more sensitive analytical techniques, other proteins are being identified and added to the list of minor proteins. Recently, it was reported that a novel protein denoted as ‘glycolactin’ with a molecular mass of about 64 000 Da has been isolated from milk.

Variability in Protein Concentration

The large variations in the concentrations and relative proportions of proteins in milk could contribute to heterogeneity in properties and functionalities of the protein component. For the milk of over 150 species that have been analyzed, the data indicate that the total protein concentration varies from 1% in human to 24% in the white tail jackrabbit, and the casein-to-whey protein ratio varies from 0.25:1 in human milk to 6.3:1 in goat milk. In many instances, a limited number of samples have been analyzed for most of the species compared to cow’s milk and hence the values obtained are not reliable. Also, the nonbovine proteins have not been analyzed in great detail, as in the bovine milk. For the bovine species, the protein content and composition of the milk vary widely depending on genetics, health conditions, and a whole host of environmental factors, including nutrition of the animal, stage of lactation, age of cow, season, and geographical location. Genetic polymorphism of milk proteins (see below) also contributes to large variations in the concentration of certain milk proteins. An example of differences according to the breed of cow is demonstrated by comparing the average protein content of 3.42, 3.61, 3.58, 3.86, and 4.02% in the milk of Holstein, Brown Swiss, Ayrshire, Jersey, and Guernsey, respectively. In five regions of California, the milk protein concentration varies from 3.32 to 3.82%, with the caseins representing 76–78% of the total protein. Total protein, casein, and whey protein contents are higher during the winter and the early stage of lactation. Reports show that the ratio of casein to whey protein decreases as cows become older or with higher incidence of mastitis, and that in a herd of cows, parity number, month of test, stage of lactation, and mastitis had significant effects on the concentrations and relative proportions of individual caseins, β-lactoglobulin, α-lactalbumin, serum albumin, and immunoglobulins. Some minor proteins, for example, lactoferrin and transferrin, occur at higher concentrations in colostrum than in mature milk.

Homology of Milk Proteins

The wide range of profiles obtained when milk proteins from different species are subjected to PAGE on the same gel slab clearly demonstrates heterogeneity across species. In several instances, the nomenclature developed for bovine milk protein has been wrongly applied to the proteins of other species. This extension of name use is justified only if homologous proteins are solidly established based on structural and functional properties. Skim milk from all observed species has a chalky white or 'milky' appearance due to the scattering of light by casein micelles. Hence, it can be assumed that all milks contain a casein component. However, the four different types of casein are present in different proportions and in some cases, one or more of the caseins may be absent. There is evidence that human milk is devoid of α_{s1}- and α_{s2}-caseins, that is, the casein micelles are made up entirely of β-and κ-caseins. Caprine milk represents an interesting situation where the α_{s1}-Cn° allele is associated with no α_{s1}-casein in the milk. Milk from all the species analyzed (except the Californian sea lion) contains lactose and because α-lactalbumin is involved in the synthesis of lactose, one can assume that the presence of α-lactalbumin is universal. β-Lactoglobulin is the protein present at highest concentration in the whey from ruminant milks. Homologous β-lactoglobulin has been characterized in the milk of cows, goats, water buffaloes, and sheep. Apparently, milk from human, kangaroo, camel, guinea pig, rat, and mouse are devoid of β-lactoglobulin. There are indications that mare's milk contains two proteins that are very similar to bovine β-lactoglobulin and can be classified as β-lactoglobulin. A protein isolated from porcine milk is somewhat similar to the ruminant β-lactoglobulin in size and composition, although it lacks a free sulfhydryl group. A cysteine-rich protein denoted as whey acid protein (WAP) has been identified in the milk of rat and mouse, with 137 and 134 amino acid residues, respectively. This protein is not found in ruminant and human milk. Analogues of serum albumin and immunoglobulins are present in the milk of all species and are representatives of the proteins circulating in the blood for the species. It is not known whether all the milk fat globule membrane proteins and enzymes associated with milk are present in all species because those milks have not been analyzed as extensively as bovine milk. The activities of milk enzymes are species dependent. Ribonuclease activity is higher in cow's milk than in human milk whereas human milk has 1000 times more lysozyme activity than bovine milk. Lactoferrin has been identified in the milk of human, mouse, guinea pig, horse, pig, cow, and goat, but is absent in the milk of rabbit, rat, and dog.

Biological Roles of Milk Proteins

Milk is intended to be the sole source of food for the suckling newborn. Milk proteins are a heterogeneous group of compounds with a wide range of molecular structures and properties. Likewise, they serve many important biological roles, some of which have not yet been determined. As discussed earlier, milk from all species contains casein micelles. The caseins have a loose structure due to a high proportion of proline and hence they are very susceptible to hydrolysis by the digestive enzymes to yield a well-balanced mixture of amino acids for the nutrition of the neonate. Because the caseins are associated with high concentrations of calcium and phosphorus, the digestion of these proteins releases significant amounts of these minerals, which become available to the young animal.

α-Lactalbumin is also of universal occurrence and is required for the biosynthesis of lactose. According to the osmoregulatory theory, the production of milk depends on the presence of lactose.

No biological roles have yet been assigned to β-lactoglobulin although there are indications that it is a retinol-binding protein and it could also be involved in the activation of lipase. Serum albumin and the heterogeneous immunoglobulins are involved in protection against infection and convey passive immunity. The roles of many enzymes are not known. In general, their main significance seems to be the defense against intestinal infection. Lysozyme acts as a bactericidal agent by degrading the bacterial cell walls to enhance the activity of immune antibodies. Protein kinases are present in the milk fat globule membrane and catalyze the phosphorylation of other proteins, thus regulating the biological activities of the latter. Mammary-derived growth inhibitor appears to regulate cellular growth and function. The iron-containing proteins (lactoferrin and transferrin), folate-binding protein, and copper-binding protein serve to convey their prosthetic groups, which are essential for the nutrition in the growing sucklings. Lactoferrin also acts as a selective antibiotic because it chelates iron and renders it unavailable to the bacterial population in the gut, and in the mammary gland it may benefit the lactating cow by reducing mastitic infection.

Genetic Polymorphism of Milk Proteins

A very significant variability in milk proteins, leading to further heterogeneity, is due to genetic events leading to the occurrence of genetic variants. Since the discovery in 1955 of the presence of two forms of β-lactoglobulin, several groups around the world have been actively engaged in research covering various aspects of genetic polymorphism of milk proteins. Several electrophoretic and isoelectric focusing methods have been modified and adapted for the identification of genetic variants of milk proteins. At the latest count (see **Table 1**) 44 genetic variants have been identified among the four caseins, β-lactoglobulin, and α-lactalbumin and the number will undoubtedly rise as more sophisticated methods for detection are developed.

Genetic polymorphism of milk proteins is due to either substitutions or deletions of amino acids in the proteins as a consequence of mutations causing changes in base sequences in the genes. This type of polymorphism should be distinguished from that caused by post-translational modification such as the extent of phosphorylation and glycosylation of the molecule, as discussed previously. Among the 44 genetic variants presented in **Table 1**, two are due to the deletion of a segment in the α_{s1}-casein. Variants A and H of α_{s1}-casein differ from variant B by the absence of amino acid sequences 14–26 and 51–58, respectively. The deletion of residues 51–59 of α_{s2}-casein A leads to the occurrence of variant D. The remaining 41 genetic variants involve amino acid substitutions. For example, κ-casein A differs from κ-casein B by having a threonine at position 136 and an aspartic acid at position 148 instead of an isoleucine and an alanine at the two respective positions. The difference between variants A and B of β-lactoglobulin is due to two amino acid substitutions at positions 64 (glycine for aspartic acid) and 118 (alanine for valine). In both cases, the presence of an extra aspartic acid residue in the A variants renders the proteins more negatively charged and hence the A variants of κ-casein and β-lactoglobulin have faster electrophoretic mobilities under alkaline conditions than their B homologues.

The subject of genetic polymorphism of milk protein polymorphism has generated a lot of interest among several groups of researchers in different fields. Some of the genetic variants of milk proteins are associated with production, composition, and industrial properties of milk. Because the genetic variants are inherited according to the simple Mendelian mode of inheritance, it is possible to breed for specific variants of milk proteins. Such a scheme of selection is being practised in certain countries to favor higher frequencies of κ-casein B and β-lactoglobulin B in the dairy cattle population. The B variant of the two proteins is associated with higher levels of fat and casein in the milk, better coagulating properties on renneting, higher cheese yield, and quality. β-Lactoglobulin A milk has a higher content of protein, mainly due to increased production of β-lactoglobulin, but a lower concentration of casein than β-lactoglobulin B milk. At the κ-casein locus, the B variant is associated with higher concentrations of κ-casein, total casein, and total protein compared to variant A. These are only two examples that serve to illustrate how genetic polymorphism could contribute to variability in amounts and relative proportions of milk proteins.

Fractionation and Isolation

The choice of methods used for the isolation and fractionation of milk proteins will depend, to a large extent, on the nature of the starting material and their concentrations therein. Starting with skim milk, whole casein could be separated from whey proteins by coagulation at pH 4.6 or by enzymatic hydrolysis of caseins with rennet. The whole casein could then be further fractionated into α_{s1}-, α_{s2}-, β-, and κ-caseins. The whey fraction is a good source of β-lactoglobulin, α-lactalbumin, serum albumin, immunoglobulins, and glycomacropeptide (in case of enzymatic hydrolysis). Immunoglobulins and minor proteins such as lactoferrin could also be obtained from colostrum where they exist at much higher concentrations than in milk. Milk-derived bioactive peptides could be obtained by hydrolysis of the proteins with specific enzymes or by proteolysis from fermentation by specific bacteria. There is a whole range of starting materials for the production of bioactive peptides, including milk, whole casein, individual caseins, whey protein fractions, and individual whey proteins. Once produced, the bioactive peptides of interest need to be separated and purified from the mixture of hydrolysates. The bases for isolation and purification of those bioactive peptides are similar to those applied to proteins as discussed later.

The heterogeneous mixture of proteins in milk can be separated and characterized by various physicochemical methods. Comprehensive reviews on different procedures for the fractionation and isolation of milk proteins are available. Many of the procedures depend on the solubility differences and the isoelectric precipitation of the caseins. Some of the caseins are not precipitated at pH 4.6 while certain non-casein proteins may be coprecipitated with the caseins. There is no practical and absolutely clear-cut method for simply fractionating casein, and only casein, from non-casein proteins. Moving boundary electrophoresis was used to resolve whole casein into three fractions denoted as α-, β-, and γ-, none of which represented a pure protein. The interaction of casein with calcium ions was exploited by the use of $CaCl_2$ solution to precipitate a calcium-sensitive fraction, α_s-casein, which contained mainly α_{s1}-, α_{s2}-, and β-caseins from κ-casein, the fraction insensitive to precipitation by calcium. Milder conditions for the precipitation of the caseins by high salt concentration, for example, $(NH_4)_2$ SO_4, have been used. Not all the caseins precipitate and some immunoglobulins and glycoproteins may be included in the precipitate. In 1938, Rowland developed a chemical method to quantify the distribution of proteins in milk and was able to partition the protein as casein, lactalbumin (precipitated by saturation with $MgSO_4$), globulins, and proteose peptone. The rates of sedimentation of proteins from skim milk after dialysis against phosphate buffer were used as a method for the isolation of some proteins. Several casein components could be prepared starting from a 50% alcohol solution of casein in the presence of ammonium acetate, followed by precipitation by varying the pH, ionic strength, and temperature. The interactions between the caseins have hampered their fractionation. Dissociating agents such as urea and disulfide-reducing agent, for example, β-mercaptoethanol, are used routinely to permit better fractionation of the caseins. Individual caseins could be obtained starting with a whole casein solution in $6\,\mathrm{mol\,l^{-1}}$ urea and adding water to precipitate out the components. The α-casein complex is insoluble in 4.5 mol $\mathrm{l^{-1}}$ urea at pH 4.6–4.8 and contains mainly α_{s1}-, α_{s2}-, and κ-caseins. β-Casein is soluble in $3.3\,\mathrm{mol\,l^{-1}}$ urea, but insoluble in $1.7\,\mathrm{mol\,l^{-1}}$ urea. Urea fractionation of casein is not precise because some κ-casein remains in the urea solution with β-casein. In the method of Zittle and Custer, acid casein is dissolved in $6.6\,\mathrm{mol\,l^{-1}}$ urea and acidified with $3.5\,\mathrm{mol\,l^{-1}}$ H_2SO_4. On dilution of the mixture with water, a precipitate rich in α_{s1}- and β-caseins forms slowly. The supernatant is a good source of κ-casein.

The non-casein component obtained in Rowland's method of protein fractionation was resolved by moving boundary electrophoresis into immunoglobulins, α-lactalbumin, β-lactoglobulin, serum albumin, and proteose peptones. The complexity of the whey protein fraction was demonstrated over a century ago with the precipitation of a globulin fraction from an albumin fraction by saturation with $MgSO_4$. α-Lactalbumin and β-lactoglobulin were isolated later in crystalline form from the albumin fraction. Aschaffenburg and Drewry described a classical method for the isolation of β-lactoglobulin. The casein and fat from whole milk were precipitated out by the addition of Na_2SO_4 to a final concentration of 20% at 40 °C. By cooling the supernatant to 25 °C and adjusting the pH to 2.0, a precipitate containing α-lactalbumin was formed. β-Lactoglobulin was crystallized out after adjusting the pH to 6.0 and addition of more Na_2SO_4. Over the years, several methods for preparing crystalline β-lactoglobulin and α-lactalbumin by the use of other precipitating agents, such as trichloroacetic acid and $(NH_4)_2\ SO_4$, have been reported.

In most instances, the above procedures do not give a final product of high purity. Further fractionation and isolation steps involving different types of electrophoresis and chromatography are necessary to achieve the level of purity required. With electrophoretic methods, one could expect to obtain pure proteins in analytical amounts only. Considerably larger quantities of pure proteins may be obtained with the use of chromatographic methods. The development of membrane filtration has revolutionized the fractionation of milk components in the dairy industry.

Zone Electrophoresis

The proteins in milk have a wide range of isoelectric points and molecular mass; hence, they could be separated by different electrophoretic procedures, which could be adapted for the fractionation and isolation of milk proteins in microgram or nanogram amounts. Electrophoretic separations of the proteins have been performed on skim milk, whole casein, or whey protein samples. Among the various supporting media, including filter paper, cellulose acetate, starch, agarose, and polyacrylamide gels, that have been used for the electrophoresis of milk proteins, polyacrylamide is the most convenient and widely used. The concentrations of acrylamide and cross-linking reagent can be modified to prepare gels of different pore size in order to enhance separation based on molecular mass. Polyacrylamide gels can also be made with a concentration gradient of acrylamide. The inclusion of SDS in PAGE also resolves the proteins, according to their molecular mass. Denaturing agents, such as SDS and urea; chelating agents, for example, ethylenediaminetetraacetic acid (EDTA); and reducing agents, for example, mercaptoethanol or dithiothreitol, may be included in the gel to enhance separation of the proteins. A wide variety of gel and electrode buffers, differing in type, concentration, and pH, have been used for electrophoresis. Under alkaline conditions, and in the presence of urea, the mobility is in the following order: α_{s1}- > α_{s2}- > β- > κ-casein. Under acidic conditions, the genetic variants of β-casein migrate in the order $C > B > A^1 > A^2 > A^3$. The order for separation of major whey protein is: β-lactoglobulin > α-lactalbumin > serum albumin > immunoglobulins. Isoelectric focusing, which is considered as a modification of electrophoresis, has also been applied extensively for the resolution of milk proteins. The more recent literature abounds with the application of capillary electrophoresis for the resolution of milk proteins. This latter technique is more applicable for analytical work and may not be suitable for isolation and fractionation of milk proteins.

Chromatography

Different types of chromatography, based on electrical charge, molecular mass, or hydrophobic interactions, have been developed for the fractionation and isolation of milk proteins. Several review articles dealing with the chromatographic separation of milk proteins have been published.

Gel filtration (molecular sieving) chromatography has been used to fractionate and isolate proteins from skim milk, whole casein, or the whey protein fraction. The principle is based on the capacity of different proteins, depending on their molecular mass, to penetrate the pores of the gel stationary phase. Large proteins are excluded from the gel and are eluted rapidly. Chromatography of skim milk on a Sephadex G200 column with pH 7.0 phosphate buffer resolved three fractions containing mixtures of κ-, β-, and α_s-caseins followed by β-lactoglobulin and α-lactalbumin. Gel permeation chromatography is not suitable for fractionating the casein because they occur as micelles of different size. Removal of calcium results in dissociation of the micelles into large polydisperse aggregates containing various proportions of the different caseins. In the presence of urea and reducing agents, the caseins dissociate to monomeric forms, ranging in molecular mass from about 19 000 to 25 000 Da (see **Table 1**), which are too close for an effective separation. Whey proteins have been fractionated successfully into β-lactoglobulin, α-lactalbumin, serum albumin, and lactoferrin by gel filtration chromatography. The use of a Superose 12 column gives satisfactory fractionation of whey proteins in the order: immunoglobulins, serum albumin, β-lactoglobulin, and α-lactalbumin.

Chromatography on a hydroxyapatite column is interesting for the fractionation of caseins because the separation is based on phosphate content. As shown in **Table 1**, κ-casein has the least number (1) and α_{s2}-casein has the largest number (10–13) of phosphate residues. The most commonly used buffer is phosphate, pH 6.8, containing dithiotreitol and urea. The higher the net negative charge on a protein, the more tightly it is bound to the solid phase. Different proteins are separated by gradually increasing the phosphate concentration in the eluting buffer. Using such a method, whole casein can be fractionated into γ-casein, κ-casein with different degree of glycosylation, β-casein, and α_s-casein. The latter fraction indicates poor resolution of α_{s1}-casein from α_{s2}-casein.

Ion-exchange chromatography is by far the most commonly used chromatographic method for the fractionation of milk proteins. This method is based on binding the mixture of electrically charged proteins to the matrix and eluting the components with increasing salt concentration. Although several anion and cation exchangers have been used to fractionate milk proteins, the former is used more frequently. In both instances, NaCl provides counterions, with Na^+ as the cation and Cl^- as the anion. Fractionation of proteins in skim milk by ion-exchange chromatography is not as effective as from whole casein or whey protein preparation. The presence of urea and a reducing agent, such as 2-mercaptoethanol or dithiothreitol, is essential for the effective fractionation of the caseins. Satisfactory fractionation of whole casein into γ-, κ-, β-, α_{s2}-, and α_{s1}-caseins can be obtained with a diethylaminoethyl cellulose (DEAE-cellulose) column and eluting with a NaCl gradient in Tris buffer, pH 8.6, containing 6 mol l^{-1} urea. Many commercial ion exchangers have been used to fractionate the caseins, for example, DEAE-TSK-5PW, Mono Q HR 5/5, Protein Pak DEAE-15HR, and macro Q 50, to name just a few.

DEAE-cellulose chromatography gives satisfactory separation of the whey proteins with the fractionation of β-lactoglobulin, α-lactalbumin, serum albumin, and immunoglobulins. The amount of protein that can be fractionated by column chromatographic methods in the laboratory is relatively small, in the microgram to milligram range, and depends on the size of the column. To overcome this constraint, batch fractionation of whole casein on DEAE-cellulose has been achieved. This method involves suspending whole casein and DEAE-cellulose in 3.3 mol l^{-1} urea solution at pH 7.4 and desorbing the caseins by successive extractions with 0.00, 0.035, 0.085, 0.12, and 0.175 mol l^{-1} NaCl and filtration to recover the desired fractions. Starting with 20 g of whole casein, the recoveries are 2.2 g κ-casein, 6.58 g β-casein, 3.80 g α_{s2}-casein, and 4.89 g α_{s1}-casein. Semi-preparative fractionation of casein into pure κ-, β-, α_{s2}-, and α_{s1}-caseins is possible with high-performance liquid chromatography (HPLC) using a DEAE-15 HR anion exchanger with a NaCl gradient in Tris-urea buffer, pH 7.0. Commercially available cartridges containing anion exchangers, for example, diethyl (2-hydroxypropyl) quaternary amino cellulose, have been used successfully for the fractionation of individual caseins and whey proteins in gram quantities.

Although reversed-phase HPLC (RP-HPLC) and hydrophobic interaction HPLC (HI-HPLC) depend on the hydrophobic interactions between a stationary phase and the proteins to be fractionated, their applications are quite different. In RP-HPLC, adsorption occurs in an aqueous solution of low ionic strength and elution of proteins is obtained by increasing the hydrophobicity of the mobile phase. With HI-HPLC, adsorption of proteins is carried out in aqueous solution at high ionic strength and elution is achieved by reducing the ionic strength of the mobile phase. Whole casein and whey proteins can be fractionated on a phenyl hydrophobic interaction column. For whole casein, elution was done with 0.8–0.5 mol l^{-1}, pH 6.0, sodium phosphate buffer containing 3.75 mol l^{-1} urea. For whey proteins, fractionation is achieved with a 1.5–0.05 mol l^{-1} gradient of ammonium sulfate in 0.05 mol l^{-1} sodium phosphate, pH 7.0. Several studies have reported on the use of RP-HPLC to fractionate whole caseins. In a typical procedure, the whole casein is dissolved in pH 7 buffer containing urea and a reducing agent and applied to the column. The components are eluted by increasing the concentration of acetonitrile (hydrophobicity) linearly over time.

In addition to the fractionation of the caseins and the major whey proteins, all the above procedures have been used, as in other biochemical preparations, to isolate minor milk proteins, including enzymes, fat globule membrane proteins, and other miscellaneous proteins.

Industrial Fractionation

At the industrial level, proteins are fractionated for various purposes. The making of cheese is a form of protein fractionation where most of the casein, apart from the macropeptide portion of κ-casein, ends up in the curd and most of the whey proteins are in the whey. The whey can be further processed to give different protein-enriched products. Different combinations of temperature and heating time give rise to different types of cheeses, with the incorporation of varying amounts of whey protein, especially β-lactoglobulin. Heat-induced interaction between β-lactoglobulin and κ-casein alters the distribution of proteins in milk powders. Low-heat milk powders contain more soluble whey proteins and less β-lactoglobulin/κ-casein complexes. Heat, combined with pH adjustment, can be exploited to fractionate β-lactoglobulin and α-lactalbumin from whey. The manufacture of different types of whole casein is also considered as a method for protein fractionation. The whole casein can be further fractionated to yield individual caseins.

Development in membrane technology has provided different physical methods for the fractionation and isolation of milk proteins. Several review articles give details of the applications of membrane filtration in the dairy industry. In theory, the milk proteins can be separated according to their size in the following increasing order of molecular mass: α-lactalbumin < β-lactoglobulin < serum albumin < lactoferrin < immunoglobulins < casein micelles < milk fat globule membrane. Reverse osmosis requires pressures of 3500–10 000 kPa to remove water. It is conveniently used to concentrate the proteins in whey or skim milk. Ultrafiltration involves the use of membranes with a molecular cut-off range of 1–200 kDa and an operating pressure of 140–700 kPa. When applied to milk, it results in a retentate containing fat and proteins while water, minerals, and lactose pass through as the permeate. The objective of making cheese from ultrafiltered milk is to include the whey proteins in the finished product, and thereby increase yield. Microfiltration (membranes with a pore size of 0.2–2.0 μm; molecular cutoff >200 kDa) has contributed significantly in the industrial fractionation of milk proteins. Because the fractionation process is purely mechanical at a low temperature, there is no negative impact on the functionalities of the proteins. The differences between the size of casein micelles and the whey proteins are such that those two components can be fractionated easily by membrane filtration, with the whole casein being retained and the whey proteins passing through. Further fractionations can be achieved by application of other technologies. β-Casein can be isolated by microfiltration of calcium caseinate at 5 °C. Dilute solutions of sodium caseinate can be fractionated by ultrafiltration into a permeate rich in β-casein and a retentate rich in α_s-casein and κ-casein. A heat treatment and membrane separation process has been developed to separate β-lactoglobulin from whey. This involves the reversible aggregation of α-lactalbumin by heating at 55 °C for 30 min at a low pH and separation of the resulting aggregates consisting of α-lactalbumin and whey proteins other than β-lactoglobulin by microfiltration. The permeate is then processed by ultrafiltration in combination with diafiltration to yield purified β-lactoglobulin. The α-lactalbumin can be recovered from the retentate after solubilization at neutral pH, followed by ultrafiltration. Hydrophilic cellulose membranes with a large pore size have been used to fractionate whey proteins into α-lactalbumin + β-lactoglobulin and a higher-molecular-weight component containing bovine serum albumin, immunoglobulins, and lactoferrin. A protein fractionation robot coupled to an automated milking system has been used to demonstrate the concept of on-farm fraction of milk proteins. This system was adapted to isolate lactoferrin and lactoperoxidase using cation-exchange chromatography of raw milk.

Conclusions

With the progress being made in protein engineering and in molecular genetic techniques, further heterogeneity of milk proteins, as outlined above, is expected by modification of the milk protein genes and controlling the amounts of specific genes being expressed. Just a few examples will serve to illustrate this point. Breeding programmes are already in place to reduce the frequency of the α_{s1}-Cn° allele in dairy goats and to increase the frequency of the κ-casein B allele in bovine populations in order to increase the amount of casein in milk and improve its cheesemaking characteristics. The expression of α-lactalbumin, which is involved in lactose synthesis, could be controlled so that the lactose content of milk can be modified. The amount and type of κ-casein being expressed could be altered so as to improve micellar structure and the cheesemaking properties of the milk. The properties of β-lactoglobulin could be modified by altering its primary structure in such a way as to increase the degree of glycosylation or formation of disulfide bridges. In contrast to the above modifications of milk proteins that have direct implications for the dairy industry, proteins exogenous to the mammary gland have been successfully incorporated into milk: for example, the expression of β-lactoglobulin in mouse milk and of factor IX in ovine milk. The latter type of modification of milk proteins will be of great interest to pharmaceutical companies. Isolation and fractionation of milk proteins will still be based on the intrinsic physiochemical properties of the proteins. Different chromatographic techniques are more widely used for this purpose and in the future better solid matrices will be developed. On an industrial scale, membrane filtration techniques will play a major role in the isolation of milk proteins.

Introduction

The caseins of cows' milk are very important because of their nutritional and functional properties. For the newborn, they are readily metabolized and they carry substantial quantities of the important body-building elements calcium, magnesium, and phosphorus (as phosphate). In cheese, caseins provide the structural elements responsible for the textural and melting properties and, in some cases, its emulsification capacity. Their ready hydration and strong interactions with each other and with various other components make them valued ingredients in both food (e.g., emulsification mixes and nondairy creamers) and nonfood (e.g., glues and plastics) applications.

In the milk of most species, there are four gene products that, after post-translational modification, give rise to α_{S1}-, α_{S2}-, β-, κ-, and γ-caseins. In fresh milk, the caseins are present in the form of essentially spherical particles containing many protein molecules and amorphous calcium phosphate; these particles average 150 nm in diameter with sizes ranging from 15 to about 1000 nm in diameter. These particles are known as casein micelles. Apart from κ-casein, which is mostly found on or near the external surface of the micelle, the caseins appear to be more or less evenly distributed within the micelle.

Whole casein is isolated from milk by acidic destabilization of the micelle suspension or by size fractionation, and whole casein can be fractionated to give a number of pure caseins. Each casein has a sequence and properties different from those of the other caseins and, within each casein category, there are a number of separate protein species. This microheterogeneity is caused by varying levels of post-translational phosphorylation of serine (or threonine) and/or gylcosylation of threonine residues, by various mutational changes in the casein genes, by proteolysis by the indigenous milk enzymes, and by oxidation of cysteine to disulfide bonds.

In contrast to globular proteins, for example, β-lactoglobulin, the three-dimensional (3D) structures of the major caseins, α_{S1}-, α_{S2}-, β-, and κ-, cannot be determined precisely by X-ray crystallography, because they cannot be crystallized. Nuclear magnetic resonance (NMR) spectroscopy is limited because of concentration problems, and at the time of writing, many casein structural features are not amenable to NMR analysis. However, global estimates of structural features have been made by implications from the proteins and their peptides as determined by circular dichroic (CD), FTIR, Raman, and NMR spectroscopies, by biochemical and enzymatic modifications, and by association and physicochemical studies. Using these data, coupled with sequence-based secondary structural predictions, working, three-dimensional models have been produced, as shown in **Figure 1**.

An important feature of the caseins is their strong interactions with one another under physiological conditions and the marked effects that divalent cations have on their interaction and solubility at neutral pH. This characteristic is reflected in the high viscosity of casein solutions and in their ready ability to form foams and emulsions, and is critical to their functionality as ingredients in products.

Nomenclature

Initially, casein was considered to be a single entity, although as early as 1888 there was evidence that fractionation could give proteins with different properties. Sedimentation and electrophoretic studies on the solubilized proteins of milk in the late 1930s showed that there were a number of components, although the identity of these components was not particularly clear for another 30 years. Two important factors were the advent of high-resolution gel electrophoresis and the discovery that the caseins could be dissociated to non-interacting single polypeptides at near-neutral pH by a combination of disulfide-bond reduction and addition of urea to a concentration of 6 mol l^{-1}. Once separation and isolation of pure proteins were achieved, the primary sequence and post-translational modifications of each of the proteins were determined and a systematic nomenclature was devised and applied to the bovine caseins. Further research using these techniques showed that nearly all of the lower molecular weight components of the casein fraction are actually proteolytic fragments of the four parent caseins namely α_{S1}-, α_{S2}-, β-, and κ-casein. The caseins of other species have been classified by analogy with the bovine caseins, at either the amino acid or the nucleotide level.

The sequences of the four major bovine caseins and most of the various known genetic variations are

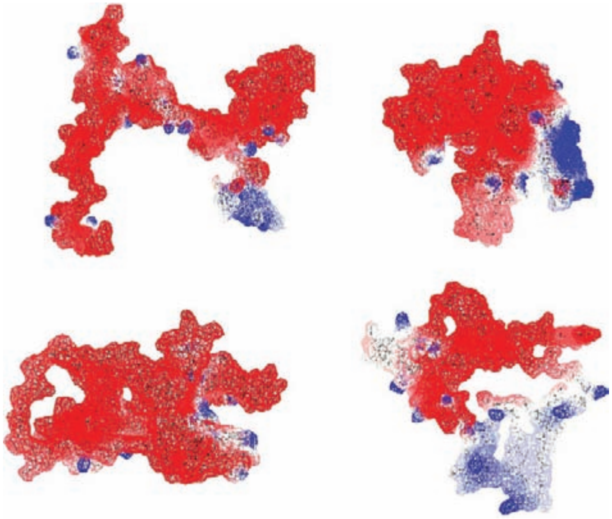

Figure 1 Three-dimensional molecular models of the caseins obtained from sequence-based secondary structural predictions and aligned with spectroscopic data. *Top*: *left* α_{S1}-casein, *right* α_{S2}-casein; *bottom: left* β-casein, *right* κ-casein. The models display a pseudo-charged surface potential with red being negative, light being neutral and/or hydrophobic, and blue positive. These models represent a working view of casein structure and are subject to change as experimentation progresses.

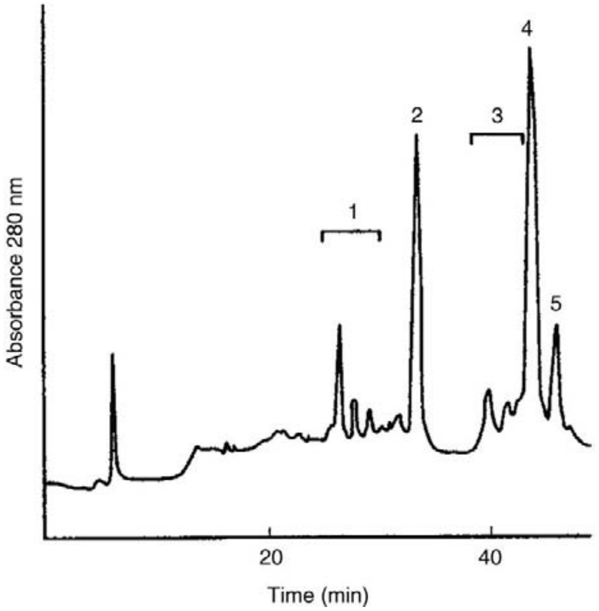

Figure 2 Diagram showing a typical analytical ion-exchange separation of the components of whole casein. The caseins were treated with dithioerythritol and then separated on a 7.5 × 75 mm column of TSK gel DEAE-5PW using a gradient of increasing NaCl concentration in a 0.02 mol l^{-1} Tris-HCl buffer, pH 8.0, and containing 4.5 mol l^{-1} urea. The regions and peaks identified as 1–5 are (1) the various κ-casein entities, (2) β-casein, (3) the variously phosphorylated α_{S2}-caseins, (4) α_{S1}-casein B-8P and (5) α_{S1}-casein B-9P. discussed elsewhere (*see* **Milk Proteins**: Heterogeneity, Fractionation, and Isolation). The names for the caseins used therein are those recommended by the Nomenclature Committee of the American Dairy Science Association. The use of the latter nomenclature indicates the polypeptide sequence, that is, the genetic variant and the degree of phosphorylation, and, in the case of the γ-caseins, the particular fragment of β-casein; this nomenclature is generally restricted to definitions of a particular fraction that is used in that piece of work. A review of the various genetic variants of the caseins as well as their primary structures has been recently published by the above-noted committee. In general, the most common variants in the milk of Friesian cattle are α_{S1}-casein B, α_{S2}-casein A, β-casein A^2,and κ-casein A.

High-performance liquid chromatography (HPLC), either reversed phase (RP) or ion exchange, is also a good method for resolving the caseins; an example is shown in **Figure 2**. RP-HPLC relies on the total hydrophobicity of the caseins in the particular solvent and, to a lesser extent, on the net charge on the protein and the matrix. In ion-exchange chromatography, differences in net charge predominate and hydrophobic interactions between the solute and the matrix have only a minor effect. This is different for ion exchange or RP-HPLC of native globular proteins with a moderately rigid tertiary structure, where the surface character can be important. As with polyacrylamide gel electrophoresis (PAGE), it is necessary to minimize casein–casein interactions by modifying the solvent. Thus, it is common to include ethylene diamine tetra acetic acid (EDTA) in the solvent buffer to chelate the polyvalent cations, and the solvent often contains 4.5 mol l^{-1} urea or an organic solvent such as acetonitrile.

Casein Structure

The amino acid sequences of the major caseins (*see* **Milk Proteins**: Heterogeneity, Fractionation, and Isolation) have been known since the early 1970s, and it was immediately apparent that the sequences were quite dissimilar to those of the typical compactly folded globular proteins. In particular, most globular proteins have a mainly α-helical structure (e.g., bovine serum albumin) or a mainly β-sheet structure (e.g., β-lactoglobulin) and periodicities of particular amino acids and particular types of amino acids with hydrophobic and hydrophilic side chains. In addition, there are also regions with amino acids such as aspartic acid, proline, or tyrosine that favor various kinds of tight turns. Although the caseins have some of these features, there seems to be a lack of the large-scale periodicity seen in most globular or fibrous proteins. However, they have regions that are essentially acidic, basic, or neutral, and hydrophobic or hydrophilic, as seen when the primary sequence (*see* **Milk Proteins**: Heterogeneity, Fractionation, and Isolation) is displayed as a linear distribution of charge and hydrophobicity (**Figure 3**). The charges shown are for the proteins in solutions buffered at neutral pH with only monovalent cations present. **Figure 3** also shows the major plasmin cleavage sites for α_{S1}- and β-caseins and the major chymosin cleavage sites in α_{S1}- and κ-caseins. The other common feature of the secreted globular proteins, noted above, that is missing from the caseins is the presence of strategically placed cysteine residues which form intramolecular disulfide bonds that stabilize the tertiary structure of the protein; in contrast, κ-casein forms primarily intermolecular disulfide bonds with other κ-casein molecules. There are two important structures found in the caseins of all milks: the chymosin (or pepsin) cleavage site in κ-casein, which is critical for the proper coagulation of the casein micelles (*see* **Cheese**: Rennet-Induced Coagulation of Milk); and the phosphorylation sites, which are critical for the proper bonding of the caseins to the hydrated calcium phosphate entities present in the casein micelles.

All of the above information has led to the inclusion of the caseins in a new class of proteins which have been termed ‘intrinsically unstructured’ or ‘natively unfolded’. Previously, globular proteins such as those noted above were thought to fold or denature (unfold) in a concerted one-step process. The ‘New View’ of protein structure argues that the defined secondary structure leads to protein folding (or unfolding) in a multistep process. Uversky

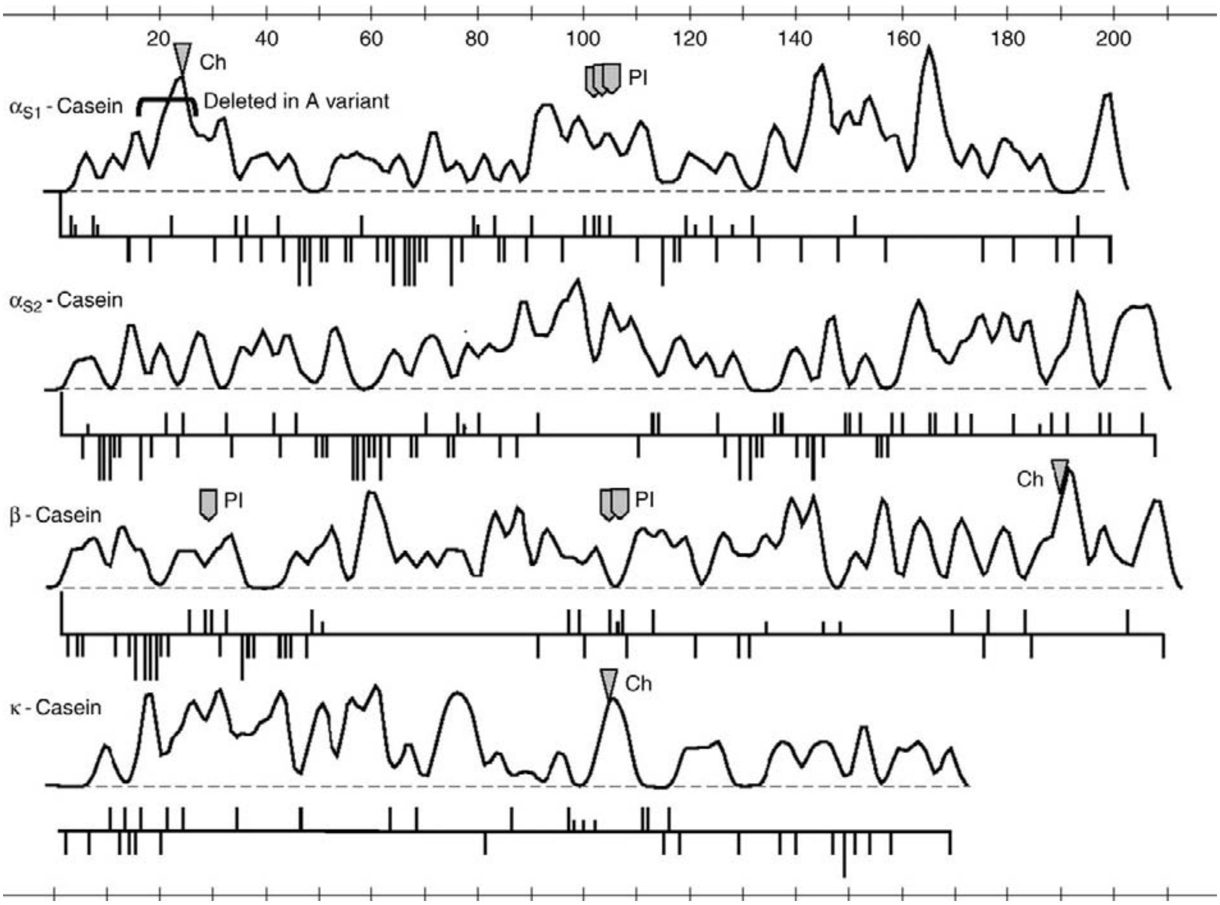

Figure 3 Plots of charge and hydrophobicity as a function of sequence position for the four major caseins, α_{S1}-casein B-8P, α_{S2}-casein A-11P, β-casein A^2-5P, and aglyco-κ-casein B-1P. The continuous curve for each protein is the distribution of smoothed hydrophobicity of the individual amino acids whereas the lines with vertical bars show the discrete charges for each amino acid in the sequence. The vertical bars below the horizontal lines show the phosphoserine (long bars), glutamic, and aspartic acid side chains and the C-terminal acid group. The bars above the horizontal line show the histidine (shorter bars), lysine, and arginine side chains. The charges on the terminal amino groups are also shown (note that κ-casein has a pyroglutamate terminus). The arrows indicate the most susceptible bonds, and Ch indicates chymosin and Pl indicates plasmin susceptibility. Adapted with permission from Creamer LK (2002) Milk Proteins Casein nomenclature, structure and association properties. In: *Encyclopedia of Dairy Sciences*, pp. 1895–1902. London: Elsevier Science.

has used a progressive nomenclature for this process with defined intermediate states ranging from unfolded coil to pre-molten globule to molten globule to natively folded protein. In this scheme the monomeric forms of α_{S1}-, α_{S2}- and β-casein are classified as natively unfolded pre-molten globules, whereas κ-casein is classified as a natively unfolded coil. However, upon self-association, three of the caseins become more compact, with β- and κ-casein classified as molten globules and α_{S2}-casein becomes a pre-molten globule. Interestingly α_{S1}-casein remains an unfolded coil. The 3D models in **Figure 1** demonstrate clearly that α_{S1}-casein is the least compact molecule.

It could be said, then, that the native states of the α_{S1}-, α_{S2}-, β-, and κ-caseins are the states in which they exist when fully immersed in the casein micelle (see **Milk Proteins**: Casein, Micellar Structure), in which most of the very acidic or very basic regions (**Figure 3**) are bound to hydrated calcium phosphate complexes and the hydrophobic regions of all the caseins are intermingled, with κ-casein molecules close to other κ-caseins and with the C-terminal (macro peptide) region of the κ-casein surrounded by the serum. The 3D models in **Figure 1** are more in accord with the structures of the caseins within the casein polymers rather than as isolated monomers.

α_{S1}-Casein

This major component of the caseins has the highest net negative charge in neutral pH buffer with only monovalent cations present and has a calculated hydrophobicity of 1170 kcal mol^{-1}. The hydrophobicity (**Figure 3**) is high near residues 25, 90–110, and 140–190. The last region is found between 10 and 7 o'clock in the 3D model of α_{S1}-casein (**Figure 1**) and close to the C-terminus. Clearly, α_{S1}-casein has a very acidic region between residues 38 and 78, which is responsible for the tight binding of calcium, and occurs at about 2 o'clock in the α_{S1}-casein model in **Figure 1**. In contrast, the N-terminal region (1–26 and 4 o'clock in the 3D model) is positively charged and could possibly bind inorganic phosphate.

Circular dichroism (CD) or Raman spectral analysis indicates that there is a low level of α-helix (~14%), an intermediate level of turn-like structure (24%), and a significant level of extended or β-sheet (~40%). Prediction methods indicate that likely positions for helix formation are near residues 60, 100, and 125. Interestingly, plasmin, which hydrolyzes bonds adjacent to lysine or arginine, cleaves this protein most rapidly at several sites (102–103, 103–104, and 105–106) in a predicted helical region found as the central link in the α_{S1} model in **Figure 1**. A major cleavage site for chymosin is bond 23–24, which is in a region predicted to have β-sheet propensity and is in a significantly hydrophobic region (**Figure 3**). Clearly, these regions are accessible to enzyme attack in the associated protein and must be sufficiently exposed to the solvent to allow the respective enzymes to form enzyme–substrate complexes.

Association studies of α_{S1}-casein at 20 °C have shown that there is a wide range of polymer sizes, from dimer to hexamer, which occurs in a progressive manner and which is dependent on pH and ionic strength. It is likely that the polymers are more or less rod-like. This has suggested that the hydrophobic regions near residues 20–25 and a region near the C-terminus could be alternatively involved in the polymers. However, recent work has shown that at 37 °C, the higher-order polymers are broken down and the protein is essentially a dimer under physiological conditions (**Table 1**). It has been shown that the dimerization involves residues 136–160 of each monomer (10 o'clock in the α_{S1}-casein model in **Figure 1**).

α_{S2}-Casein

This minor component is the least hydrophobic casein (1100 kcal mol^{-1}) and is the most highly and variably phosphorylated of the caseins. There are three phosphopeptide regions (5–18, 49–68, and 126–145) in the casein sequence (left side of the model of α_{S2}-casein in **Figure 1**) and a large central hydrophobic region (90–120) with very little charge (region of α_{S2}-casein protruding from the center of the model to 6 o'clock in **Figure 1**). There is a second large hydrophobic region (160–207) – but it has a number of positively charged residues – which represents the highest positively charged area for any casein (**Figure 3** and the right side of the α_{S2}-casein model in **Figure 1**).

Table 1 Weight average molecular weights of selected caseins and mixtures by analytical ultracentrifugation at 37 °C

Casein or mixture	*Wt. avg. molecular weight*	*Wt. avg. polymeric size*	*Rotor speed*
α_{S1}-Casein	56 000	Dimer	12 000
β-Casein	1 250 000	52 mer	3000
RCM κ-Casein	3 040 000	160 mer	3000
1.5 α_{S1}-: 1 RCM κ-	316 000	15 mer	3000
4 α_{S1}-: 1 RCM κ-	92 400	Tetramer	6000
4β-: 1 RCM κ-	1 010 000	43 mer	3000
1β-: 1α_{S1}-	213 000	Nonamer	3000
RCM whole casein	110 000	Hexamer	6000

All data were obtained at 37 °C, pH 6.75 in 25 mmol l^{-1} disodium piperazine-*N*,*N′*-bis(2-ethane sulfonic acid) with 80 mmol l^{-1} KCl to mimic milk salt conditions in the mammary gland in the absence of calcium; the rotor speeds were appropriate to the weight average molecular weight as previously described. RCM = reduced and carboxymethylated. Modified from Farrell HM, Jr., Malin EL, Brown EM, and Qi PX (2006) Casein micelle structure: What can be learned from structural biology? *Current Opinion in Colloid & Interface Science* 11: 135–147.

In milk, the majority (~90%) of the protein occurs with an internal disulfide bond between cysteine residues 36 and 40 forming a small loop in the structure. In addition, a small proportion of this protein exists as disulfide-bonded dimers as well as polymers with κ-casein.

CD and FTIR spectral analysis indicates that for α_{S2}-casein there is a relatively high level of α-helix (30–40%), an intermediate level of turn-like structure (~20%), and a similar level of extended or β-sheet (~20%). Prediction methods indicate that likely positions for helix formation are near both the acidic N-terminal and the basic C-terminal regions. This protein is readily hydrolyzed by plasmin at a number of sites, primarily in the afore-noted C-terminal region, so that at neutral pH these positively charged residues are primarily at the surface and could actively participate in the binding of inorganic phosphate.

Association studies at 20 °C show that monomeric α_{S2}-casein behaves in a very similar way to α_{S1}-casein except that there is a maximum association at an NaCl concentration of about 0.2 mol l^{-1}. However, at 37 °C this protein has been found to form elongated amyloid structures, perhaps through associations of the central hydrophobic core noted above.

β-Casein

This major casein component is the most hydrophobic (1335 kcal mol^{-1}) of the intact caseins and has the largest regions of high hydrophobicity (55–90 and 130–209) with a very acidic N-terminal region of 24 amino acids (**Figure 3**). The acidic N-terminal region is at the right top of the model in **Figure 1**. There are two regions where plasmin readily cleaves the protein (at bonds 28–29 and 105–106/107–108, respectively; 3 and 4 o'clock in the β-casein model in **Figure 1**). Cleavage at these sites by plasmin yields the fragments previously known as γ-caseins 1 and 2, respectively. β-Casein has one site which is particularly sensitive to chymosin (189–190/192–193; found at about 7 o'clock in the β-casein model in **Figure 1**). Loss of the C-terminal peptide (193–209) by chymosin cleavage substantially reduces the association–dissociation equilibrium. When the native protein is brought to higher temperatures, chymosin cleavage is much slower, presumably because access of the enzyme to the cleavage site is restricted by β-casein self-association. This leads to the unusual situation in which increasing the reaction temperature reduces the cleavage rate.

CD and FTIR spectral analysis indicates that at 6 °C, β-casein has a relatively low level of α-helix (~15%), an intermediate level of turn-like structure (~29%), and a similar level of extended or β-sheet (~30%) in dilute, low ionic strength, neutral solutions. However, there are significant increases in ellipticity at 220 nm when the solution temperature is increased from 6 to 37 °C. β-Casein is predicted to contain a significant amount (30%) of polyproline II structure, but these structures have been shown to occur at about 20% in β-casein by Raman spectroscopy FTIR and CD. Thus, it is possible that increases in both β-strand and polyproline II structures are responsible for this temperature-dependent structural change. It is also possible that, as the protein associates, incipient β-strands form interprotein H bonds that give rise to sheetlike structures.

The self-association of this protein is (detergent) micelle-like, and both ionic strength and temperature increase the quantity of polymer present (i.e., increased association constant) and the degree of association (n):

$$n\ \beta - \mathrm{CN} \leftrightarrow \beta - \mathrm{CN}_n$$

The number of monomer proteins in these micelle-like near-spherical polymers ranges from about 15 at 0.1 mol l^{-1} ionic strength at pH 7 and 20 °C to about 52 at 0.110 mol l^{-1} ionic strength at pH 6.7 and 37 °C (**Table 1**). The intrinsic volume of an individual β-casein within the polymer is significantly low and represents a molten globule-like state. Note that the 3D model for β-casein (**Figure 1**) represents the more compact form of the monomer within the polymer. The effect of temperature on intrinsic tryptophan and hydrophobic probe fluorescence both indicate that changing hydrophobicity or structure of the probe environment is an important consequence of association.

κ-Casein

This protein, which constitutes 10–12% of whole casein, plays a crucial role in stabilizing the casein micelles in milk and, after enzymatic cleavage, destabilizing the colloidal casein system. The enzymatic cleavage that brings about this transformation is important for the nutrition of the suckling young and for the production of many cheese varieties (*see* **Cheese**: Rennet-Induced Coagulation of Milk). This is achieved by the molecule having two distinctly different domains that can be separated by cleavage of a bond that is hydrolyzed by an acid protease at neutral pH. As seen in **Figure 3** (and the bottom portion of the κ-casein model in **Figure 1**), the N-terminal domain (residues 1–95) carries a net positive charge, is very hydrophobic, and interacts strongly with the other casein molecules. The C-terminal domain (residues 113–169) carries a net negative charge and contains a preponderance of polar residues (top portion of the κ-casein model in **Figure 1**); the overall hydrophobicity of the protein is 1205 kcal mol^{-1}. These two domains are joined by a peptide (residues 96–112; 10 o'clock in the κ-casein model in **Figure 1**) that carries a net positive charge, is generally predicted to be β-strand, is generally well conserved in most species, and contains a motif that is readily recognized by chymosin and rapidly and specifically cleaved to give a large positively charged hydrophobic peptide (para-κ-casein: κ-casein (f1–105)) and a smaller hydrophilic peptide (caseinomacropeptide (CMP), also called glycomacropeptide (GMP) or κ-casein (f106–169)). About half of the κ-casein molecules are post-translationally glycosylated with short oligosaccharide chains at one or more of the threonine sites 131, 133, 135, 136 (B variant only), and 142, and most of the κ-casein molecules are phosphorylated at Ser149.

CD and FTIR spectral analysis indicate that for κ-casein there is a relatively low level of α-helix (15%), an intermediate level of turn-like structure (~25%), and a higher level of extended or β-sheet (~30%). These structures appear to be thermostable.

As a reduced isolated protein, at 20 °C κ-casein self-associates in a manner similar to β-casein to a 600 000 Mw polymer. However, the reduced carboxymethylated (RCM) protein at 37 °C forms amyloid bodies which were first discovered in this casein. These amyloids have a soluble Mw of over 3 million (**Table 1**). The β-sheet structures at 6 o'clock in the model of κ-casein in **Figure 1** are thought to promote amyloid formation. In milk, κ-casein exists as a series of intermolecular disulfide bonded aggregates and this aggregation may well have occurred after the casein micelles have been assembled in the epithelial cells. Most of the properties of this protein are not affected by the state of aggregation, but about 10% of the cysteine residues in total are not disulfide bonded and may react with other proteins or participate in oxidation reduction reactions, for example, formation of complexes with β-lactoglobulin in heated products.

Casein–Casein Interactions

In addition to the studies on the interactions of individual casein species in solution, there have been a number of studies involving primarily binary mixtures. Such studies have shown that, in the absence of polyvalent cations and at 37 °C, α_{S1}- and κ-caseins associate most strongly, followed by α_{S1}- and β-caseins. As noted above, RCM-κ-casein forms high molecular weight amyloid structures. In brain diseases, amyloid structures form entanglements symptomatic of the disease. The Mw of these aggregates is greatly reduced by the presence of α_{S1}-casein at the ratio of 4:1 found in milk (**Table 1**). β-Casein has a much less effect on the amyloids as seen in **Table 1**. In addition, the high molecular weight polymers of β-casein are readily broken down by α_{S1}-casein (**Table 1**). In the New View of protein structure noted above, α_{S1}-casein can be considered to be a natively unfolded assembler in that it is able to break down aggregates of β- or κ-casein and lead to successful transit through the mammary secretory system prior to the addition of calcium in the Golgi apparatus. Recently, it has been shown that the amyloid bodies formed by α_{S2}-casein can also be broken down by α_{S1}-casein.

Sodium caseinate (whole casein in the absence divalent cations) is an excellent ingredient and finds many applications in food processing. This product can have somewhat varying properties depending on its method of preparation. The mixed associations of the individual caseins discussed above bring about the formation of a rather stable polymer with an average diameter of 18 nm and a Mw of about 280 000. Laboratory-prepared preparations of sodium caseinate can dissociate into monomers and small polymers at concentrations below 1%; note that at 0.1% the weight average Mw of RCM-whole casein is only 110 000 (**Table 1**).

Properties, such as viscosity, of casein solutions are concentration-dependent and a 15–20% casein solution is very viscous because of the associations of the molecules with one another and the absence of compact folded structures for any of the molecules, as discussed in the previous section. A number of emulsion and foaming studies have been done using either the individual pure proteins or various commercial whole proteins, for example, total milk protein (TMP) or milk protein concentrate (MPC) or whole casein materials.

Casein–Mineral Interaction

From the point of view of their functions in various dairy or industrial products, or in the casein micelles in milk, one of the very important characteristics of the caseins is the changes brought about by their binding of calcium. In the absence of calcium, the casein molecules, as described earlier, have separate mechanisms of self-association. Let us consider a simple system of α_{S1}-casein dissolved as described in **Table 1**. Increasing the concentration of calcium in such a casein solution gradually changes the system. Although there is little obvious visual change at low calcium concentrations (3 mmol l^{-1}), as viewed by sedimentation analysis, the α_{S1}-casein has bound several calcium ions and two peaks representing a tetramer and an octamer appear. However, once the number of calcium ions bound to the acidic (phosphoserine, glutamic, and aspartic acids) clusters (**Figure 3**) on the molecules have reduced the net charge (~6 mmol l^{-1}), the overall molecular interactions shift toward a lower net repulsion between the protein molecules, with an increase in the size of the casein aggregates. Once sufficient calcium has become associated with the α_{S1}-casein to reduce the net charge on the protein to almost zero, casein aggregates become very large and form a separate phase, which can precipitate, gel, or form colloidal suspensions. Similar precipitates occur for β- and α_{S2}-caseins but at lower and higher concentrations of calcium, which are related to their respective degrees of phosphorylation (**Figure 3**). Caseins are capable of binding almost all physiologically important divalent cations.

In contrast to the precipitation behavior described for α_{S1}-casein or α_{S2}- and β-caseins, κ-casein is affected little by moderate concentrations of calcium salts. However, when it is mixed with the other caseins, it interacts with them strongly and thus affects their behavior with minerals. When calcium is added to mixtures containing κ-casein, the calcium binds strongly to the phosphate-containing caseins, lowering the net charge of the complexes. However, instead of forming very large colloidal particles or precipitates of α_{S1}-, α_{S2}-, or β-casein, the κ-casein, strongly associated with these proteins, limits the size of the aggregates formed and generates colloidal particles, the size of which is determined by the proportion of κ-casein in the protein mixture. This characteristic is dependent on the structure of the hydrophilic C-terminal, 30% of the κ-casein molecule (*see* **Milk Proteins**: Casein, Micellar Structure).

In the presence of added orthophosphates, the behavior of the system becomes more complex because the inorganic phosphate competes with the protein phosphoserine-rich acidic clusters for the ionic calcium and forms complexes with the soluble calcium and these can react with casein molecules in preference to the simple calcium ions. In addition, inorganic phosphate binds to the positively charged areas of the caseins only in the presence of calcium. *In vitro* casein phosphopeptides react with inorganic calcium and phosphate to form nanoclusters of defined shape and size. Complexes of phosphopeptides and calcium do indeed enhance calcium uptake in experimental animals. However, for whole casein molecules, it must be noted that strong protein–protein interactions precede the binding of calcium and phosphate, which is not the case for phosphopeptides. All of these reactions and their products are very important for the behavior of the caseins and they not only lead to colloid formation but also affect many of the food and industrial uses of casein-containing products.

Introduction

All mammals secrete milk for the nourishment and sustenance of their newborn offspring. As food for the suckling, this complex fluid is a blend of all the essential dietary constituents – lipids, proteins, carbohydrates, and minerals. These components are found in proportions generally specific to the nutritional and growth demands of each species. Milk composition therefore varies widely between species, and in some mammals this composition varies during lactation to meet specific developmental requirements. Between species, protein content can range from less than 10 g l^{-1} (human milk) to about 200 g l^{-1} (milk of some rabbits), with total calcium phosphate content varying in proportion. Delivering such levels of minerals and proteins to the offspring could present problems to the transport system (the mammary gland), but nature has neatly solved this by combining them in the casein micelle. Casein micelles are the colloidal aggregates of the caseins and mineral calcium phosphate. They have been found in the milk of all species that have been examined.

As a packaging system, these micelles convert milk into a free-flowing low-viscosity fluid and provide the means to transport the high levels of calcium and phosphate that would normally precipitate in the mammary gland in the absence of the caseins. Having converted the milk into a colloidally stable dispersion to overcome delivery problems, nature has also built into this casein micelle its own instability mechanism, which is necessary for efficient digestion of the nutritional material when ingested by the young. Thus, in the stomach of the calf, the enzyme chymosin hydrolyzes the κ-casein and induces destabilization of the micelle, forming a soft clot, which aids digestion and assimilation. The casein micelles are also destabilized by acidification, and in other species, the stomach acids achieve clot formation by this mechanism. Furthermore, these two destabilization pathways are exploited by man in cheese manufacture and in the production of fermented milk products, major preserved food sources for man and extensive outlets for dairy farm produce.

Central to our understanding of all these functional properties of the casein micelle is knowledge of the physicochemical properties of the different casein proteins. These dictate how the structural assembly, which we call the casein micelle, is built, and they govern the response of the micelle to destabilizing influences. Caseins and casein micelles have been studied extensively over a long period. Several different models for micellar assembly have emerged. Early primitive models, such as the submicelle model, have been discredited. Shortcomings in the more recent model of Holt have been identified, and it appears that fewest problems are encountered with the dual-binding model. This dual-binding model plausibly explains micelle assembly, and models observed micellar behavior in scenarios where application of earlier models was not even attempted. Furthermore, since its publication, more and more supporting evidence is emerging.

This article summarizes the pertinent physicochemical properties of the individual caseins, concentrating on those that govern their self-assembly and interactions. It briefly reviews the earlier micellar models and outlines the dual-binding model. The discussion is confined largely to bovine caseins because these have been most intensively studied, but, where possible, interspecies comparisons will be made throughout the text.

Casein Molecular Properties

Sequence Characteristics

Caseins constitute over 80% of the total protein in bovine milk, almost all of it aggregated with calcium phosphate in casein micelles. Originally defined as phosphoproteins precipitated from milk at pH 4.6, they are now defined by their sequence and their homology to the four distinct gene products constituting the primary members of the bovine group. Because the caseins utilize the same calcium-sequestering mechanism to regulate the calcium phosphate concentration of their environment, they have recently been identified as members of a wider family of secretory calcium-binding phosphoproteins descended from a common ancestor gene. These secretory phosphoproteins include enamel matrix proteins, dentine, salivary proteins, bone extracellular matrix proteins, and caseins, among others. The bovine caseins are designated α_{S1}-, β-, α_{S2}-, and κ-caseins. Sequences were first elucidated for all bovine members but cDNA and derived amino acid sequences are now available for many more individual caseins from a range of species.

Genetic variants have been detected for many of these sequences. The majority of these are amino acid interchanges at single sites or short deletions. The level of expression is also under genetic control. Null variants of α_{S1}-casein exist in the goat and the sheep, and that of β-casein also in the sheep. Since α_{S1}-casein is low in human milk also, there is the possibility that this too is the result of the existence of a null variant. There are also reports of some milk samples from Mongolian mares lacking κ-casein homologues. All such changes in sequence and casein composition have important consequences for the functional behavior of the casein proteins, although the major impact is often in the fine detail.

Two post-translational modifications of the newly synthesized casein molecules have a major impact on their physicochemical, functional, and assembly properties. These reactions are glycosylation and phosphorylation. In bovine milk, only κ-casein is found glycosylated. There are few details for other species. The reaction occurs at threonine residues, occasionally serine, in the hydrophilic C-terminal end of the κ-casein molecule. A great deal of heterogeneity is observed both in the numbers of residues reacted and in the lengths of the relatively short sugar chains attached, but all such reactions increase both the hydrodynamic bulk and the hydrophilicity of this end of the κ-casein molecule.

The second post-translational reaction is phosphorylation. All of the caseins are phosphorylated at serine, or rarely threonine, to varying extents. The phosphorylation reaction requires a unique sequence template, - Ser–X–A-, where X is any amino acid and A is Glu, SerP, or rarely Asp.

Because of the placing of the serine residues along the molecular sequences of α_{S1}-, α_{S2}-, and β-casein, most of the phosphorylated residues are found in clusters. Such clusters in the α_S- and β-caseins are highly conserved, and their numbers attest to the significance of the calcium phosphate requirement for post-natal growth in mammals. Thus, four of the five phosphorylated serine residues in bovine β-casein are found between positions 15 and 19, with the fifth at position 35. Four of the eight phosphorylated serines in bovine α_{S1}-casein are located between positions 64 and 68, with two more downstream at positions 46 and 48, and singlets upstream at positions 75 and 115. An additional serine in α_{S1}-casein is occasionally found phosphorylated at position 41, producing the protein previously called α_{S0}-casein but now designated as α_{S1}-casein-9P. α_{S2}-Casein can have a variable level of phosphorylation from 10 to 13 mol of P per mole of protein. The most abundant of these, α_{S2}-casein-11P, has three groupings of phosphorylated residues, one cluster of three from residues 8 to 10, four SerP spread as a group of three from 56 to 58 with the fourth member at 61, with the third cluster of two at positions 129 and 131. The remaining two single SerP residues of the total 11 are located at positions 16 and 135. The α_{S2}-casein molecule has two further potentially reactive sites at positions 31 and 135. Interestingly, one of the genetic variants of α_{S2}-casein, α_{S2}-casein D, results from the deletion of nine residues between 51 and 59 encompassing one of the phosphoseryl clusters. This should have a major influence on the physical and self-assembly properties of this protein. κ-Casein is unique among the caseins in the absence of phosphoseryl clusters. Most molecules of κ-casein contain only one phosphoserine residue, rarely two or three, and all are singlets located in the hydrophilic C-terminal region.

Bovine caseins are almost always fully phosphorylated to the level of their potential. At most, only one of the template serine sites is found without its expected phosphate residue in α_{S1}- and β-casein; most gaps are found with α_{S2}-casein, where the variability ranges from 10 to 13. This contrasts with the variations found in other species. In human milk, the level of phosphorylation of β-casein ranges from 0 to 5 mol of P per mole of casein. Similarly, wide heterogeneity in the level of phosphorylation is found in ovine and equine milk. The consequences of this for micelle assembly are considered later.

Molecular Structure in Solution

Secondary Structure

Attempts to predict the secondary structure of the caseins have met with little success. They are neither globular proteins, nor are they truly random-coil polymers. They have been described as rheomorphic proteins, indicating that the molecules adopt structures in solution dictated by the circumstances in which they find themselves; their structures ‘go with the flow’ but are also open and flexible. The caseins have little α-helical structure, no denaturation temperature, and high hydrodynamic volumes. Their open conformation allows easy access to proteolytic enzymes, facilitating rapid and extensive degradation. It has been suggested that some α-helical behavior exists on either side of the phosphate clusters, causing these centers to exist at the apex of a loop structure, but little consistency has been found in secondary structure predictions for other regions of these molecules.

Caseins as Amphiphilic Molecules: Adsorption and Self-Association

When categorized simply as nonpolar hydrophobic or polar/charged hydrophilic groups, the amino acids of the caseins show distinct segregation into different regions of the molecular chains.

Each casein provides its own pattern, and this has helped to rationalize the self-association behavior of caseins and the conformations they adopt on adsorption to a hydrophobic interface.

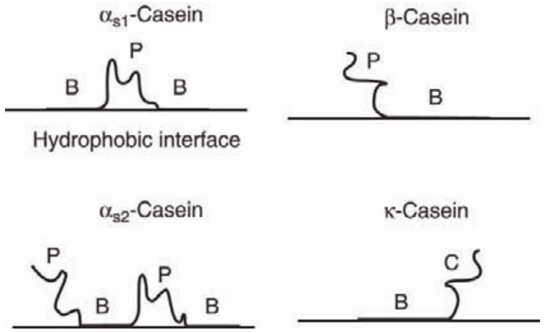

Figure 1 Part of the polymer network built up in the casein micelle according to the dual-binding model. Bridging of casein molecules across calcium phosphate nanoclusters, crosslinking of caseins via hydrophobic interaction sites and chain termination by k-casein are illustrated. B, hydrophobic regions; P, hydrophilic regions containing phosphoserine clusters.

Thus, in β-casein, there is a distinct grouping of charged hydrophilic residues, including the phosphoseryl cluster in the N-terminal region up to around residue 50, with a large number of hydrophobic amino acids in the remaining three-quarters of the protein chain from there to the C-terminus. Considerable experimental evidence has accumulated to suggest that it is this latter region that adsorbs strongly to hydrophobic oil or air interfaces with the N-terminal phosphorylated region extending out into the aqueous phase. The conformation of the adsorbed molecule predicted by self-consistent field (SCF) calculations reproduces this behavior (for schematic representation see **Figure 1**). This presents the hydrophobic region as a featureless block but the hydrophobic amino acids in this region also show grouping or clustering, which might suggest that hydrophobic interactions between such regions on different molecules might exhibit more of a velcro effect.

In α_{S1}-casein, the hydrophilic residues around the phosphoserines are in a more central position in the chain with bunching of hydrophobic residues earlier and later in the molecular sequence. Similar SCF calculations show that α_{S1}-casein adopts the loop structure also shown in **Figure 1** with a hydrophobic train of residues on either side of the loop, each train binding to the hydrophobic surface and the hydrophilic loop projecting out into the aqueous phase. Closer inspection of the α_{S1}-casein sequence reveals that the hydrophobic residues also exhibit clustering, allowing multiple weak interactions with hydrophobic surfaces. In an analogous fashion, such groupings of the hydrophobic and hydrophilic residues can be recognized in the sequences of both α_{S2}-casein and κ-casein. α_{S2}-Casein presents itself as having a hydrophilic N-terminal tail with a phosphoseryl cluster, followed by a hydrophobic train containing several hydrophobic clusters, a loop containing the major groupings of phosphoseryl residues, and then an extended hydrophobic C-terminal train broken up into several distinct hydrophobic clusters (**Figure 1**). κ-Casein has a hydrophobic N-terminal region leading up to the chymosin proteolysis site at Phe_{105}–Met_{106}. The C-terminal peptide cleaved off by chymosin is very hydrophilic since it also carries the glycosyl side chains on several of its threonyl residues, but, importantly, it has no phosphoseryl clusters.

Interaction properties: Self-association

Individual caseins in solution exhibit strong tendencies to self-associate, and the form of the structure adopted reflects both the distribution of hydrophobic/hydrophilic residues described earlier and the strictures applied by the demands of the highly charged phosphoseryl clusters wanting to be as spatially distant as possible from one another. Thus, β-casein, which resembles a detergent molecule with a hydrophilic head and a hydrophobic tail, forms detergent-like micelles, as in **Figure 2**, with the tails forming a central core and the highly charged hydrophilic heads sticking out into the aqueous phase, like the bristles of a hedgehog. Similarly, α_{S1}-casein self-associates in solution to form a wormlike chain

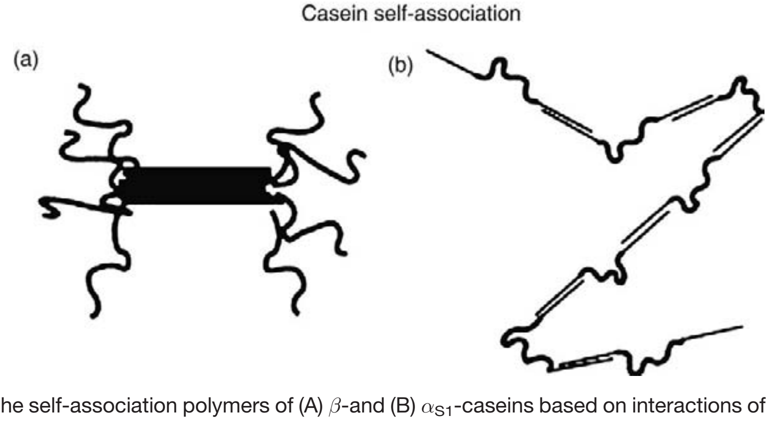

Figure 2 Structures of the self-association polymers of (A) β-and (B) α_{S1}-caseins based on interactions of their hydrophobic regions. Beta-casein forms detergent-like micelles, whereas aS1-casein molecules form a chain polymer.

polymer with the hydrophobic ends of different molecules interacting as depicted in **Figure 2**. κ-Casein also self-associates in solution, interacting via its hydrophobic N-terminal region, but here, polymer growth is also influenced by the intermolecular disulfide linkages produced by reaction of its cysteine residues.

For α_{S1}-casein and β-casein, it was demonstrated that the size of the α_{S1}-casein polymer or the β-casein micelle produced by self-association depends on pH and ionic strength, and also sensitively on temperature in the case of β-casein. Temperature is important for the strength of hydrophobic interaction but pH and ionic strength govern electrostatic repulsion and its range. The balance of these attractive and repulsive components in the overall interaction free energy equation thus controls aggregate size.

Interaction properties: Calcium binding and calcium-induced precipitation

This is also confirmed in the precipitation of the individual caseins induced by the addition of calcium chloride, a direct consequence of the calcium-binding properties of the molecules. The extent of calcium binding is directly related to the number of phosphoserine residues in the molecules. Thus, α_{S2}-, α_{S1}-, and β-casein have high binding capacities for calcium (and other divalent cations), and their order of sensitivity to calcium-induced precipitation reflects this capacity. κ-Casein with only one, occasionally two, phosphoserines binds little calcium, does not precipitate in its presence, and in mixtures with other caseins, restricts the growth of aggregates to colloidal dimensions. Mistakenly in the past, these aggregates have often been referred to as casein micelles. They contain no inorganic phosphate and are not casein micelles.

Precipitation is the direct result of the reduction on the negative charge of the protein molecule consequent on binding a number of calcium cations. The rate of calcium-induced precipitation can be quantitatively related to the square of the net protein charge, $Q = Z_0 + 2\nu$, where Z_0 is the protein charge carried at the pH and ionic strength of interest and ν is the number of Ca^{2+} bound under those solution conditions for the calcium ion concentration added. This relationship also holds when the charge on the protein is changed by chemical modification. Thus, converting a positively charged lysine residue into a neutral or even negatively charged residue increases the negative protein charge by one or two units and decreases the rate of calcium-induced precipitation accordingly. If the chemically modified residue becomes more hydrophobic, an enhancement of the rate of precipitation may also be observed, indicating that, as in self-association, attractive hydrophobic interactions also play a part in moderating the overall interaction potential governing the aggregation process.

If phosphate is introduced into the mix prior to the addition of calcium, another precipitation pathway is followed, with the phosphate playing an active role in this. This observation has important consequences for micellar assembly and formation.

Casein Micelle Properties

Almost all of the casein proteins present in bovine milk are incorporated into the casein micelles, together with a high proportion of the available calcium and inorganic phosphate. These micelles have average molecular weights of $\sim 10^8$ Da and mean diameters of ~ 100 nm (range 50–600 nm). The micelles are very open, highly hydrated structures with typical hydration values of 2–3 g $H_2O\,g^{-1}$ protein, depending on the method of measurement. The structure is not rigidly fixed but dynamic. The soluble casein level is strongly type and temperature dependent. Cooling from an udder temperature of 37 °C to refrigeration temperatures during storage brings about solubilization of a significant fraction of β-casein, some κ-casein, and much lower levels of α_{S1}- and α_{S2}-caseins. Raising the temperature back to 37 °C reverses this process. Almost complete disintegration of the micelles can be achieved either through the addition of a strong calcium sequestrant, such as ethylenediaminetetraacetic acid (EDTA), or through the addition of high concentrations of urea. Dissociation to molecular level is not achieved, however, and the dissociated species have average diameters on the order of 10–15 nm and are also of variable composition.

Micelle Size

Unless something is done to disintegrate or destabilize the casein micelle, average micelle size remains constant with the storage time of the milk. It does not change significantly on cooling or following mild heat treatments such as pasteurization. If an aggregation process forms the micelles, then some compositional factor must limit their growth to the size range observed.

Casein micelles can be fractionated from the initial wide size range found in milk by subjecting the milk to centrifugation steps of increasing speed and duration. The pellet may be resuspended in ultrafiltrate for sizing by dynamic light scattering and its composition and mineral content determined. The supernatant is used as the sample for the succeeding step. Largest micelles are found in the pellets produced by the slowest speed and shortest time combinations, the size decreasing as duration and speed increase.

Such experiments demonstrate that the proportion of α_{S1}- and α_{S2}-caseins is independent of micelle size and that κ-casein content is inversely proportional to micelle size. Changes in colloidal calcium phosphate content per mole of casein are consistent with the increasing content of κ-casein and the compensating decrease in β-casein fraction with decreasing micelle size. For a solid object such as a sphere, the surface-to-volume ratio is inversely proportional to size (radius), implying that the κ-casein component resides on the micelle surface, where it controls micellar surface area and hence micellar size. The results also imply that colloidal calcium phosphate and the other caseins are found primarily in the micellar core, contributing only to its volume.

Micellar Stability

The technological properties of milk are strongly influenced by the stability of the casein micelles. Deliberate destabilization of the casein micelles resulting in coagulation or gelation is exploited in the production of a range of dairy products, including all cheese varieties and fermented milk. Micellar destabilization can also be induced by addition of ethanol or any other organic solvent, or by extreme heat treatments, where its occurrence can create serious problems during processing (e.g., during the sterilization of concentrated milks) or storage (e.g., age gelation of ultra-high temperature (UHT)-treated milks).

Much research activity has centered on the curd formation reaction, which is the first stage in cheese-making. The κ-casein molecules that make up the outer surface of the micelle are thought to provide a steric stabilizing (hairy) layer, with their hydrophilic C-terminal peptides protruding into the aqueous phase. Curd formation is a direct consequence of the proteolysis of the κ-casein by chymosin, the casein being specifically cleaved at the Phe_{105}–Met_{106} bond, releasing the hydrophilic peptide and destabilizing the micelle. The gradual loss of peptide is accompanied by a decline in the micellar zeta potential from ~ -20 to ~ -10 mV. Before the aggregation events, the lower levels of κ-casein proteolysis are accompanied by a decrease in micellar hydrodynamic size as the hairy layer is shaved off enzymatically. Similar decreases in micellar size are seen at concentrations of ethanol too low to induce micellar destabilization, where the hairs are thought to collapse and fold in the nonsolvent mixture. Proton nuclear magnetic resonance (NMR) studies also indicate that the flexibility of the κ-casein hairs is diminished in the presence of ethanol.

Micellar Appearance

Viewing the casein micelle as a hairy sphere, sterically stabilized by its bristly coat, is adequate to explain many of the technological properties. Direct visualization by electron microscopy has provided a few options, some probably now recognized as artifacts of sample preparation. In early micrographs, the casein micelle strongly resembles a raspberry. This gave rise to the notion that the micelle is itself an assembly of subunits of defined structure, each with an estimated diameter of $\sim$15 nm. Neutron and X-ray scattering measurements can also be interpreted to support these notions. Transmission electron micrographs appearing in the literature in the last few years show the casein micelle as a diffuse structure with numerous small regions of high scattering density, akin to the appearance of currants in a bun. Interestingly, these currants disappear when pictures are taken at pH values around 5.5, their disappearance accompanied by the loss of the shoulder in the X-ray scattering profile apparent at high pH. It is now accepted that the regions of high density are calcium phosphate nanocrystals, spatially separated in the micelle by an average of $\sim$10–15 nm, which are solubilized and disappear when milk pH is reduced.

Micelle Models

There is no universally accepted model for the structure of the casein micelle. The major contenders are the subunit model, the Holt model, and the dual-binding model of Horne, introduced to overcome criticisms leveled at the first two.

Submicelle Model

Drawings representing the casein micelle as an agglomerate of spherical submicelles appear in all dairy science textbooks. It is suggested that the submicelles are linked together by calcium phosphate. To produce the κ-casein outer coating for the casein micelle, two different subpopulations of subunits must be created. Those rich in κ-casein provide the outer reaches of the structure, and those devoid of κ-casein form the micellar core. While this broadly satisfies the requirements of a picture of the micellar structure in terms of the largely discredited early electron micrographs, no mechanism has been proposed to account for the assembly of these subunits or to suggest a driving force for the creation of subunits of different composition. It is this latter failing – a failure to explain why κ-casein should associate with the other caseins to form the external submicelles but be totally excluded from the interior ones composed of the same caseins – that is the main criticism of the submicelle model, although other failings are apparent on deeper examination.

Holt Model

The Holt model suggests that the nodes for micellar assembly are calcium phosphate nanoclusters dispersed through the micelle. These interact with the phosphoserine clusters of the casein molecules. Because some of the individual caseins, α_{S1}- and α_{S2}-casein, have more than one such grouping, cross-linking and network formation are possible to give a microgel particle. Accepting the nanoclusters as providing regions of high scattering density, this model provides an explanation for the heterogeneity in appearance and scattering behavior of the micelle. Unfortunately, there is no inherent mechanism in this model that limits gel growth. It could continue until the milk was composed of a single giant micelle, a macrogel. There are vague suggestions of limitation by substrate exhaustion, and ring closure remains a possibility, but the chief criticism of this model is that it has no role for κ-casein. κ-Casein has no cluster of phosphoserines to bind with the nanoclusters, and consequently the Holt model has no explanation for the observed surface location of κ-casein in the natural micelle.

Dual-Binding Model for Micelle Assembly and Structure

In the dual-binding model, micellar assembly and growth take place by a polymerization process involving, as the name suggests, two distinct forms of bonding. These are cross-linking through hydrophobic regions of the caseins or through bridging across calcium phosphate nanoclusters. Central to the model is the concept that micellar integrity, and hence stability, is maintained by a localized excess of hydrophobic attraction over electrostatic repulsion. The individual casein molecules behave and interact as they did in their self-association equilibria described previously. Each casein molecule effectively functions as a block copolymer, as detailed in **Figure 1**, with each block possessing different and, possibly, multiple functionality for the cross-linking paths.

Thus, α_{S1}-casein can chain polymerize through the hydrophobic B blocks, through the hydrophobic clusters dispersed along this region, giving the observed wormlike chain of **Figure 2**. Further growth here is limited by the electrostatic repulsion of the hydrophilic regions, but in the casein micelle, the clusters of phosphoserine residues located therein form a template for the growth of calcium phosphate nanoclusters or for termination of a facet of their growth. Neutralization of the phosphoserine negative charges through incorporation into the calcium phosphate nanocluster reduces that electrostatic repulsion component and permits further molecules to enter and become hydrophobically linked to blocks B upstream or downstream of the nanocluster link, providing cross-links to other polymerization paths (**Figure 3**). Multiple protein binding into each nanocluster also exists, allowing a different network pathway to be built up. β-Casein, with only two blocks, the phosphoserine cluster (P) and the hydrophobic region (B), can form polymer links into the network through both and thus chain growth can extend through these. α_{S2}-Casein is envisaged in this model as having two of each block (**Figure 1**), two phosphoserine clusters, and two hydrophobic regions. It is only a small fraction of the total casein but, by being able to sustain growth through all its blocks, it is likely to be bound tightly into the network. κ-Casein is the most important of the caseins in this dual-binding model of micellar

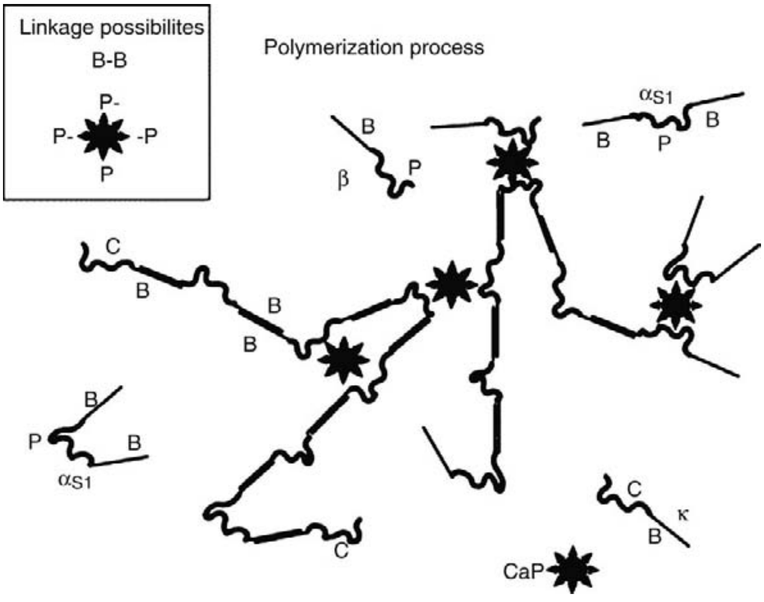

Figure 3 Schematic depiction of the conformations adopted by the caseins on adsorption at a hydrophobic interface. Those for α_{S1}-and β-caseins are based on calculated predictions from self-consistent ® eld theories; the diagrams for α_{S2}- and κ-caseins were developed by analogy. Hydrophobic regions (B) are represented by the bar structures, which do not imply any form of rigidity; hydrophilic regions containing phosphoserine clusters are denoted by P and the hydrophilic caseino-macropeptide of κ-casein by C.

assembly and structure. It can link into the growing chains through its hydrophobic N-terminal block, but its C-terminal block (denoted C in **Figure 1**) has no phosphoserine cluster and therefore cannot extend the polymer chain through a nanocluster link. Chain and network growth are therefore terminated here, leaving the casein micelle network with an outer layer of κ-casein molecules, a prime requirement for any structural model.

A major failing of the other micelle models is their lack of a plausible mechanism for assembly, growth, and more importantly termination of growth. All of these elements are in place in the dual-binding model. Furthermore, the concept of bonding occurring as a result of a localized excess of hydrophobic attractions over electrostatic repulsions successfully accommodates the response of the micelles to changes in pH, temperature, urea addition, or removal of calcium phosphate by sequestrants. Urea disrupts the hydrophobic bonds, bringing about micellar disintegration. Removal of calcium from the calcium phosphate nanocluster by EDTA addition restores the negative charge of the hydrophilic region and shifts the hydrophobic attraction/electrostatic repulsion balance in favor of repulsion and the micelle breaks up. Lowering the milk pH solubilizes the calcium phosphate, but the micellar negative charge is also titrated away, leaving the micelle largely intact. If the pH of that milk is restored by dialysis against milk at its natural pH, then the micelles of the treated milk again fall apart. Dropping the temperature decreases the level of hydrophobic attraction; any β-casein not linked through its phosphoserine cluster could then be released into the serum phase, behavior of the type shown by the breakup of the detergent-like micelles of β-casein (**Figure 2**) on lowering the solution temperature.

The dual-binding model also satisfies the appearance and scattering behavior shown by the native micelle. It reproduces the heterogeneity in structure required by X-ray and neutron scattering data. The dense calcium phosphate nanoclusters are seen as currants in the micellar 'bun' in recent electron micrographs, separated by a correlation length of some 10–15 nm estimated from X-ray scattering spectra. Also, loss of the currants from their micelle electron micrograph on lowering the pH and the parallel disappearance of the shoulder feature in the X-ray spectrum were demonstrated, while micelle integrity was maintained at this pH. The model can also accommodate the production of the raspberry-like appearance created artifactually in early micrographs, through the collapse of loosely linked more mobile regions onto those more densely cross-linked. Also, disintegration of the micelles into pieces by random breakage of bonds could lead to segments varying in composition. Those originating from surface regions would be rich in κ-casein, while those originating internally would lack κ-casein, but this is a one-way path. There is no requirement for these structures to be formed as a stage along the route to the creation of the casein micelle, as is necessary in the submicelle model.

Because the dual-binding model naturally provides a surface location for κ-casein in a growth-limiting role, it readily explains the destabilization of the micelle system on proteolysis of the κ-casein by chymosin and the loss of the steric-stabilizing layer. Indeed, once it is recognized that the proteolysis reaction affects only the surface regions and that internal micellar integrity is unaffected, the adhesive sphere model of rennet-induced gelation emerges as a special case of the dual-binding model. Limitations in the adhesive sphere aggregation model become apparent for acid-induced gelation because here there are effects on micelle integrity. These can, however, be accommodated very successfully within the framework of the dual-binding model. Similarly, the action of ethanol in collapsing the κ-casein hairs, which superficially follows the adhesive sphere model, requires the complexity of the dual-binding model when the nuances of this behavior are studied. Not enough is known about heat-induced destabilization of the micellar system, its aggregation pathway, and its chemistry, to test the ability of the dual-binding model to predict and reproduce such behavior. Dealing with the complexity of the many effects of heating milk remains a challenge for the future.

The dual-binding model imposes no specific requirements on the chemistry of the caseins at the amino acid level. It also has no demands for a defined secondary structure. The requirements are solely that the casein molecules be amphiphilic and that the majority possess a phosphoserine cluster. Major differences in composition between species can thus be tolerated with no loss of ability to assemble micelles from the proteins synthesized. In the milk of goats with the null variant of α_{S1}-casein, micelles are still found because the other caseins are present at a sufficient amount to construct the network. Again, in caprine milks with the α_{S1}-casein F variant with the deleted phosphoserine cluster sequence, micelles are again obtained. The model would predict that some of this α_{S1}-F would have a surface location. Although the levels of expression of this variant are low, measurements of casein composition variation with micelle size for milks with this protein indicate behavior consistent with such a location. Reports also exist of mare's milk that does not gel on treatment with chymosin. Such milk contains no κ-casein but still has micelles. Here, the sterically stabilizing entity is a dephosphorylated β-casein. Without a phosphoserine cluster, it cannot enter into chain polymerization through this link and hence fulfills the role of the missing κ-casein as a chain terminator. There is also the possibility that dephosphorylated β-casein could act in a similar fashion in human milk, where large numbers of small micelles are encountered. The dual-binding model also successfully accommodates the changing composition of marsupial milk and its partial disintegration in the presence of EDTA.

Introduction

α-Lactalbumin is a major protein component of the whey fraction of bovine milk and was first isolated more than 70 years ago. Because of its relative abundance and ease of purification, α-lactalbumin served as a model for the early development of methods for investigating the chemical and biophysical properties of proteins. Although initially it had been considered to have only nutritional significance, in 1967–68 it was discovered that α-lactalbumin has a key function in the biosynthesis of lactose and the production of the aqueous phase of milk. Contemporaneous structural studies also revealed that bovine α-lactalbumin is similar in amino acid sequence and disulfide bond arrangements to type-c lysozymes from birds and mammals. α-Lactalbumin was the subject of an early exercise in homology-based modeling, which showed that its amino acid sequence is consistent with a close similarity in three-dimensional structure to lysozyme; this early model was surprisingly correct, but this was not confirmed until the first three-dimensional structure of an α-lactalbumin was determined in 1989. The common ancestry of the genes for α-lactalbumin, which is found only in mammals, and lysozymes, which are ubiquitous in eukaryotes, suggests that the α-lactalbumins developed through duplication of an ancestral lysozyme gene followed by mutational divergence that led to the development of a new protein function. This gene duplication event, which is believed to have been a key evolutionary step in the development of the unique ability of mammals to synthesize lactose and produce copious milk secretions, must have occurred early in mammalian evolution because the echidna, a representative of the egg-laying monotremes, expresses an α-lactalbumin in its milk, although it is present at relatively low concentrations; it is even possible that an early form of lactation developed in a premammalian synapsid. Unlike many of the type-c lysozymes, including the well-characterized human and chicken proteins, α-lactalbumin contains a tightly bound Ca^{2+}, which has been found to have a crucial role in its structure and function. At first, this appeared to be a unique property of α-lactalbumin, but further research has identified families of lysozymes that also contain a structural Ca^{2+} bound at the same site. The evolutionary relationship of α-lactalbumins and lysozymes is complicated by the existence of other lysozyme homologues that, like α-lactalbumin, have diverged functional properties.

Structure and Metal Binding

Bovine α-lactalbumin is synthesized as a pre-protein of 142 amino acids of which the first 19 form a secretion signal sequence, which is removed to produce the mature protein of 123 residues, which has a molecular weight of 14 128. Its polypeptide chain contains eight cysteines that are connected by four intramolecular disulfide bonds. A small fraction of bovine α-lactalbumin molecules are N-glycosylated at asparagine 71; this is a rare protein N-glycosylation site, which has the sequence Asn-Ile-Cys, as compared with the 'normal' N-glycosylation sequence Asn-X-Ser/Thr. The polypeptide chains of the mature α-lactalbumins from other mammalian species range in length from 121 to 140 amino acid residues. Their sequences differ in degrees that increase with the evolutionary separation of the species. The greatest difference may be between α-lactalbumins from eutherian mammals and those from monotremes, which have less than 50% identity in sequence.

A tightly bound Ca^{2+} is present in all α-lactalbumins that have been investigated; this metal ion is not required for its function in lactose biosynthesis, but has an important role in structure and stability. The calcium can be removed at low pH or using chelating agents to produce the apo-protein. The binding of Ca^{2+} to apo-α-lactalbumin is very tight under physiological conditions with a K_a in the order of $10^7\,\text{mol}\,l^{-1}$. At low ionic strength and physiological temperatures and pH, apo-α-lactalbumin has a molten globule structure, a state characterized by the presence of a large proportion of secondary structure but no fixed tertiary structure. A transition to the molten globule state of α-lactalbumin is promoted also by low pH, denaturants, and detergents. This form of α-lactalbumin is fairly compact and, unlike the native protein, can bind some hydrophobic dyes, such as

8-anilino-1-naphthalene sulfonic acid (ANS), and lipids. Stable partially folded states are relatively rare in proteins, although unfolded proteins and domains are not uncommon. Partially folded states can serve as models for intermediate states in protein folding processes, and the structure and stability of the α-lactalbumin molten globule state has been the subject of much research. As discussed below, this form of α-lactalbumin may have some biological and biomedical relevance.

At this time, X-ray crystallographic structures have been determined for the α-lactalbumins from cow, goat, human, baboon, and mouse, in different crystal forms and complexes with metals, and with bovine β-1,4-galactosyltransferase-1 and various ligands. These structures are similar to those of the related type-c lysozymes, having what is classified as an α plus β fold that consists of two lobes of structure, an α-helical lobe, and a β-sheet lobe that are separated by a cleft (**Figure 1**). The cleft corresponds to the open active-site cleft in the lysozymes that can accommodate an extended oligosaccharide substrate but, in α-lactalbumin, the cleft is closed at one end. The larger α-helical lobe is formed by the amino- and carboxyl-terminal sections of the polypeptide chain (residues 1–34 and 86–123), whereas the smaller β-lobe, which encompasses a small three-stranded antiparallel β-sheet, a short 3_{10} helix, and some irregular structure, is formed by residues 35–85 that represent the central section of the polypeptide chain.

The primary binding site for calcium ions (see **Figure 1**) is located in a loop of structure close to the junction between the two lobes, which has a high content of aspartic acid residues. The consensus amino acid sequence of this region in different α-lactalbumins is Lys^{79}-h-h-Asp-Asp-p-h-Asp-Asp^{88}, where h is a hydrophobic amino acid, and p, a polar amino acid such as Asp, Glu, or Asn. The Ca^{2+} coordinates with the carboxyl groups of aspartates 82, 87, and 88, the peptide carbonyl groups of Lys79 and residue 84, and two water molecules. The structures of calcium-binding lysozymes from echidna, horse, and dog have also been determined and show similar coordination fields. α-Lactalbumin can bind a second Ca^{2+} with lower affinity and an array of other metals including manganese (Mn^{2+}), zinc (Zn^{2+}), and lanthanides. The second Ca^{2+} binds at a site adjacent to the primary calcium-binding site (**Figure 1**), and Mn^{2+} appears to bind at a site similar to the binding site

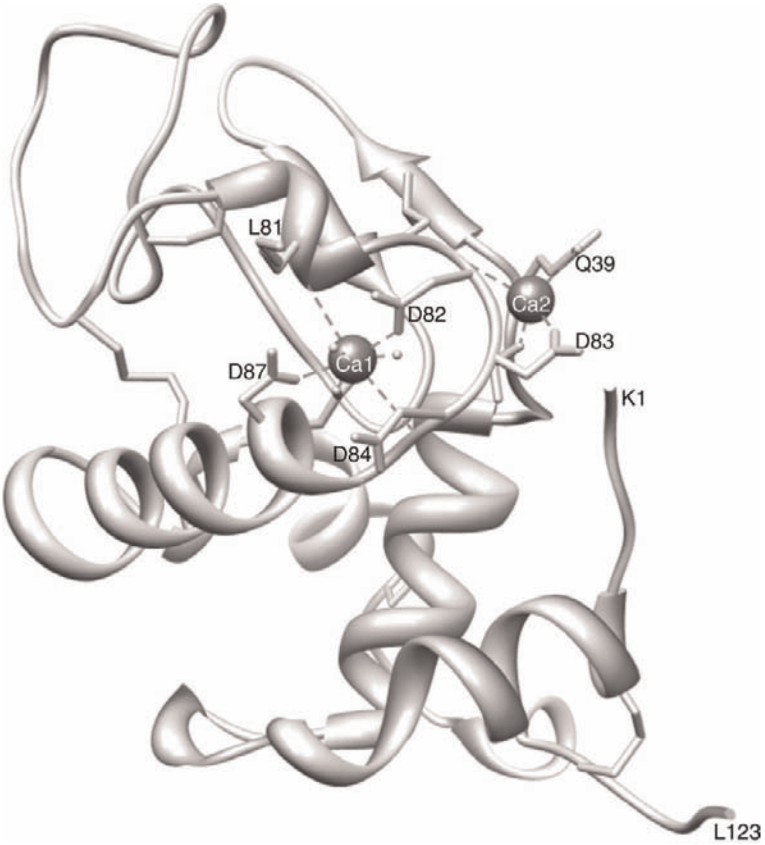

Figure 1 Ribbon structure of human α-lactalbumin complexed with two Ca^{2+}. The picture was generated from 1A4V.pdb using the graphics program CHIMERA. The side chains of residues that interact with the two Ca^{2+} are displayed and labeled together with the amino- and carboxy-terminal residues of the polypeptide chain.

of the second Ca^{2+}. Zn^{2+} promotes dimerization of α-lactalbumin by simultaneously interacting with two α-lactalbumin molecules. The full biological significance of Ca^{2+} binding to α-lactalbumin is not entirely clear. It is required for generating a functional α-lactalbumin molecule, because in its absence unfolded preparations of α-lactalbumin with reductively cleaved disulfide bonds are unable to fold to the native structure with appropriate pairing of cysteines in disulfide bonds, suggesting that it is required *in vivo* for the correct folding of α-lactalbumin in the endoplasmic reticulum following translation.

Apo-α-lactalbumin has a stable native structure at high ionic strength, and an X-ray crystallographic structure of bovine apo-α-lactalbumin has been determined. A comparison with the structure of the holo-protein shows that the overall structures are closely similar with only minor adjustments in the structure around the metal-binding site. However, a significant change was found on the opposite face of the protein that reflects an increased separation of the α-helical and β subdomains, probably as the result of a change initiated in the Ca-binding site that causes a rearrangement of α-helix 3. This change opens up the structure around Tyr103 and suggests that Ca^{2+}-binding may enhance folding by promoting the formation of long-range interactions between residues of the two subdomains – a possible rate-limiting step in the folding process.

Function in Lactose Synthesis

α-Lactalbumin acts as the regulatory protein of lactose synthase (EC 2.4.1.22), a role in which it modulates the affinity of the catalytic component UDP-galactose β-*N*-acetylglucosaminide β1,4-galactosyltransferase-1 (β4-galactosyltransferase-1; EC 2.4.1.38), for acceptor substrates through a reversible protein–protein interaction. Galactosyltransferase-1 is a member of a family of seven homologous galactosyltransferases (β4-galactosyltransferase-1 to β4-galactosyltransferase-7) found in mammals, which have somewhat overlapping specificities and vary in tissue distribution; this family of glycosyltransferases is ancient, being present in invertebrates as well as vertebrates. Like most mammalian glycosyltransferases that function in the processing of glycoproteins and glycolipids, β4-galactosyltransferase-1 encompasses a short N-terminal cytoplasmic domain, a transmembrane hydrophobic α-helix, a stem region, and a C-terminal catalytic domain. Forms of β4-galactosyltransferase-1 are expressed in most secretory cells including mammary epithelial cells, and it is an intrinsic component of the trans-Golgi membranes. In most cells, it catalyzes the transfer of galactose from UDP-galactose into a β-linkage with the 4-hydroxyl group of nonreducing terminal β-linked *N*-acetylglucosaminyl residues in glycan chains (**Figure 2**). Although β4-galactosyltransferase-1 can catalyze lactose synthesis (the transfer of galactose to free glucose) *in vitro*, it is ineffective as a catalyst for this reaction under physiological conditions because of its low affinity for glucose, reflected in a K_m of about 2 mol l^{-1}. α-Lactalbumin, which appears to be expressed only in the lactating mammary gland, binds reversibly with β4-galactosyltransferase-1 to form 1:1 complexes with a concomitant 1000-fold increase in its affinity for glucose. This interaction, which allows the efficient production of lactose at physiological concentrations of glucose, occurs in the lumen of the Golgi apparatus where β4-galactosyltransferase-1 is a relatively stationary component of the membranes. α-Lactalbumin is a secreted protein and becomes a transient soluble component of the contents of the Golgi lumen during its passage through the cell. This arrangement couples lactose synthesis with continued milk protein synthesis during lactation and results in the production of lactose in the lumen of the Golgi apparatus. As lactose cannot cross the Golgi membranes, and is a major osmole in milk, it also results in a flow of water into the Golgi lumen, which is important for the formation of the aqueous phase of milk. Lactose and α-lactalbumin are both secreted from lactating mammary epithelial cells into milk by packaging into secretory vacuoles whose contents are released from the cell by exocytosis. The importance of α-lactalbumin for lactation is highlighted by studies with transgenic animals. In mice, inactivation of the α-lactalbumin gene results in the production of thick milk, devoid of lactose, and an inability to sustain offspring, while replacement with a human α-lactalbumin gene restored lactose synthesis and milk production. Among the promising developments in this area is the observation that transgenic pigs that overexpress bovine α-lactalbumin show enhanced lactose levels in milk, increased milk production, and improved piglet growth rates.

The gene for β4-galactosyltransferase-1 is transcribed as two mRNA species by initiation at two different sites: a longer form associated with a general housekeeping promoter and a shorter form from a mammary-specific promoter. The utilization of the second promoter allows the synthesis of high levels of β4-galactosyltransferase-1 protein in the lactating mammary gland through enhanced transcription and as the result of the translation of a shorter polypeptide chain. Thus, the ability of most mammalian species to produce large quantities of lactose and sufficient milk to nurture their offspring is associated with adaptational changes in both proteins of the lactose synthase system.

Alternative Structures, Apoptosis, and Mammary Involution

The concept that proteins often have multiple functions is now broadly accepted, and research during the past decade has drawn attention to a biological activity in

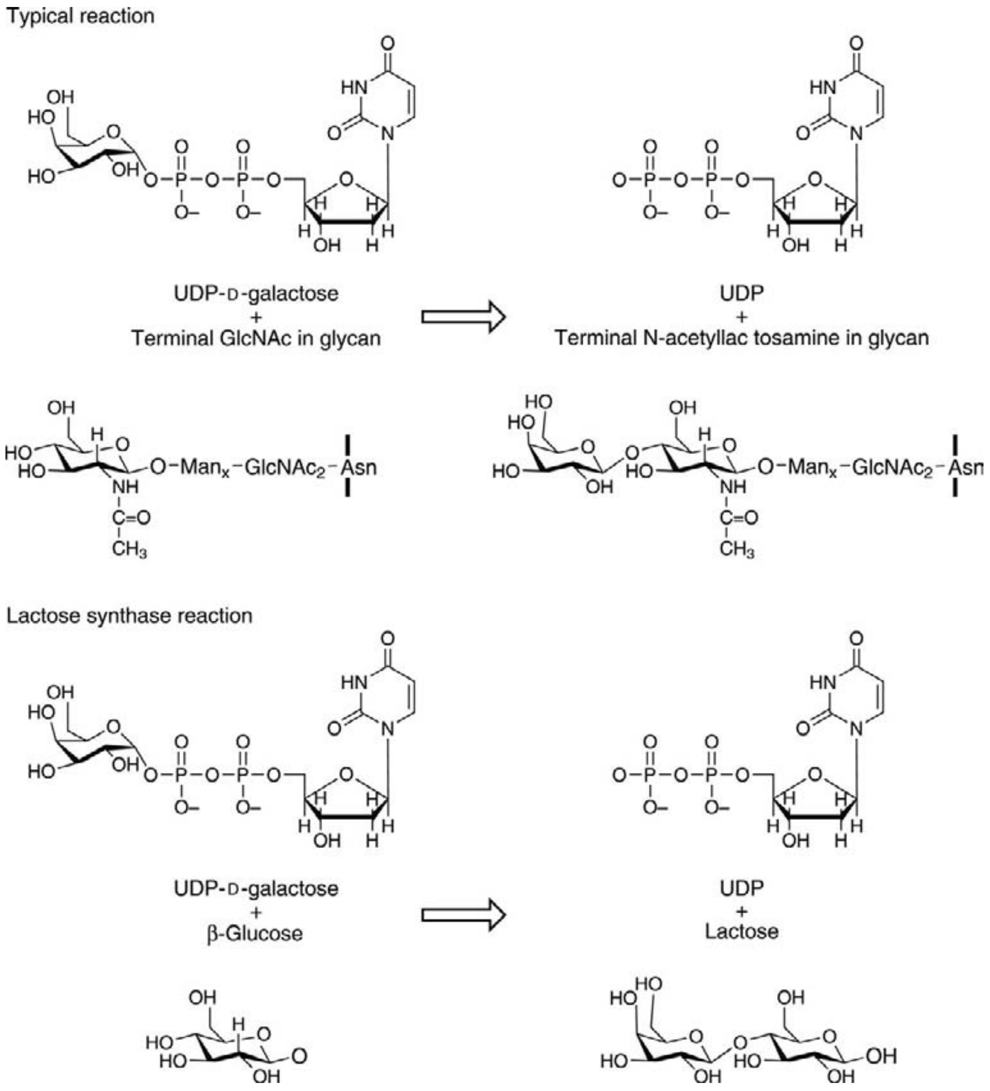

Figure 2 Reactions catalyzed by β4-galactosyltransferase-1, alone and lactose synthase.

α-lactalbumin that is distinct from its role in lactose biosynthesis. The partially folded molten globule state of α-lactalbumin, which has more exposed nonpolar side chains, has been the subject of many studies. Human milk was found to have apoptotic effects on a human lung cancer cell line, and this activity was found to be associated with a multimeric form of α-lactalbumin isolated from the casein fraction. Further work showed that this molecule can be generated from human apo-α-lactalbumin by chromatography on an ion-exchange column that has been conditioned with oleic acid. This form of α-lactalbumin, apparently a non-native state stabilized by complex formation with oleic acid, has been found to selectively induce apoptosis in tumor cells and has been designated HAMLET (Human α-lactalbumin made lethal to tumor cells). It has generated interest as a novel approach for cancer treatment. The mechanism through which it triggers apoptosis involves interaction with mitochondria to promote the release of cytochrome c, after transfer into the cell, followed by activation of caspases; it has also been shown to disrupt chromatin in the nucleus by binding to histones. HAMLET appears to have a more native structure than the molten globule state but differs from both native and molten globule forms. Although it can bind Ca^{2+}, like native α-lactalbumin, it differs in undergoing irreversible denaturation by heat or urea with the loss of its apoptotic activity.

Bovine α-lactalbumin has been reported to reduce the viability of bovine mammary epithelial cells and to induce apoptosis in Cape fur seal mammary cells. Involution of the mammary gland in most mammalian species generally occurs with the termination of suckling when milk accumulates in the ducts of the mammary gland; this appears to be regulated locally and, besides physical damage to tissue produced by increased pressure, it has been suggested that a factor or factors in the accumulated milk may trigger mammary gland involution following weaning. Recently, it has been proposed that α-lactalbumin may function as an inducer of involution based on its pro-apoptotic effects, as in the unusual case of the Cape fur seal. These otariid seals produce milk that is devoid of lactose but with high levels of protein and lipid. After giving birth, female fur seals develop a pattern of intensive suckling of their pups for 2–3 days on land with copious quantities of rich milk, followed by extended foraging trips lasting up to 23 days. In most mammals, a period of 23 days without milk removal would result in apoptosis and involution of the mammary glands, but this does not occur in the fur seal. In these animals, the α-lactalbumin gene is mutated so that little or no protein is produced. Also, the protein product is shorter than normal, containing only 104 amino acid residues so that it lacks amino acids that are essential for its activity in lactose synthesis and formation of a stable molten globule state. It has been proposed that these changes prevent apoptosis triggered by α-lactalbumin so that mammary function can be retained during the long intervals between suckling activities. These are interesting observations that suggest a possible regulatory role for α-lactalbumin in terminating lactation, in addition to its established function in initiating and maintaining lactose synthesis. However, the evidence is circumstantial and involves extrapolation from what may be a unique adaptation in one species to mammals in general.

Cetaceans (whales and dolphins) also produce milks that have high contents of lipid and proteins but low levels of lactose; their lactation time varies in length between 5 months and 3 years. Parts of the amino acid sequence of α-lactalbumin are known for many species in this order, and all differ from other known α-lactalbumins in having a unique unpaired cysteine at position 36. This could have a major effect on structure and/or activity but, at present, there are no reports regarding the properties of any α-lactalbumin from this group of mammals.

Molecular Basis of the Action of α-Lactalbumin in Lactose Synthesis

α-Lactalbumin interacts with β4-galactosyltransferase-1 only in the presence of substrates, forming 1:1 complexes in the presence of glucose, *N*-acetylglucosamine, or a combination of the metal cofactor, Mn^{2+}, and UDP-galactose (or other UDP-sugar). Synergistic binding of α-lactalbumin and glucose to the galactosyltransferase, reflected in mutual stabilization of complexes, results in a reduction of the K_m for glucose by about three orders of magnitude. Thus, the presence of α-lactalbumin changes glucose from being a very marginal substrate to a good substrate. In contrast, disaccharide substrates such as diacetyl chitobiose, or even a β-glycoside of GlcNAc, and α-lactalbumin bind in a mutually exclusive manner to galactosyltransferase-1; so α-lactalbumin is a competitive inhibitor of galactose transfer to such substrates. Mutational studies showed that Phe31, His32, Leu110, Gln117, and Trp118 are important residues in α-lactalbumin action, the first three of these having an effect on glucose binding while the latter two specifically stabilize the protein–protein association. X-ray crystallographic structures of various complexes of recombinant forms of mouse α-lactalbumin and the catalytic domain of bovine galactosyltransferase-1 have now been elucidated. The catalytic domain of β4-galactosyltransferase-1 has a GT-A fold, one of the two predominant classes of structure found among nucleotide-sugar utilizing glycosyltransferases. It consists of a central twisted β-sheet, containing both parallel and antiparallel strands, surrounded by α-helices. In the lactose synthase complex, 1310 $\mathring{A}^2$ of the combined surface area from the two proteins becomes buried in their interaction interface, amounting to 20% of the accessible surface in α-lactalbumin and 11% surface in β4-galactosyltransferase-1. From **Figure 3**, it can be seen that residues identified by mutagenesis as important for the action of α-lactalbumin in lactose synthesis, Phe31, His32, Met110, Gln117, and Trp118 (in the mouse variant Met replacing Leu110 of bovine α-lactalbumin), interact with a largely nonpolar region of β4-galactosyltransferase-1 comprising Phe280, Tyr286, Gln288, Tyr289, Phe360, and Ile363. The D helix, formed from residues 105 to 111 of mouse α-lactalbumin, interacts with a helix (residues 359–365) of β4-galactosyltransferase-1. Although the donor substrate (UDP-gal) stabilizes the complex between the two proteins, it does not interact directly with α-lactalbumin in the complex. Instead, the binding of UDP-galactose to β4-galactosyltransferase-1 induces a rearrangement of residues 345–365, including the formation of an α-helix by residues 359–365 and a reorientation of the side chain of Trp314. When *N*-acetylglucosamine binds an acceptor substrate, a hydrophobic pocket formed by Arg359, Phe360, and Ile363 interacts with the 2-acetamido group. Glucose has a hydroxy rather than acetamido at the 2-position, and in the complex of α-lactalbumin and glucose, α-lactalbumin binds to the hydrophobic pocket and interacts directly with glucose acceptor substrate by H-bond formation between the Nδ1 of the imidazole group of His32 and the C-1 and C-2 hydroxy groups of glucose. This substrate-induced structural change in β4-galactosyltransferase-1 is consistent with kinetic studies, which indicate that substrates bind to the enzyme in an obligatory ordered manner, donor substrate prior to acceptor, while the interaction of α-lactalbumin with the C-1 hydroxy group of glucose provides a molecular mechanism for the switch between synergistic binding of α-lactalbumin and acceptor in the case of monosaccharides and mutually exclusive binding in the case of oligosaccharide or glycoside acceptor substrates. α-Lactalbumin lowers the K_m values of other weak-binding acceptor substrates of galactosyltransferase-1, including

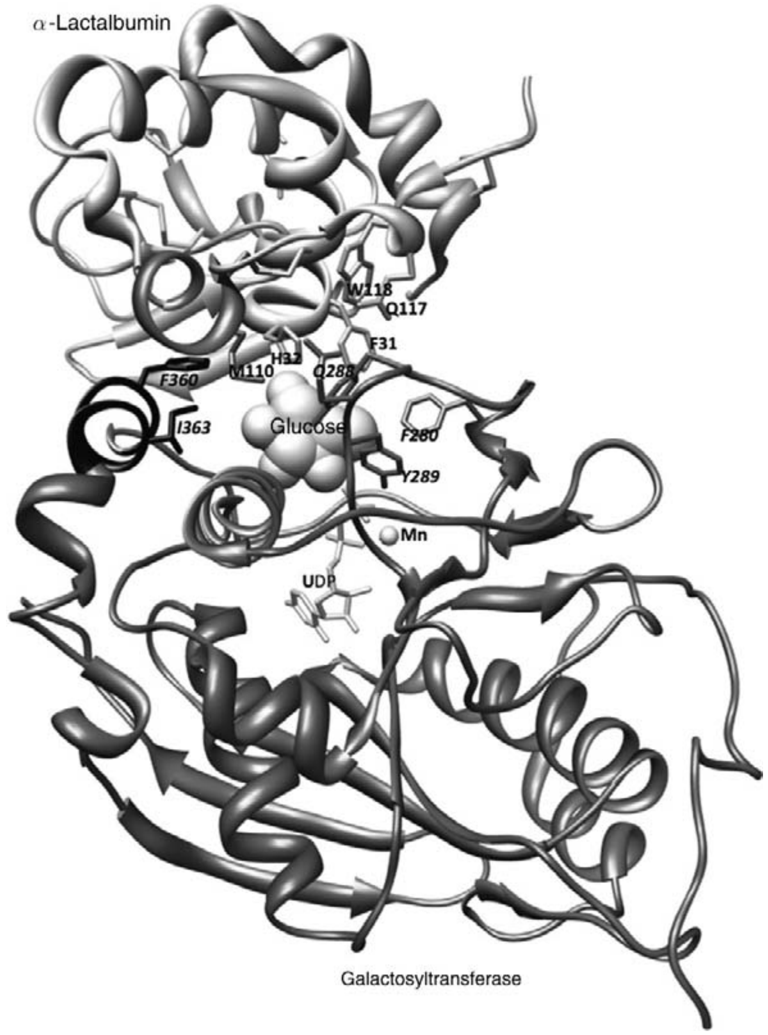

Figure 3 Ribbon structure of mouse α-lactalbumin in a complex with the catalytic domain of bovine β-4-galactosyltransferase-1 in the presence of glucose, Mn^{2+}, and UDP-*N*-acetylgalactosamine. The image was generated from 2FYD.pdb using CHIMERA. The side chains of residues from the two proteins that are involved in their interaction and in binding glucose are displayed and labeled, those from β-4-galactosyltransferase-1 are italicized. The helices from the two proteins that are important in the interaction are shaded more darkly than the rest of the structures.

xylose and cyclitols, and promotes the transfer of monosaccharides from marginal donor substrates such as UDP-glucose, presumably by stabilizing catalytically competent complexes of such substrates with β4-galactosyltransferase-1. Consequently, the α-lactalbumin–galactosyltransferase-1 system has practical applications in the enzymatic synthesis of novel glycans.

Conclusion

Despite about four decades of research following the discovery of the primary function of α-lactalbumin in lactose synthesis and the initial realization of its structural similarity to lysozyme, several questions remain regarding its function and properties. One significant issue discussed above is that of its possible role in triggering mammary involution and its connection with the partially folded molten globule state. A second related question is regarding the pro-apoptotic form of α-lactalbumin, HAMLET, which appears to have promise as an anticancer treatment. Modified proteins have proved to be effective treatments for other diseases, and it will be interesting to see if this novel ligand-stabilized misfolded protein can be translated into a clinical treatment.

Introduction

β-Lactoglobulin is present in the milk of most mammals and generally accounts for about 50% of the whey proteins in ruminants and about 10% of the total milk protein in cow's milk. The ratio of caseins to whey proteins is dependent on the species, with high casein to whey protein ratios being associated with the rapidly growing mammals, such as lambs and calves. These mammals are also those that are most commonly cultivated for their milk production.

β-Lactoglobulin is globular in nature with a well-defined three-dimensional structure. It has an α-helix along one side of a β-barrel and, in ruminant milk at least, exists as a dimer from pH 3 to 7. At about pH 7.5, the ruminant protein undergoes a well-defined change known as the Tanford transition. All β-lactoglobulins examined bind a range of small hydrophobic and amphiphilic molecules, and their structural similarity to other members of the large family of lipocalins, or extracellular lipid-binding proteins, indicates they could have a transport role for the newborn. Nevertheless, the biological function of this protein has not been clarified, and the absence of this protein from rat, mouse, hare, and human milk but presence in possum and baboon milk suggests that it may not be essential for many species.

Although cow's β-lactoglobulin exists in a large number of genetically determined forms (variants), it is generally present as either the A or the B variant. This variation is correlated with a number of milk characteristics, and milk processability and product function are clearly associated with different responses to heat treatments of the different variants.

Most of our knowledge of the characteristics and behavior of this protein has resulted from the extensive studies on the bovine protein, which is readily isolated in a pure state from milk by simple procedures, or can be purchased in a moderately pure state. This has led to its being used as one of the 'standard' proteins, along with serum albumin, ovalbumin, and α-lactalbumin, in many biophysical and biochemical studies.

As the major component of whey protein concentrates, it has also become a valuable food ingredient because of its combination of nutritional and functional advantages. As a result, the ways in which it unfolds and aggregates, particularly with other proteins, continue to be studied intensively.

Nomenclature

The proteins of milk were originally (pre-1890 or so) classified as either casein or whey proteins, and the precipitate from heated whey was called lactalbumin. This name continues to be used for a commercial product made by this process.

Some proteins of whey were found (about 1890) to be precipitated by saturating acid whey with magnesium sulfate or half-saturating it with ammonium sulfate. This fraction was called 'lactoglobulin', and the protein material that remained soluble was called 'lactalbumin'. Further research in the 1930s identified a crystallizable material in the 'lactalbumin' fraction, and two proteins were isolated and were called α-lactalbumin and β-lactoglobulin (β-lg). Later, bovine serum albumin was also found in this fraction.

Thus, there were two different materials called lactalbumin and another called α-lactalbumin. In the commercial and legislative area, there is the potential for confusion as to the composition and origin of some products and whether they are albumins or globulins.

Once the three-dimensional structure of β-lg had been determined, it became clear that the eight-strand β-barrel or calyx fold was very similar to that of serum retinol-binding protein. Since then, a large family of proteins called lipocalins has been identified with similar folds, and they rather specifically bind small hydrophobic or amphiphilic molecules. If the β-lg molecule were being named now, it might well be called 'milk fatty acid-binding protein' or 'milk lipocalin'.

In the 1950s, it was found that β-lgs exists in two forms, called the A and B variants, and the differences between these proteins were genetically determined. Since then, a number of rarer genetic variants have been identified (*see* **Milk Proteins**: Heterogeneity, Fractionation, and Isolation). It was also noted that β-lg A was present at higher concentrations in milk than β-lg B, and it is now recognized that β-lg A is expressed at about a 30% higher concentration than β-lg B in both homozygous and heterozygous cows. Control of expression level resides in the unexpressed upstream region of the gene. One important consequence is that the whey protein:casein ratio is higher in β-lg A milk and thus the results of experiments using milk from selected groups of cows may not extrapolate to the milk of another group or to bulk milk.

A number of genetic variants of β-lg have been identified in the milk of sheep and goats, and because the designation of A, B, and so forth, has been arbitrary, the relative differences between bovine B and C variants, for example, has no bearing on differences between sheep B and C variant structure or behavior.

Separation and Isolation

The proteins of whey or whey products can be separated readily using either native- or sodium dodecyl sulfate (SDS)-polyacrylamide gel electrophoresis (PAGE). With care, appropriate standards, and using amido-black dye, quantitative assessments can be made. Both ion exchange (**Figure 1**) or reversed-phase high-performance liquid chromatography (RP-HPLC) are useful for separation and for quantitation. Capillary electrophoresis and molecular sieves are becoming accepted methods also.

Traditionally, β-lg is prepared by fractional precipitation with $(NH_4)_2SO_4$ at a low pH, followed by repeated crystallization. Modern chromatographic methods have allowed it to be isolated by size exclusion and cation or anion exchange chromatography. One specific and rather unusual method is by affinity chromatography on a column of immobilized retinal, which is a ligand that is strongly and reversibly bound by β-lg.

A commonly used purification method involves separation of the fat and casein from fresh raw milk by centrifugation followed by acidification to about pH 4.5 at 35–40 °C. The clarified whey fraction is concentrated, adjusted to pH 2.5–3.0, and NaCl added to give a concentration of 7% (w/v) at about 20 °C. Most proteins except β-lg form a loose precipitate that can be separated from the β-lg-containing solution. The β-lg can be separated from the remaining whey by dialysis or by precipitation on increasing the NaCl concentration to 30%.

β-Lg can also be purchased from various sources. A typical SDS-PAGE comparison of a commercial product and a scrupulously prepared laboratory sample is shown in **Figure 2**. Clearly for precise work, it is better to purify the protein and not subject it to temperatures over 45 °C, freeze-drying, a pH above 6.5, denaturing solvents, or long-term storage. Any of these treatments can covalently modify or polymerize the protein. Even shaking solutions of β-lg can alter the protein.

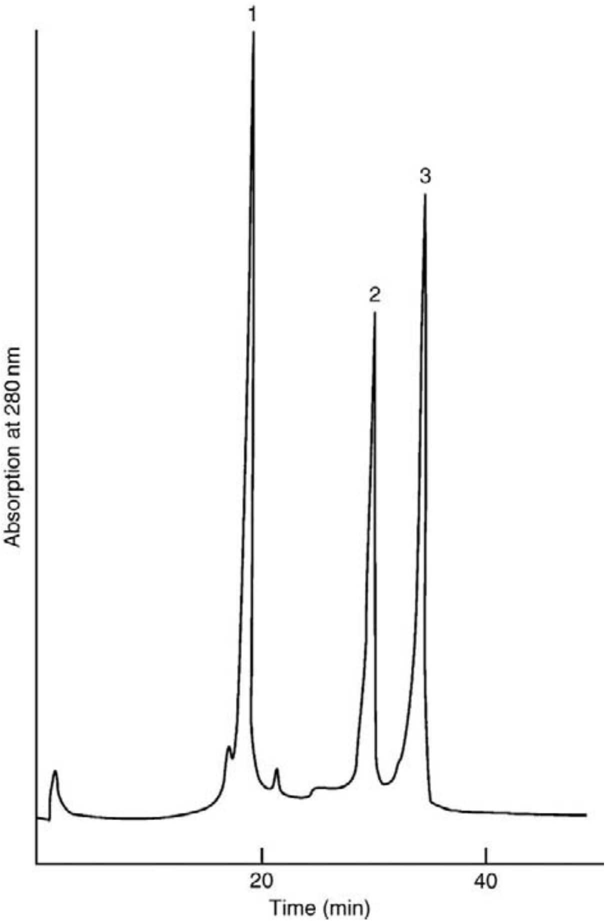

Figure 1 Typical analytical ion exchange separation of the components of whole acid whey that had been dialyzed against the starting buffer to remove orotic acid and other low molecular mass compounds. The column was a Mono Q HR5/5, and the buffer was 0.02 mol l $^{-1}$ piperazine-HCl, pH 6.0, and the proteins were eluted with 0 ± 0.4 mol l $^{-1}$ NaCl. The three major peaks were identified as (1) α-lactalbumin, (2) β-lactoglobulin B, and (3) β-lactoglobulin A.

Structure

Primary

The amino acid composition of β-lg was first reported in 1949, and refinements were made during the following decade. Partial sequences were published during the 1960s, and the complete sequence was published in 1972. Nevertheless, there was some controversy about the exact position of one of the disulfide bridges (i.e., whether it was between residues 106 and 119, between residues 106 and 121, or indeed a mixture of both). Early low-resolution X-ray structures were unhelpful, but

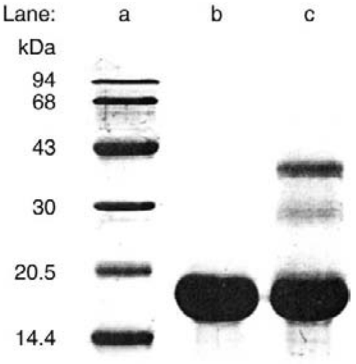

Figure 2 (a) SDS-PAGE patterns of molecular mass standards, (b) carefully purified β-lactoglobulin, and (c) commercial product. All samples were reduced with 2-mercaptoethanol. Whey was prepared from skim milk by acid precipitation of the casein, and the pH was raised to 7.2. β-Lactoglobulin was isolated by an adsorption-desorption step from diethylaminoethyl Sepharose-CL6B. This material was chromatographed on a size-exclusion column of Superdex 75BPG to give the pure sample (b). Reproduced with permission from de Jongh HHJ, Groenveld T, and de Groot J (2001) Mild isolation procedure discloses new protein structural properties of β-lactoglobulin. *Journal of Dairy Science* 84: 562–571.

high-resolution X-ray and NMR studies confirmed the chemical studies that suggested the disulfide bond was exclusively between Cys106 and Cys119 and that Cys121 was the free thiol. Nevertheless, this thiol is fairly unreactive in the native protein and is 'available' for reaction only after the protein had been unfolded in some way (e.g., raising the pH renders the thiol susceptible to heavy metal ions or in a solution containing at least 6 mol l^{-1} urea the reactivity is that of a free thiol). Heat treatment at near-neutral pH also exposes up to one thiol group per β-lg molecule.

Secondary

Estimates of the secondary structure of β-lg have been made since the 1960s using optical rotatory dispersion, circular dichroism, and infrared spectroscopy. On the basis of these results, β-lg was considered to have about 50% β-sheet and 10% α-helix. Attempts were also made to use predictive methods to identify the sites of the β-strands, helical regions, and various tight turns by applying structural probabilities (based on early X-ray structures of a range of mostly globular proteins) to the primary sequence. Once the medium-resolution X-ray structure was known, the predictions were found to be correct for the major helix and most of the β-strands, including all those in the major sheet. After heat treatments, the β-sheet content identified spectrally is essentially unchanged, but much of the α-helix content is lost. High pressure has similar effects, but exposure to chaotropic solvents reversibly reduces all of the secondary structures. More recently, NMR studies have revealed that some of the β-strand structure in the N-terminal half of the molecule can exist as α-helix that appears to be an essential intermediate in the folding pathway of the native structure.

Tertiary and Quaternary

Early studies showed that under conditions close to physiological, both β-lg A and B formed dimers reversibly and that dimerization was ionic strength-, pH-, temperature-, and protein concentration-dependent. β-Lg A also formed octamers at about pH 4.5 and around 4.5 °C.

Recently, high-resolution structures of β-lg have been obtained using both NMR and X-ray methods. Despite the considerable environmental differences (pH 2–3, monomeric protein and low ionic strength for the NMR and some rigidity in the crystals that were grown at pH 6.2–8.2 with either high (>3 mol l^{-1}) or low (<0.05) ionic strength), the folding of the polypeptide chains is very similar within the various structures and among the A, B, and C genetic variants. All show a stable β-sheet with an α-helix on one side and a second β-sheet on the other (**Figure 3**). Both X-ray and NMR show considerable main chain and side chain flexibility in the long loops.

Recent NMR work with the A34C mutation that produces a stable dimer at neutral pH not only confirmed that the core structure is stable and that dimerization does not cause large variations in the structure but also has allowed the refolding of the protein to be followed in some detail. Differences do exist, mostly in the external loops both within the various bovine crystal and NMR structures and, less surprisingly, between bovine, porcine, and reindeer crystal structures and also the equine NMR structure. Whereas bovine, ovine, and reindeer β-lg have very similar dimer structures involving an antiparallel arrangement of strand I, the dimer present in pig at pH 3.2 is quite distinct, does not utilize strand I, and involves a domain swap even though β strand I is H-bonded to strand A and is part of the major β-sheet for all three structures.

Variants

The structures of the A, B, and C variants of bovine β-lg have been analyzed by X-ray crystallography; the differences in the tertiary structures are minor. Closer examination and consideration of the energetics of the loss of native structure as a function of temperature (**Figure 4**) lead to the conclusion that Ala to Val (B → A) at position 118 changes the hydrophobicity within the cavity of β-lg, but the change of Gly to Asp (B → A) at position 64 alteres the charge on the CD loop as well as on the protein as a whole. This change could affect the stability of the Cys66-Cys160 disulfide bond.

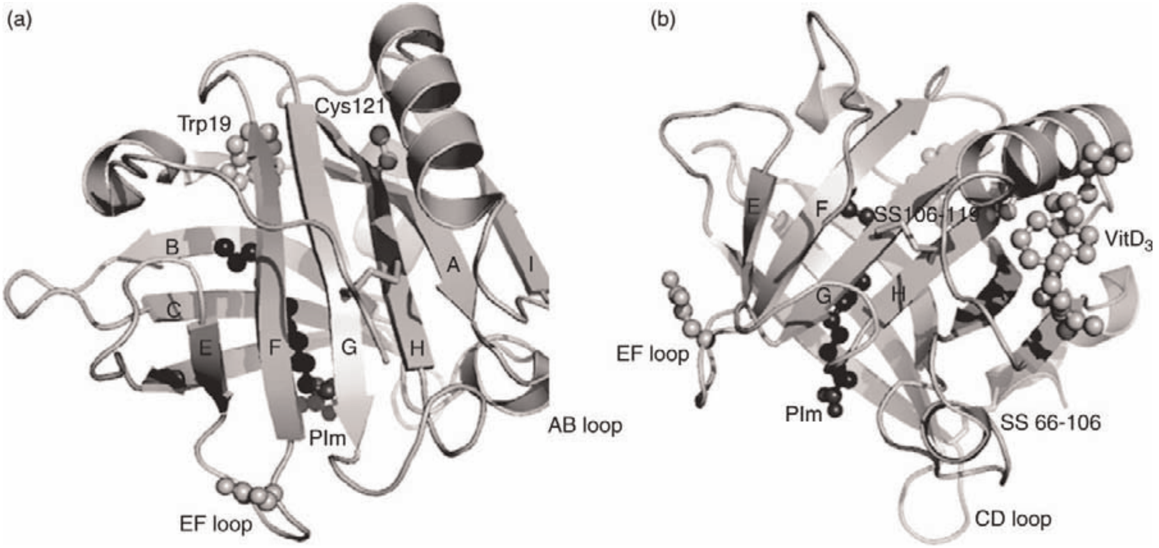

Figure 3 Cartoon representations of bovine β-lactoglobulin (variant A in crystal form Z containing the bound ligands), sodium palmitate (Plm; PDB:1gxa), and vitamin D_3 (VitD$_3$; transformed from PDB:2gj5) drawn using the program PyMol (W. L. Delano, The PyMOL Molecular Graphics System: DeLano Scientific, San Carlos, CA, 2002). The β-strands are labeled A–I. The CD and EF loops are labeled, and the side-chains of Trp19, which lies at the base of the hydrophobic cavity, Glu89 that triggers the Tanford transition, and the free Cys121 are also shown. (a) A view of the molecule from the 'top', with the entrance to the calyx behind the EF-loop which is in the open position. (b) A more end-on view of the calyx, showing the second binding site between the three-turn helix and strands A and I.

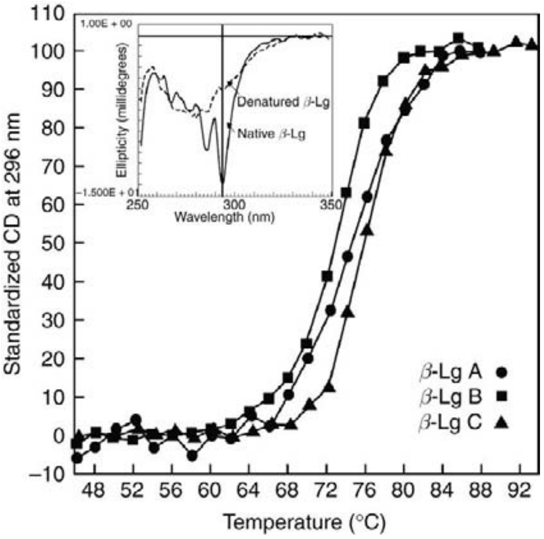

Figure 4 Effect of heating β-lactoglobulin A, B, and C on near-UV ellipticity. The three proteins (1.7 mg ml^{-1} in pH 6.7 phosphate buffer) were heated for 10 min at temperatures between 46 °C and 93 °C. The cooled samples were diluted to 1 mg ml^{-1} and scanned from 250 to 350 nm at 21 °C. The ellipticities at 293 nm were normalized prior to plotting. The inset shows the spectrum of an unheated β-lactoglobulin A sample and one that had been heated at 86 °C. Reproduced with permission from Manderson GA, Hardman MJ, and Creamer LK (1997) Spectroscopic examination of the heat induced changes in β-lactoglobulin A, B and C. In: *Milk Protein Polymorphism, Proceedings of the IDF Seminar in Palmerston North*, pp. 204–211. New Zealand. Brussels: International Dairy Federation SI 9702.

Tanford Transition

It was noticed that the titration of β-lg gave an anomalous result for one ionizable residue of the protein. It appeared that a glutamic or aspartic acid residue had a pK$_a$ of about pH 7.3 instead of pH 4.5–5.0, as expected. Structural analysis showed that Glu89 was H-bonded to Ser116 at pH 6.2 but not at pH 8.2. It was also found that loop EF was folded down onto the protein at pH values below about 7.5 as a consequence of this H-bond, and this prevented access of retinol and other ligands to the hydrophobic binding cavity. This structural change is also responsible for the pH-dependent changes in optical levorotation noted and possibly changes in the accessibility of the thiol group. Recent NMR data confirm this and propose that the mechanism of the transition is initiated by the deprotonation of Glu89 that allows a rearrangement of the H-bonding of Ile84, Asn90, and Glu108 in the hinge region of the EF-loop. This is then followed by the opening of the EF-loop permitting access to ligands like palmitate and retinol.

Ligand Binding

It has been known for a long time that the two major hydrophobic and amphipathic ligand binders in milk are serum albumin and β-lg. The binding characteristics of some β-lg-ligand complexes are shown in **Table 1**. The possibility that β-lg could be a useful drug carrier has been explored, and it has been speculated that β-lg could

carry retinoids through the hostile stomach (abomasum) environment, or that β-lg is important in transporting fatty acids from the lipolysis site to the gut wall during milk digestion. It is now clear that fatty acids and retinoids, at least, are bound within the calyx (hydrophobic cavity) of native β-lg. There are other possible sites for ligands, such as 1,8-anilino-naphthalene sulfonate (ANS), which do not bind in the cavity but on the outer surface of the protein between the helix and strands A and I in the dimer interface. This site has also been found to bind vitamin D_3 in addition to its binding in the central calyx. Clearly, pure proteins are required for these studies because impurities such as serum albumin or denatured β-lg bind amphiphiles that the native protein does not.

Structure and Function of the β-Lactoglobulins in Milk

The polypeptide chain adopts a fold typical of the lipocalin family. This family is widely distributed and contains members with varied functions, though all are secreted from the cell and appear to be able to bind small, generally hydrophobic, molecules. The closest lipocalin member to β-lg is glycodelin found in the endometrium of human and baboon during the first trimester of pregnancy. High-resolution X-ray structures are now available for bovine, ovine (95% identical to the bovine protein), porcine (56% identity), and reindeer (94% identity) β-lgs, together with the NMR structures of bovine, porcine, and equine (69% identity) β-lgs and, for comparison, glycodelin (**Table 2**). In each case, the core structure of the protein is an eight-stranded, antiparallel β-sheet made up of two layers (β-strands A1–D and E–H, A2). Together, these form a conical binding cavity because the A strand is kinked significantly, forming sub-strands A1 and A2, around residue 22, allowing it to engage with strand H, and the general twist of the sheet strands also permits D and E to interact with one another (see **Figure 3**). In all cases, there is a three-turn α-helix after strand H and before a ninth strand, I. In the bovine, ovine, and reindeer proteins, strand I makes an antiparallel interaction with strand I of a second β-lg polypeptide to form part of the dimer interface at neutral pH. The helix is on the outer surface of the protein and located over, partially burying, the free thiol group of Cys121. Each β-strand is joined to the next one by a loop. Before strand A, in the loops AB (between strands A and B) and GH and in the C-terminal section, there are helical turns. Further, the extended loop AB makes contacts with the same loop from the other molecule of the dimer, thus strengthening the dimer interface. Loops BC, DE, and FG are at the ‘back’ of the molecule; that is, they are at the closed end of the central ligand-binding cavity (surrounding Trp19, **Figure 3**(**a**)). The loops joining the other ends of the strands, AB, CD, EF, and GH, are at the open end (near the foot of **Figure 3**(**a**), lower left of **Figure 3**(**b**)) and show signs of significant flexibility. In particular, the loop EF can adopt two independent positions depending upon the pH. At low pH, where the protein does not bind ligands readily, this loop forms a closure to the binding site whereas at high pH the loop is folded back, allowing ready access of the ligands to the hydrophobic cavity. Indeed, it is this loop that contains the anomalous carboxylate (Glu89) identified

Table 2 Percentage (%) sequence identities of selected β-lactoglobulins and glycodelin

by Tanford and responsible for the pH-dependent transition that bears his name. Also at low pH, protonation of Asp33 in loop AB weakens its interaction with Arg40 from the other subunit, thereby promotes dissociation. It is not clear why the A variant of bovine β-lg should form octamers (i.e., four dimers associating), but it is interesting that the pH of maximum association corresponds with the pK_a of a side-chain carboxyl group and that the A variant has an additional carboxyl at Asp64, the start of the CD-loop, that might facilitate a carboxyl-carboxylate association.

Neither porcine nor equine β-lg is a dimer at neutral pH although porcine β-lg dimerizes around pH 4, the pH at which the crystal structure was determined. Interestingly, the dimer interface is quite distinct from that observed in the bovine protein, involving an intertwining of the N-termini before strand A. Similarly, NMR studies of the equine protein in solution reveal a monomer at neutral pH. NMR studies on bovine β-lg have been carried out at around pH 2 because at this pH the protein is a monomer. The structures obtained are closely related to those observed by crystallography with the EF-loop in the 'closed' position. The folding of the protein has been observed by NMR techniques to involve the transient formation of a helical region involving β-strand A and, further, the upper and lower sheets (strands A1–D and E–H) fold essentially independently. Palmitate binding to β-lg has also been monitored by NMR and shown to mirror the Tanford transition in that binding is not observed below pH 6, whereas above that pH the ligand exhibits conformational variability at the carboxyl end. This is also in good agreement with the crystallographic results that show fatty acid or retinol bound within the central cavity. NMR structural data have also been obtained from the A34C mutant at neutral pH that are also in good agreement with the crystallographic studies. Recently, crystal structures that show the existence of a second binding site in the dimer interface region close to residues 136–148 have been obtained. ANS binds close to Arg148 in the loop between the end of the helix and the strand I while vitamin D_3 binds both in the same external region and also in the central cavity.

The physiological function of β-lg has been enigmatic with the consensus view being that it is a transporter of some sort. However, the wide selection of small hydrophobic molecules that bind does not provide any real clue to the identity of the physiological ligand(s). Fatty acids, principally palmitic acid, are detected bound to freshly isolated protein, but as porcine β-lg does not bind fatty acids, at least not at physiologic pHs, it is improbable that fatty acids are the true ligand. The species distribution also shows that the presence of β-lg in milk is widespread but not universal; there is no β-lg in human, rodent, or lagomorph milk. However, β-lg has been identified in the milk of the baboon and the macaque. Further, in cat, dog, and horse, for example, there are at least two distinct genetic loci, and pseudogenes have been identified in cow and goat. Estimated relationships between the known amino acid sequences of the available β-lgs, together with the most closely related sequence that emerges from the other lipocalins, indicate that the endometrial protein, glycodelin, appears to be a retinol-binding protein produced in significant quantities in the first trimester of pregnancy. It is possible therefore that β-lg is merely a convenient nutritional protein, in some cases with fortuitous additional properties, left over from the essential role provided by glycodelin in fetal development. One might expect to be able to identify pseudogenes for the protein in those species whose milk lacks β-lg.

Processing-Induced Structural Changes

During the processing of milk, a number of physical and chemical reactions can occur because of exposure of reactive groups, or because the higher energy (temperature or pressure) allows reactions to proceed faster. β-Lg is involved in many of these processes and has been studied extensively, particularly at the molecular level.

Intraprotein and Interprotein Reactions

When the environment of β-lg is altered, the structure of the protein changes. These changes are generally reversed when the previous environmental conditions are restored as long as the FGH triple-strand motif can re-form readily. An essential element of this re-formation is the retention of the Cys106-Cys119 disulfide bond. If either of these Cys residues becomes disulfide-bonded to a different residue, for example, this particular motif cannot re-form and hence the native structure that builds upon this stable motif cannot occur. This effect is probably common to perturbation by both heat and pressure, which change the energetic relationships that relate to the hydrophobic effect.

When β-lg is heated by itself at neutral pH at a temperature over 60 °C, it forms a series of polymers that are readily seen using PAGE analysis. These are formed by thiol-catalyzed disulfide bond interchange. In its simplest form, a free Cys residue interacts with a disulfide bond to bind itself to one of the partners, thereby freeing the other partner,

$$\begin{aligned} &R^1\text{-CysH} + R^2\text{-Cys=Cys-}R^3 \\ &\quad \leftrightarrow R^2\text{-CysH} + R^3\text{-Cys=Cys-}R^1, \end{aligned}$$

where R^1, R^2, and R^3 are the schematically shown different protein chains.

Thus, the native proteins containing intramolecular disulfide bonds are turned into a single large aggregate held together by intermolecular disulfide bonds. Early in the heat treatment of β-lg there are not only disulfide-bonded dimers and trimers but also monomers containing nonnative disulfide bonds (i.e., an internal Cys-disulfide exchange). There are also hydrophobically associated complexes of disulfide-bonded dimers and nonnative monomers.

The A, B, and C variants of β-lg denature to different extents for heat treatments at different temperatures. **Figure 4**, which shows how Trp61 is affected, is representative of other molecular parameters that demonstrate the same effects. The difference in response shown by β-lgs B and C is purely a change in the mid-point temperature, whereas the difference between β-lg A and either β-lg B or β-lg C also involves a change in the slope of the ellipticity (extent of denaturation) versus temperature. This conclusion explains the apparent disparity shown between different studies comparing the denaturation rates of β-lgs A and B.

Reactions involving structural change as a consequence of disulfide-bond interchange are responsible for the heat-induced gels made from whey protein isolates and concentrates, and also for protein fouling on heated surfaces in dairy plants. Reactions in milk often involve β-lg and κ-casein, whereas those in whey-derived material involve β-lg and α-lactalbumin (α-la). In each case, β-lg supplies the free thiol, but with κ-casein the free thiol can be either in the native protein or in various β-lg aggregates. With α-lactalbumin, the only reaction is between native β-lg and α-la. In this case, β-lg can also catalyze the formation of polymers of α-la.

H/D exchange at low pH/pD (where polymerization is very limited) has shown which parts of the tertiary structure are the most stable at low pH. As expected, the amide protons on the non-H-bonded peptide groups exchange rapidly at 37 °C. The various β-strands involved in β-sheets exchange over the temperature range 45–85 °C. At about 65 °C, the exchange of the helix protons occurs, and only at the highest temperature does exchange occur for the H-bonded residues in strands G and H. Thus, the stablest motif is that involving strands G and H, which encompasses the disulfide bond between residues 119 and 106.

At higher pH, reactions involving Cys and Lys residues can generate stable covalent interprotein and intraprotein lysinoalanine cross-links that can reduce protein digestibility.

Under certain conditions, β-lg is capable of self-assembling into long, thin fibrils. This occurs in a matter of weeks at room temperature in the presence of denaturants such as methanol, trifluoroethanol, or urea, or in a matter of hours during heating at low pH and low ionic strength. Fibrils typically have a diameter of approximately 5 nm, and can be as long as several micrometers. They are thought to have a 'cross-beta' structure similar to amyloid protein fibrils.

Many proteins are capable of self-associating into amyloid-like fibrils. Partial denaturation is a precursor to fibril formation, and hydrolysis is required in some cases, but a common mechanism of self-assembly has not been identified. Fibrillar aggregates of β-lg increase viscosity in a more efficient way than most other types of aggregates, and for this reason, β-lg fibrils are of interest as potential food ingredients and biomaterials.

Reaction with Lactose

The reactions of reducing sugars with the amino groups of proteins are well known as the Maillard reaction. The later products of this reaction are important in foods as they are major contributors to the flavor of caramel. One of the first steps in this reaction is the formation of β-lg-lactose adducts, and these can be observed as individual peaks in the mass spectra of such materials. When β-lg is heated in a lactose solution, the reaction is primarily with Lys47, but in a dried product, such as milk powder, there does not appear to be any specificity. The small reduction in the number of lysine residues does not adversely affect the nutritional value of the protein substantially. However, severe heat treatment or extended reaction times at moderate temperatures can cause extensive loss of lysine.

Hydrolysis

The allergenicity of β-lg, which is the most antigenic of the bovine milk proteins for humans, can be reduced by hydrolysis of the protein because the particular peptide sequences that react with the antibodies are cleaved into smaller fragments The epitopes on β-lg have been partially identified for the intact protein.

Bovine β-lg is readily hydrolyzed by proteolytic enzymes into peptides. The activity of the pancreatic protease, trypsin, has been studied extensively, and at the pH optimum of the enzyme (about 8.0), the variants are initially hydrolyzed in the order A > B > C.

Introduction

The dynamics of the composition of the protein components of milk from the first lacteal secretion of colostrum through to the development of mature milk assist us in defining the functional significance of many constituent proteins. These secretions should be viewed more in a developmental context as an extension of the maternal influence over the development of the neonate in the face of the stimuli associated with the extrauterine environment than merely as a source of nutrient substrate. Analyses of the functional significance of the casein and whey protein components in the development of the neonate have now been superseded by the development of genomic and proteomic strategies, which are being used to expand our knowledge of the roles of these proteins and importantly their constituent peptides in developmental processes. However, there are many proteins and peptides that are not derived from the classical milk proteome but increase the functionality of colostrum and milk. Binding proteins associated with the transportation of nutrients, for example, not only act to deliver vitamins, minerals, and growth factors to their site of action, but may also exert their own biological activity through functional receptors.

The Role of Milk Proteins in the Developmental Programming of the Neonate

While the dominant class of proteins in milk is the casein family, comprising 80% of bovine milk proteins, the whey proteins and a large pool of proteins found in lower abundance provide a disproportionate contribution to the total bioactivity of the milk proteome. Interestingly, many of these are encrypted within the native amino acid sequences of the major protein constituents and some activities are duplicated within both casein and whey protein sequences.

A number of these proteins are now known to be multifunctional in the neonate. Many provide a specialized developmental input while at the same time boosting host defense mechanisms against pathogenic bacteria as the newborn develops its own immune defense system. Thus, the exposure of the developing neonate to the diversity of milk proteins and peptides provides a mechanism that regulates an animal's development. The most overt example of this potential resides within the large number of hormones and growth factors that have been identified in colostrum or milk. These include hormones of the hypothalamic-pituitary axis, thyroid and parathyroid hormones, gastrointestinal regulatory hormones as well as the classical growth factors. Although the provision of peptides as a source of amino acids to support the rapid increase in protein synthesis is a major role of milk proteins, we now recognize that the bioactivities residing within their sequences may be much more important in directing their development.

This article covers a number of minor proteins associated with the key biological functions of milk (**Table 1**).

Minor Milk Proteins and the Development and Control of the Vascular System

Several milk proteins play a role in angiogenesis while others regulate blood pressure and nutrient partitioning. Thus, the ingestion of colostrum and milk not only directs the vascularization of tissue but is also capable of influencing nutrient supply to tissues.

The Angiogenins

The angiogenins are monomeric proteins of approximately 14 kDa that belong to the pancreatic ribonuclease superfamily. Their name is derived from their ability to promote the development of the capillary blood system in tissues with the first discovered of these, human angiogenin, inducing neovascularization in a wide array of systems, including the chicken chorioallantoic membrane, rabbit cornea, and rabbit knee meniscus. The link between the ribonuclease activity and angiogenic capacity of these proteins seemed tenuous until site-directed mutagenesis studies of the catalytic domain of murine angiogenin 4 showed that ribonuclease activity was essential for angiogenic activity.

Table 1 Some properties of minor milk proteins

Protein	*Molecular weight (Da)*	*Source*	*Concentration in milk (mg l^{-1})*
Angiogenin 1	14 577[a]	Mammary gland	4–8 (bovine)
Angiogenin 2	14 522[a]	Mammary gland	0.15 (bovine)
Heparin affin regulatory protein	18 000[a]	Mammary gland	0.017–0.060(human milk–colostrum)
Kininogens	>68 000 and 16 000[a]	Blood	
β_2-Microglobulin	11 630[b]	Monocytes	9.5 (bovine)
Osteopontin	29 283[b]	Mammary gland	18 (bovine)
Proteose peptone 3	28 000[a]	Mammary gland	300 (bovine)
Folate-binding protein	25 720[a]	Mammary gland	8 (bovine)
Vitamin D-binding protein	52 000[a]	Blood	250 (colostrum)–6 (milk) (bovine)
Vitamin B$_{12}$-binding protein (haptocorrin)	Human – 68 000[a] Bovine – 44000[a]	Mammary gland	0.1–0.2 (bovine)
Riboflavin-binding protein	37 000[a]	Mammary gland	
Bovine serum albumin	66 433[b]	Blood	100–400 (bovine)
Muc 1	78 700–58 500[a]	Mammary gland	
Muc 15	130 000[a]	Mammary gland	

[a] Apparent molecular weight, glycosylated or phosphorylated.
[b] Calculated molecular weight.

More recently, these proteins have been associated with regulatory roles in the nervous system, with mutations being associated with familial as well as sporadic forms of amyotrophic lateral sclerosis (ALS), a fatal neurodegenerative disorder characterized by selective destruction of motor neurons. Several genetic variants have been identified with varying function, while murine angiogenin 1 (ANG-1) is expressed in developing mouse nervous tissue and is associated with the neural differentiation of stem cells. Both ANG-1 and ANG-2 have been observed in bovine milk. Both have similar calculated molecular weights (14 577 and 14 522 Da, respectively), contain a similar number of amino acids (125 and 123 amino acids, respectively), and the conformation of each contains three disulfide bonds.

Bovine ANG-2 differs from ANG-1 in the presence of a single glycosylation site, which results in a reduction in its ribonuclease activity compared with ANG-1. While there is some homology between bovine ANG-1 and ANG-2 (57%), ANG-1 includes an integrin receptor recognition sequence, which may influence its role in angiogenesis.

Although we understand little of the function of bovine angiogenins, we now know that they are mainly responsible for the inhibitory effect of bovine milk on osteoclast-mediated bone resorption, and that they exert their activity by acting directly on the osteoclasts. They also induce the production of cytokines interleukin (IL)-1β, IL-6, and tumor necrosis factor (TNF)-α in human leukocytes.

Milk also delivers an antiangiogenic factor in the form of the pepsin-produced N-terminal fragment of iron- and heparin-binding lactoferrin, lactoferricin (LfcinB). LfcinB strongly inhibits both bovine fibroblast growth factor (bFGF)- and vascular endothelial growth factor (VEGF)165-induced angiogenesis by competing for binding sites on vascular endothelial cells.

Other Milk-Borne Proteins or Peptides That Regulate Vascular Function

Angiotensin-converting enzyme-inhibitory peptides

While the function of many angiogenic milk proteins is not well defined, the role of milk-derived peptides in inhibiting angiotensin-converting enzyme (ACE), responsible for the conversion of angiotensin 1 to the active angiotensin 2 and the degradation of the vasodilator bradykinin, is well established. Thirty-four ACE-inhibitory peptides have been identified in casein family sequences, while α-lactalbumin (α-La) and β-lactoglobulin contribute 18 similar functional sequences. Bovine serum albumin (BSA), lactoferrin, and β_2-microglobulin contribute a further five peptide sequences that may have a similar influence. The necessity for such a diversity of functional ACE-inhibitory sequences may be a result of the complexity of ACE bioactivity and its multiple sites of action. Its role as a central neuroregulator of vasopressin and neurotensin is consistent with a vasoregulatory function. ACE may also have roles in fertility by regulating gonadotropin-releasing hormone, and pain perception through substances P and K: all of these functions are associated with the control of lactation either directly or indirectly. ACE is also involved in hematopoiesis, the inflammatory response as well as tissue repair. Clearly, it is an important developmental molecule since the milk proteins have evolved multiple peptide systems to regulate its function in the growing neonate.

Heparin affin regulatory peptide

Heparin affin regulatory peptide (HARP), also known as pleiotrophin, heparin-binding growth-associated molecule, heparin-binding growth factor 8, and heparin-binding neurite-promoting factor, is a 136 amino acid (18 000 Da) growth factor displaying high affinity for heparin that is expressed in the mammary gland, brain, uterus, and prostate. It is expressed in both human colostrum and milk, with threefold higher concentrations being found in colostrum. It is present in the extracellular matrix of many tissues, interacting with heparin sulfate and dermatan/chondroitin sulfate glycosaminoglycans. It influences neuronal migration and epithelium–mesenchyme interactions during development.

Previously, HARP has been implicated in the control of angiogenesis and its effects are mimicked, at least in part, by synthetic peptides that correspond to its N and C termini. HARP is cleaved by plasmin, leading to the production of five peptides that correspond to distinct domains of the molecule. These peptides affect *in vivo* and *in vitro* angiogenesis and modulate the angiogenic activity of VEGF on human umbilical vein endothelial cells. This is associated with the role of this protein in regulating mitogenesis, cell motility, oncogenesis, differentiation, and synaptic plasticity: it promotes proliferation of human mammary and myoepithelial cell lines. It is also used as a tumor marker and importantly is elevated in response to proinflammatory cytokines.

Kininogen

Two kininogen molecules have been isolated from bovine milk, a high-molecular-weight form (greater than 68 000 Da) and a low-molecular-weight form (16 000–17 000 Da), which are different from those identified in bovine plasma. High-molecular-weight kininogen found in plasma (78 000 Da) is cleaved by the plasma protease, kallikrein, to release four fragments: heavy chain, bradykinin, fragment 1.2, and light chain. All of these fragments have been identified in bovine milk and the fragment 1.2 exhibits the ability to stimulate osteoblast proliferation. This fragment has been shown to be a multifunctional edible protein that promotes bone formation and inhibits bone resorption and its biological activity is resistant to pepsin.

Minor Milk Proteins and the Immune Defense System

The presence in colostrum and milk of a wide range of peptides and proteins that contribute to host defense mechanisms in the newborn is not surprising in view of the underdevelopment of the neonatal immune system. Many of these act as bacteriostatic molecules by preventing pathogens from interacting with the intestinal mucosa. While lactoferrin is recognized for its function as a high-affinity iron transporter, it is now considered one of a growing family of proteins that appear to have varying functions in different environments. Similarly, α-La is a calcium-binding milk protein, which plays a role in lactose synthetase activity; besides this function, both trypsin and chymosin hydrolysates of α-La have been shown to have bactericidal properties against Gram-positive organisms. Both of these proteins are not generally considered minor proteins of milk and thus are discussed elsewhere in this encyclopedia.

β_2-Microglobulin

β_2-Microglobulin has a calculated molecular mass of 11 630 Da and appears in bovine milk as a multimer but can also be found in other body fluids. Evidence from protease inhibitor treatment suggests that β_2-microglobulin is released as a product of the digestion of the cellular component of milk. β_2-Microglobulin has also been implicated in immune and histocompatability antigen mechanisms, but it is unclear what role this protein has, if any, in the mammary gland physiology of the cow or in the tissues of the neonate.

Osteopontin

Osteopontin is a secreted phosphoprotein first identified in the mineralized matrix of bovine bone; more recently, it has been detected in many tissues and fluids, including urine and milk.

Within the 262 amino acid sequence are a large number of serine or threonine residues that may be phosphorylated or glycosylated. The calculated molecular weight of the protein is 29 283 Da and includes a cell adhesion sequence (RGD) that may bind to integrins and facilitate its action.

Interestingly, this protein is upregulated in response to inflammation in a similar fashion to lactoferrin; it is also present in a 10-fold higher concentration in human milk than in bovine milk, as is lactoferrin. Evidence is now available to show that in milk this protein may act as a binding protein for the transport of lactoferrin, thereby enhance the effectiveness of this protein as a potent antimicrobial agent.

The importance of the interaction of minor milk proteins is further demonstrated through the anti-inflammatory actions of the milk fat globule-epidermal growth factor-8 protein (MFG-E8) by impeding the binding of cell surface integrins to osteopontin, which becomes activated during the gastrointestinal inflammatory disease, colitis. Osteopontin may also play a role in mammary involution as well as in casein synthesis. The expression of the gene encoding this protein, SPP1, is markedly upregulated in mammary tissue at involution, while suppression of the gene using small interfering RNA (siRNA) technology in bovine primary mammary epithelial cells decreases casein gene expression.

Proteose Peptone 3

Proteose peptone 3 is a phosphorylated glycoprotein with an apparent molecular mass of 28 000 Da composed of 135 amino acid residues isolated from the proteose peptone fraction of bovine milk. The peptide contains serine residues at positions 29, 34, 38, 40, and 46, all of which are phosphorylated. Two O-linked carbohydrate groups are located at Thr16 and Thr86, while one N-linked carbohydrate group is present at Asn77. Thr16 is only approximately 50% glycosylated. The amino sugar detected by the amino acid analyzer at Thr86 provides a linkage for galactosamine although glucosamine can also be found on this residue. In contrast, both glucosamine and galactosamine are found in the carbohydrate group linked to Asn77. This peptide is part of a family of glycoproteins, including glycomacropeptide, lactoferrin, and κ-casein, that may influence the immune response.

Transporter-Binding Proteins

A number of binding proteins responsible for the transport of key nutrients are also found in milk. Presumably, they serve a similar function by providing a mechanism for these important nutrients to be delivered to the neonate through the medium of colostrum and milk.

Folate-Binding Protein

Folate-binding protein is typically found in milk as a monomer exhibiting a molecular weight of approximately 25 720 Da. The 222 amino acid protein exhibits up to eight disulfide bonds and is glycosylated at two amino acids. It has a role in the sequestration of folate to facilitate cellular uptake including in the gastrointestinal tract. Folate has a critical role in embryonic development, with deficiencies associated with neural tube defects like *spina bifida*. Similar to other binding proteins, folate-binding protein in milk may regulate folate absorption in different parts of the gastrointestinal tract and sequester folate away from gastrointestinal microflora.

Vitamin D-Binding Protein

Vitamin D-binding protein (DBP), also known as group-specific protein, is found in the milk of several species and is likely to be derived from serum. The ~52 000 Da (human) protein of 458 amino acids is observed in the whey of colostrum and milk as well as serum although it is at a much higher concentration in serum and colostrum than in mature milk. These binding globulins from human, monkey, porcine, and bovine sources are of similar size although the bovine protein seems to lack a smaller binding protein. They may have a number of roles, including long-chain fatty acid binding as well as leukocyte chemotaxis. Other milk proteins have also been indicated in vitamin D transport in milk.

Vitamin B_{12}-Binding Protein

The importance of vitamin B_{12} (VitB_{12}; cobalamin) to ruminant species relates to the VitB_{12} dependence of the key hepatic pathway converting glucose to succinate. This vitamin and a number of its analogues, which are structural isoforms, are synthesized by bacteria. The ability of ruminant species to access VitB_{12} across the placenta or in milk or even retain the vitamin from direct injection is considered to be poor. VitB_{12} is obtained from dietary sources in nonruminant species. The human VitB_{12}-binding protein (haptocorrin) has a molecular weight of approximately 68 000 Da, 34% of which consists of carbohydrate, and seems to bind VitB_{12} to inhibit microbial uptake and thus may have a role in modulating the growth of gastrointestinal microflora.

Riboflavin-Binding Protein

Riboflavin-binding protein (Rfbp) is a protein of approximately 37 000 Da found in bovine milk (possibly sequestered from plasma) and it binds riboflavin. Its concentration in mammalian milk is higher than in plasma during lactation. The active carrier-mediated transport mechanism of riboflavin is regulated by the Ca^{2+}/calmodulin pathway, while there also appears to be a receptor-mediated endocytic component for riboflavin. The role of this carrier is most important in regulating the role of riboflavin in fetal development. Interestingly, the sequences of chicken Rfbp are 30% homologous with the sequences of chicken folate-binding protein, with eight of the nine disulfide bonds conserved between the two proteins, suggesting that the sequences for these important transport proteins have been conserved.

Other Minor Proteins of Milk

Bovine Serum Albumin

BSA is a protein found predominantly in the circulatory system of the cow but is also a constituent of the whey of bovine milk. BSA has a molecular weight of 66 433 Da (583 amino acids) and is believed to be found in milk due to a deterioration of the tight junctions between mammary epithelial cells, which restrict movement of molecules from the blood through to the secretary compartment of the bovine mammary gland. This observation is enhanced by the various reports of the identification of increased concentrations of BSA in bovine milk coinciding with mastitis and the corresponding immune/inflammatory response and the increased concentration of BSA in response to changes in milking frequency (e.g., from twice-a-day to once-a-day milking), which have been shown to affect the integrity of mammary epithelial cell tight junctions.

BSA in bovine milk has also been implicated in the allergic reactions in humans to bovine milk and has even been investigated as a possible cause for the stimulation of autoimmune disease leading to insulin-dependent diabetes mellitus in humans.

Mucins

Approximately 20 mucin proteins have been identified in humans and a variable number of glycosylated forms of the mucin core identified in bovine milk, with mucin 1 (Muc 1) and 15 (Muc 15) the best characterized. Bovine Muc 1 and 15 are present at higher concentrations in mature milk than in colostrum, yet the mucins are present in small quantities in bovine milk with Muc 15 representing only 0.08% of total protein in mature bovine milk.

Bovine Muc 1 is secreted by bovine mammary epithelial cells as a component of the milk fat globule membrane and may have a role in protecting epithelial surfaces from pathogens. A number of variants have been identified in bovine milk, with the longest being a protein of 460 amino acids and with a molecular weight of 78 700 Da and the shortest of approximately 140 amino acids and with a molecular weight of 50 400 Da. The protein has a carbohydrate content comprising 50–60% of its mass, is resistant to proteolysis, and may have some role in maintaining mammary structure as it lines the mammary ducts and as it is negatively charged may repel the opposite side of the duct to maintain the lumenal space.

Bovine Muc 15 is similarly highly glycosylated and is found in the milk fat globule membrane. Its carbohydrate content accounts for ~65% of its mass (~130 000 Da); Muc 15 is 307 amino acids in length.

The increasing complexity of the milk proteome demonstrates that this article cannot be exhaustive. Metal-binding proteins, prosaposin, and various other glycoproteins also are important contributors to the development and control of the immune and vascular systems of the neonate. Other peptides such as the lactocrine peptide, relaxin, appear to be involved in the process of gut closure. Doubtless, many additional members of this family of minor proteins will be identified in future as our understanding of these physiological systems develops.

Lactoferrin

Introduction

Lactoferrin (LF), also referred to as lactotransferrin, is an iron-binding glycoprotein and was identified in cow's milk already in 1939 but was isolated only in the early 1960s. LF is closely related to serum transferrin, which also occurs in milk but in a lower amount. However, LF and transferrin are distinct molecules, are different gene products, and behave differently in biological systems. Also, affinity for iron is much stronger in LF than in transferrin. All mammals seem to be able to produce these iron-binding proteins in milk, although their concentrations vary between species. LF is synthesized in the epithelial cells of the mammary gland, but also in other exocrine glands, and consequently is found in all external secretions, for example, saliva, pancreatic fluid, tears, sweat, and semen. Also, LF is present at high concentrations in synovial fluid and neutrophils (**Table 1**). LF synthesis is tissue-specific and is considered to be hormonally regulated. LF present in plasma is predominantly derived from secondary granules of circulating neutrophils. Human milk is particularly rich in LF, the concentration ranging from <1 to 16 $\mathrm{g\,l^{-1}}$ in colostrum and about 1 $\mathrm{g\,l^{-1}}$ in mature milk. In bovine colostrum, the LF content is, on average, 1.5 $\mathrm{g\,l^{-1}}$, ranging from 0.2 to 5 $\mathrm{g\,l^{-1}}$ and decreases to about 0.1 $\mathrm{g\,l^{-1}}$ in mature milk. Very high concentrations (up to 50 $\mathrm{g\,l^{-1}}$) of LF are found in secretions of non-lactating human and bovine mammary glands. LF is also present in the milk of other species, for example, goat, horse, pig, mouse, and guinea pig, but is virtually absent in milk from the rabbit, rat, and dog. In these species, transferrin is the principal iron-binding protein. LF is promptly delivered by circulating neutrophils to sites of microbial invasion. In the blood of septic patients, in inflamed synovial fluid, or in mastitic milk, the LF content increases manifold due to activated and degranulating neutrophils. Thus, LF may have a protective role in the mammary gland. LF has a high affinity for iron, a property that is linked to the majority of LF's proposed biological activities. Many non-iron-related functions have been described, as well. Apart from antimicrobial effects, LF enhances the bioavailability of iron and inhibits iron-mediated oxidative reactions, regulates inflammatory reactions, and modulates the intestinal microflora and possibly bone growth. In view of these functions, LF is considered to play an important role in the natural nonspecific defense system of the body. The expanding knowledge about the multifunctional role of LF has enlarged its scope of applications from food preservation to infant formulae, health-promoting foods and supplements, health-care products, oral hygiene products, cosmetics, and animal feeds. Also, clinical trials to develop LF-based products for the treatment of different diseases, for example, some cancers and ulcers, are under way.

Structure and Biochemical Properties

LF is a glycoprotein and is composed of a single-chain polypeptide and carbohydrate moieties. Human LF contains 691 and bovine LF 689 amino acids per molecule; the degree of sequence homology is 69%. Shared antigenic determinants have been demonstrated for human, bovine, and pig LF. The molecular weight (MW) of human LF is between 77 and 82 kDa, depending on the attached carbohydrates, and the molecule contains 16 disulfide bonds. Bovine LF has an MW of 80–84 kDa depending on the degree of glycosylation and it differs from human LF by a few amino acids and the glycan side chain.

The molecular and spatial structures of human and bovine LF have been characterized in detail and the genes encoding these proteins have been cloned and sequenced. In humans, a single functional LF gene has been identified, although gene polymorphism may occur. In the cow, LF present in milk and neutrophils also appears to be the product of the same gene. Bovine milk LF is heterogeneous with two major glycosylation forms identified. It is not known if the differences in glycosylation affect biological functions of LF but fully glycosylated LF is more resistant to proteases, like trypsin, than a nonglycosylated LF molecule. The degree of glycosylation of LF does not, however, affect its iron-binding capacity.

Each LF molecule can bind two ferric ions ($\mathrm{Fe^{3+}}$) with the concomitant incorporation of bicarbonate ($\mathrm{HCO_3^{-}}$) or carbonate ($\mathrm{CO_3^{2-}}$) ion. The affinity of LF to bind iron is very high ($K_\mathrm{d} \sim 10^{-30}$), being about 300 times higher than that of transferrin, which has the iron-transporting function in serum. The LF-bound iron is strongly attached even at pH 3, while bound ferric ions dissociate from transferrin already at pH 5 or in the presence of strong iron scavengers, such as citrate ions. The level of iron saturation of LF is relatively low in human milk, about

Table 1 Concentration of lactoferrin in various biological secretions

Biological secretions	*Concentration (mg ml^{-1})*
Human	
Colostrum (1–5 days)	4.6 (0.6–16)
Milk (0.5–6 months)	1.5 (0.3–4.2)
(>6 months)	0.7 (0.1–3.5)
Tear fluid	2.2
Seminal plasma	0.4–1.9
Synovial fluid	0.01–0.08
Saliva	0.007–0.010
Bovine	
Colostrum	1.5 (0.2–5.2)
Milk	0.1 (0.07–0.12)

In: Jensen RG (ed.) *Handbook of Milk Composition*, pp. 115–221. San Diego, CA: Academic Press, Inc.

6–8%, compared to 20–30% for bovine LF. In its natural state, LF has a salmon-pink color, the intensity of which depends on the degree of iron saturation. Iron-depleted LF with less than 5% saturation is called apo-LF, whereas the iron-saturated form is referred to as holo-LF. In addition to iron, LF also binds other metal ions, like copper, cobalt, zinc, and manganese. Under physiological conditions (pH 7.5), LF is positively charged and binds strongly polyanions, such as heparin, bacterial lipopolysaccharides (LPSs), lysozyme, immunoglobulins (especially IgA), casein, and DNA. On the other hand, at a low pH, as in the stomach, LF is cleaved by pepsin into several polypeptides, some of which have strong antimicrobial and immune system-regulating properties. LF has a very high isoelectric point (pI). The theoretical pI value calculated for bovine and human LF is 9.4 and 9.5, respectively.

Technological Properties

The thermal stability of LF has been studied mainly in model systems using buffered aqueous solutions or when added to milk. According to many experimental studies, the standard pasteurization regimes (72 °C for 15 s) used in the dairy industry have practically no effect on LF structure, antibacterial activity, and bacterial interaction. Also, preheating at 70 °C for 3 min followed by ultra-high temperature (UHT) treatment (130 °C for 2 s) leads to only 3% loss in residual iron-binding capacity. UHT treatment, however, abolishes the ability of iron-saturated LF to bind to bacteria, as well as the bacteriostatic activity of apo-LF. In spray-drying of milk, a marginal loss of LF activity is observed. In the above heat treatments, apo-LF denatures faster than holo-LF. LF seems to protect unsaturated fatty acids against oxidation and may contribute to the extension of the shelf life of iron-enriched and high-fat dairy or plant-derived foods.

Biological Importance

The potential biological role of LF has been studied extensively over the last 40 years. Originally, LF's function was considered to be essentially an antimicrobial one, but later this glycoprotein has proven to be far more multifunctional. At present, the major known or speculated *in vivo* activities of LF in lacteal secretions are

1. defense against infections of the mammary gland and the gastrointestinal tract (antimicrobial activity, regulation of the immune system),
2. nutritional effects (bioavailability of iron, source of amino acids),
3. mitogenic and trophic activities on the intestinal mucosa and gastrointestinal tract-associated lymphoid tissue and on bone tissue, and
4. antineoplastic activity in the gastrointestinal tract.

These activities are summarized in **Table 2** and will be discussed in more detail below.

Antimicrobial and Antiviral Effects

The *in vitro* antibacterial, antifungal, and antiviral activities of LF are well demonstrated and documented. LF exerts its antimicrobial effects by different mechanisms, which can be divided into four main patterns:

1. iron sequestering in order to produce iron deprivation,
2. binding of LF or its cleavage products to membrane structures of microbes, leading to disruption of cellular metabolism,
3. protease-like antimicrobial activity toward some bacterial virulence factors, and
4. induction of apoptosis in host cells infected by some intracellular pathogenic bacteria.

The best known mechanism is mediated by binding of iron from the environment to apo-LF. Iron is an essential factor for the growth of many microorganisms and an important factor for the virulence of many pathogenic bacteria. In inflammatory sites, high amounts of activated neutrophils degranulate and release LF, leading to effective scavenging of iron. Iron deprivation leads to the inhibition of *in vitro* growth of a variety of bacteria and yeasts, for example, *Escherichia coli*, *Helicobacter pylori*, *Klebsiella*, *Salmonella*, *Proteus*, *Pseudomonas*, *Listeria*, *Bacillus*, *Streptococcus*, and *Candida albicans*. The iron deprivation-related bacteriostatic

Table 2 Potential biological effects of lactoferrin or lactoferrin-derived peptides

Activity	*Proposed mechanism*
Iron carrier	Increase in the solubility of iron and receptor-mediated uptake
Oxidation inhibition	Reduction in the formation of free iron-mediated free reactive oxygen species
Antibacterial	Inhibition of cell growth and spore germination by scavenging iron, bactericidal effect by membrane disruption, decrease of bacterial virulence by inhibition of adhesion, by disruption of bacterial plaques, and by protease-like activity on virulence factors
Antiviral	Prevention of virus attachment to host cells
Antifungal	Stimulation of immune functions
Anti-inflammatory	Binding of bacterial lipopolysaccharide, inhibition of phagocyte priming, reduction of proinflammatory cytokine production, stimulation of anti-inflammatory cytokine production, inhibition of complement classical pathway
Immunostimulating	Stimulation of the activity of immune cells, for example, natural killer cells, acceleration of T-cell maturation, stimulation of immunoglobulin production by B cells, stimulation of chemotaxis and phagocytosis by leukocytes
Anticarcinogenic	Stimulation of immune functions, stimulation of apoptosis, inhibition of angiogenesis

Adapted from Nuijens JH, van Berkel PHC, and Schanbacher FL (1996) Structure and biological actions of lactoferrin. *Journal of Mammary Gland Biology and Neoplasia* 1(3): 285–295; Baveye S, Elass E, Mazurier J, Spik G, and Legrand D (1999) Lactoferrin: A multifunctional glycoprotein involved in the modulation of the inflammatory process. *Clinical Chemistry and Laboratory Medicine* 37(3): 281–286; Vorland LH (1999) Lactoferrin: A multifunctional glycoprotein. Review article. *Acta Pathologica, Microbiologica, et Immunologica Scandinavica* 107: 971–981; Kruzel ML, Actor JK, Boldogh I, and Zimecki M (2007) Lactoferrin in health and disease. *Postepy Higieny i Medycyny Doświadczalnej* 61: 261–267; Weinberg ED (2003) The therapeutic potential of lactoferrin. *Expert Opinion on Investigational Drugs* 12(5): 841–851.

effect is most pronounced for *E. coli*, while some other bacterial strains are unaffected by this mode of action. By chelating iron, LF can in many cases block biofilm development by bacteria. Iron deprivation stimulates bacterial surface motility, causing the bacteria to wander across the surface instead of forming cell clusters and biofilms. The bacterial transition from a free-living form into biofilms can be devastating for the host, because biofilms protect bacteria effectively from the host defense mechanisms and antibiotics. LF is able to block biofilm development by *Pseudomonas aeruginosa* at concentrations below those that kill or prevent growth.

LF can have a direct bacteriostatic or bactericidal effect on Gram-negative bacteria by destabilizing their outer membrane, which results in the liberation of LPSs. Enhanced synergistic antibacterial action of LF is achieved in the presence of specific antibodies or lysozyme. Lysozyme and LF are present at high concentrations in neutrophil granules and at sites of inflammation. Lysozyme alone is not very effective against Gram-negative bacteria due to the LPS layer in the outer membrane but, by binding to the LPS layer, LF enables lysozyme to gain access to the peptidoglycan in the bacterial cell wall. The synergistic actions of LF and lysozyme are suppressed if LF is iron-saturated.

The addition of apo-LF to many other antimicrobial agents enhances their antimicrobial activity. The inhibitory concentrations of several antibiotics like vancomycin are lowered *in vitro* in the presence of LF.

On the other hand, some iron-requiring pathogenic microorganisms synthesize and secrete small iron-chelating molecules, siderophores, which bind ferric ions with a high affinity and transport them into cells through specific receptors. Some pathogens, such as *H. pylori*, *Neisseria* sp., *Treponema*, and *Shigella* sp., express specific outer cell membrane receptors for uptake of LF and may exploit iron (which is bound in LF) for promoting their growth and pathogenicity. These bacteria may benefit from the inflammatory reaction of the host.

Furthermore, partial hydrolysis of the LF molecule by heat or by pepsin results in the formation of an antibacterial peptide, known as lactoferricin (LFcin), which exerts a much stronger antimicrobial effect than the intact molecule. LFcin is derived from the N-terminal region of bovine (f17–41) or human (f1–47) LF. Recently, several other antibacterial peptides have been purified from the same region. Bovine LFcin consists of 25 amino acids, whereas human LFcin is composed of 47 amino acid residues, including a region homologous to bovine LFcin. Both LFcins have been shown to display variable antimicrobial activity against a wide range of Gram-negative and Gram-positive bacteria, fungi, molds, and protozoa. There is direct evidence for the generation of LFcin in human stomach after ingestion of bovine LF. LFcins are particularly bactericidal against enteropathogenic bacteria. Bovine LFcin has been found to be active against clinical isolates of enterohemorrhagic *E. coli* O157H:7 at concentrations significantly lower than those of the LF hydrolysate or LF itself. The mechanism of the action of LFcin is not known in detail but is probably similar to that of other cationic and amphipathic antibacterial peptides. The peptide binds to LPS in Gram-negative bacteria and to teichoic acid in Gram-positive bacteria through electrostatic interactions. In binding to the cytoplasmic membrane, LFcin kills susceptible microorganisms by causing depolarization and increase in permeability of the cell membrane, leading to disruption of the general energy metabolism and inhibition of macromolecular biosynthesis of microbial cell.

Also, protease-like antimicrobial activities toward some bacterial virulence factors have been found for LF. For example, human LF has been shown to reduce the invasiveness of an enteropathogenic *E. coli* strain by blocking proteins that contribute to adherence and cause hemolysis. Recently, bovine LF and LFcin have been shown under *in vitro* conditions to induce apoptosis, programmed cell death, in *Listeria monocytogenes*-infected THP-1 cells and in Caco-2 epithelial cells.

Experimental studies have shown that large amounts of orally administered bovine LF can, probably after cleavage of LF to LFcin, significantly reduce the counts of *H. pylori* colonizing the stomach. The glycans present in LF may bind to the bacterial adhesins, thus interfering with the attachment of this bacterium to the epithelial cells. LF and LFcin inhibit the growth of fungi and protozoa but the mechanism of action is not yet fully known. Bovine apo-LF and LFcin directly bind to *Candida* cells and are highly effective in disrupting the cell membrane. LF has been demonstrated to inhibit *in vitro* the multiplication of a wide spectrum of RNA and DNA viruses, such as human cytomegalovirus, human immunodeficiency virus, herpes simplex virus 1 and 2, human hepatitis C virus, and human poliovirus type 1, and also some naked viruses, for example, rotavirus. LF prevents the binding of several viruses to host cells by interaction with cell surface glycosaminoglycans and low-density lipoprotein receptors, which act as binding sites for some enveloped viruses. The antiviral activity does not involve iron binding. Apo-LF has been shown to be less effective than holo-LF and bovine LF to be more active against viruses than human LF.

There is increasing evidence suggesting that innate LF is actively involved in the prevention of certain microbial infections *in vivo*. Also, orally administered bovine LF may be beneficial in the prevention and treatment of various microbial infections in humans and farm animals. Many microbes isolated from mastitic milk are sensitive to bovine LF or bovine LFcin, whereas many pathogenic strains of *E. coli* and *Staphylococcus aureus* show resistance or can develop resistance to LF. However, bovine LF has a synergistic effect with penicillin G against several mastitic strains of *S. aureus*. Results of recent studies suggest that bovine LF added to penicillin G may offer an effective combination for the treatment of chronic infections caused by *S. aureus* strains showing high resistance to β-lactam antibiotics.

In newborn calves and piglets, LF-supplemented feeds have been proven to be beneficial in lowering the incidence of scouring. Feeding of bovine LF or LFcin to pathogen-free mice has been demonstrated to be effective in suppressing the growth of various intestinal bacteria, for example, clostridia, and bacterial translocation of *E. coli* from the intestine into other organs. Also, LF has been shown to protect mice against a lethal dose of *E. coli* in experimental infection. There is some evidence about the contribution of ingested LF against microbial infections in humans but further substantiation in clinical studies is required. Bottle-feeding of human infants with LF-supplemented infant formulae has been shown to reduce the number of coliform bacteria and simultaneously to increase the number of bifidobacteria in the feces. Promising preliminary results have been reported about the topical application of LF in the treatment of fungal diseases, such as tinea pedis and mucosal candidiasis. In human studies, the favorable effect of yogurt supplemented with bovine LF on rotavirus gastroenteritis and a similar effect of LF-containing tablets on chronic hepatitis C, rotaviral gastroenteritis, and *H. pylori* gastric infection have been reported. In dogs and cats, the therapeutic effect of LF-containing pet food on dermatitis has been demonstrated.

Modulation of the Immune System and Inflammatory Response

LF has the ability to bind to the surface of different immune cells, and receptors for LF have been found in several other cell types. It is likely that orally administered LF or peptides derived therefrom promote both local and systemic effects. Both stimulatory and inhibitory effects of LF on lymphocyte proliferation have been described. LF has been reported to induce *in vitro* maturation of T and B lymphocytes, to increase the activity of natural killer (NK) cells, and to enhance the phagocytic activity of neutrophils.

Orally administered bovine LF ($50\,\mathrm{mg\,day^{-1}}$) increased significantly the proportion of neutrophilic precursors in the peripheral blood of healthy human volunteers. Also, the same dosage reduced the spontaneous production of interleukin (IL)-6 and tumor necrosis factor (TNF)-α by cultured peripheral blood mononuclear cells and enhanced chemotactic reactions of leukocytes. Furthermore, oral application of LF has been reported to increase leukocyte turnover and phagocytic activity and to enhance polymorphonuclear leukocyte (PMN) adherence to the endothelium in healthy humans. Recently, human recombinant LF has been demonstrated to induce the maturation of dendritic cells from human monocytes *in vitro*, suggesting that a key immunomodulative function of LF may be to link the innate immune response to an adaptive one by promoting dendritic cell maturation.

In mice, bovine LF has been shown to induce both the mucosal and systemic immune responses. Cell culture studies have demonstrated that LF influences the production of various cytokines that regulate the immune and inflammatory responses of the body. LF can suppress *in vitro* the release of pro-inflammatory cytokines IL-1, IL-6, and TNF from monocytes in response to activation by LPS. Furthermore, LF and LFcin stimulate the release of chemotactic cytokine IL-8 from human PMNs. It is postulated that LF can control the cytokine-induced pro-inflammatory cascade during the development of a systemic inflammatory response.

LF seems to regulate the inflammatory response by various mechanisms, which are still only partly known. In inflammatory sites, activated neutrophils release LF from secondary granules. The LF augments chemotactic activity of neutrophils and thus favors the rapid recruitment of PMN from blood to the inflammatory sites. The released LF binds to specific receptors on monocytes and capillary endothelial cells and inhibits priming reactions and the onset of production of pro-inflammatory cytokines IL-1β, IL-6, and TNF-α, and stimulates the production of anti-inflammatory cytokines IL-4 and IL-10. LF also suppresses the progressive inflammatory cascade caused by bacterial endotoxin by binding bacterial LPS and preventing its interaction with leukocytes. LF also reduces the oxidative damage to host tissues due to the neutrophil oxidative burst reaction during inflammatory processes by effectively scavenging free iron from the immediate vicinity. In particular, LF seems to prevent peroxidation of cell membrane lipids. Furthermore, LF has been shown to inhibit the classical pathway of complement reaction. Experimental studies have demonstrated that feeding LF can protect against endotoxin lethal shock in germ-free piglets.

LF has been shown to be transported into the cell nucleus where it can bind DNA, suggesting that LF may regulate the phenotypic traits of the host. Recent studies suggest that LF and LF-derived peptides participate in the defense against the development and progression of tumors. Bovine LFcin is reported to be cytotoxic against a variety of human and rodent cancer cells *in vitro*. Human LF has been shown to suppress the growth of fibrosarcoma cells and to inhibit experimental metastasis of melanoma cells in mice. Bovine LF has been reported to reduce the development of neoplastic cells in the esophagus, colon, and lungs in rats treated with carcinogens. Bovine LF also had a synergistic effect in the prevention of chemically induced genotoxicity and development of carcinomas in hamsters. So far, relatively little is known about the mechanisms by which LF exerts its anticancer effect. Bovine LFcin is a potent inducer of apoptosis in several different human leukemia and carcinoma cell lines *in vitro*. Results from animal model studies suggest that both orally administered bovine LF and intraperitoneally administered bovine LF participate in the regulation of angiogenesis, inhibiting the growth of new capillaries essential for the progression and metastasis of solid tumors. The effect may be mediated by blocking the endothelial function and inducing the production of angiogenesis-inhibiting cytokines INF-γ and IL-18. LF has also been demonstrated to activate NK cells, PMNs, and lymphokine-activated killer cells. Thus, the antitumor activity may be mediated by the activating effect on cell-mediated cytotoxic immune reactions against neoplasia. A phase III clinical trial is in progress with the purpose of developing recombinant human LF-based pharmaceuticals for the treatment of non-small cell lung cancer.

Growth Factor-Like Effects

LF has been suggested to exert mitogenic and trophic effects in the gastrointestinal tract. It has been suggested that LF stimulates protein synthesis in endothelial cells, measured as thymidine incorporation into DNA. The potential regulatory role of LF in the intestinal maturation of the infant warrants, however, further research as the observed effects may have been of nonspecific character.

Both bovine LF and human LF have been reported to have an anabolic effect on bone tissue *in vivo* in a mouse model when injected locally into adult mice. In *in vitro* studies, bovine LF has been shown to stimulate osteoblast proliferation and differentiation, inhibit apoptosis of osteoblasts, stimulate chondrocyte proliferation, and inhibit development of osteoclasts. Thus, LF may also have a regulatory role in bone growth.

Nutritional Significance

LF is one of the major whey proteins in human milk and is also relatively abundant in bovine colostrum. From a nutritional point of view, LF is of interest as a dietary protein source of amino acids and for the bioavailability of iron.

LF has an amino acid composition that indicates a high nutritional value, but nutrition may not be the major role of LF, as it is known to be quite resistant to digestive enzymes. Although the amount of intact LF found in feces constitutes only about 10% of the amount ingested, it is thought to be supportive of a physiological role of LF in the gut of the infant. LF may exert its biological functions as undigested and partially digested forms in the gastrointestinal tract.

In toxicity studies using rat models with orally administered bovine LF and human LF as well as with purified recombinant human apo-LF and holo-LF, no adverse findings have been observed at a dose level of 1.8 g per day per kg of body weight for 13 weeks or with a diet containing 0.2% of bovine LF for 40 weeks.

The role of LF in the absorption of iron from milk is still controversial. The high bioavailability of iron from human milk and the discovery of LF receptors on intestinal brush border membranes of many species provide a basis for the assumption that LF promotes iron absorption in breast-fed infants. However, animal model studies with human LF and bovine LF and clinical studies on infants fed formula supplemented with bovine LF have failed to show any significant improvement in iron absorption. It has been suggested that the absorption capacity is affected by the highly species-specific receptors of LF. They may have an impact on the uptake of iron by endocytosis. Recently, orally administered bovine LF has been shown to increase hemoglobin and total iron concentration in the blood serum of pregnant women and to prevent the lowering of hemoglobin level in female long-distance runners during the training period without any side effects that are common with ferrous sulfate. In another study on young US women, iron was equally well absorbed from purified recombinant human LF as from ferrous sulfate. Thus, oral LF can influence iron homeostasis.

Application and Safety Aspects

Since the 1970s, several gel filtration and chromatographic methods have been developed for the isolation and purification of LF from colostral or cheese whey. Large-scale production techniques, based on cation-exchange resins, followed by gel filtration or ultrafiltration (UF) have been employed to isolate both LF and lactoperoxidase (LP) from cheese whey. Other methods developed for the isolation of LF include microporous membranes containing immobilized sulfonic acid, high-performance liquid chromatography (HPLC) coupled with cation exchanger, metal chelate interaction chromatography, monoclonal antibody immunoaffinity, and affinity chromatography using immobilized ferritin, heparin, DNA, or textile dyes.

The industrial large-scale production of bovine LF started in Belgium in 1985, but commercial exploitation of bovine LF has developed relatively slowly until recent years. Asian companies have utilized bovine LF already for more than 20 years as an ingredient of commercial foodstuffs, most of them being milk-based products, for example, infant formulae, yogurt, skim milk, and milk-type drinks. Also, bovine LF-containing food supplemental tablets, pet food, oral care products (mouthwash, gel, toothpaste, and chewing gum), and cosmetics have been launched on the markets in many countries. The US Food and Drug Administration (FDA) has approved the use of bovine LF (at not more than 2% by weight) as a spray to reduce microbial contamination on the surface of raw beef carcasses. The FDA has granted bovine LF a 'generally recognized as safe' (GRAS, GRN 67) status and this determination accounts for uses at defined levels in beef carcasses, subprimals, and finished cuts. Bovine LF and recombinant human LF are now commercially available for applications in preservatives, nutraceuticals, and pharmaceutical products. Toxicological studies in rats for 13 weeks with a daily oral administration of bovine LF and of recombinant human LF produced in transgenic cows have revealed that the level with no observed adverse effect was at least 2 g per kg of body weight per day.

Immunoglobulins

P Marnila and H Korhonen, MTT, Agrifood Research Finland, Biotechnology and Food Research, Jokioinen, Finland

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Immunoglobulins (Igs), also called antibodies, are proteins present in the milk and colostrum of all lactating species. The biological function of milk Igs is to give the offspring immunological protection against microbial pathogens and toxins and to protect the mammary gland against infections. To this end, the major mechanisms provided by milk and colostral Igs are augmenting phagocytosis and cell-mediated cytotoxicity reactions by leukocytes, agglutination of bacteria, neutralization of microbes and toxins, and activation of the complement system in milk. Igs are divided into classes having different physicochemical properties, structures, and biological activities. The major classes in bovine and human milk are IgA, IgG, and IgM.

The concentration of different Ig classes in milk and colostrum varies considerably according to species, breed, age, stage of lactation, and health status and is often different from that in blood (**Table 1**). For example, in human milk and colostrum, the IgA class comprises about 90% and in blood 15–20% of total Ig whereas in cow the IgG class is dominant in milk, colostrum, and blood (about 60–70, 80–90, and 90% of total Ig, respectively).

The transport of Igs from serum to milk is a selective process, favoring in most species homologous IgG. Specific receptors are involved in the process, enabling the characteristic concentration of Ig isotypes in milk and colostrum. In many species, the absorption of Igs from intestine is also selective and receptor mediated. However, in ruminants, for example, in the cow, the absorption of Igs takes place nonselectively during the first 12–36 h after birth of the offspring. Ruminant neonates are born virtually without Igs and the colostral Igs are essential for survival. Thus, in ruminants the colostrum contains remarkably higher amounts of Igs than the mature milk. Mature bovine milk contains only 1–2% of the Igs present in colostrum.

The Ig fraction of milk is used commercially as feed supplements and replacers of colostrum, mainly for neonatal calves and pigs, in order to prevent gastrointestinal infections. Increasing interest has recently been focused on the development of colostrum-based Ig products that contain specific antibodies for the prevention or treatment of infections in humans.

Structure and Functions of Immunoglobulins

Structure of Immunoglobulin Classes

The Ig classes in milk and colostrum of the cow are IgG, IgM, and IgA and of human, IgG, IgM, IgA, and IgD, respectively. The basic structure of all Igs is similar. They are composed of two identical light chains (molecular weight of each around 23 kDa) and two identical heavy chains, each of 53 kDa (**Table 2**). There are two types of light chains (κ and λ), differing in chain structure but having homologous amino acid sequences. The light chains contain a constant region (C_L) and variable region (V_L). The V_L region determines the immunological specificity. Light chains are attached to the heavy chains by a disulfide bond and the two heavy chains are held together by disulfide bonds near a hinge region. The hinge region gives the molecule flexibility needed in antibody–antigen interactions. The two identical antigen-binding sites needed in these interactions are formed by the N-terminal part of one heavy chain and the variable region of one light chain. The complete Ig, or ‘antibody’, molecule has a molecular mass that varies around 160 kDa. The bovine IgG molecule occurs predominantly in two subclasses: IgG_1 and IgG_2 (**Figure 1**(**a**)).

Monomeric IgM and IgA have a similar basic structure to IgG except for the addition of a C-terminal octapeptide to the heavy chains. IgA occurs as a monomer or dimer, the latter comprising two IgA molecules joined together by a J-chain and a secretory component. This complex is called secretory IgA (sIgA) and has a molecular weight of about 380 kDa. IgM consists of five subunits, similar to monomeric IgA, which are linked together in a circular mode by disulfide bonds and a J-chain; the molecular weight of pentameric IgM is approximately 900 kDa (**Figure 1**(**b**)).

Human sIgA consists of two identical monomers joined together by a 15 kDa J-chain and connected to secretory component, an 83 kDa epithelial glycoprotein. In human serum, the principal form is a monomer. Both human serum and milk IgM have a pentameric structure but, unlike the serum IgM, some of milk IgM is combined with the secretory component.

In humans the high diversity in structures of variable chains comprising the antigen-binding sites of Igs is

Table 1 Concentration of immunoglobulins in serum and mammary secretions of some species

		Concentration ($g\ l^{-1}$)		
Species	*Ig class*	*Serum*	*Colostrum*	*Milk*
Cow	IgG total	25.0	60 (20–200)	0.47 (0.15–0.8)

generated via rearrangements of a large number of divergent Ig gene segments which produce the genes encoding the variable regions of light and heavy chains, respectively. In contrast, cow and sheep having germline Ig gene pools of limited diversity employ alternative post-arrangement mechanisms for antibody diversification. Cow and sheep generate Ig diversity by non-antigen-dependent somatic hypermutations. The cow also has an exceptionally long complementary determining region 3 of the heavy-chain regions of IgM to compensate the lesser diversity of germline variable heavy-chain genes. However, the understanding of the processes that form bovine Ig repertoire is still incomplete.

Functions of Immunoglobulins

All Ig classes bind antigens and, in addition, exhibit one or more effector functions. While one part of an antibody (Fab) binds to antigen, other parts (mostly the Fc region) interact with other elements. In effect, the antibodies function as flexible adaptors linking various parts of the cellular and humoral immune system.

The prevention of the adhesion of microbes to surfaces like intestinal epithelial linings may be the most important mechanism of colostral and milk antibodies in protecting the host. The attachment of a pathogenic organism to the epithelial lining is the most critical step in the establishment of infection. The ability of Igs to agglutinate bacteria reduces the capability of bacteria to adhere to epithelial surfaces or to tooth enamel. Normal colostrum and milk are known to contain agglutinating Igs for a large number of pathogenic and non-pathogenic microorganisms. Igs can inhibit bacterial metabolism and reduce the production of harmful components, such as toxins, by blocking enzymes and receptors. This blocking may also reduce the pathogen's ability to produce structures needed in adherence to epithelia. Milk Igs, also partially degraded ones, can benefit the offspring by binding and inactivating toxins produced by pathogenic microbes and by neutralizing viruses. In clinical studies, colostral and milk Igs have been demonstrated to be able to protect the offspring against a variety of viral infections. Igs also augment the recognition and phagocytosis of bacteria by leukocytes (opsonization).

Leukocytes are an integral part of normal milk and colostrum and are of vital importance in defending the mammary gland against pathogens. Recent studies have shown that colostral leukocytes enhance the calf's defense against infection. The effector functions include also binding of Igs to leukocytes or to host tissues. In blood and tissues, the most important function of Igs is possibly the activation of complement-mediated bacteriolytic reactions, but the significance of this mechanism in milk remains obscure. Bovine and human colostra contain an active complement system participating in the immune defense of the udder (**Table 2**).

IgM antibodies, although produced in smaller amounts than IgG, are considerably more efficient than IgG with regard to most of the above activities, including complement fixation, opsonization, and agglutination of bacteria. IgM can prevent the migration of bacteria by binding to the flagellas used in movement. Bovine IgA, in contrast, does not fix complement or opsonize bacteria, but agglutinates antigens and neutralizes viruses and bacterial toxins. The main function of sIgA is to protect the mucosal barriers by binding viruses and bacteria, thus preventing them from attaching to mucosal epithelial cells. Mucosal IgA also contributes to the antigen presenting. The milk Igs have also been found to act synergistically with non-specific antimicrobial components of milk, such as lactoferrin and lysozyme, as well as the lactoperoxidase–thiocyanate–hydrogen peroxide system.

Concentrations of Immunoglobulins in Milk and Colostrum

Bovine colostrum contains substantially higher concentrations of Igs than mature milk. In bovine colostrum, Igs make up to 70–80% of the total protein content, whereas in mature milk, the Igs account for only 1–2% of the protein. The main change from colostrum to normal milk occurs in the first few days after parturition and continues at a reduced rate for approximately 5–7 days (see Colostrum). **Table 1** provides data on the concentrations of Igs in serum, colostrum, and milk of selected mammal species.

In the cow, the major Ig class is IgG. Its concentration at first milking *post-partum* ranges from 15 to 180 g l^{-1}, the mean being approximately 60 g l^{-1}. Thereafter, the IgG concentration falls sharply to about 1 g l^{-1} at 12th–14th milking. The concentration of the various bovine Igs in serum and lacteal secretions varies according to the breed, age, health status, and stage of lactation of the animal. The major IgG subclass of colostrum and milk is IgG_1, which accounts for about 50–80% of total Igs. The average concentrations of IgG_2, IgM, and IgA are relatively small compared to IgG_1 (see **Table 1**). Bovine colostrum contains about 1–6 g l^{-1} of IgA and mature milk 0.05–0.1 g l^{-1}. The concentration of IgM in bovine colostrum varies from 3 to 5 g l^{-1} and from 0.04 to 0.1 g l^{-1} in mature milk.

In serum, both IgG subclasses are present at about equal concentrations (IgG_1 11.2 g l^{-1}, IgG_2 9.2 g l^{-1}), while IgA and IgM occur at concentrations of about 0.4 and 3.1 g l^{-1}, respectively (see **Table 1**).

Cows in their first lactation produce significantly less (total yield about half or less) IgG than cows in later lactations due to both a lower IgG concentration and a smaller volume of colostrum.

In Indian buffalo (*Bos bubalus bubalis*), the concentrations of Igs in colostrum and milk are of the same order of magnitude as those of its close relative, the cow (*Bos taurus*). The IgG concentration in first colostrum and in transient milk has been reported to be about 50 and 150% higher, respectively, than in the cow. In buffalo, IgG_1 is the dominant Ig subclass and the content of IgG_2, IgA_1, IgA_2, and IgM is substantially smaller than that of IgG_1. IgG_1 and IgG_2 of buffalos and cows have very similar chemical and biological properties and are antigenically closely related.

In colostrum of the dromedary camel (*Camelus dromedarius*), the major Ig class is IgG but, unlike in bovines, IgG includes three subclasses IgG_1, IgG_2, and $IgG_{3.}$ IgA and IgM are present only in minor amounts. Camel Ig classes are antigenically very different from the bovine Igs and have several structural characteristics different from bovine Igs. In horse and pig colostrum, IgG is a major and IgA a minor component, but after transition of colostrum to mature milk, IgA becomes the major component (see **Table 1**). Also, in domestic cat, dog, and rat colostrum, IgG is the major class but after the transfer of Ig has ceased, IgA becomes dominant in the milk of these species. In human colostrum and mature milk, IgA is the dominant Ig class, comprising over 90% of all Igs, whereas IgG is the most abundant Ig in blood. The main form of human milk IgA is dimeric secretory IgA (sIgA), comprising over 90% of total IgA.

Transfer of Immunoglobulins

Main Pathways

Igs represent the mother's specific immune response to the antigens encountered in the past. This immunological protection is transferred from the mother to the offspring either *in utero* or via colostrum or milk. In the *in utero* pathway, Igs pass from the mother's blood into the fetus across the placenta or yolk sac. In transfer via colostrum or milk, the Igs, which are derived from blood or are synthesized in the mammary gland, are transported through mammary secretory cells into the colostrum or milk. The ingested Igs are transferred from the gut across intestinal cells into the blood of the offspring.

The eutherian mammals can be divided roughly into three groups according to their Ig transfer pathways. Species like human and rabbit have only placental transfer. Human infants are born with serum concentrations of IgG which equal those of their mothers. Most farm animals (pig, horse, cow, sheep, and goat) have no *in utero* transfer of Igs but an extensive lacteal transport. The newborns of these species are virtually agammaglobulinemic. Species like dog, mouse, and rat use both pathways. In marsupials, there is little evidence that maternal antibody transfer takes place across the placental barrier but several reports suggest that in the marsupial pouch, the young depends on passive immune protection from mother's milk for a long period after birth.

Transport Mechanisms

Transfer to milk

The epithelium sheet lining the mammary gland separates the milk space from the interstitial space. During the dry period, the epithelium is permeable to fairly large molecules, such as Igs, whereas during lactation (except during mastitis) this lining is impermeable to small molecules. Thus, a vast majority of IgG in bovine colostrum and milk is derived from blood plasma. The transport by cellular uptake involves binding of IgGs to Fcγ receptors in the basal membranes of the udder. The appearance and presence of specific high-affinity Fcγ receptors for IgG_1 and lower-affinity receptors for IgG_1 and IgG_2 on the mammary gland acinar epithelium corresponds to the amounts of these subclasses in colostrum and milk at the time of maximal IgG transport. The Fc receptor-mediated endocytosis is followed by vesicular transport and exocytosis at the apical membrane. In contrast to IgA transport, the receptor does not remain with the IgG in the milk.

The Igs are produced by B lymphocytes. Some Igs are carried on the surface of B lymphocytes where they act as receptors and the others are free in body fluids. Contact between B lymphocytes and antigen is needed to cause the B lymphocytes to develop into antibody-forming and secreting plasma cells. The ruminant mammary gland contains plasma cells adjacent to the site of transfer of Igs. These cells produce mainly IgA but IgM and IgG are also synthesized to a small extent. The transport of IgA appears to be similar in the mammary secretory cells to that present in other secretory tissues. Secretory component is synthesized in secretory cells and moved to the basolateral membrane as a receptor where it binds dimeric IgA with a J-chain synthesized in adjacent plasma cells. The complex is transported through the secretory cell to the apical membrane where sIgA is secreted by exocytosis and a segment of the secretory component is cleaved off. IgM is secreted similarly but a small amount of IgM of blood origin also appears in milk. IgA in bovine colostrum is derived partly from intramammary synthesis and partly from the blood.

Transfer from gastrointestinal tract to blood

The passage of ingested Igs across intestinal cells of the neonate can be specific or non-specific, depending on the species, and it occurs only for a certain period after birth. The gut of the suckling calf, pig, or foal is non-selective and open to the transport of a variety of macromolecules from 12 up to 36 h after birth, corresponding to the time of the highest IgG content of colostrum. The main Ig class of bovine colostrum is IgG_1, but the passive transport of other Ig classes, although in smaller amounts, is also considered important for the calf. In species which transfer the Igs both *in utero* and via colostrum after birth (e.g., rat and mouse), the absorption of ingested Igs from the intestine is selective. The $\mathrm{Fc}\gamma$ receptors on the enterocytes of the small intestine mediate selective binding and transcytosis of IgG until the day of weaning. Also in the human infant, the colostral Igs are absorbed in small quantities for a short period of 18–24 h after birth.

Importance of Colostral and Milk Immunoglobulins to the Offspring

Protection against Microbial Infections

Bovine colostral and milk antibodies represent the cow's immune response against a variety of microorganisms present in the cow's environment and food. Thus, Igs contribute to the natural antimicrobial properties of milk. Maternal milk of farm animals is well known to protect the newborn offspring against microbial pathogens.

Receiving colostrum within 12 h after birth is essential for the survival of newborn calves and piglets. Newborn calves and piglets which do not receive colostrum show a high mortality and poor weight gain during the first weeks of life. Calves deprived of colostrum or given colostrum of poor quality promptly suffer severe long scour episodes. To protect the calf against scouring, a newborn calf should receive a minimum of 2 l of first colostrum, containing about 100–120 g Igs, to achieve a normal serum IgG level of $10\,\mathrm{g\,l^{-1}}$. Twice as high mortality rates and higher odds of pneumonia have been observed in calves with $<10\,\mathrm{g\,l^{-1}}$ serum IgG, with tripled risk of pneumonia when the dam had clinical mastitis. The colostrum from the first two milkings is most important, since the concentration of Igs decreases steeply after the first milkings (*see* **Milk**: Colostrum and **Table 1**). A variety of colostral whey- and cheese whey-based antibody preparations have been used as feed supplements or colostrum substitutes for neonatal calves and pigs in order to prevent diarrheal diseases caused, for example, by rotaviruses and enterotoxigenic *Escherichia coli* strains.

In human colostrum, sIgA is predominant, the IgG being transported via placenta. Dimeric IgA is secreted by lymphocytes associated with mammary gland epithelia and is transferred by a polymeric Ig receptor to milk. The sites of the immune protection by Igs are restricted mainly to the gastrointestinal tract because the milk Igs apparently are not absorbed in significant quantities from the infant gut. Especially IgA antibodies appear to be particularly important during the first days *post-partum*, when the infant's own mucosal IgA production is deficient. Breast feeding has been shown to reduce the risk of intestinal infections, morbidity in gastroenteritis and diarrhea, otitis media, and pneumonia in suckling neonates. Breast milk also contains a variety of non-specific defense factors, which contribute to its antimicrobial effect. Milk IgA may contribute to the prevention of food allergies by blocking antigen entry at the intestinal surface of the infant. Low levels of total and specific IgA against food allergens are proposed to correlate adversely with the risk of developing allergy to these antigens.

Digestion of Antibodies

IgG, IgM, and IgA without secretory component, when ingested by humans, are normally degraded by proteases in the stomach and intestine into small peptides and amino acids which are subsequently absorbed. Proteolytic enzymes, pepsin, trypsin, chymotrypsin, carboxypeptidase, and elastase, initially degrade the antibodies to $\mathrm{F(ab')_2}$, Fab, and Fc fragments. Proteolytic degradation abolishes their agglutinating properties and dramatically decreases their functional affinity. However, $\mathrm{F(ab')_2}$ and Fab fragments from high-affinity antibodies retain some of the neutralizing and attachment-inhibiting activity of intact antibodies. The secretory form of milk IgA is relatively resistant to proteolytic digestive enzymes in the gastrointestinal tract due to the secretory piece but can be sensitive to a group of microbial enzymes. About 20–80% of sIgA present in human colostrum passes undegraded through the gut of the human infant. In contrast, the secretory component in IgM is not covalent and does not provide resistance against enzymatic cleavage.

In addition, bovine milk Igs, which have been subjected to proteolytic conditions of the human intestine, retain at least partially their immunological activity. Bovine colostral Igs are quite resistant to gastric acids but are degraded by proteases and are rather sensitive to trypsin. However, IgG_1 is an exception since it is rather resistant to trypsin. Bovine colostrum and mastitic milk contain a compound which inhibits trypsin activity. A part of bovine colostral IgG_1 contains *O*-glycans which increase their resistance to pepsin. From 10 to 30% of orally administered bovine Igs can be recovered from the stool of human infants and adults. These recovered Igs are in the form of $\mathrm{F(ab')_2}$, Fab, and Fc fragments. The survival of IgG in the ileum can be increased by encapsulation.

Utilization of Immunoglobulins

Technological Properties of Immunoglobulins

Milk Igs affect many dairy processes. Igs inhibit or retard the activity of renneting enzymes of bacterial origin. In normal milk, this is not noticed due to the relatively low Ig concentration but, if the Ig concentration in milk is increased, for example, by adding colostrum or if the milk is mastitic, renneting may be retarded. The antimicrobial properties of Igs may adversely affect fermentation processes. A slower fermentation by dairy starters is noted in colostrum and mastitic milk, which contain increased amounts of Igs. Also, high Ig concentrations may adversely affect the tests for antibiotic based on microbial growth, causing false positive results.

Igs contribute to cream formation by agglutinating fat globules, thus accelerating the ascent of cream to the surface. This phenomenon is attributed primarily to IgM which have been termed cryoglobulins or 'cold agglutinins'. The agglutination property of Igs is, however, abolished by heat treatment (pasteurization) and by mechanical agitation.

Among dairy technological processes, the properties of Igs are affected most by the thermal treatments. In high-temperature/short-time (HTST) pasteurization (72 °C/15 s) less than 30% of the Ig activity is lost, whereas ultra high temperature (UHT) treatment (138 °C/4 s) and evaporation processing destroy most of the specific immune activity of milk due to denaturation of Igs. A rapid heat inactivation of IgG starts at temperatures higher than 65 °C, and at 81 °C, as much as 90% of the virus-neutralizing capacity of Igs is lost in less than 2 min. On the other hand, heating high-quality colostrum at 60 °C for at least 120 min has no effect on mean IgG concentration or titer of neutralizing antibodies against bovine viral diarrhea virus type 1. A heat treatment of 60 °C for 30 min has been demonstrated to destroy viable *Mycobacterium bovis, Listeria monocytogenes, Escherichia coli* O157:H7, and *Salmonella enteritidis* added to colostrum. Bovine IgG added to UHT-treated milk has been shown to retain its specific immune activity for several months. Also, Ig molecules seem to retain their specific activity well in milk powder, irrespective of the storage temperature.

Commercial Utilization of Immunoglobulins

Over the last 20 years, considerable progress has been made in isolation and enrichment techniques for Igs from bovine colostrum and cheese whey. Separation technologies, such as membrane filtration and chromatography, have been used alone or in combination. Using these methods, the recovery of Igs has varied from 40 to 70% of the level present in the starting material. Specific chromatographic techniques, such as immobilized metal chelate chromatography, immunoaffinity chromatography, and cation exchange chromatography, have been applied to improve the yield and purity of Ig preparations.

Commercial whey or colostral antibody preparations have been used for a long time as feed supplements or substitutes for farm animals in order to prevent gastrointestinal infections. They are used mainly for neonatal calves and pigs and have proven effective in preventing diarrheal diseases caused by, for example, rotaviruses and enterotoxigenic *E. coli* strains.

If the animal is immunized by a vaccination protocol against a certain pathogen (or antigenic structure derived from it) the specific antibody titer of colostrum or milk may increase up to 100–400 times of that in normal milk or colostrum. In field experiments, active immunization of the dam has improved the protection of the offspring against the pathogens used in the vaccine. Biotechnology industries have shown increasing interest in possibilities of raising specific antibodies in bovine colostrum by hyperimmunizing cows with vaccines made of human pathogenic microbes or their specific structures like toxins or other virulence factors. Numerous clinical studies have been carried in humans with the purpose of demonstrating the efficacy of hyperimmune colostral preparations in the prevention or treatment of infectious diseases. Promising results have been reported for the prevention of infections and also in treatment of diseases when infection is maintained through recurrent reattachment and reinfection inside the oral cavity or gastrointestinal tract. Encouraging results have also been obtained in clinical studies where toxins or inflammatory compounds are involved and have been neutralized by specific Igs (see **Table 3**).

A few immune milk preparations, for example, against rotavirus, are already on the market. The main limitation of the clinical use of bovine milk antibodies for humans is that they originate from a foreign species and thus can be used only orally against gastrointestinal pathogens. To overcome this limitation, trans-chromosomic cows have been cloned for producing human polyclonal Igs. However, several challenges, for example, expression of bovine antibody, remain to be overcome before large-scale production of human Igs for therapeutic purposes can begin. Bovine colostral or milk products from non-immunized cows that exploit IgG content have become expensive niche products worldwide on highly competitive markets for natural 'wellness' products.

Currently, the US Food and Drug Administration (FDA) has accepted the safety of hyperimmune milks on the basis of clinical studies which show no adverse health effects from these products.

Table 3 Examples of recent clinical human studies on the efficacy of bovine whey or colostral preparations

Microorganism used in immunization	*Target disease*	*Treatment regimen*	*Efficacy*	*References*
Five or one strains of *Escherichia coli*	Diarrhea	Once per day orally 0.5 g of IgG per kg of body weight, follow-up period for 6 months	Lower incidence of diarrhea and shorter duration of diarrhea episodes	Tawfeek *et al*. (2003)
No immunization	Upper respiratory tract infections	60 g of colostral protein daily for 8 weeks	Reduced significantly incidence of self-estimated symptoms of respiratory infections but no difference in duration	Brinkworth and Buckley (2003)
No immunization	Mild hypercholesterolemia	Orally 5 g of blood derived IgG daily for 3 or 6 weeks	Both total cholesterol and LDL levels decreased from baselines	Earnest *et al*. (2005)
No immunization	HIV-associated diarrhea	Orally for 4 weeks	Reduced diarrhea and increase in body weight, decrease in fatigue	Florén *et al*. (2006)
Clostridium difficile toxin and *C. difficile* whole cells	*C. difficile* diarrhea	Orally for 2 weeks as supportive treatment after antibiotic treatment	*C. difficile* toxins eradicated from 15 of 16 patients and no relapses in any patient during 11-month follow-up period	Van Dissel *et al*. (2005)
C. difficile whole cells	*C. difficile* diarrhea	Orally 1.6 g of Ig in 200 ml twice per day for 2 weeks	At day 14 after starting 89% of patients had responded positively to the treatment	Mattila *et al*. (2008)

This article is a revision of the previous edition article by D. Tomé, Volume 3, pp 1990–1994, © 2002, Elsevier Ltd.

Introduction

Dietary protein quality is related to the ability of a dietary protein source to achieve defined metabolic actions in relation to optimal health. Protein provides nitrogen and amino acids, and protein quality is usually related to the ability of protein to satisfy nitrogen and essential amino acid requirements for tissue growth, maintenance, pregnancy, lactation, and energy homeostasis. The corresponding dietary protein properties integrate amino acid composition, protein digestibility, amino acid bioavailability, and subsequent amino acid and protein metabolism. Milk represents a major dietary source for the young and adult humans, and cow milk proteins are considered to have a high nutritional quality. Milk protein is a complex mixture of different protein components present in different proportions in different mammalian species. Protein concentration is higher in bovine milk than in human milk (30–34 and 9–14 $\mathrm{g\,l^{-1}}$, respectively) (**Table 1**). Bovine milk nitrogen is constituted by a major casein fraction (78% of milk nitrogen), a whey protein fraction (17% of milk nitrogen), and a small non-protein fraction (5% of milk nitrogen). Whey protein is a mixture of soluble proteins with wide-ranging chemical, physical, and functional properties.

Milk Protein, Amino Acid Digestibility, and Nitrogen Retention

The first important aspect of protein quality is related to amino acid bioavailability, that is, the extent to which dietary protein is digested and absorbed in the gastrointestinal tract in the form of amino acids available for metabolic processes. Digestibility represents the proportion of dietary nitrogen and amino acid that is absorbed. It is usually determined from the difference between nitrogen intake and nitrogen losses. The two main difficulties with the measurement of true nitrogen digestibility is the presence of endogenous nitrogen secretion and that colon metabolism is not taken into account in quantifying the fecal digestibility. The presence of endogenous nitrogen secretions implies the need for discriminating between exogenous nitrogen (food) and endogenous nitrogen (secretions, desquamations, etc.). After their transit through the distal ileum, colonic bacteria metabolize most of the unabsorbed amino acids. As a consequence, the ileal rather than the fecal digestibility must be considered as a critical biological parameter for amino acid digestibility and availability.

Different methods have been proposed to determine ileal flux and both endogenous and exogenous amino acid absorption and losses. The determination of endogenous secretions in fecal or ileal nitrogen fractions may be achieved using a protein-free diet. Techniques based on stable isotopes allowed discriminating between dietary and endogenous nitrogen. It is possible to label with stable isotopes (^{15}N or ^{13}C) animal or vegetable protein intended for human consumption. These methods present the direct assessment advantage of true digestibility calculated from $[\mathrm{N_{ingested}} - (\mathrm{N_{feces}} - \mathrm{N_{fecal\ endogenous}})]/\mathrm{N_{ingested}}$. Analysis of milk protein digestion indicates a high true ileal digestibility of 95% in humans. For comparison, the true ileal digestibility for soy and rice protein is 91 and 88%, respectively (**Table 2**). Since metabolic availability of essential amino acids is a limiting step in protein quality, it is important to establish that nitrogen digestibility is a reliable reflection of the digestibility of amino acids, particularly the essential amino acids. The true ileal digestibility of some individual essential amino acids measured in humans for milk and soy protein indicated digestibilities in the range of 93% (Thr) to 96% (Val) for milk protein and 89% (Thr) to 95% (Phe, Lys) for soy protein (**Table 3**).

Another important marker of protein quality is related to nitrogen retention, that is, the extent to which absorbed dietary protein nitrogen is retained in tissues. The traditional approach for the determination of net nitrogen retention is derived from nitrogen balance measured in subjects after adaptation to different protein levels over several days. Diets containing poor-quality protein are associated with an increase in nitrogen losses owing to the inefficient utilization of indispensable amino acids. The nitrogen balance indicates the amount of nitrogen that is retained in the body according to the following formula:

$$\begin{aligned}\text{Nitrogen balance} = {} & \text{Ingested nitrogen} \\ & - \text{Excreted nitrogen (urine and feces)}\end{aligned}$$

The net protein utilization (NPU) allows evaluation of the N ingested proportion that is retained in the body: $NPU = N_{retained}/N_{ingested}$. The biological value (BV) is the percentage of absorbed nitrogen retained: $BV = N_{retained}/N_{absorbed}$.

Similar to the digestibility, these values represent true or apparent nitrogen retention depending on whether the endogenous secretion is taken into account or not. Endogenous losses may be estimated either from a protein-free diet or by using stable isotope tracer methodologies. Thus, it follows that

$$NPU = \frac{\{N_{ingested} - [(N_{fecal} - N_{endogenous}) + (N_{urinary} - N_{endogenous\ urinary})]\}}{N_{ingested}}$$

where $NPU = BV \times$ digestibility.

Assessing the post-prandial utilization of dietary proteins is also a good marker of dietary proteins' nutritional quality, since it is known to influence protein synthesis and proteolysis. Different methods based on nitrogen digestibility and short-term nitrogen retention have been proposed for the determination of short-term utilization of dietary proteins. The net post-prandial protein utilization (NPPU) is calculated from true ileal digestibility and deamination of dietary protein measured during the 8 h following the ingestion of a standard meal by healthy human subjects. NPPU values of 78–80 and 70–72% were determined for milk protein and soy protein, respectively (**Table 4**). Taken together, these different data show that milk protein nitrogen and amino acid show high digestibility and retention in humans.

Milk Protein, Nitrogen, and Indispensable Amino Acid Requirements and the Protein Digestibility Corrected Amino Acids Score (PDCAAS)

The assessment of protein quality is related to the amino acid composition in conjunction with nitrogen and essential amino acid requirements. This approach needs to precisely quantify these requirements and to further

Table 5 Nutritional classification of amino acids

Strictly essential amino acids	Lysine, threonine
Other essential amino acids	Histidine, isoleucine, leucine, methionine, phenylalanine, tryptophan, valine
Conditionally essential amino acids (indispensable under specific pathological or physiological conditions)	Cysteine, tyrosine, taurine, glycine, arginine, glutamine, proline
Non-essential amino acids	Aspartic acid, asparagine, glutamic acid, alanine, serine

evaluate the ability of each dietary protein to satisfy these requirements under specific physiological and dietary conditions.

Protein requirement has been determined from nitrogen balance (difference between nitrogen intake and nitrogen losses) at a value of 0.83 g kg^{-1} d^{-1} in adults. Nine amino acids are considered essential for humans, including lysine, threonine, valine, isoleucine, leucine, methionine, phenylalanine, tryptophan, and histidine (**Table 5**). Amino acid requirements are summarized in **Table 6**. Lysine requirement has received most attention, given its nutritional importance as the limiting amino acid in cereals. Threonine has been suggested to be the second rate-limiting amino acid in some dietary protein sources. Sulfur-containing amino acids, methionine and cysteine, are low in vegetables and abundant in cereals and animal protein. Tryptophan content in proteins is generally lower than that of many other amino acids. Its content is low in cereals, especially corn, and in some varieties it is the nutritionally limiting amino acid. Leucine is the most abundant amino acid in tissue and food proteins. Its non-protein functions remain unclear but it has been suggested that leucine is implicated in the control of protein synthesis and satiety. Compared to plant proteins, animal proteins are rich in essential amino acids. Milk protein presents a well-balanced amino acid composition and cow's milk is considered an excellent source of high-quality proteins (**Table 7**).

PDCAAS was introduced by the Food and Agriculture Organization of the World Health Organization (FAO/WHO) in 1991 and is the current internationally approved method for protein quality assessment. PDCAAS is based on the combination of an age-related amino acid reference pattern that represents human requirements and estimates of the digestibility of the protein. The amount of potentially limiting amino acids in the test protein is compared with their respective contents in the appropriate reference pattern, identifying the single most limiting amino acid that determines the amino acid score. The current consensus is that meeting the minimum requirements for lysine, methionine, and tryptophan, the most limiting amino acids in poor-quality proteins, determines the amino acid score and will lead to a plateau of nitrogen retention. At the plateau of nitrogen balance, any further increase in plasma amino acids would stimulate increased oxidation and elimination of the excess amino acids, implying that protein quality that exceeds requirements does not lead to any nutritional gain. This score is assumed to predict BV, or the anticipated ability of the absorbed test protein to fulfill human amino acid requirements. The score is then corrected for digestibility giving the PDCAAS value, which is assumed to predict NPU. Milk protein and, in general, animal proteins have a PDCAAS value >100% (**Table 2**). For adults, there are no limiting amino acids in milk proteins. Therefore they are often defined as reference proteins in this test.

Milk Protein and the Rate of Amino Acid Delivery

Digestion rate of dietary protein affects post-prandial protein metabolism and nitrogen retention. Indeed, the magnitude and the duration of changes in amino acid availability determine the anabolic effects of protein ingestion. Amino acids and insulin are two main factors regulating amino acid and protein metabolism after a meal. Typical meal ingestion leads to hyperaminoacidemia and hyperinsulinemia which are involved in the control of protein turnover in splanchnic and peripheral areas. Post-prandial hyperaminoacidemia is more important in splanchnic tissues because of adjoining splanchnic tissues position after absorption.

Nb, number. Adapted from FAO/WHO/UNU (2007) Protein and amino acid requirements in human nutrition: Report of a joint WHO/FAO/UNU expert consultation. *World Health Organ Technical Report Series #935*. Geneva, Switzerland: FAO; WHO; UNU.

It has been demonstrated that casein and whey proteins are digested differently in the intestinal lumen, since whey proteins are rapidly emptied from the stomach, mainly in an intact form, whereas caseins are slowly emptied as degraded products. Unlike casein, whey protein ingestion mediates large increases in post-meal peripheral aminoacidemia. The differences in amino acid delivery kinetics are responsible for different effects on whole-body protein metabolism in humans ingesting either casein or whey protein. Casein is considered a slow-digested protein and whey protein a fast-digested protein. Usually, total milk proteins are defined as protein mixtures which are slowly absorbed. Heat treatment or fermentation of milk can reduce the digestive transit of casein. Soy protein that has digestion rate similar to whey protein is defined as a fast-digested protein.

Recent studies have proven that leucine improves protein synthesis. The protein type can specifically influence post-meal aminoacidemia and it has been observed that leucine appears rapidly and transiently in the peripheral blood after whey protein ingestion whereas blood leucine level measured after casein ingestion is lower but lasts for a more prolonged period. Consequently, it has been demonstrated that in young adults whey protein improves peripheral protein synthesis but does not affect proteolysis whereas casein and total milk protein increase protein synthesis and inhibit proteolysis. A very fast delivery of dietary leucine cannot support the anabolic requirements throughout the post-prandial period. In young adult humans, ingestion of milk protein increases post-prandial nitrogen retention in the peripheral tissues, owing to its relation to a more favorable pattern of amino acids available for peripheral protein synthesis. As a consequence, in a young adult, a slowly digested protein like total milk protein and casein induces a higher postprandial utilization of dietary nitrogen than does a rapidly digested protein like whey or soy protein. However, the rate of amino acid delivery modulates protein turnover differently in young and elderly subjects; in elderly people, a fast delivery of amino acids and of leucine was demonstrated to be more efficient in improving post-prandial leucine and nitrogen balance than was the case with a slow-digested protein.

Conclusions

Animal proteins and particularly milk proteins have a high level of essential amino acids. Milk proteins represent a high-quality dietary protein source for protein nitrogen and essential amino acids requirements. As a consequence, a diet rich in milk protein efficiently supports nitrogen and essential amino acids requirements. Compared to plant proteins, milk proteins have a higher oro-ileal digestibility and demonstrate both a higher NPPU value and a higher PDCAAS value. In addition, milk proteins can play a functional role as a specific metabolic regulator of various physiological functions.

Inter-Species Comparison of Milk Proteins: Quantitative Variability and Molecular Diversity

P Martin, C Cebo, and G Miranda, Institut National de la Recherche Agronomique, Jouy-en-Josas, France

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Milk is a complete and complex food suited to the specific offspring's requirements for growth and development. This is the result of a long and slow adaptive evolutionary process which started 150 million years ago, far before domestication of ruminants, which took place (*c.*10 000 years ago) in the Fertile Crescent region.

There is increasing substantial evidence that milk contains many health-promoting compounds, impacting physiological functions or reducing disease risk. This statement is true for the main milk components, such as lipids, carbohydrates (including oligosaccharides), and proteins, as well as for minerals or vitamins. As far as milk proteins are concerned, numerous substantiated or potential bioactive protein components have been found and many others remain to be identified either as intact proteins or as derived peptides, encrypted in the sequence of milk proteins. This is probably one of the greatest challenges facing milk science in the immediate future to provide the food industry and consumers with the basis for health-promoting properties before their inclusion as ingredients into functional foods.

Milk proteins are found mostly in the aqueous phase, either in the soluble (whey proteins of which few are synthesized in the mammary epithelial cells while the large majority have a serum origin) or in the colloidal (caseins) state, but also in the lipid phase, associated with the milk fat globule membrane (MFGM).

It has been shown that caseins, which can account for more than 80% of milk proteins, have evolved rapidly and are highly divergent proteins across mammalian milks. However, it appears that although both copy number and sequence variation contribute to the diversity of milk proteins across species, milk and mammary genes are more highly conserved, on average, than other genes in the bovine genome. For a long time, we have believed that they were devoid of biological functions and were designed only to ensure amino acids supply and phosphate and calcium absorption. This is no longer true since we now know that peptides displaying proven biological activity are encrypted within caseins as well as whey proteins such as α-lactalbumin (LALBA), which can attain new functions by changing its three-dimensional (3D) structure.

Regarding the casein fraction, several genetic variants have been characterized so far in cow, ewe, and goat milks (**Table 1**). The past 20 years have seen remarkable progress in the understanding of milk protein genes' structure and function. Developments in molecular biology, genomics, and proteomics (mass spectrometry) have particularly highlighted how such genomic rearrangements contribute to changes in the milk protein gene complement of mammalian species and how genetic polymorphism is responsible for the extreme complexity and large variability (qualitative and quantitative) of the milk protein fraction, between, but also within, species. High conservation of MFGM protein-encoding genes between monotreme and placental mammal genomes strongly suggests that they are crucial for lipid secretion and that the secretory function was already established 150 million years ago.

Our purpose here is to provide the reader with an overview of our current knowledge of milk protein variability between species, at both the structural (amino acid sequence, post-translational modifications) and quantitative (ultimately absence) levels. Genetic polymorphisms when responsible for deep modifications will also be considered. Since a separate article covering the MFGM, including proteins, is given in this Encyclopedia, these proteins will not be considered here (*see* **Milk Lipids**: Milk Fat Globule Membrane).

Caseins

Caseins are phosphoproteins synthesized by the mammary epithelial cells (MECs) under multihormonal control as more or less large and stable particles, referred to as casein micelles and which appear like raspberries in electron micrographs. These spherical particles might be the result of aggregation of smaller discrete subunits or submicelles, cemented by a calcium phosphate salt (colloidal calcium phosphate). However, this casein micelle model remains a topic of discussion and controversial debates. Casein micelles are present in the milk of all mammals and have a statistically broad distribution in size, ranging in size between 60 and 600 nm. In bovine milk, the most thoroughly studied milk to date, casein micelles are made up of several casein molecules arising from the expression of four single-copy autosomal genes

Data taken from Ng-Kwai-Hang KF and Grosclaude F (2003) In: Fox PF and McSweeney PLH (eds.) *Advanced Dairy Chemistry, Vol. 1: Proteins*, 3rd edn., Part B, pp. 739–816. New York: Kluwer Academic; Plenum Publishers.

which encode four distinct polypeptide chains, α_{s1}-, β-, α_{s2}-, and κ-caseins.

These four genes (five in some species, see thereafter), of which the structures are known in several species, are clustered (physically linked), in this order, on the same chromosome (six in cattle and goats, five in mouse, and four in human), whatever the species. Differences reported between species will be discussed briefly, since such genomic data provide clues that can plausibly improve our understanding of the mechanisms responsible for specific variations in the number and relative proportions of caseins as well as in their total concentration across mammalian milks. Caseins amount to nearly 80% (i.e., 25–28 g l^{-1}) of the whole protein in ruminants' milk, whereas in breast milk, the casein percentage does not exceed 50% (i.e., 5–8 g l^{-1}). Conversely, the casein content of some lagomorphs' milk can reach 200 g l^{-1} (**Figure 1**).

Besides this wide quantitative variability, it is worth noting that, between species, a high rate of sequence divergence generally occurs in orthologous gene products. Hence, the casein fraction of milk is a complex

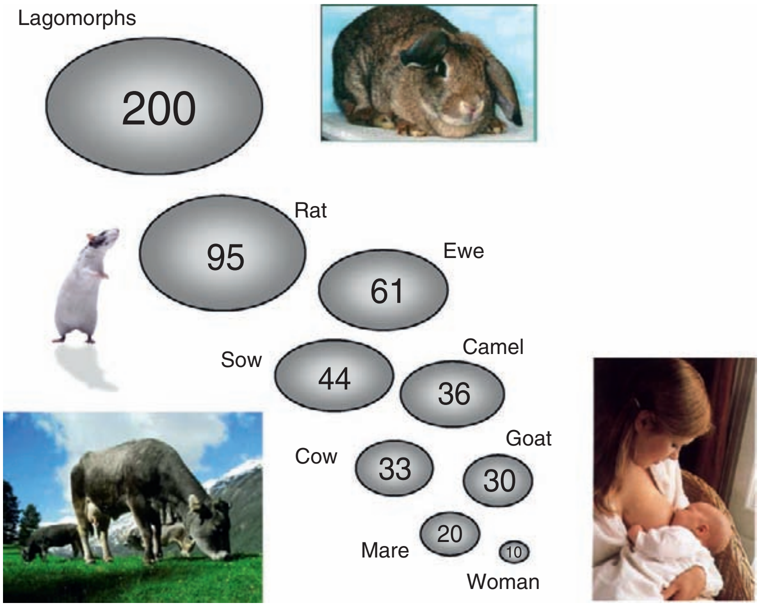

Figure 1 Concentration (g l^{-1}) of milk proteins in eight species.

and specific system which deserves to be considered in terms of diversity, particularly in light of the growing number of biologically active peptides derived from milk proteins, including caseins, identified during the past 20 years.

In addition, post-translational processing, such as phosphorylation, glycosylation, and limited proteolysis by plasmin, increases the heterogeneity of this system, which is complicated even more by the occurrence of genetic variants. The primary focus of this article will be interspecies comparisons in terms of quantitative and structural variability. Nevertheless, within-species variability will also be considered. Particular attention will be paid to discrete phosphorylation and exon-skipping events which contribute to protein diversity and evolution and very likely to specific micellar organization.

The Casein Gene Locus (*CSN*) and Quantitative Variability

Caseins are present in the milk of all mammals. However, their total concentration and their relative proportions are largely species dependent. The species studied so far produce more or less large quantities of milk, the protein content of which ranges between 10 and 200 g kg^{-1} (**Figure 1**). Breast milk shows one of the lowest protein content (10 g kg^{-1}), whereas that of rabbit milk is undoubtedly one of the highest (200 g kg^{-1}). Amongst dairy ruminants, with more than 50 g kg^{-1}, sheep milk shows the highest total protein content. Beyond this large variability in the milk protein content, there are large differences in the relative proportions of caseins between species (**Figure 2**). Thus, in human milk, β-casein is, by far, the main casein component. Conversely, α_{s1}-casein predominates in rabbit milk. Rat, porcine, and bovine milk contain approximately the same proportion of β- and α_{s1}-caseins. Today, human milk remains the only thoroughly studied milk in which α_{s2}-casein has not been found. The presence of two different α_{s2}-caseins has been detected recently in Equidae milk.

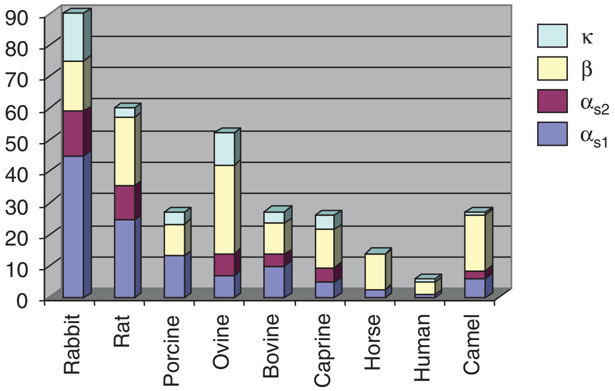

Figure 2 Comparative ratio of milk caseins for nine species. Numbers correspond to mean values from several data sets in the literature. The percentage of α_{s1}-casein given for sow's milk corresponds to α_s-caseins ($\alpha_{s1} + \alpha_{s2}$).

A comparative analysis of the casein locus organization (**Figure 3**) appears to indicate that it is highly conserved between species, even for ancestral mammals such as monotremes (platypus), in which casein genes are tightly clustered in the genome, as they are in placental mammals. The genomic organization of the platypus casein locus has been elucidated and compared with other mammalian genomes, including the marsupial opossum and several eutherians. Whereas the physical linkage of casein genes has been confirmed in platypus, a recent duplication of *CSN2* was observed in the monotreme lineage, as opposed to more ancient duplications of *CSN1S2* in the eutherian lineage, while marsupials possess only single copies of α- and β-casein-encoding genes. Another striking feature is the close proximity between *CSN1* and the main *CSN2*. The lineage-specific gene duplications that have occurred within the casein locus of monotremes and eutherians but not marsupials, which may have lost part of the ancestral casein locus, emphasize the independent selection of milk provision strategies to the young, most likely linked to different developmental strategies.

The four (or five) genes are confined to a 250–350 kb region on chromosome 6, in cattle and goats, and arranged in the order α_{s1}, β, α_{s2}, and κ. Loci encoding α_{s1}- and β-caseins were shown to be very close (between 10 and 20 kb apart) and convergently transcribed. These results were confirmed in cattle for which the genomic organization of the casein gene locus was determined. Despite some differences in the distance separating casein genes and their numbers, the overall organization of the locus is fairly conserved and the presence of dominant *cis*-acting regulatory elements, required for the high-level coordinate expression of the casein genes, is suspected in the α_{s1}/β-region.

Indeed, all four genes are coordinately expressed at high levels in a tissue- and stage-specific fashion. The three genes encoding the 'calcium-sensitive' caseins (α_{s1}, α_{s2}, and β), which are related through evolution, share common regulatory motifs in the proximal 5′-flanking region. Although the organization of the 5′-flanking region of the κ-casein gene is different, its expression pattern seems to be similar to that of the other casein genes. There is more and more evidence demonstrating that a common set of transcription factors is required, in most mammalian species, for the expression of milk protein genes. Mechanisms controlling milk protein gene expression, especially pertaining to the behavior of Stat5, in the cow are significantly different from those in the mouse. More precisely, the different organization of the hormone response regions of casein genes, to the binding of factors such as Stat5 and C/EBP, in different

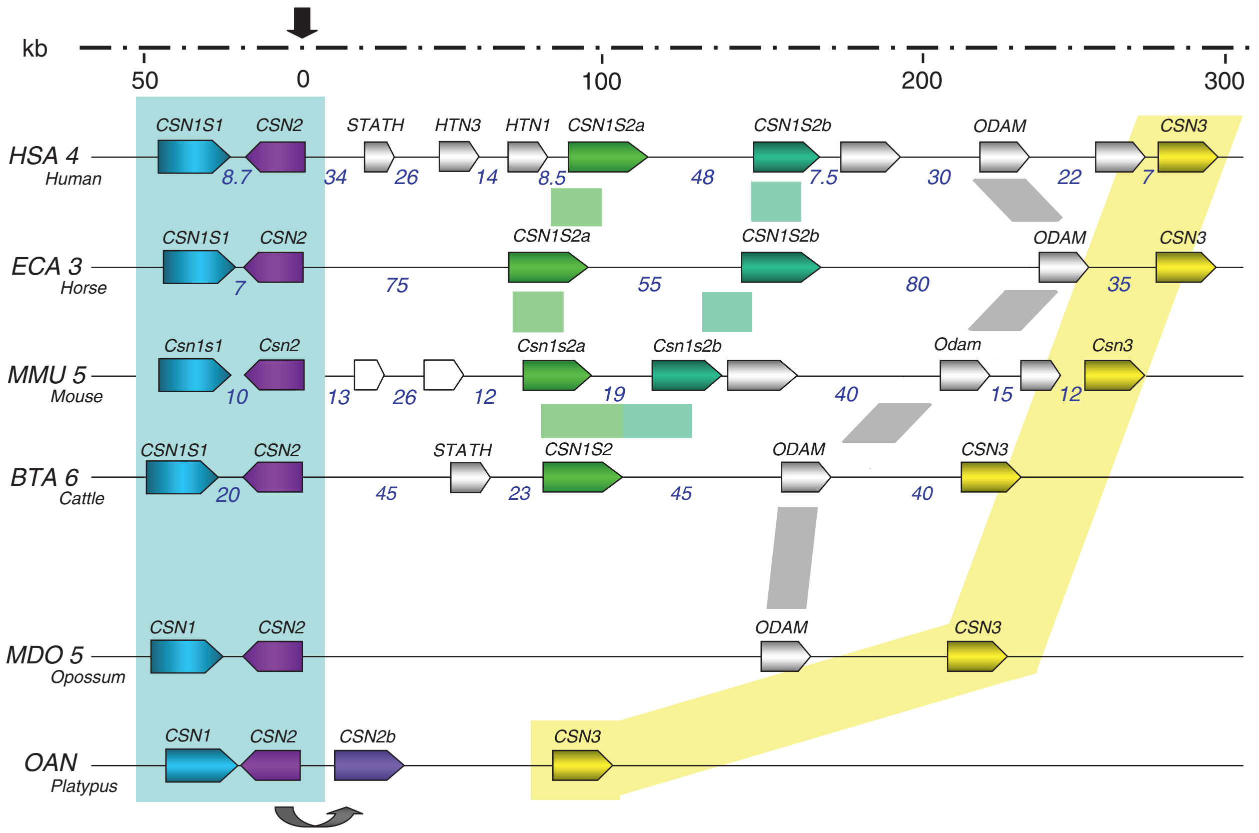

Figure 3 Evolution of the casein locus organization. The casein loci from platypus (*Ornithorhynchus anatinus*), opossum (*Monodelphis domestica*), cattle (*Bos taurus*), mouse (*Mus musculus*), horse (*Equus caballus*), and human (*Homo sapiens*) genomes are drawn approximately to scale in order to underline the expansion of this locus during the course of mammalian evolution. Genes are depicted by 'arrow boxes', giving the orientation of transcription. Blank boxes represent putative genes based on similarity, of which the expression remains to be demonstrated. Intergenic region sizes are given in kb. The human and horse loci have approximately the same size (320/330 kb), whereas the cattle locus (250 kb) is ~80 kb shorter. While the marsupial (opossum) locus is close in size to the cattle locus, on the other hand, the monotreme (platypus) locus is significantly smaller (less than 150 kb) with a duplication of *CSN2* (gray arrow) that occurred recently in this lineage. *STATH* (statherin) and *HTN3* and *HTN1* (histatins) are genes having a common origin and encoding salivary proteins that protect teeth by regulating the spontaneous precipitation of calcium phosphate salts on enamel surface. *ODAM* is a gene highly conserved across species encoding the odontogenic ameloblast-associated protein, a tooth-associated epithelia protein that probably plays a role in odontogenesis, possibly incorporated into the enamel matrix at the end of the mineralization process, but also conspicuous by its expression in several epithelial tissues. Adapted from Lefèvre CM, Sharp JA, and Nicholas KR (2009) Characterisation of monotreme caseins reveals lineage specific expansion of an ancestral casein locus in mammals. *Reproduction, Fertility and Development* 21: 1015–1027 and Warren WC, Hillier LW, Marshall Graves JA, *et al*. (2008) Genome analysis of the platypus reveals unique signatures of evolution. *Nature* 453(7192): 175–183, taking into account additional genomic information from the NCBI.

mammalian species, apparently does not result in fundamental differences in their responsiveness to lactogenic hormones, at least in transfected cell lines. The species-specific arrangement of transcription factor binding sites in the β-casein gene appears to be crucial for the strength and stage at which this gene is expressed in different species, including humans, rodents, and ruminants. For example, the bovine, but not the mouse, β-casein gene is strongly induced shortly before parturition. This difference in stage-specific expression was recapitulated in the expression of a bovine β-casein transgene (including 16 kb of 5′- and 8 kb of 3′-flanking regions) in transgenic mice, indicating that *cis*-acting sequences might be, at least in part, responsible for species-specific expression patterns.

Nevertheless, transcription is not the only level at which regulation of gene expression may occur. In the following, we will see that there are many other factors acting at the post-transcriptional level, including messenger RNA stability and processing as well as a translational regulation. The protein-coding regions of most vertebrate genes, including those encoding caseins in mammals, are split. Most eukaryotic messenger RNAs are thus transcribed as precursors (pre-messengers) containing intervening sequences (introns) which have to be removed to generate mature and functional mRNAs.

The process of intron removal, and exon joining (splicing), is a major function ensured, in the nucleus, by a large multicomponent (5 small nuclear RNAs and more than 50 proteins) complex, called spliceosome, assembled in a stepwise pathway. This accurate mechanism is governed by a set of rather strict rules to achieve high fidelity and efficiency in splicing. However, caseins spliced variants are widely spread across species. A dysfunction of this machinery may have dramatic biological consequences by modifying the message and accordingly the primary structure of the protein. This is well exemplified in mare's milk, in which a low-molecular-weight β-casein variant, showing a 132 amino acid residue internal deletion, has been characterized as arising from a cryptic splice site usage occurring within exon 7, during the course of primary transcript processing. Such deviant splicing behavior might be regulated by an intronic splicing enhancer, sometimes located far away from the splice site, as was shown for the gene encoding β-casein in mare mammary gland.

Primary Structure of Caseins: Comparison across Species

Since the elucidation of the primary structure of bovine α_{s1}-casein in the early 1970s, the complete amino acid or nucleotide (cDNA, gene) sequence of the four (five) caseins has been determined in a number of species (including humans, horses, ruminants, and rodents). Multiple alignments, which help to define functional domains, performed with sequences available today, can reach highly informative levels, provided that the structural intron/exon organization of the gene is taken into account. Indeed, in such a way, multiple alignments, in which gaps were introduced to maximize the alignment, reveal the conserved regions and also highlight their evolutionary pathways. This is particularly true for α_s-caseins, the genes of which are extremely split, comprising up to around 20 exons.

α_{s1}-Casein

A multiple alignment of α_{s1}-casein from 12 species is presented in **Figure 4**. Even tuning the alignment, taking into account the exon modular splitting derived from the known gene structural organization, there are few, even short, segments of amino acid identity across the 12 species. Conversely, such a method of alignment immediately indicates the occurrence of insertion/deletion events. Exon skipping, first found in goat α_{s1}-casein, was shown to be responsible for such events and for the apparent relatively high structural divergence observed between α_{s1}-caseins from different species, as well as for its wide variability in size. α_{s1}-Casein ranges from 183 to 199 amino acid residues, in guinea pig and cattle, respectively, whereas, due to the insertion of a tandem-repeated hexapeptide sequence (QASLAQ), the protein is significantly larger (from 280 to about 300 amino acid residues) in mouse and rat. This sequence was shown to correspond to a short 'virtual exon' occurring within intron 13 of the bovine gene (*CSN1S1*) and surrounded by quite perfect consensus splice sequences. In addition, the same short sequence is recognized as an exon in the porcine α_{s1}-casein mRNA.

The three hydrophobic domains identified in the bovine molecule, spanning residues 1–44, 90–113, and 132–199, are more or less well conserved between species. The most highly conserved region, except the signal peptide, remains, however, the multiple phosporylation site, encoded by the 3′-end of exon 9. This SerP cluster is confined within a sequence (encoded by exons 7–10) carrying a high net negative charge (seven SerP, three Asp, and eight Glu, in bovine), at the natural pH of milk, while the remainder of the molecule is, under such conditions, essentially uncharged. These features are rather conserved in the 12 compared species, exemplified herein by the third hydrophobic domain (residues 132–199), corresponding to the 17th exon, probably being one of the most conserved parts of the molecule. α_{s1}-Casein does not contain a cysteinyl residue or cystine, except in rodents and humans, a feature which is usually found in α_{s2}-casein. In this connection, it is worth noting that, at least in human milk, in which the presence of α_{s2}-casein still remains to be demonstrated, α_{s1}-casein is capable of forming disulfide-linked heteromultimers with κ-casein, which contains only one cysteinyl residue.

β-Casein

With 209–217 residues, in cattle and pig, respectively, without a cysteinyl residue or cystine, this casein is the most hydrophobic of the four caseins. It is especially rich in proline and displays, in all species, an amphipathic structure with a single multiple phosphorylation site, located in the N-terminal part of the molecule. At the pH of milk, the extreme N-terminal part (30 last residues) is highly negatively charged (an average of 11 negative charges: 7 Glu and 4 SerP, in ruminants, concentrated in the 21 first N-terminal amino acid residues), whereas the rest of the peptide chain, which is highly hydrophobic, has no net charge. Such a feature explains the property of β-casein, which allows for micellar aggregates to be formed in solution.

Of the same 12 species, except the guinea pig, 11 are compared and aligned (**Figure 5**). There is no evidence in the extensive literature related to guinea pig caseins for the existence of β-casein. However, there is no irrefutable evidence for its absence from guinea pig milk. Again, as previously mentioned for α_{s1}-caseins, the conservation of the leader peptide is strikingly notable. Moreover, with ~80% homology between α_{s1}- and β-casein signal peptides, the evolutionary relationship between the genes encoding calcium-sensitive caseins is further substantiated. The close proximity of the main α- and

Figure 5 Multiple alignment of the amino acid sequence of β-casein from 11 eutherians. Abbreviations and accession numbers are given in parentheses: cow (bov, M15132), water buffalo (buf, AJ005165), sheep (she, X16482), goat (goa, AH001195), camel (cam, AJ012630), pig (pig, X54974), rabbit (rab, X13043), rat (rat, J00711), mouse (mou, X04490), human (hum, X17070), and horse (hor, NM_001081852, Q9GKK3 on Expasy UniProtKB). Two marsupials, tammar wallaby (wal, X54715) and possum (pos, AF128397), as well as a monotreme (platypus: pla, FJ548612) sequences are also given. Peptide sequences are split into blocks of amino acid residues to visualize the exonic modular structure of the protein as deduced from the known splice junctions of the rat, bovine, sheep, rabbit, and human genes. Exon numbering (in bold) is that of the ruminants' genes. Additional exons are numbered with ′ and ″ (in italics) for platypus sequence. Large blue boxes, within blocks, depict species-specific constitutively outspliced exons. Red and black boxes, between eutherian and marsupial sequences, identify highly conserved amino acid residues (>10/14) between species and anchoring points of marsupial sequences, respectively. Italics correspond to signal peptides, of which the cleavage site is indicated by the vertical blue arrow. Dashes (–) are inserted gaps introduced to maximize the alignment. Underlined and bold amino acids in the marsupial sequences depict duplications and the basic motif of the tandem octapeptide repeats found in marsupials, respectively.

β-caseins in monotremes strongly supports this statement. On the other hand, at the level of the mature proteins, the polyphosphorylated region (encoded by exon 4) is no longer the only region showing a clear conservation between species. Indeed, all along the large and mainly hydrophobic sequence, encoded by exon 7 (more than 160 amino acid residues), a rather high level of homology (30%) is observed. This ratio is quite good, given the number of sequences aligned, having a number of isolated amino acid residues (Q, P, K, and L) conserved. Furthermore, most of the substitutions tend to be conservative.

Albeit less frequently, probably owing to its less split genomic organization, exon skipping also occurs during the course of the processing of primary transcripts from β-casein-encoding gene (*CSN2*) in humans and horse. Despite apparent high dissimilarity with those of eutherian species, two marsupial (tammar wallaby and brushtail possum) sequences and one monotreme (platypus) sequence have been included in the alignment (**Figure 5**). Interestingly, this attempt strongly suggests again an outsplicing of exon 3, as reported for humans. Elsewhere, tammar β-casein and that isolated from the milk of the common brushtail possum, which are by far larger than the others (270 amino acid residues for the mature polypeptide chain vs. 209 in cattle), display a tandemly repeated (16 or 17 times) octapeptide sequence (RESLLAHE) in the C-terminal part of the molecule. This strongly supports the notion that the gene encoding β-casein may have grown through intragenic duplication, eventually coupled with (or followed by) changes of splice sites, before being subjected subsequently to duplications, giving rise to the cognate genes that have then evolved divergently.

Considered together, these observations support the hypothesis of a presumed primitive and common ancestral gene resulting from the recruitment into a functional gene with a minimum of five exons: the first and the last corresponding to the 5′- and 3′-noncoding regions, the second encoding the signal peptide, the third a highly hydrophilic region including a multiple phosphorylation site, and the penultimate coding for a hydrophobic sequence required to ensure aggregation properties, which in turn is essential for casein micelle formation. Sequence similarities between the first exons of the genes encoding the three calcium-sensitive caseins confirm such an assumption.

α_{s2}-Casein

α_{s2}-Casein was the last bovine casein to be sequenced. Of the calcium-sensitive caseins, it is the most highly phosphorylated. α_{s2}-Casein occurs in milk in several forms and differs in the level of phosphorylation (10–13 phosphate groups/molecule). The peptide chain is 207 amino acid residues long and the phosphate groups are clustered in three regions of the molecule (7–31, 55–66, and 129–143). Peptide segments spanning residues 68–125 and the C-terminal part of the protein are predominantly hydrophobic. Given that human milk does not appear to contain α_{s2}-like casein and the equine sequence is still not available, amino acid sequence comparisons are restricted to only 10 eutherian species (**Figure 6**).

The structural organization of the α_{s2}-casein-encoding gene (*CSN1S2*), the longest of the four bovine casein-encoding genes, provides evidence that although it appears to be similar to that of the α_{s1}-casein-encoding gene (*CSN1S1*), sequence comparisons and the length of exons indicate that genes encoding α_{s2}- and β-caseins are more closely related to each other than to *CSN1S1*. However, analyses of interspecies relationships performed at the transcript level show that α_{s2}-caseins have diverged through extensive sequence rearrangements and a high level of nucleotide substitution. A tandem repeat was first detected in the amino acid sequence of bovine α_{s2}-casein. On the basis of the gene sequence, the large internal repeat was precisely extended to codons 43–124 and 125–204, which resulted in the formation of exons 12–16 by a duplication of exons 7–11. In addition, from both amino acid and nucleotide sequence comparisons, it is still evident that, with up to 60% similarity, exons 3–5 also arise from a duplication event of exons 8–10. Therefore, it can be hypothesized that this gene has been subjected to two successive duplications of a 5-exon module followed by the loss of one upstream (exon 7/12) and one downstream (exon 11/16) exon.

The same observation can be made for the other artiodactyls, camel, rat, and guinea pig sequences, while for the mouse and the rabbit the situation is not so clear and complicated by the existence of two (ϵ/δ and γ or α_{s2}-a and α_{s2}-b, respectively) α_{s2}-casein genes. In these species, the α_{s2}-like caseins are shorter than the others since they are 143, 184, 180, and 182 amino acid residues long, respectively, and all the duplicated sequences were apparently lost in the mouse ϵ/δ-casein. Thus, there are marked differences in size. Here, too, deleted segments, emphasized by multiple alignments based on the structure of the bovine gene, correspond to exon sequences outspliced from the mature messengers during the processing of the primary transcripts. Camel α_{s2}-casein, with 178 amino acid residues, lacks two internal stretches of 9 and 15 amino acid residues, very likely corresponding to exons 8 and 10. It now remains to demonstrate the presence, at the genomic level, of the relevant nucleotide sequence (encoding the missing peptide segment) and to characterize mutations responsible for this double exon skipping event, as had been done for the bovine α_{s2}-casein D variant. On the other hand, as previously mentioned for α_{s1}-casein, additional exons may also break out from intron sequences. The presence of an extra peptide sequence (IQSGEELST), between exons 11 and 12 in

Figure 6 Multiple alignment of the amino acid sequence of α_{s2}-casein from 10 mammalian species. Abbreviations and accession numbers are given in parentheses: cow (bov, M16644), water buffalo (buf, AJ005431), sheep (she, X03238), goat (goa, X65160), camel (cam, AJ012629), pig (pig, X54975), rabbit (rab a, X76907; rab b, X76909), mouse (mou ϵ, J00379; mou γ, D10215), guinea pig (cav, X00374), and rat (rat γ, J00712). Two sequences are given for rabbit (a and b) and mouse (δ/ϵ and γ). Sequences for the rat and guinea pig correspond to the γ-casein and casein A, respectively. Peptide sequences are split into blocks of amino acid residues to visualize the exonic modular structure of the protein, as deduced from the known splice junctions of the bovine gene. Additional exons are numbered with ′ and ″ (in italics). Large blue boxes, within blocks, depict species-specific constitutively outspliced exons. Red boxes identify highly conserved amino acid residues (>10/12) between sequences. Italics correspond to signal peptides, of which the cleavage site is indicated by the vertical blue arrow. Dashes (–) are inserted gaps introduced to maximize the alignment.

pig α_{s2}-casein, could be due to this kind of event. Similarly, one can anticipate the probable existence of an additional exon sequence within intron 14 of the gene encoding α_{s2}-casein b in the rabbit genome.

One of the main biochemical features of α_{s2}-casein, usually underlined and plausibly having an important functional role, is its ability to form disulfide bridges, owing to the presence of two close cysteinyl residues at positions 36 and 40, in the mature bovine peptide chain. These residues are encoded by exon 6, the sequence of which is rather well conserved, when present, with both cysteinyl residues at the same position. In contrast, in rat (γ), mouse (ϵ/δ and γ), and rabbit α_{s2}-casein, which lack this exon, both cysteinyl residues are obviously removed. Nevertheless, with a single and two contiguous cysteinyl residues in the middle of the peptide sequence encoded by exon 11 in rat and mouse γ-caseins, respectively, and since rat, mouse, and human α_{s1}-caseins contain at least one cysteinyl residue, there is no eutherian milk in which any α_s-casein is devoid of a cysteinyl residue.

κ-Casein

Glycosylated at various levels, κ-casein is highly heterogeneous, soluble in the presence of calcium and differing considerably in structure from the calcium-sensitive caseins. The functional duality of κ-casein, which is to interact hydrophobically with the other caseins and at the same time provide a hydrophilic and negatively charged surface on the micelle to stabilize the colloidal suspension, is strikingly reflected by its amphipathic primary structure. Its hydrophilic and flexible C-terminal part (caseinomacropeptide or CMP) is cleaved specifically by chymosin (between residues Phe_{105} and Met_{106}, in ruminants), thus leading to the destabilization of the micelle, to which the highly hydrophobic and insoluble N-terminal part (*para*-κ-casein) remains anchored. Two cysteine residues are found in the *para*-κ-casein region.

Although it belongs to the same chromosomal casein locus, the gene encoding κ-casein does not share any common structural organization scheme with the other casein genes. It is thought to be evolutionarily related to the γ-fibrinogen gene, which encodes a protein similarly involved in a clotting process (blood), following a limited proteolytic cleavage.

Interspecies comparison reveals that the κ-casein gene is identically organized in ruminants. The transcription unit invariably comprises five exons, three of which are small (65, 62, and 33 nucleotides in bovine), encoding the 5′-untranslated region (5′-UTR; exon 1) and the signal peptide (exons 2 and 3), which is longer (21 vs. 15 residues in the calcium-sensitive caseins). Therefore, the majority of the mature protein sequence (160 amino acid residues) is encoded by exon 4, while the last exon encodes the 3′-UTR.

Multiple alignments from the same 12 species, considered in this article, are shown in **Figure 7**. Gaps have been introduced to maximize similarity, taking into account comparisons performed at the nucleotide level of exon 4 for higher ruminants and extended to 21 species including cetaceans, hippo, deer, giraffe, tapir, and zebra.

Molecular Diversity of Caseins: Interspecies Variability

In addition to the differences in primary structure across species, examined above, which reflect changes at the genomic level within coding sequences and/or flanking sequences (splice site consensus sequences), further sources of variation occur at a post-transcriptional level. They affect mainly the processing of primary transcripts, and post-translational modifications such as phosphorylation (all caseins) and glycosylation (κ-casein). The extent of this variability and the complexity of the specific pattern within each species provide further criteria of distinctiveness between species.

Defect in the processing of primary transcripts: Splice variants

Two kinds of events may arise during the processing of primary transcripts, both leading to a shortening in the peptide chain length. The first event, referred to as cryptic splice site usage, primarily due to a ‘slippage’ of the splicing machinery, is induced by a ‘favorable’ junction sequence. As far as caseins are concerned, this defect in accuracy leads to the loss of the first codon (usually a CAG) of the 3′-exon. The second event, which is particularly well exemplified by small ruminants, gives rise to a stochastic alternative exon skipping (sometimes referred to as casual or non-allelic exon skipping). It is thought to be caused by weaknesses in the consensus sequences, either at the 5′- and/or 3′-splice junctions or at the branch point, or both.

Stochastic usage of cryptic splice sites

The casual deletion of a glutaminyl residue (Gln_{78} or Q_{78}), first detected in goat α_{s1}-casein, seems to be a rather frequent phenomenon, occurring in most of the species examined so far. This codon skipping, which is likely due to an erroneous 3′- cryptic splice site usage when exons 10 and 11 are joined, has been found in the four major ruminant species. It is worth noting that this kind of event may play a functional role in the structure and stability of casein micelles, since Q_{78} is located at the junction between the polar cluster of phosphoseryl residues and the hydrophobic domain of the protein. Interestingly, such a cryptic splice site activation does not only occur in ruminants. In humans, α_{s1}-casein transcript, in which exon 11 is lacking, a glutaminyl residue (Q_{37} in the mature protein), encoded by the first codon of exon

Figure 7 Multiple alignment of the amino acid sequence of κ-casein from 12 mammalian species. Abbreviations and accession numbers are given in parentheses: cow (bov, M36641), water buffalo (buf, AJ011387), sheep (she, X51822), goat (goa, X60763), camel (cam, Y10082), pig (pig, X51977), rabbit (rab, Z18243), guinea pig (cav, X56020), rat (rat, K02598), horse (hor, NM_001081884), mouse (mou, M10114), and human (hum, M73628). Peptide sequences are split into blocks of amino acid residues to visualize the exonic modular structure of the protein, as deduced from the known splice junctions of the bovine, rabbit, and human genes. Red boxes identify highly conserved amino acid residues (>10/12) between species. Italics correspond to signal peptides, of which the cleavage site is indicated by the vertical blue arrow. Dashes (–) are inserted gaps introduced to maximize the alignment. The chymosin-sensitive bond is indicated by the green vertical arrow. X corresponds to the basic motif of the repeated sequence (underlined) in the guinea pig. The platypus (pla, FJ548626) sequence is also given, taking into account the structural organization of the gene (Casein sequences in monotreme and platypus Lefèvre CM, Sharp JA, and Nicholas KR (2009) Characterisation of monotreme caseins reveals lineage specific expansion of an ancestral casein locus in mammals. *Reproduction, Fertility and Development* 21: 1015–1027).

6′ (an additional exon found in the intron bridging exons 6 and 7), was also shown to be casually absent.

Examples of ‘Q’ insertion/deletion in protein, due to cryptic splice site usage, are well documented. It also occurs with other calcium-sensitive casein pre-messengers and for species other than humans and ruminants. It has been shown recently in rodents and horse. This loss in accuracy of the splicing machinery would be due to the nucleotide sequence at the intron–exon junction. The mechanism by which the 3′-splice site AG is accurately and efficiently identified involves a 5′-to-3′ scanning process. The first AG downstream from the branch point/polypyrimidine tract is preferentially selected. A second AG, competitive with the proximal one, can be used alternatively. Starting the exon sequence with a CAG (coding for a glutaminyl residue) would be a facilitating situation. The short size of the intron might be an enhancing factor. Indeed, introns 6 and 10, involved in human and ruminant genes encoding α_{s1}-casein, are 150 and 100 bp long, respectively.

'Species-specific' stochastic exon skipping

Structural characterization of caseins and/or analyses of relevant mRNA have enabled the identification, in the four ruminant species, of multiple forms of α_{s1}-casein. However, the extent of this heterogeneity depends on the species. While α_{s1}-casein phenotypes consist of a mixture of two forms (199 and 198 amino acid residues) in cattle and water buffalo, due to the alternative deletion of Q_{78}, there are, in sheep and goats, at least seven molecular forms that differ in their peptide chain length, regardless of genetic polymorphism. The main component corresponds to the 199-residue form initially described in goat milk. The others, in lower amounts, are shorter forms of α_{s1}-casein differing in deleted sequences (residues 110–117 and/or 141–148). Genomic and mRNA analyses demonstrated that these forms originated from exon-skipping events affecting exon 13 (encoding peptide 110–117) and/or exon 16 (encoding peptide 141–148) during the processing of the primary transcripts. Deletion of peptide 110–117, which contains four charged residues (SP_{115}, E_{110}, E_{117}, and K_{114}), and that of peptide 141–148, which contains only one (E_{141}), produce proteins with a different net charge.

The alternative splicing of exon 13 and/or 16 reported for small ruminant species has not been detected in cattle and water buffalo. Such differences in the processing of α_{s1}-casein pre-messengers in these closely related species are amazing and hard to explain, since none of the mutations (substitution or deletion) identified between small ruminants and cattle affects consensus splice sites. Long and short variants of α_{s1}-casein, which differ by the presence or absence of a stretch of eight amino acid residues encoded by exon 16, have been observed in camel milk also.

This phenomenon is clearly not restricted to ruminants. The existence of three α_{s1}-casein transcripts has been reported in the human mammary tissue. This heterogeneity is due to a differential splicing of exon 7 (bovine gene numbering) and to the usage of a cryptic splice site. Likewise, porcine α_{s1}-casein also shows such heterogeneity, with multiple forms differing by internal deletion. However, exons (12 and 13′, using the bovine gene numbering) showing such a casual alternative splicing are different from those reported for the other species.

Multiple forms arising from casual alternative splicing have been reported also in ovine α_{s2}-casein. Two non-allelic forms of α_{s2}-casein differing by an internal deletion of nine amino acid residues at positions 34–42 in the peptide chain have been found in ovine milk. Analysis of the products obtained by reverse transcription of mRNAs has shown a greater heterogeneity of α_{s2}-casein transcripts. In addition to the expected deletion of codons (34–42) affecting 30–40% of mRNA, another structural difference involving an internal stretch of 44 nucleotides in the 5′-UTR has been reported subsequently and shown to be caused by casual exon skipping.

Exon skipping is therefore to be considered as a frequent event, mainly in the case of α_{s1}- and α_{s2}-casein genes, for which the coding region is divided into so many short exons. However, since these pioneering works, a lot of additional examples have been found and the existence of intronic *cis*-element (intronic splicing enhancer) increasing the inclusion of 'weak' exons or influencing cryptic splice site usage has been reported in the equine β-casein gene. Do those deletions in calcium-sensitive caseins simply reflect the lack of accuracy of an intricate processing mechanism whenever mutations induce conformational modifications of pre-mRNA, preventing or enhancing the normal progress of events? Notwithstanding, these phenomena are mainly responsible for the great complexity of casein composition.

Genetic polymorphisms increase casein heterogeneity in peptide chain length

In addition to casual exon skipping, genetic polymorphism of milk proteins may sharply increase the heterogeneity of caseins in milk. Studies performed on goat milk have reported extensive genetic polymorphism of α_{s1}-casein, with at least 15 alleles at the goat α_{s1}-casein (*CSN1S1*) locus, distributed in seven different classes of protein variants, associated with four levels of expression. α_{s1}-Casein A, B, C, and E variants differ from each other in amino acid substitutions, while α_{s1}-casein variants F and G, associated with a low level of protein synthesis, are internally deleted. The establishment of the overall organization of the goat α_{s1}-casein gene (19 exons scattered along 17 kb), the characterization of allele F at the genomic level, as well as the analysis of their transcription products demonstrated that the internal deletion of 37 amino acid residues, occurring within variant F, arises from the outsplicing of three consecutive exons (9, 10, and 11), skipped *en bloc* during the processing of the primary transcripts. Furthermore, the α_{s1}*-CasF* allele was shown to yield multiple alternatively spliced transcripts, among which were transcripts lacking 24-nucleotide-long sequences encoded by exons 13 and 16. By comparison with the non-defective α_{s1}*-CasA, -CasB,* and *-CasC* alleles, a reduction in the amount of mRNA, due to mRNA decay and therefore accounting for a lower α_{s1}-casein content in milk, was observed. A single-point deletion in exon 12 of the α_{s1}-casein gene, leading to truncated proteins and hence a low content of α_{s1}-casein in the milk, has been described as being unique to the Norwegian goat population.

Likewise, a single-nucleotide deletion resulting in a premature stop codon is associated with a marked reduction in the amount and an extensive heterogeneity of transcripts from goat β-casein null allele in Créole and Pyrenean breeds. The occurrence of multiple and shorter β-*Cas0* transcripts has been shown. They differ from their full-length counterparts in large nucleotide stretches that are missing within exon 7. Four in-frame nonsense codons, due to a one-nucleotide deletion, were found in the β-*Cas0* allele and the cognate mRNA. Another β-casein null allele, identified in a Neapolitan goat breed, was shown to differ from the wild type by a transition C-T, affecting codon 157 in exon 7. The resulting premature termination codon is associated with a 10-fold decrease in β-casein mRNAs. However, data are lacking about the possible occurrence of multiple mRNAs.

As regards both α_{s1}-*CasF* (as well as a Norwegian *CSN1S1* allele) and β-*Cas0*, mutations are responsible for the existence of premature stop codons, associated with a decrease in the relevant level of transcripts and responsible for the presence of multiple forms of messengers, due to alternative splicing. Many reports have drawn attention to a possible relationship between nonsense codons and exon skipping. Indeed, some genes containing premature codons express alternatively spliced mRNA in which the exon containing the nonsense codon has been skipped. Among the hypotheses proposed to explain such a safeguard mechanism, one can mention 'nuclear scanning' which recognizes nonsense codons and then has an effect on exon definition. This raises the question: How is a normal termination codon (which does not usually mediate a reduction in the abundance of mRNA) distinguished from a premature stop codon? A rule has been proposed for the position of the termination codon. It must be located less than 50–55 nucleotides upstream from the 3′-most exon–exon junction. The normal termination codon in α_{s1}-casein, as well as in β-casein, transcripts is in part or fully encoded by the penultimate exon (exons 18 and 8, respectively) at 43 and 36 nucleotides upstream from the last exon–exon junction, respectively, thus conforming perfectly with the stated rule. Conversely, stop codons identified both with α_{s1}-*CasF* and the French and Italian β-*Cas0* alleles are located well beyond the 55-nucleotide limit. Therefore, they could be suspected to mediate mRNA decay and promote the occurrence of multiple forms of transcripts.

Differences in post-translational modifications

Our present knowledge of casein heterogeneity is rather advanced for a large number of species including cattle, goats, and even, until now, less thoroughly investigated species such as sheep, humans, or horse. With the growing resolving power of 2D electrophoretic techniques, the development of immunochemical procedures coupled with gel electrophoresis, and an increasing usage of mass spectrometry-based proteomics, we now have a clear vision of the complexity of the casein fraction in most of the species studied so far. Genetic polymorphisms remain one of the factors determining casein heterogeneity through alterations in electrical charge, molecular weight, and hydrophobicity of proteins. However, other factors such as post-translational modifications including phosphorylation and glycosylation (κ-casein) also contribute significantly. These factors will be examined below.

Phosphorylation

Phosphorylation of caseins is a post-translational event occurring in the Golgi apparatus and ensured by specific kinase(s) that recognize an amino acid triplet where the determinants are dicarboxylic residues (mainly Glu) or phosphoseryl residues. The occurrence of the tripeptide sequences Ser–X–Glu/SerP is a necessary but not a sufficient condition for phosphorylation of caseins to occur. Possible factors of constraint such as different intrinsic properties of both phosphate acceptor residues and acidic determinants, the characteristics of the local environment, secondary structure and steric hindrance, an insufficient available pool of kinase(s), etc., may explain incomplete phosphorylation.

Indeed, unlike milk from various ruminant species, human and equine milks display complex phosphorylation patterns. While bovine β- and α_{s1}-caseins exist predominantly as single phosphoforms, containing five and eight phosphate groups, respectively, equine and human β-caseins have variable phosphorylation levels with three to seven and zero to five phosphates, respectively. This notion, however, has to be considered cautiously, since in ewe's milk, α_{s1}-casein has been reported to exist as multiple phosphoforms with 7–11 phosphate groups. This is also true for β-casein (two to seven phosphates).

In **Table 2** is gathered our current knowledge on the phosphorylation level of the four main caseins from 12 mammals. The greatest amount of data refers to the four widely studied ruminant species while only limited information is currently available regarding the other species, with the exception for human and horse. Experimental data are compared to the theoretical number of sites expected on the basis of Mercier's rule.

Five variants of ovine α_{s1}-casein (A–E) have been described so far, associated with quantitative variation in casein content. The primary structure of three of them, A, C, and D (formerly called Welsh variant), has been determined. They differ from each other by few amino acid substitutions and the degree of phosphorylation. Differences between the three genetic variants, A, C, and D, are 'silent' substitutions affecting the degree of protein phosphorylation: variant C differs from variant

For each species, the number of amino acid residues of the mature chain and of the signal peptide and the number of phosphorylation sites (putative, p/effective, e) are indicated

A for the substitution Ser13-Pro, which determines the loss of a phosphate group at site 12 of the peptide chain, PSer12-Ser; a further substitution, PSer68-Asn, causes the disappearance of the phosphate group on both phosphorylated residues, Ser64 and Ser66, in variant D, which is widespread in Italian breeds.

As for other species, ovine α_{s2}-casein appears to be the most heterogeneous fraction because of its high degree of multiphosphorylation, with 9–12 phosphate groups. In sows' milk, polymorphism of α_{s2}-casein consisted of a fast-migrating band with a minor satellite band, which is absent from some samples, suggesting that this is determined by incomplete phosphorylation.

Camel caseins are less phosphorylated than bovine caseins. Six putative phosphorylation sites (Ser at positions 18, 68, and 70–73) have been identified in the camel α_{s1}-casein sequence, with a possible incomplete saturation. Although there are four predicted phosphorylation sites in the β-casein peptide sequence, from molecular mass measurements (matrix-assisted laser desorption ionization technique-mass spectrometry (MALDI-MS)) it was observed that the most frequent form has only three phosphate groups. One of the deletions that shortens camel α_{s2}-casein, likely due to the skipping of exon 8, is responsible for the loss of the phosphorylated serine cluster Ser56–Ser57–Ser58.

Two phosphorylation sites have been identified up to now (PSer151 and PSer168) out of five potentially phosphorylable sites (also including Ser127, Thr135, and Thr137) in the bovine κ-casein peptide chain. Using a proteomic approach (2D electrophoresis, combined with mass spectrometry) to analyze the casein fraction of milk from a single cow, homozygous for the B variant of κ-casein, 17 isoforms with different posttranslational modifications (PTMs) have been characterized and a previously unrecognized site (Thr166) that could be phosphorylated or glycosylated has been identified.

Glycosylation

Ovine κ-casein is O-glycosylated and Thr residues at positions 156, 158, and 159 have been proposed as putative glycosylation sites. The oligosaccharide units of ovine κ-casein contain both *N*-acetyl and *N*-glycolyl neuraminic acids at all stages of lactation. The disaccharide Galβ(1-3)GalNAc and the tetrasaccharide Galβ(1-3)[Galβ(1-4)GlcNAcβ(1-6)GalNAc] occur in mature ovine κ-casein, whereas defined tetra- and pentasaccharide structures are present in κ-casein from colostrum, indicating an evolution of the sugar moiety as a function of the time after parturition. In a comparative study, the caseinoglycopeptide from ewes' milk was shown to have greater antithrombotic activity than that of the cow.

The carbohydrate content of κ-caseinoglycopeptide is significantly higher in human milk (55%) than for bovine milk (10%). The monosaccharides Gal, GalNAc, and NeuAc are common to the κ-casein from both species, whereas Fuc and GlcNAc are specific for human κ-casein. An increasing number of oligosaccharide structures for human κ-caseinoglycopeptide are available. Among these oligosaccharides, GlcNAcβ(1-6)GalNac and GalNAcβ(1-4)GlcNAcβ(1-6)GalNAc represent novel types of core structures for mucin-type carbohydrate chains.

Although the primary structure of κ-casein from several species is available, glycosylation sites are essentially documented for bovine and human κ-caseins. Seryl residues were not glycosylated in either bovine or human κ-casein, whereas 9 out of 10 putative Thr-containing consensus sequences of human κ-casein are actually glycosylated. Potentially bovine κ-casein could have up to 12 NeuAc residues if all six glycosylation sites (only five in the B variant) were modified with the major tetrasaccharide, NeuAcα(2-3)Galβ(1-3)[NeuAcα(2-6)]GalNAc, identified. However, using 2D electrophoresis coupled with mass spectrometry, only fragment masses corresponding to a maximum of four NeuAc residues were observed in the multiply glycosylated forms. On the other hand, the core disaccharide, Galβ(1-3)GalNAc, to which the NeuAc residues are attached, appeared to be relatively stable, and fragment ions with up to three disaccharides were observed allowing the number of oligosaccharides attached to be determined.

Whey Proteins

A significant number of proteins synthesized or not in the mammary gland, with functions not fully understood, occur in the whey. We will discuss briefly hereafter variation across species taking into account quantitative as well as structural and biological aspects of selected major whey proteins.

Variation in the milk protein gene copy number potentially conributes to the diversity of milk protein composition. This is particularly well exemplified by the gene encoding β-lactoglobulin (*BLG*), which is one of the major whey proteins of ruminant species, apparently absent in humans, camels, rabbits, and rodents. Surprisingly, another major whey protein – the whey acidic protein or WAP – is frequently found instead of β-lactoglobulin (BLG). However, the presence of WAP in human milk has still to be demonstrated. On the other hand, both proteins are found in marsupial and monotreme milks (**Figure 8**). Up to now, swine is the only eutherian species for which WAP as well as BLG have been identified.

β-Lactoglobulin: A Singular and Enigmatic Whey Protein

β-Lactoglobulin (BLG) has been extensively studied across species and a comprehensive review was published few years ago. Despite relatively weak sequence homologies, multiple alignments reveal some striking features and short peptide sequences precisely conserved across species, including marsupials (**Figure 9**). The genomic organization of the gene encoding BLG is highly conserved across species, with seven exons, encompassing an ~5 kb genomic segment, located on chromosome 11 in cattle. With the release and assembly of the *Bos taurus* genome, it appeared that the gene encoding BLG is duplicated in cattle as it is in dog and horse genomes. The duplicated gene, first described in cattle as a pseudogene, shows similarities to *BLG-II* genes identified in the horse and cat. However, there is no evidence for its expression in the bovine mammary gland, thus being without any effect on the concentration of BLG in bovine milk. On the other hand, mutations within *BLG-I* gene, including its promoter region, seem to impact the BLG expression level.

The amino acid sequence and 3D structure of BLG show that this protein belongs to the widely diverse lipocalin superfamily, whose members share relatively low sequence similarity but have highly conserved exon/intron structure and 3D protein folding. Most of them bind small hydrophobic ligands and thus may act as specific transporters, as serum retinol-binding protein does. Bovine BLG binds a wide range of ligands, but this may not be the reason for its presence in milk. The structure and physicochemical properties of the protein have been reviewed recently. The apparent ability of the binding site to accommodate a wide range of ligands may point to a possible physiological function. However, by considering the lipocalin family, in general, and the species distribution of BLG in particular, some speculation can be made. It has been reported as being implicated in

hydrophobic ligand transport and uptake, enzyme regulation, and the neonatal acquisition of passive immunity. However, these functions do not appear to be consistent between species. Sequence comparisons among members of the lipocalin family reveal that glycodelin (also known as PP14, placental protein 14, or progestagen-associated endometrial protein (PAEP)), found in the human endometrium during early pregnancy, is the most closely related to BLG. Although the function of glycodelin is not fully elucidated, it appears to have essential roles in regulating a uterine environment suitable for pregnancy and possibly to have effects on the immune system and/or to be involved in differentiation.

Twelve polymorphic variants of BLG are known in cattle (**Table 1**), but the most frequent two (A and B) were shown to be associated with differences in milk protein yield and composition. These variants differ by two amino acid substitutions in the polypeptide chain arising from two single-nucleotide substitutions in *BLG-I* gene: Asp64 (GAT)-Gly (G*G*T) and Val118 (GTC)-Ala (G*C*C). The latter T-C transition creates a *Hae*III restriction site, thus enabling a restriction fragment length polymorphism (RFLP) analysis at the *BLG* locus.

Quantitative effects of these common variants on milk composition and cheese-making properties have been reported. Allele B is associated with high casein and fat contents in cow's milk, while Holstein cows with BLG AA genotype were shown to produce milk containing more whey and total proteins than those of the other genotypes. This question and the impact of milk protein variants, including BLG, on milk composition have been studied extensively. Two studies dealing with this issue in cattle have been recently published. In addition, a higher expression of allele A has been described in heterozygous (AB) animals. This differential allelic expression has been explained by nucleotide differences in the promoter regions associated with these two alleles. Fourteen single-nucleotide polymorphisms (SNPs) were identified within the 5′-flanking region and two in the 5′-UTR (exon 1) of the bovine β-lactoglobulin gene. Some of them are located in potential binding sites for *trans*-acting factors or in the 5′-UTR. Sequences of 5′-flanking regions and *BLG* genotypes suggest that alleles A or B in the coding regions were connected with distinct promoter variants. Such intragenic haplotype associations may explain the observed differences in the effects of A or B variants of BLG on milk production traits particularly on BLG synthesis (A > B) in heterozygous cows.

By sequence analysis of the 5′-flanking regions of the main milk protein-encoding genes, altogether 65 variable sites have been revealed. Sixty were base substitutions and five were deletions/insertions. About 50% of the variable sites were located in potential protein binding sites. In cell culture tests, the investigated promoter variants led to different reporter gene expression. The promoter variant of the *BLG* A allele produced up to 3.5 times greater expression of a reporter gene than the promoter associated with the B allele. Differential expression was also shown using a reporter gene fused to bovine BLG A or B promoter variants in transiently transfected HC11 cells, the A variant driving more efficient expression than the B variant (57 vs. 43%).

More recently, Braunschweig and Leeb have shown the existence of an SNP (C-to-A transversion) 215 bp upstream the translation initiation site (g.-215C >A), segregating perfectly with a differential phenotypic expression of two *BLG* B alleles (B and B*). The sequence of the *BLG* B allele in the region of the mutation is highly conserved among four related ruminant species. The mutation site corresponds to a putative consensus-binding sequence for transcription factors c-Rel and Elk-1. These results support the hypothesis according to which sequence variation within the promoter of the *BLG* gene is probably one of the factors responsible for the differences in the protein content in milk.

Whey Acidic Protein

Whey acidic protein (WAP) has been identified in the milk of only a few mammalian species, including mouse, rat, rabbit, camel, pig, tammar wallaby, brushtail possum, echidna, and platypus, but it is absent in ruminant milks due to a frameshift mutation in the WAP encoding gene. The three ruminant WAP sequences reveal the same deletion of a single nucleotide at the end of the first exon when compared with the pig sequence. Due to the frameshift induced, the putative proteins encoded by these sequences do not harbor the features of a usual WAP protein with 2 four-disulfide core (4-DSC) domains, approximately 50 amino acids of which contain 8 cysteine residues in a conserved arrangement. Moreover, RT-PCR (Real Time-Polymerase Chain Reaction)experiments have shown that these sequences are not transcribed. This loss of functionality of the gene in ruminants raises the question of the biological role of the WAP.

The WAP proteins share limited amino acid sequence identities with the exception of these cysteine residues (at least one, usually two, 4-DSC domains in eutherian and even three in metatherian mammals) and positional conservation of several proline (P), glutamic acid (G), aspartic acid (D), and lysine (K) residues. Unlike the eutherian WAP sequences, marsupial WAP displays a conserved motif (KXGXCP) at the beginning of each 4-DSC domain (**Figure 10**). However, currently no functional significance has been ascribed for this motif, although it was thought to be important for correct folding of the protein. The presence of 4-DSC domain sequences on chromosome 20 (WFDC2 or HE4 protein) within the human genome raises the possibility (not yet demonstrated) that a secreted WAP may be present in human milk.

WFDC2/HE4 protein is a small secretory protein, shown to function as an antiproteinase (protease inhibitor) involved in the innate immune defense of multiple epithelia. The relevant gene is highly expressed in pulmonary epithelial cells and saliva and was also found to be expressed in some ovarian cancers and epididymis.

The organization of eutherian *WAP* genes is highly conserved and composed of four exons with exon 1 encoding the 5′-UTR, signal peptide, and first 8–10 amino acids of the mature protein. Exons 2 and 3 encode the two 4-DSC domains and exon 4 encodes the last 8–10 amino acids of the protein and the 3′-UTR. While the size of each exon remains rather conserved between species, intron size varies considerably. Exon 3, encoding 4-DSC domain II, has the higher degree of sequence conservation between species. It was proposed to be the primordial domain, with domain I likely to have arisen by intragenic duplication.

A third 4-DSC domain encoded by an additional exon has been identified in marsupial WAP as well as in platypus, whereas the *WAP* gene structure of echidna is different and closer to that of the *WFDC2* gene, with only two 4-DSC domains (**Figure 10**). It is possible that domain III of the marsupial WAP gene may be the ancestral gene, which was subsequently lost during evolution in eutherian species. It has been suggested that the evolution of the WAP gene in the mammalian lineage may be either through exon loss from an ancient ancestor or by rapid evolution via the process of exon shuffling.

Whereas eutherian WAP is expressed in the mammary gland throughout lactation, marsupial WAP is expressed only during mid–late lactation. This transient expression pattern in marsupials has to be correlated with a short gestation, giving birth to an immature young followed by a long lactation during which milk progressively changes in composition to suit the developing young requirements. This suggests that WAP may play a role in the development of the mammary gland or influence the development of the young. Interestingly, tammar mammary gland was shown to express a second WAP-like protein (WFDC2) at a high level during pregnancy, at a reduced level in early lactation, before disappearing into-midlate lactation. These different temporal expression patterns of WAP and WFDC2 suggest that they play complementary roles.

α-Lactalbumin

Among the main milk proteins, LALBA is so far the only one with an enzymatic activity. Together with β-1,4-galactosyltransferase it forms the lactose synthase complex which catalyses the formation of lactose from glucose and UDP-galactose, in the Golgi apparatus of mammary epithelial cells. LALBA was shown to be a calcium metalloprotein, in which the calcium ion has an unusual role in folding and structure. Most of the molecular structure and function is known and was reviewed by K. Brew. This protein has experienced a renewed interest with 'HAMLET' (human α-lactalbumin made lethal to tumor cells) a partially unfolded LALBA which aquires, after binding oleic acid, a tumoricidal function.

LALBA is present in the milk of almost every species of mammals, except some Otariidae (*Arctocephalus pusillus*: Cape fur seal) of which the milk is rich in fat (more than 20% long-chain fatty acids, mainly unsaturated) and devoid of lactose and LALBA. The female fur seal modulates its lactation by turning milk production 'on' and 'off' without regression and involution of the mammary gland. After undergoing a perinatal fast of 2–3-day suckling pups on shore, the mother leaves its young and the colony to forage at sea for 3 weeks to replenish body stores during which time the mammary gland remains active without initiating involution, demonstrating an apoptotic function for LALBA. This apoptotic potential, which is consistent with observations made on LALBA-deficient mice, has to be compared with the tumoricidal function of HAMLET.

Figure 10 Schematic representation of the structure and evolution of the whey acidic protein (WAP) gene. (a) The ancestral progenitor is depicted by six exons (boxes) numbered from 1 to 6. Colored boxes represent exons (2–5) encoding 4-DSC domains while shaded boxes represent exons encoding the signal peptide (*SP*) and the N-terminal part (N) of the mature protein (exon 1) and the C-terminal part (C-ter) of the protein (exon 6). In eutherian WAP, 4-DSC domains (DI and DIIa) are encoded by exons 3 and 4. The two 4-DSC domains of echidna WAP are encoded by exons 2 (DIII) and 4 (DIIa). Marsupial and platypus WAPs comprise three 4-DSC domains in different configurations: DIII–DI–DIIb and DIII–DIIa–DIIb, respectively. Evolution of *WAP* genes in mammalian species would have proceeded step by step by loss of exon to lead to the present *WAP* genes in monotremes (platypus and echidna) and marsupial and placental mammals. (b) Alignment of eutherian, marsupial, and monotreme WAP sequences shows conservation of protein structure. The 4-DSC domains represented by eight cysteine residues (C) are highlighted with a pink background in each domain (exon). Highly conserved residues are highlighted with a yellow background. Mouse (P01173), rat (P01174), pig (O46655), camel (P09837), and rabbit (P09412) for eutherian sequences have been aligned with brushtail possum (Q95JH3), tammar wallaby (Q9N0L8), platypus (A7J9L3), and echidna (A7J9L2) to maximize similarity within exons depicted by boxes for which the color code of (a) has been retained. Adapted from Sharp JA, Lefèvre C, and Nicholas KR (2007) Molecular evolution of monotreme and marsupial whey acidic protein genes. *Evolution and Development* 9: 378–392.

The gene structure and protein sequence are highly conserved across species, with more divergence in rodents than in primates. Because of its prominent role in milk synthesis, LALBA is considered a valuable genetic marker for milk production traits in cattle. However, LALBA appears rather weakly polymorphic in cattle (three variants) and sheep (two variants). After screening at the protein as well as the nucleotide level, few mutations have been found, mainly within the regulatory sequences of the LALBA-encoding gene.

Three SNPs, occurring at positions +15, +21, and +54 relative to the mRNA transcription start point, were identified in cattle within an approximately 2-kb fragment including 1952 bp of 5′-flanking region and 66 bp of the protein-coding region. The +15 and +21 variations occurred in the 5′-UTR of the mRNA, whereas the +54 polymorphism is a silent mutation in the signal peptide-coding region of the gene. SNP at position +15 (A/G) was shown to occur only in Holstein breed and to be associated with an increased milk yield. Cows with the A allele had higher milk yield, protein yield, and fat yield; the B allele was associated with a higher percentage of protein and fat. These data suggest that, although not located in the gene promoter, this SNP potentially alters the LALBA expression at the translational level and may be associated with differences in milk yield. In addition to SNP/+15, a second SNP (also a transition A-G), located at position −1689 from the transcription start point, was identified. The allele showing an adenine at position −1689 was designated as allele A, and that with a guanine at this position was designated as allele B. The −1689 and +15 polymorphisms were compared within the Holstein population to determine their linkage relationship. In this study, the +15 A variant was always linked to the variant A at −1689. These results suggest the existence of a haplotype A (+15A and −1689A) associated with higher milk, protein, and fat yields.

Lysozyme

Lysozyme is a bacteriocidal agent, structurally related to LALBA, sharing 40% similarity. Ranging in molecular mass between 14 and 18 kDa, this enzyme, also called β-1,4-*N*-acetylmuramidase, cleaves a glycosidic linkage in the peptidoglycan component of bacterial cell walls, resulting in a loss of cell wall integrity and in cell lysis. The concentration of lysozyme in milks varies from 1–3 mg l^{-1} in bovine milk to 400 (in human) and even 800 mg l^{-1} in mare's milk.

Lactoferrin

Lactoferrin (LTF) is of mammary origin and is found in the milk of most species. LTF is an iron-binding glycoprotein with a molecular mass around 80 000 Da, belonging to the transferrin family that is expressed and secreted by epithelial cells and found in the secondary granules of neutrophils from which it is released in infected tissues and blood during the inflammatory process. Initially described as an iron-binding molecule with bacteriostatic properties, LTF is now known to be a multifunctional or multitasking protein with multiple biological activities. It is a major component of the innate immune system of mammals. Its protective effects range from direct antimicrobial activities against a large panel of microorganisms, including bacteria, viruses, fungi, and parasites, to anti-inflammatory and anticancer activities. While iron chelation is central to some of its biological functions, other activities involve interactions of LTF with molecular and cellular components of both hosts and pathogens.

The internal structure of LTF is highly conserved, and is dedicated to binding iron. On the other hand, the external structure (its molecular surface) is much more variable across species, making it more difficult to identify functionally important sites. Recent work shows that the cationic N-terminus and associated lactoferricin domain on the N-lobe of LTF, in addition to its role in antibacterial activity and probable role in DNA binding, is also involved in complex formation with other proteins. Finally, it may be time to re-examine the importance of glycosylation, given the growing evidence that many pathogens depend on binding to glycans for pathogenesis.

The overall structural organization of the human, mouse, cattle, dog, and horse LTF genes is rather conserved, at least in terms of size and number of exons ($n = 17$). LTF is encoded by an approximately 30 kb gene (ranging in size between 23.5 kb in mice and 33.4 kb in cattle), located on chromosome 3 in human, 9 in mice, and 22 in cattle.

A total of 60 LTF nucleotide sequences with the complete coding sequence (CDS) and corresponding amino acids belonging to 11 species were recently analyzed, and differences within and across species studied. The length of the LTF cDNA with the complete CDS varies greatly, from 2055 to 2190 bp, due to deletion, insertion, and stop codon mutation, resulting in elongation. Observed genetic diversity was higher across species than within species, and *Sus scrofa* had more polymorphisms than any other species. Novel amino acid variation sites were detected within several species (8 in *Homo sapiens*, 6 in *Mus musculus*, 6 in *Capra hircus*, 10 in *Bos taurus*, and 20 in *S. scrofa*), illustrating functional variation.

Concluding Remarks

The past 10 years have seen a fantastic breakthrough in the knowledge of genome structure and organization. New insights and clues to better understand mechanistic details involved in the regulation and variability of gene expression have been provided already and are still expected. Data now available on the architecture of the casein locus in several species, including monotremes and marsupials, will contribute to our understanding of the mechanisms responsible for variations and heterogeneity in milk casein composition. However, it is perhaps in the functional field that we might progress significantly in the near future.

Development of instrumental techniques has played a determinant role in these breakthroughs, particularly in the field of post-translational modifications. Although we now know many of the details of casein structure, a number of questions remain unanswered in our understanding of the biogenesis of casein micelles. How caseins interact between themselves and with colloidal calcium phosphate? At what stage they are modified? How this process is influenced by (or influences) the cellular pathway of protein folding and assembly?

Although post-translational modifications and genetic polymorphisms were for a long time considered as the most potent factors capable of generating multiple protein products starting from a single gene, it is now obvious that alternative splicing is responsible for a considerable proportion of proteomic complexity in mammals. It is clear that this process must be intimately related to the great diversity and heterogeneity of caseins as well as to their evolution pathway. As frameshift mutations, which deeply change the nature of the message and/or lead to premature termination (linked to mRNA decay), such mechanisms, by promoting deletion or addition of protein domains through exon skipping or cryptic splice site usage, undoubtedly provide a real plasticity to gene information. With at least a total of 21 coding exons that can be, according to the species, constitutively included or skipped, the gene encoding α_{s1}-casein is one of the most impressive examples, in this regard.

Obviously, such a wide structural diversity is unlikely to be without consequences for the characteristics and the properties of casein micelles, particularly if one considers the possible unique function that seems to be played by α_{s1}-casein in the micelle assembly, transport, and secretion. In mammary epithelial cells of small ruminants, α_{s1}-casein appears to be a complex mixture of more or less internally deleted proteins. The occurrence of genetic polymorphisms disturbing the splicing machinery adds further to the complexity of the casein fraction. With up to 40 variants of α_{s1}-casein produced in the milk of a single goat, heterozygous A/F at the *CSN1S1* locus, the secretion pathway may be disturbed dramatically with an impact on milk composition and quality, including modifications in fat structure and composition, as well as in its susceptibility to lipolysis.

Notwithstanding, the growing number of casein genes displaying such complex patterns of splicing, thus increasing the coding capacity of genes, supports the notion that the extreme protein isoform diversity generated from a single gene can no longer be considered as an epiphenomenon. A parsimonious vision of this issue addresses the question of its biological meaning. Important new insights are expected in this field in the near future.

Introduction to Proteomics

Definition of 'Proteomics'

Proteomics is a term in the study of genetics that refers to all the proteins expressed by a genome; proteomics involves the identification of proteins and the determination of their role in physiological functions. It is a new science that focuses on the study of proteins: their roles, their structures, and their interactions. It involves a large-scale screening of proteins, their expression, and their modifications by using high-throughput approaches. The word 'proteome' is a combination of 'protein' and 'genome'. The proteome is the entire complement of proteins, including the modifications made to a particular set of proteins, produced by an organism or system.

Proteomics is much more complicated than genomics, mostly because, whereas an organism's genome is more or less constant, the proteome differs from cell to cell. This is because distinct genes are expressed in distinct cell types, meaning that even the basic set of proteins that are produced in a cell needs to be determined.

'Proteomic analysis' (analytical protein chemistry), which corresponds to the characterization of proteins and their post-translational modifications, can be linked to 'expression proteomics' (differential display proteomics), which corresponds to the profiling of expressed proteins using quantitative methods.

Milk Proteomics

Milk from all species is dominated by the presence of just a few primary proteins. In bovine milk, these proteins are α_{s1}-casein, β-casein, κ-casein, α_{s2}-casein, β-lactoglobulin (β-Lg), α-lactalbumin (α-Lac), and bovine serum albumin (BSA), with relative abundances of approximately 30:30:10:12:10:4:1, respectively. Despite this, the milk proteome is still extremely complex. A great deal of this complexity is the consequence of abundant post-translational modifications (glycosylation, phosphorylation, proteolysis, protein interaction, and association) and the presence of numerous genetic variants of this limited list of proteins. An additional level of complexity arises from the many proteins of low abundance that require some form of enrichment to be visible against the background of abundant caseins and whey proteins.

In recent years, a number of articles have reported proteomic applications of high-resolution two-dimensional electrophoresis (2DE) of milk proteins from a limited number of species. Human and bovine milk dominate these articles, with other limited applications including analyses of goat, wallaby, and mouse milk.

The application of proteomic methodologies presents a unique opportunity for dairy protein science. The combination of high-resolution separation techniques and powerful yet versatile mass spectrometry (MS) analysis allows the acquisition of previously unattainable information. Although reported studies of milk proteomics are relatively limited, the area is growing at a rapid rate, with virtually all published studies in the area appearing over the past 5 years. In line with this increase in quantity, the studies completed are also becoming more sophisticated. Post-translational modification analysis and differential expression analysis are key areas within proteomics with great potential for dairy applications.

It is likely that 2DE techniques will continue to dominate proteomic analyses of milk for some time. With its high resolution, 2DE allows the separation of protein isoforms containing the slightest of differences, a key in the comprehensive analysis of individual milk samples. Pre-fractionation procedures, multiple separation techniques, and intelligent MS strategies are the keys to successful milk proteomics.

Two proteomic strategies for the analysis of global proteins have appeared in the last 10 years: 'gel-based' proteomics, the separation of proteins using 2DE followed by an MS identification of the proteins/spots obtained; and 'gel-free' proteomics, a first optional step, the separation of the proteins/peptides by liquid chromatography, followed by large-scale MS analysis of the proteins/peptides.

This article is focused on 'gel-based' proteomics (2DE coupled to MS), a mature and well-established technique, largely applied in biology and medicine, and a methodology that is becoming more and more attractive in food and agricultural sciences for studying the behavior of proteins in processed products.

Two-Dimensional Electrophoresis of Milk

Solubilization of Proteins

Milk and dairy products present a great advantage. They contain a large amount of protein; consequently, in most cases, there is no limitation of fresh material for a 2DE analysis. Nevertheless, it is essential to take care in selecting the buffer used to solubilize the proteins. For example, caseins are known to be highly hydrophobic and not easy to dissolve. The next paragraph focuses on 2DE-compatible compounds that are used to make the solubilization buffer.

A traditional solubilization buffer contains 7 or 9 mol l^{-1} urea, 0–2 mol l^{-1} thiourea (with a limitation of 9 mol l^{-1} urea + thiourea), 4% CHAPS (3-[(3-cholamidopropyl)dimethylammonio]-1-propanesulfonate), and 60 mmol l^{-1} dithiothreitol (DTT) as a reducing agent. For samples with DNA (with cells), 30 mmol l^{-1} spermine can be added to remove nucleic acids. Also, 0.05% (v/v) Triton X-100 can be added to improve protein solubility. The proposed solubilization buffer contains a saturated solution of urea and thiourea. These chemical compounds are neutral chaotropic agents, which means that they can help in the solubilization and denaturation of the proteins by removing non-covalent interactions (hydrogen and hydrophobic bonds). Urea is not completely stable in solution; it can be degraded to ammonium cyanate, especially at high temperatures. This cyanate can react with NH_2 (amino) groups of lysine and arginine and with cysteine, leading to isoelectric modifications of the proteins, which can be observed during isoelectric focusing (IEF). To prevent such artifacts, the urea buffers must not be heated above 35 °C.

CHAPS is a zwitterionic detergent that is able to cover hydrophobic parts of a protein, and is an excellent detergent for 2DE. It contains ionic charges, but the global net charge is zero. Because of the presence of charges, CHAPS has better solubilization power than nonionic detergents such as Triton X-100. As a complement to urea, CHAPS and Triton X-100 limit protein aggregation and aid in the extraction and solubilization of proteins.

DTT is used to solubilize proteins. It is a reducing agent, is able to break disulfide bonds within proteins (helps to unfold the tertiary structure), and can break disulfide bonds between different proteins, which are frequently observed after a heat treatment of milk proteins.

An aliquot of 100 μl of milk can be diluted (1/10, v/v) in 900 μl of solubilization buffer to obtain an approximately 3 mg ml^{-1} solution of protein, which is large enough for 2DE. Solubilization can be improved with gentle agitation at room temperature for a couple of hours. Before the first dimension of the 2DE, the protein solution should be clarified by ultracentrifugation (1 h at 100 000 ***g***) to remove insoluble material. The protein content of the solubilized samples can be estimated using a classical colorimetric method.

Isoelectric Focusing of Proteins: The First Dimension

Proteins are amphoteric molecules; they carry positive, negative, or zero net charge, depending on their amino acid composition. The net charge of a protein is the sum of all the negative and positive charges. The isoelectric point (pI) of a protein is the specific pH at which the net charge of the protein is zero. Proteins are positively charged at pH values below their pI and are negatively charged at pH values above their pI. IEF is an electrophoretic separation method based on this specific biochemical characteristic of proteins.

Basically, the first dimension of the 2DE is achieved with a 'strip'. It is a dry gel that is formed by the polymerization of acrylamide monomers, linked by bisacrylamide with molecules of covalently linked immobilin. Immobilins are chemical components that are derived from acrylamide and have additional ionizable non-amphoteric functions. Immobilins of various p*K*a can create an immobilized pH gradient inside the acrylamide gel. Immobilin was developed by Righetti and Görg in the early 1990s and is now widely used in 2DE because the IEF gradient is very stable over time and in a high electric field, and shows good reproducibility and a large capacity for separation.

The strips of acrylamide gel are dried and cast on a plastic backing, 7–24 cm long. Prior to use, they are rehydrated in a solution containing a cocktail of carrier ampholytes to the corresponding pI range and with the correct amount of proteins in the solubilization buffer. In most cases, 50–250 μg of protein are sufficient for an analytical gel. The carrier ampholytes are amphoteric molecules with a high buffering capacity near their pI. Commercial carrier ampholyte mixtures, which comprise species with a pI spanning a specific pH range, help the proteins to move.

When an electric field is applied, the negatively charged molecules (proteins and ampholytes) move toward the anode and the positively charged molecules move toward the cathode. When the proteins are aligned according to their pI, the global net charge is zero and the protein is unable to move and is then focused. Focusing is achieved with a dedicated apparatus that is able to deliver up to 8000 or 10 000 V, but with a limitation in current intensity (50 μA maximum per strip) to reduce heat. The strips are usually first rehydrated without current for at least 5 h (passive rehydration), rehydrated with 50 V for 9 h (active rehydration), and then focused until 50–100 kV h^{-1}.

Equilibration of the Strips

The equilibration step is critical for 2DE. In this step, the strips are saturated with sodium dodecyl sulfate (SDS), an anionic detergent that can denature proteins and form a negatively charged protein–SDS complex. The amount of SDS bound to a protein is directly proportional to the mass of the protein. Thus, proteins that are completely covered by negative charges are separated on the basis of molecular mass.

The equilibration solution also contains buffer, with urea and glycerol. Equilibration of the strips is achieved in two steps: (1) with an equilibration solution containing DTT, to maintain a reducing environment; and (2) with an equilibration solution containing iodoacetamide, to alkylate reduced thiol groups, preventing their reoxidation during electrophoresis.

SDS-PAGE: The Second Dimension

In SDS polyacrylamide gel electrophoresis (SDS-PAGE) separations, migration is determined not by the intrinsic electric charge of polypeptides but by their molecular weight. The SDS-denatured and reduced proteins are separated according to an apparent molecular weight, in comparison with a molecular weight marker. A linear relationship between the logarithm of the molecular weight and the distance of migration of the proteins can be used; it depends essentially on the percentage of polyacrylamide.

Equilibrated strips are embedded in 1% (w/v) low melting point agarose in Tris–glycine–SDS running buffer and with 0.01% bromophenol blue on the top of the second dimension acrylamide gel.

It is recommended that 1 or 2 W of current be applied during the first hour, followed by 15 mA per gel overnight, with the temperature regulated at 10 °C.

Gel Staining

When the bromophenol blue migration front reaches the bottom of the gel, the second dimension is finished and the acrylamide gel can be removed from the glass plates. The gel must firstly be immersed in a fixation solution containing acid (phosphoric acid or acetic acid) and alcohol (ethanol or methanol) as a function of the staining protocol selected. Different stains can be used, but with very different costs. Conventional 'visible' dyes are Coomassie blue, colloidal Coomassie blue, and silver nitrate, with quite different sensitivities: 50, 10, and 0.5 ng of detectable protein per spot, respectively. Commercially available fluorescent dyes such as Sypro Ruby, Flamingo, and Deep Purple have sensitivities of about 1 ng of detectable protein per spot. Fluorescent dyes have the advantage of a 2–4 log dynamic linear range but have the disadvantage of being more expensive. In comparison with fluorescent dyes, silver nitrate stain has a dynamic linear range of only 1.5 log, and is not recommended for a gel comparison study.

Image Analysis

Stained gels are scanned on a 'visible' or 'fluorescent' scanner according to the staining protocol selected. The image can then be imported to specific software to be analyzed and compared. For a comparison study, at least three repetitions of the same sample should be run; many migration artifacts can occur during 2DE and, to reduce such variability, a mean of several gels is essential. Software such as Image Master, Progenesis, PDQuest, and SameSpots can be used to detect spots and to compare the spot intensity between samples. Spots of interest, that is, spots specific to a sample or spots overexpressed under a condition/treatment, can be selected for further MS analysis.

Protein Identification by Mass Spectrometry

Preparative Gel

To identify the proteins within the spots of interest (according to the image analysis), a gel with a greater amount of protein, at least 200–800 μg, is prepared. In this case, the IEF step must be performed until at least 100 kV h^{-1}. The other steps of the 2DE are very similar to the previously described protocol. Colloidal Coomassie blue or fluorescent dyes are recommended for the staining of the preparative gel, because they have good compatibility with MS. In contrast, silver nitrate will give poor results. It should be noted that a specific spot picker robot, able to work with fluorescence, is essential when working with fluorescent dyes.

Stained spots are removed from the gel and digested with trypsin, and the solution of protein fragments is analyzed using MS.

MALDI-TOF Mass Spectrometry

Matrix-assisted laser desorption ionization-time of flight (MALDI-TOF) MS is the fastest and cheapest method of protein identification. Single protein species can be identified by peptide mass fingerprinting using this technology.

The proteins are first 'in-gel digested' with a highly specific endoproteinase such as trypsin, and the resulting peptides are extracted, mixed with a matrix, spotted on a target, and analyzed by MS. Peptides with different molecular weights (m/z ratio) are measured accurately by the mass spectrometer (accurate to at least 0.01 Da). A list of these peptide masses is produced to give a 'fingerprint', which is unique to each protein. Identification of a particular protein can then be achieved by submitting the peptide list to a protein-searching database. A probability is obtained and the protein identification is linked with a significant score.

Analysis of High-Abundance Proteins: An Example of Milk Protein Separation by 2DE and Identification by MALDI-TOF MS

The presence of numerous genetic variants and post-translational modifications makes the milk proteome extremely complex. Post-translational modifications, such as glycosylation, phosphorylation, disulfide bond formation, and proteolysis, have the potential to create a large number of different protein variants from a single gene product.

A typical 2DE gel of milk proteins is shown in **Figure 1**. Each spot on the gel represents a single protein isoform in milk. The protein isoforms are clearly very well resolved from each other, as they migrate to different positions based on their size and pI, and are subsequently visualized using a protein-specific stain (Coomassie blue). The resolution and the information obtained are much greater than would be achievable with a standard one-dimensional gel electrophoresis, as observed on the right-hand side of the gel.

This 2DE gel was prepared with 400 μg of milk proteins, using an 18 cm wide pI range (4−7) for the first dimension and a 20 cm large gel with 12% acrylamide for the second dimension. All the major milk proteins are presented on this 2D map. Spots for several caseins (α_{S1}-, α_{S2}-, β-, and κ-caseins), β-Lg, α-Lac, and BSA are observed.

Analysis of Low-Abundance Proteins

The analysis of low-abundance proteins from sub-cellular compartments is becoming increasingly common in cellular proteomics. Analysis of individual compartments not only provides information on protein localization, but also allows detection of protein populations otherwise not detectable in whole-cell proteomes.

The detection and identification of low-abundance proteins in milk is particularly problematic. Studies involving simple one-step preparations with positive matrix factorization (PMF) analysis often fail to detect and identify large proportions of this important group of milk proteins.

Precipitation of casein at pH 4.6, ultracentrifugation, and immunoabsorption can be used to remove most of the major milk proteins (caseins, β-Lg, α-Lac, and BSA). Analogous to this approach is the analysis of the proteins in the milk fat globule membrane (MFGM).

The MFGM proteins form a unique sub-category of milk proteins (approximately 2–4% of the total protein in human milk), the content of which is still largely

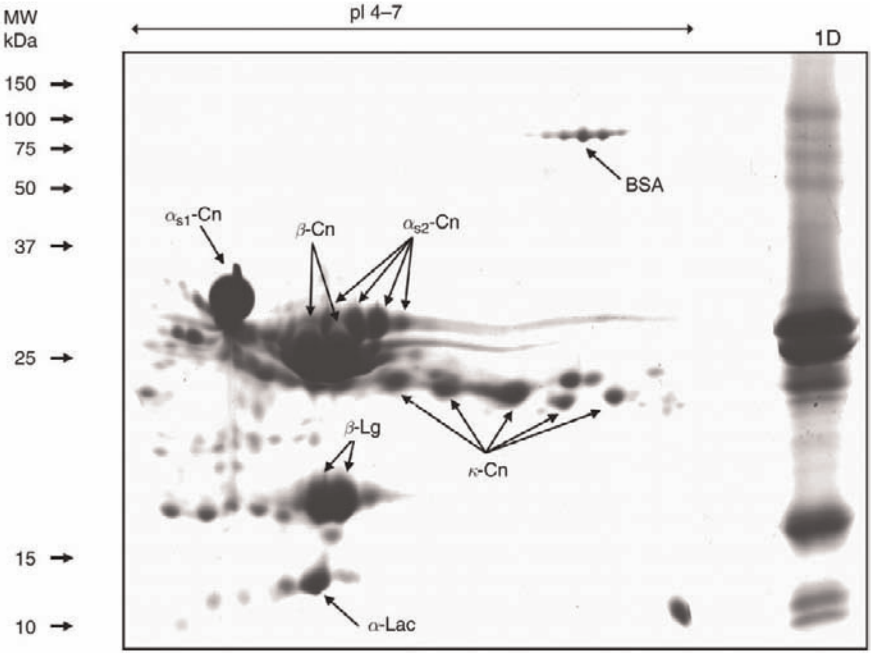

Figure 1 Two-dimensional electrophoresis map of proteins in bovine milk separated using an 18 cm pH 4−7 pI range for the first dimension and a 12% acrylamide gel for the second dimension. The most abundant spots as indicated by arrows were submitted for MS identification by MALDI-TOF peptide mass fingerprinting. BSA, bovine serum albumin; α_{s1}-Cn, α_{s1}-casein; α_{s2}-Cn, α_{s2}-casein; β-Cn, β-casein; κ-Cn, κ-casein; α-Lac, α-lactalbumin; β-Lg, β-lactoglobulin.

unknown. Many of the MFGM proteins are difficult to solubilize because they are highly hydrophobic, posing problems for their application to 2D-PAGE. The most productive strategies make use of a two-step procedure, with the first step using a detergent/reducing agent solution and the second step using an organic solvent extraction. Such strategies not only improve MFGM protein recovery, but also prepare the sample for optimum 2D-PAGE analysis. This strategy enhances the availability of MFGM proteins and reduces the amounts of several overabundant proteins, including the vast majority of caseins, allowing for more efficient detection of the MFGM proteins.

Post-translational Modification Analysis

Milk proteins are characterized by great heterogeneity and the presence of several molecular forms. These proteins are excellent examples of the complex heterogeneity that post-translational modifications can confer on proteins. They display significant levels of phosphorylation and glycosylation. Several post-translational modifications of milk proteins are well known: phosphorylation on serine residues of α_{S1}-casein (9 potential phosphorylation sites), α_{S2}-casein (12 potential phosphorylation sites), β-casein (5 potential phosphorylation sites), and κ-casein (2 potential phosphorylation sites); and six potential O-linked glycosylations on κ-casein.

These post-translational modifications induce phospho- and glycovariants, which are usually discernible on 2D-PAGE with noticeable pI and/or molecular weight modifications (**Figure 1**).

Conclusion

This article highlights proteomics as becoming a powerful tool for the characterization of milk and dairy products. The application of 2DE has proven to be of great use and, with the advent of MS techniques, new challenges have emerged. A merely descriptive view of milk proteins, aiming to provide information exclusively on their compositional complexity, has been replaced by a more complete view, which aims to also identify the proteins and to characterize them in terms of their structure, localization, modifications, interactions, biological activity, and functionality. Specific detection techniques that open new perspectives for the resolution of such research objectives are being developed. The application of proteomic methodologies presents a unique opportunity for dairy protein science. The combination of high-resolution separation techniques and powerful, yet versatile, MS analysis allows the acquisition of previously unattainable information. In the case of milk, the full characterization of milk from different species may reinforce the development of methodologies dedicated to the detection of milk adulteration. Techniques regarding protein polymorphism and post-translational modifications are being improved, which will facilitate the comprehension of structure–function relationships of caseins or whey proteins. Additionally, as the identification of minor milk proteins becomes an easier task, their potential biological roles and health implications may be postulated.

Milk Protein Concentrate

Introduction

Milk protein concentrates (MPCs) could be loosely described as protein-enriched forms of skim milk that are usually processed and marketed in spray-dried form. They fall outside of the traditional classification of preserved and dried milk products, with preference being given to their description as functional dairy ingredients. MPCs owe their origin to the technological innovation that accompanied the application of developments in ultrafiltration (UF) in dairy processing. UF facilitates selective concentration of larger molecular size constituents such as milk proteins and, hence, enables the typical protein in dry matter content of skim milk powder (~35%) to be enriched, with the additional aid of diafiltration, to in excess of 85% protein in dry matter – the upper protein constraints being dictated by retained lipids and colloidal calcium phosphate (**Figure 1**). Given the wide band of protein concentration possible (40–85% protein), the hyphenated double-digit figure accompanying MPC usually denotes its protein content, for example, MPC-85 denoting 85% protein in dry matter (**Table 1**). At such levels of protein enrichment, high-protein MPCs come within the proximate compositional range of other milk protein ingredients such as caseins and caseinates. The term milk protein isolate (MPI) is used increasingly to distinguish a particular subgroup of MPCs that contain greater than 90% protein.

The retention of whey proteins as well as the native micellar state of the caseins distinguishes MPCs from caseinates – the latter having been isolated selectively under isoelectric pH conditions that also dissolve casein-associated colloidal calcium phosphate. Resolubilization of acid-precipitated curd using a choice of alkali (NaOH being the most common) is required to give a salt (e.g., Na)-solubilized, functional form of caseinate for use in food formulation. Consequently, there is considerable interest in the functional comparisons between these two groups of milk protein ingredients and the extent to which they may substitute for one another in product formulations. For example, studies using model whipped topping systems suggest that high-protein MPCs give emulsion and foaming properties comparable with those provided by sodium caseinate.

Proprietary technologies other than UF are used frequently to enrich protein content in skim milk-based concentrates so that the resulting products may also be described as MPCs. An investigation by the United States Trade Commission in the early 1990s concluded that such practices at the lower end of protein enrichment (typically MPC-42) did give rise to some trade distortion through displacement of regular skim milk powder markets, but recognized that innovation in functionality was a key driver behind technological developments in the manufacture of MPCs with higher protein contents.

The antecedent in ingredient terms to MPCs would have been the so-called 'coprecipitates', that is, adapted casein coagulation processes that succeeded in coprecipitating whey proteins and caseins. These relatively crude processes relied on the use of added calcium chloride and/or heat treatment in order to entrap whey proteins during aggregation and precipitation. The resulting weaker curd was more difficult to recover and had poor functionality following subsequent drying. Although at the time they were regarded as nutritionally superior to caseinates due to the incorporated whey proteins, coprecipitates never gained significant market attention because of limited functionality. Concerted research efforts by Australian and New Zealand researchers during the 1970s led to some process refinements; however, market application never succeeded in getting beyond the use of coprecipitates in nutritionally fortified biscuits.

UF-Based Manufacture of MPC

The use of high-quality milk is emphasized for MPC manufacture given that relatively modest levels of heat treatments are used, particularly during the early processing stages (milk preheating, cream separation, skim milk pasteurization). Consequently, surviving microorganisms, spores, and any enzymes resulting from microbial activity will be retained by UF membranes and concentrated over the course of processing. UF processing at industrial level may be undertaken at either 10 or 50 °C, but the lower temperature is now generally preferred in order to limit microbial proliferation and enzymatic activity.

A typical manufacturing process for obtaining MPC involves UF of skim milk with or without the use of diafiltration. The resulting retentate, depending on the desired level of protein enrichment, is subjected to preheat treatment ideally in a steam infusion heater, evaporation in a one- or two-stage falling-film tubular evaporator, and spray-drying, preferably in a tall-form spray dryer, followed by 'after-drying' and cooling in an external fluid bed. Since the viscosity of the retentate increases as proteins are selectively enriched, the capacity of UF plants to maximize solid concentration is affected by a rapid decline in permeate flux across UF membranes; hence, additional thermal evaporation is necessary in order to increase retentate solids further so that the resulting spray-dried product has desired physical characteristics such as bulk density.

Effect of Processing Conditions on MPC Quality

Concentration and drying affect the quality of milk powders to varying degrees, mainly because of the exposure of highly concentrated constituents to the prevailing thermal conditions. Modern spray-drying approaches have evolved to minimize some negative effects through the use of multistage drying, and reduction of residence time in the primary drying zone. However, it is to be expected that the protein-enriched nature of MPC is likely to be even more challenged during drying given that the typical ionic environment provided by the soluble salts of milk has been depleted during membrane filtration. This may well be a factor associated with variability in the functionality of commercial MPCs on the market. A survey of MPCs from 10 different countries revealed wide variation in MPCs with respect to solubility, viscosity, foaming, and emulsification. A small number of high-protein MPCs gave emulsion and foaming properties in a model whipped-topping system comparable with those of sodium caseinate. Only four selected MPCs, with a protein content ranging from 82 to 86%, showed correlation between solubility and factors such as protein content, pH, and viscosity.

Properties of MPC-70 affected by spray dryer outlet temperature include moisture, water activity, bulk density, particle size of subsequently hydrated material, as well as rate of hydration. However, protein denaturation, foaming, and emulsion properties are unaffected by outlet temperature within the range of 65–90 °C. An increase in the inlet temperature (from 200 to 300 °C) causes an increase in the volume-weighted particle size *D*(4,3) and mean particle size *D*(0.5). The ease of dissociation of hydrated particles decreases significantly as the inlet temperature decreases. An increase of 4 °C in retentate heating temperature at 72 °C increases viscosity by 26% prior to spray drying MPC-80. A change to 76°C does not affect the volume-weighted particle size *D*(4,3) or mean particle size *D*(0.5), but results in increased surface-weighted particle size *D*(3,2) and decreased surface area. Milk powder insolubility is a particular challenge during spray drying because of thermal exposure of concentrated heat-labile components at the advanced stages of the process. MPC appears to be even more sensitive to heat at higher moisture contents than skim milk powder and the concomitant concentrations of lactose and minerals present also contribute to insolubility. Insoluble material consists of large particles (~100 μm) where the casein micelles are fused together by some form of protein–protein interactions. The amount of insoluble material in MPC powders increases with storage time at elevated temperatures and consists predominantly of α- and β-caseins. This material, formed largely by weak non-covalent (hydrophobic) protein–protein interactions, is dissociable under sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) conditions. Disulfide-linked protein aggregates (analyzable by two-dimensional (2D) SDS-PAGE) present in MPC powders consist of κ-casein, β-lactoglobulin, and some α_{s2}-casein, and may not always be sedimentable. While it is speculated that the insolubility of the MPC-85 is due to cross-linking of the proteins at the surface of the MPC-85 powder, further evidence is emerging to suggest that protein dissociation (particularly κ-casein) takes place from casein micelles at an advanced stage of MPC processing, and the subsequent aggregation of this associated protein along with β-lactoglobulin contributes to insolubility through the formation of a 'skin' on the surface of powder particles. However, other mechanisms, such as cross-linking of the proteins by hydrophobic and/or hydrogen bonding, are not ruled out. Lactosylation is also mentioned as a possible contributor, although it is not clear whether there is sufficient residual lactose present, particularly in high-protein MPCs, for this to happen. On the other hand, there is evidence to suggest that lactosylation gets underway in the early stages of milk processing.

Applications of MPCs

MPCs are being used increasingly as milk protein ingredients in food formulation, cheese, and health-related products.

Food Emulsions

The surface coverages of emulsions made with MPC-85 are approximately 10× greater than those prepared using sodium caseinate or whey protein concentrate although MPC-85 is less efficient as an emulsifier due to the more aggregated nature of its protein. However, emulsions made with the large casein aggregates found in MPC-85 and skim milk powder are more stable to creaming than those made with caseinate. It is believed that the protein aggregates in MPC may be too large to cause significant depletion flocculation, or alternatively, that they trigger a high degree of depletion flocculation and thus form very viscous emulsions, which will also reduce creaming. A comparison of emulsion properties in simple oil-in-water emulsions with those in the model coffee whitener formulation shows that the lower emulsifying ability of aggregated protein may be partially compensated by the addition of other ingredients.

Cheesemaking

Developments in UF technology in the early 1980s heralded new opportunities for pre-concentration of milk prior to cheesemaking. Greater productivity was anticipated since the classical separation duties associated with syneresis during cheesemaking could be supplanted by prior concentration using UF. Certain categories of cheeses, for example, cast and structured Feta, were readily adapted to the new technology. Greater problems, however, were encountered when adapting the traditional manufacturing processes of more established semi-hard cheese varieties. The formation of heavier milk coagulum during gelation and its subsequent handling demanded the construction of special handling equipment. The APV SiroCurd process was developed for the manufacture of Cheddar cheese from partially concentrated UF retentate. While the prospect of increased yield was an initial driving force behind commercialization of the technology, at the end of the day retained whey proteins gave rise to textural deficits and bitter flavors during ripening. As a result, the cheese manufacturing industry took a conservative view and continued to rely on traditional processes. In the meantime, UF milk retentates as they were initially known became firmly established in the market in the form of dried MPCs with a protein in dry matter content varying from 42 to 90%. Increasingly, these MPCs are finding their way back into cheesemaking for the purpose of protein standardization of cheese milk or as part of innovative processes for whey-less cheese manufacture.

Standardization of the protein content of cheese milk using MPC or similar protein-enriched sources has a beneficial effect on Cheddar cheese yield. An increase in milk protein from 3.3 to 4.0% improves milk fat and protein recovery in cheese, reduces cheese moisture, and increases the moisture-adjusted yield per 100 kg of milk, particularly when cheese milk protein is raised from 3.3 to 3.6% using MPC. Protein retention and cheese yield are also increased when MPC is used to fortify milk protein to 5.38% (Mozzarella) or 5.42% (Feta). Cheddar made from 4.56% protein milk and the Mozzarella and Feta show no defect in sensory characteristics when comparing fortified with control vats.

Addition of MPC also improves the yield of pizza cheese manufactured irrespective of whether culture-based fermentation or direct acidification is used. In the case of reduced-fat Cheddar cheese, improved recovery of total solids may double the yield and also contribute to less brothy and bitter scores. Lowering the setting pH of whole milk standardized with MPC-64 to pH 5.6–5.8 during the manufacture of low-moisture part-skim Mozzarella made by direct acidification improves meltability and produces a softer cheese.

Cheese functionality may also be modified by adapting MPC processing conditions, for example, partial depletion of β-casein using cold microfiltration of milk results in less firm cheese with a lower storage modulus and higher meltability and flow.

If early application of UF for pre-concentration of milk for cheesemaking was problematic, then it certainly would appear to have enthused researchers in the meantime to find solutions given the number of patents that are being filed steadily claiming innovation in the application of MPCs for whey-less cheese production. A whey-less process for production of natural Mozzarella cheese features the use of dry ingredients such as MPC and anhydrous milk fat in combination with whey protein concentrate, whey protein isolate, calcium caseinate, sodium caseinate, rennet casein, acid casein, and non-fat dry milk. White-brined cheeses with a protein content ranging from 12 to 17.0% but with similar total solids (approx. 40%) may be produced by direct recombination using MPC, skim milk powder, and anhydrous milk fat. Owing to the limited syneresis and the use of milk powders, considerable amounts of whey protein nitrogen (0.17–0.26%) and lactose (1.6–5.9%) were retained in the experimental cheese at the end of ripening. In addition, increasing protein content appears to hinder proteolysis.

The rehydration behavior of proteins prepared using typical MPC processes impacts on the quality of cheeses made subsequently. Calcium depletion by cation exchange during the preparation of MPC or MPI with >70% protein in dry matter enables cheese to be produced that is free from nuggets (thin protein gels of a different color from the cheese). The addition of at least one monovalent salt to MPI or MPC-70 achieves the same effect by enhancing solubility when dried and obviates the need for use of cation exchange treatment. Solubilization may also be improved by adjustment of the monovalent and divalent cation content of MPC during reconstitution.

Gel formation of MPCs containing 35–55% dry matter may be accelerated using defined high shear conditions so that the resulting gel structure is homogeneous and compact in order to achieve the final curd texture and consistency. The kinetics of rennet gel formation are readily favored when MPCs are reconstituted at high protein concentrations. Cast Feta cheese made from MPC-56 dispersions has more defined irregular structure characteristics and a harder texture compared with MPC-85 cheese, which possesses more void spaces, a sponge-like structure, and a very soft texture. Overall, satisfactory cast Feta cheese may be made from recombined MPC-56 and MPC-70, and also with MPC-85 to which lactose is added.

Heat treatment of recombined milk prepared from MPC results in a slower rate of increase in the storage modulus (G') of rennet-induced gels, a reduction in the gelation time, and a decrease in the yield force required to fracture gels. The extent of whey protein denaturation (as a result of heat treatment) is related to the decrease in the G' value of gels as well as the yield force. Rennet coagulation studies conducted on reconstituted non-fat dry milk solutions supplemented with MPC-82, prepared from milks subjected to either of two pasteurization conditions (73 and 85 °C, 17 s) at a protein concentration ranging from 4.65 to 6.25% by weight, showed that rennet clotting time was not significantly influenced by heat treatment, suggesting that whey protein denaturation (12 and 26%) in this instance is not a factor. There is a significant effect of retentate pH on rennet clotting time – samples with added MPC produced from pH 6 retentate have significantly higher levels of ionic calcium.

The total calcium present in MPC increases with increasing concentration of protein; however, the total calcium-to-protein ratio is lower in MPC-90 than in lower protein variants. The level of whey protein denaturation, the presence of κ-casein–whey protein aggregates in the supernatant after centrifugation, and the amount of caseins dissociated from the micelle increase as MPC protein concentration in the powder is raised. The total amount of casein macropeptide released is lower in samples from powders with a higher protein concentration than for MPC-56 or the skim milk control.

The gelation time of MPC dispersions (5% protein) is considerably lower and the gel modulus higher than those of reconstituted skim milk with similar protein concentration. When MPC dispersions are dialyzed against skim milk, a significant decrease in the gelation time and modulus occurs, with a complete loss of gelling functionality when MPC-90 is dispersed in water. This demonstrates that ionic equilibrium is central to the functionality of MPC.

Processed and Analogue Cheeses

A relaxation of the regulatory requirements governing minimum inclusion of natural cheese is accompanied by greater substitution with MPC in processed cheese formulations. Hence, research is currently addressing the relationships between processing conditions, particle size in MPC, emulsifying salt conditions, and final product characteristics in order to improve the understanding of the physicochemical relationships in the processed cheese systems. Emulsifying salts such as tetrasodium pyrophosphate (TSPP) induce gelation in reconstituted MPC dispersions when the added TSPP acts with calcium as a cross-linking agent between dispersed caseins and when the balance between (a reduced) electrostatic repulsion and (enhanced) attractive (hydrophobic) interactions becomes suitable for aggregation and eventual gelation of casein molecules.

A modified MPC, MPI, or micellar casein suitable for use as a complete or partial rennet casein replacer or extender in analogue Mozzarella and processed and imitation cheeses is the subject of an invention in which a high-protein retentate is prepared from pasteurized liquid skimmed milk, whole milk, MPC, or reconstituted milk feedstock and subjected to proteolytic breakdown using an enzyme, for example, chymosin, to modify the protein. The resultant cheeses may be used in frozen pizzas and other food products.

Spread-type processed cheese analogues with a fat in dry matter of ∼43% may be made by substituting up to 30% of rennet casein with MPC-85 powders. The inclusion of MPC increases firmness and sliceability, but decreases meltability. Increasing the NaCl concentration from 1.8 to 2.6% increases cheese meltability, but only slightly affects other physical properties.

Yogurt

MPC may be used as a replacer for skim milk concentrate, skim milk powder, and whey protein concentrate in low-fat set-type yogurt milks with comparable viscosity and syneresis index.

Ice Cream

Substituting the protein content of ice cream mix by up to 50% using MPC results in formulations with higher mix viscosity, larger amount of fat destabilization, narrower ice melting curves, and better shape retention. However, MPC does not result in significant modifications of the physical properties of ice cream when formulated on a constant protein basis with up to 50% replacement of protein supplied by skim milk powder. MPC usage in ice cream formulations may offer ice cream manufacturers an alternative source of milk solids non-fat, especially in mixes reduced in lactose or fat, where higher milk solids non-fat are needed to compensate for the reduced content of other milk constituents. There is also some suggestion that maltodextrin acts as an effective fat replacer in fat-free ice cream where MPC is used as a protein source.

Ice cream enriched with up to 60% more protein in its formulation may also be made by the addition of MPC without impairing texture. In fact, ice crystal size is favorably reduced at protein fortification levels up to 30%.

Spreads

Combinations of sodium caseinate and MPC-50 (3:1 ratio, respectively) perform more satisfactorily as emulsifying and stabilizing agents in model low-fat spreads provided that there is a minimum protein content of 11.7% in the aqueous phase. Viscosity control and protein solubility are judged to be more critical functional attributes than surface activity.

Coffee Cream and Whipping Cream

MPC addition may also be used to improve the keeping quality of coffee cream and whipping cream. For coffee cream, it is concluded that increasing milk protein content by 2–6 g kg^{-1} is sufficient to reduce the risk of cream separation. A complete replacement of carrageenan by MPC in whipping cream is not recommended, and it is recommended to use a combination of carrageenan and MPC in order to achieve optimal results.

Protein–Polysaccharide Interactions

The dilemma posed by the use of polysaccharides in dairy foods to increase viscosity and improve stability raises concerns about the potential risk of phase separation taking place. When milk protein ingredients (skim milk powder, MPC, whey protein isolate, and sodium caseinate) are combined with xanthan gum or κ-carrageenan in aqueous solutions, viscosity decreases markedly with increased shear rate. At low shear rates, the viscosity of the milk protein containing dispersions is higher than that of xanthan gum alone. Protein particles also appear to be more homogeneously suspended in solutions containing xanthan gum or κ-carrageenan.

Added pectin disrupts native intact casein micelles during acid-induced gelation of MPC, which is evident from a gradual change in shear modulus. On the other hand, a synergistic effect is obtained when pectin is added to dissociated casein at a later stage of acid gelation.

Nutritional and Therapeutic Products

'Clinically lactose-free formulae' for lactose-intolerant applications may be prepared using MPC. A formulation of an enzyme-treated easily digested MPC, named Unipro 50, containing 50% protein, 33% carbohydrate, 3% fat, minerals, and vitamins is aimed at therapeutic and sports applications. Solubility is improved by the addition of phosphatidylcholine and by granulation.

A patented immunization protocol that results in increased production of IgA in ruminant milk was accomplished by immunizing cows with a common pathogenic yeast, *Candida albicans*, resulting in the production of elevated levels of antigen-specific IgA antibodies in their milk. The resulting spray-dried MPC-80 reduces adherence of *C. albicans* cells in *in vitro* adherence assays. A special MPC prepared from the milk of hyperimmunized cows, previously shown to express anti-inflammatory and anti-arthritic activity in humans, has also been shown to be effective in the treatment of orthopedic disabilities of dogs.

A translucent milk-based drink may be obtained by passing a modified milk protein (selected from skim milk, MPC, or MPI) in the pH range 5.7–6.5 through a cation exchanger until the percentage transmission increases to at least 40%. The treated milk may be used as a base for a carbonated milk beverage that is nutritionally superior to conventional carbonated soft drinks. The beverages may contain vitamins, preservatives, thickeners, and flavor enhancers.

Selenium-enriched (1 mg kg^{-1}) MPC is superior to yeast Se in terms of Se bioavailability and capacity to suppress colonic oncogenesis. Suppression is believed to be a consequence of more effective enhancement of apoptotic deletion of DNA-damaged cells and the subsequent reduction in the frequency of K-ras mutations. Consequently, supplementation of Se via dairy products is a practical and effective approach to increasing human Se intake and preventing colorectal cancer.

Introduction

The industrial production of casein from bovine milk has been ongoing for most of the last century. Initially, the majority of bovine casein produced was used for technical (or non-food) applications, such as in glues. Since the 1960s, there has been a significant change from technical to edible uses of casein products, with caseins now regarded as high-esteem food ingredients used in a vast array of dairy products such as cheese analogues, yogurts, and powdered coffee creamers, while also being extensively used in nondairy food products such as beverages, bakery, and convenience foods, and in numerous nutritional, medical, and pharmaceutical applications. World production of casein products is currently estimated at 325 000 tonnes per annum; New Zealand and the European Union are the major producers of casein with Japan and the United States being the main end-user markets. This article describes the industrial processes used for production of casein ingredients, their compositional standards, and some regulatory aspects of the main casein products.

The Manufacture of Casein/Caseinate

A number of commercial casein-derived ingredients may be produced from bovine milk (acid casein, rennet casein, caseinates, and micellar casein). Good-quality raw milk (low bacterial count and low somatic cell count) is a prerequisite for producing high-quality edible casein ingredients. Bactofugation or microfiltration may be used to reduce both the bacterial load and spore count in milk, ensuring a casein product of high microbiological quality. For the production of casein products, the fat is removed from raw milk by centrifugal separation to yield skim milk which is then heat treated prior to manufacture of the casein. Casein is manufactured from skim milk to minimize possible flavor defects arising from deterioration of lipids in the dried casein products. Heat treatments can vary from thermization (65 °C for 15 s) to pasteurization (72 °C for 15 s) to ultraheat treatment of the milk (140 °C for up to 5 s).

Acid Casein

Acidification

When heat treated skim milk (pH ~6.6) is acidified, the calcium and inorganic phosphate are removed from the casein micelles, the net charge on the micelles decreases, and the micelles become less and less stable until the casein precipitates. Complete precipitation of the casein occurs at the isoelectric point, pH ~4.6. Precipitation can be achieved by acidification of the milk by one of the following processes:

1. Inoculation of milk with lactic acid-producing bacteria such as *Lactococcus lactis* subsp. *lactis* or *cremoris*. These bacteria, commonly known as starters, convert some of the lactose in the milk to lactic acid during the period of incubation (~16–18 h) at ~30 °C. This is the most commonly employed method of manufacture in New Zealand (**Figure 1**).
2. Chemical acidification which involves the direct addition of a dilute mineral acid (typically 1–2 mol l^{-1} HCl) or carbonic acid (CO_2 is added under pressure and combines with H_2O forming carbonic acid) into the milk at ~30 °C (**Figure 1**). Sulfuric acid is more commonly used in New Zealand.
3. Indirect acidification of skim milk by mixing milk (pH 6.6) at ~10 °C with sufficient cation exchange resin in the form of hydrogen to allow exchange of cations in the milk for the H^+, resulting in a milk acidified to pH ~2.0; separation of the acidified milk and resin and subsequent mixing of this acidified milk with untreated milk to achieve the desired pH. A number of alternative processes have also been patented in which skim milk is acidified by (1) addition of acidified whey or (2) electrodialysis. It is believed that these processes have relatively minor commercial significance.

Cooking/Acidulation

In the manufacture of acid casein, acidification of the milk is followed by heating of the mixture. Heating promotes agglomeration of the casein curd particles which subsequently synerese (shrink) to expel whey. At the same

time, the curd becomes firmer and is able to withstand the mechanical processing that follows. Heating of the acidified milk is sometimes termed 'cooking' (as used in cheese manufacture) and may be carried out, usually in the temperature range 45–60 °C, by:

1. Direct injection of steam into the pipeline carrying the acidified milk.
2. Indirect heating by means of a heat exchanger.
3. A combination of both of the above – preheating through a heat exchanger, with steam injection to complete the heating process (**Figure 1**).

In each case, the cooked curd and whey are held in a 'cooking pipe' for a period of about 10–60 s before they emerge into an 'acidulation' vat. The curd and whey may remain here for a period varying from 30 s to about 15 min, during which time the curd is gently agitated in the whey until equilibrium (especially between the calcium in the curd and that in the whey) is attained. Alternative processes may employ a 'syneresis tube'; the cooked curd and whey are held in a large-diameter tube for a period of several minutes (also undergoing acidulation or equilibration).

Dewheying and Washing

Following acidulation, the curd is separated from the whey using vibratory, moving, or stationary inclined nylon or stainless-steel mesh screens, or polyester fabric screens in a cascade arrangement, or using mechanical devices such as a horizontal bowl centrifuge (decanter) or a roller press. A combination of screening and decanter dewheying can be used to reduce the hydraulic load on the decanter. After separation of the curd from the whey, the curd is washed with potable water to remove residual whey constituents such as lactose, salts, and whey proteins. The temperature of the wash water may be varied, depending upon particular requirements. Washing systems used include multistage countercurrent systems and countercurrent tower washing systems with wash cycle temperatures varying in the range of 35–75 °C (**Figure 1**). A gradient of purified wash water is normally used where the curd is washed in a counterflow to the direction of the curd, with the purest curd meeting the cleanest water. Sufficient washing of the curd is normally achieved using minimum volumes of wash water.

Dewatering

After washing, the curd is mechanically 'dewatered' to minimize the quantity of water to be removed during the subsequent drying. As drying is a relatively expensive operation, it is obviously worthwhile to remove as much water as possible from the curd before transferring the casein to the drier. The texture of the curd is affected by temperature; as the temperature of the wash water is increased, the curd releases more water during dewatering but becomes tougher and more plastic and is consequently harder to break up and dry. Therefore, it is necessary to regulate carefully the temperature at the end of washing to optimize the conflicting requirements of minimum water content and maximum friability of the curd. Equipment for dewatering casein curd consists of roller or belt presses or decanting centrifuges. Roller press, which has been in use for many years, is designed to reduce the moisture content of the curd to ~55%. Belt press will also reduce the moisture content to a similar level. Solid bowl decanters or screen bowl centrifuges are capable of reducing the moisture content of acid casein curd to ~45–55%.

Drying

In accordance with internationally recognized compositional standards for edible casein products, the casein curd is dried to a final moisture content of <12%. Drying of casein curd is commonly carried out using a horizontal vibrating fluid-bed drier. This drier has two or more perforated stainless steel decks (**Figure 1**). The combined effect of vibration of the decks and the flow of hot air (typical temperature range 75–115 °C) up through the holes in the decks causes the casein curd to become fluidized and materially helps in the removal of moisture from the particles. Most of the water is removed during the early stages of drying of the casein, as it is evaporated from the surface of the particle. The later stages of drying require the transfer of moisture from the centre to the surface of the particles, and this is a much slower process. Pneumatic-conveying ring driers and attrition driers are also widely used for drying casein. A pneumatic ring drier consists of a large stainless-steel ring-shaped duct through which high velocity, heated air, and moist, disintegrated casein curd are circulated continuously prior to being classified into dry and moist particles according to density differences using centrifugal forces; the dry casein particles are then collected and removed from the drier while the semidry casein is returned to the duct for further drying. The dry casein particles are then conventionally milled. Attrition drying involves grinding and drying in a single operation; the drier consist of a fast-revolving multichambered rotor and a stator with a serrated surface. Turbulence, vortices, and cavitation effects in the drier result in highly efficient grinding that pulverizes the casein curd into very small particles which are simultaneously dried in a hot air stream that flows through the drier with the curd to produce a dry product with an overall average particle size of ~100 μm (similar to spray dried casein). Attrition driers also employ internal classifiers, which grade the casein particles based on size.

Cooling, Tempering, Milling, Sifting, Blending, and Packing

Casein produced using fluid-bed or ring driers is warm and soft and unsuitable for immediate grinding in some types of mills, such as the roller mills. Consequently, the casein may be cooled and then transferred to 'tempering' bins where equilibration of moisture can occur in and between all the particles during a period of 8–24 h; this is often followed by blending to achieve a uniform moisture content.

The casein may then be ground and sieved, using multideck, gyrating screens, into various particle sizes, usually <600 μm. Very fine casein (e.g., <150 μm) is generally produced using pin mills. Blending after sifting is often used to achieve uniform particle size of the product.

Table 1 Typical composition and properties of commercial casein and caseinate products

	Acid casein	*Rennet casein*	*Sodium caseinate (Spray dried)*	*Micellar casein (Spray dried)*
Composition	*Amount per 100 g*

Dried acid casein is usually classified using 30-, 60-, 90-, and 120-mesh sieves which correspond to mesh openings of 595, 250, 175 and 125 μm, respectively.

Casein is then packed into 25 kg multiwall paper bags with plastic liners and stored. A typical composition of acid casein is shown in **Table 1**.

Rennet Casein

Clotting of Skim Milk

In the manufacture of rennet casein, heat-treated skim milk at its natural pH and at ~30 °C (or lower) is mixed with a proteolytic enzyme preparation such as calf rennet or, increasingly, genetically engineered chymosin or rennet substitutes such as microbial (aspartic) proteinases in the approximate ratio (by volume) of 1:7500 and held for 20–40 min to induce clotting of the casein. If a lower temperature setting is used, renneting time must be correspondingly increased. It is also possible to reduce the quantity of rennet added under these conditions and consequently allow a longer time for the renneting action to occur. Nevertheless, renneting results in cleavage of the κ-casein on the surface of the micelles to form para-κ-casein and soluble glycomacropeptides; consequently, the modified casein micelles become susceptible to the calcium present in the serum phase of the milk and coagulate at temperatures above 20 °C.

Cooking

The usual technique for the cooking of rennet casein involves the injection of steam into a cooking line of coagulum pumped from a vat. However, the vat cooking technique (similar to that used in cheese manufacture) is also practiced in some countries. The cooking temperature employed in making rennet casein usually varies in the range of ~50–60 °C. Where indirect cooking of rennet casein is employed, a tubular heat exchanger may be used to cook the curd and whey to a temperature similar to that used in the ‘direct cook’ (steam injection) process. Other processing steps are similar to those described above for acid casein, and no acidulation step occurs after cooking of the rennet casein.

A typical composition of rennet casein is shown in **Table 1**. As no acid is added during the manufacture of rennet casein, the calcium and inorganic phosphate associated with the casein in the micelles are retained in the casein. Consequently, rennet casein has a much higher ash content (consisting of the oxides of calcium and phosphorus), and a correspondingly lower protein content, than acid casein (**Table 1**). Rennet casein is also devoid of caseinomacropeptide which is lost in the whey resulting in a reduction in yield by ~4%.

Caseinates

Acid casein is not soluble when redispersed in water but can be solubilized by the addition of alkali to produce caseinates. A number of caseinates are available which vary with respect to the method and the counter ion used for manufacture. All caseinates are substantially water soluble and are typically prepared as a solution of ~20% solids prior to spray drying. Roller-dried caseinates may be prepared from more concentrated solutions. It is also possible to prepare granular, partly soluble, or semidispersible forms of caseinate in which the casein and alkali have only been partly reacted. Conversion of casein to caseinate in the presence of a limited amount of water can also be achieved using extrusion techniques. Spray-dried sodium caseinate is the most common form of the water-soluble casein used in food applications. Sodium caseinate is prepared by mixing wet acid casein curd with water at 40 °C to a solid content of about 25% (or alternatively, dry acid casein in a slurry with water) prior to passing it through a colloid mill. NaOH (~2.5 mol l^{-1}) is mixed with the slurry to give a final pH of 6.6–6.8. The viscous slurry is then vigorously agitated and heated to ~75 °C in a series of vats to complete solubilization and then further heated to 95 °C in a plate heat exchanger. The pH of the solution is adjusted with NaOH, if necessary, to give a caseinate of the required pH; the viscosity of the solution is measured and controlled by addition of hot water, if necessary, ensuring efficient atomization, and the sodium caseinate solution is then spray dried (**Figure 2**). The dried powder dissolves completely in water to produce a viscous, sticky, straw-colored solution.

When Ca $(OH)_2$ is used as the base, calcium caseinate is produced, which gives a thin, opaque, white colloidal dispersion similar in appearance to milk, when dispersed in water. Other caseinates, such as those of potassium and ammonium, are similar in general properties to sodium caseinate. Magnesium caseinate has properties that are intermediate between those of sodium and calcium caseinates. However, relatively insignificant commercial quantities of these products are manufactured at the present time. A typical composition of sodium caseinate is shown in **Table 1**. On a moisture-free (dry) basis, it has a slightly lower protein content than the acid casein from which it is made, as a result of the sodium incorporated into it on reaction of the casein with sodium hydroxide (or other sodium alkali).

In the great majority of applications, in both edible and technical (non-food) uses, casein must first be made soluble before it can be employed in its final application. In the case of technical applications, most users dissolve the casein at their own factories. For edible applications, however, some users will themselves convert the dry casein to caseinate, whereas others tend to purchase the caseinate directly from the producer.

Micellar Casein

Micellar casein, generally referred to as phosphocaseinate, has compositional and physical characteristics similar to those of the native casein micelles in milk.

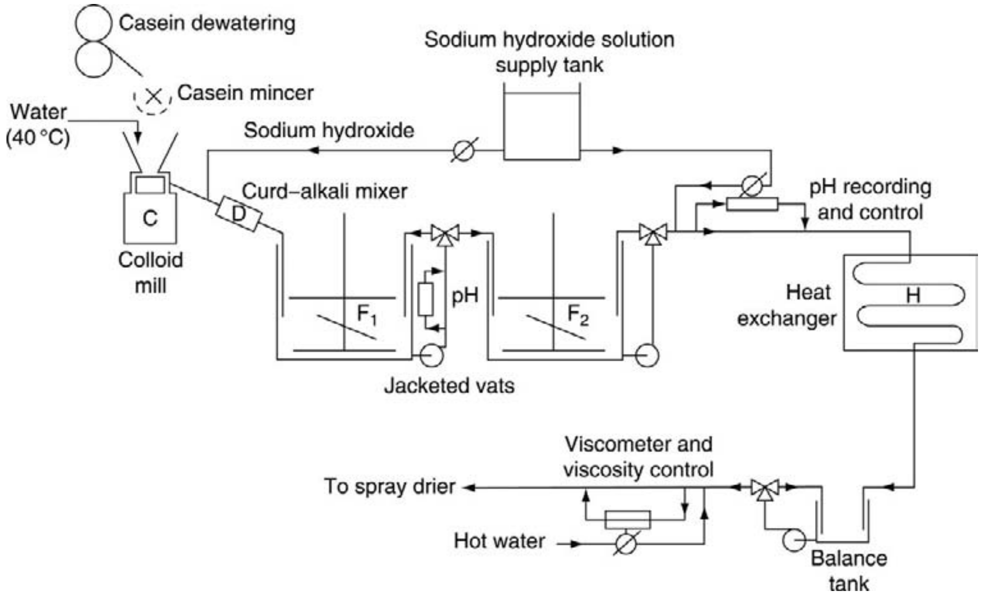

Figure 2 Suggested plant layout for dissolving casein in sodium caseinate manufacture. Dewatered casein curd is minced, mixed with water, and finely milled in a colloid mill (C). The curd–water slurry is then mixed (D) with dilute sodium hydroxide solution and transferred to the first of two jacketed dissolving vats (F_1) each equipped with an agitator. The sodium caseinate solution is subsequently pumped from the second dissolving vat (F_2) and extra alkali is added if necessary. The solution is heated by means of a tubular heat exchanger (H) and then pumped via a balance tank to the spray (or roller) drier for drying. The viscosity of the solution may be monitored and reduced, if necessary, by addition of hot water. Reproduced with permission from Southward CR (1985) Manufacture and applications of edible casein products. I. Manufacture and properties. *New Zealand Journal of Dairy Science and Technology* 20: 79–101.

In contrast to casein that requires the partial or full disruption of the casein micelle, micellar casein is manufactured by microfiltration at ~10 or 50 °C of heat-treated skimmed milk that has been standardized at pH 6.6 using a suitable membrane of pore size 0.1–1.0 μm that allows permeation of the serum proteins, soluble constituents, and low molecular weight nitrogenous compounds (peptides and free amino acids), whilst retaining the intact casein micelles. Other soluble permeable constituents are removed by ultrafiltration, which is often followed by diafiltration with water, and the retained solution (retentate) is spray dried. A typical composition of micellar casein is shown in **Table 1**.

Annual Production of Casein and Caseinate Products

The data in **Table 2** show the annual production of casein and caseinate products by the principal casein-manufacturing countries during the period 1994–2007. Major producers are New Zealand, France, and the Republic of Ireland.

New Zealand, like Australia and the Republic of Ireland, exports essentially all of its casein products, whereas the European countries engage in the import and export of casein products, some of which are used for domestic consumption.

Regulatory Aspects

Definition

From a regulatory and commercial perspective, casein is defined as a mixture of phosphoproteins obtained from cow's milk. The water-soluble salts of casein (produced by reacting acid casein with food-grade alkalis, neutralizing agents, enzymes, buffers, or sequestrants) are known as caseinates. Casein can be described as an off-white to cream colored, amorphous powder or granules without odor or taste, derived from the coagulum formed by treating skim milk with a food-grade acid (acid casein), enzyme (rennet casein), or other food-grade precipitating agent. It is very sparingly soluble in water and in nonpolar organic solvents, but is soluble in aqueous solutions of alkalis. It can be dissolved with some difficulty in acids. Thus, it can be considered amphoteric, forming salts with both acids and bases.

Compositional Standards, Specifications and Methods of Analysis of Casein Products

Standards for the composition, sensory and physical properties, and microbiological quality of casein products are shown in **Tables 3** and **4**. These standards have been issued by the European Union and the United States, and by international organizations such as the

International Dairy Federation (IDF) and the Food and Agriculture Organization of the United Nations/World Health Organization (FAO/WHO). These organizations collaborated within the Codex Alimentarius Commission to produce the Codex Alimentarius internationally recognized standards and specifications for casein products (**Table 3**). In addition, most casein manufacturing and exporting companies have issued their own standards and specifications for casein products (**Table 4**), and many large users and buyers of casein products also have their own specifications. The majority of these standards and specifications are not published, but remain confidential to the buyers and sellers involved. Although the responsibility for the safety and suitability of casein products lies with the manufacturer, the code of hygienic practice for milk and milk products (CAC/RCP 57-2004) provides guidance to reach an appropriate level of public health protection for the product at all stages of production.

All standards and specifications must be related to standard methods of analysis. Official methods for the analysis of casein products are published by organizations such as the IDF and the Food Chemicals Codex, and by many individual countries' food regulatory authorities. Recommended methods of analysis and sampling of casein products are listed in Codex Standard 234-1999. In addition, nutritional evaluation

Table 5 Industrial safety properties of casein

Property	*Value/comment*
Chemical Abstracts Service registry number	9001-71-9
Boiling point/melting point	Dry casein does not melt or boil, but will char and decompose at sufficiently high temperature (e.g., >150 °C)
Reactivity with air	Nonreactive under normal conditions of storage (e.g., temperature 20-25 °C; relative humidity <70%)
Reactivity with water	Absorbs water and swells to about twice its dry volume. In this wet state, it can be degraded by bacteria and molds within a few days
Explosibility of dust	
Minimum ignition temperature	460 °C
Minimum ignition energy	60 mJ
'Lower limit of ignition'	45 g m^{-3}
Maximum rate of pressure rise	8500 kPa s^{-1}
Maximum explosion pressure	450 kPa
Density	
Bulk density of powder in air	0.5–0.6 g ml^{-1}
Water-free density of particles	1.36 g ml^{-1}
Health hazard information	
External (skin)	Very low risk. Not normally causing skin irritation, but has been known to produce itching and eczema on the skin, face, hands, and arms of persons sensitive to milk protein
Inhaled	Low risk. Not normally causing occupational respiratory disease but has been known to cause asthma in persons sensitive to milk protein

test procedures (for measurement of protein quality by means of rat bioassay and chemical methods) are published by the Association of Official Analytical Chemists (AOAC).

Health Aspects

The health aspects of casein and caseinates as food ingredients were reviewed in 1979 by the Federation of American Societies for Experimental Biology. It was concluded that there is no evidence to suspect a hazard from the use of casein or caseinates in food or packaging materials at current or expected future use levels. An assessment of caseinates as food additives has also been undertaken by the Codex Alimentarius Commission. That body has prescribed consumption of a food additive in terms of its acceptable daily intake (ADI). The ADI is defined as the amount of a food additive, expressed on a body weight basis, that can be ingested daily over a lifetime without appreciable health risk (standard man = 60 kg). The ADI is expressed as milligrams of the additive per kilogram of body weight. The phrase "without appreciable health risk" is taken to mean "the practical certainty that injury will not result after a lifetime's exposure".

In 1983, the ADI for sodium caseinate was declared 'N.S.' (not specified), meaning that, in the opinion of the Joint FAO/WHO Expert Committee on Food Additives, the total daily intake of the substance, arising from its uses in accordance with good manufacturing practice, does not represent a hazard to health; for this reason, the establishment of an ADI is not deemed necessary.

Safety Aspects

Numerous standards (for instance, as Material Safety Data Sheets) have been issued for the safe handling of compounds and chemicals that are used industrially. Such safety aspects have also impacted casein because of its long history of use in technical, nonfood, uses, for instance in glues and adhesives, paper coatings, and plastics. A list of the properties of casein relevant in terms of its industrial safety is shown in **Table 5**.

Membrane-Based Fractionation

Reverse Osmosis

Considerable pressures are required to reverse the transport phenomenon (osmosis) that prevails when water migrates across a semipermeable membrane in order to equilibrate the osmotic effect created by solutes present in the solution on the other side of barrier. The effect is demonstrated classically when water and sucrose solution are separated by a semipermeable membrane. Hence, whey with its relatively high content of lactose (~5.0%) was originally seen as an appropriate medium for the application of reverse osmosis (RO) technology as an economical means of dewatering.

In skim milk or whey, the osmotic pressure is around 0.7 MPa, a pressure that must be exceeded in RO before permeate (i.e., essentially water) will flow through the membrane. However, when milk or whey is concentrated by RO or evaporation to 25% total solids (commonly referred to as retentate), the osmotic pressure increases to 2.7–3.5 MPa. Thus, the osmotic effect of increasing lactose and mineral concentration in RO retentates limits both permeate flux and maximum concentration achievable. During the course of RO, component transport occurs by diffusion through the membrane, or essentially through the thin layer of the membrane which is semipermeable, and the porous remainder of the membrane is merely a support. The rate of transportation is proportional to the solubility of the component in the membrane and to its effective diffusivity. Factors diminishing the effective pressure difference during operation include the increasing concentration gradient near the membrane's surface as well as the likelihood of gel layer formation.

Nanofiltration

Like RO, from which it evolved, nanofiltration (NF) is also a pressure-driven membrane separation process which is capable of reversing the osmotic effects of liquids (**Figure 1**). In addition to dewatering/concentration, simultaneous transmission of ions represents a further bonus in certain processing applications, as NF membranes are also partially permeable to mineral ions and other low molecular weight constituents. NF membranes are usually fabricated as thin-film composites by forming, for example, a polyamide layer on a microporous polysulfone (PS) support to give surfaces rich in carboxylate groups.

At the time of its introduction to the dairy industry during the 1980s, a variety of terms were used to identify this membrane process, for example, Loose RO, Leaky RO, and a proprietary term Ultra-OSMOSIS®. NF is now the adopted nomenclature, as separation of solutes occurs in the nanometer (10^{-9} m) range. A size exclusion range of 10–100 Da suits the permeation of water, mineral ions, and low molecular weight nitrogenous compounds. However, some lactose is also lost.

NF membranes are highly selective to the permeation of monovalent ions (~55%), for example, Na^+ and K^+, but have a high rejection of cations (~90%) such as Ca^{2+} and Mg^{2+}. Ion removal is also susceptible to the Donnan effect, and this has been demonstrated by addition of citrate to increase the permeation of chloride in the case of acid casein whey.

Lactose losses of 1–2% demand the biological treatment of permeate before waste discharge. Ongoing efforts at improving the performance of NF membranes suggest that attempts at reducing lactose losses are likely to be at the expense of mineral permeability.

Ultrafiltration

Ultrafiltration (UF) is a membrane filtration process that separates components on the basis of molecular sieving. Macromolecular material such as protein (and fat if present) is readily recovered from solutions such as whey, while lower molecular weight material (lactose, minerals, other solutes, and water) permeate the membrane. UF operates at much lower pressures when compared to RO and NF, with transmembrane pressures of 70–170 kPa being typical.

The transition from earlier cellulose acetate membranes to polymeric membranes has played a significant role in providing the dairy industry with protein separation processes that are operationally robust and hygienic. A variety of polymers may be used, but the more commonly used membranes are constructed of either a PS or a polyethersulfone (PES) active layer deposited on a more porous PS support. Other polymers in use include polyvinylidene fluoride (PVDF) and

polyacrylonitrile (PAN). Modifications to the surface layer of membranes have also been suggested in order to improve performance with more difficult products (see 'Fouling'). Although identified more closely with microfiltration duties, membranes constructed of inorganic materials such as zirconium oxide and alumina are available in UF specification also.

Cross-Flow Microfiltration

Cross-flow microfiltration (cMF), as a pressure-driven membrane separation process, could be described as a more porous form of UF – instead of using a molecular weight cut-off criterion, cMF membranes are usually identified by their pore size cut-off in microns (μm). Fat, aggregated materials, bacteria, and somatic cells are usually retained during cMF, while protein passes through the more porous membrane. Fluid flow is usually tangential to the membrane surface, where its velocity is used to reduce deposit formation, hence the use of terms such as 'cross-flow MF' or 'tangential-flow MF'. The fouling tendency of organic cMF membranes when presented with protein solutions has limited their applications in dairy processes, although the UF-like behavior of a protein-fouled cMF membrane is occasionally exploited. Some of the more interesting, recent developments in the application of membrane processes have taken place, however, with cMF inorganic membranes.

Applications

Preconcentration/Partial Demineralization of Whey

Undoubtedly, the benefit of achieving a partial demineralization (40% max.) of whey during simultaneous preconcentration has been a major factor in the widespread adoption of NF technology, particularly when transporting over geographical distance, for instance, whey from regional cheese production units to large centralized processing plants. The opportunity to upgrade the quality of whey with a high ash content such as acid casein and fresh cheese (Quark, Cottage Cheese) is also appealing. The so-called 'white' whey released from cheese curd during the advanced stages of Cheddar manufacture contains a high level of added salt and may also be recovered using NF.

Permeate preconcentration to produce an enriched lactose concentrate may also be beneficial in some processes. Furthermore, the ion removal role of NF complements other dedicated demineralization processes such as electrodialysis (ED) and ion exchange (IE). The ultimate economic benefit of combining both processes may be specific to the individual circumstances of each case as it arises.

Whey Protein Concentrates and Isolates

Selective concentration of protein in whey by UF is used to produce whey protein concentrates (WPCs) with varying protein contents within the approximate range 20–80%. The upper limit is usually dictated by the residual fat content of the starting whey – fat too is preferentially concentrated along with protein. A commonly traded form of WPCs containing 35% protein (WPC-35) is usually aligned in gross compositional terms with skim milk powder. Thus, whey with its relatively low protein content (~0.7%) is initially concentrated by UF to yield a retentate containing 3–4% protein and ~9% dry matter. This retentate is concentrated further by evaporation before spray drying.

WPC with a higher protein content (e.g., 50–80%) can only be produced by the introduction of a diafiltration step in combination with UF; that is, water is introduced during UF to facilitate the removal of lactose and ionic constituents according as the retentate becomes more concentrated and permeate flux declines.

First-generation whey protein isolate (WPI) (protein content 90%+) products were produced by ion exchange treatment of whey and subsequent concentration of the eluate by UF. However, the later success of cMF using either a 0.1 or a 0.2 μm pore size ceramic membrane in removing the residual fat content of whey (*defatting of whey*) now enables the resulting WPCs prepared by UF to achieve a protein content of up to 90%. Either of the two approaches may be used: (1) separation of flocculated lipid material according to the 'thermocalcic process' by adjusting [Ca^{++}] to 0.03 mol l^{-1}, followed by a pH increase to 6.7–7.2 with heating to ~50°C; or more commonly, (b) separation of unflocculated lipid material by cMF of either unprocessed whey or whey protein retentates obtained following preconcentration by UF. Process optimization is aimed at minimizing protein retention while striving to attain maximum fat removal.

Such delipidation steps have the added benefit of reducing the microbial load in the resulting ingredients produced. This is further aided by the widely adopted 'cold filtration' processing of whey by UF – a technological advance that was greatly facilitated by the robustness, compactness, and cost effectiveness of spiral-wound membrane systems. Exacting microbiological specifications are expected when high protein WPCs and WPIs are incorporated into nutritional products and beverages.

Milk Protein Standardization

The efficiency of manufacturing processes for certain dairy products is improved by standardizing the protein content of the milk feed. Partial preconcentration of cheese milk using UF to increase milk protein content to 4.0–4.5% improves yield during Cheddar cheese manufacture. According to Codex Alimentarius standard Cx 207 for preserved milks, standardization of protein content to a minimum of 34 and 26% for skim milk powder and whole milk powder, respectively, is permissible using permeate produced by ultrafiltration of milk or other permitted ingredients, that is, where the natural milk protein level is in excess of the Codex minimum for milk powders. Conversely, should the naturally occurring protein level fall below the minimum, then the addition of milk protein retentate is permitted to raise its concentration.

Milk Protein Concentrate

Selective concentration of protein in skim milk by UF may be used to produce milk protein concentrates (MPCs) containing up to 80% protein, or more. A particular value of this approach is that the naturally occurring ratio of casein to whey protein (~80:20) is retained, and at the same time steps may be taken during processing to minimize changes to their native structure. The establishment of MPCs' unique functional and nutritional properties, for example, use in recombined dairy products, cheesemaking, and dietetic products, has expanded the markets for high-protein dairy ingredients, which were traditionally dominated by casein and caseinates. MPCs with protein contents of 90% or more are frequently described as milk protein isolates (MPI), and particular attention is given during UF processing to attain such a high degree of protein selectivity.

Native Phosphocasein

Casein in its native micellar form with a total protein content in excess of 80% may now be produced industrially by cMF. Technological developments based on ceramic membranes have been, particularly, to the fore in enabling selective concentration of micellar casein while permitting the permeation of whey proteins and lower molecular weight constituents. The resulting casein retentates may be concentrated further and dried to produce new functional protein ingredients. Also, the cMF 'whey' permeate arising from phosphocasein separation is of high quality and an ideal substrate for further advanced processing and fractionation options.

Skim Milk Powder With Enhanced Renneting Properties

To overcome the negative effect of thermal treatment on the cheesemaking properties of milk powders incurred during milk concentration and drying, a French patent for the manufacture of skim milk powder with superior renneting characteristics exploits the above principle of selective casein separation by cMF in combination with UF of the milk permeate arising from cMF so as to remove its whey protein content. The resulting protein-free permeate is recycled with the native phosphocasein-enriched retentate to reinstate the original skim composition, except for whey protein depletion. A high-quality

WPC is also obtained as a by-product (UF retentate stream) from the process.

Extending the Shelf Life of Retail Milk

The adoption by Tetra Laval of special hydrodynamic considerations – high cross-flow velocities and uniform trans-membrane pressure control (UTMP) – represented a major breakthrough in the successful application of ceramic cMF membranes for bacteria removal (Bactocatch®) from skim milk without the penalty of significant in-process fouling (**Figure 2**).

As a result, the shelf life of retail milk (the so-called liquid milk or market milk) may be increased from a typical 16 days to 42 days by a combination of cMF and thermal processes embodied in the Tetra Therm ESL™ system. It is claimed that the process replicates the sensory and chemical properties of pasteurized milk (72°C, 15 s) with the added benefit of achieving a significantly lower bacterial content. With bacteria reduction being in the order of 90–97% (1–2 log units) in normal pasteurized milk, the Tetra Therm ESL™ process improves this to 3–5 log units (i.e., 100–10 000 times better).

The process is based on dividing milk into its cream and skim milk phases so as to process each stream separately: skim milk is microfiltered using membranes (1.4 μm pore size or less) with high bacteria removal efficiency; that part of the skim milk which is retained by the MF membrane (retentate) is combined with the cream before heat treatment of the mixture at 120–130°C for 2–4 s. The final process steps, namely, mixing of all process streams, homogenization, and pasteurization, are performed in an enclosed system to minimize postpasteurization contamination.

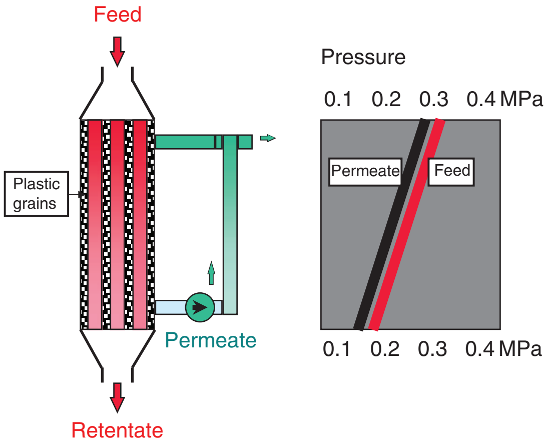

Figure 2 Tubular ceramic membrane module configured with permeate recirculation loop according to the principle of uniform trans-membrane pressure (UTMP) originally patented by Alfa Laval. Note the inclusion of plastic grains in the permeate channels. An alternative approach by APV for achieving a similar permeate pressure gradient is to surround the membrane elements with a contoured shroud within the module.

The claims for the Tetra Therm ESL™ system are based on milk with an initial bacterial contamination of 30 000 ml^{-1}, and may be improved further if the initial microbiological load in the raw milk is lower.

Designs

Membranes and Modules

The processing limitations (restricted temperature and pH tolerance) associated with cellulose acetate-based membranes originally used in the dairy industry were promptly surmounted through developments using polymeric materials. The evolution of different polymer types and their formation are reflected in the terminology now used to characterize various types of organic membranes.

Asymmetric structure

Asymmetric membranes are fabricated from the same polymer material throughout, except that the active separation layer is thin and relatively dense (0.1–0.25 μm) with defined pore size when compared to the porous (~100 μm) support. It is believed that rejection of different solutes is determined to a large extent by the pore size distribution of the skin layer, and that permeability is also influenced by the thickness of the skin layer rather than that of the whole membrane.

Skinless membranes

Skinless membranes are used mostly for microfiltration and consist of either isotropic or anisotropic microgels.

Composite membranes

Ultrathin films featuring the desired rejection properties are first formed and then laminated to a porous support membrane of high permeability and tensile strength. Frequently referred to as 'thin film composite' membranes, they are used mainly in RO and NF applications.

Organic membranes are usually assembled in modules of various configurations of defined filtration area, for example, tube, sheet, spiral-wound, and hollow fiber.

Tubular–organic

Tubular membranes are housed according to a shell-and-tube configuration. However, there is some variation in design detail between different manufacturers. For instance, a PCI-Memtech module may contain a bundle of 18 membrane tubes (12.5 mm diameter) – each supported by a perforated stainless-steel outer casing. The end cap design of a module permits parallel as well as serial and mixed flow modes of processed fluids. Other designs may not necessarily use casing supports for individual tubes within a bundle.

Tubular–inorganic

Ceramic microfiltration membranes produced by SCT (Société des Céramiques Techniques/Ceraver) consist of thin-walled channels of fine-grained ceramic (α-alumina) through which the product is fed. A typical element features 19 channels. Modules consisting of 1, 7, or 19 elements are mounted in parallel in stainless-steel housing. A surface layer of known pore size is supported by a coarser microporous support. In a typical industrial installation, two modules are assembled in series, forming a filter loop serviced by a single retentate circulation pump and one permeate circulation pump.

Metallic oxide surface layers (ZrO_2; TiO_2) on a carbon support are a key design feature of inorganic membranes (e.g., KERASEP® and CARBOSEP® by Novasep-Orelis, and INSIDE CéRAM® and Filtanium® by Tami-Industries). The KERASEP® range of multichannel ceramic membranes is constructed of monolithic Al_2O_3–TiO_2 material with internal diameter options of 6, 4.8, 3.5, and 2.2 mm in respect of units with number of channels 7, 8, 19, or 44; external diameter 25 mm; and length 1,178 mm.

Plate and frame

Plate-and-frame modules consist of a series of membrane disks mounted as a vertical stack or horizontally in a manner that is analogous to a plate heat exchanger configuration. Feed is pumped through very narrow channels that may be configured for parallel flow or as a combination of parallel and serial channels. Examples include the designs pioneered by DDS (*module* series 35...39) and Novasep-Orelis *Pleiade*® (UFP10, RP 2030; RP 2060; RP 2085).

A DDS module is usually divided into sections, in each of which the flow between pairs of membranes is in parallel. The sections are separated by a special membrane-support plate in which one hole is closed with a stop disc to reverse the direction of flow, giving serial flow between successive sections. In DDS module 38, the channel height is increased to 0.97 mm (from 0.72 mm).

Plate-and-frame designs were promoted, in particular, for concentration of milk to a high solids level during the preparation of 'pre-cheese', that is, milk retentate that was fermented and renneted before salting and packaging (e.g., Feta-type cheese), and coagulation and curd-handling (e.g., the so-called UF cheese or the UF versions of well-known cheese varieties) or for further concentration (scraped-surface evaporation) to produce cheese base (processed cheese-type applications). DDS module UF 37 enables whole milk retentates with a dry matter content of 48–49% to be obtained (compared to 38–40% for module 36).

Spiral-wound

A spiral-wound element may be obtained by wrapping two membrane sheets, separated by a supporting sheet and two mesh feed spacers, around a permeate collecting tube. A separate channel spacer allows permeate passing through the membrane to flow freely to the collection point at one end – achieved by sealing the assembled membrane along both sides and the other end. Channel spacers are also designed to promote turbulence, especially where low retentate velocities prevail. Anti-telescoping devices are fitted between the downstream ends of the membranes to limit the risk of membrane layer slippage into one another due to effects of fluid velocity.

Spiral-wound modules lend themselves to the design of very compact membrane separation systems, and thus contribute to reduced capital cost and installation requirements. Considerable progress over the years has been made in relation to the development of robust adhesives and improved sanitary features in module design. Wider spacers between membranes are also used to extend the range of UF applications to include concentration of more viscous products such as fermented milks, for example, fresh cheeses and cream cheeses. Well-established names of spiral-wound membranes in use by the dairy industry include, amongst others, Koch, Dow, and Novasep-Orelis – the latter now is offering their flat sheet *Pleiade*® membrane in spiral-wound configuration (PERSEP™). Koch's HFK-131 six-inch (refers to diameter) UF dairy spiral module (length 965 mm) is available with spacer thickness options of 0.7, 1.1, and 2.0 mm and respective membrane filtration areas of 19.5, 16.2, and 9.7 m^2. Dow FILMTEC® NF 45 series spiral-wound membranes figure prominently in whey nanofiltration applications.

Hollow fiber

Despite exhibiting some similarities, hollow-fiber membranes differ from their tubular counterparts in several respects. First, the membranes are narrower with diameters ranging from 0.5 to 2.7 mm. The active membrane surface is on the inside, whereas the outside of the fiber wall has a rougher structure and membrane support. The feed stream flows through the inside of these fibers; permeate is collected outside and removed at top of the tube. Back-flushing is possible by recirculating through the outer permeate connection to remove product deposits on the membrane surface.

Hollow-fiber modules contain bundles of between 45 and 3000 fiber-like membranes per cartridge. The fibers are oriented in parallel; all are embedded in a resin at their ends and enclosed in a permeate-collecting tube formed using epoxy.

Although efficient in terms of compact filtration area, this type of membrane has become less popular for dairy applications mainly because of hydraulic and fouling constraints associated with flow of viscous products through narrow-bore materials. Tami-Industries' introduction in

1999 of their Dahlia® series of ceramic membranes based on a 39 channel geometry with hydraulic diameter of 2.5 mm and filtration surface of 0.5 m^2 represents a close approximation of the hollow-fiber design in inorganic form.

Membrane Module Configuration

Most of the experimental evaluations of membrane applications are usually undertaken using either retentate recirculation (batch) or a feed-and-bleed (continuous) system in which a portion of the retentate with the desired solid concentration is bled from the plant at a rate that is consistent with the membrane's performance.

Industrial plants are usually configured to operate continuously on a multistage recycle basis (MSR) with limited recirculation (**Figure 3**). In this manner, the declining volume of the retentate due to concentration is handled in a separate stage where steps are taken to correct for the diminishing velocity and increasing viscosity.

Dynamic Membrane Systems

Dynamic membranes represent an emerging separation technology that may have potential uses in future dairy ingredient developments. Additional design features are incorporated that increase shear at the membrane surface, reduce fouling, and enhance permeate flux. Rotating disk filters may be configured with an impermeable disk rotating above a stationary membrane disk or with a stationary baffle next to a rotating membrane disk. Stationary membrane disk filters require less power input for given flow rates and rotational speeds, whereas rotating membrane disk filters produce a higher shear stress on the membrane surface which may reduce fouling. The PallSep™ (Pall Corporation) Vibrating Membrane Filter (VMF) utilizes vibrational energy generated by an AC motor that spins an eccentric mass (flat disc membrane pack) that is mounted near the edge of a seismic mass. When the rotational speed of the eccentric mass is increased, the filter stack oscillates in response to the seismic mass with a 180° phase lag. Microporous, UF, and NF membrane types may be employed. Another membrane vibration-based technology VSEP® (Vibratory Shear Enhanced Process) was created by New Logic Research of Emeryville, California, to eliminate membrane-blinding by vibrating its surface at an extremely high frequency.

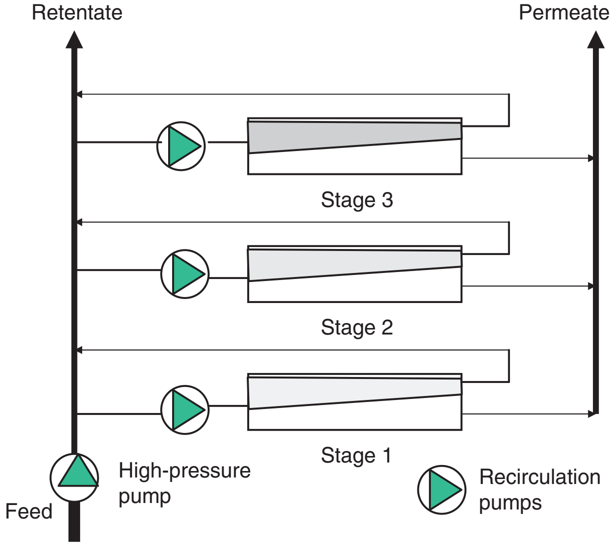

Figure 3 Outline of multistage membrane separation unit (three stages) showing separate recirculation loops.

Recent research suggests that such systems have the potential to selectively separate the two major whey protein fractions, namely, β-lactoglobulin and α-lactalbumin.

Low-Pressure, Immersed Membrane Technology

The dairy industry is a significant user of low-pressure, immersed membrane technology for waste-water treatment. Typically, modular cassettes containing MF/UF membrane fibers are immersed in the waste water being treated, where they rely on slight suction to the end of the fibers to draw water through their microscopic pores. With a nominal size of only 0.04 mm, the membranes prevent suspended solids, pathogens, and viruses from passing through. Automatically controlled cyclic aeration and intermittent back-pulsing are among the measures used to maintain the membrane fibers clean and operate at optimum efficiency. Conventional higher-pressure membrane filtration systems in MF or UF may also be applied.

Other Emerging Membrane Separation Systems

Although presently not widely adopted by the dairy industry, new membrane developments offer potential for advanced applications such as separation of target biomolecules. Among these are the use of charged UF membranes, UF in the presence of an electric field (electro-ultrafiltration), and membrane chromatography.

Membrane Performance

A typical membrane performance is characterized by a relatively rapid initial flux rate which drops off progressively over time – the rate of decline being dictated by the particular process (RO vs. NF vs. UF vs. cMF), applied pressures, membrane characteristics, module configuration, product characteristics, and the general state of the membrane following previous use and cleaning.

The permeate flux of water (expressed as $\mathrm{l\,m^{-2}\,h^{-1}}$) through a membrane is proportional to the applied transmembrane pressure (TMP) as described by D'Arcy's law:

$$\mathrm{J} = \frac{\mathrm{TMP}}{\mu_{\mathrm{p}} . R_{\mathrm{m}}}$$

where R_{m} is the membrane hydraulic resistance, μ_ρ is permeate viscosity, and TMP is the pressure drop between the retentate and permeate sides of a membrane at a particular point according to

$$\mathrm{TMP} = \frac{P_1 + P_2}{2} - P_3$$

where P_1, P_2, and P_3 are feed inlet, feed outlet, and permeate outlet pressures, respectively.

UF Processing Temperature

In general, most of the membrane separation processes are performed at temperatures in the range 40–50 °C. However, there has been a move in more recent years to perform whey UF under cold (<20 °C) conditions. The benefits of doing so include improved microbiological specifications through better control of thermoduric and spore-forming bacteria, and less alteration to protein structure. Extra filtration surface is required to compensate for reduced flux performance at lower operating temperatures but usually without undue cost penalty, because of technological advances especially in the mass production of spiral-wound membranes.

Fouling

The decline in permeate flux with time (or increase in transmembrane pressure in a constant-flux system) experienced in all pressure-driven membrane processes is attributed to product fouling. In fact, fouling would appear to be triggered by concentration polarization which occurs initially on start-up when a concentration gradient of retained components mediates the subsequent accumulation/concentration on the membrane surface (**Figure 4**). Generally, protein deposition and mineral (calcium phosphate) precipitation are major fouling agents during membrane processing of dairy products. Other product constituents such as lipid, or fat material, and peptides may contribute to a lesser extent.

Product fouling (R_{f}) adds another layer of resistance to that of the membrane (R_{m}), and the effectiveness of applied pressure is diminished by the increasing osmotic effects ($\Delta\Pi$) as macromolecular solutes become more concentrated. Hence, the following adaptation to D'Arcy's Law:

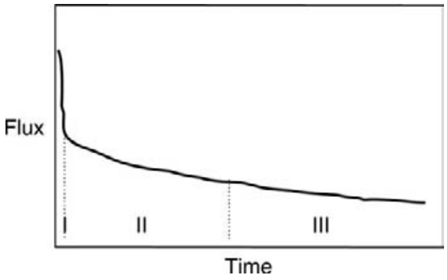

Figure 4 Conceptual diagram outlining fouling stages during UF at constant pressure: I concentration polarization; II membrane fouling; III multilayer formation via further particle deposition.

$$\mathrm{J} = \frac{\mathrm{TMP} - \Delta \prod}{\mu_{\mathrm{p}}(R_{\mathrm{m}} + R_{\mathrm{f}})}$$

In UF and RO, the general consensus is that a surface layer (also called dynamic membrane, gel layer, filter cake) forms on the membrane surface and dominates the subsequent behavior of the membrane. In cMF, both pore plugging and surface layer formation occur even with proteins considerably smaller than the pores. Indeed with protein-containing solutions such as milk or whey, the range of pore sizes where plugging occurs gets extended beyond that predicted from steric effects and severe pore plugging will eventually cause the formation of a surface layer. It is also clear that, once a surface layer has formed on a cMF membrane, its selectivity is dominated by the surface regardless of the original pore size of the membrane.

Since R_{f} is due to the combined resistance of various forms of fouling taking place, namely, adsorption (R_{a}), pore blocking (R_{p}), precipitation/gel layer formation (R_{g}), and concentration polarization (R_{cp}), a predominance of such factors may override performance as follows:

$$\mathrm{J} = \frac{\mathrm{TMP}}{R_{\mathrm{m}} + R_{\mathrm{a}} + R_{\mathrm{p}} + R_{\mathrm{g}} + R_{\mathrm{cp}}}$$

Concentration Polarization

Product concentration is more intense along the interface of a membrane as the driving pressure on the product side is opposed by the membrane's selectivity and the behavior of the rejected solutes. Concentration polarization is defined as an increase in concentration of a component in the boundary layer of the membrane as a result of its rejection. The phenomenon is characterized by a drop off in permeate flux through a membrane to a constant value irrespective of increasing TMP during RO or UF. Such fouling may become irreversible should the concentration of rejected component(s) increase to the point that deposition occurs on the membrane.

A number of models are used to describe concentration polarization. The 'film model' is considered to provide a reasonably good prediction of UF performance during protein processing. Here it is assumed that the concentration boundary layer resides within a thin laminar film at the membrane surface and that all mass transfer takes place by diffusion perpendicular to it. However, it does not apply that readily to cMF because small particles rejected by the membrane do not move away in a predictable manner.

In the 'gel model', gel formation at the membrane wall during UF occurs on reaching a limiting concentration, that is, when the polarized macromolecular layer becomes impermeable to other macromolecules. The gel layer, acting as a hydraulic barrier in series with the membrane, reduces permeate flux to the point that positive and negative mass transport forces are counterbalanced. Further increases in the transmembrane pressure result simply in the buildup of a thicker or denser cake of retained species with no benefit in terms of flux. Some caution is required when using the gel model, as its concentration and fluidity are known to deviate from predicted values depending on the prevailing hydrodynamic conditions.

The 'osmotic pressure model' is also used to describe the reversible changes in effective pressure or membrane resistance encountered in UF. Here, larger components (i.e., proteins) contribute to an exponential rise in osmotic pressure with increasing concentration. Thus, when protein is concentrated near the membrane surface, the rise in osmotic pressures may negate typical transmembrane pressures with consequences to permeate flux. It is suggested that the osmotic pressure model be applied only to solutes with a molecular weight less than 100 kD, and that gel layer limitation occurs more likely with high molecular weight solutes (>100 kD).

In practice, the influence of concentration polarization on permeate flux and to a certain extent on fouling may be minimized by improving the process hydrodynamics, for example, by increasing shear rate at the membrane surface using higher-velocity retentate circulation or other turbulence promoting measures.

Various membrane and module design approaches continue to be introduced with a view to improving overall plant performance. A patented rib design with similar-length flow channels on a flat membrane within a plate-and-frame-type module was developed to overcome uneven fluid distribution as a major contributor to fouling decay. The benefits of this new design include (1) pronounced improvement in the molecular selectivity of the membranes, (2) increased flux rate, (3) higher product concentration, and (4) easier cleanability and better flux recovery thereafter. The ISOFLUX® ceramic membrane introduced by Tami-Industries is characterized by a thickness gradient in the separating layer of the membrane surface to ensure constant permeate flow throughout the length of the module. The resulting improvement in separation performance is also accomplished with more favorable plant pumping requirements. It is claimed that a 4 log reduction in the bacteria load of skim milk may be achieved during MF using the ISOFLUX® ceramic membrane at a rate of 800 $\mathrm{l\,m^{-2}\,h^{-1}}$ at 50 °C for operating periods of up to 10 h.

Influence of Feed Parameters on Protein Fouling

Feed pH, ionic strength, calcium content, and degree of protein aggregation influence the nature of the fouling layer. As a consequence, its depth and porosity affect membrane selectivity and permeate flux.

During the processing of skim milk, the behavior of casein in response to pH change dominates membrane performance. From pH 6.0 to 5.6, there is a tendency for micelles to combine while retaining their individual shape. Fouling layer structure becomes increasingly compact with minimum interstitial pore space at pH 5.6. At pH 5.45–5.2, a different, more open, structure is apparent as the casein-forming chains link together. Below pH 5.2, the deposit consists of more or less individually clumped particles (demineralized casein micelles) which form an increasingly open structure.

In whey, calcium phosphate may give rise to severe fouling above pH 6.5 when the concentrations of both minerals (Ca and P) are high. Apart from its role in calcium phosphate precipitation, calcium generally promotes fouling either through protein–protein interactions in the boundary layer or through protein–membrane interactions. At lower pH, a decrease in whey flux at the isoelectric point is generally attributed to either decreased adsorption or deposition of protein or changes in the porosity of the deposited protein. Protein layer permeability is affected by ionic strength and ion valency: ion-binding increases protein size and, thus, its porosity when present in a deposited layer.

Protein Adsorption

In almost all instances of fouling, protein adsorption occurs on membrane surfaces. Both membrane hydrophobicity and charge influence protein adsorption. Such protein–membrane interactions are usually irreversible, and, because of their tightly bound nature, may be removed only by cleaning. Further increases in transmembrane pressure lead to further protein deposits on the membrane. This deposit, consisting of many protein multilayers, is not as strongly bound as the protein adsorbed directly to the membrane surface.

Changes in membrane hydrophobicity and charge difference between the membrane and protein may reduce the quantity of protein strongly adsorbed to the membrane surface. The availability of hydrophilic membranes represents a significant improvement, but no practical benefits have been obtained when using such polymer cMF membranes, thus leading to the conclusion that hydrophobicity and associated protein–membrane electrostatic interactions are not the only factors involved in membrane fouling.

The preferred view is that permeate flux is controlled more by the quantity of loosely deposited protein (fouling layer thickness) and the porosity of its multilayer structure, rather than by what is strongly bound to the membrane. These parameters are influenced by the properties of the product feed.

Calcium Phosphate Precipitation

Mineral-related fouling is experienced only when calcium phosphate precipitates during the filtration process. The precise conditions that lead to precipitation are not very well characterized, but factors such as high temperature, high pH, and high calcium concentration as well as the absence of protein, for example, permeate, all contribute to the likelihood of fouling. When operating conditions give rise to mineral precipitation, fouling is severe and is dominated by calcium phosphate with some protein complexation. In the absence of calcium phosphate precipitation, proteins are the main constituent of the fouling layer.

Fouling of Inorganic Membranes

The structural properties of inorganic membranes facilitate greater control of hydrodynamics such as turbulent flow and high wall shear stress as well as permit the use of permeate counter-pressure with or without permeate circulation. Inorganic membranes are used in cross-flow MF in the dairy industry.

UF and cMF membranes exhibit different fouling phenomena due to the diffused pore size distribution of the former and the differences in pore size range. UF separation results in surface fouling with the creation of a more or less homogeneous polarization layer of retained species (proteins). cMF separation/fractionation allows passage of proteinaceous material and particles through the membrane and its reactive porous support results in internal fouling such as adsorption which can eventually lead to pore narrowing. Moreover, a deposit of varying porosity of heterogeneously sized rejected particles, aggregates, and proteins is formed on the membrane's surface. The reduction of pore diameter or even complete pore blocking is the reason for loss of filtering areas during cMF processes, and thus for reduced permeability and increased rejection.

Introduction

Whey protein ingredients are protein-enriched fractions of whey that are designed for specific functional, nutritional, and nutraceutical applications. They range in protein content from 2.5 to over 90%. The non-protein components are water and various amounts of minerals, lactose, lipids, and possibly compounds produced by cheese starter bacteria. The functionality of whey protein ingredients depends on the composition of whey and interactions among compounds. A description of the different products, together with a discussion of processing and functional considerations, is given below.

Whey protein ingredients are added to foods for nutritional and functional reasons. For example, in products such as sports drinks, they provide high-quality protein that remains dispersed for the shelf life of the product. A functional requirement for such a product is heat stability, that is, at the desired pH and concentration the protein must remain dispersed and be at a target level of clarity after thermal processing and during storage also. Whey proteins also function in applications that require surface activity (emulsions and foams) and network formation (gels and edible films).

The majority of whey is processed into whey powder. The world production of whey powder has increased from 1.8 million tonnes in 1995 to more than 2.6 million tonnes in 2006. The production of whey and whey derivatives (sweet whey powder, demineralized whey, delactosed whey, whey protein concentrates (WPCs), whey protein isolates (WPIs), and lactose) in the United States and the European Union from 2003 to 2006 is listed in **Table 1**. The growth of dry whey production between 2003 and 2006 was 1–2%, approximately at the same rate as of milk volumes. Although the total dry whey production in the United States has not changed much since 1986, the amount of dry whey has shifted from animal consumption to human consumption, causing a decline in animal consumption from 14% of total production in 1986 to 5.4% in 2007. Similarly, 25% of WPCs was consumed by the feed sector in 1986 compared to 9% in 2007.

Whey derivatives are used as ingredients in a wide range of products. The derivatives having the lowest value are used predominantly by the feed industry. Derivatives with a higher value, such as WPCs and WPIs, are produced for the food, cosmetic, and pharmaceutical sectors. Recently, there has been a growing demand for whey powders and WPCs, predominantly from the food industry, resulting in an increase in their production. However, the market for value-added forms of whey, such as fractions and derivatives, is expected to have the largest growth, as much as 20% per year. The future growth is expected to be led by the industry's increasing focus on nutritional products, particularly in the dietary, sports, and clinical segments of the market. Lactose, used in food and pharmacy sectors, has been in high demand, and the production of lactose has grown 173% in the past 10 years. In 2007, in the US dairy industry, for human foods, 47.6% of dry whey was used while 27% was used as dry blends and 15.3% in the bakery industry. For WPCs, 42.4% was used by the dairy industry, while 23.4% was used in nutraceuticals, pharmaceuticals, and special dietary products, and 16.2% in infant formulae.

Whey is defined in the Unites States Code of Federal Regulations as

> . . . the liquid substance obtained by separating the coagulum from milk, cream, or skim milk in cheesemaking. Whey obtained from a procedure, in which a significant amount of lactose is converted to lactic acid, or from the curd formation by direct acidification of milk, is known as acid whey. Whey obtained from a procedure in which there is insignificant conversion of lactose to lactic acid is known as sweet whey. Sweet whey has a maximum titratable acidity of not more than 0.16 percent, calculated as lactic acid, and an alkalinity of ash of not more than 225 milliliters of 0.1 N hydrochloric acid per 100 grams. The acidity of whey, sweet or acid, may be adjusted by the addition of safe and suitable pH-adjusting ingredients.

Production of casein-based ingredients (caseins and caseinates) also provides a source of whey. The definition of whey can be modified to account for casein production by defining it as the liquid obtained after casein has been removed from milk. The components of whey are intimately associated with the process used to coagulate or remove casein. Cheesemaking practices that include the use

NR, not reported; WPC, whey protein concentrate; WPI, whey protein isolate.

of chymosin to form the casein curd will release the glycomacropeptide (GMP) portion of κ-casein into the whey. Processes that coagulate casein by lowering the pH will shift the ionic equilibrium of the casein micelles and cause additional minerals to be in the whey. Fermentation bacteria can contribute polysaccharides, enzymes, and flavor compounds. These factors result in wide variations in the starting material used to make whey protein products.

Processing Methods

Whey contains around 0.6% protein and 93% water. WPC contains 25–80% protein, and WPI contains $\geq$90% protein. For every kilogram of WPI powder produced, one has to start with 150 kg of whey and remove at least 149 kg of water and solids by various processing methods. Pressure-driven membrane techniques used to produce WPCs and WPIs are reverse osmosis, ultrafiltration, microfiltration, and nanofiltration. Electrically driven membrane processes used are electrodialysis and electrodeionization. To date, the main adsorption technique employed has been ion exchange, but with the advent of new technologies, there are potential applications of affinity binding and other techniques that have historically been economically limiting. Thermal processing to inactivate microorganisms or increase processing efficiency is also used at various stages of processing. The net result is that whey protein ingredients can contain the same amount of protein, but vary widely, by design, in the amount of various non-protein compounds. Moreover, just measuring the amount and type of non-protein molecules presents an incomplete picture because we cannot account for molecules' interactions that are caused during processing. In many cases, it is the interactions among molecules that provide the functional properties rather than the amount of one or several components.

Over the past 15 years, whey-processing developments have focused on advanced liquid-handling techniques, maximization of quality and safety, and the introduction of sophisticated separation and fractionation methods. With the emphasis on cost-effectiveness and the retention of native protein functionality, specifically bioactivity, chromatographic techniques have helped pioneer cost-effective processes for whey protein isolation and fractionation at the commercial scale. Continuous separation (CSEP) chromatographic technology provides the benefits of traditional chromatography (specificity, reproducibility, and mildness), addresses the disadvantages (cost, throughput, flexibility, productivity, and complexity), and has facilitated the manufacture of unique WPIs (enriched in β-lactoglobulin and/or GMP), lactoferrin, and bioactive factors from whey. The development of membrane adsorber in membrane processing has allowed the manufacture of a wide range of specialized whey ingredients, including high-protein/peptide isolates and fractionated/purified bioactive proteins. Whey processing results in a large volume of lactose- and mineral-rich permeate. Advanced technology in the past 10 years has provided for a simple and efficient lactose hydrolysis and isolation at commercial scale, improving the overall cost-effectiveness in whey processing.

Concentrates

WPC is defined by the United State Code of Federal Regulations as

> . . . the substance obtained by the removal of sufficient nonprotein constituents from whey so that the finished dry product contains not less than 25 percent protein. Whey protein concentrate is produced by separation

> techniques such as precipitation, filtration, or dialysis. As with whey, whey protein concentrate can be used as a fluid, concentrate, or dry product form. The acidity of whey protein concentrate may be adjusted by the addition of safe and suitable pH-adjusting ingredients.

Most WPCs on the market contain either 34–35 or ~80% protein (**Table 2**). WPCs containing ~35% protein are used in the manufacture of yogurt, processed cheese, and infant formulae, and in various bakery applications. These products are also marketed for use in stews and sauces because of their thickening properties, as well as nutritional benefit. The addition of ~35% protein WPCs to luncheon meats and meat patties is another recommended application. The 51–54% lactose and high ash content distinguish this product from 80% protein WPCs. The performance of ~35% WPCs in food applications is based on the combined effects of protein, lactose, and minerals in these products.

There are some specialized whey protein products that have a protein content of 35–80%. Extruded WPC (50% protein) is another product used in meat applications or protein bars. The addition of an extruded WPC lends mouthfeel and texture to a product, while also providing a nutritional benefit. A WPC (53–60% protein) with a high level of butterfat (15–27%) is a product specifically geared to the manufacture of processed cheese. A WPC with added active yogurt cultures is marketed toward producers of frozen desserts and yogurt coatings, as it is claimed that it gives a cultured flavor to the product.

WPCs containing 80% protein are designed for applications in which proteins play a dominant functional role. Applications such as gelation, emulsification, and foam formation are often mentioned for these products. The low carbohydrate content of this type of WPC makes it an ideal ingredient for sports nutrition and weight management products. In many cases, they are designed to compete with other protein ingredients, such as those derived from egg white. One application for these ingredients is in meat products, where high gel strength and good water-binding properties are required.

Isolates

WPIs contain ≥90% protein and 4–6% water (**Table 2**). The remaining 4–6% of the ingredient is a combination of fat, lactose, and ash. Because of their high protein purity and solution clarity, WPIs are used extensively in nutritional supplements, sports and health drinks, and protein-fortified beverages. Ion exchange chromatography is one of the methods used in the manufacture of WPIs. It provides an additional level of selectivity above membrane processing because factors other than molecular size determine protein adsorption. Because of the high protein content, WPIs function as water-binding, gelling, emulsifying, and foaming agents. There are several ways in which processors can adjust the composition and functionality of these ingredients. For example, the amount of individual proteins can be varied. Some isolates contain GMP, while others do not. While it is possible to produce WPCs without GMP by using whey streams from processes that do not cleave κ-casein, the additional fractionation techniques used to produce WPIs also allow for selective removal of GMP from cheese whey. Additionally, pH can be altered prior to drying, creating a WPI with an acidic pH, primarily designed for use in acidic beverage applications. Proteins and other components of WPC and WPI are listed in **Table 3**.

Individual Protein Fractions

The main proteins found in WPCs and WPIs are β-lactoglobulin, α-lactalbumin, GMPs, bovine serum albumin, immunoglobulins, lactoferrin, and lactoperoxidase. Each of these proteins or group of proteins has been proven or implied to have unique functional, nutritional, or nutraceutical properties. Some putative nutraceutical activities are digestive function (β-lactoglobulin), prevention of dental cavities and satiety (GMP),

Table 2 Average composition and ranges of 35 and 80% protein WPCs and WPIs based on product specification sheets of nine companies

Ingredient	*Protein (%; dry wt.)*	*Moisture (%)*	*Lactose (%)*	*Fat (%)*	*Ash (%)*	*pH*
WPC 35[a]	35.3	3.7	52.3	3.3	5.8	6.2
WPC 35 range	34.0–36.4	2.9–4.0	47.0–56.0	2.5–4.0	1.6–8.0	4.9–7.0
WPC 80	78.7	4.3	4.9	6.4	4.0	6.4
WPC 80 range	72.9–82.8	3–5.2	0.15–7.4	1–10	2.5–11.0	3.2–7.2

All values are in percentages.
BSA, bovine serum albumin; NR, not reported; WPC, whey protein concentrate; WPI, whey protein isolate.

anticarcinogenicity, sleep enhancement (α-lactalbumin), antimicrobial immunity (lactoferrin and lactoperoxidase), and passive immunity (immunoglobulins).

α-Lactalbumin is rich in essential amino acids and is the principal protein in human milk. The high content of cysteine in α-lactalbumin has been found to improve the immune system, while a high level of tryptophan may help improve mood, sleep, and cognitive performance. α-Lactalbumin binds minerals, specifically calcium, magnesium, zinc, and cobalt. By being bound to a protein, these minerals are more readily delivered for absorption in the human body. The lack of β-lactoglobulin in human milk suggests that bovine whey protein products rich in α-lactalbumin and low in β-lactoglobulin would be more appropriate for infant formulae. Because of its nutritional and health benefits, α-lactalbumin is used in infant formulae, and health and performance products.

GMP has various unique characteristics compared to other whey proteins. The 'glyco' portion of its name refers to the saccharide groups that are attached to the peptide backbone of the molecule. The most important heterogeneous sugar chain related to GMP is *N*-acetylneuraminic acid, commonly known as sialic acid. Studies have shown that sialic acid may influence digestive function and promote the growth of bifidobacteria. Beneficial biological roles attributed to GMP or peptides derived from it also include stimulation of cholecystokinin (a hormone regulating energy and food intake) release from intestinal cells, inhibition of platelet aggregation, and reduction of dental caries. The glycosylation or the amount of sialic acid of GMP varies widely and is affected by the manufacturing process. Suggested applications of GMP include beverage, nutritional bar, dietary supplements, diet foods, and pharmaceutical products.

Lactoferrin was viewed originally as an iron-binding protein in milk with bacteriostatic properties, but its physiological roles are becoming increasingly evident. These include regulation of iron homeostasis, host defense against a broad range of microbial infections, antiinflammatory activity, regulation of cellular growth and differentiation, and protection against cancer development and metastasis. Lactoferrin is used in infant formulae, nutritional foods and supplements, sports nutrition supplements, and pharmaceutical products.

The composition of some whey protein fraction products is shown in **Table 4**. The low ash and fat contents in these products are similar to WPIs; however, the range among companies in the amount of non-protein components might be one point of differentiation between the products.

The proven and putative nutritional and nutraceutical properties of whey protein ingredients have led to the development of a number of products based on a single protein or an enriched amount of one or more proteins. The versatile functionality of whey proteins has also led to the development of whey ingredients with specific functionality. Examples of these products are WPIs or WPCs having higher heat stability, solubility, dispersibility, and improved gelation and water-holding properties. Specialty whey

protein ingredients designed for specific applications are listed in **Table 5**.

Hydrolysates

Another way in which the nutritional and functional properties of whey protein ingredients can be altered is enzymatic hydrolysis. Peptides may be absorbed slightly better and more quickly than amino acids or whole protein. Because hydrolysis produces peptides with structures that are different from those in the intact protein, it is also used to reduce allergenicity. With better nutritional quality and less allergenicity, whey protein hydrolysates are currently used in infant formulae and enhanced-performance products. Different degrees of hydrolysis will impact flavor, molecular weight profile, and functional properties by different extents. Hydrolysis can improve foaming ability by increasing the amount of air incorporated into a foam (overrun) and can also increase stability. Likewise, hydrolysates can be used to increase emulsion stability. Hydrolysis can be used to change the conditions required for gelation, along with the physical properties of gels. Increased thermal stability is another application associated with whey protein hydrolysates. In this application, the hydrolysis process is designed to produce peptides that are less prone to aggregation when heat processed. Functional and allergenic properties of whey protein hydrolysates depend on the extent of hydrolysis. Generally, whey protein hydrolysates designed for nutritional applications such as sports nutrition drinks, nutritional bars, enteral formulae, and hypoallergenic infant formulae have a moderate-to-high degree of hydrolysis and a high content of short peptides. Lower levels of hydrolysis are associated with improved functionality in foaming, emulsification, and gelation. The composition of whey protein hydrolysates and the degree of hydrolysis of the products are shown in **Tables 6** and **7**, respectively.

Table 6 Composition of whey protein hydrolysates based on product specification sheets of four companies

Company	Protein (%; dry wt.)	Moisture (%)	Lactose (%)	Fat (%)	Ash (%)	pH

Whey Permeate

During ultrafiltration and diafiltration, whey proteins are retained by the filtering membrane, while substances of lower molecular weight, such as lactose and minerals, pass through the filter and become the permeate stream. Once moisture is removed from the liquid permeate, an off-white, free-flowing powder with a mild dairy flavor remains. After the protein (plus some lactose and minerals) is removed from this powder, the remaining collection of substances is called whey permeate or deproteinized whey. The composition of whey permeate varies by milk source, cheese type, and processing conditions, but its main ingredient is lactose. The typical composition of whey permeate is 65–85% lactose, 3–8% protein, 8–20% ash, <1.5% fat, and 3–5% moisture. Whey permeate can be used in a variety of processed foods and bakery applications to impart better browning characteristics to the finished product and to extend shelf life.

Conclusion

There has been a significant growth in the production and processing techniques of whey protein ingredients over the past 30 years. Manufacturers are finding more efficient ways to produce the products, while also making products for specific applications such as in nutraceuticals and cheese production, and for nutritional improvement. In the immediate future, it is likely that new whey protein products will be introduced, and existing products will continue to evolve in their production and uses.

Bioactive Peptides

A Pihlanto, MTT Agrifood Research Finland, Jokioinen, Finland

Introduction

Peptides within the sequence of a parent protein can be released by enzymatic hydrolysis, for example, during gastrointestinal digestion or food processing. Bioactive peptides refer to different peptides of plant or animal origin that may have regulatory functions in the human systems beyond normal and adequate nutrition. Research in the field of peptides has intensified during the last two decades and has been reviewed extensively. Some of these peptides may act as regulatory compounds with a hormone-like activity. The activity is based on their amino acid composition and sequence. Bioactive peptides usually contain 3–20 amino acid residues per molecule. Peptides derived from milk proteins have been shown to possess multiple biological properties, including antimicrobial activity, modulation of digestive enzymes, nutrient absorption, immune responses, and opioid, antithrombotic, and antihypertensive activities (**Table 1**). Many milk protein-derived peptides have revealed multifunctional properties; that is, specific peptide sequences may exert two or more different biological activities. Due to their physiological and physicochemical versatility, milk-borne peptides are regarded as highly prominent ingredients for health-promoting, functional foods or pharmaceutical preparations. The majority of the studies have focused on the blood pressure-lowering effect of these peptides, showing a hypotensive effect in animals and humans. This article will discuss the current knowledge about milk protein-derived bioactive peptides and their potential application for promotion of human health.

Structures and Functions of Bioactive Peptides

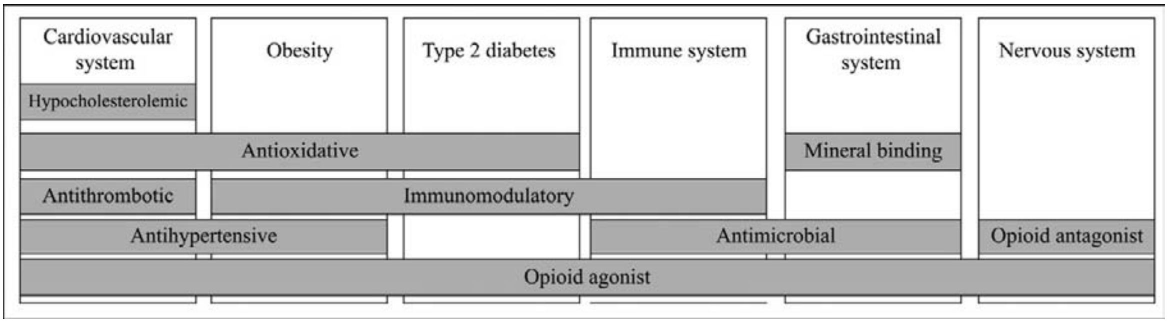
Table 2 presents examples of structural properties of milk protein-derived bioactive peptides, and **Table 3** lists some examples of peptide sequences with different bioactivities measured by *in vitro* cell cultures or *in vivo*.

Food-derived peptides with opioid activity were first recognized in the late 1970s and were termed 'exorphins' on the basis of their structural similarity to endogenous ligands (endorphins and enkephalins). Typical opioid peptides have the same N-terminal sequence, Tyr-Gly-Gly-Phe, and they exert activity by binding to specific receptors of the target cell, for example, the μ-receptor for emotional behavior and suppression of intestinal motility, the σ-receptor for emotional behavior, and the κ-receptor for sedation and food intake. The opioid peptides derived from a variety of precursor proteins are called 'atypical' opioid peptides, since they carry various amino acid sequences in their N-terminal region. Only the N-terminal tyrosine is conserved, and the presence of another aromatic amino acid at the third or fourth position forms an important structural motif that fits into the binding site of the opioid receptors. The major opioid milk peptides, β-casomorphins, are fragments of the β-casein sequence 60–70, and are characterized as μ-type ligands (**Table 3**). The α-casein exorphins were found to correspond to bovine α_{s1}-casein f(90–96), f(90–95), and f(91–96), and were σ-selective receptor ligands. Whey proteins contain opioid-like sequences in their primary structure, namely, α- and β-lactorphins. These peptides show low affinity for opioid receptors and are μ-type receptor ligands. Opioid activity has, furthermore, been found in fragments from bovine serum albumin (serorphin, f(399–404)).

Peptides from a peptic or tryptic digestion of bovine and human κ- and α_{s1}-caseins have been found to display opioid antagonistic properties. Various C-terminally methoxylated casoxins have been identified, for example, κ-casein f(33–38) (casoxin-6), f(34–38) (casoxin-5), and f(35–38) (casoxin-4). In addition, casoxin C (κ-casein f(25–34)), casoxin A (κ-casein f(35–41)), and casoxin B (κ-casein f(61–64)) showed opioid antagonistic activity, but only casoxin C's activity was comparable to that of the esterified casoxin-6 and casoxin-4. In general, the chemically modified peptides are more active than their nonmethylated derivatives. Casoxins show a preference for μ- and κ-receptors with a relatively low potency as compared to naloxone.

Angiotensin I-converting enzyme (ACE; dipeptidyl carboxypeptidase, EC 3.4.15.1) plays a major role in the regulation of blood pressure. Within the renin–angiotensin system, ACE catalyzes the conversion of angiotensin I to angiotensin II, a hormone that results in vasoconstriction, and subsequently in an increase of blood pressure. In addition, ACE degrades bradykinin, which has vasodilatory properties. Thus, ACE inhibitors lower hypertension

Table 1 An overview of the beneficial effects attributed to bioactive peptides derived from milk proteins



Modified from Hartmann R and Meisel H (2007) Food-derived peptides with biological activity: From research to food applications. *Current Opinion in Biotechnology* 18: 163–169.

Table 2 Structural properties of bioactive peptides

Activity	*Structural elements*	*Remarks*
Opioid	Tyrosine at the N-terminus, coupled with the presence of another aromatic residue, e.g., Phe or tyrosine, in the third or fourth position	Fits into the binding site of opioid receptors
ACE inhibitory	Hydrophobic amino acids or positive charge of lysine or arginine at the C-terminus	Influence on the binding to ACE
Antithrombotic	Ile^{108}, lysine^{112}, and Asp^{115} residues of casoplatelins Sugar content	Important antithrombotic activity
Antioxidant	High amounts of His and hydrophobic amino acids	Peptides with a Pro-His-His sequence showed the greatest antioxidant activity among the tested peptides
Hypocholesterolemic	Low ratios of methionine–glycine and lysine–arginine in the dietary proteins. High amounts of hydrophobic amino acids	Hydrophobic amino acids can bind bile acids and thereby enhance fecal steroid excretion
Antiobesity	Peptide length	Influence on CCK-releasing activity
	Multiple arginine residues	Necessary condition for CCK release through direct binding to intestinal cells
Antimicrobial	Positively charged residues and hydrophobic region that contains tryptophan	Trp involved in membrane interactions

Modified from Erdmann K, Cheung BWY, and Schröder H (2008) The possible roles of food-derived bioactive peptides in reducing the risk of cardiovascular disease. *Journal of Nutritional Biochemistry* 19: 643–654.

and are believed to prevent cardiovascular diseases. Since the first discovery of exogenous ACE inhibitors from snake venom, a great number of ACE inhibitory peptides have been isolated from the digests of various food proteins. The precise structure–activity specificity is not fully understood. ACE inhibitory peptides are generally short-chain peptides, carrying hydrophobic (aromatic or branched-chain) amino acid residues, like proline. For example, hypotensive peptides like Val-Pro-Pro and Ile-Pro-Pro can be released from precursor proteins (β- and κ-caseins) by the enzymes from *Lactobacillus helveticus*. Digestion with trypsin can liberate ACE inhibitory peptides from α_{s1}-casein (f(23–27), f(194–199)) and β-casein (f(43–68), f(177–183), f(191–202)). Also, whey proteins contain ACE inhibitory peptides; the highest activity has been found with peptides from β-lactoglobulin (β-Lg) (f(80–82), f(142–148)) and α-lactalbumin (α-la) (f(104–108)). The IC$_{50}$ value (inhibitor concentration leading to 50% inhibition) is used to estimate the effectiveness of different ACE inhibitory peptides. However, it is not always related to *in vivo* activity, since some peptides are susceptible to degradation or modification in the gut, vascular system, and the liver. Moreover, some long-chain candidate peptides can be degraded and new active fragments are generated by gastrointestinal enzymes.

Peptides that inhibit blood platelet aggregation and fibrinogen binding (γ-chain) to platelet surface receptors are encrypted within the sequence of bovine κ-casein, and are referred to as casoplatelins. Several casoplatelins have been reported to have an antithrombotic effect

in vitro and in guinea pigs after parenteral administration. κ-Casein f(106–116) inhibited ADP-induced platelet aggregation and combined with the fibrinogen receptors of blood platelets, consequently preventing fibrinogen binding with blood platelets. The two smaller tryptic peptides (κ-casein f(106–112) and f(113–116)) exerted an effect on platelet aggregation but did not inhibit fibrinogen binding.

Antioxidant properties that prevent enzymatic (lipoxygenase) and non-enzymatic peroxidation of essential fatty acids have been found in peptides derived from milk proteins. The identified peptides are encrypted in the sequences of α_{s1}-, β-, and κ-caseins, and β-Lg. The antioxidant activity has been attributed to the high amount of histidine and some hydrophobic amino acids.

Hypocholesterolemic effects have been reported for casein- and whey protein-derived peptides. The mechanism involved in these effects remains to be clarified. A β-Lg-derived peptide, Ile-Ile-Ala-Glu-Lys, termed lactostatin, decreases micellar solubility of cholesterol, which leads to reduced absorption of intestinal cholesterol. Lactostatin is also able to induce gene transcription of human 7α-hydroxylase, a cholesterol-metabolizing enzyme, resulting in a hypocholesterolemic effect.

Studies on the effects of peptides on immunomodulation have been conducted *in vitro* with cells of specific and non-specific immune systems. Immunomodulatory peptides can enhance immune cell functions, measured as lymphocyte proliferation, natural killer cell activity, antibody synthesis, and cytokine regulation. The casein-derived peptides, including α_{s1}-casein f(194–199) and β-casein f(63–68) and f(191–193), stimulate human and murine macrophages. Synthetic peptides (Tyr-Gly and Tyr-Gly-Gly) have been shown to enhance the proliferation of human peripheral blood lymphocytes. β-Casomorphin-7 and β-casokinin-10 suppress lymphocyte proliferation at low concentrations but are stimulatory at higher concentrations. β-Casein f(193–199) induces a significant proliferative response in rat lymphocytes. Bioactive peptides in yogurt preparations decrease cell proliferation with Caco-2-cells or IEC-6-cells. α_{s1}-Casein f(59–79) and β-casein f(1–25), having a phosphoserine-rich region, have been found to display mitogenic activity and enhance immunoglobulin production in mouse spleen cells. Lactoferrin-derived peptides have been reported to exert an influence in several cell types, for example, human monocytic and polymorphonuclear leukocyte cell lines, which are involved in the immune and inflammatory actions of the body.

The antimicrobial activity of milk is associated mainly with lactoferrin. Moreover, peptides released from lactoferrin by digestion with pepsin or by heat treatment at an acidic pH show higher antimicrobial potency than undigested lactoferrin. The identified antimicrobial peptides, named lactoferricins, originate from the N-terminal region of the molecule and have antimicrobial activity against various Gram-positive and Gram-negative bacteria, yeasts, and filamentous fungi. For example, lactoferricin B killed four clinical isolates of enterohemorrhagic *Escherichia coli* O157:H7 within 3 h at concentrations above 10 μg ml^{-1}. In addition, α_{s2}-casein f(165–203) (casocidin-I) purified from bovine milk hydrolyzed by a serine protease inhibits the growth of *E. coli* and *Staphylococcus carnosus*. The antimicrobial activity of lactoferricins and casocidin-I seems to be correlated with the net positive charge on the peptides. A distinctive feature is the high proportion and asymmetric clustering of basic amino acid residues. It is generally known that cationic amphipathic α-helical structures are related to antimicrobial activity by forming ion channels through membrane bilayers. Lactoferricins disrupt the normal membrane permeability of the cell, which is at least partly responsible for the antibacterial mechanism of lactoferrin-derived peptides. Peptides generated by enzymatic cleavage from α-La and β-Lg exhibit antimicrobial activity mostly against Gram-positive bacteria. The bactericidal peptides are negatively charged, which explains their weak effect against Gram-negative bacteria.

Tryptic digestion of casein proteins yields caseinophosphopeptides (CPPs) from the polar N-terminal region, which contain clusters of phosphorylated seryl residues. For example, α_{s1}-casein f(43–58), f(59–79), and f(43–79), α_{s2}-casein f(1–24) and f(46–70), and β-casein f(1–28), f(2–28), f(1–25), and f(33–48) have been isolated from the tryptic hydrolysate of whole casein. These phosphorylated clusters have been hypothesized to be responsible for the interaction between caseins and calcium phosphate that leads to the formation of casein micelles. CPPs retain the ability of whole casein to stabilize calcium and phosphate ions through the formation of complexes, thus enhancing their general bioavailability.

Possible Physiological Importance

The potential physiological role of bioactive peptides derived from milk proteins and the *in situ* formation of these peptides in the gastrointestinal tract are still largely unknown. It is known that di- and tripeptides are easily absorbed in the intestine. However, little is known about the absorption of larger-molecular-weight bioactive peptides in the intestine. In order to exert a beneficial effect, for example, an antihypertensive effect, the peptides have to be absorbed from the intestine and reach the target cells in the blood vessels in substantial concentrations. In fact, 6 h after absorption of fermented milk, the tripeptides (Val-Pro-Pro and Ile-Pro-Pro) in the milk were detected by HPLC in aortal tissues and ACE activity in the aorta was lower as compared to a control group that was given saline. The absorption and degradation of natural β-casomorphins and their analogues have been intensively studied. Studies have shown no intact transepithelial passage of β-casomorphins; therefore, it is generally concluded that the physiological influences are limited to the gastrointestinal tract. The situation is different in neonates, where passive transport across intestinal mucosal membranes occurs. This may lead to physiological responses such as an analgesic effect resulting in calmness and sleep in infants. The presence of caseinophosphopeptides and immunopeptides from casein in the intestinal lumen of mammals (rat, minipig, calf, human) or even absorption into plasma after ingestion of milk or a diet containing casein has already been shown. Most bioactive peptides are not absorbed in the intestinal tract. Hence, peptides may act either directly in the intestinal tract or via receptors and cell signaling in the gut.

Numerous studies in spontaneously hypertensive rats (SHRs) as well as in hypertensive human volunteers have been performed to determine the antihypertensive effect of milk protein-derived peptides. These studies demonstrated that several ACE inhibitory peptides significantly reduce blood pressure, after either intravenous or oral administration. The best-characterized ACE inhibitory peptides are Val-Pro-Pro and Ile-Pro-Pro, both found in fermented milk. About 20 studies on humans linking the consumption of products containing these two tripeptides with a significant reduction in both systolic blood pressure (SBP) and diastolic blood pressure (DBP) have been published. The maximum blood pressure reductions observed were $\cong$13 mmHg (SBP) and 8 mmHg (DBP) after active treatment as compared to placebo, and are likely to be reached after 8–12 weeks of treatment. Effective dosages of tripeptides range from 3.07 to 52.5 mg day^{-1}. *In vivo* comparative studies with captopril, a clinically used ACE inhibitor, have shown that ACE inhibitory peptides with an antihypertensive effect exhibit higher *in vivo* activity than that which could be expected from their *in vitro* activity. The mechanisms underlying this observation have not yet been identified. It has been suggested that food-derived peptides have higher tissue affinities and are subject to lower elimination. Besides ACE inhibition, other mechanisms, such as that of opioids, are responsible for the depressive effect as shown with α-lactorphin, providing further evidence for the multifunctional role of bioactive peptides. The release of vasodilatory substances, like NO and prostaglandin I_2, could also contribute to the blood pressure-lowering effects of various ACE inhibitory peptides.

The systems involved in the defense mechanism of the body are both varied and complex, and the main focus is on two peptide groups, namely, immunomodulatory and antimicrobial peptides. Only very limited information is available on the *in vivo* effects. The Tyr-Gly and Tyr-Gly-Gly peptides modulate the lymphokine production *in vitro*. Moreover, these peptides were used successfully for immunotherapy of human immunodeficiency virus infection. Furthermore, a study showed that oral administration of a commercial CPP preparation (consisting of α_{s2}-casein f(1–32) and β-casein f(1–28)) enhanced intestinal IgA levels in piglets. A hexapeptide (human β-casein f54–59) and a tripeptide Gly-Leu-Phe protected mice against *Klebsiella pneumoniae* injection after intravenous injection. An antimicrobial peptide α_{s1}-casein f(1–23), isracidin, has been shown to exhibit *in vivo* activity against *Staphylococcus aureus* and *Candida albicans* at concentrations comparable with those of known antibiotics. Moreover, bactericidal peptides may assist in protecting against microbial challenge, especially in the neonatal intestinal tract, and thus support the nonimmune defense of the gut. The immunostimulating activity may also have a direct effect on their resistance to bacterial and viral infections of adult humans.

Published data on the effect of CPPs in animal and human studies are contradictory. A rat model system indicated that CPPs increase passive calcium transport in the distal small intestine. In humans, small CPPs have been detected in the stomach and duodenum following ingestion of milk. However, no evidence has been supplied on the effectiveness of CPPs in increasing passive calcium absorption in humans. In a recent study, it was concluded that CPPs cannot enhance calcium absorption in the gut. Besides, CPPs can have anticariogenic properties, based on their ability to stabilize and localize calcium and phosphate ions at the tooth surface, promoting remineralization of enamel subsurface lesions.

It is generally accepted that protein is the most satiating macronutrient. Several studies speculate that peptides released from dietary proteins during digestion can initiate several satiety signals from the gut and thus prevent further food intake. Because these peptides act on the intestinal site, they do not need to be absorbed into the systemic circulation. It has been suggested that casein-derived peptides induce satiety by independent activation of both opioid and cholecystokinin receptors in rats. Moreover, casein- and whey protein-derived peptides appear to stimulate glucagon-like peptide-1 release. It remains to be determined which peptides are responsible for the abovementioned effects.

Production of Bioactive Peptides

A number of bioactive peptides mentioned in this article are released from host proteins by fermentation of milk, including cheese ripening. Several studies have demonstrated that *Lb. helveticus* strains are capable of releasing ACE inhibitory peptides, in particular the well-characterized tripeptides Val-Pro-Pro and Ile-Pro-Pro. The occurrence of bioactive peptides in cheese varieties has been reported in several studies, and their activity depends on the maturation of cheese. It seems that bioactive peptides liberated during cheese ripening can be further degraded into inactive fragments. Proline-specific peptidase has been found to contribute to the degradation of ACE inhibitory peptides during fermentation with an *Lb. helveticus* strain. Phosphopeptides are produced during cheese ripening by the activity of plasmin and the proteolytic enzymes derived from lactic acid bacteria. β-Casomorphins in cheeses have been found to be hydrolyzed by lactic acid bacterial enzymes. In fermented milk products, such as sour milk, yogurt, and quark, phosphopeptides, ACE inhibitory peptides, immunomodulatory peptides, and casomorphins have been found.

Another common way to produce bioactive peptides is enzymatic hydrolysis by a range of different proteolytic enzymes, such as alcalase, chymotrypsin, pancreatin, and pepsin as well as enzymes from bacterial and fungal sources. After hydrolysis, the peptides in hydrolysates have been fractionated and enriched using different methods, such as precipitation with salts or solvent, ultrafiltration, and chromatography. Application of an ultrafiltration membrane reactor, for continuous extraction of permeates enriched with bioactive fragments, has been described for the production of antithrombotic peptides. Membranes consisting of negatively charged materials have been used to desalt whey protein hydrolysates and to enrich cationic peptides having antibacterial properties. This technique provides new possibilities for enriching low-molecular-mass peptides and is easily upscaled.

Conclusions

There are plenty of reports on the bioactivity of milk protein-derived peptides that may be advantageous for human health. These effects include lowering of blood pressure and lipid levels. Evidence for the beneficial effects of bioactive peptides under the conditions of obesity has also been raised. Since cardiovascular disease is a significant public health problem worldwide, biologically active peptides may be of vital interest in maintaining a healthy population. Products that contain bioactive peptides are already on the market (**Table 4**). Until now, however, most of the claimed physiological effects of bioactive peptides have been observed *in vitro* or in animal model systems. So far, evidence for health effects exists only for a few peptides. The effect of fermented milk products, containing two tripeptides, on blood pressure has been scientifically proven in human trials.

Both casein- and whey protein-based hydrolysates exhibiting a high ACE inhibitory activity have been produced, a number of patents have been granted in this area, and such hydrolysates are now commercially available from dairy companies. Further progress in this area might be achieved by the use of predictive models and technological developments in large-scale continuous production and isolation of peptides. Studies on the interactions of bioactive peptides with other food components during processing and preparation and the effects of these interactions on their bioactivity are scarce. It cannot be excluded that processing may influence the final activity of peptides in real food systems

Table 4 Commercial dairy products/ingredients with health claims based on bioactive peptides

Brand name	*Type of product*	*Bioactive peptides*	*Health claims*	*Manufacturer*
Calpis	Sour milk	VPP, IPP	Reduction of blood pressure	Calpis Co., Japan
Evolus	Calcium-enriched fermented milk drink	VPP, IPP		Valio Oy, Finland
C12 peptide Casein DP	Casein hydrolysate	FFVAPFPEVFGK α_{s1}-casein f(23–34)		Kanebo Ltd., Japan DMV International, The Netherlands
Bio Zate	Hydrolyzed whey protein isolate	Whey protein-derived peptides		Davisco, USA
Bio PURE-GMP	Whey protein isolate	Glycomacropeptide κ-casein f(106–169)	Prevention of dental caries Antithrombotic, antimicrobial, and antiviral	Davisco, USA
Prodiet F200	Flavored milk drink Confectionery Capsules	α_{s1}-Casein f(91–100) YLGYLEQLLR	Reduces stress	Ingredia, France

since several peptides, such as ACE inhibitory peptides, have reactive amino acids in their active C-terminal zone (e.g., lysine, arginine).

Given the fact that milk protein-derived bioactive peptides are safe, they are good candidates for inclusion in healthy lifestyle changes to prevent or reduce diseases such as cardiovascular diseases, obesity, and stress.

Functional Properties of Milk Proteins

H Singh, Massey University, Palmerston North, New Zealand

Introduction

Owing to their nutritional importance and physicochemical properties, proteins are the main functional components in milk. A vast range of milk protein products, specifically designed for particular applications, is manufactured by the dairy industry. Many different grades and types of caseins and caseinates, whey protein concentrates and isolates, milk protein concentrates and isolates, and hydrolyzed proteins can be manufactured by altering processing steps during manufacture (see **Figure 1**). For successful marketing and utilization of milk protein products, it is important to understand the 'functional properties' of the product. In practical terms, the functional properties of proteins can be defined as those characteristics, except nutrition, that determine their satisfactory use in food products. These characteristics may include structure, appearance, texture, viscosity, and mouthfeel. Milk proteins possess functional properties that provide desirable textural or other attributes to the final product and for this reason have found numerous applications in traditional dairy products and in other foods. Some important functional properties for which milk proteins are added to food products and the relevant food systems are shown in **Table 1**.
